Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

From the Arts

Every Tuesday, Queen Elizabeth II of the United Kingdom (played by Dame Helen Mirren) had a private audience with her Prime Minister in the Private Audience Room on the first floor of Buckingham Palace. This is dramatized in Peter Morgan's play, The Audience. In this scene Elizabeth is meeting with Prime Minister Gordon Brown.

Elizabeth So, back to your weekend, and all this industriousness. Were you up very early?

Brown Four thirty.

Elizabeth Oh, dear.

Brown It's all right. I never sleep much.

Elizabeth Since when?

Brown Since always.

Elizabeth Harold Wilson always used to say, "The main requirement of a Prime Minister is a good night's sleep … and a sense of history." Mrs Thatcher taught herself to need very little towards the end. But I'm not sure how reassured I am by that. I like the idea of any person with the power to start nuclear war being rested. (*A beat.*) Besides, lack of sleep can have a knock-on effect in other areas.

Brown Such as?

Elizabeth One's general sense of health.

A silence.

And happiness.

A silence.

And equilibrium.

Brown looks up. A silence.

I gather there's been some concern …

Brown About what?

Elizabeth Your happiness. Don't worry. You wouldn't be the first in your position to feel overwhelmed. Despondent.

She searches for the right word.

Depressed.

From Morgan, Peter. THE AUDIENCE, Faber and Faber, 2013.
Used with permission of Mr. Peter Morgan.

Blessings on him who first invented sleep.—It covers a man all over, thoughts and all, like a cloak.—It is meat for the hungry, drink for the thirsty, heat for the cold, and cold for the hot.—It makes the shepherd equal to the monarch, and the fool to the wise.—There is but one evil in it, and that is that it resembles death, since between a dead man and a sleeping man there is but little difference.

From DON QUIXOTE
By Saavedra M. de Cervantes

"To sleep! To forget!" he said to himself with the serene confidence of a healthy man that if he is tired and sleepy, he will go to sleep at once. And the same instant his head did begin to feel drowsy and he began to drop off into forgetfulness. The waves of the sea of unconsciousness had begun to meet over his head, when all at once—it was as though a violent shock of electricity had passed over him. He started so that he leapt up on the springs of the sofa, and leaning on his arms got in a panic on to his knees. His eyes were wide open as though he had never been asleep. The heaviness in his head and the weariness in his limbs that he had felt a minute before had suddenly gone.

From ANNA KARENINA, Part IV, Chapter XVIII
By Leo Tolstoy

But the tigers come at night,
With their voices soft as thunder,
As they tear your hope apart,
As they turn your dream to shame.

From I Dreamed a Dream, LES MISÉRABLES,
with permission, Cameron Mackintosh, producer

Foreword

Don't Blink!

Perhaps my favorite phrase to parents welcoming home a newborn is: "Don't blink!" In what seems like only a moment in time, parents are suddenly reflecting on how quickly their child has grown: talking, walking, in school, driving, perhaps college, relationships, jobs, their own kids? As this sixth edition of *Principles and Practice of Sleep Medicine* is published, my question to Drs. Kryger, Roth, and Dement is: "Did you blink?"

Who could have imagined that *Principles and Practice of Sleep Medicine* would grow to 21 distinct sections that include 171 chapters? The breadth, depth, and quality represented by the scientific and clinical knowledge in this text are quite amazing. Peruse the range of topics covered across those 21 sections: normal sleep, sleep mechanisms, and phylogeny to why we dream to occupational sleep medicine to the classics of sleep medicine (insomnia, sleep disordered breathing, parasomnias, and narcolepsy). Then consider the depth of knowledge represented: 16 chapters on sleep-disordered breathing, 12 each on physiology in sleep and instrumentation and methodology, and even the "newest" areas, such as genetics and genomic basis of sleep (6 chapters) and legal topics in sleep medicine (5 chapters) have enough content for multiple chapters.

Actually, if anyone could have imagined this textbook growing so quickly and so broadly, it would include Drs. Meir Kryger, Tom Roth, and Bill Dement. *Principles and Practice of Sleep Medicine* has expanded as a reflection of the field, mirroring the incredible advancements in sleep, circadian, and sleep medicine knowledge and practice that have occurred over the past half century. However, the text is more than an invaluable resource and repository of current knowledge; it provides a vision to the future as well.

Sleep medicine, sleep, and chronobiology touch every human at our most basic cellular level (genetics and genomics) and are critical at every level of our society (e.g., occupational, legal). There is an emerging acknowledgment that our safety, health, performance, and mood are fundamentally linked to our sleep, circadian rhythms, and sleep health. While still nascent, this societal recognition grows daily due to the ever-increasing knowledge generated by the sleep medicine community and sleep and circadian scientists. The application of this knowledge and the practice of sleep medicine are creating the foundation for changing societal attitudes and behaviors about sleep, sleep disorders, and circadian factors.

So don't blink; keep your eyes wide open as sleep medicine continues to grow, evolve, and become fully integrated into the safety and health of our society. Just imagine the tenth edition of *Principles and Practice of Sleep Medicine* …

Exciting times

These are exciting times for the field of sleep medicine! The success of any field of medicine is often directly proportional to the scope and comprehensiveness of the knowledge base available to physicians, scientists, trainees, and the general public. For sleep medicine, we are fortunate in that there continues to be dramatic growth in this knowledge, derived from both patient care and clinical/basic research. When one takes a step back and reflects on the rapid development of this field, one reveals how this knowledge base has developed in so short a time. It has been less than 65 years since the discovery of rapid eye movement (REM) sleep, which initiated the organized, scientific study of sleep, and barely 30 years since the invention of continuous positive airway pressure (CPAP), which was the first effective treatment for obstructive sleep apnea. In this short time, the sleep field has expanded to the point where we have over 11,000 accredited member American sleep centers and individual members, including physicians, scientists, and other health care professionals, of the American Academy of Sleep Medicine. Our field has blossomed to the point that it is truly interdisciplinary, comprising specialists from the areas of pulmonary medicine, neurology, psychiatry, internal and family medicine, pediatrics, psychology, otolaryngology, and others. Exciting breakthroughs in sleep research have affected other disciplines of science and research as well, and it is not unusual for sleep medicine specialists to collaborate with other diverse fields of medicine, such as cardiology, endocrinology, genetics, and immunology. Additionally, sleep medicine is practiced worldwide, and a new world sleep organization will be formed in 2017 after the merger of two of our large international sleep organizations (the World Sleep Federation and the World Association of Sleep Medicine).

Despite our amazing growth, there are still many questions yet to be answered, including the holy grail of our field: the function of sleep. To explore these questions, funding from the government, industry, and foundations; support from institutions; and strong mentorship by experienced investigators are important cornerstones. As members of the field, we must collectively strive to ensure that funding, support, and mentorship continue in order to safeguard continued success, even in times of economic downturns and increased competition from other fields. For without breakthroughs in research, there won't be new diagnostic methods, medications, or treatments to help us manage the nearly 90 different sleep disorders that are currently identified.

The growth of our field and the exploration of critical research areas cannot exist without adequate education and training of our young clinicians and investigators to ensure that bright, talented, and dedicated individuals are provided the necessary tools to establish a successful independent clinical and research career. We are indeed privileged that we have excellent resources available that enable trainees to learn more about sleep and sleep medicine. For countless students, *Principles and Practice of Sleep Medicine* has served as the primary textbook, the study guide for the sleep medicine board

certification examination, and/or the basic resource for any sleep-related condition or question about sleep. Often fondly referred to as simply "P&P," it continues to rise in prominence and demand. I've had the great pleasure to learn from and collaborate with Drs. Kryger, Roth, and Dement, and not only are they among the top clinicians and scientists within our field, but they have continued to produce a sleep medicine reference that has remained the gold standard over the span of almost 30 years. Our field is deeply indebted to their dedication, hard work, and diligence.

Sixth Edition Preface

It has been about 30 years since we started to work together on the first edition of *Principles and Practice of Sleep Medicine.* The field at the time was in an embryonic stage. We have witnessed the growth of the science and the practice of sleep medicine through its birth, childhood, and adolescence. Sleep is an accepted part of scientific inquiry and the practice of medicine. Almost everyone knows someone who is being treated for a sleep disorder.

This edition continues the overall organization of the very first edition: the first part reviews the principles of sleep medicine, the second part the practice of sleep medicine. If one compares the first to this, the sixth, edition, there have been dramatic improvements that have always been a result of what readers wanted and needed to know: how best to understand the science and to treat their patients. New content areas have been added in subsequent editions. They include genetics, circadian disorders, geriatrics, women's health, cardiovascular diseases, occupational sleep medicine, legal aspects of sleep medicine, and dental sleep medicine. The latter two sections were added in this edition. The volume has gone from being a 722-page book to a volume more than twice that size, with an enormous amount of digital content that is viewable on virtually all connected devices. The spirit that drove the conception of the first edition (see the preface of that edition next) is still in our hearts.

Probably about a thousand authors have contributed to all the editions of this book. As a group, they are brilliant, have a pioneering spirit, and generously shared their knowledge. We cannot thank the section editors enough for all of their magnificent and hard work. The editors have their own unique style and methods of ensuring scientific accuracy and readability. It was an absolute pleasure working with them. The editors were given the authority to make decisions for their sections, and they had the last word on what went into their sections.

In the more than quarter century that this book has existed many authors and section editors retired, and sadly some have died. Many of the contributors started early in their careers. They established themselves and are continuing to lead the field of sleep medicine into the next generation. Some of the authors of this edition were not even born when *Principles and Practice of Sleep Medicine* was first conceived. They will lead the field into the future.

Bill Dement

First Edition Preface

Medical disorders related to sleep are obviously not new. Yet the discipline of sleep disorders medicine is in its infancy. There is a large body of knowledge on which to base the discipline of sleep disorder medicine. We hope that this textbook will play a role in the evolution of this field.

Douglas Hofstadter reviewed how ideas and concepts evolve and are transmitted.[1] In 1965, Roger Sperry[2] wrote the following: "Ideas cause ideas and help evolve new ideas. They interact with each other and with other mental forces in the same brain, in neighboring brains, and thanks to global communication, in far distant, foreign brains. And they also interact with the external surroundings to produce *in toto* a burstwise advance in evolution that is far beyond anything to hit the evolutionary scene yet, including the emergence of the living cell." Jacques Monod[3] wrote the following in *Chance and Necessity:* "For a biologist it is tempting to draw a parallel between the evolution of ideas and that of the biosphere. For while the abstract kingdom stands at a yet greater distance above the biosphere than the latter does above the non-living universe, ideas have retained some of the properties of organisms. Like them they tend to perpetuate their structure and to breed; they too can fuse, recombine, segregate their content; indeed they too can evolve, and in this evolution selection must surely play an important role." Hofstadter has called this universe of ideas the ideosphere analogous to the biosphere. The ideosphere's counterpart to the biosphere gene has been called meme by Richard Dawkins.[4] He wrote "just as genes propagate themselves in a gene pool by leaping from body to body via sperm or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain. … If a scientist hears or reads about a good idea, he passes it on to his colleagues and students. He mentions it in his articles and his lectures. If the idea catches on it can be said to propagate itself spreading from brain to brain … memes should be regarded as living structures, not just metaphorically but technically."

Thus, this textbook represents an attempt to summarize the body of science and ideas that up to now has been transmitted verbally, in articles, and in a few more specialized books. The memes in this volume are drawn from a variety of disciplines, including psychology, psychiatry, neurology, pharmacology, internal medicine, pediatrics, and basic biological sciences. That a field evolves from multidisciplinary roots certainly has precedents in medicine. The field of infectious diseases has its in microbiology, and its practitioners are expected to know relevant aspects of internal medicine, surgery, gynecology, and pediatrics. Similarly, oncology has its roots in surgery, hematology, and internal medicine, and its practitioners today must also know virology and molecular biology. Patients with sleep problems have in the past 'fallen through the cracks.' It is not uncommon to see a patient with classic narcolepsy who has seen five to ten specialists before a diagnosis is finally made. There is a clinical need for physicians to know about sleep and its disorders.

Acknowledgments

We have been working on *Principles and Practice of Sleep Medicine* for over a quarter of a century. Thousands of people have been involved in the production of the six editions. As much as we would like to thank each person, there is no way that we can thank them all. Some have retired, some have died, and some made important contributions in the production of the various editions but are unknown to us. This group includes secretaries, copyeditors, artists, designers, people who dealt with the page proofs, internet programmers, and those who physically produced the books.

We would like to acknowledge all the extraordinary Elsevier editors who gave birth to each previous edition of the book. These include Bill Lamsback, Judy Fletcher, Richard Zorab, Cathy Carroll, Todd Hummell, and Dolores Meloni. They fueled the dream that helped establish a new field of medicine.

Many people helped in the preparation of the content of this volume, the sixth edition, including those listed below.

The staff members at Elsevier who helped this book in its sixth journey were Helene Caprari, Laura Kuehl-Schmidt, Amanda Mincher, and many others involved in production and design for both the printed volume and the online content.

We also must acknowledge the family members of all the people involved in the book because they indirectly helped produce a work that we believe may have had important positive impact on the lives of thousands, perhaps millions, of people.

Finally, we wish to thank the many hundreds of authors and the magnificent work of the section editors and their deputy editors. All their contributions were so great that they cannot be measured.

Normal Sleep and Its Variants

Chapter 1

History of Sleep Physiology and Medicine

Rafael Pelayo; William C. Dement

Chapter Highlights

- Interest in sleep and dreams has probably existed since the dawn of humanity. Some of history's greatest figures have attempted to explain the physiologic and psychological bases of sleep and dreaming.
- The modern scientific study of sleep began with the discovery of the electrical activity in the brain. Further progress was marked by the discovery of and distinction between REM and NREM sleep. Identifying sleep pathology eventually led to the creation of sleep clinics.
- Sleep medicine as a medical specialty has existed for fewer than 50 years. The evolution of the field required clinical research, development of clinical services, training programs, and changes in the insurance industry and public policy that recognized the impact of sleep disorders on society.
- The field is still evolving as new disorders are being discovered, new treatments are being delivered, and basic science helps elucidate the complexity of sleep and its disorders. As sleep medicine faces new challenges, an understanding of its history can provide researchers with important insights for shaping the future of this discipline.

SLEEP AS A PASSIVE STATE

> Sleep is the intermediate state between wakefulness and death; wakefulness being regarded as the active state of all the animal and intellectual functions, and death as that of their total suspension.[1]

The foregoing is the first sentence of *The Philosophy of Sleep*, a book by Robert MacNish, a member of the faculty of physicians and surgeons of Glasgow; the first American edition was published in 1834 and the Scottish edition somewhat earlier. This sentence exemplifies the overarching historical conceptual dichotomy of sleep research and sleep medicine, which is sleep as a passive process versus sleep as an active process. Until the discovery of rapid eye movements and the duality of sleep, sleep was universally regarded as an inactive state of the brain. With one or two exceptions, most thinkers regarded sleep as the inevitable result of reduced sensory input, with the consequent diminishment of brain activity and the onset of sleep. Waking up and being awake were considered a reversal of this process, mainly as a result of bombardment of the brain by environmental stimuli. No real distinction was seen between sleep and other states of quiescence such as coma, stupor, intoxication, hypnosis, anesthesia, and hibernation.

The passive-versus-active historical dichotomy also is given great weight by the contempory investigator J. Allan Hobson.[2] As he noted in his book *Sleep*, published in 1989, "more has been learned about sleep in the past 60 years than

in the preceding 6,000." He went on, "In this short period of time, researchers have discovered that sleep is a dynamic behavior. Not simply the absence of waking, sleep is a special activity of the brain, controlled by elaborate and precise mechanisms."[2]

Dreams and dreaming were regarded as transient, fleeting interruptions of this quiescent sleep state. Because dreams seem to occur spontaneously and sometimes in response to environmental stimulation (e.g., the well-known alarm clock dreams), the notion of a stimulus that produces the dream was generalized by postulating internal stimulation from the digestive tract or some other internal source. Some anthropologists have suggested that notions of spirituality and the soul arose from primitive peoples' need to explain how their essence could leave the body temporarily at night in a dream and permanently at death.[3,4] How else to better explain seeing deceased loved ones in a dream than to imagine a spirit world and an afterlife? There should be no doubt that dreams influenced primitive cultures.

Sleep-promoting and sleep-inhibiting substances were part of ancient pharmacopeias. It had been observed in antiquity that alcohol would induce a sleeplike state. More than 5000 years ago the opium poppy was cultivated in Mesopotamia. Hippocrates in the 4th century BCE acknowledged its usefulness as a narcotic. Somewhat later, in Ethiopia, coffee consumption was thought to have begun when its power to prevent sleep was recognized. Coffee was historically associated with Sufism in Yemen, and it may have been used in religious activities. It was cultivated in the Arabian Peninsula in the 15th century, whence it spread to Europe and later the Americas.

In addition to the mere reduction of stimulation, a host of less popular theories were espoused to account for the onset of sleep. Vascular theories were proposed from the notion that the blood left the brain to accumulate in the digestive tract, and from the opposite idea that sleep was due to pressure on the brain by blood. Around the end of the 19th century, various versions of a "hypnotoxin" hypothesis were formulated in which fatigue products (toxins and the like) were accumulated during the day, finally causing sleep, during which they were gradually eliminated. This was an early mirror of current concepts on the role of adenosine accumulation leading to sleepiness.

The hypnotoxin theory reached its zenith in 1907, when the French physiologists Legendre and Pieron showed that blood serum from sleep-deprived dogs could induce sleep in other dogs that were not sleep-deprived.[5] The notion of a toxin causing the brain to sleep has gradually given way to the recognition that a number of endogenous "sleep factors" actively induce sleep by specific mechanisms.

In the 1920s, the University of Chicago physiologist Nathaniel Kleitman carried out a series of sleep deprivation studies and made the simple but brilliant observation that people who stayed up all night generally were less sleepy and impaired the next morning than in the middle of their sleepless night. Kleitman argued that this observation was incompatible with the notion of a continual buildup of a hypnotoxin in the brain or blood. In addition, he suggested that humans were about as impaired as they would get, that is, very impaired, after approximately 60 hours of wakefulness, and that longer periods of sleep deprivation would produce little additional change. In the 1939 (first) edition of his comprehensive landmark monograph *Sleep and Wakefulness*, Kleitman summarized his thinking as follows:

> It is perhaps not sleep that needs to be explained, but wakefulness, and indeed, there may be different kinds of wakefulness at different stages of phylogenetic and ontogenetic development. In spite of sleep being frequently designated as an instinct, or global reaction, an actively initiated process, by excitation or inhibition of cortical or subcortical structures, there is not a single fact about sleep that cannot be equally well interpreted as a let down of the waking activity.[6]

This statement succinctly provides insight into the historical adoption of the yin-yang symbol, ☯, as a symbol of sleep medicine.

THE ELECTRICAL ACTIVITY OF THE BRAIN

As the 20th century got under way, Camillo Golgi and Santiago Ramón y Cajal had demonstrated that the nervous system was not a mass of fused cells sharing a common cytoplasm but rather a highly intricate network of discrete cells that had the key property of signaling to one another. Luigi Galvani had discovered that the nerve cells of animals produce electricity, and Emil duBois-Reymond and Hermann von Helmholtz found that nerve cells use their electrical capabilities for signaling information to one another. In 1875, the Scottish physiologist Richard Caton demonstrated electrical rhythms in the brains of chickens. (In view of present-day concerns about the ethics of animal research, it bears mention that the key tool used today in neuroscience to monitor sleep both clinically and for research in humans was first demonstrated in such a model.) The centennial of his achievement was commemorated at the 15th annual meeting of the Association for the Psychophysiological Study of Sleep convening at the site of the discovery, Edinburgh.

It was not until 1928, however, when the German psychiatrist Hans Berger recorded electrical activity of the human brain and clearly demonstrated differences in these rhythms when subjects were awake versus asleep that a real scientific interest commenced.[7] Berger correctly inferred that the signals he recorded, which he called "electroencephalograms," were of brain origin. For the first time, the presence of sleep could be conclusively established without disturbing the sleeper, and more important, sleep could be continuously and quantitatively measured without disturbing the sleeper.

All of the classic major elements of sleep brain wave patterns were described by Loomis, Harvey, Hobart, Davis, and others at Harvard University in a series of influential papers published in 1937, 1938, and 1939.[8-10] Alfred Lee Loomis is a historically interesting figure who played a pivotal role in World War II. He developed amplifier systems to record sleep, and for reasons that are seemingly lost to history, he coined the term *K-complex*.[11] Blake, Gerard, and Kleitman added to this work from their studies at the University of Chicago. On the human electroencephalogram (EEG), sleep was characterized by high-amplitude slow waves and spindles, whereas wakefulness was characterized by low-amplitude waves and alpha rhythm.[12,13] The image of the sleeping brain completely "turned off" gave way to the image of the sleeping brain engaged in slow, synchronized, "idling" neuronal activity. Although their significance was not widely recognized at the time, these findings constituted some of the most critical developments in sleep research. Indeed, Hobson dated the

turning point of sleep research to 1928, when Berger began his work on the human EEG.[2] Used today in much the same way as they were in the 1930s, brain wave recordings with paper and ink, or more recently on computer screens, have been extraordinarily important to sleep research and sleep medicine.

Also in the 1930s, a series of investigations by Frederick Bremer seemed to establish conclusively both the passive theory of sleep and the notion that it occurred in response to reduction of stimulation and activity.[14,15] These studies were made possible by the aforementioned development of electroencephalography. Bremer studied brain wave patterns in two cat preparations. One, which Bremer called "encéphale isolé," was made by cutting a section through the lower part of the medulla. The other, "cerveau isolé," was made by cutting the midbrain just behind the origin of the oculomotor nerves. The first preparation permitted the study of cortical electrical rhythms under the influence of olfactory, visual, auditory, vestibular, and musculocutaneous impulses; in the second preparation, the field was narrowed almost entirely to the influence of olfactory and visual impulses.

In the first preparation, the brain continued to show manifestations of wakeful activity alternating with phases of sleep, as indicated by the EEG. In the second preparation, however, the EEG pattern assumed a definite deep sleep character and remained in this condition. In addition, the eyeballs immediately turned downward, with a progressive miosis. Bremer concluded that a functional (reversible, of course) deafferentation of the cerebral cortex occurs in sleep. The cerveau isolé preparation results in a suppression of the incessant influx of nerve impulses, particularly cutaneous and proprioceptive, which are essential for the maintenance of the waking state of the telencephalon. Apparently, olfactory and visual impulses are insufficient to keep the cortex awake. It probably is misleading to assert that physiologists assumed the brain was completely turned off, whatever this metaphor might have meant, because blood flow and, presumably, metabolism continued. However, Bremer and others certainly favored the concept of sleep as a reduction of activity—idling, slow, synchronized, "resting" neuronal activity.

THE RETICULAR ACTIVATING SYSTEM

After World War II, insulated, implantable electrodes were developed, and sleep research on animals began in earnest. In 1949, one of the most important and influential studies dealing with sleep and wakefulness was published: Moruzzi and Magoun's classic paper "Brain Stem Reticular Formation and Activation of the EEG."[16] These authors concluded that

> transitions from sleep to wakefulness or from the less extreme states of relaxation and drowsiness to alertness and attention are all characterized by an apparent breaking up of the synchronization of discharge of the elements of the cerebral cortex, an alteration marked in the EEG by the replacement of high voltage, slow waves with low-voltage fast activity.[16]

High-frequency electrical stimulation with electrodes implanted in the brainstem reticular formation produced EEG activation and behavioral arousal. These findings seemed to indicate that EEG activation, wakefulness, and consciousness were at one end of a continuum, and EEG synchronization, sleep, and lack of consciousness were at the other end. This view, as can be seen, is hardly different from that in MacNish's definition quoted at the beginning of this chapter.

The demonstration by Starzl and coworkers that sensory collaterals discharge into the reticular formation suggested that a mechanism was present by which sensory stimulation could be transduced into prolonged activation of the brain and sustained wakefulness.[17] By attributing an amplifying and maintaining role to the brainstem core and the conceptual ascending reticular activating system, it was possible to account for the fact that wakefulness outlasts, or occasionally is maintained in the absence of, sensory stimulation.

Chronic lesions in the brainstem reticular formation produced persisting slow waves in the EEG and immobility. The usual animal for this research was the cat, because excellent stereotaxic coordinates of brain structures had become available in this model.[18] These findings appeared to confirm and extend Bremer's observations. The theory of the reticular activating system was an anatomically based passive theory of sleep or an active theory of wakefulness. Figure 1-1 is from the proceedings of a symposium, *Brain Mechanisms and Consciousness,* which was published in 1954 and probably (other than arguably Freud's works) is the first genuine neuroscience bestseller.[19] Horace Magoun had extended his studies to the monkey, and this illustration represents the full flowering of the ascending reticular activating system theory.

EARLY OBSERVATIONS OF SLEEP PATHOLOGY

Insomnia has been described since the dawn of recorded history and attributed to many causes, including a recognition of the association between emotional disturbance and sleep disturbance. Scholars and historians have a duty to bestow credit accurately. Many discoveries, however, lie fallow for want of a contextual soil in which they may be properly understood and in which they may extend the understanding of more general phenomena. Important early observations were those of von Economo on "sleeping sickness" and of

Pavlov, who observed dogs falling asleep during conditioned reflex experiments.[3]

Two early observations about sleep research and sleep medicine stand out. The first is the description in 1880 of narcolepsy by Jean Baptiste Edouard Gélineau, who derived the term from the Greek words *narkosis* ("a benumbing") and *lepsis* ("to overtake"). He was the first to clearly describe the collection of components that constitute the syndrome, although the term *cataplexy* for the emotionally induced muscle weakness was subsequently coined in 1916 by Richard Henneberg.

Obstructive sleep apnea syndrome (OSAS), which may be called the leading sleep disorder of the 20th century, was famously described, in 1836, not by a clinician but by the novelist Charles Dickens. In a series of papers entitled the "Posthumous Papers of the Pickwick Club," Dickens described Joe, a boy who was obese and always excessively sleepy. Joe, a loud snorer, was called "young dropsy," possibly as a result of having right-sided heart failure. Of note, Joe is praised for his ability to fall asleep instantaneously after drinking alcohol! Meir Kryger and Peretz Lavie published scholarly accounts of many early references to snoring and conditions that were most certainly manifestations of OSAS.[20-22] Professor Pierre Passouant provided an account of the life of Gélineau and his landmark description of the narcolepsy syndrome.[23]

SIGMUND FREUD AND THE INTERPRETATION OF DREAMS

By far the most widespread interest in sleep by health professionals and the general public was engendered by the theories of Sigmund Freud, specifically about dreams.[24] *The Interpretation of Dreams* was first published in German in 1895 and translated into English in 1913, with several subsequent revisions.[24] Of course, the real interest was in dreaming, with sleep as a necessary concomitant. Freud developed psychoanalysis, the technique of dream interpretation, as part of his therapeutic approach to emotional and mental problems. As the concept of the ascending reticular activating system dominated behavioral neurophysiology, so the psychoanalytic theories about dreams dominated the psychological side of the coin. Dreams were thought to be the guardians of sleep and to occur in response to a disturbance, to obviate waking up, as exemplified in the classic alarm clock dream. Freud's concept that dreaming discharged instinctual energy led directly to the notion of dreaming as a safety valve of the mind. At the time of the discovery of rapid eye movements during sleep (circa 1952), academic psychiatry was dominated by psychoanalysts, and medical students all over America were interpreting one another's dreams.

From today's vantage point, the dream deprivation studies of the early 1960s, engendered and reified by the belief in psychoanalysis, may be regarded by some as a digression from the mainstream of sleep medicine. On the other hand, because the medical-psychiatric establishment had begun to take dreams seriously, it also was ready to support sleep research fairly generously under the guise of dream research.

CHRONOBIOLOGY

Most, but not all, sleep specialists share the opinion that what has been called *chronobiology,* or the study of biologic rhythms, is a legitimate part of sleep research and sleep medicine. The 24-hour rhythms in the activities of plants and animals have been recognized for centuries. These biologic rhythms were quite reasonably assumed to be a direct consequence of the periodic environmental fluctuation of light and darkness. However, in 1729, Jean Jacques d'Ortous de Mairan described an experiment in which a heliotrope plant opened its leaves during the day even after it had been moved so that sunlight could not reach it. The plant opened its leaves during the day and folded them for the entire night even though the environment was constant. This was the first demonstration of the persistence of circadian rhythms in the absence of environmental time cues. Figure 1-2, which represents de Mairan's original experiment, is reproduced from *The Clocks That Time Us,* by Moore-Ede and colleagues.[25]

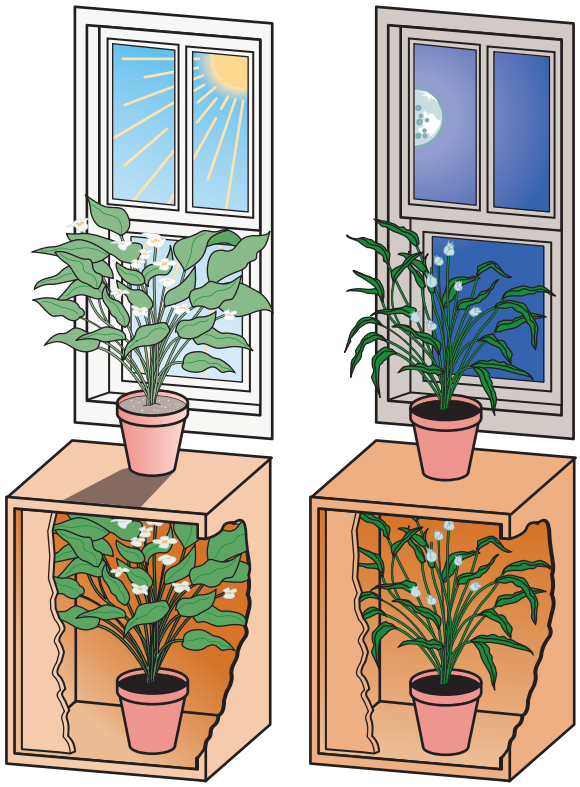

Figure 1-2 Representation of de Mairan's original experiment. When exposed to sunlight during the day (*upper left*), the leaves of the plant were open; during the night (*upper right*), the leaves were folded. De Mairan showed that sunlight was not necessary for these leaf movements by placing the plant in total darkness. Even under these constant conditions, the leaves opened during the day (*lower left*) and folded during the night (*lower right*). (Redrawn from Moore-Ede MC, Sulzman FM, Fuller CA. *The clocks that time us: physiology of the circadian timing system.* Cambridge [Mass.]: Harvard University Press; 1982. p. 7.)

Chronobiology and sleep research developed separately. Three factors appear to have contributed to this divergence:

1. The long-term studies commonly used in biologic rhythm research precluded continuous recording of brain wave activity. Certainly, in the early days, the latter was far too difficult and not really necessary. The measurement of wheel-running activity was a convenient and widely used method for demonstrating circadian rhythmicity.
2. The favorite animal of sleep research from the 1930s through the 1970s was the cat, and neither cats nor dogs demonstrate clearly defined circadian activity rhythms.

Figure 1-3 Nathaniel Kleitman (circa 1938), Professor of Physiology, University of Chicago School of Medicine.

3. The separation between chronobiology and sleep research was further maintained by the tendency for chronobiologists to know very little about sleep, and for sleep researchers to remain ignorant of such biologic clock mysteries as phase response curves, entrainment, and internal desynchronization.

THE DISCOVERY OF RAPID EYE MOVEMENT SLEEP

The characterization of rapid eye movement (REM) sleep as a discrete organismic state should be distinguished from the recognition that rapid eye movements occur during sleep. The historical threads of the discovery of rapid eye movements can be identified. Nathaniel Kleitman (Figure 1-3; Video 1-1), a professor of physiology at the University of Chicago, had long been interested in cycles of activity and inactivity in infants and in the possibility that this cycle ensured that the infant would have an opportunity to respond to hunger. He postulated that the times infants awakened to nurse on a self-demand schedule would be integral multiples of a basic rest-activity cycle. The second historical thread was Kleitman's interest in eye motility as a possible measure of "depth" of sleep. The reasoning behind this potential application was that eye movements had a much greater cortical representation than that of almost any other observable motor activity, and that slow, rolling, or pendular eye movements had been described at the onset of sleep, with a gradual slowing and disappearance as sleep deepened.[26]

In 1951, Kleitman assigned the task of observing eye movement to a graduate student in physiology named Eugene Aserinsky. Watching the closed eyes of sleeping infants was tedious, and Aserinsky soon found that it was easier to designate successive 5-minute epochs as "periods of motility" if he observed any movement at all, usually a writhing or twitching of the eyelids, versus "periods of no motility." Among the infants studied was his own child. In 1952, William C. Dement, at the time a second-year medical student at the University of Chicago, joined the research effort. The first task he was assigned was looking at the closed eyes of the research subjects, using a flashlight in the dark when electrical potentials were detected in the recording instruments in the adjacent room.

After describing an apparent rhythm in eye motility, Kleitman and Aserinsky decided to look for a similar phenomenon in adults. Again, watching the eyes during the day was tedious, and at night it was even worse. Casting about, they came upon the method of electrooculography and decided (correctly) that this would be a good way to measure eye motility continuously and would relieve the researcher of the tedium of direct observations. Sometimes in the course of recording electrooculograms (EOGs) during sleep, they saw bursts of electrical potential changes that were quite different from the slow movements at sleep onset.

When they were observing infants, Aserinsky and Kleitman had not differentiated between slow and rapid eye movements. On the EOG, however, the difference between the slow eye movements at sleep onset and the newly discovered rapid motility was obvious. Initially, there was a great deal of concern that these potentials were electrical artifacts. With their presence on the EOG as a signal, however, it was possible to watch the subject's eyes simultaneously, permitting easy detection of the distinct rapid movements of the eyes beneath closed lids.

At this point, Aserinsky and Kleitman made two assumptions:

1. These eye movements represented a "lightening" of sleep.
2. Because they were associated with irregular respiration and accelerated heart rate, they might represent dreaming.

The basic sleep cycle was not yet identified at this time, primarily because the EOG and other physiologic measures, notably the EEG, were not recorded continuously but rather were "sampled" during a few minutes of each hour or half-hour. The sampling strategy was designed to conserve paper (in the absence of research grants!); morever, no clear reason to record continuously had been identified. This schedule also made it possible for the researcher to nap between sampling episodes.

Aserinsky and Kleitman initiated a small series of awakenings, both when rapid eye movements were present and when they were not, for the purpose of eliciting dream recall. These workers did not apply sophisticated methods of dream content analysis, but the descriptions of dream content from the two conditions generally were quite different, with awakenings during periods of rapid eye movements often yielding vivid complex stories, in contrast with awakening periods, when rapid eye movements were not present, yielding nothing at all or very sparse accounts. This distinction made it possible to hypothesize that rapid eye movements were associated with dreaming. This was, indeed, a breakthrough in sleep research.[27,28] Although Dement participated in this research as a medical student, he was not credited in these early articles. His recollection is that he later coined the abbreviations REM and NREM to simplify the typing of subsequent manuscripts and publications (Dement, personal communication, 2014). These terms appear for the first time in the literature in a footnote by Dement and Kleitman in 1957.[29]

The occurrence of the eye movements was quite compatible with the contemporary dream theories that dreams occurred when sleep lightened, to prevent or delay awakening. In other words, dreaming could still be regarded as the "guardian" of sleep. It could no longer be assumed, however, that dreams were fleeting and evanescent. This recognition put an end to the concept that sleep was a passive state.

ALL-NIGHT SLEEP RECORDINGS AND THE BASIC SLEEP CYCLE

The seminal paper by Aserinsky and Kleitman, published in 1953,[27]attracted little attention, and no publications on the subject appeared from any other laboratory until 1959.[30] Staying up at night to study sleep remained an undesirable occupation by any standards. In the early 1950s, most previous research on the EEG patterns of sleep, like most approaches to sleep physiology generally, had either equated short periods of sleep with all sleep or relied on infrequent sampling during the night. Obtaining continuous records throughout typical nights of sleep seemed highly extravagant—owing in no small part to the cost of the blocks of paper required.

However, motivated by the desire to expand and quantify the description of rapid eye movements, Dement and Kleitman did just this: They recorded EEGs over a total of 126 nights with 33 subjects and, by means of a simplified categorization of EEG patterns, scored the paper recordings in their entirety.[31] On examining these 126 records, they found a predictable sequence of patterns, over the course of the night, that had been overlooked in all previous EEG studies of sleep. This sequence has now been observed throughout the world, and the original description remains essentially unchanged.

The usual sequence was that after the onset of sleep, the EEG pattern progressed fairly rapidly to slow wave sleep, which persisted for a variable period, generally approximately 30 minutes, and then a "lightening" took place. Whereas the progression from wakefulness to slow wave sleep at the beginning of the cycle almost invariably occurred through a continuum of change, the lightening usually was abrupt and coincident with a body movement or series of body movements. After the termination of stage 4, there generally was a short period of stage 2 or stage 3 sleep, which gave way to stage 1 and rapid eye movements. When the first eye movement period ended, the EEG again progressed through a continuum of change to slow wave sleep, which persisted for a time and then lightened, often abruptly, with body movement to stage 2, which again gave way to stage 1 and the second rapid eye movement period (as detailed in Dement and Kleitman's report[31]).

Dement and Kleitman found that this cyclic variation of EEG pattern occurred repeatedly throughout the night at intervals of 90 to 100 minutes from the end of one eye movement period to the end of the next. The regular occurrences of REM periods and dreaming strongly suggested that dreams did not occur in response to chance disturbances.

At the time of these observations, sleep was still considered to be a single state. Dement and Kleitman characterized the EEG pattern during REM periods as "emergent stage 1," as opposed to "descending stage 1" at the onset of sleep. The percentage of the total sleep time occupied by REM sleep was between 20% and 25%, and the periods of REM sleep tended to be shorter in the early cycles of the night. This pattern of all-night sleep has been seen over and over in normal humans of both sexes, in widely varying environments and cultures, and across the life span.

RAPID EYE MOVEMENT SLEEP IN ANIMALS

The developing knowledge of the nature of sleep with rapid eye movements was in direct opposition to the ascending reticular activating system theory and constituted a paradigmatic crisis. The following observations were crucial:

- Arousal thresholds in humans were much higher during periods of REM sleep associated with a low-amplitude, relatively fast (stage 1) EEG pattern than during similar "light sleep" periods at the onset of sleep.
- Rapid eye movements during sleep were discovered in cats; the concomitant brain wave patterns (low-amplitude, fast) were indistinguishable from those in active wakefulness.[32]
- By discarding the sampling approach and recording continuously, a basic 90-minute cycle of sleep without rapid eye movements, alternating with sleep with rapid eye movements, was discovered.[31] This basic sleep cycle characterized all episodes of nocturnal sleep. Continuous recording also revealed a consistent, low-amplitude EEG pattern during a precise interval of sleep always associated with bursts of REM, which were additionally established as periods of vivid dreaming.
- Observations of motor activity in both humans and animals revealed the unique occurrence of an active suppression of spinal motor activity and muscle reflexes.

Thus sleep consists not of one state but rather of two distinct organismic states, as different from one another as both are from wakefulness. It had to be conceded that sleep could no longer be thought of as a time of brain inactivity and EEG slowing. By 1960, this fundamental change in thinking about the nature of sleep was well established; it exists as fact that has not changed in any way since then.

The discovery of rapid eye movements during sleep in humans, plus the all-night sleep recordings that revealed the regular recurrence of lengthy periods during which rapid eye movements occurred and during which brain wave patterns resembled those of light sleep, prepared the way for the discovery of REM sleep in cats, despite the extremely powerful bias that an "activated" EEG pattern could not be associated with sleep. In the first study in cats, maintaining the insulation and hence the integrity of implanted electrodes had not yet been solved, so an alternative, placement of small pins in the scalp, was used. With this approach, the waking EEG was totally obscured by the electromyogram from the large temporal muscles of the cat. However, when the animal fell asleep, slow waves could be seen, and the transition to REM sleep was clearly observed because muscle potentials were completely suppressed. The cat's rapid eye movements and also the twitching of the whiskers and paws could be directly observed.

It is very difficult now, in the 21st century, to understand and appreciate the exceedingly controversial nature of these findings. The following personal account from Dement[33] illustrates both the power and the danger of scientific dogma:

> I wrote them [the findings] up, but the paper was nearly impossible to publish because it was completely contradictory to the totally dominant neurophysiological theory of the time. The assertion by me that an activated EEG could be associated with unambiguous sleep was considered to be

absurd. As it turned out, previous investigators had observed an activated EEG during sleep in cats[28,29] but simply could not believe it and ascribed it to arousing influences during sleep. A colleague who was assisting me was sufficiently skeptical that he preferred I publish the paper as sole author. After four or five rejections, to my everlasting gratitude, Editor-in-Chief Herbert Jasper accepted the paper without revision for publication in *Electroencephalography and Clinical Neurophysiology*.[33]

Of note, however, many early researchers (Dement included) did not recognize the significance of the absence of muscle potentials during the REM periods in cats. It remained for Michel Jouvet, working in Lyon, France, to insist on the importance of electromyographic suppression in his early papers, the first of which was published in 1959.[30,34] Hodes and Dement began to study the "H-reflex" in humans in 1960, finding complete suppression of reflexes during REM sleep, and Octavio Pompeiano and others in Pisa, Italy, worked out the basic mechanisms of REM atonia in the cat.[35,36]

DUALITY OF SLEEP

Even though the basic NREM sleep cycle was well established, the realization that REM sleep was qualitatively different from that in the remainder of the sleep cycle took years to evolve. Jouvet and colleagues performed an elegant series of investigations on the brainstem mechanisms of sleep that forced the inescapable conclusion that sleep consists of two fundamentally different organismic states.[37] Among their many early contributions were clarification of the role of pontine brainstem systems as the primary anatomic site for REM sleep mechanisms and the clear demonstration that electromyographic activity and muscle tonus are completely suppressed during REM periods and *only* during REM periods. These investigations began in 1958 and were carried out during 1959 and 1960.

It is now well established that atonia is a fundamental characteristic of REM sleep and is mediated by an active and highly specialized neuronal system. The pioneering microelectrode studies of Edward Evarts in cats and monkeys, and observations on cerebral blood flow in the cat by Reivich and Kety, provided convincing evidence that the brain during REM sleep is very active.[38,39] Certain areas of the brain appear to be more active in REM sleep than in wakefulness. By that time, the notion of sleep as a passive process was totally demolished, although a persistent attitude that NREM sleep was essentially inactive and quiet lingered for many years. By 1960, it was possible to define REM sleep as a completely separate organismic state characterized by cerebral activation, active motor inhibition, and, of course, an association with dreaming. The fundamental duality of REM versus NREM sleep was established fact. It is of historical interest that the fascination with dreaming influenced the naming of REM and everything else the rather dismissive term NREM, even though NREM took up a larger part of the sleep cycle. This rudimentary distinction may be historically analogous to early descriptions of portions of the genome as "junk DNA."

PRECURSORS OF SLEEP MEDICINE

Sleep research, which emphasized all-night sleep recordings, burgeoned in the 1960s and was the legitimate precursor of sleep medicine and particularly of its core clinical test, polysomnography. Much of the research at that time emphasized studies of dreaming and REM sleep and had its roots in a psychoanalytic approach to mental illness, which strongly implicated dreaming in the psychotic process. After sufficient numbers of all-night sleep recordings had been carried out in humans to demonstrate a highly characteristic "normal" sleep architecture, investigators noted a significantly shortened REM latency in association with endogenous depression.[40] This phenomenon has been intensively investigated ever since. Other important precursors of sleep medicine were the following:

1. Discovery of sleep-onset REM periods in patients with narcolepsy
2. Interest in sleep, epilepsy, and abnormal movement—primarily in France
3. Introduction of benzodiazepines and the use of sleep laboratory studies in defining hypnotic drug efficacy

Sleep-Onset REM Periods and Cataplexy

In 1959, a patient with narcolepsy came to the Mount Sinai Hospital in New York City to see Drs. Charles Fisher and Dement. At Fisher's suggestion, a nocturnal sleep recording was begun. Within seconds after he fell asleep, the patient showed the dramatic and characteristic rapid eye movements and sawtooth waves of REM sleep. The first paper documenting sleep-onset REM periods in a specific patient was published in 1960 by Gerald Vogel, at the time working in Chicago.[41] In a collaborative study between the University of Chicago and the Mount Sinai Hospital, data on nine narcoleptic patients with sleep-onset REM periods at night were reported in 1963.[42] Subsequent research showed that sleepy patients who did not have cataplexy did not have sleep-onset REM periods (SOREMPs), and those with cataplexy always had SOREMPs.[43] For the first time, a clinical role for the polysomnogram as a potential diagnostic tool was being identified! Sleep research was becoming sleep medicine.

The Narcolepsy Clinic: A False Start

In January 1963, after leaving Mount Sinai and moving to Stanford University, Dement was eager to test the hypothesis of an association between cataplexy and SOREMPs. However, not a single narcoleptic patient was located in the San Francisco Bay area. In desperation, the investigators placed a brief "want ad," requesting such subjects, in a daily newspaper, the *San Francisco Chronicle*. More than 100 people responded; approximately 50 of these patients were bona fide narcoleptics afflicted with both sleepiness and cataplexy.

The response to the ad was a noteworthy event in the development of sleep disorders medicine. With one or two exceptions, none of the narcoleptics had ever been correctly diagnosed. Responsibility for their clinical management had to be assumed in order to facilitate their participation in the research. The late Dr. Stephen Mitchell, who had completed his neurology training and was entering a psychiatry residency at Stanford University, joined Dement in creating a narcolepsy clinic in 1964, and soon they were managing well over 100 patients. This program involved seeing the patients at regular intervals and adjusting their medication. Nonetheless, it constituted a precursor to the typical sleep disorders clinic, because at least one daytime polygraphic sleep recording was performed in all patients to establish the presence of SOREMPs.

Patients were questioned comprehensively about their sleep. When possible, an all-night sleep recording also was carried out. Unfortunately, insurance companies declared that such recordings in narcoleptic patients were experimental. This ruling forced the closure of the clinic because of insufficient funds—foreshadowing how third party payers have influenced the practice of clinical sleep medicine in the United States.

European Interest

In Europe, a genuine research interest in sleep problems had arisen, and it achieved its clearest expression in a 1963 symposium held in Paris, organized by Professor H. Fischgold, with its proceedings published as *La Sommeil de Nuit Normal et Pathologique* in 1965.[44] The primary clinical emphasis in this symposium was the documentation of sleep-related epileptic seizures and analyses of a number of related studies on sleepwalking and night terrors. Investigators from France, Italy, Belgium, Germany, and the Netherlands took part. The important role of European sleep scientists in the establishment of clinical sleep medicine is discussed further on.

Benzodiazepines and Hypnotic Efficacy Studies

In parallel with the discoveries being made in narcolepsy, a renewed interest in the pharmacologic treatment of insomnia was emerging. Benzodiazepines were introduced in 1960 with the marketing of chlordiazepoxide (Librium). This compound offered a significant advance in terms of safety over barbiturates for the purpose of tranquilizing and sedating. It was quickly followed by diazepam (Valium) and the first benzodiazepine introduced specifically as a hypnotic, flurazepam (Dalmane). Although a number of studies had been done on the effects of drugs on sleep, the first use of the sleep laboratory to evaluate sleeping pills may have been the 1965 study by Oswald and Priest.[45] An important series of studies establishing the role of the sleep laboratory in the evaluation of hypnotic efficacy was carried out by Anthony Kales and colleagues at the University of California Los Angeles.[46] This group also carried out pioneering studies of patients with hypothyroidism, asthma, Parkinson disease, and somnambulism.[47-50]

THE DISCOVERY OF SLEEP APNEA

The original description of sleep apnea often is attributed to independent publications by Gastaut, Tassinari, and Duron in France and by Jung and Kuhlo in Germany.[51,52] Both of these groups reported their findings in 1965. Scholars have found references to this phenomenon in many places, but these publications allowed for a clear-cut recognition of the phenomenon, and they had a direct causal continuity to sleep disorders medicine as we know it today. Earlier work in this area deserves mention (Christian Guilleminault, personal communication, 2014). In a report published in German, a group from Heidelberg University Hospital in 1960 described a patient who had come to the hospital for investigation of recurring morning headaches and was observed to have respiratory pauses during sleep, with recovery breathing associated with a loud snore. A polygraphic recording during a nap was included in the publication.[53] From the National Institutes of Health (NIH), a publication by Drachman and Gumnit described evaluation of an obese woman using electroencephalography and blood gas analysis, which identified repetitive stoppage of air exchange despite persistence of thoracoabdominal movements. The patient was placed on a strict diet and after a significant weight loss saw her sleepiness disappear.[54] No further publications in the area of sleep from this group are available, so it appears their work was not appreciated at the time. Peretz Lavie has detailed the historical contributions made by scientists and clinicians around the world in helping to describe and elucidate this disorder.[21]

These important findings were widely ignored in America (Video 1-2). What should have been an almost inevitable discovery by either the otolaryngologic surgery community or the pulmonary medicine community did not occur because neither specialty included a tradition for carefully observing breathing during sleep. The well-known and frequently cited study by Burwell and colleagues—although impressive in a literary sense in its evoking of the somnolent boy Joe from *The Pickwick Papers*—erred badly in evaluating their somnolent obese patients only during waking, and in attributing the cause of the somnolence to hypercapnia.[55]

The popularity of this paper further reduced the likelihood of discovery of sleep apnea by the pulmonary community. The term *pickwickian* was an instant success as a neologism, and its colorful connotations may have played a role in stimulating interest in this syndrome by the European neurologists who also were interested in sleep.

A small group of French neurologists who specialized in clinical neurophysiology and electroencephalography were in the vanguard of sleep research. Among these was Christian Guilleminault, who was instrumental in later establishing the specialty of clinical sleep medicine at Stanford and throughout the world. Guilleminault also was the first to describe obstructive sleep apnea as a clinical syndrome.[56,57]

One of the collaborators in the French discovery of sleep apnea, C. Alberto Tassinari, joined the Italian neurologist Elio Lugaresi in Bologna in 1970. These clinical investigators, along with Giorgio Coccagna and a host of others, including Guilleminault, over the years performed a crucial series of clinical sleep investigations and, indeed, provided a complete description of the sleep apnea syndrome, including the first observations of the occurrence of sleep apnea in nonobese patients, an account of the cardiovascular correlates, and a clear identification of the importance of snoring and hypersomnolence as diagnostic indicators. These studies are recounted in Lugaresi's book, *Hypersomnia with Periodic Apneas,* published in 1978.[58]

ITALIAN SYMPOSIA

In 1967, Henri Gastaut and Elio Lugaresi (Figure 1-4) organized a symposium, the proceedings of which were published as *The Abnormalities of Sleep in Man,* that encompassed issues across a full range of pathologic sleep in humans.[59] This meeting took place in Bologna, Italy, and the papers presented covered many of what are now major topics in the sleep medicine field: insomnia, sleep apnea, narcolepsy, and periodic leg movements during sleep. It was an epic meeting from the standpoint of the clinical investigation of sleep; the only major issues not represented were clear concepts of clinical practice models and hard data on the high population prevalence of sleep disorders. However, the event that may have finally triggered a serious international interest in sleep apnea syndromes was a symposium organized by Lugaresi in 1972, which took place in Rimini, a small resort on the Adriatic coast.[54]

BIRTH PANGS

Despite all the clinical research, the concept of all-night sleep recordings as a clinical diagnostic test did not emerge unambiguously. It is worth considering the reasons for this failure, partly because they continue to operate today as impediments to the expansion of the sleep medicine field, and partly to elucidate the field's long-overdue development.

The first important reason was the unprecedented burdensome nature of an all-night diagnostic test, particularly if it was conducted on an outpatient basis. The cost of all-night polygraphic recording, in terms of its basic expense, was high enough without adding the cost of hospitalization, although hospitalization would have legitimized the patient's spending the night in a testing facility. To sleep in an outpatient clinic for a diagnostic test was a totally unprecedented, time-intensive and labor-intensive enterprise, and completely in conflict with the brief time required for accepted test protocols such as reporting to the chemistry laboratory to give a blood sample, breathing into a pulmonary function testing apparatus, and undergoing a screening radiographic examination.

A second important barrier was the reluctance of nonhospital clinical professionals to work at night. Although medical house staff physicians are very familiar with night work, they do not generally enjoy it; furthermore, clinicians could not work 24-hour days, first seeing patients and ordering tests, and then conducting the tests themselves.

Finally, only a very small number of people in relevant fields understood that complaints of daytime sleepiness and nocturnal sleep disturbance represented something of clinical significance. Even narcolepsy, which was by the early 1970s fully characterized as an interesting and disabling clinical syndrome requiring sleep recordings for diagnosis, was not recognized in the larger medical community and had too low a prevalence to warrant creating a medical subspecialty. A study carried out in 1972 documented a mean of 15 years from onset of the characteristic symptoms of excessive daytime sleepiness and cataplexy to diagnosis and treatment by a clinician. The study also showed that a mean of 5.5 different physicians were consulted without benefit throughout that long interval.[60]

EARLY DEVELOPMENT OF STANFORD SLEEP MEDICINE CLINICAL PRACTICE

Creation of the sleep disorders clinic at Stanford University was in many ways a microcosm of how sleep medicine evolved throughout the world. Dement arrived at Stanford in 1963 to establish a sleep research program. A need for clinical application of the knowledge being acquired soon became obvious. By 1964 subjects in narcolepsy trials also were managed as patients. Patients complaining of insomnia were enrolled in hypnotic efficacy research studies. This arrangement brought the Stanford group into contact with many patients afflicted with insomnia and demolished the notion that a majority of such patients had psychiatric problems. An early concern was the reliability of the subjective descriptions of their sleep. The classic all-night sleep recording gave an answer and yielded a great deal of information. Throughout the second half of the 1960s, as a part of their research, the Stanford group continued to manage patients with narcolepsy and insomnia. As the group's reputation for expertise grew, it began to receive referrals for evaluation from physicians all over the United States. Vincent Zarcone, a psychiatrist, joined this effort to develop the field of clinical sleep medicine at Stanford. In 1970 a sleep clinic was formally established at Stanford. Not surprisingly, the fledging clinic immediately struggled with reimbursement issues.

When the clinic was opened in 1970, the central role of obstructive sleep apnea as a mechanism of sleep-related pathology was not yet appreciated. It took an international meeting in Bruges, Belgium, for the Stanford group to recognize the importance of this entity. At that meeting, Dr. Zarcone was particularly impressed with Christian Guilleminault, a neurologist with knowledge of sleep apnea who had previously performed sleep research at Stanford with Dr. Steve Hendrickson. At that Bruges meeting, Dr. Zarcone suggested to Dement that they try to recruit Guilleminault. Dement had already been considering recruiting a neurologist to Stanford. Guilleminault welcomed the opportunity to strengthen the clinical sleep medicine program at Stanford. The synergy of these three physicians set in motion the creation of the first successful sleep medicine clinic, which served as a model for the rest of the world.

In January 1972, Christian Guilleminault formally joined the Stanford group. He had extensive knowledge of the European studies of sleep apnea. Until his arrival, the Stanford group had not routinely used respiratory and cardiac sensors in their all-night sleep studies. Starting in 1972, these measurements became a routine part of the all-night diagnostic test. This test was given the permanent name of *polysomnography* in 1974 by Dr. Jerome Holland, a member of the Stanford group. Publicity about narcolepsy and excessive sleepiness resulted in a small flow of referrals to the Stanford sleep clinic, usually with the presumptive diagnosis of narcolepsy. During the first year or two, the goal for the Stanford practice was to see at least four new patients per week. To foster financial viability, the group did as much as possible (within ethical limits) to publicize its services. As a result, the clinic also acquired a small number patients, often self-referred, with chronic insomnia. The diagnosis of obstructive sleep apnea in patients with profound excessive daytime sleepiness was nearly always completely unambiguous.

Toward the end of 1972, the basic concepts and formats of sleep disorders medicine were sculpted to the extent that it was possible to offer a daylong course through Stanford University's Division of Postgraduate Medicine. In this course, titled "The Diagnosis and Treatment of Sleep Disorders," the topics covered were normal sleep architecture; the diagnosis and treatment of insomnia, with drug-dependent insomnia, pseudoinsomnia, central sleep apnea, and periodic leg movement as diagnostic entities; and the diagnosis and treatment of excessive daytime sleepiness or hypersomnia, with narcolepsy, NREM narcolepsy, and obstructive sleep apnea as diagnostic entities.

The cardiovascular complications of severe sleep apnea were alarming and often completely disabling. Unfortunately, the treatment options at this time were limited to often ineffective attempts to lose weight and chronic tracheostomy. The dramatic results of chronic tracheostomy in ameliorating the symptoms and complications of obstructive sleep apnea had been reported by Lugaresi and coworkers in 1970.[61] The notion of using such a treatment, however, was strongly resisted at the time by the medical community. One of the first patients referred to the Stanford sleep clinic for investigation of this severe somnolence and who eventually had a tracheostomy was a 10-year-old boy. From the very beginning of the development of clinical sleep medicine, children and adults were treated together.

In addition to medical skepticism, a major obstacle to the practice of sleep disorders medicine was the retroactive denial of payment by insurance companies, including the largest insurance company in the United States at the time. At a meeting with insurance company officials, Dr. Dement was even accused of being a "charlatan" when he tried to convey the importance of obstructive sleep apnea. A 3-year period of dogged educational efforts directed toward third party payers finally culminated in the recognition of polysomnography in California as a reimbursable diagnostic test in 1974. This landmark event opened the doors for the practice of sleep medicine throughout the nation. In retrospect, it seems clear that educational effort exerted and resulting policy decisions have undoubtedly saved countless lives and improved the health and well-being of perhaps millions of people worldwide.

CLINICAL SIGNIFICANCE OF EXCESSIVE DAYTIME SLEEPINESS

Christian Guilleminault, in a series of studies, had clearly shown that excessive daytime sleepiness was a major clinical complaint in several sleep disorders, as well as a pathologic phenomenon unto itself.[62] It was recognized, however, that methods to quantify this symptom and the underlying condition were not adequate to quantify the treatment outcome. The subjective Stanford Sleepiness Scale, developed by Hoddes and colleagues, did not give reliable results.[63] With the creation of sleep medicine clinics, a new problem emerged: how to objectively quantitate sleepiness.

The apparent lack of interest in daytime sleepiness by individuals who were devoting their careers to the investigation of sleep at that time has always been puzzling. Unquestionably, the current active investigation of this phenomenon is the result of the early interest of sleep disorders specialists. The neglect of sleepiness in previous research is all the more difficult to understand today, when sleepiness and the tendency to fall asleep during the performance of hazardous tasks are now widely recognized as important public health problems affecting our society. A number of reasons have been put forward. One is that sleepiness and drowsiness are negative qualities. A second is that the societal failure to confront the issue was fostered by language ambiguities in identifying sleepiness. A third is that the early sleep laboratory studies focused almost exclusively on REM sleep and other nighttime procedures, with little concern for the daytime except for psychopathology. Finally, the focus with regard to sleep deprivation was on performance from the perspective of human factors, rather than on sleepiness as representing a homeostatic response to sleep reduction.

An early attempt to develop an objective measure of sleepiness was that of Yoss and coworkers, who observed pupil diameter directly by video monitoring and described changes in sleep deprivation and narcolepsy.[64] Subsequently designated *pupillometry,* this technique has not been widely accepted. Dr. Mary Carskadon, while at Stanford, deserves most of the credit for the development of the latter-day standard approach to the measurement of sleepiness, called the Multiple Sleep Latency Test (MSLT).[65] She noted that subjective ratings of sleepiness made before a sleep recording frequently predicted the sleep latency. In the spring of 1976, she undertook to establish sleep latency as an objective measurement of the state of "sleepiness-alertness" by measuring sleep tendency before, during, and after 2 days of total sleep deprivation.[66] The protocol designed for this study has become the standard protocol for the MSLT. The choices of a 20-minute duration of a single test and a 2-hour interval between tests were essentially arbitrary and dictated by the practical demands of that study. This test was then formally applied to the clinical evaluation of sleepiness in patients with narcolepsy and, later, in patients with OSAS.[67,68] Of note, Dr. Gary Richardson as a student at Stanford coauthored these publications.

Carskadon and colleagues then undertook a monumental study of sleepiness in children by following them longitudinally across the second decade of life, which happens to also be the decade of highest risk for the development of narcolepsy. Using the new MSLT measure, these investigators found that 10-year-old children were completely alert in the daytime, but by the time the subjects reached sexual maturity, they were no longer fully alert even though they obtained almost the same amount of sleep at night as that in the period of childhood studied. Results of this remarkable decade of work and other studies are summarized in an important review.[69] In an effort spearheaded by Dr. Rafael Pelayo, Stanford University acknowledged the importance of this historic work by installing a permanent plaque in 2012 at the dormitory that housed this research.

Early MSLT research established the following important advances in thinking:

1. Daytime sleepiness and nighttime sleep are components of an interactive continuum, and the adequacy of nighttime sleep absolutely cannot be understood without a complementary measurement of the level of daytime sleepiness or its antonym, alertness.
2. Excessive sleepiness, also known as impaired alertness, was sleep medicine's most important symptom.

FURTHER DEVELOPMENT OF SLEEP MEDICINE

As the decade of the 1970s drew to a close, the consolidation and formalization of the practice of sleep disorders medicine were largely completed. What is now the American Academy of Sleep Medicine was formed and provided a home for professionals interested in sleep and, particularly, in the diagnosis and treatment of sleep disorders. This body, the Association of Sleep Disorders Centers (ASDC), began with five members in 1975. The organization then was responsible for the initiation of the scientific journal *Sleep.* It fostered the setting of standards through center accreditation and an examination for practitioners by which they were designated Accredited Clinical Polysomnographers.

The first international symposium on narcolepsy took place in the French Languedoc in the summer of 1975, immediately after the Second International Congress of the Association for the Physiological Study of Sleep (APSS) in Edinburgh. The former meeting, in addition to being scientifically productive, was of landmark significance because it produced the first consensus definition of a specific sleep disorder, drafted, revised, and unanimously endorsed by 65 narcoleptologists of international reputation.[70] The first sleep disorders patient volunteer organization, the American Narcolepsy Association, also was formed in 1975. The ASDC/APSS Diagnostic Classification of Sleep and Arousal Disorders was published in fall 1979 after 3 years of extraordinary effort by a small group of dedicated persons who made up the "nosology" committee chaired by Dr. Howard Roffwarg.[71] This early nosology was the precursor to the subsequent versions of the International Classification of Sleep Disorders.

Before the 1980s, the only effective treatment for severe OSAS was chronic tracheostomy. This highly effective but personally undesirable approach was replaced by two new procedures—one surgical, the other mechanical.[72,73] The first was uvulopalatopharyngoplasty(UPPP), which at the time was considered an advance, eventually fell into disfavor owing to its being both painful and often ineffective. UPPP did pave the way for more sophisticated and effective surgical options. The second was the widely used and highly effective continuous positive nasal airway pressure (CPAP) technique introduced by the Australian pulmonologist Colin Sullivan (Video 1-3). The first CPAP machines were very loud and uncomfortable. Fortunately, as the technology improved, CPAP devices entered the medical mainstream. The combination of the high prevalence of OSAS and, at the time, newly effective treatments fueled a strong expansion of sleep centers and clinicians. The ramifications of this growth are still being felt today.

The decade of the 1980s was capped by the publication of sleep medicine's first textbook, the first edition of *Principles and Practice of Sleep Medicine*.[74] For many years only one medical journal devoted to sleep existed; today, several are in publication, including *Sleep, Journal of Clinical Sleep Medicine, Journal of Sleep Research, Sleep and Biological Rhythms, Sleep & Breathing, Sleep Medicine, Sleep Medicine Reviews,* and *Sleep Research Online.* Articles about sleep are now routinely published in the major pulmonary, neurology, ear-nose-throat (ENT), pediatric, primary care, and psychiatric journals.

The 1990s saw an acceleration in the acceptance of sleep medicine throughout the world. Nonetheless, adequate sleep medicine services are still not readily available everywhere.[75,76]

In the United States, the National Center on Sleep Disorders Research (NCSDR) was established by statute as part of the National Heart, Lung, and Blood Institute of the National Institutes of Health.[77] The mandate of the NCSDR is to support research, promote educational activities, and coordinate sleep-related activities throughout various branches of the U.S. government. It is perhaps too easy to criticize any government body or to decry insufficient research funding, yet the mere recognition by the federal government of the importance of sleep by establishing the NCSDR is a huge achievement when taken in the perspective of how the sleep field began. This government initiative led to the development of large research projects dealing with various aspects of sleep disorders and the establishment of awards to develop educational materials at all levels of training.

The 1990s also saw the establishment of the National Sleep Foundation, as well as other organizations for patients. This foundation points out to the public the dangers of sleepiness and sponsors the annual National Sleep Awareness Week.

As the Internet increases exponentially in size, so does the availability of sleep knowledge for physicians, patients, and the general public. The average person today knows a great deal more about sleep and its disorders than the average person did at the end of the 1980s. It is perhaps unique to the sleep field that the Internet, on the one hand, has increased the availability of information on sleep. On the other hand, it seems self-evident that the Internet also has accelerated humanity's march toward a sleepless 24-hour society and has increased the pressure for sleep deprivation and poor hygiene, in particular among the young.

THE 21ST CENTURY AND BEYOND

The historical early development of clinical sleep medicine culminated with its acceptance in 2003 by the Accreditation Council on Graduate Medical Education (ACGME) as a formal training program. The field emerged from its embryonic origins to worldwide acceptance in a relatively short period of time, owing in no small part to the great public need for healthier sleep and alertness. The recognition of the importance of sleep as a health and wellness component was exemplified by the appointment of Dr. Mark Rosekind to the National Transportation Safety Board (NTSB) in 2010. For the first time in its history, the NTSB had a trained sleep scientist as a board member (Figure 1-5). The impact of this recognition is likely to be very far-reaching for public safety.

From today's vantage point, the greatest challenge for the future is the cost-effective expansion of sleep medicine to provide benefit to the increasing number of patients in society. The management of sleep deprivation and its serious consequences in the workplace, particularly in those industries that depend on sustained operations, continues to need increased attention. Healthy sleep needs to be a priority for all.

The education and training of all health professionals have far to go. This situation was highlighted by the report of the Institute of Medicine.[76] These problems also represent grand opportunities for research. Sleep medicine has come into its own. It has made concern for health a truly 24-hours-a-day

Figure 1-5 Dr. Mark Rosekind is sworn in by Dr. William Dement as the first sleep scientist at the National Transportation Safety Board (NTSB). Drs. Mary Carskadon and Deborah Babcock look on. enterprise, and it has energized a new effort to reveal the secrets of the healthy and unhealthy sleeping brain.

Looking back at the history of sleep medicine forces the medical profession, and society as a whole, to look forward to the future. The future of sleep research indeed promises to be exciting. Finally answering the ancient questions about the basic functions of sleep and dreaming may be within the grasp of the current generation of young scientists. They would not be poised for these future discoveries if not for the early work described in this chapter.

Many times the young sleep medicine field seemed to be doomed to fail, yet the huge need to understand sleep and its disorders continued to push it forward. Currently, as the field faces new challenges with changes in health care and reimbursement policies, it is easy to be pessimistic about its future. Yet such challenges constitute part of a natural process of change. The forces that have driven the field forward are, if anything, expanding. The population is growing and getting older. Increasingly, people are expected to be alert and productive in a 24-hour society. Consequently, sleep medicine needs to continue to adapt to these societal changes. All practitioners in both sleep medicine and sleep research should keep in mind that millions of people have benefited from their work, and that billions more still need their help.

We remain realistically optimistic about the future of sleep medicine.

CLINICAL PEARL

Recent advances in sleep science, sleep medicine, public policy, and communications will foster an educated public that will know a great deal about sleep and its disorders. Clinicians should expect that their patients may have already learned about their sleep disorders from the information sources that are readily available. They also may have received considerable misinformation from these same sources. Sleep professionals need to know the history of sleep medicine for proper perspective and useful insights as the field evolves.

SUMMARY

Interest in sleep dates to antiquity and has influenced all cultures and religions. Ancient medical texts describe treatments for sleep problems such as insomnia. Just over a hundred years ago, sleep was thought of as a passive state. The discovery of electroencephalography led to concept of sleep as an active state. The discovery of REM sleep in the 1950s allowed the empirical challenge to the previously held beliefs. The formal study of sleep disorders using polysomnography progresses in the 1960s. Obstructive sleep apnea was described mostly by researchers based in Europe at that time. Despite a series of false steps, clinical sleep medicine was established at Stanford University in 1970 and shortly thereafter in other institutions. The organization of these groups led to the creation of professional sleep societies and further worldwide growth and recognition of sleep medicine. Sleep medicine was recognized in 2003 by the Accreditation Council on Graduate Medical Education (ACGME) as a formal training program. The field continues to evolve. As sleep medicine faces new challenges, an appreciation of its historical background can provide practitioners with insights for shaping the future of the discipline.

Chapter 2

Normal Human Sleep: An Overview

Mary A. Carskadon; William C. Dement

Chapter Highlights

- Normal human sleep comprises two states—rapid eye movement (REM) and non–REM (NREM) sleep—that alternate cyclically across a sleep episode. State characteristics are well defined: NREM sleep includes a variably synchronous cortical electroencephalogram (EEG; including sleep spindles, K-complexes, and slow waves) associated with low muscle tonus and minimal psychological activity; the REM sleep EEG is desynchronized, muscles are atonic, and dreaming is typical.
- A nightly pattern of sleep in mature humans sleeping on a regular schedule includes several reliable characteristics: Sleep begins in NREM and progresses through deeper NREM stages (stages 2, 3, and 4 using the classic definitions, or stages N2 and N3 using the American Academy of Sleep Medicine Scoring Manual definitions) before the first episode of REM sleep occurs about 80 to 100 minutes later. Thereafter, NREM sleep and REM sleep cycle with a period of about 90 minutes. NREM stages 3 and 4 (or stage N3) concentrate in the early NREM cycles, and REM sleep episodes lengthen across the night.
- Age-related changes are also predictable: Newborn humans enter REM sleep (called active sleep) before NREM (called quiet sleep) and have a shorter sleep cycle (about 50 minutes); coherent sleep stages emerge as the brain matures during the first year. At birth, active sleep is about 50% of total sleep and declines over the first 2 years to about 20% to 25%. NREM sleep slow waves are not present at birth but emerge in the first 2 years. Slow wave sleep (stages 3 and 4) decreases across adolescence by about 40% from preteen years and continues a slower decline into old age, particularly in men and less so in women. REM sleep as a percentage of total sleep is about 20% to 25% across childhood, adolescence, adulthood, and into old age, except in dementia.
- Other factors predictably alter sleep, such as previous sleep-wake history (e.g., homeostatic load), phase of the circadian timing system, ambient temperature, medications and drugs, and sleep disorders.

A clear appreciation of the normal characteristics of sleep provides a strong background and template for understanding clinical conditions in which "normal" characteristics are altered as well as for interpreting certain consequences of sleep disorders. In this chapter, the normal young adult sleep pattern is described as a working baseline pattern. Normative changes associated with aging and other factors are summarized with that background in mind. Several major sleep disorders are highlighted by their differences from the normative pattern.

WHAT CHARACTERISTICS AND MEASURES ARE USED TO DEFINE SLEEP?

According to a simple behavioral definition, sleep is a reversible behavioral state of perceptual disengagement from and unresponsiveness to the environment. It is also true that sleep is a complex amalgam of physiologic and behavioral processes. Sleep is typically (but not necessarily) accompanied by postural recumbence, behavioral quiescence, closed eyes, and all the other indicators commonly associated with sleeping. In the unusual circumstance, other behaviors can occur during sleep. These behaviors can include sleepwalking, sleeptalking, teeth grinding, and other physical activities. Anomalies involving sleep processes also include intrusions of sleep—sleep itself, dream imagery, or muscle weakness—into wakefulness, for example.

Within sleep, two separate states have been defined on the basis of a constellation of physiologic parameters. These two states, rapid eye movement (REM) and non–rapid eye movement (NREM), exist in virtually all mammals and birds yet studied, and they are as distinct from one another as each is from wakefulness. (See Box 2-1 for a discussion of sleep stage nomenclature.)

NREM (pronounced *non-REM*) sleep is conventionally subdivided into four stages defined along one measurement axis, the electroencephalogram (EEG). The EEG pattern in NREM sleep is commonly described as synchronous, with such characteristic waveforms as sleep spindles, K-complexes, and high-voltage slow waves (Figure 2-1). The four NREM stages (stages 1, 2, 3, and 4) roughly parallel a depth-of-sleep continuum, with arousal thresholds generally lowest in stage 1 and highest in stage 4 sleep. NREM sleep is usually

Box 2-1 SLEEP MEDICINE METHODOLOGY AND NOMENCLATURE

In 2007, the American Academy of Sleep Medicine (AASM) published a new manual* for scoring sleep and associated events. This manual recommends alterations to recording methodology and terminology that the AASM will demand of clinical laboratories in the future. Although specifications of arousal, cardiac, movement, and respiratory rules appear to be value-added to the assessment of sleep-related events, the new rules, terminology, and technical specifications for recording and scoring sleep are not without controversy.

The current chapter uses the traditional terminology and definitions on which most descriptive and experimental research has been based since the 1960s.[1] Thus where the AASM uses the terms *N* for NREM sleep stages and *R* for REM sleep stages, *N1* and *N2* are used instead of stage 1 and stage 2; *N3* is used to indicate the sum of stage 3 and stage 4 (often called *slow wave sleep* in human literature); and *R* is used to name REM sleep. Another change is to the nomenclature for the recording placements. Therefore calling the auricular placements *M1* and *M2* (rather than *A1* and *A2*) is unnecessary and places the sleep EEG recording terminology outside the pale for EEG recording terminology in other disciplines. Although these are somewhat trivial changes, changes in nomenclature can result in confusion when attempting to compare with previous literature and established data sets and are of concern for clinicians and investigators who communicate with other fields.

Of greater concern are changes to the core recording and scoring recommendations that the AASM manual recommends. For example, the recommended scoring montage requires using a frontal (*F3* or *F4*) EEG placement with visual scoring of the recordings, rather than the central (*C3* or *C4*) EEG placements recommended in the standard manual. The rationale for the change is that the frontal placements pick up more slow wave activity during sleep. The consequences, however, are that sleep studies performed and scored with the frontal EEG cannot be compared with normative or clinical data and that the frontal placements also truncate the ability to visualize sleep spindles. Furthermore, developmental changes to the regional EEG preclude the universal assumption that sleep slow wave activity is a frontal event.

Other issues are present in this new AASM approach to human sleep; however, this is not the venue for a complete description of such concerns. In summary, the AASM scoring manual has not yet become the universal standard for assessing human sleep and might not achieve that status in its current form. Specifications for recording and scoring sleep are not without controversy.[2-7]

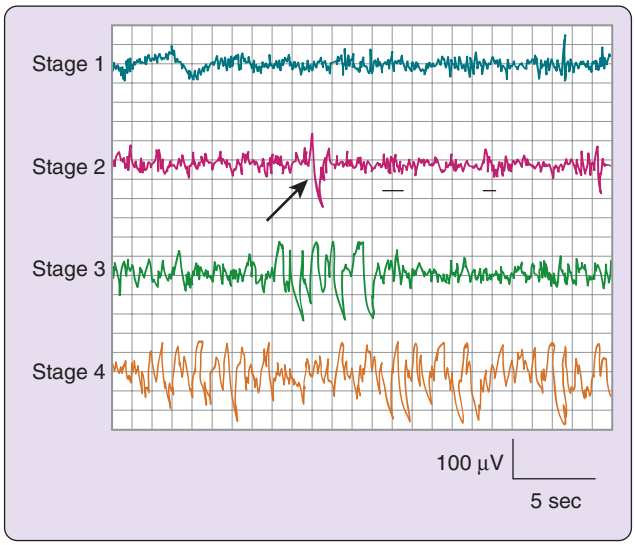

Figure 2-1 The Stages of NREM Sleep. The four electroencephalogram tracings depicted here are from a 19-year-old female volunteer. Each tracing was recorded from a referential lead (C3/A2) on a Grass Instruments (West Warwick, RI) Model 7D polygraph with a paper speed of 10 mm/sec, time constant of 0.3 sec, and ½-amplitude high-frequency setting of 30 Hz. On the second tracing, the *arrow* indicates a K-complex and the *underlining* shows two sleep spindles.

On the *right side,* there are additional rapid eye movements as well as twitches on the electromyographic (EMG) lead. The interval between eye movement bursts and twitches illustrates tonic REM sleep.

associated with minimal or fragmentary mental activity. A shorthand definition of NREM sleep is a relatively inactive yet actively regulating brain in a movable body.

REM sleep, by contrast, is defined by EEG activation, muscle atonia, and episodic bursts of rapid eye movements. REM sleep usually is not divided into stages, although tonic and phasic types of REM sleep are occasionally distinguished for certain research purposes. The distinction of tonic versus phasic is based on short-lived events such as eye movements that tend to occur in clusters separated by episodes of relative quiescence. In cats, REM sleep phasic activity is epitomized by bursts of ponto-geniculo-occipital (PGO) waves, which are accompanied peripherally by rapid eye movements, twitching of distal muscles, middle ear muscle activity, and other phasic events that correspond to the phasic event markers easily measurable in humans. As described in Chapter 164, PGO waves are not usually detectable in humans. Thus the most commonly used marker of REM sleep phasic activity in humans is, of course, the occurrence of rapid eye movements (Figure 2-2); muscle twitches and cardiorespiratory irregularities often accompany the REM bursts. The mental activity of human REM sleep is associated with dreaming, based on vivid dream recall reported after about 80% of arousals from this state of sleep.[8] Inhibition of spinal motor neurons by

brainstem mechanisms mediates suppression of postural motor tonus in REM sleep. A shorthand definition of REM sleep, therefore, is an activated brain in a paralyzed body.

SLEEP ONSET

The onset of sleep under normal circumstances in normal adult humans is through NREM sleep. This fundamental principle of normal human sleep reflects a highly reliable finding and is important in considering normal versus pathologic sleep. For example, the abnormal entry into sleep through REM sleep can be a diagnostic sign in adult patients with narcolepsy.

Definition of Sleep Onset

The precise definition of the onset of sleep has been a topic of debate, primarily because there is no single measure that is 100% clear-cut 100% of the time. For example, a change in EEG pattern is not always associated with a person's perception of sleep, yet even when subjects report that they are still awake, clear behavioral changes can indicate the presence of sleep. To begin a consideration of this issue, let us examine the three basic polysomnographic measures of sleep and how they change with sleep onset. The electrode placements are described in Chapter 165.

Electromyogram

The electromyogram (EMG) may show a gradual diminution of muscle tonus as sleep approaches, but rarely does a discrete EMG change pinpoint sleep onset. Furthermore, the presleep level of the EMG, particularly if the person is relaxed, can be entirely indistinguishable from that of unequivocal sleep (Figure 2-3).

Electrooculogram

As sleep approaches, the electrooculogram (EOG) shows slow, possibly asynchronous eye movements (see Figure 2-3) that usually disappear within several minutes of the EEG changes described next. Occasionally, the onset of these slow eye movements coincides with a person's perceived sleep onset; more often, subjects report that they are still awake.

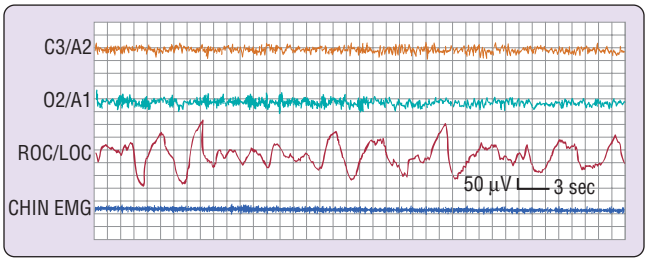

Figure 2-3 The Transition from Wakefulness to Stage 1 Sleep. The most marked change is visible on the two electroencephalographic (EEG) channels (C3/A2 and O2/A1), where a clear pattern of rhythmic alpha activity (8 cps) changes to a relatively low-voltage, mixed-frequency pattern at about the middle of the figure. The level of electromyographic (EMG) activity does not change markedly. Slow eye movements (right outer canthus [ROC]/left outer canthus [LOC]) are present throughout this episode, preceding the EEG change by at least 20 seconds. In general, the change in EEG patterns to stage 1 as illustrated here is accepted as the onset of sleep.

Electroencephalogram

In the simplest circumstance (see Figure 2-3), the EEG changes from a pattern of clear rhythmic alpha (8 to 13 cycles per second [cps]) activity, particularly in the occipital region, to a relatively low-voltage, mixed-frequency pattern (stage 1 sleep). This EEG change usually occurs seconds to minutes after the start of slow eye movements. With regard to introspection, the onset of a stage 1 EEG pattern may or may not coincide with perceived sleep onset. For this reason, a number of investigators require the presence of specific EEG patterns—the K-complex or sleep spindle (i.e., stage 2 sleep)—to acknowledge sleep onset. Even these stage 2 EEG patterns, however, are not unequivocally associated with perceived sleep.[9] A further complication is that sleep onset often does not occur all at once; instead, there may be a wavering of vigilance before "unequivocal" sleep ensues (Figure 2-4). Thus, it is difficult to accept a single variable as marking sleep onset. As Davis and colleagues[10] wrote many years ago (p. 35):

> Is "falling asleep" a unitary event? Our observations suggest that it is not. Different functions, such as sensory awareness, memory, self-consciousness, continuity of logical thought, latency of response to a stimulus, and alterations in the pattern of brain potentials all go in parallel in a general way, but there are exceptions to every rule. Nevertheless, a reasonable consensus exists that the EEG change to stage 1, usually heralded or accompanied by slow eye movements, identifies the transition to sleep, provided that another EEG sleep pattern does not intervene. One might not always be able to pinpoint this transition to the millisecond, but it is usually possible to determine the change reliably within several seconds.

Behavioral Concomitants of Sleep Onset

Given the changes in the EEG that accompany the onset of sleep, what are the behavioral correlates of the wake-to-sleep transition? The following material reviews a few common behavioral concomitants of sleep onset. Keep in mind that "different functions may be depressed in different sequence and to different degrees in different subjects and on different occasions" (p. 35).[10]

Simple Behavioral Task

In the first example, sleepy volunteers sitting at desks were asked to tap two switches alternately at a steady pace. As shown in Figure 2-5, this simple behavior continues after the onset of slow eye movements and may persist for several

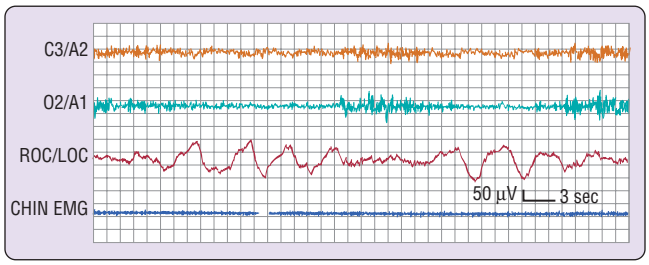

Figure 2-4 A Common Wake-to-Sleep Transition Pattern. Note that the electroencephalographic pattern changes from wake (rhythmic alpha) to stage 1 (relatively low-voltage, mixed-frequency) sleep twice during this attempt to fall asleep. Figure 2-5 Failure to Perform a Simple Behavioral Task at the Onset of Sleep. The volunteer had been deprived of sleep overnight and was required to tap two switches alternately, shown as pen deflections of opposite polarity on the channel labeled SAT. When the electroencephalographic (EEG; C3/A2) pattern changes to stage 1 sleep, the behavior stops, returning when the EEG pattern reverts to wakefulness. LOC, left outer canthus; ROC, right outer canthus; SEMs, slow eye movements. (From Carskadon MA, Dement WC. Effects of total sleep loss on sleep tendency. *Percept Mot Skills* 1979;48:495–506.)

seconds after the EEG changes to a stage 1 sleep pattern.[11] The behavior then ceases, usually to recur only after the EEG reverts to a waking pattern. This is an example of what one may think of as the simplest kind of "automatic" behavior pattern. That such simple behavior can persist past sleep onset and as one passes in and out of sleep may explain how impaired, drowsy drivers are able to continue down the highway.

Visual Response

A second example of behavioral change at sleep onset derives from an experiment in which a bright light is placed in front of the subject's eyes and the subject is asked to respond when a light flash is seen by pressing a sensitive microswitch taped to the hand.[12] When the EEG pattern is stage 1 or stage 2 sleep, the response is absent more than 85% of the time. When volunteers are queried afterward, they report that they did not see the light flash, not that they saw the flash but the response was inhibited. This is one example of the perceptual disengagement from the environment that accompanies sleep onset.

Auditory Response

In another sensory domain, the response to sleep onset is examined with a series of tones played over earphones to a subject who is instructed to respond each time a tone is heard. One study of this phenomenon showed that reaction times became longer in proximity to the onset of stage 1 sleep, and responses were absent coincident with a change in EEG to unequivocal sleep.[13] For responses in both visual and auditory modalities, the return of the response after its sleep-related disappearance typically requires the resumption of a waking EEG pattern.

Olfactory Response

When sleeping humans are tasked to respond when they smell something, the response depends in part on sleep state and in part on the particular odorant. In contrast to visual responses, one study showed that responses to graded strengths of peppermint (strong trigeminal stimulant usually perceived as pleasant) and pyridine (strong trigeminal stimulant usually perceived as extremely unpleasant) were well maintained during initial stage 1 sleep.[14] As with other modalities, the response in other sleep stages was significantly poorer. Peppermint simply was not consciously smelled in stages 2 and 4 NREM sleep or in REM sleep; pyridine was never smelled in stage 4 sleep, and only occasionally in stage 2 NREM and in REM sleep.[14] On the other hand, a tone successfully aroused the young adult participants in every stage. One conclusion of this report was that the olfactory system of humans is not a good sentinel system during sleep.

Response to Meaningful Stimuli

One should not infer from the preceding studies that the mind becomes an impenetrable barrier to sensory input at the onset of sleep. Indeed, one of the earliest modern studies of arousability during sleep showed that sleeping humans were differentially responsive to auditory stimuli of graded intensity.[15] Another way of illustrating sensory sensitivity is shown in experiments that have assessed discriminant responses during sleep to meaningful versus nonmeaningful stimuli, with meaning supplied in a number of ways and response usually measured as evoked K-complexes or arousal. The following are examples.

- A person tends to have a lower arousal threshold for his or her own name versus someone else's name.[16] In light sleep, for example, one's own name spoken softly will produce an arousal; a similarly applied nonmeaningful stimulus will not. Similarly, a sleeping mother is more likely to hear her own baby's cry than the cry of an unrelated infant.
- Williams and colleagues[17] showed that the likelihood of an appropriate response during sleep was improved when an otherwise nonmeaningful stimulus was made meaningful by linking the absence of response to punishment (a loud siren, flashing light, and the threat of an electric shock).

From these examples and others, it seems clear that sensory processing at some level does continue after the onset of sleep. Indeed, one study has shown with functional magnetic resonance imaging that regional brain activation occurs in response to stimuli during sleep and that different brain regions (middle temporal gyrus and bilateral orbitofrontal cortex) are activated in response to meaningful (person's own name) versus nonmeaningful (beep) stimuli.[18]

Hypnic Myoclonia

What other behaviors accompany the onset of sleep? If you awaken and query someone shortly after the stage 1 sleep EEG pattern appears, the person usually reports the mental experience as one of losing a direct train of thought and of experiencing vague and fragmentary imagery, usually visual.[19] Another fairly common sleep-onset experience is hypnic myoclonia, which is experienced as a general or localized muscle contraction very often associated with rather vivid visual imagery. Hypnic myoclonias are not pathologic events, although they tend to occur more commonly in association with stress or with unusual or irregular sleep schedules.

The precise nature of hypnic myoclonias is not clearly understood. According to one hypothesis, the onset of sleep in these instances is marked by a dissociation of REM sleep components, wherein a breakthrough of the imagery component of REM sleep (hypnagogic hallucination) occurs in the absence of the REM motor inhibitory component. A response by the individual to the image, therefore, results in a movement or jerk. The increased frequency of these events in association with irregular sleep schedules is consistent with the

increased probability of REM sleep occurring at the wake-to-sleep transition under such conditions (see later). Although the usual transition in adult humans is to NREM sleep, the REM portal into sleep, which is the norm in infancy, may become partially opened under unusual circumstances or in certain sleep disorders.

Memory Near Sleep Onset

What happens to memory at the onset of sleep? The transition from wake to sleep tends to produce a memory impairment. One view is that it is as if sleep closes the gate between short-term and long-term memory stores. This phenomenon is best described by the following experiment.[20] During a presleep testing session, word pairs were presented to volunteers over a loudspeaker at 1-minute intervals. The subjects were then awakened either 30 seconds or 10 minutes after the onset of sleep (defined as EEG stage 1) and asked to recall the words presented before sleep onset. As illustrated in Figure 2-6, the 30-second condition was associated with a consistent level of recall from the entire 10 minutes before sleep onset. (Primacy and recency effects are apparent, although not large.) In the 10-minute condition, however, recall paralleled that in the 30-second group for only the 10 to 4 minutes before sleep onset and then fell abruptly from that point until sleep onset.

In the 30-second condition, therefore, both long-term (4 to 10 minutes) and short-term (0 to 3 minutes) memory stores remained accessible. In the 10-minute condition, by contrast, words that were in long-term stores (4 to 10 minutes) before sleep onset were accessible, whereas words that were still in short-term stores (0 to 3 minutes) at sleep onset were no longer accessible; that is, they had not been consolidated into long-term memory stores. One conclusion of this experiment is that sleep inactivates the transfer of storage from short- to long-term memory. Another interpretation is that encoding of the material before sleep onset is of insufficient strength to allow recall. The precise moment at which this deficit occurs is not known and may be a continuing process, perhaps reflecting anterograde amnesia. Nevertheless, one may infer that if sleep persists for about 10 minutes, memory is lost for the few minutes before sleep. The following experiences represent a few familiar examples of this phenomenon:

- Inability to grasp the instant of sleep onset in your memory
- Forgetting a telephone call that had come in the middle of the night
- Forgetting the news you were told when awakened in the night
- Not remembering the ringing of your alarm clock
- Experiencing morning amnesia for coherent sleeptalking
- Having fleeting dream recall

Patients with syndromes of excessive sleepiness can experience similar memory problems in the daytime if sleep becomes intrusive.

Learning and Sleep

In contrast to this immediate sleep-related "forgetting," the relevance for sleep to human learning—particularly for consolidation of perceptual and motor learning—is of growing interest.[21,22] The importance of this association has also generated some debate and skepticism.[23] Nevertheless, a spate of recent research is awakening renewed interest in the topic, and mechanistic studies explaining the roles of REM and NREM sleep and particular components of the sleep EEG pattern (e.g., sleep spindles) more precisely have shown compelling evidence that sleep plays an important role in learning and memory (see Chapter 22).

PROGRESSION OF SLEEP ACROSS THE NIGHT

Pattern of Sleep in a Healthy Young Adult

The simplest description of sleep begins with the ideal case, the healthy young adult who is sleeping well and on a fixed schedule of about 8 hours per night (Figure 2-7). In general, no consistent male versus female distinctions have been found in the normal pattern of sleep in young adults. In briefest summary, the normal human adult enters sleep through NREM sleep, REM sleep does not occur until 80 minutes or longer thereafter, and NREM sleep and REM sleep alternate through the night, with about a 90-minute cycle (see Chapter 165 for a full description of sleep stages).

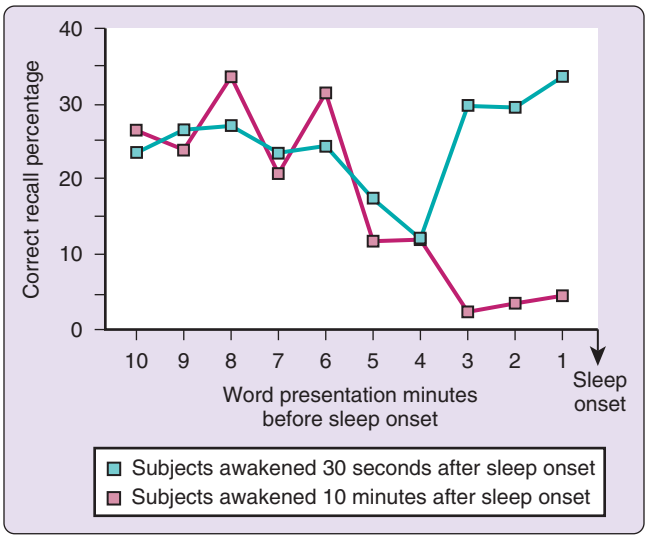

Figure 2-6 Memory is impaired by sleep, as shown by the study results illustrated in this graph. Refer to text for explanation.

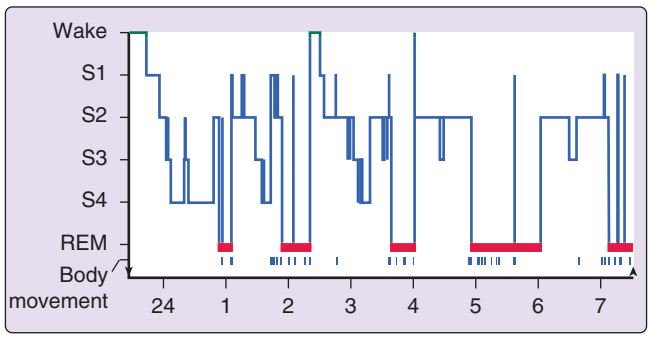

Figure 2-7 The progression of sleep stages across a single night in a normal young adult volunteer is illustrated in this sleep histogram. The text describes the ideal or average pattern. This histogram was drawn on the basis of a continuous overnight recording of electroencephalogram, electrooculogram, and electromyogram in a normal 19-year-old man. The record was assessed in 30-second epochs for the various sleep stages. REM, rapid eye movement.

First Sleep Cycle

The first cycle of sleep in the normal young adult begins with stage 1 sleep, which usually persists for only a few (1 to 7) minutes at the onset of sleep. Sleep is easily discontinued during stage 1 by, for example, softly calling a person's name, touching the person lightly, quietly closing a door, and so forth. Thus, stage 1 sleep is associated with a low arousal threshold. In addition to its role in the initial wake-to-sleep transition, stage 1 sleep occurs as a transitional stage throughout the night. A common sign of severely disrupted sleep is an increase in the occurrences and percentage of stage 1 sleep.

Stage 2 NREM sleep, signaled by sleep spindles or K-complexes in the EEG (see Figure 2-1), follows this brief episode of stage 1 sleep and continues for about 10 to 25 minutes in the first sleep cycle. In stage 2 sleep, a more intense stimulus is required to produce arousal. The same stimulus that produced arousal from stage 1 sleep often results in an evoked K-complex but no awakening in stage 2 sleep.

As stage 2 sleep progresses, high-voltage slow wave activity gradually begins to appear in the EEG. Eventually, this activity meets the criteria[1] for stage 3 NREM sleep, that is, high-voltage (at least 75 μV) slow wave (2 cps) activity accounting for more than 20% but less than 50% of the EEG activity. Stage 3 sleep usually lasts only a few minutes in the first cycle and is transitional to stage 4 as more and more high-voltage slow wave activity occurs. Stage 4 NREM sleep—identified when the high-voltage slow wave activity comprises more than 50% of the record—usually lasts about 20 to 40 minutes in the first cycle of a healthy young adult. An incrementally larger stimulus is usually required to produce an arousal from stage 3 or 4 sleep than from stage 1 or 2 sleep. (Investigators often refer to the combined stages 3 and 4 sleep as slow wave sleep [SWS], delta sleep, or deep sleep, or N3 in the newer nomenclature.)

A series of body movements usually signals an "ascent" to lighter NREM sleep stages. A brief (1- or 2-minute) episode of stage 3 sleep might occur, followed by perhaps 5 to 10 minutes of stage 2 sleep interrupted by body movements preceding the initial REM episode. REM sleep in the first cycle of the night is usually short-lived (under 10 minutes). The arousal threshold in this REM episode is variable, as is true for REM sleep throughout the night. Theories to explain the variable arousal threshold of REM sleep have suggested that at times, the person's selective attention to internal stimuli (i.e., dreaming) precludes a response, or that the arousal stimulus is incorporated into the ongoing dream story rather than producing an awakening. Certain early experiments examining arousal thresholds in cats found highest thresholds in REM sleep, which was then termed *deep sleep* in this species. Although this terminology is still often used in publications about sleep in animals, it should not be confused with human NREM stages 3 and 4 sleep, which is also often called *deep sleep*. In addition, the term *SWS* is sometimes used (as is *synchronized sleep*) as a synonym for all of NREM sleep in other species and is thus distinct from SWS (stages 3 and 4 NREM) in humans.

NREM-REM Cycle

NREM sleep and REM sleep continue to alternate through the night in cyclic fashion. REM sleep episodes usually become longer across the night. Stages 3 and 4 sleep occupy less time in the second cycle and might disappear altogether from later cycles as stage 2 sleep expands to occupy the NREM portion of the cycle. The average length of the first NREM-REM sleep cycle is about 70 to 100 minutes; the average length of the second and later cycles is about 90 to 120 minutes. Across the night, the average period of the NREM-REM cycle is about 90 to 110 minutes. Across the night, stage 1 sleep will account for about 2% to 5%, stage 2 about 45% to 55%, SWS about 10% to 20%, and REM sleep about 20% to 25% of sleep in a healthy young adult.

Distribution of Sleep Stages Across the Night

In the young adult, SWS dominates the NREM portion of the sleep cycle toward the beginning of the night (about the first one third); REM sleep episodes are longest in the last one third of the night. Brief episodes of wakefulness tend to intrude later in the night, usually near REM sleep transitions, and they usually do not last long enough to be remembered in the morning. The preferential distribution of REM sleep toward the latter portion of the night in normal human adults is linked to a circadian oscillator, which can be gauged by the oscillation of body temperature.[24,25] The preferential distribution of SWS toward the beginning of a sleep episode is not thought to be mediated by circadian processes but shows a marked response to the length of prior wakefulness,[26] thus reflecting the homeostatic sleep system, highest at sleep onset and diminishing across the night as sleep pressure wanes or as "recovery" takes place. Thus these aspects of the normal sleep pattern highlight features of the two-process model of sleep as elaborated on in Chapter 36.

Length of Sleep

The length of nocturnal sleep depends on a great number of factors—of which volitional control is among the most significant in humans—and it is thus difficult to characterize a "normal" pattern. Most young adults report sleeping about 7.5 hours a night on weekday nights and slightly longer, 8.5 hours, on weekend nights. The variability of these figures from person to person and from night to night, however, is quite high. Sleep length also depends on genetic determinants,[27] and one may think of the volitional determinants (staying up late, waking by alarm, and so on) superimposed on the background of a genetic sleep need. Length of prior waking also affects how much one sleeps, although not in a one-for-one manner. Indeed, the length of sleep is also determined by processes associated with circadian rhythms. Thus *when* one sleeps helps to determine *how long* one sleeps. In addition, as sleep is extended, the amount of REM sleep increases because the occurrence of REM sleep depends on the persistence of sleep into the peak circadian time.

Generalizations About Sleep in the Healthy Young Adult

A number of general statements can be made regarding sleep in the healthy young adult who is living on a conventional sleep-wake schedule and who is without sleep complaints:

- Sleep is entered through NREM sleep.
- NREM sleep and REM sleep alternate with a period near 90 minutes.
- SWS predominates in the first third of the night and is linked to the initiation of sleep and the length of time awake (i.e., sleep homeostasis).

- REM sleep predominates in the last third of the night and is linked to the circadian rhythm of body temperature.
- Wakefulness in sleep usually accounts for less than 5% of the night.
- Stage 1 sleep generally constitutes about 2% to 5% of sleep.
- Stage 2 sleep generally constitutes about 45% to 55% of sleep.
- Stage 3 sleep generally constitutes about 3% to 8% of sleep.
- Stage 4 sleep generally constitutes about 10% to 15% of sleep.
- NREM sleep, therefore, is usually 75% to 80% of sleep.
- REM sleep is usually 20% to 25% of sleep, occurring in four to six discrete episodes.

Factors Modifying Sleep Stage Distribution

Age

The strongest and most consistent factor affecting the pattern of sleep stages across the night is age (Figure 2-8). The most marked age-related differences in sleep from the patterns described earlier are found in newborn infants. For the first year of life, the transition from wake to sleep is often accomplished through REM sleep (called *active sleep* in newborns). The cyclic alternation of NREM-REM sleep is present from birth but has a period of about 50 to 60 minutes in the newborn compared with about 90 minutes in the adult. Infants also only gradually acquire a consolidated nocturnal sleep cycle, and the fully developed EEG patterns of the NREM sleep stages are not present at birth but emerge over the first 2 to 6 months of life. When brain structure and function achieve a level that can support high-voltage slow wave EEG activity, NREM stages 3 and 4 sleep become prominent.

SWS is maximal in young children and decreases markedly with age. The SWS of young children is both qualitatively and quantitatively different from that of older adults. For example, it is nearly impossible to wake youngsters in the SWS of the night's first sleep cycle. In one study,[28] a 123-dB tone failed to produce any sign of arousal in a group of children whose mean age was 10 years. In addition, children up to midadolescence often "skip" their first REM episode, perhaps because of the quantity and intensity of slow wave activity early in the night. A similar, although less profound qualitative difference distinguishes SWS occurring in the first and later cycles of the night in older humans. A marked quantitative change in SWS occurs across adolescence, when SWS decreases by about 40% during the second decade, even when length of nocturnal sleep remains constant.[29] Feinberg[30] hypothesized that the age-related decline in nocturnal SWS, which parallels loss of cortical synaptic density, is causally related to this cortical resculpting. More recent findings by de Vivo and colleagues in an animal model question that hypothesis.[30a] By midadolescence, youngsters no longer typically skip their first REM, and their sleep resembles that described earlier for young adults. By age 60 years, SWS is quite diminished, particularly in men; women maintain SWS later into life than men.

REM sleep as a percentage of total sleep is maintained well into healthy old age; the absolute amount of REM sleep at night has been correlated with intellectual functioning[31] and declines markedly in the case of organic brain dysfunctions in elderly people.[32]

Arousals during sleep increase markedly with age. Extended wake episodes of which the individual is aware and can report, as well as brief and probably unremembered arousals, increase with aging.[33] The latter type of transient arousals may occur with no known correlate but are often associated with occult sleep disturbances, such as periodic limb movements during sleep (PLMS) and sleep-related respiratory irregularities, which also become more prevalent in later life.[34,35]

Perhaps the most notable finding regarding sleep in elderly people is the profound increase in interindividual variability,[36] which thus precludes generalizations such as those made for young adults.

Prior Sleep History

A person who has experienced sleep loss on one or more nights shows a sleep pattern that favors SWS during recovery (Figure 2-9). Recovery sleep is also usually prolonged and deeper—that is, having a higher arousal threshold throughout—than basal sleep. REM sleep tends to show a rebound on the second or subsequent recovery nights after an episode of sleep loss. Therefore, with total sleep loss, SWS tends to be

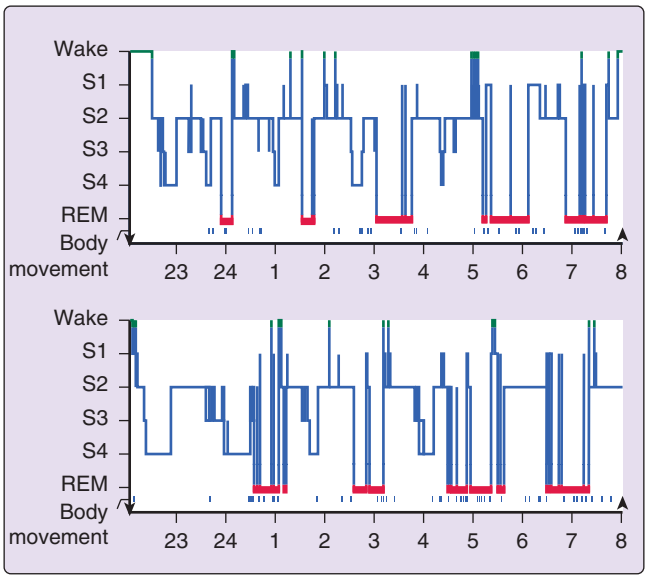

Figure 2-9 The *upper histogram* shows the baseline sleep pattern of a normal 14-year-old female volunteer. The *lower histogram* illustrates the sleep pattern in this volunteer for the first recovery night after 38 hours without sleep. Note that the amount of stage 4 sleep on the lower graph is greater than on baseline and that the first REM sleep episode is markedly delayed.

preferentially recovered compared with REM sleep, which tends to recover only after the recuperation of SWS. Thus both states of sleep show evidence of homeostatic regulation.

Cases in which a person is differentially deprived of REM or SWS—either operationally, by being awakened each time the sleep pattern occurs, or pharmacologically (see later)—show a preferential rebound of that stage of sleep when natural sleep is resumed. This phenomenon has particular relevance in a clinical setting, in which abrupt withdrawal from a therapeutic regimen may result in misleading diagnostic findings (e.g., sleep-onset REM periods [SOREMPs] as a result of a REM sleep rebound when REM suppressant medication is withdrawn) or could conceivably exacerbate a sleep disorder (e.g., if sleep apneas tend to occur preferentially or with greater intensity in the rebounding type of sleep).

Chronic restriction of nocturnal sleep, an irregular sleep schedule, or frequent disturbance of nocturnal sleep can result in a peculiar distribution of sleep states, most commonly characterized by premature REM sleep, that is, SOREMPs. Such episodes can be associated with hypnagogic hallucinations, sleep paralysis, or an increased incidence of hypnic myoclonia in persons with no organic sleep disorder.

Although not strictly related to prior sleep history, the first night of a laboratory sleep evaluation is commonly associated with more frequent arousals and a disruption of the normal distribution of sleep states, characterized chiefly by a delayed onset of REM sleep.[37] Often this delay takes the form of skipping the first REM episode of the night. In other words, the NREM sleep stages progress in a normal fashion, but the first cycle ends with an episode of stage 1 or a brief arousal instead of the expected brief REM sleep episode. In addition, REM sleep episodes are often disrupted, and the total amount of REM sleep on the first night in the sleep laboratory is also usually reduced from the normal value.

Circadian Rhythms

The circadian phase at which sleep occurs affects the distribution of sleep stages. REM sleep, in particular, occurs with a circadian distribution that peaks in the morning hours coincident with the trough of the core body temperature rhythm.[24,25] Thus, if sleep onset is delayed until the peak REM phase of the circadian rhythm—that is, the early morning—REM sleep tends to predominate and can even occur at the onset of sleep. This reversal of the normal sleep onset pattern may be seen in a healthy person who acutely undergoes a phase shift, either as a result of a work shift change or as a change resulting from jet travel across a number of time zones. Studies of persons sleeping in environments free of all cues to time show that the timing of sleep onset and the length of sleep occur in association with circadian phase.[38,39] Under these conditions, sleep distribution with reference to the circadian body temperature phase position shows that sleep onset is likeliest to occur on the falling limb of the temperature cycle. A secondary peak of sleep onsets, corresponding to afternoon napping, also occurs; the offset of sleep occurs most often on the rising limb of the circadian body temperature curve.[40]

Temperature

Extremes of temperature in the sleeping environment tend to disrupt sleep. REM sleep is commonly more sensitive to temperature-related disruption than is NREM sleep. Accumulated evidence from humans and other species suggests that mammals have only minimal ability to thermoregulate during REM sleep; in other words, the control of body temperature is virtually poikilothermic in REM sleep.[41] This inability to thermoregulate in REM sleep probably affects the response to temperature extremes and suggests that such conditions are less of a problem early during a night than late, when REM sleep tends to predominate. It should be clear, as well, that such responses as sweating or shivering during sleep under ambient temperature extremes occur in NREM sleep and are limited in REM sleep.

Drug Ingestion

The distribution of sleep states and stages is affected by many common drugs, including those typically prescribed in the treatment of sleep disorders as well as those not specifically related to the pharmacotherapy of sleep disorders and those used socially or recreationally. Whether changes in sleep stage distribution have any relevance to health, illness, or psychological well-being is unknown; however, particularly in the context of specific sleep disorders that differentially affect one sleep stage or another, such distinctions may be relevant to diagnosis or treatment. A number of generalizations regarding the effects of certain of the more commonly used compounds on sleep stage distribution can be made.

- Benzodiazepines tend to suppress SWS and have no consistent effect on REM sleep.
- Tricyclic antidepressants, monoamine oxidase inhibitors, and certain selective serotonin reuptake inhibitors tend to suppress REM sleep. An increased level of motor activity during sleep occurs with certain of these compounds, leading to a pattern of REM sleep without motor inhibition or an increased incidence of PLMS. Fluoxetine is also associated with rapid eye movements across all sleep stages ("Prozac eyes").

- Withdrawal from drugs that selectively suppress a stage of sleep tends to be associated with a rebound of that sleep stage. Thus, acute withdrawal from a benzodiazepine compound is likely to produce an increase of SWS; acute withdrawal from a tricyclic antidepressant or monoamine oxidase inhibitor is likely to produce an increase of REM sleep. In the latter case, this REM rebound could result in abnormal SOREMPs in the absence of an organic sleep disorder, perhaps leading to an incorrect diagnosis of narcolepsy.
- Acute presleep alcohol intake can produce an increase in SWS and suppression of REM sleep early in the night, which can be followed by REM sleep rebound in the latter portion of the night as the alcohol is metabolized. Low doses of alcohol have minimal effects on sleep stages, but they can increase sleepiness in the late evening.[42,43]
- Acute effects of marijuana (tetrahydrocannabinol [THC]) include minimal sleep disruption, characterized by a slight reduction of REM sleep. Chronic ingestion of THC produces a long-term suppression of SWS.[44]

Pathology

Sleep disorders, as well as other nonsleep problems, have an impact on the structure and distribution of sleep. As suggested before, these distinctions appear to be more important in diagnosis and in the consideration of treatments than for any implications about general health or illness resulting from specific sleep stage alterations. A number of common sleep-stage anomalies are associated with sleep disorders.

Narcolepsy. Narcolepsy is characterized by an abnormally short delay to REM sleep, marked by SOREMPs. This abnormal sleep-onset pattern occurs with some consistency, but not exclusively; that is, NREM sleep onset can also occur. Thus one diagnostic test consists of several opportunities to fall asleep across a day (see Chapter 173). If REM sleep occurs abnormally on two or more such opportunities, narcolepsy is extremely probable. The occurrence of this abnormal sleep pattern in narcolepsy is thought to be responsible for a number of the characteristic symptoms of this disorder. In other words, dissociation of components of REM sleep into the waking state results in hypnagogic hallucinations, sleep paralysis, and, most dramatically, cataplexy.

Other conditions in which a short REM sleep latency can occur include infancy, in which sleep-onset REM sleep is normal; sleep reversal or jet lag; acute withdrawal from REM-suppressant compounds; chronic restriction or disruption of sleep; and endogenous depression.[45] Reports have indicated a relatively high prevalence of REM sleep onsets in young adults[46] and in adolescents with early rise times.[47] In the latter, the REM sleep onsets on morning (8:30 AM and 10:30 AM) naps were related to a delayed circadian phase as indicated by later onset of melatonin secretion.

Sleep Apnea Syndromes. Sleep apnea syndromes may be associated with suppression of SWS or REM sleep secondary to the sleep-related breathing problem. Successful treatment of this sleep disorder, as with nocturnal continuous positive airway pressure, can produce large rebounds of SWS or REM sleep when first implemented (Figure 2-10).

Sleep Fragmentation. Fragmentation of sleep and increased frequency of arousals occur in association with a number of sleep disorders as well as with medical disorders involving physical pain or discomfort. PLMS, sleep apnea syndromes, chronic fibrositis, and so forth may be associated with tens to hundreds of arousals each night. Brief arousals are prominent in such conditions as allergic rhinitis,[48,49] juvenile rheumatoid arthritis,[50] and Parkinson disease.[51] In upper airway resistance syndrome,[52] EEG arousals are important markers because the respiratory signs of this syndrome are less obvious than in frank obstructive sleep apnea syndrome, and only subtle indicators may be available.[53] In specific situations, autonomic changes, such as transient changes of blood pressure,[54] can signify arousals; Lofaso and colleagues[55] indicated that autonomic changes are highly correlated with the extent of EEG arousals. Less well studied is the possibility that sleep fragmentation may be associated with subcortical events not

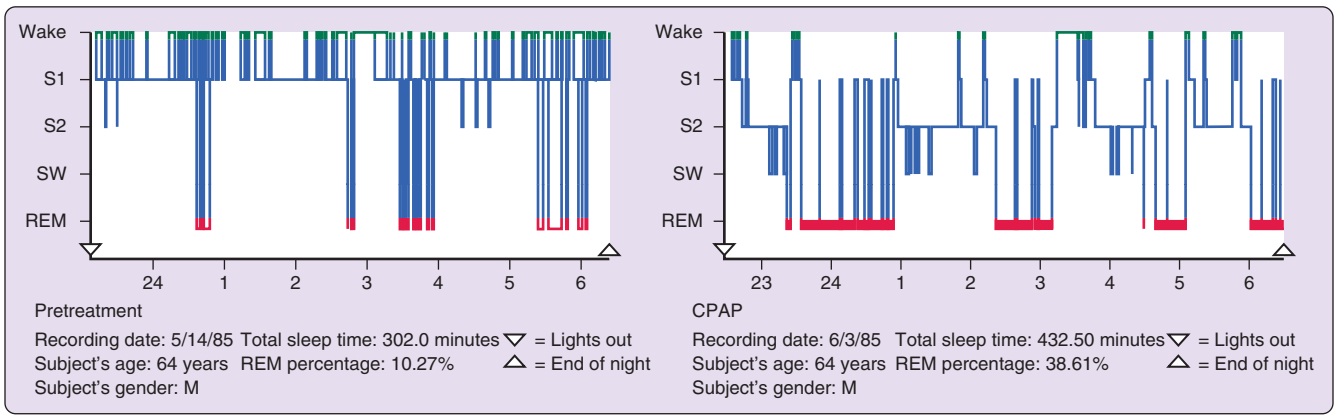

Figure 2-10 These sleep histograms depict the sleep of a 64-year-old male patient with obstructive sleep apnea syndrome. The *left graph* shows the sleep pattern before treatment. Note the absence of slow wave (SW) sleep, the preponderance of stage 1 (S1), and the very frequent disruptions. The *right graph* shows the sleep pattern in this patient during the second night of treatment with continuous positive airway pressure (CPAP). Note that sleep is much deeper (more SW sleep) and more consolidated and that REM sleep in particular is abnormally increased. The pretreatment REM percentage of sleep was only 10%, compared with nearly 40% with treatment. (Data supplied by G. Nino-Murcia, Stanford University Sleep Disorders Center, Stanford, CA.)

visible in the cortical EEG signal. These disorders also often involve an increase in the absolute amount of and the proportion of stage 1 sleep.

CLINICAL PEARLS

- The clinician should expect to see less slow wave sleep (stages 3 and 4; N3) in older persons, particularly men.
- Clinicians or colleagues might find themselves denying middle of the night communications (nighttime calls) because of memory deficits that occur for events proximal to sleep onset. This phenomenon might also account for memory deficits in excessively sleepy patients.
- Many medications (even if not prescribed for sleep) can affect sleep stages, and their use or discontinuation alters sleep. For example, REM-suppressant medications can result in a rebound of REM sleep when they are discontinued.
- Certain patients have sleep complaints (insomnia, hypersomnia) that result from attempts to sleep or be awake at times not in synchrony with their circadian phase.
- Patients who wake with events early in the night might have a disorder affecting NREM sleep; patients who wake with events late in the night may have a disorder affecting REM sleep.
- When using sleep restriction to build sleep pressure, treatment will be more effective if sleep is scheduled at the correct circadian phase. The problem of napping in patients with insomnia is that naps diminish the homeostatic drive to sleep.

SUMMARY

This chapter provides an overview of human sleep, with a focus on the healthy young adult as a template against which to evaluate and understand the expected changes that can occur as well as unusual circumstances and clinical conditions. Thus we find that maturational changes from infancy through old age carry different associations with the sleep of a healthy young adult and frame the first questions we should ask when confronted with an unknown case: what is the age? We also learn that sleep and the stages of sleep have important concomitants for cognitive function, perception, and the internal milieu. Later chapters catalog many specific properties of sleep physiology, neurochemistry, and sleep disorders; this chapter provides a foundation to support integration of that detailed information.

Chapter 3

Normal Aging

Donald L. Bliwise; Michael K. Scullin

Chapter Highlights

- The integrity of sleep with advancing years is challenged not only by changes in circadian and homeostatic processes but also by medical, cognitive, and psychiatric morbidities.
- Sleep-disordered breathing and restless legs syndrome show age dependence and may contribute to poor sleep quality in old age.
- Both descriptive and interventional data suggest that sleep disturbances of all types in aging may contribute to a wide array of morbidities and, possibly, mortality and should not be dismissed by the sleep medicine specialist.
- Basic science implies that the breakdown of sleep processes in the aged organism may reflect physiologic aging at the system, cellular, and molecular levels.

As the populations of industrialized societies age, knowledge of defining how sleep is affected by age will assume greater importance. Within the United States, where the average current life expectancy is 78.7 years, the fastest growing segment of the population is those who are 85 years and older. These huge numbers force the sleep medicine specialist to confront the definition of what is "normal." Researchers often use the term *normal* to connote a variety of meanings. In sleep medicine, confusion often occurs because the term is used descriptively, to indicate representativeness, as well as clinically, to indicate absence of disease.

Aging is also subject to semantic confusion. Chronologic age has been shown repeatedly only to approximate physiologic (biologic) age. The decline in slow wave sleep (SWS), for example, can occur at a chronologic age (at least in men) far earlier than most age-related declines in other biologic functions. Some researchers in gerontology have noted that distance from death may be a far better approximation of the aging process, but too few longitudinal sleep studies in humans exist to yield these types of findings. However, studies of invertebrates have shed new light on relationships between physiologic age and sleep that can affect the functional significance of age-dependent changes (see Basic Science Considerations, later).

In addition to the issue of physiologic age, subjective age must be considered. Because the practice of sleep disorders medicine in geriatrics relies heavily on the increased self-reports of sleep disturbance seen in aging, subjective appraisal of the older person's symptoms must be considered. Whether an aged person views 75% sleep efficiency as insomnia or merely accepts this as a normal part of aging may depend largely on that person's perspective on growing old and what that means to him or her. It has been reported that older people are more likely to perceive themselves as having sleep problems if they have difficulty falling asleep rather than staying asleep, even though the latter continues to be a generally more commonly endorsed symptom (see Bliwise[1] for review). In addition, some have suggested that self-reports of sleep (relative to sleep measured by polysomnography [PSG]) are inherently less accurate and valid in older relative to younger subjects, although evidence for such age differences in other studies is decidedly mixed and varies according to the variables under consideration or the subject's sex.

Finally, normal aging must be viewed in counterpoint to pathologic aging (see Chapter 96). Although the prevalence of dementing illnesses is high in late life, determination of the number of normal elderly persons who may be in incipient stages of dementia has seldom been addressed. Additionally, recognition of mental impairments in the more limited domains of memory, executive function, language, attention, and visuospatial ability characterized as of lesser severity has led to the use of an intermediate diagnostic category termed *mild cognitive impairment* (MCI).[2] Few sleep studies of normal aging rely on extensive diagnostic work to eliminate persons in the earliest stages of mental impairment, even though PSG studies in well-defined MCI patients are now appearing.[3]

The point here is not to dismiss all that is known about sleep patterns in normal aging as inadequate but rather to point out the complexities of defining normal aging. Normal aging can never be defined without some arbitrary criteria. Throughout this chapter, we will refer to aging across several species, encompassing both what in humans may be considered "middle-aged" (approximately 40 to 65 years) and "elderly" (older than 65 years). We recognize fully the otherwise arbitrary nature of these verbal and numeric descriptors of processes that are most assuredly gradual and continuous and vary widely across individuals. It is also important to recognize that the age-dependent alterations in sleep may simply be secondary manifestations of senescence.

As in all areas of medicine, genetics are becoming increasingly recognized as affecting physiology, and this seems

particularly true for age-dependent changes in sleep patterns. In mice, age-dependent changes were strain dependent, and rebound effects (particularly for slow wave activity) from sleep deprivation were moderated by genotype.[4] In large populations of elderly persons, various actigraphic measures of sleep continuity were associated with several novel single nucleotide polymorphisms.[5]

SLEEP ARCHITECTURE

Although age-dependent alterations in sleep architecture have been described for many years,[6] only recently have attempts been made to summarize this large body of cross-sectional data using meta-analytic techniques.[7,8] Results from the first of these analyses[7] indicated that although sleep efficiency showed clear age-dependent declines up to and beyond age 90 years, most age-dependent changes in sleep architecture occurred before the age of 60 years, with few changes in SWS (now referred to as *N3 sleep* in the revised American Academy of Sleep Medicine [AASM] nomenclature[9]; see later), rapid eye movement (REM) sleep, and stage 1 percentage (N1) occurring after that.[7] Some variables (total sleep time, REM) appeared best characterized as linear decline, whereas others (SWS, wake after sleep onset) followed a more exponential course. Sleep latency showed no clear age effect after age 60 years, although it increased up to that point. A second meta-analysis focused only on REM percentage and noted a cubic trend, with REM apparently increasing after age 75 years and then demonstrating an even steeper drop after age 90 years.[8] The meaning of the latter data is unclear and raises many questions as to the extent of the precision of chronologic age to capture biologic processes in these upper age ranges. Published population-based longitudinal data on sleep architecture would assist in addressing many of these uncertainties.

Although meta-analyses can provide cumulative information on age-dependent values across many laboratories, enormous variability in parameter values exists across studies,[7] and much of the sleep architecture was not scored blindly to the patient's chronologic age or sex. This might limit the value of meta-analytic approaches for extrapolation of readily usable, age-dependent laboratory norms. By contrast, the systematically collected, rigorously acquired data derived from the centralized scoring center for the Sleep Heart Health Study (SHHS), although subject to survivor effects and based on single-night data derived from composite cohorts, offer detailed appreciation of how comorbidities, demographics, and sleep-disordered breathing (SDB) can affect observed sleep architecture values employing traditional Rechtschaffen and Kales rules.[10] Some have viewed the SHHS sleep architecture data as broadly representative of the elderly population generally because persons with a wide variety of medical conditions were not excluded.[11]

Percentage of Time Spent in Each Sleep Stage

Table 3-1 provides sleep architecture values for 2685 SHHS participants aged 37 to 92 years, excluding persons who use psychotropic medications and who have high alcohol intake, restless legs syndrome symptoms, and systemic pain conditions. About one third of these participants were hypertensive, and about 10% had a history of cardiovascular disease or chronic pulmonary disease. Results clearly show that although age effects were apparent in some measures, gender occupied a far more dramatic role in sleep architecture, in some cases showing considerable divergence when comparing women and men. Most notable in this regard was percentage of time spent in N3 (sleep stages 3 plus 4), which showed enormous gender differences at every age and, in fact, showed no appreciable decline with aging in women, relative to men.

Men demonstrate a marked cross-sectional decline with aging, as well as huge individual differences in every age group. In fact, the extent of these individual differences is emphasized by the fact that even within men as a group, coefficients of variation (ratio of variance to mean) in percentage of time spent in N3 far exceeded those for all other sleep variables in both men and women. Although gender differences in SWS have been noted previously (see Bliwise[6] for review), the fact that the age-dependent decline may be confined to men suggests a more limited utility of this often-characterized aging biomarker for women. Confirmatory results from another normative database including exceptionally healthy older adults and including only second-night data also showed stronger age-associated decline in SWS in men, though at higher absolute levels of N3.[12] The higher values may have

reflected second-night adaptation effects, not available in SHHS, which relied only on single night data.

In contrast to the results of the SHHS, these gender differences in SWS were not confirmed meta-analytically.[7] At least one study has proposed that gender differences in delta activity are more likely to be a function of overall lower electroencephalogram (EEG) amplitude in men relative to women.[13] When corrected for overall amplitude, the decreased growth hormone secretion seen in postmenopausal women was accompanied by lower delta amplitude than in comparably aged men.[14] A decline in the amplitude and the incidence of the evoked K-complex over the age range of 19 to 78 years has been reported in both women and men, suggesting that similar deficits in delta synchronization processes operate equally in both sexes.[15] Gender did not play a significant role when assessed as the homeostatic response of nighttime delta power to daytime napping in either young or elderly subjects.[16] Furthermore, in a group of 20- to 60-year-olds, increased age was associated with lower slow wave density in both men and women; however, the specific characteristics of slow waves differed across genders such that women tended to show higher amplitude, faster frequency, steeper slope, and shorter positive phases for slow waves than men.[17]

Percentage of time spent in sleep stage 1 also showed similar gender-related effects in SHHS, and age-dependent increases in this sleep stage, usually considered to represent a feature of fragmented, transitional sleep, were confined to men. By contrast, percentage of time spent in REM sleep showed a modest decline with age, but the effect was detected in both men and women. REM percentages of 18% to 20% in 75- to 85-year-olds were derived from curve smoothing in a meta-analysis focused on only REM sleep measures in normal aging,[8] which were slightly lower than, but essentially similar to, SHHS data (see Table 3-1). In SHHS, sleep efficiency also declined with age, with mean values of 85.7 (standard deviation [SD] = 8.3) in the 37- to 54-year-old group, 83.3 (SD = 8.9) in the 55- to 60-year-old group, 80.6 (SD = 11.7) in the 61- to 70-year-old group, and 79.2 (SD = 10.1) in the older-than-70-years group, but without differential effects of gender, findings corroborated meta-analytically in persons older than 60 years.[7] However, the declines in percentage of time spent in REM sleep and the (male-specific) increases in percentage of time spent in sleep stage 1 seen in SHHS were not confirmed meta-analytically in persons older than 60 years.[7] The density of eye movements in REM is reduced with aging,[18] but lack of standardization across laboratories precludes examination of this aspect of REM using meta-analytic techniques.

Arousals during Sleep

Brief arousals during sleep, representing one component of the microarchitecture of sleep, continue to attract considerable interest as a metric, with particular relevance for the aged population. When examined in the laboratory, healthy older persons wake up from sleep more frequently than younger persons do, regardless of circadian phase, but they have no greater difficulty falling back to sleep.[19] Failure to maintain continuous sleep has, as its basic science counterpart, short bout lengths, a feature highly characteristic of sleep in many aged lower mammalian species (see Bliwise[6] for review) as well as nonhuman primates.[20] In elderly persons without SDB, arousal indexes from 18 to 27 events per hour have been reported.[21] Among the predominantly elderly subjects (mean age, 61 years) in SHHS, the mean (SD) arousal index showed significant but relatively small increases with age: 16.0 (8.2) for 37- to 54-year-olds, 18.4 (10.0) for 55- to 61-year-olds, 20.3 (10.5) for 62- to 70-year-olds, and 21.0 (11.6) for subjects older than 70 years.[10] Values approximating these have been reported[22] in another group of subjects without sleep apnea or periodic leg movements, thus further corroborating these SHHS values. Greater arousal index during N3 discriminated healthy older adults from patients with mild cognitive impairment.[23]

Other phasic events of non–rapid eye movement (NREM) sleep, such as K-complex and spindle density, also decrease with age.[24] Spindle density is thought to reflect, at least partially, the corticothalamic functional integrity of gamma-aminobutyric acid–ergic (GABAergic) systems. Using an automated spindle detector, one study that included adults aged 20 to 73 years found that middle-aged and older adults had reduced spindle density, amplitude, and duration, particularly in anterior derivations (Fp1 and F3 channels) that were independent of gender.[25]

Although, like other metrics of impaired sleep quality, brief arousals show a male predominance (also seen meta-analytically using wake after sleep onset[7]), the influences of age and gender are not as pronounced as the effects of breathing events (Table 3-2). In fact, when accounting for the presence of brief arousals in elderly persons, the respiratory disturbance index (RDI) predicts 10-fold more variance than age and 5-fold more variance than gender. Higher levels of RDI were also associated with slightly lower percentage of time spent in REM sleep in both men and women and with lower percentages of time spent in N3 in men.

Murine models have suggested that age differences in ability to maintain consistency of sleep state (defined with 4-second epochs) is more likely to reflect transitions involving NREM, rather than REM, sleep[26]—an effect also noted in some studies of older humans, using 2-minute bout durations.[27] Novel correlates of sleep fragmentation in elderly persons have been noted. For example, beta activity (but not delta activity) in the sleep EEG correlates strongly with sleep fragmentation regardless of circadian phase.[28] Visually

scored arousals in older persons have been shown to be preceded by relatively lower and more temporally limited increments in delta band power relative to similarly scored arousals in middle-aged subjects.[29] Within a population of women and men aged 55 to 100 years who wore wrist actigraphy for an average of nine 24-hour periods, chronologic age was strongly correlated with fragmentation of the rest-activity rhythms,[30] the effect being more pronounced in men and for the transition from rest to activity than from activity to rest.

Comorbidities

Insofar as comorbidities are concerned, SHHS sleep architecture data showed substantial convergence with meta-analytically derived data. In SHHS, selected medical comorbidities (e.g., a positive history of cardiovascular disease, hypertension, and stroke) were associated with disturbed sleep architecture. Consistent with results suggesting that reduced sleep amounts or quality might predispose one to the metabolic syndrome in old age, diabetic patients had smaller percentages of time in stages 3 plus 4 sleep, lower sleep efficiencies, and higher numbers of brief arousals and percentage of time spent in sleep stage 1. In most cases, however, these effects appeared to be less salient (i.e., predicted less variance) for sleep architecture than demographic variables such as gender, age (to a lesser extent), and, in some cases, ethnicity,[10] except for the arousal index, for which RDI was by far the single most powerful predictor. Less disease-specific moderator effects from meta-analytic approaches also suggested that across the entire life span, age effects were reduced substantially when persons with medical and psychiatric conditions were included.[7] The inclusion of persons with sleep apnea showed some evidence of reducing the effects of age in sleep efficiency, wake after sleep onset, and SWS when considered across the entire adult life span,[7] data that are compatible with SHHS.

Slow Wave Sleep

The gender differences in SWS reported by SHHS notwithstanding, several aspects of these data must be viewed in the context of prior literature on age-dependent changes in architecture. When analyzed with period-amplitude analyses, the major change in SWS ascribed to aging has been a decline in delta wave amplitude rather than wavelength (Figure 3-1) (see Bliwise[6] for review). The decrease in delta amplitude simply may be a more readily identifiable visual change of the sleep EEG, which is present at frequencies up to about 10 Hz, though it is difficult to see above this.[31] When scored visually using central derivations and employing a 75-μV threshold, typical figures for the amount of stages 3 plus 4 sleep in elderly persons have often been considered to fall in the 5% to 10% range. Thus the figures reported by SHHS, particularly for women, are somewhat higher than these conventionally accepted figures. Whether these values represent a more precise rendering of delta activity within sleep, perhaps engendered by the visual analyses of EEG waveforms on digital display or the simultaneous availability of precise calibration of the 75-μV criterion for delta waves stipulated by the Rechtschaffen and Kales guidelines, is unclear. Nonetheless, the controlled visual analyses conducted by SHHS are likely to represent a standard of PSG technology aspired to by the field of sleep medicine, thus arguing that these metrics may well represent how sleep architecture measures should be benchmarked.

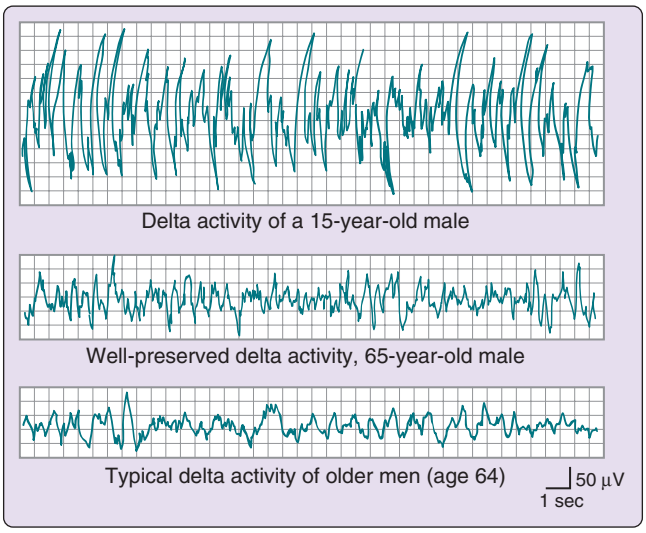

Figure 3-1 Age differences in delta activity. The *top tracing* shows typically abundant high-amplitude delta in an adolescent. The *middle tracing* shows particularly well-preserved delta in an older man. Note the marked decrease in amplitude relative to the adolescent. The *bottom tracing* is a more typical example of delta activity in an older man. Note the number of waves failing to meet the 75-μV amplitude criterion. (From Zepelin H. Normal age related change in sleep. In: Chase MH, Weitzman ED, editors. *Sleep disorders: basic and clinical research*. New York: Spectrum; 1983. p. 431–45.)

Given the current AASM guidelines for sleep stage scoring,[9] much of the foregoing normative data on sleep architecture may have limited relevance for laboratories that elect to adopt such changes. For example, slow wave activity has higher amplitude when recorded from frontal derivations relative to central derivations. This would be expected to result in increased levels of visually scored slow wave (i.e., N3) sleep. One study comparing recordings scored with both revised AASM and traditional Rechtschaffen and Kales criteria have shown a number of significant differences in resulting measures.[32] Predictably, particularly in older persons, the revised scoring system resulted in higher percentages in N3 sleep. Given that middle-aged subjects also show decreases in delta activity, most pronounced frontally but also in central and parietal and occipital derivations,[17] such effects are probably not limited to elderly persons. Beyond creating the need to establish new normative data, the mechanistic and functional significance or the diagnostic and therapeutic importance of such a revisionary approach remain obscure. Much the same effect could be obtained by adopting alternative scoring thresholds of less than 75 μV for defining delta wave activity. Such proposals were put forth in the 1990s (see Bliwise[6] for review), but have not led to enhanced understanding of the age-dependent changes in SWS. Eventually, digitized indexes of delta activity (e.g., fast Fourier transform, zero-crossing, or hybrid techniques) might come to replace such conventional measures; however, considerable controversy regarding filtering, sampling rates, and data storage formatting leaves formal adoption of such approaches dubious for routine clinical purposes at this time,[33] though such efforts at signal processing are yielding important new clues regarding the significance of sleep-related delta activity for aging. Appreciation of individual differences in slow wave activity must also take into

account that the amount of delta demonstrated may reflect, at least in part, the variable number of tandem repeats in the PER3 polymorphism, an association first demonstrated in younger, and now in elderly, persons.[34]

Slow wave activity during sleep may represent synaptic downscaling and memory consolidation processes, which are viewed as critical for neural efficiency and memory retention[35,36] (see Chapter 22). Given at least some data suggesting decreased SWS with age, such findings might fit with mild impairments in cognition that characterize normal aging. Extremely low-frequency (<1.0 Hz) slow wave activity in NREM sleep has been thought to hold particular significance as a more immediate reflection of cellular processes than conventionally defined delta activity.[37] In dementia, the integrity of the normal auditory evoked response (K-complex) may be impaired,[38] whereas in normal aging, there is some suggestion that spectral power at frequencies below 0.7 Hz might demonstrate fewer age differences than at between 0.7 and 3.0 Hz.[39] Other attempts to examine NREM sleep in old age using nonlinear, dynamic EEG approaches yield compatible findings. The sleep EEG of healthy older adults in the first NREM period may resemble patterns of compensatory activation similar to those seen in young adults during sleep subsequent to sleep deprivation.[40] Whether such phenomenologic parallels of altered functional connectivity in sleep deprivation and aging hold prognostic or practical significance at the individual case level is unknown but certainly plausible. Nonlinearity of the NREM sleep EEG increases with normal aging[40] and sample entropy, a novel measure reflecting dynamic probabilities of state,[41] also changes with age. Less SWS in older humans was related to greater cortical atrophy as determined neuopathologically.[42]

CIRCADIAN RHYTHMS IN AGING

In humans, most descriptive data collected under entrained conditions have suggested that the amplitude of the sleep-wake rhythm, body temperature (Figure 3-2),[43] and some hormones decrease with aging. Sex differences in such phenomena have also been reported (see Bliwise[44] for review). However, in exceptionally healthy older adults such differences might not always appear,[45] and a study of centenarians indicated relatively robust neuroendocrine profiles.[46] A phase advance of aging has often been ascribed to the timing of sleep patterns in older adults. Many sleep medicine specialists use this designation as an abbreviation for indicating that older persons go to bed earlier in the evening and wake up earlier in the morning than younger persons, findings corroborated in age differences in the timing of bedtimes and wake-up times in dozens of cross-sectional surveys (see Bliwise[6] for review) and even longitudinally.[47]

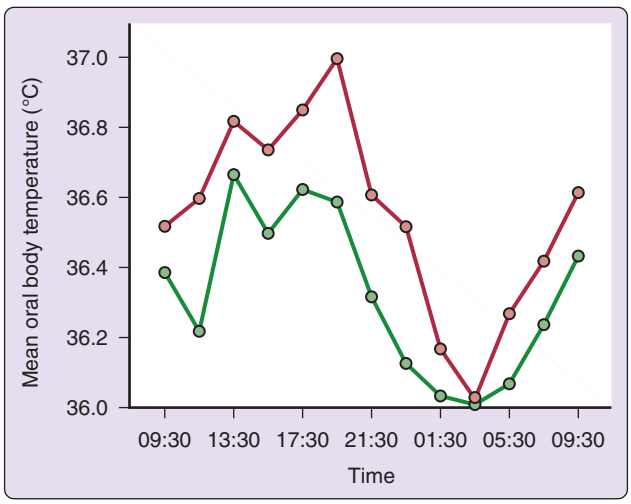

Figure 3-2 Oral temperatures in young (*red circles*) and old (*green circles*) subjects, showing apparent decreased amplitude and earlier phase in body temperature cycle as a function of aging. Data were obtained under entrained conditions. (From Richardson GS, Carskadon MA, Orav EJ. Circadian variation of sleep tendency in elderly and young adult subjects. *Sleep* 1982;5[Suppl 2]:S82–94.)

However, the reader should be aware that fundamental changes in phase relationships in human circadian rhythms might not always substantiate the notion of such an advance. For example, in the constant routine protocol, older subjects' typical earlier bedtimes and wake-up times relative to younger subjects actually were more phase delayed, rather than phase advanced, relative to their peaks in melatonin.[48] The implication of this finding is that the earlier bedtimes and wake-up times may be due to homeostatic factors. Studies using 28-hour forced desynchrony, an experimental protocol that requires subjects to sleep on a 2:1 wake-to-sleep ratio outside the limits of entrainment of the circadian system, have shown absence of age differences in estimates of tau, the endogenous period length of the human core temperature rhythm.[49] Again, these results implicate factors other than circadian ones that may be responsible for the earlier bedtimes of older humans. Further evidence of interaction between circadian and homeostatic factors comes from a study of age differences in the melatonin rhythm under the constant routine protocol, during which younger subjects showed elevated melatonin levels during the higher homeostatic pressure induced by this procedure, whereas older subjects did not.[50]

The interaction between homeostatic and circadian influences in older humans has been described elegantly in the forced desynchrony protocol, which has shown that throughout the assigned (9.33-hour) sleep period, elderly subjects awakened more frequently than younger subjects, regardless of circadian phase.[51] The duration of awakenings was virtually identical in young and old subjects, but the largest differences in the frequency of awakenings between young and older subjects were detected early, rather than late, in the sleep period. These results appear incompatible with the broadly defined phase-advanced hypothesis of sleep in elderly persons, in which differences in sleep consolidation would be predicted to be most pronounced late in the sleep period (corresponding to early morning awakening) and least pronounced just after sleep onset (corresponding to early evening sleepiness). This study also analyzed sleep structure immediately before awakenings from consolidated periods of sleep. With circadian phase controlled, older subjects were far less likely to awaken from stage 1 and far more likely to awaken from stage 2 than were young subjects, suggesting that awakenings in the older subjects probably represented abrupt transitions from NREM sleep rather than gradual lightening of sleep.[51] These findings can be interpreted as an indication of a reduced homeostatic pressure for continuous bouts of sleep independent of circadian phase in the sleep of older persons.

A well-described feature of the circadian system in the aged organism is the relative impairment in the ability to

phase-shift. This may in part reflect loss of rhythmic function within the suprachiasmatic nucleus.[52] In humans, the sleep-wake system appears particularly vulnerable to such changes in phase shifting[53] and might account for some of the apparent self-selection out of shift work typically seen in older people (see Bliwise[54] for review). In rodents, such impairments in phase shifting have also been described.[55] Although both photic and nonphotic influences on impaired phase-shifting ability have been described in aging (see Bliwise[54] for review), the ability to phase-shift and entrain to light in old age might be expected to be particularly impaired because of challenges to the visual system that occur as a part of human aging (e.g., cataracts, macular degeneration). Perhaps as a consequence, in epidemiologic studies, elderly persons with visual impairments were 30% to 60% more likely to have impaired nighttime sleep relative to visually unimpaired elderly subjects.[56] In the laboratory setting, however, disagreement exists as to whether, among persons without visual impairment, responsiveness of the circadian system, as indexed by melatonin rhythms, is decreased[57] or unchanged[58] by light exposure. Finally, another study examined the ability of a nonphotic stimulus (evening exercise) to phase-shift melatonin onset in young and elderly persons and found comparable phase delays subsequent to exercise in both groups, arguing for the importance of entraining factors other than bright light to affect rhythms in elderly persons.[59] Despite this, neuroimaging indicated that alternate exposure to darkness and blue light indicated that aging was associated with impaired reactivity in an array of visual, alertness, and executive function–related brain regions in older relative to younger adults.[60]

Invertebrate models in studies of sleep and aging have been broadly confirmatory for many of the changes described in mammals, such as the decline in nocturnal sleep durations.[61] Several studies in the fruit fly (*Drosophila melanogaster*)[62] and in the honeybee (*Apis mellifera*)[63] have indicated a dispersal of sleep around the 24-hour day occurring with aging. Perhaps more noteworthy is that these studies have also implied that total amount of sleep per 24 hours does not merely redistribute (by shorter bout length and increased number of bouts) but also might increase in quantity with advanced physiologic age. These changes appeared particularly pronounced in male fruit flies[62] and female honeybees[63] near the end of life. Because an avowed function of the mammalian master clock, located in the suprachiasmatic nucleus, is to provide clock-dependent alerting, these data are consistent with early studies that demonstrated such a role for the suprachiasmatic nucleus in primates using lesion models.[64] Although studies involving neurodegenerative disease in aged humans have shown increased sleep per 24 hours consistent with level of dementia (see Chapter 96), the invertebrate data imply that increased rather than decreased sleep durations would be likely to occur in aged humans normatively on a population-wide basis. In this regard, it is noteworthy that the largest single compilation of human sleep durations ever published (more than 1 million subjects) shows that reported sleep durations increase, rather than decrease, with age.[65] Taken together, these data suggest that increased sleep durations in aged humans might fundamentally represent biologic rather than sociocultural factors.

Among lower vertebrates, aged zebrafish (*Danio rerio*) have been shown to demonstrate reduced rest-activity rhythm and shorter nocturnal sleep durations across the life span (from 1 to 4 years), and these were associated with decreased brain melatonin during the dark period.[66] Melatonin administration was shown to partially restore sleep durations and simple measures of learning in this species. Zebrafish aging was also shown to be associated with gene expression in several clock genes (*Bmal1, PER1*),[66] although the translation of this finding back to older humans might not be clear.[67] Additionally, in rodents, age effects in the expression of several clock genes may occur equally in both wild-type and mutant lines.[68]

CAUSES AND CONSEQUENCES OF POOR SLEEP IN OLD AGE

Causes

The prevalence of insomnia in older adults varies across studies, but figures between approximately 20% and 40% are typically reported. In one of the largest surveys of an American population (the Established Populations for Epidemiologic Studies of the Elderly, with more than 9000 participants), 29% of the older-than-65-years population reported difficulty maintaining sleep.[69] Relative to sleep maintenance, sleep latency is less likely to be problematic for the elderly population, with prevalence figures on the order of 10% to 19% typically seen, although one study[70] reported a relatively high prevalence of sleep latency problems (36.7%) in a largely rural aged population. In nearly all studies, elderly women have a greater probability of sleep complaints and sedative-hypnotic use than elderly men (see Bliwise[1] for review). Conflicting data exist on racial differences in sleep complaints,[71] though health disparities in sleep durations did not appear to depend on age.[72] Some large-scale survey data have questioned whether reports of sleep as a "problem"[73] or having "insufficient" sleep[74] show any age dependence whatsoever,[75] but such approaches ultimately confound elderly persons' reports of their health behaviors with their judgments of well-being, which generally improve with advancing chronologic age. Social science research has shown that as people age, perceived life satisfaction increases, reflecting what has been termed a "positivity effect"[76] or a "paradox of aging"[77] in many domains of life.[78] These types of biases are likely operating when populations are asked about their sleep using questions such as these.

Figures for regular use of sedative-hypnotics in elderly populations range from as low as 5% per year to as high as 16% over 4.5 years, 29% over 8 years, 34% over 1 year, and 62% over 3 years (see Bliwise[1] for review). Although subjective reports of poor sleep invariably increased with age, and numerous changes in sleep architecture have been frequently noted (see earlier), the relationship between these two domains is significant, though relatively weak, with women showing slightly higher levels of association relative to men.[79]

Disturbed sleep is thought to both contribute to and reflect allostatic load of illness in old age and might reflect physiologic age of the organism. When other causes of poor sleep are taken into account, chronologic age might explain little of the observed higher prevalence in elderly persons. Psychiatric conditions have always been considered to play a major role in the insomnia of old age. A study of more than 3000 older men reported that depressive symptoms were associated with difficulties in falling asleep, but not lower sleep efficiency or total sleep time.[80] Among women, although the caregiving

role per se was not associated with poor sleep, for women who were depressed, caregiving was associated with reported sleep problems.[81] Regardless of caregiving status, anxiety appeared to play a larger role in predicting poor sleep quality in these older women, even relative to depressed mood per se.[82] However, poor sleep, left untreated, appears to be a risk factor for incident depression in elderly persons.[83]

Limitations in mobility, visual impairment, lack of regular exercise, alcohol use, and smoking all contribute to declining sleep quality in older persons, as do chronic pain conditions, such as arthritis, hip fracture, fibromyalgia, headache, and back pain; cardiovascular diseases such as hypertension, myocardial infarction, stroke, congestive heart failure, and angina; respiratory conditions such as asthma and bronchitis; and other systemic diseases such as diabetes, gastroesophageal reflux, and duodenal ulcer (see Carrier and Bliwise[84] for review). When persons with such comorbidities are eliminated from consideration, the resulting insomnia prevalence in elderly populations may be only 1% to 3%,[85] reiterating the decreased significance of chronologic age per se in predicting poor sleep. In women, some evidence suggests that menopause may also be associated with declining sleep quality (see Chapter 159). Retirement from work has been shown to be related to fewer sleep problems.[86]

Additionally, in both women and men, the otherwise mundane occurrence of nocturia (nightly awakenings to void) appears to be associated with poor sleep,[87] even when other factors such as pain and medical comorbidity are taken into account. In fact, nocturia may be the single most common factor associated with poor sleep in elderly persons.[87] The duration of the first uninterrupted sleep period, otherwise referred to as the time to first void, has been shown to correlate with nearly all measures of whole-night sleep quality,[88] and lengthening of the first uninterrupted sleep period in a population containing a substantial portion of elderly persons was associated with improvements in many such measures.[89] Effects were independent from age. Nocturia is an important consideration in the lives of older people because it has been related to lower quality of life,[90] depression,[91] and mortality, even with some control over comorbidities.[92] Some have questioned the basis of the causal association between nocturia and poor sleep, arguing that the effects on disturbed sleep appear of small magnitude[93] when measured actigraphically[94] or that awakenings precede the voiding episodes. The latter explanation appears incompatible with evidence that elevated detrusor activity during sleep temporally precedes such episodes,[95] as well as improvements in sleep when nocturnal diuresis is treated.[96]

SDB was associated with the presence of nocturia in the Sleep Heart Health Study,[97] perhaps through increased levels of brain naturietic peptide or decreased levels of arginine vasopressin (see Bliwise[98] for discussion), though the former appeared more likely in one case series of men older than 60 years.[99] A Danish case-control study found an association between nocturia and SDB only when nocturnal polyuria (i.e., >33% of urine volume produced at night) was present.[100] Treatment with continuous positive airway pressure (CPAP) has been reported to reduce the number of nocturnal voids in some[101] but not all[102] studies, though interestingly, behavioral treatments for poor sleep in the absence of SDB can also reduce nocturia.[103] Although the relation between nocturia and lower sleep quality has been noted to be independent of age, and individuals of all ages report being "bothered" by the phenomenon,[90] an association between nocturia and SDB was reported to weaken with age in one study,[104] which might account for the negative findings in a recent major CPAP trial in elderly persons.[102]

Several longitudinal studies examining the incidence (development of new cases) of insomnia over periods of up to 10 years have been reported. The single best predictor of insomnia continuing longer than 10 years was insomnia at a previous time, although cardiovascular and pulmonary comorbidities conferred risk as well in the older-than-65-years population.[105] Reported remissions were less likely in older subjects than in younger ones.[106] The Established Populations for Epidemiologic Studies of the Elderly data indicated a yearly incidence of insomnia complaints in the aged population of about 5%, with a spontaneous remission rate of about 50% over 3 years.[107] In these data, incident insomnia was related to heart disease, stroke, hip fracture, and new-onset depression. Spontaneous remission of insomnia was related to the resolution of depression, physical illness, and physical disability affecting activities of daily living,[107] whereas in the Cardiovascular Health Study, persistence of insomnia was associated with unresolved depression.[108] Important from the standpoint of prevention, another study reported that higher levels of physical activity were protective for incident insomnia over an 8-year period.[109] Two Scottish cohorts of different ages at entry (36 to 57 years and 56 to 76 years), including both men and women followed over 20 years for sleep complaints, found strong evidence that manual labor was associated with chronic (unremitting) and incident insomnia.[110]

Potential Consequences

A major question regarding the frequent complaints of poor sleep among elderly persons involves whether these have an impact on their health. If the poor sleep of old age, although annoying and distressing for many, represents primarily a quality-of-life issue, albeit one modifiable by medical or behavioral interventions, it might cast a different perspective on this problem, than would a medical disorder such as SDB, for which negative outcomes may be better defined and quantified. There is no question that almost universally, poor nocturnal sleep is distressing and related to lower quality of life of many older persons. This has been demonstrated in elderly populations in the United States,[111] Canada,[112] Europe,[113] Asia,[114] and Africa.[115]

Most work-relating poor sleep quality or duration to putative adverse outcomes has been observational, which, although often provocative, lacks the definitive element of proof of causation that is afforded by randomized clinical trials. Unfortunately, with few exceptions, most pharmacologic and nonpharmacologic randomized clinical trials attempting to treat poor sleep in elderly persons seldom rely on outcomes other than conventional subjective and PSG measures of nocturnal sleep per se. Rare exceptions to the latter have been several insomnia treatment studies among older adults that have demonstrated increases in selected quality-of-life measures such as the SF-36[116] or decreased daytime napping.[117] Data relevant to interventions for poor sleep and their effects on other medical outcomes in old age (e.g., hypertension, insulin resistance) have yet to be published.

Among observational studies, the association between nocturia and insomnia has led to speculation that the more likely

a person is to rise from bed during the night to use the bathroom, the more likely the person is to fall.[87] Considerable evidence for this association exists at the population level, where studies have shown associations between insomnia and falls.[118] Sleep durations of less than 5 hours were associated with an increased risk for falls of more than 50%.[119] Risk for increased falls with short duration of sleep or poor quality of sleep (or both) is also consistent with data suggesting that insomnia is associated with impaired physical function. For example, lower sleep efficiencies were associated with lower grip strength and slower walking speed in a population of elderly men.[120] Short sleep durations were associated with a slightly different set of markers of physical impairment in elderly women, primarily consisting of chair-to-stand speed.[121] Although the increased risk for falls in older populations has been typically ascribed to psychotropic and sedative-hypnotic medications, reanalyses of some of these databases have suggested that poor sleep per se may be a more relevant predictive factor.[122]

Relative to poor-quality sleep, at least some data suggest adverse outcomes associated with short sleep durations in older populations. Gangwisch and colleagues[123] reported that sleep durations of less than 5 hours were associated with higher rates of all-cause mortality in subjects 60 years and older, a finding that was not present in persons ages 32 to 59 years. Sleep durations of less than 5 hours per night in even older populations (67 to 99 years old) were associated with obesity as well,[124] a finding otherwise well acknowledged in populations younger than 65 years, in women in one study[125] and in men and women in another.[126] Hypertension has also been associated with short sleep durations in elderly persons,[127] and with decreased N3,[128] but other studies of older populations indicated that neither short sleep durations[129] nor complaints of poor sleep[130] were associated with this morbidity. Diabetes and impaired glycemic control were associated with sleep durations of less than 6 hours (but not insomnia complaints) across the age range of 53 to 93 years[131] and were independent of age across an even broader age range.[132] As mentioned earlier, these are all observational studies, which, although impressive by size of the samples studied and control over confounding variables, did not manipulate sleep quality or sleep duration to demonstrate improvement in any of these putative adverse outcomes in older persons.

An area of emerging interest is whether changes in sleep with aging have ramifications for memory and cognitive changes.[133] In young adults, sleep is theorized to benefit learning, memory, and cognition through synaptic downscaling,[134] memory reactivation,[135] and increased alertness (see Chapter 22). With increasing age and disease, there are not only changes in sleep quality (as described previously) but also declines in memory, attention, executive function, and processing speed cognitive domains.[136] Thus it is possible that poor sleep might contribute to declining cognition in aging adults and possibly to the development of cognitive disorders such as MCI and Alzheimer disease.

A substantial literature has now reported significant correlations between sleep measures (self-report, actigraphy, and PSG) and performance on cognitive tests in middle-aged and older adults, after correcting for demographic and health-related confounding variables. In cross-sectional studies, middle-aged adults consistently demonstrate detrimental relationships between cognitive performance and self-reported short sleep, long sleep, difficulty falling asleep, and nighttime awakenings; by contrast, older adults only consistently show cross-sectional associations between cognitive performance and self-reported long sleep duration or delayed sleep-onset latency.[133] Cause and effect are difficult to distinguish in such correlational studies, but several longitudinal studies have now connected short and long (self-reported) sleep at baseline in middle-aged adults to subsequent cognitive decline up to 28 years later.[137] For example, in the Whitehall II middle-aged cohort that included more than 5000 participants, reported short and long sleep at baseline, as well as longitudinal changes in sleep duration, was predictive of accelerated cognitive decline on a battery of tests 5.4 years later.[138] Some large cross-sectional studies have suggested that different aspects of reported lower sleep quality, rather than measured SDB, were most strongly associated with both amnestic and nonamnestic types of MCI.[139] Epidemiology studies—including Study of Osteoporotic Fractures (SOF) and Osteoporotic Fractures in Men (MrOS)—that have use actigraphy to define sleep-wake state, have tended to provide converging results using more abbreviated cognitive test batteries and typically implicate wake after sleep onset or sleep efficiency rather than total sleep duration[140] as relevant correlates of impaired cognition. Few studies have evaluated age-dependent cognitive changes in relation to PSG variables since Irwin Feinberg's seminal work,[141] but lower REM sleep quantity and density have been related to cognitive decline in both 3-year[142] and 14-year[143] longitudinal studies. It remains unclear whether declining REM sleep causes cognitive functioning to worsen or if age- and disease-related declines in cholinergic neurotransmission drive both REM sleep declines and cognitive declines.

Experimental studies that have manipulated sleep duration or specific features of sleep have also produced noteworthy findings. Almost every sleep deprivation study that examined cognitive outcomes in relation to aging (see Scullin and Bliwise[133] for review) has shown that sleep deprivation has less of an impact on cognitive performance in older adults than in young adults (e.g., see Duffy and colleagues[144]). This pattern might indicate that older adults need sleep less than young adults, but defining age-dependent change in sleep need and the overall meaning of sleep deprivation effects in older adults is still vigorously debated. Another experimental approach is to attempt to increase total sleep duration (e.g., by having adults take afternoon naps). When measuring cognitive performance before and after a single nap (relative to a wake condition), nap-related benefits to cognitive performance are consistently observed in middle-aged adults.[145] Similar nap-related benefits to cognition also seem to emerge in interventional studies in which participants are asked to attempt to take an afternoon nap every day for a month.[146] However, perhaps corresponding to the sleep deprivation literature, napping studies that have used older age groups have often failed to observe any cognitive benefits of napping.[147] Pharmacologic enhancement of sleep, specifically defined as increases in spindles[148] and slow wave activity, seems to benefit cognition in young and middle-aged adults[149] but does not greatly benefit older adults.[150] A rodent study suggested that sleep deprivation resulted in increased dendritic branching in prefrontal cortex in older animals but decreased density in the hippocampal CA1 layer,[151] which is consistent with the divergence of results shown in the human behavioral studies cited previously. The mechanisms involved in these differential

results by age are uncertain, though some speculation has focused on age differences in the adenosine A(2A) receptor gene in response to sleep loss.[152]

One mechanism by which poor sleep could affect cognitive functioning with advancing age is by reducing the efficiency of sleep-dependent memory consolidation (i.e., the stabilization and integration of learned experiences during the day). Animal studies have found reduced hippocampal reactivation of place cells during sleep (i.e., memory "replay").[153] In humans, sleep-dependent memory consolidation also appears to decline steadily across the life span. Memory consolidation effects are larger in children than in young adults,[154] larger in young adults than in middle-aged adults,[155] and larger in middle-aged adults than in older adults.[156] Aging appears to detrimentally affect both procedural (motor) memory and declarative (episodic or explicit) memory consolidation, and adults in the eighth and ninth decades of life may show no memory consolidation effects at all.[157]

Another, not mutually exclusive mechanistic influence whereby poor sleep could accelerate cognitive decline involves amyloid deposition. Basic science studies have found that sleep facilitates the clearance of brain metabolites including ß-amyloid[158] and that sleep deprivation in rodents is linked to increased amyloid plaque burden.[159] In humans, self-reported short sleep duration and actigraphy-measured sleep efficiency have been associated with higher ß-amyloid burden, as measured with positron emission tomography[160] or cerebrospinal fluid (CSF).[161] It is therefore perhaps not surprising that epidemiology studies have found that poor sleep quality can predict development of MCI[162] and Alzheimer disease.[163]

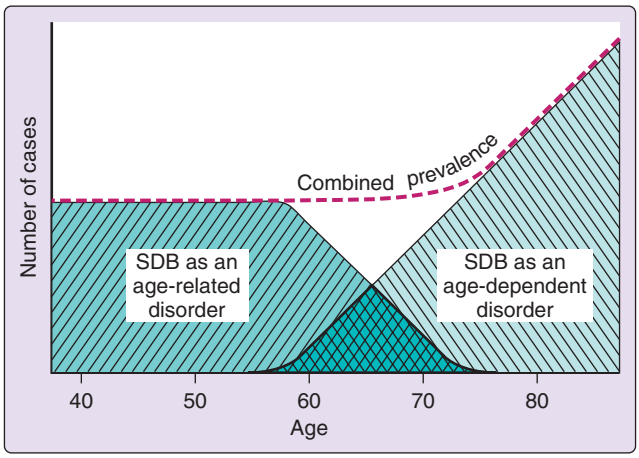

Figure 3-3 Heuristic model suggesting that sleep-disordered breathing (SDB) is both an age-related and an age-dependent condition with potential overlap of distributions in the 60- to 70-year-old age range. Cross-sectionally, note that the number of cases observed can remain high and increase with age, despite a presumed decrease in age-related SDB.

RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENTS DURING SLEEP

One specific cause of insomnia in elderly persons is restless legs syndrome (RLS) (see Chapter 95). This condition, characterized by an urge to move the legs, which is usually accompanied by sensations of discomfort, aggravation of symptoms by rest and temporary relief of symptoms by movement, and worsening during the evening or nocturnal hours, is exceedingly common in elderly populations. Estimates vary, but the condition appears to be more prevalent in northern European[164] relative to Asian populations,[165] and several genotypes have been identified (see Chapter 95). Peak prevalence was noted in the group aged 60 to 69 years for women (16.3%) and 50 to 59 years for men (7.8%),[164] though the population sampled included persons up to age 90 years. Another European study including subjects up to their 80s also showed similar gender differences (14.7% in women; 6.8% in men), with peak prevalence for both genders in the 50- to 59-year-old range.[166] Thus, in some respects, RLS prevalence appears to be more age related than age dependent (see later and Figure 3-3), although at least one study of a Dutch population noted that prevalence was highest in the oldest subjects (80 to 100 years of age).[167]

A Finnish longitudinal study of individuals in their 60s at baseline reported decreased prevalence over 10 years, but a survivorship phenomenon could not be ruled out.[168]

Periodic limb movements during sleep (PLMS) are stereotypic, repetitive, nonepileptiform movements of the legs usually consisting of dorsiflexion of the ankle but occasionally limited to flexion of the great toe or incorporating flexion at the level of knee or hip. They often, but not invariably, occur in conjunction with RLS. The intermovement interval has been reported to decrease with age from about 24 to 28 seconds before the age of 55 years to about 14 to 16 seconds after the age of 65 years.[169] Age-dependent increases in the occurrence of PLMS have been noted cross-sectionally in series without a drop in the oldest (e.g., >80 years) groups.[170] Curiously, longitudinal follow-up of elderly subjects did not show increases consistently,[171] perhaps owing to inherent variability in PLMS. Prevalence, defined as a periodic leg movements index of 15 movements or more per hour, has been estimated as high as 52% in a population of older women.[172] When measured with wrist actigraphy in that population, the presence of PLMS was associated with sleep durations of less than 5 hours of sleep,[173] though earlier population-based studies have presented conflicting data as to whether PLMS, in the absence of frank RLS symptoms, were associated with poor sleep.[170] One study of men aged 40 to 60 years noted poorer sleep quality when the periodic leg movements index exceeded 10.[174] Other studies demonstrating the mixed pattern of results correlating PLMS with sleep complaints have been reviewed elsewhere.[175] Noteworthy is a large study reporting on simultaneous PSG measurements of sleep architecture and piezoelectric recordings of leg movement activity in 2872 men that reported strong associations between higher levels of PLMS or PLMS with arousals and multiple measures of poor sleep quality (lower sleep efficiency, higher N1 percentage, lower N3 percentage).[176] In a normative study of more than 1000 individuals across a broad age range, PLMS increased with aging in both men and women, but the age effect was three times as strong in men.[177]

One possible explanation for the variability of results across studies is that PLMS may vary considerably from night to night. A 15-night study suggested that estimated prevalence for PLMS might stabilize only after multiple nights of measurement.[178] The discrepancy between the higher prevalence of PLMS relative to RLS and the failure of a number of studies to show associations between their presence and

specific symptoms suggests that in many elderly persons, PLMS may be an incidental finding.[175]

The worsening of RLS and PLMS with aging suggests that this syndrome may be associated with other conditions known to be common in older populations. Given the likelihood of anemia among elderly persons, current attention has focused largely on iron transport and storage deficiencies.[179] Elderly RLS patients with serum ferritin levels of less than 45 mg/mL showed subjective improvement following use of ferrous sulfate, although their total iron levels were no different.[179] These findings were later replicated by the same research group.[180] Because iron represents a key component of production of dopamine, it could play a role in presence of RLS in some elderly subjects. One population-based study could not confirm the ferritin finding,[181] although another report indicated that higher serum-soluble transferrin receptor levels (often characteristic of early-stage anemia) and lower serum iron levels were associated with RLS.[164] An interesting perspective on iron metabolism and aging was based on examination of ferritin levels in the CSF of elderly RLS patients. Older patients had higher CSF ferritin levels than did younger patients; however, for elderly patients whose RLS had been long-standing, lower levels were associated with a more severe condition.[182]

Heightened awareness of both PLMS and RLS as phenomena associated with cardiovascular comorbidities (see Chapter 95) provides new impetus that these conditions are taken seriously. In a cross-sectional analysis of more than 500 patients in their mid-60s, the presence of a periodic limb movements index higher than 35/hour was associated with multiple measures of left ventricular dysfunction[183] and, in a subset of these patients, was also predictive of progression of atrial fibrillation over a median interval of nearly 3 years.[184]

SLEEP-DISORDERED BREATHING

Specific considerations related to diagnosis and treatments of SDB in elderly persons are covered in Chapter 152. This section deals with more general issues involving age dependence.

The previously proposed heuristic model for SDB (see Figure 3-3) posits that SDB represents both an age-related phenomenon (with a specific vulnerability confined to middle age) and an age-dependent phenomenon (with a prevalence that steadily increases throughout the human life course).[1] The articulation and differentiation of these two presumably separate but chronologically overlapping distributions represent a major challenge to clinicians. Practically, if the health consequences of SDB in elderly populations are diminished, the necessity to treat the enormous numbers of elderly persons who have the condition is reduced. Age dependence implies that SDB risk factors might be best considered markers of physiologic or biologic age.[185] Chronologic age may thus serve only as a proxy for other risk factors that are themselves age dependent.

Risk Factors

Risk factors for SDB in the older population may differ to some extent from those in middle-aged populations. In SHHS, several markers of obesity that were significant cross-sectional predictors of SDB in middle-aged populations (neck circumference and waist-to-hip ratio) were no longer significant predictors by age 70 years and 80 years, respectively,[186] although body mass index continued to be correlated with SDB, even past age 80 years, albeit with a somewhat diminished effect. Although the male predominance in SDB is thought to equalize in old age, this was not the case within SHHS.[186] Other cohort studies including older subjects suggested roughly equal prevalence in elderly men and women.[187,188]

The prevailing view for many decades was that most SDB in elderly persons consisted of central (i.e., diaphragmatic) events, whereas in the middle-aged population, obstructive events predominated; however, this is unsubstantiated by both descriptive studies, showing the predominance of obstructive apneas, and by pathophysiologic studies, which show increased tendency for upper airway collapse with aging.[189] Upper airway resistance has been reported to be higher in both REM and NREM sleep in older men relative to younger men,[190] and closing pressures during sleep were higher in older subjects in N2 sleep relative to younger subjects.[190a] Acute reduction of CPAP pressure during NREM sleep results in enhanced collapsibility of the upper airway in older, relative to younger, persons.[189] Aging has been associated with lengthening of the soft palate and with upper airway fat pad deposition, both of which may contribute to oropharyngeal collapse during sleep.[191] Lower lung volumes have been shown to predict incident SDB in elderly persons over time,[192] perhaps by providing less caudal traction on the trachea and hastening upper airway collapse during sleep. In older animals, the pharyngeal muscles appear to have a worse profile for endurance relative to the diaphragm, which may enhance susceptibility to collapse,[193] and a shift from type IIa to IIb fibers occurred in the genioglossus in 24-month-old rats, a finding interpreted as conferring susceptibility to fatigue.[194] Remodeling of the motor unit firing pattern of the genioglossus in older human subjects may be a counterpart to these histologic changes.[195] Associations between weight loss and SDB development over intervals of up to 30 years in aged humans represents proof of concept that generalized muscle weakness (sarcopenia) could underlie incident SDB in older adults.[196]

Predisposing influences on SDB in elderly human populations are not limited to neuromuscular factors. Ventilatory control instability,[197] which may be accentuated by the decrease of N3 sleep with age, might also predispose to SDB in elderly persons, though not all studies report high loop gain in older subjects.[198] Recent modeling studies using abrupt decreases of CPAP pressures have suggested diminished ventilatory feedback in the sleep of older, relative to younger, subjects, a finding shown to reflect decreased controller gain.[189] These and other potential age-dependent risk factors for SDB are shown in Figure 3-4.

Outcomes

Potential outcomes relevant to SDB in old age include mortality, cardiovascular and neurobehavioral morbidities, and morbidities related to other potential end-organ damage (see Figure 3-4). The prevailing viewpoint in sleep medicine has been that SDB demonstrates weakened associations with morbidities in elderly, relative to middle-aged, persons. Offered here is a brief description of studies in older populations suggesting otherwise.

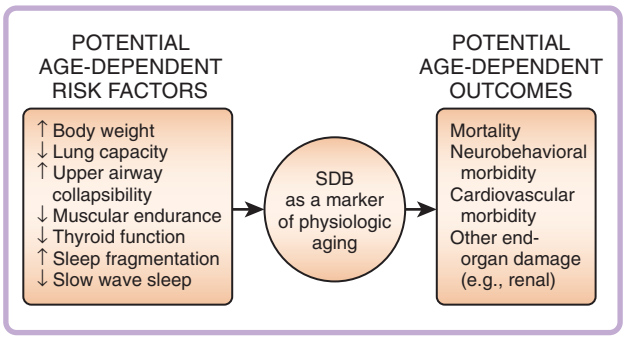

Figure 3-4 Sleep-disordered breathing (SDB) in older adults as an age-dependent condition. Other potentially associated age-dependent risk factors and outcomes are shown.

In elderly persons, SDB has been associated cross-sectionally with clinically defined hypertension,[199] a nondipping blood pressure pattern,[200] composite cardiovascular disease history (in men),[201] stroke,[202] reduced kidney function (in men),[203] poorer physical function (in men),[120] nocturia,[204] overactive bladder,[205] and impaired cognition (in women).[206] Longitudinal data have shown relationships between snoring and daytime sleepiness and incident cardiovascular disease[207] and between declining mental status test scores and the development of SDB,[208] though the effect sizes for such associations may be small for cognition.[209] Additionally, higher health care costs were associated with sleep apnea in both middle-aged and elderly persons.[210] An important association between SDB and frailty has also been noted in older women,[211] which is particularly important given the fact that, as a well-acknowledged geriatric syndrome, frailty is highly predictive of other morbidities and of mortality.[212] Moderate to severe SDB was related to all-cause, cancer, and stroke mortality in a middle-aged population studied over 20 years,[213] and, at least for all-cause mortality, the presence of daytime sleepiness conferred additive risk.[214] As outlined elsewhere,[1] whether age moderates the relationship between SDB and mortality is controversial. Several natural history studies of SDB in old age continue to report absence of associations between SDB and mortality[215] or present data interpreted as suggesting that SDB does not progress over a relatively short interval of 3 years.[216] Longitudinal data collected over 20 to 30 years suggest otherwise.[196]

In SHHS, when subjects with prevalent cardiovascular disease were excluded, relationships between SDB (as measured by quartiles of the apnea-hypopnea index) and various morbidities (including diabetes and hyperlipidemia) were clearly lower in the older-than-65-years population than in the younger-than-65-years population, but only in men, not women, where the associations were similar.[217] By contrast, Haas and colleagues[218] reported that isolated systolic hypertension was unrelated to SDB in any age range but that systolic and diastolic hypertension were related to SDB in only those younger than 60 years. In another report examining associations between multiple measures of SDB and more broadly defined cardiovascular disease (including coronary heart disease, congestive heart failure, and stroke), relationships with SDB, although reduced to some extent by age, were still age independent.[219] Echocardiography suggests that left ventricular diastolic and systolic dysfunction occurs in elderly patients with SDB.[220]

Despite this suggestive evidence, other studies continue to minimize the significance of SDB for elderly populations. For example, it has been contended that sleep apnea has little effect on quality of life in elderly persons,[221] and others have argued that ischemic preconditioning essentially renders the SDB of old age innocuous because some component of protective adaptation is likely to have occurred.[222] Associations with both cognition[223] and daytime sleepiness[224] have been questioned. Pulse transit time, often used as a proxy for SDB screening in middle-aged patients, was shown to be less valid as a marker for SDB in an aged population,[225] and electrophysiologic changes intrinsic to cardiac control (less variability and decreased entropy) during REM sleep in old age in the absence of SDB have also been described.[226] Autonomic changes with aging, including an age-dependent reduction of parasympathetic modulation (as measured from R-R intervals in REM) in patients with SDB were noted by others,[227] but such changes in cardiorespiratory coupling are conceptualized as indicative of more disease and as more permissive for sympathetic influence, rather than less.[228] Goff and colleagues[229] have shown that cardiovascular responses (elevations in heart rate and blood pressure) to auditory stimulation are reduced during normal sleep in older relative to younger persons, and they also noted a similar blunting of response during flow-limited breathing.[230] These findings were interpreted as consistent with reduced associations between SDB and systemic hypertension that have been reported in some studies of older persons. Other evidence indicates that aortic pulse wave velocities in relation to SDB were exaggerated rather than dampened in elderly subjects,[231] and elderly women with SDB were shown to be at higher risk for both clinic-measured and 24-hour elevations in blood pressure.[232] The consequences of SDB in older populations thus remain an area rife with controversy, and the sleep medicine specialist should be cognizant of these issues. For further discussion, the reader is directed elsewhere (see Bliwise[1] for review) and to other chapters in this volume (Chapter 152).

The emergence of several relatively large-scale recent intervention studies specifically administrating CPAP to geriatric populations with sleep apnea have suggested at least modest benefit of treatment for elderly patients. The United Kingdom–based PREDICT trial noted improvements in self-reported daytime sleepiness, as well as some health care cost savings in a population older than 65 years studied for 12 months.[102] Blood pressure reductions with CPAP were noted to be as marked in subjects older than 60 years as those seen in individuals younger than 60 years,[233] and a large clinical trial of nearly 1000 elderly patients from Spain noted a doubling of risk for cardiovascular mortality when comparing individuals with untreated severe SDB and those using CPAP.[234]

WHY DO OLDER PEOPLE NAP?

A time-honored question, asked by both professionals and the lay public, involves the significance of napping in old age. From the layperson's perspective, the question is most typically: "Is it normal to nap?" or "Are naps good or bad for my health?" The sleep medicine specialist may ask fundamentally similar, though more diagnostically inclined, questions, such as "What is the probability that daytime naps in a 75-year-old indicate SDB?" "Does excessive sleepiness during the day in

an older person portend dementia?" or "To what extent does daytime napping adversely affect sleep at night?" These are highly relevant questions that are made even more difficult to answer by cultural issues related to napping, the complexities in relying on self-reports to derive estimates of the physiologic tendency of sleep during the daytime hours, and the fact that, overarching all other issues, sleeping during the daytime hours in old age is most assuredly a multidetermined phenomenon.

Elsewhere we have reviewed the complex matrix of results that suggest that napping is both a beneficial and potentially protective event in the life of an older person as well as an identifiable risk factor for numerous morbidities and even mortality.[1] A case-control PSG study[235] comparing sleepy and nonsleepy older adults and measuring a wide array of variables including comorbid medical disease, psychopathology, medications, alcohol, smoking, measurements of SDB and PLMS, and physical pain showed that male sex, poor sleep quality, sleep interruptions because of nocturnal pain or bathroom trips, and medications known to induce sleepiness differentiated cases and controls. Only severe SDB (>30 events per hour) predicted sleepiness, but PLMS did not.[235] In contrast, at least one major cohort study failed to find any association between SDB and multiple sleep latency test–confirmed sleepiness in adults older than 60 years.[224] Taken together, these findings suggest there are many factors that predict why an older person may be sleepy during the day.

Napping has also been associated with falls,[236] CSF amyloid,[161] incipient cognitive decline,[237] and depression (in women)[238] and with nocturia,[239] diabetes,[240] and lower quality of life[241] in both men and women. On the other hand, evidence continues to accrue that naps may be protective for cardiovascular events,[242] might improve daytime function,[243] do not adversely affect nocturnal sleep,[244] and might even be associated with longer sleep duration the previous night.[245] Other studies suggest that naps and hypersomnolence portend mortality[246] or ischemic heart disease[247] and that daytime fatigue or anergy predict diverse morbidities[248] or all-cause mortality.[249] Again, however, not all population-based studies concur, and some suggest absence of excess mortality risk associated with napping,[250] particularly in elderly persons.[242] A study of a British population showed that napping conferred all-cause mortality risk only in individuals younger than 65 years.[251] Several observational, cross-sectional studies of longevous populations from the Mediterranean[252] and China[253] (the latter including more than 2700 individuals older than 100 years) imply that napping may indeed have survivorship benefits, though longitudinal data from a subset of the Chinese cohort also implied mortality risk in men.[254] Finally, one study of older individuals aged 75 to 94 years reported that, if short nighttime sleep durations were taken into account, daytime naps were indeed protective for mortality, but in the presence of nocturnal sleep longer than 9 hours, naps were associated with increased mortality risk.[255] The latter study is consistent with suggestions that data on sleep durations be balanced with the related but distinct notion of "insufficient" sleep as an independent risk.[256] Clearly, the many reasons for daytime napping and sleepiness in older populations continue to be elusive and outcomes associated with the phenomenon are disparate (see Bliwise[1] for review). Additionally, the methodologic issues involved in defining napping (e.g., some studies specify durations whereas others do not) are substantial and undoubtedly affect the lack of comparability across studies.[257]

BASIC SCIENCE CONSIDERATIONS

The mechanistic basis for the age-dependent decline in sleep includes likely interactions between hypocretin and degradation of proteins associated with neurodegeneration, such as β-amyloid (Aβ42) and tau. Hypocretin neurons are lost with senescence,[258] their expression is reduced in older animals,[259] and hypocretin administration, particularly of hypocretin-1, shows diminished effects on wake promotion with aging.[260] Widespread age-dependent loss of this neuropeptide-activating system in lower animals and humans[261] invites comparison with studies suggesting positive associations between impaired cognition and daytime sleepiness noted previously. Nevertheless, a feed-forward interaction between increased hypocretin and β-amyloid in mice also has been implied.[159] In Alzheimer disease, higher CSF hypocretin-1 levels were related to both higher Aβ42 and tau in CSF,[262] though neuropathologic studies in such patients have suggested lower counts of hypocretin-1 immunoreactive neurons in the hypothalamus.[263] Associations between Aβ42 burden and poor sleep quality were noted earlier in this chapter using both neuroimaging[159] and CSF markers.[160] Higher tau density (defined postmortem by relative presence of neurofibrillary tangles) was associated with worse antemortem sleep recorded actigraphically, with some evidence of effect modification by genotype in a community population,[264] and other data have confirmed a relationship between disturbed sleep and elevated CSF tau, but not Aβ42.[265] Taken together, these data suggest some disagreement regarding the role of hypocretin in the sleep disturbance accompanying the neurodegenerative diseases of old age. Perhaps the most fundamental question raised by these studies is whether the associations between disrupted wake-sleep function and markers of Alzheimer disease pathology are mediated by hypocretin-1 expression or whether loss of sleep per se (regardless of how this occurs) plays the more crucial role. At least for β-amyloid, basic science studies generally favor the latter. For example, genetic manipulation of the hypocretin system in mice that did not express this peptide suggested that Aβ deposition results from sleep loss.[266] Curiously, those same animals were noted to sleep longer and have lower Aβ pathology than transfected controls.

The ultimate significance of alterations in sleep with advancing years remains enigmatic. If one views such changes in sleep merely as epiphenomenal to components of the aging process, they may be merely a consequence of more fundamental changes in the biology of the organism operating at the systemic, cellular, or molecular levels. On the other hand, might age-dependent alterations in sleep and rhythms themselves be potential influences on physiologic aging? If that is indeed the case, then manipulations or interventions that alter sleep might modify disease course, change fundamental processes of aging, or perhaps even contribute to the longevity of the organism. Research in this exciting area is only just beginning, but certain provocative clues are emerging, particularly as we learn more about sleep's functions.

A particularly intriguing area involves what is now acknowledged to be a fundamental biomarker of cellular aging, telomere shortening, and how that may relate to sleep.

Telomeres are noncoding, repetitive segments of DNA that function to seal and protect the ends of chromosomes during mitosis. With successive cell divisions, telomere length decreases; hence the marker has seen widespread use in studies of aging. Among middle-aged and older men and women, telomere shortening was associated with poorer quality sleep,[267] though data from the (female) Nurses Health Study showed associations in younger women (<50 years).[268] Another study in the Whitehall II cohort demonstrated an association only in older men.[269] Given that SDB may represent a good marker for physiologic age (see earlier), it is not surprising that an association between short telomere length and a history of SDB has also been reported,[270] a finding equally strong in both men and women. Inferences of causality in such descriptive human studies must always be made circumspectly; however, associations between disturbed sleep, short sleep, or SDB and inflammatory markers, such as interleukin-6, tumor necrosis factor-α, or C-reactive protein, in many of these[271] and similar elderly population studies involving either only men[272] or men and women combined[273] provide a plausible biologic substrate whereby sleep could affect cellular aging. Associations between telomere length, aging, and inflammation have been well established.[274]

Invertebrate models also have proved invaluable in understanding more about how sleep is related to the aging process. The relative strength of the sleep-wake cycle and the length of sleep bouts have been shown to break down with age in *Drosophila* species, and the extent of the disruption was magnified under higher temperatures (29°C) relative to more moderate (25°C) or cooler (18°C) temperatures,[62] an important observation because *Drosophila* are known to have a longer life span in cooler temperatures. Additionally, incorporation of paraquat, an herbicide known to induce oxidative stress, into the flies' food supply produced similar results in shortening life span. The possibility of "rescue" of functional senescence in older *Drosophila* has recently been demonstrated using social enrichment manipulations that improve sleep, which appear to operate through dopamine and alerting signaling pathways.[275] Caloric restriction is known to extend life span across many species, and there is now evidence that excessive caloric intake increases sleep fragmentation, at least in one mutant line lacking a functional dopamine transporter gene.[276] The sirtuins, which are a class of proteins involved in energy transfer and linked to such nutrient restriction, have been shown to be associated with extended life span not only in *Drosophila* but also in mammals.[277] In mice, a wide array of hypocretinergic, wake-promoting neurons throughout brainstem regions were shown to express the sirtuin-1 protein, but older animals incurred a deficit in its expression, which was manifested as lipocuscin aggregation throughout the cytoplasm in neurons of these areas.[278] These data are important because they link a protein known to be involved in the longevity-promoting functions of caloric restriction to a neuropeptide-regulating wakefulness.

Examination of sleep in *Drosophila* mutants with exceedingly short sleep durations and rapid physiologic aging (i.e., shortened life span) also suggested that sleep may indeed play a vital role in survival.[279] In the first of these, the *minisleep (MNS)* line derived from an exhaustive search of 9000 mutant lines, homozygous flies showed reductions in sleep durations of 37% of female flies and 32% of male flies relative to wild-type flies.[280] Genotyping suggested that the *MNS* line was characterized by a point mutation in the *Shaker* gene, thought to regulate potassium channel repolarization and broadly defined neuronal excitability. Perhaps most important from the standpoint of aging, survivorship to very old age in these flies (defined in this study as 56 days) was substantially lower than in flies with other *Shaker* locus mutations or in wild-type controls; in some cases the effects approached a fivefold reduction in life span.[280] A different fly line, called *sleepless (sss),* which overexpresses another *Shaker*-related protein involved in the downregulation of potassium influx, has been shown to be associated with even more dramatic reductions in sleep amount (85% for males, 80% for females).[281] In this mutant, reductions in survivorship were even more profound, with virtually none of the *sss* flies surviving beyond 50 days (median, about 30 days) relative to the median survival of control flies (about 70 days).[281] These data certainly imply that absence of sleep is associated with more rapid aging, though they do not suggest what function ascribed to sleep may be related to acceleration of such aging processes. By contrast, studies of sleep deprivation in mammals might afford a broader perspective on such issues.

Sleep deprivation studies in humans during the past 30 years have shown repeatedly that sleep loss interacts with aging in several key ways. Homeostatic pressure for sleep may be somewhat diminished in humans and in some rodent species, particularly when recovery sleep is characterized by changes in both sleep duration and delta activity pressure. In humans, the behavioral consequences of sleep loss, framed in terms of both greater daytime sleepiness and more impaired waking performances, appear diminished, rather than enhanced, with aging (see Scullin and Bliwise[133] for a review of this area). These facts imply, but cannot prove, that sleep might have less significance and, as a corollary, loss of sleep may be of less consequence—or at the very least, no more consequence—as the organism ages. The data presented throughout this chapter notwithstanding, such results might be interpreted hastily as suggesting *less* of a need to intervene in the sleep of older persons.

By contrast, important new molecular evidence suggests that at the subcellular level, sleep deprivation may be *more* detrimental for function in aging animals than in young animals. More specifically, the unfolded protein response within the endoplasmic reticulum occurring after sleep deprivation[282] may be modified substantially by aging. Protein aggregation is a well-acknowledged feature of many neurodegenerative conditions in late life and appears to occur as one of the earliest signs of impending neuronal death. The unfolded protein response, which consists of a host of molecular changes involving attenuation of translation of adverse proteins, degradation of misfolded proteins, and promotion of factors (chaperones) protective for normal function of the endoplasmic reticulum, shows synergistic age and sleep-deprivation effects. For example, expression of a major chaperone, BiP/GRP78, is known to be downregulated in both the brain and liver of aged animals, but it showed major upregulation following sleep deprivation in young, but not old, mice.[282,283] Perhaps even more relevant were changes in proapoptotic proteins (e.g., caspase-12). Aging was associated with greater expression of these markers of apoptosis, and sleep deprivation in the mouse activated this pathway as well. Strikingly, sleep deprivation in the older animal further accentuated such markers of preprogrammed cell death beyond those seen in

normal aging and beyond those in sleep deprivation,[283] and there is evidence of greater unfolded protein response to sleep loss in pancreatic beta cells of older mice relative to younger mice.[284] If these findings were in any way translatable to humans, they would suggest a *greater*, rather than *lesser*, necessity to attend to the many sleep problems in old age.

CLINICAL PEARLS

- In old age, in particular, the sleep medicine specialist should always remember that there are numerous overlapping and contributing reasons that the elderly patient has disrupted sleep at night or may be sleepy during the day.
- Napping should never be assumed to be innocuous, nor should excessive sleepiness during the day be attributed unequivocally to active or subclinical disease.
- SDB may be associated with adverse outcomes in elderly populations as well as middle-aged populations and might warrant treatment.
- Poor sleep may not only reduce the quality of life of the older person but also portend adverse health consequences.

SUMMARY

Defining normality in elderly populations remains a challenging task. However, an ever-increasing database informs the sleep medicine specialist about potential morbidities that may be associated with poor sleep and various sleep disorders in old age. Multiple factors contribute to poor sleep at night and excessive sleepiness during the day in the older adult. Although most studies have been observational and descriptive, the examination of sleep in lower animals may allow greater understanding of age-dependent changes in sleep as an indicator of biologic or physiologic age and shed new light on the importance of treating sleep problems in human aging.

Chapter 4

Daytime Sleepiness and Alertness

Timothy Roehrs; Mary A. Carskadon; William C. Dement; Thomas Roth

Chapter Highlights

- Sleepiness is a common problem in the general population that can be caused by reduced sleep time in otherwise healthy adults, by fragmented and disrupted sleep in primary sleep disorders, by sedating drugs, and by various neurologic and medical disorders.
- Sleepiness is a physiologic need state that is evident by rapid and unintended sleep onsets throughout the day, a relative irreversibility, and increased duration.
- Excessive and persistent sleepiness is life-threatening, but when its presence is recognized and its etiology identified, it can be successfully treated or at least minimized.

Sleepiness is a physiologic drive state basic to the survival of an organism. Although as yet no single or combination of biologic markers of sleepiness are known, its presence and intensity can be inferred by how readily sleep onset occurs, how easily sleep is disrupted, and how long sleep endures with an enforced bedtime and no sleep disorder or environmental interruption. Sleepiness is normally expressed in a 24-hour rhythm linked to the environmental light-dark cycle. Excessive daytime sleepiness (EDS) can be seen in otherwise healthy individuals who do not have an adequate opportunity or circumstances for sleep. Most important, EDS is a symptom associated with serious life-threatening medical conditions. Since the development of clinical sleep medicine, a growing scientific literature on the nature of sleepiness and its determinants in clinical populations, selected populations of healthy volunteers, and the general population has emerged.

This chapter reviews information regarding the prevalence of sleepiness in the population. The various methods used to measure sleepiness in the population and laboratory are described, and guidelines regarding clinical assessment of sleepiness are offered. The nature and neurobiologic substrates of sleepiness are discussed, and the known determinants of sleepiness are described. Finally, the clinical and public health significance of persistent complaints of sleepiness is discussed.

EPIDEMIOLOGY OF SLEEPINESS

Prevalence estimates of sleepiness in the population vary widely depending on the definition of sleepiness used and the type of population sampled. Surveys and questionnaires have queried the experience of a mood or feeling of a state of sleepiness, fatigue, or tiredness; about falling asleep unintentionally; or about struggling to stay awake and fighting sleep onset. Developments in the epidemiology of sleepiness have included using standardized sleepiness scales and physiologic assessments of sleepiness that measure the behavior of falling asleep, its estimated likely occurrence, or the speed of its actual occurrence.

In a study representative of the Finnish population, 11% of women and 7% of men reported daytime sleepiness almost every day.[1] In another survey, representative of a large geographic area in Sweden, 12% of respondents thought their sleep was insufficient.[2] In that survey, insufficient sleep, and not its consequent daytime sleepiness, was the focus of the questions. The U.S. Centers for Disease Control and Prevention analyzed results from the Behavioral Risk Factor Surveillance System in four states and found that 10.1% of U.S. adults reported receiving insufficient rest or sleep on all of the preceding 30 days.[3]

Two studies representative of the U.S. population assessed sleepiness with a physiologic measure, the Multiple Sleep Latency Test (MSLT). Given the necessary time commitment required of participants for MSLT studies, the representative integrity of study results is critically dependent on the recruitment response rate. From a large Southeastern Michigan random sample ($n = 1648$) representative of the U.S. population, a subsample ($n = 259$) with a 68% response rate was recruited to undergo a nocturnal polysomnogram and MSLT the following day. The prevalence of excessive sleepiness, defined as a MSLT average sleep latency of less than 6 minutes, was 13%.[4] In another probability sample of 6947 Wisconsin state employees, a subsample ($n = 632$), collected with a 52% response rate, slept at home and then completed an MSLT in the laboratory the next day. Twenty-five percent had an average sleep latency of less than 5 minutes.[5] These two studies also used the Epworth Sleepiness Scale (ESS), a validated self-report scale about the likelihood of falling asleep in various situations, to assess perceived sleepiness; in the Michigan study 20% had ESS scores higher than 10 and in the Wisconsin study 25% had scores higher than 11. The higher prevalence in the Wisconsin study, despite the more stringent definition of sleepiness (MSLT of 5 vs. 6 minutes and ESS of 11 vs. 10), could be attributed to an age difference

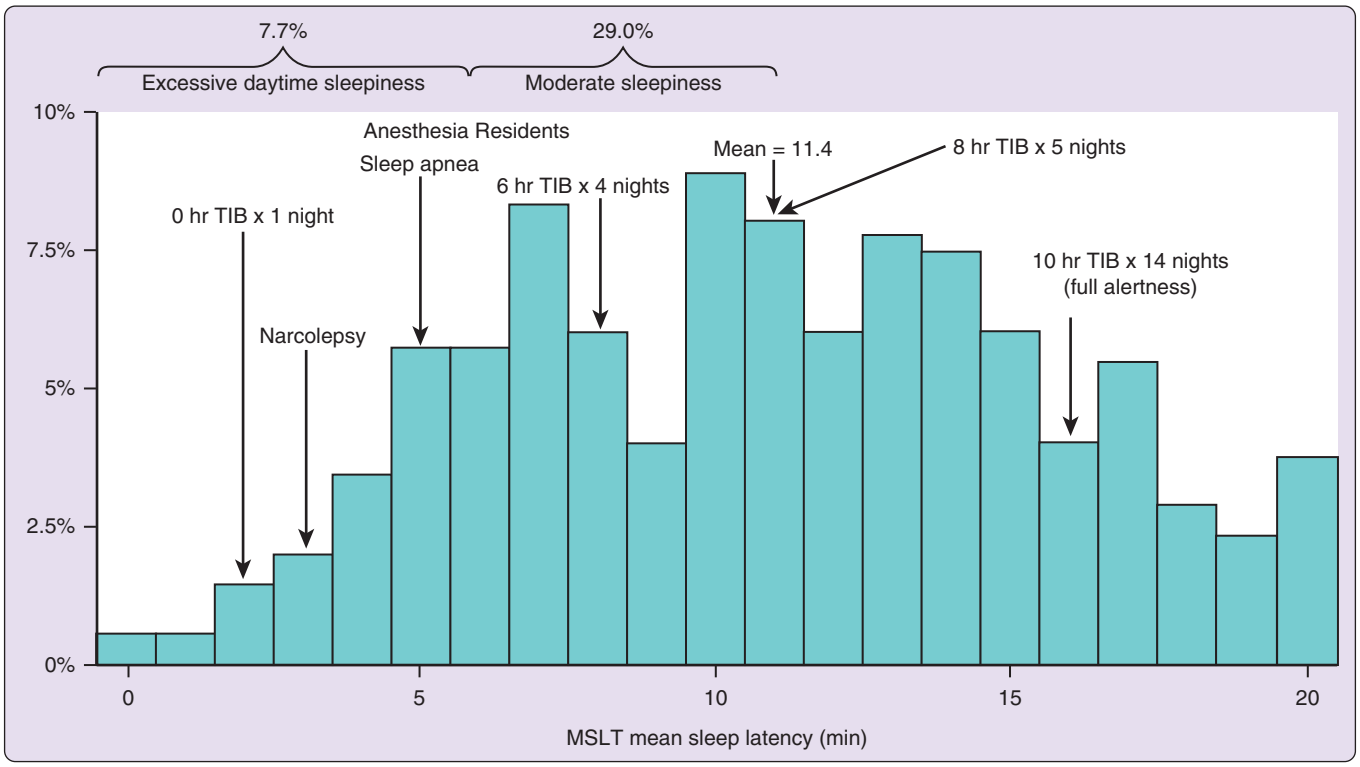

Figure 4-1 The distribution of mean daily sleep latency (minutes) on the Multiple Sleep Latency Test (MLST) in a subsample (n = 259) recruited (68% response rate) from a large southeastern Michigan random sample (n = 1648) representative of the U.S. population. The population mean is 11.4 minutes, and this is compared with means reported for various patient groups[59,69,70] and the means found in healthy normal individuals after various bedtime manipulations.[22,61] TIB, Time in bed.

in the samples (51 vs. 42 years on average) or the previous night's sleep time and circumstances (habitual at home, on average 7.1 hours vs. standard laboratory 8.5 hours). In Figure 4-1 the distribution of sleepiness, defined as average sleep latency on the MSLT, is illustrated for the Michigan population representative sample. The average sleep latencies (MSLT) of various clinical samples and experimental sleep time manipulations are provided for comparisons.

Risk Factors for Sleepiness

The risk factors for sleepiness identified in the various surveys include hours of daily sleep, employment status, marital status, snoring, and depression. Among 26- to 35-year-old members of a large health maintenance organization in Michigan, respondents reported 6.7 hours of sleep on weekdays and 7.4 hours on weekend days, on average.[6] The hours of sleep were inversely related to daytime sleepiness scores on the Sleep-Wake Activity Inventory. Both these variables were related to employment and marital status, with full employment and being single predicting less sleep time and greater sleepiness. Self-reported snoring and depression, as measured by a structured diagnostic interview, were also associated with increased sleepiness. In the Finnish study cited earlier, sleepiness was associated with moderate to severe depression and with snoring more than three times per week.[1]

Prevalence rates for sleepiness of 15% and greater also have been found for specific age groups, which are consistent with smaller laboratory studies using the physiologic measure of sleepiness, the MSLT, which is described later. Young adults were sleepier, on average, than a comparison group of middle-aged adults, and about 20% of the young adults had mean daily sleep latencies of less than 5 minutes, a level of sleepiness considered pathologic.[7] Healthy elderly persons also were found to be physiologically sleepier than middle-aged adults.[8] In surveys of the workforce engaged in shift or night work, complaints of excessive sleepiness during waking hours are more frequent than among day workers, and continuous ambulatory electroencephalographic (EEG) field monitoring has confirmed the sleepiness.[9]

NATURE OF SLEEPINESS

Physiologic Need State

Sleepiness, according to a consensus among sleep researchers and clinicians, is a basic physiologic need state.[10] Sleepiness has been likened to hunger or thirst, which are physiologic need states basic to the survival of the individual organism. The presence and intensity of this state can be inferred by how readily sleep onset occurs, how easily sleep is disrupted, and how long uninterrupted sleep endures. Deprivation or restriction of sleep increases sleepiness, and as hunger or thirst is reversible by eating or drinking, sleep reverses sleepiness in healthy individuals. In the organism's daily homeostatic economy, severe deprivation states do not normally occur and hence are not routinely responsible for regulating eating or drinking; other factors (i.e., taste, smell, time-of-day, social factors, biologic variables) modulate these behaviors before

severe deprivation states develop. Similarly, routine consumption of sleep is not purely homeostatic but is greatly influenced by the circadian light-dark cycle and by social (i.e., job, family, and friends) and environmental (i.e., noise, light, and bed) factors.

The subjective experience of sleepiness and its behavioral indicators (yawning, eye rubbing, nodding) can be reduced under conditions of high motivation, excitement, exercise, and competing needs (e.g., hunger, thirst); that is, physiologic sleepiness may not necessarily be manifest. The expression of mild to moderate sleepiness can be masked by any number of factors that are alerting, including motivation, environment, posture, activity, light, or food intake. Studies have shown that average sleep latency on the MSLT is increased by 6 minutes when sitting compared with lying in bed and also by 6 minutes when immediately preceded by a 5-minute walk.[11] When physiologic sleepiness is most severe and persistent, the ability to reduce its impact on overt behavior wanes. The likelihood of sleep onset increases, and the intrusion of microsleeps into ongoing behavior occurs. On the other hand, a physiologically alert (*sleepiness* and *alertness* are used here as antonyms) person does not experience sleepiness or appear sleepy even in the most soporific situations. Heavy meals, warm rooms, boring lectures, and the monotony of long-distance automobile driving unmask physiologic sleepiness when it is present, but they *do not* cause it.

Within a conventional 24-hour sleep and wake schedule, maximum sleepiness ordinarily occurs in the middle of the night when the individual is sleeping, and consequently this sleepiness typically is not experienced or remembered. When forced to be awake in the middle of the night, one experiences loss of energy, fatigue, weariness, difficulty concentrating, and memory lapses. When significant physiologic sleepiness (as a result of reduced sleep quantity or quality) intrudes on one's usual waking activities during the day, similar symptoms are experienced.

Adaptation to the *experience* of chronic sleepiness most probably occurs. Clinicians have reported anecdotally that successfully treated patients will frequently comment that they had forgotten the experience of complete alertness. Reduced sensitivity to chronic sleepiness is a likely explanation for the disparities between subjective assessments, even when done with validated scales, and the MSLT[8,11] Typically, it is the most sleepy individuals that show the greatest disparity in subjective versus objective assessments.[8,11] Such individuals deny sleepiness despite significant objective indicators of sleepiness. On the other hand, basally alert individuals (ESS mean = 5.6, standard error of the mean = 0.3) after a one-night acute sleep restriction were quite accurate in estimating their sleepiness as gauged by increases in EEG theta activity shown during a simulated driving task.[12] Studies have also shown that compensation occurs to the cognitive and behavioral effects of experimental sleep restriction and increased sleepiness, particularly when the sleep loss is mild and accumulates at a slow rate.[13] The absence of a readily apparent behavioral deficiency to the sleepy individual probably also contributes to the subjective-objective disparity seen in chronically sleepy individuals. Finally, findings from a general population study indicate that subjective sleepiness has multiple dimensions, beyond an increased tendency to fall asleep.[14] Consequently, patients often mistake chronic debilitating fatigue for sleepiness.[15]

The specific nature of this physiologic need state is unclear. Whether sleepiness is unidimensional, varying only in severity, or multidimensional, varying as to etiology or chronicity, has been discussed.[16] If it is unidimensional, whether or not sleepiness and alertness are at opposite poles of the dimension is also an issue. Earlier, it was noted that sleepiness and alertness are being used as antonyms, which suggests a unipolar state. However, it is possible that sleepiness varies from presence to absence and is distinct from alertness. It was noted that sleepiness may be multidimensional, and among the different types of sleepiness cited are rapid eye movement (REM) versus non–rapid eye movement (NREM) and core versus optional sleepiness.[16] A complete discussion of the heuristic value and evidence to support these distinctions is beyond the scope of this chapter. Nonetheless, the point must be made that these theoretical perspectives may be colored by different measures, experimental demands, populations studied, and subject or patient motivations (i.e., sensitivity to and capacity to counteract sleepiness).

Neural Substrates of Sleepiness

The substrates of sleepiness have yet to be determined. It is assumed that sleepiness is a central nervous system (CNS) phenomenon with identifiable neural mechanisms and neurochemical correlates. Various electrophysiologic events suggestive of incipient sleep processes appear in behaviorally awake organisms undergoing sleep deprivation. In sleep-deprived animals, ventral hippocampal spike activity, which normally is a characteristic of NREM sleep, increases during behavioral wakefulness and in the absence of the usual changes in cortical EEG indicative of sleep.[17] Humans deprived, or restricted, of sleep show identifiable microsleep episodes (brief intrusions of EEG indications of sleep) and increased amounts of alpha and theta activity while behaviorally awake.[18] The evidence suggests that these electrophysiologic events are indicants of sleepiness.

An emerging literature of neuroimaging studies, both structural and functional, has suggested specific brain systems that may be involved in sleepiness. Sleep deprivation in young healthy volunteers reduced regional cerebral glucose metabolism, as assessed by positron emission tomography, in thalamic, basal ganglia, and limbic regions of the brain.[19] Functional magnetic resonance imaging (fMRI) after chlorpheniramine (a sedating antihistamine) compared with placebo showed increased frontal and temporal activation.[20] Because fMRI was conducted while the subject was performing cognitive tasks, the authors interpreted the observed brain activation to have resulted from the increased mental effort necessary to counteract sleepiness required to perform the task. Two groups of patients with severe or slight hypersomnia associated with paramedian thalamic stroke on an MRI showed lesions involving dorso- and centromedial thalamic nuclei, bilateral lesions in the severe group and unilateral in the slight group.[21] As yet, these imaging data are not conclusive. They do suggest it may be possible to identify brain regions and functions that vary with sleepiness. But the nature of the alteration may depend on the behavioral load imposed on the sleepy subject as well as the cause of the sleepiness.

The neurochemistry of sleepiness-alertness involves critical and complex issues that have not yet been fully untangled (see Chapters 7, 8, and 9 for a complete discussion).

First, a basic issue concerns whether sleepiness-alertness has a neurochemistry specific and unique from that associated with the sleep process. Second, it is not clear whether sleepiness and alertness are controlled by separate neurochemicals or by a single substance or system. Third, the relation of the neurochemistry of sleepiness-alertness to circadian mechanisms has not yet been determined. Given the number of questions, it should be of no surprise that these are areas of active research.

Neurophysiologic studies of sleep and wake mechanisms have implicated adenosine, gamma-aminobutyric acid (GABA), histamine, serotonin, the catecholamines, and acetylcholine in control of wake and sleep.[22] Evidence from animal studies suggests extracellular adenosine is the homeostatic sleep factor reflecting sleep drive, with brain levels accumulating during prolonged wakefulness and declining during sleep.[23] Adenosine may be a biomarker of sleepiness.[23] It stimulates both $A_1$and A_2 receptors, and a positron emission tomography study in humans has shown upregulation of A_1 receptors in cortical and subcortical regions of the brain during 24 hours of sleep deprivation.[24] On the other hand, a microdialysis study in patients undergoing depth electrode implantation for control of epileptic seizures failed to find an accumulation of adenosine in the hippocampus, amygdala, and cortex during sleep deprivation.[25] These data raise fundamental questions: Does adenosine act globally or locally? Does it accumulate or are receptors sensitized? The basal forebrain, the ventral lateral preoptic area, and the lateral hypothalamus are all potential sites, owing to their known involvement in the control of sleep and wake, at which to assess levels and receptor upregulation.

The peptide hypocretin, also called orexin, has received much attention for its role in the pathophysiology of narcolepsy.[26] It is considered to be a major wake-promoting hypothalamic neuropeptide, and a hypocretin/orexin deficiency has been found in human narcolepsy; however, its interactive role in the homeostatic control of sleep and sleepiness has yet to be determined. Hypocretin/orexin is discussed in greater detail in Chapters 8 and 89.

Pharmacologic studies provide other interesting hypotheses regarding the neurochemistry of sleepiness-alertness. For example, the benzodiazepines induce sleepiness and facilitate GABA function at the $GABA_A$ receptor complex, thus implicating this important and diffuse inhibitory neurotransmitter.[24] Another example involves histamine, which is now considered a CNS neurotransmitter and is thought to have CNS-arousing activity.[24] Antihistamines that penetrate the CNS produce sleepiness.[27] A recent functional neuroimaging study of histamine H_1 receptors in human brain found that the degree of sleepiness associated with cetirizine (20 mg) was correlated to the degree of H_1 receptor occupancy.[28]

Stimulant drugs indicate the involvement of several other transmitters and neuromodulators. The mechanism of action of one class of drugs producing psychomotor stimulation and arousal, the amphetamines, is blockade of catecholamine uptake.[29] Another class of stimulants, the methylxanthines, which include caffeine and theophylline, are adenosine receptor antagonists. Adenosine has inhibitory activity on the two major excitatory neurotransmitters acetylcholine and glutamate. In conclusion, although it is widely held that sleepiness is a physiologic state, its physiologic substrates are as yet not fully defined.

ASSESSMENT OF SLEEPINESS

Quantifying Sleepiness

The behavioral signs of sleepiness include yawning, ptosis, reduced behavioral activity, lapses in attention, and head nodding. An individual's subjective report of his or her level of sleepiness also can be elicited. As noted earlier, a number of factors such as motivation, stimulation, and competing needs can reduce the behavioral manifestation of sleepiness. Thus behavioral and subjective indicators often underestimate physiologic sleepiness.

Assessment problems were evident early in research on the daytime consequences of sleep loss. Sleep loss compromises daytime functions; virtually everyone experiences dysphoria and reduced performance efficiency when not sleeping adequately. Nevertheless, many of the tasks used to assess the effects of sleep loss are insensitive.[30] In general, only long and monotonous tasks are reliably sensitive to changes in the quantity and quality of nocturnal sleep. An exception is a 10-minute visual vigilance task, completed repeatedly across the day, during which lapses (response times ≥500 msec) and declines in the best response times are increasingly observed as sleep is lost, either during total deprivation or cumulatively over nights of restricted bedtimes.[31]

In various measures of mood, including factor analytic scales, visual analogue scales, and scales for specific aspects of mood, subjects have shown increased fatigue or sleepiness with sleep loss. Among the various subjective measures of sleepiness, the Stanford Sleepiness Scale is the best validated.[32] Yet clinicians have found that chronically sleepy patients may rate themselves alert on the Stanford Sleepiness Scale even while they are falling asleep behaviorally.[33] Such scales are state measures that query individuals about how they feel at the present moment. Another perspective is to view sleepiness behaviorally, as in the likelihood of falling asleep, and thus ask individuals to rate that likelihood in different social circumstances and over longer periods. The ESS has been validated in clinical populations, showing a 74% sensitivity and 50% specificity relative to the MSLT in a study of sleep disorders patients.[34] It asks about falling asleep in settings in which affected patients typically report falling asleep (e.g., while driving, at church, in social conversation). The time frame over which ratings are made is typically 2 to 4 weeks.

The standard physiologic measure of sleepiness is the MSLT, which has been studied extensively, with more than 7500 citations to "MSLT and sleep" in a Google Scholar August 2014 search. The MSLT similarly conceptualizes sleepiness as the tendency to fall asleep by measuring the speed of falling asleep. The MSLT has gained wide acceptance within the field of sleep and sleep disorders as the standard method of quantifying sleepiness.[35] Using standard polysomnographic techniques, this test measures, on repeated opportunities at 2-hour intervals throughout the day, the latency to fall asleep while lying in a quiet, dark bedroom. The MSLT is based on the assumption, as outlined earlier, that sleepiness is a physiologic need state that leads to an increased tendency to fall asleep. The metric typically used to express sleepiness has been average daily sleep latency (i.e., mean of the four or five tests conducted), but survival analyses have also been successfully used.[36] The reliability and validity of this measure have been documented in a variety of experimental and clinical situations.[37] In contrast to tests of performance, motivation

does not seem to reduce the effect of sleep loss as measured by the MSLT. After total sleep deprivation, subjects can compensate for impaired performance, but they cannot stay awake long while in bed in a darkened room, even if they are instructed to do so.[38]

An alternative to the MSLT, suggested by some clinical investigators, is the Maintenance of Wakefulness Test (MWT). This test requires that subjects lie in bed or sit in a chair in a darkened room and try to remain awake.[39] Like the MSLT, the measure of ability to remain awake is the latency to sleep onset. The test has not been standardized: there are 20-minute and 40-minute versions, and the subject is variously sitting upright in a chair, lying in bed, or semirecumbent in bed. The reliability of the MWT has not been established either. One study reported sensitivity to the therapeutic effects of continuous positive airway pressure (CPAP) in patients with sleep apnea,[40] and several studies reported sensitivity to the therapeutic effects of stimulants in narcolepsy.[41] A study attempted to tease apart the critical factors being measured by the MWT and concluded that, unlike the MSLT, which measures level of sleepiness, the MWT measures the combined effects of level of sleepiness and the degree of arousal as defined by heart rate.[42]

The rationale for the MWT is that clinically the critical issue for patients is how long wakefulness can be maintained. A basic assumption underlying this rationale, however, may not be valid: it assumes that a set of circumstances can be evaluated in the laboratory that will reflect an individual's probability of staying awake during daily activities. Such a circumstance is not likely because environment, motivation, circadian phase, and any competing drive states all affect an individual's tendency to remain awake. Stated simply, an individual crossing a congested intersection at midday is more likely to stay awake than an individual driving on an isolated highway in the middle of the night. The MSLT, on the other hand, addresses the question of the individual's risk for falling asleep by establishing a setting to maximize the likelihood of sleep onset: all factors competing with falling asleep are removed from the test situation. Thus the MSLT identifies sleep tendency or clinically identifies maximum risk for the patient. Obviously, the actual risk will vary from individual to individual, from hour to hour, and from environment to environment.

Relation of Sleepiness to Behavioral Functioning

Given that the MSLT is a valid and reliable measure of sleepiness, the question arises as to how this measure relates to an individual's capacity to function. Direct correlations of the MSLT with other measures of performance under normal conditions have not been very robust. Several studies have found, however, that when sleepiness is at maximal levels, correlations with performance are high. For example, MSLT scores after sleep deprivation,[43] after administration of sedating antihistamines,[44] and after benzodiazepine administration[45] correlate with measures of performance and even prove to be the most sensitive measure. Studies also have compared levels of sleepiness to the known performance-impairing effects of alcohol.[46] A study relating performance lapses on a vigilance task to the cumulative effects of sleep restriction found a function comparable to that of the MSLT under a similar cumulative sleep restriction[47] (Figure 4-2). The reason many studies have found weak correlations between performance and MSLT at normal or moderate levels of sleepiness is that laboratory performance and MSLT are differentially affected by variables such as age, education, and motivation.

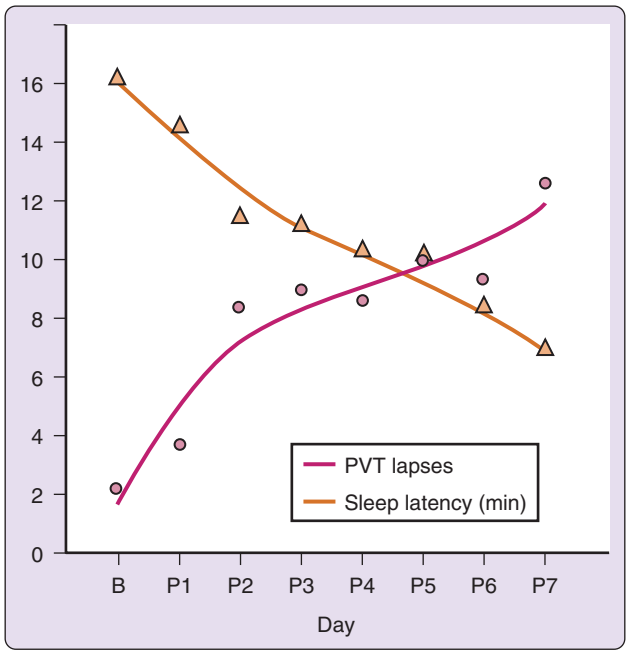

Figure 4-2 Similar functions relating mean daily sleep latency on the Multiple Sleep Latency Test (MSLT) and mean daily lapses on the visual psychomotor vigilance test (PVT) to the cumulative effects of sleep restriction (about 5 hours of bedtime nightly) across 7 consecutive nights (P1 to P7). (Modified from Dinges DF, Pack F, Williams K, et al. Cumulative sleepiness, mood disturbance, and psychomotor vigilance performance decrements during a week of sleep restricted to 4–5 hours per night. *Sleep* 1997;20:275.)

For the most part, the literature relating sleepiness and behavioral functioning has focused on psychomotor and attention behaviors, with the major outcomes being response slowing and attentional lapses. These impairments can be attributed to slowed processing of information and microsleeps, that is, intrusion of sleep-preparatory and sleep-onset behaviors. Research has focused on other behavioral domains not as clearly associated with sleep-mediated behaviors, including decision making and pain sensation. Several studies have shown that increased sleepiness is associated with poor risk-taking decisions.[48] Sleep loss and its associated sleepiness have also been shown to increase pain sensitivity.[49]

Clinical Assessment of Sleepiness

Assessing the clinical significance of a patient's complaint of excessive sleepiness can be complex for an inexperienced clinician. The assessment depends on two important factors: chronicity and reversibility. Chronicity can be explained simply. Although a healthy normal individual may be acutely sleepy, the patient's sleepiness is persistent and unremitting. As to reversibility, unlike the healthy normal person, increased sleep time may not completely or consistently ameliorate a patient's sleepiness. Patients with excessive sleepiness may not complain of sleepiness per se but rather its consequences: loss of energy, fatigue, lethargy, weariness, lack of initiative, memory lapses, or difficulty concentrating.

To clarify the patient complaint, it is important to focus on soporific situations in which physiologic sleepiness is more likely to be manifest, as was discussed earlier. Such situations might include watching TV, reading, riding in a car, listening to a lecture, or sitting in a warm room. Table 4-1 presents the commonly reported "sleep-inducing" situations for a large sample of patients with sleep apnea syndrome. After clarifying the complaint, one should ask the patient about the entire day: morning, midday, and evening. In the next section, it will become clear that most adults experience sleepiness over the midday. However, patients experience sleepiness at other times of the day as well, and often throughout the day. When necessary (i.e., patients nonresponsive to treatment or in jobs carrying personal or public risk) objective documentation of sleepiness and its severity should be sought. As indicated earlier the standard and accepted method to document sleepiness objectively is the MSLT.

Guidelines for interpreting the results of the MSLT are available[35] (see Figure 4-1). A number of case series of patients with disorders of excessive sleepiness have been published, with accompanying MSLT data for each diagnostic classification.[50] These data provide the clinician with guidelines for evaluating the clinical significance of a given patient's MSLT results. Although these data cannot be considered norms, a scheme for ranking MSLT scores to indicate degree of pathology has been suggested.[51] An average daily MSLT score of 5 minutes or less suggests pathologic sleepiness, a score of more than 5 minute but less than 10 minutes is considered a diagnostic gray area, and a score of more than 10 minutes is considered to be in the normal range (see Figure 4-1 for MSLT results in the general population). The MSLT is also useful in identifying sleep-onset REM periods (SOREMPs), which are common in patients with narcolepsy.[51] The American Academy of Sleep Medicine Standards of Practice Committee has concluded that the MSLT is indicated in the evaluation of patients with suspected narcolepsy.[51] However, the prevalence of multiple SOREMPs in the general population is 4% to 9%, and excessive sleepiness as found in shift workers, young adults, and patients with apnea is predictive of multiple SOREMPs.[52,53] MSLT results also must be evaluated with respect to the conditions under which the testing was conducted. Standards have been published for administering the MSLT, which must be followed to obtain a valid, interpretable result.[35]

It should be emphasized that neither the MSLT nor the MWT is diagnostic of a sleep disorder. These tests merely confirm the presence and intensity of sleepiness. In fact, studies have failed to find differences between samples of patients with sleep disorders and age-matched controls.[54] As illustrated in Figure 4-1 the distribution of MSLT latencies in the general population includes individuals who would be considered excessively sleepy. As noted previously they differ from patients in that increased nightly bedtime and a consequent increase in sleep time reverses the sleepiness, which does not occur in patients until treated.

DETERMINANTS OF SLEEPINESS

Quantity of Sleep

The degree of daytime sleepiness is directly related to the amount of nocturnal sleep. The performance effects of acute and chronic sleep deprivation are discussed in Chapters 5. As to sleepiness, partial or total sleep deprivation in healthy normal subjects is followed by increased daytime sleepiness the following day.[37] Therefore modest nightly sleep restriction accumulates over nights to progressively increase daytime sleepiness and performance lapses (see Figure 4-1).[55] However, the speed at which sleep loss is accumulated is critical, and studies have shown adaptation to a slow accumulation of 1 to 2 hours nightly sleep loss occurs, which then increases the duration of the subsequent recovery process.[13] Increased sleep time in healthy, but sleepy, young adults by extending bedtime beyond the usual 7 to 8 hours per night produces an increase in alertness (i.e., reduction in sleepiness).[56] Further, the pharmacologic extension of sleep time by an average of 1 hour in elderly persons produces an increase in mean sleep latency on the MSLT (i.e., increased alertness).[57]

Reduced sleep time explains the excessive sleepiness of several patient and nonpatient groups. For example, a subgroup of sleep clinic patients has been identified whose excessive daytime sleepiness can be attributed to chronic insufficient sleep.[58] These patients show objectively documented excessive sleepiness and "normal" nocturnal sleep with unusually high sleep efficiency (time asleep/time in bed), and they report about 2 hours more sleep on each weekend night than each weekday night. Regularizing bedtime and increasing time in bed produces a resolution of their symptoms and normalized MSLT results.[59] The increased sleepiness of healthy young adults also can be attributed to insufficient nocturnal sleep. When the sleepiest 25% of a sample of young adults is given extended time in bed (10 hours) for as long as 5 to 14 consecutive nights, their sleepiness is reduced to a level resembling the general population.[56]

Individual differences in tolerability to sleep loss have been reported.[60] These differences can be attributed to a number of possible factors. A difference in the basal level of sleepiness at the start of a sleep time manipulation is quite possible given the range of sleepiness in the general population (see Figure 4-1). The basal differences may reflect insufficient nightly sleep relative to a person's sleep need.[56] Also there may be differences in the sensitivity and responsivity of the sleep homeostat to sleep loss (i.e., how large a sleep deficit the system can tolerate and how robustly the sleep homeostat produces sleep when detecting deficiency). Finally, genetic differences in sleep need, the set point around which the sleep homeostat regulates daily sleep time, have long been

hypothesized, and one study has suggested that a gene polymorphism may mediate vulnerability to sleep loss.[61] These all are fertile areas for research.

Quality of Sleep

Daytime sleepiness also relates to the quality and the continuity of a previous night's sleep. Sleep in patients with a number of sleep disorders is punctuated by frequent, brief arousals of 3 to 15 seconds' duration. These arousals are characterized by bursts of EEG speeding or alpha activity and, occasionally, transient increases in skeletal muscle tone. Standard scoring rules for transient EEG arousals have been developed.[62] A transient arousal is illustrated in Figure 4-3. These arousals typically do not result in awakening by either Rechtschaffen and Kales sleep staging criteria or behavioral indicators, and the arousals recur in some conditions as often as 1 to 3 times per minute. The arousing stimulus differs in the various disorders and can be identified in some cases (apneas, leg movements, pain) but not in others. Regardless of etiology, the arousals generally do not result in shortened sleep but rather in fragmented or discontinuous sleep, and this fragmentation produces daytime sleepiness.[63]

Correlation evidence suggests a relation between sleep fragmentation and daytime sleepiness. Fragmentation, as indexed by number of brief EEG arousals, number of shifts from other sleep stages to stage 1 sleep or wake, and the percentage of stage 1 sleep, correlates with EDS in various patient groups.[63] Treatment studies also link sleep fragmentation and excessive sleepiness. Patients with sleep apnea syndrome who are successfully treated by surgery (i.e., number of apneas are reduced) show a reduced frequency of arousals from sleep as well as a reduced level of sleepiness, whereas those who do not benefit from the surgery (i.e., apneas remain) show no decrease in arousals or sleepiness, despite improved sleeping oxygenation.[64] Similarly, CPAP, by providing a pneumatic airway splint, reduces breathing disturbances and consequent arousals from sleep and reverses EDS.[65] The reversal of daytime sleepiness following CPAP treatment of sleep apnea syndrome is presented in Figure 4-4. The hours of nightly CPAP use predicts both subjective and objective measures of sleepiness.[66]

Experimental fragmentation of the sleep of healthy normal subjects has been produced by inducing arousals with an auditory stimulus. Several studies have shown that subjects awakened at various intervals during the night demonstrate performance decrements and increased sleepiness on the following day.[67] Studies have also fragmented sleep without awakening subjects by terminating the stimulus on EEG signs of arousal rather than on behavioral response. Increased daytime sleepiness (shortened latencies on the MSLT) resulted from nocturnal sleep fragmentation in one study,[68] and in a second study, the recuperative effects (measured as increased latencies on the MSLT) of a nap following sleep deprivation were compromised by fragmenting the sleep on the nap.[69]

One nonclinical population in which sleep fragmentation is an important determinant of excessive sleepiness is the elderly population. Many studies have shown that even elderly individuals without sleep complaints show an increased number of apneas and periodic leg movements during sleep.[70] As noted earlier, elderly people as a group are sleepier than other groups.[8] Furthermore, it has been demonstrated that elderly people with the highest frequency of arousal during sleep have the greatest daytime sleepiness.[71]

Circadian Rhythms

A biphasic pattern of objective sleep tendency was observed when healthy normal young adult and elderly subjects were tested every 2 hours over a complete 24-hour day.[72] During the sleep period (11:30 PM to 8 AM) the latency testing was accomplished by awakening subjects for 15 minutes and then allowing them to return to sleep. Two troughs of alertness—one during the nocturnal hours (about 2 to 6 AM) and another during the daytime hours (about 2 to 6 PM)—were observed.

Other research protocols have yielded similar results. In constant routine studies, in which external environmental stimulation is minimized and subjects remain awake,

superimposed on the expected increase in self-rated fatigue resulting from the deprivation of sleep is a biphasic circadian rhythmicity of self-rated fatigue similar to that seen for sleep latency.[73] In another constant routine study in which EEG was continuously monitored, a biphasic pattern of "unintentional sleep" was observed.[74] In studies with sleep scheduled at unusual times, the duration of sleep periods has been used as an index of the level of sleepiness. A pronounced circadian variation in sleep duration is found, with the termination of sleep periods closely related to the biphasic sleep latency function in the studies cited earlier.[75] If individuals are permitted to nap when they are placed in time-free environments, this biphasic pattern becomes quite apparent in the form of a midcycle nap.[76]

This circadian rhythm in sleepiness is part of a circadian system in which many biologic processes vary rhythmically over 24 hours. The sleepiness rhythm parallels the circadian variation in body temperature, with shortened latencies occurring in conjunction with temperature troughs.[72] Nevertheless, these two functions, sleep latency and body temperature, are not mirror images of each other; the midday body temperature decline is relatively small compared with that of sleep latency. Further, under free-running conditions, the two functions become dissociated.[77] However, no other biologic rhythm is as closely associated with the circadian rhythm of sleepiness as is body temperature.

Earlier, it was noted that shift workers are unusually sleepy, and jet travelers experience sleepiness acutely in a new time zone. The sleepiness in these two conditions results from the placement of sleep and wakefulness at times that are out of phase with the existing circadian rhythms. Thus not only is daytime sleep shortened and fragmented but also wakefulness is required at the peak of sleepiness or trough of alertness. Several studies have shown that pharmacologic extension and consolidation of out-of-phase sleep can improve daytime sleepiness[78] (see Chapter 40 for more detail). Yet the basal circadian rhythm of sleepiness remains, although the overall level of sleepiness has been reduced. In other words, the synchronization of circadian rhythms to the new sleep-wake schedule is not hastened.

Central Nervous System Drugs

Sedating Drug Effects

CNS depressant drugs, as expected, increase sleepiness. Many of these drugs act as agonists at the $GABA_A$ receptor complex. The benzodiazepine hypnotics hasten sleep onset at bedtime and shorten the latency to return to sleep after an awakening during the night (which is their therapeutic purpose), as demonstrated by a number of objective studies.[79] Long-acting benzodiazepines continue to shorten sleep latency on the MSLT the day following bedtime administration.[79] Finally, ethanol administered during the daytime (9 AM) reduces sleep latency in a dose-related manner as measured by the MSLT.[80]

Second-generation antiepileptic drugs, including gabapentin, gabatrol, vigabatrin, pregabalin, and others, enhance GABA activity through various mechanisms that directly or indirectly involve the $GABA_A$ receptor.[81] The sedating effects of these various drugs have not been thoroughly documented, but some evidence indicates they do have sedative activity. $GABA_B$ receptor agonists are being investigated as treatments for drug addictions, and the preclinical animal research suggests these drugs may have sedative activity as well.[82]

Antagonists acting at the histamine-1 (H_1) receptor also have sedating effects. One of the most commonly reported side effects associated with the use of H_1 antihistamines is daytime sleepiness. Several double-blind, placebo-controlled studies have shown that certain H_1 antihistamines, such as diphenhydramine, increase sleepiness using sleep latency as the objective measure of sleepiness, whereas others, such as terfenadine or loratadine, do not.[83] The difference among these compounds relates to their differential CNS penetration and binding. Others of the H_1 antihistamines (e.g., tazifylline) are thought to have a greater peripheral compared with central H_1 affinity, and, consequently, effects on daytime sleep latency are found only at relatively high doses.[83]

Antihypertensives, particularly β-adrenergic receptor blockers, are also reported to produce sedation during the daytime.[84] These CNS effects are thought to be related to the differential liposolubility of the various compounds. However, we are unaware of any studies that directly measure the daytime sleepiness produced by beta blockers; the information is derived from reports of side effects. As noted earlier, it is important to differentiate sleepiness from tiredness or fatigue. Patients may be describing tiredness or fatigue resulting from the drugs' peripheral effects (i.e., lowered cardiac output and blood pressure), not sleepiness, a presumed central effect.

Sedative effects of dopaminergic agonists used in treating Parkinson disease have been reported as adverse events in clinical trials and in case reports as "sleep attacks" while driving.[85] It is now clear these "sleep attacks" are not attacks per se but are the expression of excessive sleepiness. Although the dose-related sedative effect of these drugs has been established, the mechanism by which the sedative effects occur is unknown. The dopaminergic agonists are also known to disrupt and fragment sleep.[86] Thus the excessive sleepiness may be secondary to disturbed sleep or to a combination of disturbed sleep and direct sedative effects.

Alerting Drug Effects

Stimulant drugs reduce sleepiness and increase alertness. The drugs in this group differ in their mechanisms of action. Amphetamine, methylphenidate, and pemoline block dopamine reuptake and to a lessor extent enhance the release of norepinephrine, dopamine, and serotonin. The mechanism of modafinil is not established; some evidence suggests that modafinil has a mechanism distinct from the classic stimulants. Amphetamine, methylphenidate, pemoline, and modafinil are used to treat the EDS associated with narcolepsy, and some have been studied as medications to maintain alertness and vigilance in normal subjects under conditions of sustained sleep loss (e.g., military operations). Studies in patients with narcolepsy using MSLT or MWT have shown improved alertness with amphetamine, methylphenidate, modafinil, and pemoline.[87] There is dispute as to the extent to which the excessive sleepiness of narcoleptics is reversed and the comparative efficacy of the various drugs. In healthy normal persons restricted or deprived of sleep, both amphetamine and methylphenidate increase alertness on the MSLT and improve psychomotor performance.[88,89] Caffeine is an adenosine receptor antagonist. In doses equivalent to 1 to 3 cups of coffee, caffeine reduced daytime sleepiness on the MSLT in normal subjects after 5 hours of sleep the previous night.[90]

Influence of Basal Sleepiness

The preexisting level of sleepiness-alertness interacts with a drug to influence the drug's behavioral effect. In other words, a drug's effect differs when sleepiness is at its maximum compared with its minimum. As noted previously, the basal level of daytime sleepiness can be altered by restricting or extending time in bed[60]; this in turn alters the usual effects of a stimulating versus a sedating drug. A study showed comparable levels of sleepiness-alertness during the day following 5 hours in bed and morning (9 AM) caffeine consumption compared with 11 hours in bed and morning (9 AM) ethanol ingestion.[91] Follow-up studies explored the dose relations of ethanol's interaction with basal sleepiness.[92] Dose-related differences in daytime sleepiness following ethanol and 8 hours of sleep were diminished after even 1 night of 5-hour sleep, although the measured levels of ethanol in breath were consistent day to day. In other words, sleepiness enhanced the sedative effects of ethanol. In contrast, caffeine and methylphenidate produced a similar increase in alertness, regardless of the basal level of sleepiness. Clinically, these findings imply, for example, that a sleepy driver with minimal blood ethanol levels may be as dangerous as an alert driver who is legally intoxicated.[92]

The basal state of sleepiness also influences drug-seeking behavior. The likelihood that a healthy normal person without a drug abuse history will self-administer methylphenidate is greatly enhanced after 4 hours of sleep the previous night compared with 8 hours of sleep (see Figure 4-4). Although not experimentally demonstrated as yet, self-administration of caffeine also is probably influenced by basal state of sleepiness. The high volume of caffeine use in the population probably relates to the high rate of self-medication for sleepiness due to chronic insufficient sleep in the population.

Central Nervous System Pathologies

Pathology of the CNS is another determinant of daytime sleepiness. The previously noted hypocretin/orexin deficiency is thought to cause excessive sleepiness in patients with narcolepsy.[93] Another sleep disorder associated with excessive sleepiness due to an unknown pathology of the CNS is idiopathic CNS hypersomnolence. A report of a series of rigorously diagnosed cases ($n = 77$) found moderate MSLT scores (8.5-minute mean latency) relative to narcoleptics (4.1-minute mean latency).[94] As yet hypocretin/orexin deficiency has not been shown in this disorder. These two conditions are described in detail in Chapters 89 and 91.

Excessive sleepiness is reported in other neurologic diseases. A study in patients with myotonic dystrophy type 1 reported excessive sleepiness on the MSLT and reduced cerebrospinal levels of hypocretin/orexin.[95] "Sleep attacks" have been reported in Parkinson disease, and assessment with the MSLT suggests these "attacks" are the expression of excessive daytime sleepiness.[96] What remains unresolved in the excessive sleepiness of Parkinson disease is the relative contribution of the disease itself, the fragmentation of sleep due to periodic leg movements or apnea, and the dopaminergic drugs used in treating Parkinson disease.[97] The previously cited study found no differences in sleepiness as a function of prescribed drug or sleep fragmentation, although further assessment in larger unselected samples is necessary to confirm this finding.

CLINICAL AND PUBLIC HEALTH SIGNIFICANCE OF SLEEPINESS

Although the patients at sleep disorders centers are not representative of the general population, they do provide some indications regarding the clinical significance of sleepiness. Their sleep-wake histories directly indicate the serious impact excessive sleepiness has on their lives.[91] Nearly half the patients with excessive sleepiness report automobile accidents; half report occupational accidents, some life threatening; and many have lost jobs because of their sleepiness. In addition, sleepiness is considerably disruptive of family life.[98] An elevated automobile accident rate (i.e., sevenfold) among patients with excessive sleepiness has been verified through driving records obtained from motor vehicle agencies.[99]

Population-based information regarding traffic and industrial accidents also suggests a link between sleepiness and life-threatening events. Verified automobile crashes occurred more frequently in a representative sample of people with MSLT scores of 5 minutes or less.[100] The highest rate of automobile crashes occurs in the early morning hours, which is notable because the fewest automobiles are on the road during these hours. Also during these early morning hours, the greatest degree of sleepiness is experienced.[101] Long-haul truck drivers have crashes most frequently (even corrected for hours driving before the accident) during the early morning hours, again when sleepiness reaches its zenith.[102]

Workers on the graveyard shift were identified as a particularly sleepy subpopulation. In 24-hour ambulatory EEG recordings of sleep and wakefulness, workers (20% in one study) were found to actually fall asleep during the night shift.[2] Not surprisingly, the poorest job performance consistently occurs on the night shift, and the highest rate of industrial accidents is usually found among workers on this shift.[103] Medical residents are another particularly sleepy subpopulation. In surveys, subjects reporting 5 or fewer hours of sleep per night were more likely to make medical errors and report serious accidents, and they were two times more likely to be named in medical malpractice suits.[104,105] In a survey of medical house staff, 49% reported falling asleep while driving and 90% of the episodes occurred postcall compared with 13% of fall-asleep episodes reported by the medical faculty, and 20 of the 70 house staff were involved in automobile crashes compared with 11 of the 85 faculty.[105]

Cognitive function is also impaired by sleepiness. Adults with various disorders of excessive sleepiness have cognitive and memory problems.[106] The memory deficiencies are not specific to a certain sleep disorder but rather specific to the sleepiness associated with the disorder.[107] When treated adequately, sleepiness is rectified and the memory and cognitive deficits similarly improve.[108] Results of sleep deprivation studies in healthy normal patients support the relation between sleepiness and memory deficiency. Even modest reductions of sleep time are associated with cognitive deficiencies.[109]

Sleepiness also depresses arousability to physiologic challenges: 24-hour sleep deprivation decreases upper airway dilator muscle activity[110] and decreases ventilatory responses to hypercapnia and hypoxia.[111] In a canine model of sleep apnea, periodic disruption of sleep with acoustic stimuli (i.e., sleep fragmentation, in contrast to sleep deprivation) resulted in lengthened response times to airway occlusion, greater oxygen desaturation, increases in inspiratory pressures, and

surges in blood pressure.[112] Depressed physiologic responsivity due to sleepiness is clinically significant for patients with sleep apnea and other breathing disorders because they are all exacerbated by sleepiness. The emerging data on sleepiness and pain threshold, cited earlier, are also clinically significant in the management of both acute and chronic pain conditions.

Finally, life expectancy data directly link excessive sleep (not specifically sleepiness) and mortality. A 1976 study found that men and women who reported sleeping more than 10 hours a day were about 1.8 times more likely to die prematurely than those sleeping between 7 and 8 hours daily.[113] This survey, however, associated hypersomnia and increased mortality and not necessarily EDS, for which the relation is currently unknown.

CLINICAL PEARL

Sleepiness, when most excessive and persistent, is a signal to the individual to stop operating: It is dangerous and life-threatening to continue without sleep. To the clinician, that signal warns that there may be some underlying pathology that can be successfully treated or in the very least minimized as to its vital, life-threatening impact.

SUMMARY

Sleepiness is a problem reported by 10% to 25% of the population, depending on the definition of sleepiness used and the population sampled. It is most common in young adults and elderly persons. Sleepiness is a physiologic need state, with its intensity evident by how rapidly sleep onset occurs, how easily sleep is disrupted, and how long sleep endures. Validated self-rated scales and physiologic measures are available to assess the presence and degree of sleepiness. Relative to sleepy, healthy adults, the chronicity and irreversibility of sleepiness indicate its clinical and pathologic significance. Sleepiness is caused by reduced sleep time as often seen in otherwise healthy adults, by fragmented and disrupted sleep as found in patients with primary sleep disorders, by administration of sedating drugs and discontinuation of alerting drugs, and by various neurologic disorders. Sleepiness has a normal circadian rhythm that is increased in circadian rhythm misalignments such as those occurring in shift work or jet lag. Excessive and persistent sleepiness is life threatening, but when its presence is recognized and its etiology identified, it can be successfully treated or at least minimized.

Chapter 5

Sleep Deprivation

Chapter Highlights

- Surveys indicate that 35% to 40% of the adult U.S. population report sleeping less than the usually recommended 7 to 8 hours on weekday nights, and about 15% report sleeping less than 6 hours.
- Neurobehavioral deficits accumulate across days of sleep restriction to levels equivalent to those found after 1 to 3 nights of total sleep deprivation.
- Neurobehavioral responses to sleep deprivation have been found to be stable and consistent, suggesting they are trait-like and possibly genetic.
- Recovery appears to be affected by the type of sleep loss (acute versus chronic), the recovery sleep duration, and the number of days allowed for recovery. In addition, although an individual may report feeling recovered, performance may remain impaired, increasing risk for accidents and injury.

Both sufficient sleep continuity and sleep duration are prerequisites for the recuperative effects of sleep.[1] Acute total sleep deprivation refers to wake periods that extend beyond the typical 16 to 18 hours, whereas sleep restriction refers to not getting enough sleep per 24 hours for one or multiple nights. Sleep restriction (i.e., too little sleep for prolonged periods) occurs frequently and results from a number of factors, including medical conditions (e.g., pain), sleep disorders, work demands (including extended work hours and shift work), and social and domestic responsibilities.[2] Shift work affects one of five working Americans and is projected to increase in the future. Shift work includes working evenings and nights or rotating shifts, and because sleep is often scheduled at an adverse circadian phase, it is shorter and more disrupted.[3]

Both types of sleep restriction (acute and chronic) affect sleep recuperation and neurobehavioral performance. Neurobehavioral deficits accumulate as sleep loss increases. This can then result in an increased risk for workplace errors and injuries, traffic accidents, personal conflicts, health complaints, and drug and alcohol use. Well-controlled sleep studies found that restriction of sleep to between 3 and 7 hours of time in bed per 24 hours for a period of 1 to 2 weeks resulted in declining behavioral alertness and cognitive performance across days in a near-linear and dose-response fashion.[4,5] The cumulative deficits in performance on the Psychomotor Vigilance Test (PVT) that developed during 2 weeks of sleep restricted to 4 hours per night were comparable to those after 3 nights of total sleep deprivation,[5] showing that sleep restriction can induce waking brain deficits equivalent to the most severe total sleep deprivation.

Short-term sleep restriction occurs when one fails to obtain a usual amount of sleep.[6] A half-century ago, Kleitman[7] first used the phrase "sleep debt" to describe the circumstances of delaying sleep onset time while holding sleep termination time constant. He described the increased sleepiness and decreased alertness in individuals on such a sleep-wake pattern and proposed that those subjects who were able to reverse these effects by extending their sleep on weekends were able to "liquidate the debt."

Based on the manner in which the concept of sleep debt is most often used, it refers to increased pressure for sleep that results from an inadequate amount of physiologically normal sleep. To determine the effects of sleep loss on a range of neurobehavioral and physiologic variables, a variety of paradigms have been used, including controlled, restricted time in bed for sleep opportunities in both continuous and distributed schedules (e.g., nocturnal anchor sleep with a daytime nap),[8] gradual reductions in sleep duration over time,[9] selective deprivation of specific sleep stages,[10] and situations in which the time in bed is individualized, such that it is reduced to a percentage of the individual's habitual time in bed.[11] These studies have ranged from 24 hours[12] to 8 months[9] in length, but they typically involved subjects outside the laboratory in uncontrolled conditions.

Many of the early experimental reports and reviews published before 1997 concluded that sleep restriction in the range commonly experienced by the general population (i.e., sleep durations of 4 to 7 hours) resulted in some increased subjective sleepiness but had little or no effect on cognitive performance capabilities. Consequently, there was a widely held belief that individuals could "adapt" to reductions in sleep duration, to 4 to 5 hours per day. However, nearly all of these early reports of adaptation to sleep loss were limited either by lack of experimental control over a considerable number of

critical variables, including sleep actually obtained at night and during the day (i.e., naps) and the use of stimulants (caffeine, nicotine), or by a reliance on subjective reports of sleepiness, which have since been shown to be a poor reflection of actual neurobehavioral impairment due to sleep restriction. Most of these early studies also used small sample sizes, failed to include a control group, lacked physiologic measures of sleep and waking, focused on only a few assays of performance or used performance assessments contaminated by practice effects, had infrequent assessment times within and between days, and failed to test quantitatively for cumulative performance changes relative to the cumulative sleep loss experienced by the subjects.[11] They are a reminder that inadequate scientific methods result in erroneous results. Since 1997, experiments that have corrected for these methodologic weaknesses have found markedly different results from those earlier studies and have documented cumulative objective changes in outcomes as sleep restriction progressed.[6]

At the same time, epidemiologic studies have found that habitual short sleep duration is associated with negative health consequences, including obesity,[13] diabetes,[14] hypertension,[15] cardiometabolic risk factors[16] and cardiovascular disease,[17] declines in cognitive function,[18] and all-cause mortality.[19] The finding is particularly important when it is observed in prospective population studies. Evidence from experimental studies shows that both acute total sleep deprivation and sleep restriction cause inadequate pancreatic insulin secretion,[20] decreased insulin sensitivity,[21] changes in the appetite-regulating hormones leptin and ghrelin,[22] attenuated immune response to vaccination,[23] and increased sympathetic activity and venous endothelial dysfunction in healthy adults.[24] These effects provide biologic plausibility for a causal relationship between short sleep and negative health outcomes as well as all-cause mortality when considered with the well-documented safety risks of reduced sleep (e.g., the increased risk for motor vehicle crashes).

This chapter reviews the cognitive and neurobehavioral consequences of acute total sleep deprivation and sleep restriction in healthy individuals and the theoretical explanations for these effects.

INCIDENCE OF SLEEP DEPRIVATION

Human sleep need, or more precisely, the duration of sleep needed to prevent feeling sleepy during daytime, elevated sleep propensity, and cognitive deficits, has been a long-standing controversy central to whether sleep restriction may compromise health and behavioral functions. Despite the scientifically documented benefits of sufficient sleep for cognitive performance, safety, and health, current representative surveys indicate that 35% to 40% of the adult U.S. population report sleeping less than the usually recommended 7 to 8 hours on weekday nights, and about 15% report sleeping less than 6 hours.[25] Importantly, these are self-reported sleep time estimates that have been shown to overestimate actigraphically or polysomnographically measured sleep by up to 1 hour.[26,27] Less is known about the prevalence of acute total sleep deprivation in the population, but given the ever-increasing pervasiveness of shift work in our 24/7 society, it is likely that the prevalence of acute total sleep deprivation experienced while transitioning into and out of night shift work is increasing as well.

EFFECTS OF SLEEP DEPRIVATION

Acute Total Sleep Deprivation

The first total sleep deprivation and cognition study was conducted in the late nineteenth century. Studies at this time involved substantial sleep deprivation periods (36 to 90 hours) and demonstrated that memory and response time were significantly impaired.[28] Over time, hundreds of studies of total sleep loss have found significant cognitive deficits (for review, see[29]). Many facets of waking function are affected by sleep deprivation. These include reduced cognitive processing speed,[30] constructive thinking,[31] verbal memory,[32] and spatial working memory[33] as well as increased tendency for false memories.[34] Further, there are changes in subjective sleepiness and in mood and emotional processing (including reading positive emotional expressions), reduced threshold for stress, and elevated stress reactions.[35,36] Interestingly, reasoning and complex cognitive tasks appear to remain substantively unaffected by acute total sleep deprivation.[37]

One of the most sensitive and widely used cognitive tasks in studies of sleep loss is the PVT,[38] which is a measure of vigilant attention.[39] Studies have consistently shown that sleep deprivation increases PVT response slowing and lapses,[40] which are thought to reflect microsleeps.[7,41] As sleep deprivation accumulates, microsleeps or brief lapses of a half-second can increase to 10 seconds and longer.[7,41,42] It has been suggested that these lapses involve shifts in neuronal activity in frontal, thalamic, and secondary sensory processing areas of the brain.[43] In sleep-deprived subjects, cognitive performance contains lapses of attention that occur unpredictably, and they increase in frequency and duration as a function of the length of the sleep deprivation. This has led to the "wake state instability" hypothesis.[39,40,42,43] This instability appears to involve moment-to-moment fluctuations in the relationship between neurobiologic systems mediating wake maintenance and sleep initiation.[43] State instability is manifested in increased failures to respond to stimuli (errors of omission) as well as increased responses in the absence of stimuli (errors of commission).[29,42]

It has been demonstrated that the negative impact of total sleep deprivation captured in these laboratory studies is not only measurable but also meaningful. The performance effects of sleep deprivation and alcohol intoxication have been demonstrated to be qualitatively and quantitatively similar.[44] Dawson and Reid[44] found that performance impairment after 17 hours awake was equivalent to that produced by a blood alcohol concentration of 0.05%.

An overarching finding from the studies of total sleep deprivation is that waking function is influenced by a sleep homeostatic process that builds up during wakefulness and declines during sleep in a nonlinear fashion (as measured by slow wave energy or delta power in the non–rapid eye movement sleep electroencephalogram) and a circadian process, with nearly 24-hour periodicity.[45] The combined influences of these factors are described as the two-process model.[46] Since its inception, the two-process model has gained widespread acceptance for its explanation of the timing and structure of sleep. Its use has extended to predictions of waking alertness and neurobehavioral functions in response to different sleep-wake scenarios.[46] This extension of the two-process model was based on observations that as sleep pressure accumulated with increasing time awake, so

did waking neurobehavioral or neurocognitive impairment; as sleep pressure dissipated with time asleep, performance capability improved during the following period of wakefulness. In addition, forced-desynchrony experiments revealed that the sleep homeostatic and circadian processes interacted to create periods of stable wakefulness and consolidated sleep during normal 24-hour days.[47]

The two-process model has been used in the development of tools to model changes in sleep, alertness, and performance on the basis of recent sleep-wake (or work) history. These are discussed in detail in Chapter 74. In general, these models accurately predict waking performance and self-reported responses to total sleep deprivation. However, they often fail to adequately predict sleepiness and cognitive performance responses during sleep restriction.[48] Recent model extensions have started to deal with these shortcomings.[49] It is clear that the two-process model has had a profound theoretical influence on predictions of sleepiness based on total sleep deprivation data, but its inability to capture all the dynamic changes in PVT performance or cognitive tasks during sleep restriction suggests there are additional biologic factors relevant to the brain's response to sleep restriction.

Sleep Restriction

The effects of sleep loss may be quantified by physiologic, behavioral, cognitive, and subjective tools. Two large-scale, controlled laboratory studies identified dose-related effects of short-term sleep restriction on neurobehavioral performance measures.[4,5] In one study, truck drivers were randomized to 7 nights of 3, 5, 7, or 9 hours of time in bed for sleep per night and performance was assessed with the PVT.[4] Subjects in the 3- and 5-hour time-in-bed groups experienced a decrease in performance across days of the sleep restriction protocol, with increases in the mean reaction time, in the number of lapses, and in the speed of the fastest reaction on the PVT.[4] A significant decrease in response speed was seen in subjects who had 7 hours of time in bed per night. Performance in the group allowed 9 hours of time in bed was stable across the 7 days.

In another major sleep restriction experiment,[5] young adults had their sleep duration confined to 4, 6, or 8 hours of time in bed per night for 14 nights. Deficits in cognitive functions were observed, including reduced vigilant attention (Figure 5-1), impaired memory task, and slowed mental processing speed. These performance deficits accumulated across the experimental protocol in those subjects allowed less than 8 hours of time in bed for sleep per night.[5] Data from this study demonstrate that sleep restriction–induced deficits continued to accumulate beyond the 7 nights of restriction used in other experiments.[4,11] On day 14 of the sleep restriction schedule, subjects in the 4-hour time-in-bed condition had performance similar to that after 1 or 2 nights without any sleep[5] (Figure 5-1).

It also appears that the neurocognitive effects of restricting nocturnal sleep to 6 or 4 hours per night for multiple nights are fundamentally the same as when sleep is split each day into two sleep opportunities.[50] Cognitive performance deficits also accumulate across consecutive days in which restricted sleep occurs during the daytime and wakefulness occurs at night.[51] The primary difference between the nocturnally[5] and diurnally[51] placed restricted sleep periods is that the magnitude of neurobehavioral impairment is significantly greater with daytime sleep.

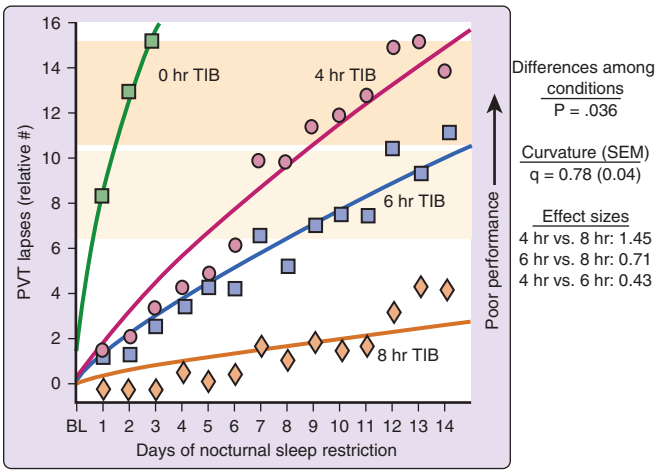

Figure 5-1 Psychomotor Vigilance Test (PVT) performance lapses under varying doses of daily sleep. Displayed are group averages for subjects in the 8-hour (*diamond*), 6-hour (*blue square*), and 4-hour (*circle*) sleep period time in bed (TIB) across 14 days and in the 0-hour (*green square*) sleep condition across 3 days. Subjects were tested every 2 hours each day; data points represent the daily average (0730 hours to 2330 hours) expressed relative to baseline (BL). The curves through the data points represent statistical nonlinear model-based best-fitting profiles of the response to sleep deprivation for subjects in each of the four experimental conditions. The mean ± standard error of the mean (SEM) ranges of neurobehavioral functions for 1 and 2 days of 0 hours of sleep (total sleep deprivation) are shown as *light and dark bands*, respectively, allowing comparison of the 3-day total sleep deprivation condition and the 14-day sleep restriction conditions. (Modified from Van Dongen HP, Maislin G, Mullington JM, et al. The cumulative cost of additional wakefulness: dose-response effects on neurobehavioral functions and sleep physiology from sleep restriction and total sleep deprivation. *Sleep* 2003;26:117–26.)

All these studies suggest that when time in bed for sleep is restricted to less than 7 hours per night in healthy adults (aged 21 to 64 years) for multiple nights, cumulative deficits in a variety of cognitive performance functions can accumulate. In addition, these deficits can be similar to those seen after 1 night or even 2 nights of total sleep deprivation. Collectively, they suggest that there is a neurobiologic integrator that accumulates either homeostatic sleep drive or the neurobiologic consequences of excess wakefulness.[4,5] No definitive evidence exists yet as to what this neurobiologic integrator might be, but one hypothesis suggests that it may involve extracellular adenosine in the basal forebrain.[52]

In contrast to reports of continuing accumulation of cognitive deficits associated with sleep restriction, subjective assessments of sleepiness and alertness demonstrate near-saturating functions across periods of sleep restriction.[5] Self-reported mood, sleepiness, and fatigue do not parallel the continuing decline in cognitive performance associated with nightly restriction of sleep to 7 hours or less.[5] This suggests that individuals frequently underestimate the impact of sleep deprivation on their performance. Experiments using driving simulators have found similar results, with drivers unable to accurately recognize crash risk.[53]

There is increasing evidence of physiologic and health-related consequences of sleep loss. Alterations in physiologic parameters, such as endocrine and immune function, have

been recognized and have implications for health status and risk. An elevated mortality risk in those individuals who reported sleeping less than 6.5 hours per night has been found.[54] As outlined before, the literature points to a strong relationship between insufficient sleep and poor metabolic health characterized by conditions such as cardiovascular disease,[55] type 2 diabetes,[56] and obesity.[57] A meta-analysis study found a consistent increased risk of obesity among short sleepers in both children (sleeping <10 hours per night) and adults (sleeping <5 hours per night), but as the authors pointed out, causal inference was difficult because of the lack of control of confounders and inconsistency in the methodologies used.[58] On the other hand, a recent laboratory-based experimental study of the effects of sleep restriction to 4 hours per night for 5 nights in 198 healthy adults did find that relative to control subjects allowed up to 10 hours of sleep per night, sleep-restricted adults gained an average of nearly 1 kg of weight during the sleep restriction period.[59]

Extended wakefulness appears to have a metabolic cost that triggers neuroendocrine and immune function changes.[60] In a seminal experimental study that compared sleep restriction (4 hours per night for 6 nights) with sleep extension (12 hours per night for 6 nights), evening cortisol was elevated, sympathetic activation was increased, and thyrotropin activity and glucose tolerance were decreased.[61] It has been long recognized that a relationship exists between sleep and immune function. Changes in natural killer cell activity,[62,63] lymphokine-activated killer cell activity,[62] interleukin-6,[64] and soluble tumor necrosis factor-alpha receptor 1[65] have been reported with total sleep deprivation and sleep restriction. C-reactive protein is a predictive inflammatory marker of increased risk for cardiovascular disease, and increased C-reactive protein has been reported after both total sleep deprivation[66] and sleep restriction (4 hours of time in bed for sleep per night) in healthy individuals.[67]

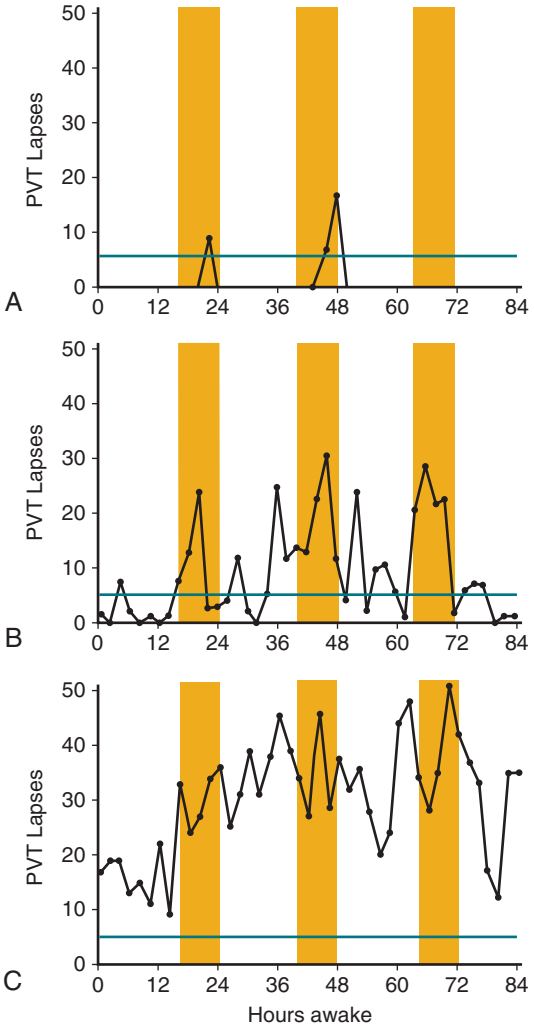

Figure 5-2 Individual differences in the response to sleep deprivation (D.F. Dinges, unpublished data). The three subjects in **A** to **C** performed a 10-minute Psychomotor Vigilance Test (PVT) every 2 hours during 88 hours of acute total sleep deprivation. The *horizontal line* reflects 5 PVT lapses (number of reaction times >500 ms), and *bars* indicate the period from 0000 hours to 0800 hours. **A,** A resilient response. **B,** Affected by sleep deprivation but with daytime improvement. **C,** A vulnerable response to sleep deprivation. These individual differences in the response to sleep deprivation on the PVT were not accounted for by demographic factors, IQ, or sleep need. (From Basner M, Rao H, Goel N, Dinges DF. Sleep deprivation and neurobehavioral dynamics. *Curr Opin Neurobiol* 2013;23:854–63, with permission.)

INDIVIDUAL DIFFERENCES IN RESPONSES TO SLEEP LOSS

Whereas the majority of healthy adults experience sleepiness and related cognitive deficits under conditions of total sleep deprivation or sleep restriction, interindividual variability in the neurobehavioral and physiologic responses is substantial.[7,29,42,68] There are certain individuals who display minimal impairment during sleep loss, some who are moderately affected, and others who are particularly vulnerable (Figure 5-2).[69] To date, research has not supported the suggestion that differences in vulnerability reflect baseline scores (following adequate rest), nor have studies found that demographic factors, such as IQ, habitual sleep amount, or personality, account for these differences.[70] Studies investigating whether the same individuals are vulnerable to total sleep deprivation and sleep restriction have yielded mixed results, likely due to small samples and varied methods.[71,72]

Importantly, however, within subjects repeatedly exposed to the same sleep loss intervention, neurobehavioral responses to sleep deprivation have been found to be stable and consistent, suggesting they are trait-like.[73] This also seems to be true for total sleep deprivation and sleep restriction.[68] It has therefore been suggested that these trait-like differences in vulnerability may reflect underlying genetic differences.[70] A number of possible genetic contributors have been considered in the literature. These include *PERIOD3* variable number tandem repeat (*PER3*)[74,75] and *ADORA2A* polymorphisms.[75] Whereas some work has suggested a connection between *PER3* and performance vulnerability to total sleep deprivation[76] and sleep restriction,[75] other researchers have found that sleep homeostatic responses, rather than performance responses during sleep restriction, were related to *PER3*.[74] It has also been suggested that the importance of *PER3* and *ADORA2A* polymorphisms as they relate to performance variability during sleep restriction may be influenced by the length and severity of the sleep loss.[75] Currently, this work requires larger replicate samples to untangle some of these relationships.

DETECTION OF SLEEPINESS

Sleepiness is often defined as the "propensity to fall asleep" and can be measured both objectively and subjectively[77]; however, as mentioned before, self-reported sleepiness has been shown to be unreliable (i.e., not reflecting performance capability) during sleep loss.[78] This stresses the need for brief, objective, and unobtrusive measures of sleepiness that can be readily applied under operational conditions.

The measures that best track the subtle changes in performance caused by sleep deprivation are neural state indicators (such as electroencephalography, electrooculography, and functional magnetic resonance imaging) or behavioral indicators of attention stability, like the PVT.[79] The PVT has been shown to be among the most sensitive measures of sleep loss, partly as it prevents compensatory stimulation and is not confounded by aptitude and learning effects like other performance measures.[39,79] It also reflects performance that has ecologic validity (i.e., vigilant attention is needed for learning, safe driving). The PVT is thus often used as a "gold standard" measure for the neurobehavioral consequences of sleep loss against which other fatigue detection technologies are measured.

Chua et al[80] investigated how well several objective physiologic variables as well as subjective measures of sleepiness correlated with the PVT during 1 night of acute total sleep deprivation. The highest correlation was found for the percentage of slow eye closures, in agreement with several authors who found oculomotor responses to be sensitive to sleep restriction.[81] Eyelid closure and slow rolling eye movements are part of the initial transition from wake to drowsiness; they are associated with vigilance lapses and have been found to be a sign of drowsiness while driving.[82] Increased slow eye movements attributed to attentional failures have been reported to be increased by reduced sleep time in medical residents.[83] Sleep restriction has also been found to decrease saccadic velocity and to increase the latency to pupil constriction in subjects allowed only 3 hours or 5 hours of time in bed for sleep over 7 nights.[84] Other variables that correlated highly with PVT performance included the power spectral density of the electrocardiogram RR interval in the range of 0.02 to 0.08 Hz, electroencephalogram delta power in the range of 1 to 4.5 Hz, followed by self-reported measures of sleepiness.[80] The high correlation between heart rate variability and the PVT has recently been replicated for sleep restriction as well.[85]

SLEEP DEPRIVATION AND BRAIN METABOLISM

Sleep deprivation induces changes in brain metabolism and neural activation that involve distributed networks and connectivity.[1] Early positron emission tomography sleep deprivation studies found metabolic rate reductions in thalamic, parietal, and prefrontal regions associated with prolonged sleep loss.[4,86] More recent blood oxygenation level–dependent functional magnetic resonance imaging (fMRI) studies showed significant declines in regional brain activation during cognitive task performance after 1 night of total sleep deprivation. These changes included reduced frontoparietal activation during lapses on a visual selective attention task[87] and were mainly observed in vulnerable subjects with larger performance deficits, whereas resilient subjects demonstrated a trend toward increased parietal activation during performance lapses,[87] suggesting a potential compensatory mechanism after sleep loss. Recent positron emission tomography studies have observed downregulation of striatal dopamine receptors[88] and increased cerebral serotonin receptor binding with sleep deprivation.[89] This may reflect a complex adaptive response of the brain to sleep deprivation.

Poudel et al[90] used arterial spin-labeled perfusion fMRI to measure resting cerebral blood flow (CBF) changes after 1 night with 4-hour sleep opportunity. Only drowsy participants (established with video of the eyes during the scan) exhibited a significantly reduced frontoparietal CBF after sleep deprivation, whereas nondrowsy subjects maintained frontoparietal CBF and increased CBF in basal forebrain and cingulate regions. These findings support a compensatory mechanism after sleep loss,[90] which may explain some of the variance between those resilient and those vulnerable to sleep loss. Recent resting-state functional connectivity fMRI (FC-fMRI) studies have consistently shown an organized mode of resting brain function.[91] Two recent FC-fMRI studies reported reduced functional connectivity within the default mode network and between the default mode network and its anti-correlated network associated with sleep deprivation,[92] suggesting that functional connectivity of the brain changes as a result of sleep loss. A recent meta-analysis on the effects of acute total sleep deprivation on the attending brain found decreases in brain activation in the frontoparietal attention network (prefrontal cortex and intraparietal sulcus) and in the salience network (insula and medial frontal cortex) but increases in thalamic activation (the salience network segregates the most relevant internal and external stimuli to guide behavior). The authors speculated that the latter may reflect a complex interaction between the dearousing effects of sleep loss and the arousing effects of task performance on thalamic activity.[93]

RECOVERY FROM SLEEP LOSS

An emerging area of research has begun to focus on recovery processes from acute total sleep deprivation and sleep restriction. Results from these studies suggest that the recovery process may be slower and more complex than originally thought. Recovery appears to be affected by the type of sleep loss (acute versus chronic), the recovery sleep duration, and the number of days allowed for recovery. In addition, aspects of neurobehavioral functioning appear to recover at different rates, and although an individual may report feeling recovered, performance may remain impaired, increasing risk for accidents and injury. It is therefore critically important to understand how much sleep people need to recover from periods of sleep loss.

Recovery following Sleep Restriction

Few studies have examined recovery sleep after periods of sleep restriction. Two important sleep restriction studies that also included a short in-laboratory recovery phase were those by Dinges et al[11] and Belenky et al.[4] In the Dinges study, sleep was restricted below habitual sleep duration by 33% (average, 4.98 hours per night; standard deviation, 0.57) for a consecutive 7 nights, after which participants were allowed one or two

10-hour recovery sleeps.[11] In the Belenky study, participants were permitted 3, 5, 7, or 9 hours in bed each night, for 7 nights, followed by three 8-hour recovery opportunities.[4] These studies showed that either two 10-hour or three 8-hour sleep opportunities are sufficient to recover performance to baseline levels. Although participants felt that their functioning was restored, with subjective reports of sleepiness and performance recovering to baseline, subjective measures do not appear to accurately parallel objective measures of neurobehavioral recovery. These findings suggest that more than 2 or 3 nights of extended sleep may be needed to return neurobehavioral functions to baseline levels. This may be especially important in situations in which individuals are not able to choose or to extend the length of their recovery sleep period.

Recent studies have extended this work by manipulating the amount of sleep obtained before a period of sleep restriction in a prophylactic manner, the duration of the recovery period (longer than 3 days), and the length of the recovery sleep opportunity. Rupp et al[94] extended the recovery period to five 8-hour sleep opportunities, following a week of sleep restricted to 3 hours of time in bed each night.[94] Despite the extra recovery nights, performance still failed to return to baseline levels. In a second group that extended their sleep prophylactically to 10 hours of time in bed before the period of sleep restriction, performance declined at a slower rate and recovered to baseline more quickly, suggesting that sleep restriction and recovery vary as a function of prior sleep.[94] Therefore, sleep extension or supplemental nap sleeps can be used as a prophylactic measure or countermeasure to lessen the performance effects of sleep deprivation during periods of extended wakefulness or sleep deprivation.

In the first study to systematically investigate different doses of recovery sleep (0, 2, 4, 6, 8, and 10 hours of time in bed) after sleep restriction of 4 hours per night for 5 nights, Banks et al[30] found that the extended 10-hour recovery sleep opportunity was not enough for full recovery of sustained attention, subjective sleepiness, or fatigue. Importantly, it was observed that each recovery sleep dose had equivalent restorative value (i.e., linear) for sleep and objective sleepiness measures. However, in contrast, recovery of performance outcomes, sustained attention, and subjective sleepiness was exponential, indicating that the restorative value of the recovery sleep doses decreased with increasing sleep time.

Overall, work to date suggests that complete recovery from a period of sleep restriction may necessitate a sleep opportunity of more than 10 hours or more than 3 days if sleep is restricted to 8 hours a night. In addition, different aspects of performance and neurobehavioral function appear to recover at different rates, with different trajectories.

Recovery following Acute Total Sleep Deprivation

Both the number of nights needed for recovery and extended recovery sleep opportunities following total sleep deprivation have been investigated.[95,96] In one particular study, participants were deprived of sleep for 1 or 2 nights, followed by a consecutive 5 nights for recovery that were either restricted to 6 hours or extended to 9 hours of time in bed. Independent of the severity of the prior sleep loss or the length of recovery opportunity, slow wave sleep returned to baseline levels after the first recovery sleep, and participants in each of the groups obtained comparable amounts of slow wave sleep. Performance was also complete after 1 night of extended recovery sleep following 1 night of sleep deprivation. However, when the period of sleep deprivation was more severe (i.e., 2 nights), cognitive performance remained significantly below baseline even after 5 nights of extended recovery sleep. Neither performance nor subjective sleepiness recovered to baseline when recovery sleep time was 6 hours of time in bed per night.

These studies underscore the importance of not restricting recovery sleep opportunities to less than 6 hours. Indeed, it is apparent that adding just 1 hour extra can significantly increase the rate of recovery from sleep deprivation. Moreover, it appears that the more severe the sleep loss, the longer the recovery sleep opportunity required.

CLINICAL PEARL

Physicians should be aware that sleep deprivation can be caused by sleep disorders, work schedules, and modern lifestyles. The consequences of sleep deprivation include excessive daytime sleepiness and poor mood, impaired cognitive performance, and driving safety and appear to play a role in chronic health diseases, such as cardiovascular disease, obesity, and type 2 diabetes.

SUMMARY

Sleep is important for healthy functioning, but sleep deprivation is common in many sectors of the community. Sleep deprivation causes a multitude of changes to cognitive and behavioral functioning and also increases the risk for chronic diseases, such as type 2 diabetes, obesity, and cardiovascular disease. There are large individual differences in the cognitive responses to sleep deprivation. These individual differences are stable across multiple exposures and types of sleep loss, suggesting a trait-like (possibly genetic) basis. The negative effects of sleep deprivation can be recovered by extending sleep, but recovery appears to be dependent on the type of sleep loss (acute versus chronic), the recovery sleep duration, and the number of days allowed for recovery. Biomathematical models and the development of unobtrusive technologies to detect fatigue while working are ways in which the deleterious effects of sleep deprivation can be managed in our 24/7 society.

Genetics of Normal Human Sleep

Hyun Hor; Mehdi Tafti

Chapter Highlights

- Twin studies indicate that 20% to 50% of variance in sleep habits, duration, and organization can be explained by genetic factors, whereas the heritability of the electroencephalogram (EEG), both waking and sleep, is among the highest in humans.
- Single genes with large effects on sleep are unknown. Such genes affecting the sleep EEG are found in animal models but not yet in humans.
- Recent studies concentrated on the genetics of subjective (self-reported) sleep duration, but so far genetic variants with small effect sizes have been identified. These findings have not been replicated to date and must therefore be considered preliminary.
- Large-scale objectively (EEG-based) measured sleep studies are needed to discover the molecular bases of sleep and the sleep EEG.

The first edition of *Principles and Practice of Sleep Medicine* contained no information about how genes contribute to sleep and circadian biology. Sleep is such a universal component of life that it is not surprising that recent research has shown that genetics plays a pivotal role in its regulation, that humans share many elements of genetic control of sleep and circadian rhythms with other life forms (see Chapters 16 to 30), and that genetics plays an important role in some sleep disorders (see Chapter 31).

Genetics of sleep in humans can be divided in two main categories: the genetics of normal sleep and the genetics of abnormal sleep. Whereas the study of sleep disorders from the genetic point of view follows approaches similar to those in the study of many other rare and common diseases (see Chapter 31), the study of normal human sleep is a challenging task for different reasons. First of all, human sleep can be considered a complex trait with a wide phenotypic variability. Genetic factors have been suggested to play an important role as certain sleep characteristics can be repeatedly found within families, but numerous environmental factors, especially those that arise from today's lifestyle, are major confounders in clearly determining a specific sleep pattern or phenotype, which is an important prerequisite of identifying genetic factors of human sleep. Furthermore, the identification of genetic factors contributing to sleep phenotypes in humans is even more difficult because the target tissue, namely, the brain, is inaccessible for in-depth genetic and molecular studies, in contrast with animal model studies of sleep (rats, mice, and fruit flies), in which, for example, transcriptome analyses of the brain have identified major genetic contributors to the regulation of sleep.[1-3]

Taking into account these limitations, we summarize the recent advances in this field from both the epidemiologic and the genetic points of view.

GENETIC EPIDEMIOLOGY OF SLEEP WITH FOCUS ON TWIN STUDIES

Substantial evidence suggesting that sleep is a complex trait with a strong genetic component has arisen from twin studies. In the field of human genetics, twin studies are a major tool to characterize the genetic and environmental contribution to a certain trait or phenotype because monozygotic twins share the same genetic background, whereas dizygotic twins share only half of the segregating alleles. The characterization of specific phenotypes, taking into account the underlying genetic background in twin studies, thus allows us to quantify the additive genetic effects, the contribution of environmental factors, or the interaction of both genetic and environmental factors.

Sleep studies in twins cover both subjective reports on sleep habits and patterns, including sleep quality and quantity, and objective measurements of sleep phenotypes based on polysomnography analyses and electroencephalographic patterns of sleep.

Numerous twin studies have been published to date focusing on subjective sleep characteristics. Sleep duration constitutes the largest amount of data, and studies yield partially conflicting results. Some studies showed low or modest genetic contribution in children and school-aged twins[4,5] as well as overall heritability estimates of 0.44[6] and 0.3[7] in large-scale studies in adults, indicating a stronger genetic contribution to sleep duration with increasing age; other studies in monozygotic and dizygotic young adult twins living either together or apart showed low or no evidence of genetic influence but a strong environmental contribution to sleep duration.[6,8] These conflicting results have been explained by the potentially important role of voluntary control influenced by lifestyle factors, such as staying out late and sleeping in late.[9] In

contrast, the genetic influence on subjective sleep quality appeared stable across different age groups in twins, in whom heritability estimates ranged from 33% to 46%.[6,8,10]

Twin studies using subjective methods have also been useful to assess the heritability of the human circadian rhythm or, more specifically, the diurnal preference in humans (better known as morningness and eveningness types). These studies also indicate a consistent strong genetic effect on this trait with heritability estimates ranging from 44% to 50%, a finding that was also observed in monozygotic and dizygotic twins who had been raised apart.[8,11-13] Also, this effect seemed stable across all age groups, although the diurnal preference was shown to shift from evening-type in adolescence to morning-type at an advanced age. In this context, we should point out the identification of *PER3* as a gene associated with diurnal preference in an age-dependent manner (see later section on candidate gene analysis).

Objective measurements take advantage of electroencephalographic sleep recordings used in polysomnographic investigations of human sleep. The sleep electroencephalogram (EEG) offers the possibility of gaining detailed information about sleep patterns, including sleep duration, latency, onset, and efficiency, as well as more global measures, such as the sleep architecture reflected by the EEG power spectra and the sleep stage organization. A number of such twin studies revealed a substantial genetic influence on various sleep patterns, such as different sleep stages (sleep stage 2, slow wave sleep) and spindle density, as well as the time of rapid eye movement (REM) sleep and wake after sleep onset.[9,14-20] A strong genetic effect on non-REM (NREM) sleep EEG has been consistently described in a recent study,[21] and other studies even demonstrate that NREM sleep EEG can be reliably distinguished between subjects, irrespective of sleep pressure.[22-25] These "individual fingerprints" of NREM sleep EEG were therefore claimed as one of the most heritable traits in humans. In contrast, whether human REM sleep is under genetic control remains controversial. Whereas some studies did not find clear differences in REM sleep patterns between monozygotic and dizygotic twins,[16,17,19] others estimated a strong heritability of REM sleep amount and especially REM density.[14,16-19,26] Overall, sleep duration and structure have moderate to high heritability (up to 60%), whereas the sleep EEG is strongly heritable (up to 98%). The latter is supported by mouse studies[27-29] and was used to map and to identify major genes regulating the theta oscillations in REM and delta oscillations in NREM sleep.[30,31] These studies strongly suggest that electroencephalographic features of sleep, more than its amount or distribution, are the best candidates for genetic studies because these phenotypes are the most heritable sleep traits.

CANDIDATE GENE ANALYSES FOR NORMAL SLEEP AND CIRCADIAN PHENOTYPES

Twin studies have successfully demonstrated that many human sleep traits are under genetic control. However, what are the genes regulating these traits, and more important, what methods are currently available to address this question and to identify the underlying genetic factors? In contrast to animal studies, in which genes can be identified by sleep recordings and transcriptome analysis of brain tissue samples (e.g., by expression quantitative trait locus analysis of different mouse inbred strains after sleep deprivation), the identification of genes regulating sleep or circadian rhythms in humans was to date mainly restricted to candidate gene analysis. However, the choice of candidate genes was in turn restricted by previous findings that were mainly based on the knowledge of the physiology and genetics of sleep and circadian rhythm regulation in other species.

Candidate Gene Analyses of Circadian Clock Genes in Humans

Genes regulating circadian rhythms have been subject to genetic analysis to identify regulators of human sleep and diurnal preference. As discussed in detail in Chapters 26 to 30, the circadian clock consists of a group of genes that undergo an autoregulatory negative feedback loop. Here we discuss the genes of this loop, which plays an important role in the regulation of human sleep with distinct consequences on the timing and duration of sleep. Whereas we aim to focus on genes regulating normal human sleep, we need to stress that some genes have been identified in traits that show marked deviations from the average sleep patterns and therefore have been in some cases defined as "disorders." Nevertheless, we consider them as natural variations of normal human sleep presenting as an extreme phenotype of a specific trait.

CLOCK

The *CLOCK* gene was one of the first genes shown to have an effect on diurnal preference. Katzenberg et al[32] identified a single nucleotide polymorphism (SNP) in the 3′ untranslated region associated with a delayed sleep phase. However, this initial finding was only partially replicated in follow-up studies.[32-36] *CLOCK* was also associated with sleep duration in an extended candidate gene association study based on linkage disequilibrium.[37] For this purpose, 194 SNP markers in 19 "clock" genes were studied in a discovery and subsequent replication study comprising a total number of 1294 subjects from two different populations (South Tyrol and Estonia) with either short (<7 hours) or long (>8.5 hours) habitual sleep habits.

Period2 (PER2)

A syndrome characterized by an advanced sleep phase was first reported in 1999 by Jones et al,[38] who described a large family from Utah presenting with a syndrome with an approximately 4- to 6-hour advanced sleep phase without major impact on the quality or quantity of sleep. Subsequent linkage and positional cloning analyses by Toh et al[39] finally identified a mutation in the casein kinase I–binding domain of *PER2* as the cause of this syndrome.

Casein Kinase I (CSNK1D)

Since the initial identification of a mutation in *PER2*, a candidate gene association study identified novel mutations in the *CSNK1D* gene as a cause of familial advanced sleep phase syndrome.[40] This finding was further supported by functional analyses in transgenic mice and fruit flies that displayed an altered diurnal preference indicating the identification of a central regulator of the circadian clock.

DEC2

In a small family with two affected members, He et al[41] identified a mutation in the *DEC2* gene as a cause of the short

sleeper phenotype. This gene is a transcriptional repressor within the mammalian circadian clock and was therefore one of the subjects of investigation in a candidate gene approach, followed by the engineering of transgenic mice carrying the identified mutation, which displayed shorter sleep, corroborating the association in humans. Sequencing of the *DEC2* gene identified an additional heterozygous variant in one twin of a dizygotic pair among a cohort of sleep-deprived individuals (either acute or partially chronic).[42] This finding was confirmed by polysomnography recordings revealing reduced sleep duration and less recovery sleep following sleep deprivation compared with the other twin carrying the homozygous major allele. However, the amount of NREM sleep remained the same between twins.

Period3 (PER3)

Various studies have shown that SNPs and a variable number tandem repeat (VNTR) polymorphism in the promoter and coding region of *PER3* are associated with diurnal preference or delayed sleep phase syndrome (DSPS).[43-47] Ebisawa et al[44] were the first to report on a possible association of structural polymorphisms of *PER3* with DSPS, and particularly the VNTR polymorphism, represented by either a short (4 repeats) or a long (5 repeats) allele, was the subject of further investigation. Whereas homozygosity for the longer variant (5/5) was associated with the morningness type, the shorter one was associated with eveningness type. In addition, individuals homozygous for the long allele (5/5) presented a higher amount of slow wave sleep in NREM and an increased theta and alpha activity in wakefulness and REM sleep.[43] Interestingly, 75% of individuals diagnosed with DSPS were carriers of the homozygous short variant (4/4).[45] However, one independent study so far did not successfully replicate the VNTR association with diurnal preference,[48] suggesting that further investigations with larger sample sizes are needed to clarify this putative association.

Candidate Gene Analyses Related to Adenosinergic Neurotransmission in Humans

Adenosine plays a major role in the regulation of sleep and wakefulness.[49] Early evidence in mice and subsequent genetic and pharmacogenetic studies in humans confirmed its important role in sleep regulation. Adenosine deaminase is an enzyme that degrades adenosine to inosine. A known SNP (c.22G>A) in the gene encoding adenosine deaminase has a major functional effect; carriers of c.22G>A display a lower enzymatic activity than homozygous carriers of the major allele, which thus leads to a lower adenosine degradation rate. As a consequence, this SNP has been further studied for its role in sleep regulation. This study revealed an increased amount of slow wave sleep as well as higher delta power in NREM sleep, a marker of sleep need, in individuals carrying c.22G>A.[50] This finding was further supported by a sleep deprivation study (40 hours of prolonged wakefulness) that showed increased slow wave sleep and delta activity in NREM sleep during the recovery night in carriers of c.22G>A, suggesting that this genetic variation leads to an enhanced sleep pressure through reduced degradation of adenosine.[51]

Additional evidence for the importance of the adenosinergic neurotransmission in sleep regulation came from the genetic study of adenosine receptors. Four receptor subtypes mediate the cellular effects of adenosine, with the two subtypes A_1 and A_{2A} mainly involved in mediating the effect of adenosine in sleep.[49] The A_{2A} receptor was principally studied from the genetic point of view because of its involvement in the response to caffeine, which mainly acts as a competitive antagonist at adenosine receptors.[52] Regardless of the effect of caffeine, an SNP (c.1083T>C) in *ADORA2A*, the gene that encodes the A_{2A} receptor, was shown to affect the duration of slow wave sleep as well as sleep intensity.[53] In fact, homozygous carriers of the G/G genotype showed fewer awakenings, longer time spent in slow wave sleep, and higher delta power during sleep. More important, in a follow-up study on the effect of and sensitivity to caffeine in different genotype and haplotype carriers of *ADORA2A*,[54] the minor C allele of the c.1083T>C SNP conferred higher sensitivity to caffeine-induced sleep disturbances. Interestingly, a specific haplotype comprising eight SNPs in this gene was associated with a missing effect of caffeine on NREM sleep in recovery sleep, whereas carriers of other haplotypes presented reduced rebound in slow wave sleep on caffeine intake. The missing effect correlated with a failure of caffeine to rescue the vigilance decline after sleep loss; thus, reduced slow wave sleep reflected the successful counteraction to vigilance decline by caffeine. A recent genome-wide association study confirmed the association of *ADORA2A* with caffeine-related sleep disturbances.[55]

The results of these studies strengthened the hypothesis that adenosine and its receptors play an important role in sleep regulation, particularly in NREM sleep homeostasis.

Candidate Gene Analyses Related to Glutaminergic and Dopaminergic Neurotransmission

GRIA3

In a population-based study in humans, an SNP in the inotropic glutamate receptor gene (*GRIA3*), located on the X chromosome, was previously identified to be associated with depressive disorder. As sleep disturbances are potential precipitating factors for the initiation of depressive disorders,[56] this gene was tested, among others, as a candidate gene for sleep duration.[57] In this study, a significant association was found between rs687577 and sleep duration in healthy women, a finding that still needs to be independently replicated. *GRIA3* encodes the glutamate receptor 3 (GluR3) subunit, which is one of the four AMPA receptor subunits and is expressed, among others, in the thalamus.[58] Electroencephalographic recordings in *GluR3* knockout mice have revealed marked changes in the EEG, particularly during NREM sleep, suggesting an important role of the GluR3 subunit in the generation of cortical slow oscillations,[59] as well as consistent changes of the expression level of GluR3, which increases in the cortex under sleep deprivation and decreases during recovery sleep.[60]

COMT

The dopaminergic system is considered to play an important role in sleep regulation as many stimulants and wake-promoting drugs are known to act through dopaminergic neurotransmission.[61] Therefore, a functional SNP leading to Val158Met in catechol-*O*-methyltransferase (COMT), an enzyme metabolizing cerebral dopamine, has been studied in connection with subjective and objective measures of sleep homeostasis. Two studies[62,63] revealed no difference in subjective sleepiness after sleep deprivation between Val and Met

homozygous genotypes. However, the objective measures collected by Goel et al showed larger declines of slow wave sleep after sleep deprivation in homozygous Met carriers compared with homozygous Val carriers, whereas the study of Bodenmann et al revealed no major change in slow wave sleep activity between both genotypes but an increase in power of certain NREM frequency bands during recovery sleep after modafinil administration in Val/Val genotype carriers.[62,64] Moreover, both studies showed no difference between cognitive and executive functioning at baseline condition between genotypes, but Bodenmann et al found that modafinil is able to maintain these baseline performances after sleep deprivation in Val/Val but not in Met/Met carriers. These results highlight the important role of COMT genetic variation, enzyme activity, and dopamine levels, particularly in the prefrontal cortex, in the regulation of sleep and wakefulness in normal subjects.

GENOME-WIDE ASSOCIATION STUDIES OF NORMAL SLEEP PHENOTYPES

Candidate gene analyses led to the discovery of genes associated with certain sleep traits and phenotypes. However, these approaches did not yield replicable results in a considerable number of cases. During the past years, genome-wide association studies (GWAS) have become a well-established tool to identify genetic variants and genes associated with different disorders and traits, and they allow us to study the genetics of a given trait in a hypothesis-free manner. This methodology has proved successful in identifying true genetic variants that have mostly been successfully replicated in follow-up studies.

The first large-scale GWAS on sleep phenotypes was published in 2007 by Gottlieb et al, who took advantage of the Framingham Heart Study, which was initially founded to investigate the epidemiology of cardiovascular diseases,[65] but numerous other phenotypes were collected by questionnaires.[66] In a subset of 749 subjects, both phenotype data on sleepiness, usual bedtime, and usual sleep duration and genotype data for 100,000 SNPs were available. Family-based association tests revealed a linkage peak on chromosome 16 including the *CSNK2A2* gene to usual bedtime, whereas sleep duration was linked to the region encompassing the *PROK2* gene on chromosome 3. *CSNK2A2* and *PROK2* reached LOD scores above 2 and are known components of the circadian clock. Other SNPs in various genes with lower LOD scores (<2) were identified, among which one should be noted that is linked to usual bedtime, the *CLOCK* gene on chromosome 4. Population-based association tests, on the other hand, identified an intronic SNP in the phosphodiesterase 4D gene (*PDE4D*) to be associated with sleepiness (as measured by the Epworth Sleepiness Scale score), reaching genome-wide significance. Of note, the results of the population- and family-based association tests were poorly correlated. The only SNP in a coding region with the highest significance in both association tests was located in *NPSR1*, a component of the neuropeptide S receptor, and associated with usual bedtime. One of the major limitations of this study is the fact that many genes previously linked to various sleep phenotypes (see earlier), especially those forming part of the circadian clock, such as *PER2*, *CSNK1D*, and *PER3*, were either not or only poorly represented on the genotyping platform used. Although promising, the results presented in this study have not been replicated in an independent study. In this context, an attempt to replicate the *NPSR1* association by objective measures using actigraphy failed to replicate. However, this study including 393 subjects found an association of the studied variant with duration of sleep and rest, indicating that objective measurements such as actigraphy could most probably lead to more reliable and precise association results.[67]

Another GWAS with focus on sleep duration collected data from seven different European populations[68] and comprised a discovery phase with GWAS data using up to 2.5 Mio SNPs in 4251 subjects of European ancestry and a replication phase involving 5949 subjects. The study revealed a genome-wide significant association of sleep duration with an intronic variant in the *ABCC9* gene (ATP-binding cassette, subfamily C, member 9). However, this association became significant only after the analysis in a subgroup of the replication sample that was chosen for the season of entry and chronotype, as the season is known to influence the circadian entrainment and sleep behavior. The associated variant explained 5% (10 minutes) of the variation in sleep duration. Nevertheless, functional analysis in *Drosophila* of the ATP-sensitive potassium channel subunit (SUR2), which is the ortholog of *ABCC9* in *Drosophila*, confirmed its important influence on sleep duration. In fact, knock-down experiments of *dSUR* in neurons resulted in a marked reduction of nighttime sleep with a delay of sleep onset of 3 hours, whereas there was little effect on daytime sleep. Given that earlier studies in *Drosophila* indicated an involvement of potassium channel activity in the regulation of sleep duration,[69,70] this finding strengthens the hypothesis that potassium channel regulatory proteins in the brain might play an important role in the modulation of sleep across species. The *ABCC9* variant was also associated with sleep duration in the British G1912 cohort, although only in a recessive model given a rare homozygous genotype of the minor allele.[71]

A GWAS using samples and data from the Australian Twin Registry collected six sleep measures phenotyped by questionnaires, including sleep onset time, latency, quality, depth, and duration, in a total of 2323 subjects from whom both genotype and phenotype data were available.[72] The discovery phase using 2.3 Mio imputed SNPs did not reveal any genome-wide significant associations, but the authors pointed out SNPs in the *CACNA1C* gene on chromosome 12, a gene that had been previously linked to bipolar disorder, schizophrenia,[73,74] and narcolepsy,[75] that showed some evidence of association with sleep latency and quality. However, the replication study did not confirm this association. More importantly, none of the variants identified by Gottlieb et al[66] replicated in this study. Nonetheless, a replication of variants associated with sleepiness was not possible because no data on sleepiness (as measured, for example, by the Epworth Sleepiness Scale) were included in this study. However, Parsons et al[71] finally reported on a successful replication of a variant in the *CACNA1C* gene in the British G1219 cohort with sleep quality, using an additive model of inheritance.

A GWAS published by Ollila et al[76] used a Finnish discovery sample of 1941 subjects and replication sample of 6834 searching for genes influencing sleep duration. Similar to previous GWAS, no genome-wide significant association was identified and therefore 31 variants with suggestive association were included in the replication study, which were derived

from various study settings and designs. Nevertheless, variants in three genes nominally reached significance at $P < 5 \times 10^{-5}$ and were further analyzed by an expression quantitative trait locus analysis of sleep duration in 207 samples. *KLF6* was the only gene with an expression level correlating with sleep duration, a finding that was then subjected to replication in a small sleep restriction study including nine cases and four controls. In cases carrying the *KLF6* allele associated with shorter sleep duration, the gene expression after sleep restriction (4 hours during 5 nights) as well as after 2 nights of recovery sleep was significantly higher than in controls. Of note, previously identified associations by GWAS, notably *ABCC9* with sleep duration[68] and *PDE4D* with sleepiness,[66] were not replicated in this study.

The latest GWAS published by Gottlieb et al[77] included a total number of 47,180 individuals of European ancestry from 18 different population-based cohorts representing the largest GWAS studying subjective sleep duration to date. Of note, some of these cohorts have already been used in the aforementioned studies. Variants in two genes reached genome-wide significance; however, only one of them replicated in an independent cohort of African American origin comprising a sample of 4747 individuals. The associated variants in this gene were located in an intergenic region upstream of *PAX8*, which encodes a transcription factor regulating thyroid development and function. Although replicated, the strongest associated SNP contributed to a marginal effect characterized by a prolongation of 3.1 minutes per copy of its minor allele.

CONCLUSIONS AND FUTURE OUTLOOK

Epidemiologic twin studies clearly demonstrated that human sleep, including various sleep patterns and measures, is genetically determined. Candidate gene analyses and, more recently, GWAS have been the major tools to identify underlying genes and genetic factors controlling human sleep. Our summary of the recent findings revealed obvious weaknesses in both applied methods that substantially lower the chances of identifying true genetic causes and associations with sleep phenotypes. One of the main problems in genetic studies of normal sleep is the accuracy and common consensus of the studied sleep phenotypes. Many sleep patterns, such as sleep duration, latency, and quality, are quantitative traits and have been to date mainly studied by subjective measurements using questionnaires. Although many association studies have used standardized questionnaires, such as the Epworth Sleepiness Scale or the Horne and Östberg questionnaire, the value of these measures can often be contested as they do not take into account many confounding and environmental factors, such as shift work, voluntary sleep restriction, underlying medical conditions, stress, diet, and other lifestyle factors. Furthermore, several studies, or even discovery and replication phases within the same association study, are hardly comparable as different questionnaires or different scales were used to measure the same phenotype. Hence, association studies are often underpowered, although up to a few thousand subjects have been included. As a consequence, even much larger sample sizes would be needed to overcome these inconsistencies and to increase the power to detect truly associated genetic variants. In this context, the more precise a phenotype is, the lower the population size needed in association studies to identify responsible genes for a given phenotype. So far, the phenotypes used, such as self-reported sleep duration or timing, are extremely noisy, leading to inconsistent associations. Therefore, standardized and validated questionnaires are needed to define specific sleep phenotypes, similar to diagnostic criteria for medical diseases.

If questionnaires, or, in other words, subjective assessments of sleep phenotypes, are not able to correct for confounding factors, the solution is to focus on objective measures, such as actigraphy or, even better, polysomnographic phenotypes with strict inclusion criteria of study subjects. This is all the more an important issue considering the known and frequent discrepancy between self-assessed and objective sleep characteristics.[78] Efforts are ongoing to study large cohorts including genetics and the characterization of sleep phenotypes by polysomnographic studies.

Replication is crucial in genetic studies, but many of the identified associations have not been independently replicated. Thus, especially associations of sleep patterns to genes that have been identified on the basis of questionnaires should be considered preliminary.

In analogy to studies of rare and common diseases, the genetics of normal human sleep will most probably also move toward large-scale sequencing efforts by exome or whole genome sequencing. These technologies should allow us to identify rare, common, and structural genetic variants implicated in extreme forms of specific phenotypes, such as short and long sleepers with regard to sleep duration. Nevertheless, apart from a direct search for genetic factors regulating normal human sleep, this research will remain strongly dependent on basic research on sleep in other species as well as on the study of human sleep disorders that allows us to link phenotypes of sleep disorders to mechanisms regulating physiologic sleep and its biologic substrates and underlying genes.

CLINICAL PEARL

Various sleep phenotypes have a strong genetic component, but the underlying genetic contributions to these phenotypes still need to be fully discovered. Therefore, in clinical terms, genetic factors have a major impact on determining and predicting a wide range of sleep patterns in humans. This includes pharmacogenetic interactions, as illustrated by the involvement of genetic variants in the adenosinergic and dopaminergic systems in sleep and wakefulness responses to caffeine or modafinil, respectively.

SUMMARY

Sleep and the EEG are complex phenotypes, poorly understood at the molecular level. Nevertheless, evidence indicates that several sleep phenotypes have heritability estimates in the range of 30% to 50% and that the EEG (both waking and sleep EEG) is highly heritable (up to 98%). The heritability of sleep duration and sleep timing has been documented for decades, but genes controlling these phenotypes remain largely unknown. As opposed to animal models such as mice and *Drosophila*, in which molecular genetics has proved extremely successful in discovering genes involved in sleep and the sleep EEG, the genetics of human sleep has made little progress during the past 20 to 30 years. Based on sleep physiology and pharmacology, the candidate gene approach found substantial

effect of genetic variations in several neurotransmitter pathways (e.g., adenosinergic and dopaminergic). Although a single gene variant (*DEC2*) was found to be causally involved in sleep duration (short sleep), recent genome-wide association studies found genetic variants with small effects (explaining just a small percentage of variance in sleep length). Because the sleep EEG is highly heritable and mouse genetics has identified several genes with major effects, it is expected that large-scale electroencephalography-based sleep studies in humans might also reveal major genes regulating electroencephalographic features characteristic of sleep (delta and theta oscillations).

Sleep Mechanisms and Phylogeny

Chapter 7

Neural Control of Sleep in Mammals

Dennis McGinty; Ronald Szymusiak

Chapter Highlights

- Mammalian sleep and wake states are regulated by multiple neuronal systems located in the brainstem, diencephalon, and telencephalon. Although the isolated brainstem is capable of generating non–rapid eye movement (NREM)-like and REM-like states, lesions of several brainstem and forebrain regions in the otherwise intact brain can be associated with altered amounts of NREM and/or REM sleep.
- Arousal and waking are facilitated by chemically distinct neuronal groups localized in the midbrain, the posterior and lateral hypothalamus, and the basal forebrain. Functionally important arousal systems include histaminergic, orexinergic, serotoninergic, cholinergic, dopaminergic, and noradrenergic neurons.
- Arousal systems have widespread projections that regulate global aspects of arousal including changes in electroencephalographic, motor, sensory, autonomic, and integrative functions. Arousal systems control the excitability of thalamic and cortical neurons. Reduced activity in arousal systems promotes synchronous discharge of intracortical and thalamocortical circuits that underlie NREM sleep patterns on the electroencephalogram.
- The preoptic anterior hypothalamus—the preoptic area (POA)—contains gamma-aminobutyric acid (GABA)-ergic/galaninergic neurons that exhibit increased activity during NREM and REM sleep and respond to physiologic signals that increase sleep, such as warming, sustained wakefulness, and endogenous sleep factors. POA sleep-active GABAergic neurons project to histaminergic, orexinergic, serotoninergic, and noradrenergic arousal systems and, through coordinated inhibition of these arousal systems, promote transitions from waking to sleep.
- Sleep-promoting molecules are related to the multiple functions of sleep: adenosine to resupply brain energy reserves, cytokines to facilitate immune functions, growth hormone–releasing hormone to promote anabolic processes, unfolding protein response signals to prevent protein misfolding, and oxidative stress signaling molecules to prevent oxidative stress–induced cell damage.

DIVERSE BRAIN REGIONS MODULATE WAKING AND NON–RAPID EYE MOVEMENT SLEEP

Isolated Forebrain

The capacity of various brain regions to generate sleep and awake states was first studied by isolating or removing major regions. The physiology of the chronically maintained isolated forebrain, or chronic *cerveau isolé,* preparation has been examined in dogs and cats.[1] Immediately after complete midbrain transections, the isolated forebrain exhibits continuous slow waves and spindles on the electroencephalogram (EEG). Thus structures below the midbrain normally must facilitate awake-like EEG states. By contrast, if a brainstem transection was made at the midpontine level, an activated or wake-like forebrain EEG state predominated immediately after the transection, but with some residual episodes of EEG slow wave activity. In this preparation, the forebrain exhibited evidence of classical conditioning and other signs of an integrated waking state. These studies argue that neuronal groups localized between the midpons and upper midbrain are important for generating a waking (wakefulness)-like state. After 5 to 9 days of recovery, the chronic cerveau isolé rat preparation exhibits a circadian pattern of EEG activation and synchronization.[2] In this preparation, the creation of preoptic area (POA) lesions is followed by a continuously activated EEG pattern. Thus the isolated forebrain can generate a sustained wake-like state, and the POA must play a critical role in initiating the sleep-like EEG state of the isolated forebrain (see later). Wake-like and sleep-like EEG states appear to depend on a balance between wake-promoting and sleep-promoting systems. The terms *wake-like* and *sleep-like* are used here because these preparations cannot exhibit the full behavioral spectrum of sleep and wake states.

Diencephalon

Chronic diencephalic cats, in which the neocortex and striatum have been removed, exhibit behavioral waking with persistent locomotion and orientation to auditory stimuli, a quiet sleep-like or non–rapid eye movement (NREM)-like state with typical cat sleeping postures, and a REM-like state including muscle atonia, rapid eye movements, muscle twitches, and pontine EEG spikes.[3] EEG patterns recorded in the thalamus showed increased amplitude in conjunction with the NREM sleep–like state, although true spindles and slow waves were absent. The thalamic EEG exhibits desynchronization during the REM-like state.

In summary, the neocortex and striatum are not required for any behaviorally defined sleep-wake states, and an NREM-like state occurs in the absence of sleep spindles and slow waves.

Thalamus

Cats subjected to complete thalamectomy continue to exhibit episodes of EEG and behavioral sleep and waking, although spindles are absent on the EEG,[4] and the animals exhibit reductions in both NREM and REM sleep. Fatal familial insomnia[5] is a rare neurodegenerative disease in humans characterized by progressive autonomic hyperactivation, motor disturbances, loss of sleep spindles, and severe NREM sleep insomnia. Neuropathologic examination findings include severe cell loss and gliosis in the anterior medial thalamus, including the dorsomedial nucleus. However, patients with paramedian thalamic stroke, with magnetic resonance imaging-verified damage to the dorsomedial and centromedial nuclei, present with either severe hypersomnolence or increased daytime sleepiness, not insomnia.[6] In summary, the thalamus plays a critical role in regulating cortical EEG patterns during waking and sleep, and specific regions within this structure appear to have either wake-promoting or hypnogenic functions.

Lower Brainstem

After recovery from the acute effects of the complete midbrain transections in cats (as just described), the lower brainstem can generate rudimentary behavioral waking, an NREM-like state, and a REM-like state.[3] Waking is characterized by crouching, sitting, attempts to walk, dilated pupils, and head orientation to noises. In the first sleep-like state, these cats lie in a random position, pupils exhibit reduced but variable miosis, and eyes exhibit slow and nonconjugate movements, and the animals can be aroused by auditory or other stimuli. If this stage is not disturbed, these cats enter another stage, characterized by complete pupillary miosis, loss of neck muscle tone, and rapid eye movements, identifying a REM-like state. Additional studies support the hypothesis that the lower brainstem contains sleep-facilitating processes. Low-frequency electrical stimulation of the dorsal medullary reticular formation in the nucleus of the solitary tract produced neocortical EEG synchronization.[7] Lesioning or cooling of this site was followed by EEG activation.[8] Recently, a population of sleep-active neurons has been identified in the rostral medulla of rats and mice, located lateral and dorsal to the facial nerve.[9] Many of these sleep-active medullary neurons express inhibitory neurotransmitters such as gamma-aminobutyric acid (GABA) or glycine (see later). Excitotoxic lesions of the parafacial zone are associated with increased waking and decreased NREM sleep.[9]

In summary, widespread structures in the mammalian nervous system, from the neocortex to the lower brainstem, have the capacity to facilitate both sleep-like and waking-like states and to modulate the amounts of sleep.

RETICULAR ACTIVATING SYSTEM AND DELINEATION OF AROUSAL SYSTEMS

The transection studies just described support the concept of a pontomesencephalic wake-promoting or arousal system. No discovery was historically more significant than the description of the reticular activating system (RAS) by Moruzzi and Magoun.[10] Introduction of large lesions of the core of the rostral pontine and mesencephalic tegmentum was followed by persistent somnolence and EEG synchronization, and electrical stimulation of this region induced arousal from sleep. Interruption of sensory pathways did not affect EEG activation. It was hypothesized that cells in the RAS generated forebrain activation and wakefulness.

The concept of the RAS has been superseded by the finding that arousal is facilitated not by a single system but instead by several discrete neuronal groups localized within and adjacent to the pontine and midbrain reticular formation and its extension into the hypothalamus (Figure 7-1). These neuronal systems are differentiated by the expression of enzymes that synthesize specific neurotransmitters and neuromodulators. These include neurons that synthesize serotonin,

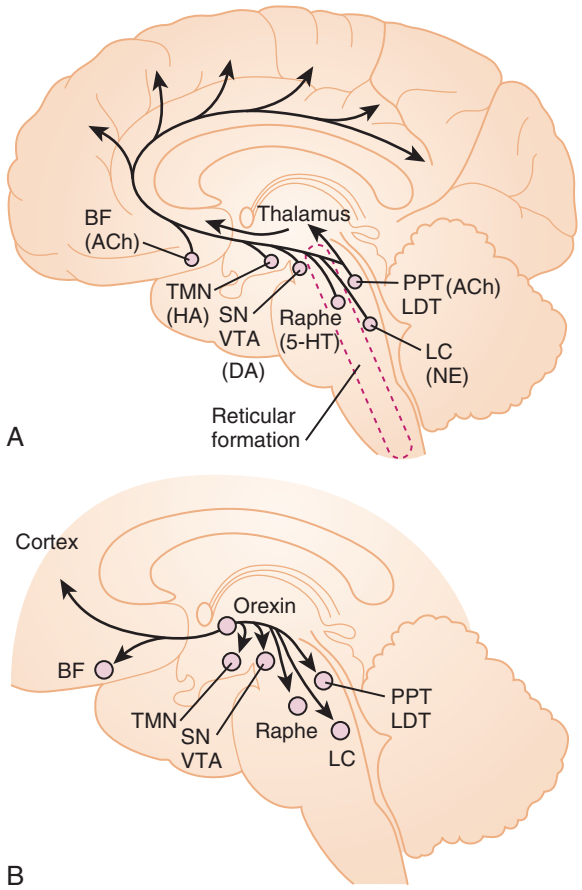

Figure 7-1 A, Sagittal view of a brain providing an overview of the wake-control networks described in the text. The upper brainstem, posterior and lateral hypothalamus, and basal forebrain (BF) contain groups of neurons with identified phenotypes with arousal-inducing properties. These clusters include neurons expressing serotonin (5-HT), norepinephrine (NE), acetylcholine (ACh) in both pontomesencephalic and basal forebrain clusters, dopamine (DA), and histamine (HA). **B,** Sagittal view of brainstem and diencephalon showing localization of orexin-containing neurons and their projections to both forebrain and brainstem. All of these groups facilitate EEG arousal (waking and REM) and/or motor-behavioral arousal (waking). The arousal systems facilitate forebrain EEG activation both through the thalamus and the basal forebrain and through direct projections to neocortex. Arousal systems also facilitate motor-behavioral arousal through descending pathways. norepinephrine (noradrenaline), histamine, acetylcholine, and orexin/hypocretin (herein called orexin). Each of these systems has been studied extensively in the context of the control of specific aspects of waking behaviors. Presented next is a brief overview of each of these *arousal systems,* focusing on their contribution to generalized brain arousal or activation. As background, some general properties of these neuronal systems are summarized in the following list:

1. Arousal is a global process, characterized by concurrent changes in several physiologic systems, including autonomic, motor, endocrine, and sensory systems, as well as in EEG tracings. All of the arousal systems share one critical property: Their neurons give rise to long, projecting axons with extensive terminal fields that impinge on multiple regions of the brainstem and forebrain. In this chapter, the emphasis is on the ascending projections from the brainstem and hypothalamus to the diencephalon, limbic system, and neocortex, because these are particularly germane to the generation of cortical arousal. Some arousal systems give rise to descending projections as well, which also are likely to play a role in regulating certain properties of sleep–wake states, such as changes in muscle tone and autonomic function.
2. Most arousal systems have been studied by recording the discharge patterns of neurons in "freely moving" animals, relative to those in spontaneously occurring wake and sleep states. Increased discharge during arousal or wake states compared with sleep constitutes part of the evidence for an arousal system.
3. The actions of a neurotransmitter on a target neuronal system are determined primarily by the properties of the receptors in the target. The neurotransmitters and neuromodulators underlying arousal systems each act on several distinct receptor types, with diverse actions. In addition, postsynaptic effects are regulated by transmitter-specific "reuptake" molecules, which transport the neurotransmitter out of the synaptic space, terminating its action. Pharmacologic actions are usually mediated by actions on specific receptor types or transporters (see examples further on).
4. Chronic lesions of individual arousal systems or genetic knockout of critical molecules have only small or sometimes no effect on sleep-wake patterns (with the exception of serotonin and orexin knockouts; see later), even though acute manipulations of these same systems have strong effects on sleep-wake. The absence of chronic lesion or knockout effects is likely to be due to the redundancy of the arousal systems, such that, over time, deficiency in one system is compensated for by other systems or by changes in receptor sensitivity.
5. Electrophysiologic studies show that the arousal systems normally are activated and deactivated within seconds of a change in behavioral state. Thus effects of acute experimental manipulations of neurotransmitters that mediate arousal, as generated by acute administration of drugs, may best mimic the normal physiologic pattern and be more informative than chronic lesions regarding their function.
6. REM sleep is a state associated with behavioral and muscle quiescence and intense cortical EEG arousal. In parallel with these two aspects of REM sleep, arousal systems can be classified into two types: ones that are "off" in the REM state, befitting its sleep-like property, and others that are "on" in the REM state, befitting its wake-like properties. Some arousal-promoting systems (summarized later) also play a role in REM sleep control. Detailed analyses of the control of the role of these systems in REM sleep are presented in Chapter 8.

WAKE-ON, RAPID-EYE-MOVEMENT–OFF AROUSAL SYSTEMS

Serotonin

Neurons containing serotonin, or 5-hydroxytryptamine (5-HT), are found in the dorsal raphe and median raphe nuclei of the midbrain. These neurons project to virtually all regions of the diencephalon, limbic system, and neocortex. It initially was hypothesized that serotonin might be a sleep-promoting substance,[11] but evidence shows that the immediate effect of serotonin release is arousal (as reviewed by Ursin[12]). Although some heterogeneity is typical, the

discharge rates of most dorsal and median raphe neurons are highest during waking and lower during NREM, with minimal discharge in REM. Release of serotonin in the forebrain is highest in waking. Because of the diversity of serotonin receptors (there are at least 14 types), the effects of serotonin on target neurons are complex. Some receptor types are inhibitory, some are excitatory. At least one class of receptors, 5-HT_{2A}, appears to facilitate NREM sleep, because 5-HT_{2A}–knockout mice have reduced NREM.[13] Another type, 5-HT_{1A}, is inhibitory to REM sleep: 5-HT_{1A}–knockout mice have increased REM.[14] Selective serotonin reuptake inhibitors and serotonin-norepinephrine reuptake inhibitors, which augment the actions of serotonin, are used to treat a variety of medical and psychiatric problems, and some drugs in this class have arousing or alerting properties.

Norepinephrine

Norepinephrine-containing neuronal groups in mammals are found throughout the brainstem, but the primary nucleus giving rise to ascending projections is the locus coeruleus. Norepinephrine neurons in this nucleus project throughout the diencephalon, forebrain, and cerebellum. Most locus coeruleus neurons exhibit regular discharge during waking, reduced discharge during NREM sleep, and near-complete cessation of discharge in REM sleep, a pattern congruent with a role in behavioral arousal.[15] Acute inactivation of the locus coeruleus or introduction of a lesion in the ascending pathway from this nucleus increases slow wave EEG activity during sleep.[16] Distinct roles for alpha-1, alpha-2, and beta norepinephrine receptor types are established. Direct application of alpha-1 and beta agonists in POA and adjacent basal forebrain sites induces increased wakefulness (reviewed by Berridge[17]). The arousal-producing effects of psychostimulant drugs such as amphetamines depend partly on induction of increased norepinephrine release and inhibition of norepinephrine reuptake, as well as on enhanced dopamine action (see later).

Histamine

Histamine-containing neurons in mammals are discretely localized within the tuberomamillary nucleus (TMN) and adjacent posterior hypothalamus (PH). Histamine neurons project throughout the hypothalamus and forebrain, including to the neocortex, as well as to the brainstem and spinal cord (reviewed by Haas and colleagues[18]). Administration of histamine type 1 (H_1) receptor antagonists (antihistamines) that penetrate the blood-brain barrier can result in sedative effects.[18] Transient inactivation of the TMN region results in increased NREM sleep.[19] Histamine neurons exhibit regular discharge during waking, greatly reduced discharge during NREM sleep, and cessation of discharge in REM sleep.[20] These neurons express H_3-type histamine receptors that are inhibitory, so-called autoreceptors. Thus the neurons are inhibited by histamine. Administration of an antagonist of this receptor causes disinhibition of histamine neurons and increased waking.[21]

Orexin

The loss of orexin neurons is known to underlie the human disease narcolepsy, the major symptoms of which are cataplexy and excessive sleepiness.[22,23] Orexin-containing neurons are localized within the midlateral hypothalamus, and like other arousal systems, they give rise to projections to all brain regions including the brainstem.[24] Among the targets of orexin terminals are other arousal-promoting neurons including histamine, 5-HT, and norepinephrine neurons. Orexin-containing neurons are active in waking, and they are "off" in both NREM and REM sleep.[25,26] Local administration of orexin in several brain sites induces arousal.[27] (See also Chapter 8.)

WAKE-ON, RAPID-EYE-MOVEMENT–ON AROUSAL SYSTEMS

Acetylcholine

Acetylcholine (ACh)-containing neurons are localized within two regions: the dorsolateral pontomesencephalic reticular formation, including the pedunculopontine tegmental (PPT) and laterodorsal tegmental (LDT) nuclei, and the basal forebrain.[28] The pontomesencephalic ACh neuronal group projects to the thalamus, hypothalamus, and basal forebrain; the basal forebrain group projects to the limbic system and neocortex. Neurons in both groups exhibit higher rates of discharge in both waking and REM sleep than in NREM sleep,[29] and release of ACh also is increased in these states.[30] Pharmacologic blockade of ACh receptors induces EEG synchrony and reduces vigilance, and inhibition of the ACh-degrading enzyme cholinesterase enhances arousal.[31]

Dopamine

Dopamine-containing neurons are localized primarily within the substantia nigra and the adjacent ventral tegmental area of the midbrain and the basal and medial hypothalamus.[32] Putative dopaminergic neurons in the ventral tegmental area exhibit highest activity in waking and REM sleep. An additional population of dopamine-containing wake-active neurons is localized in the rat ventral periaqueductal gray matter, and destruction of ventral periaqueductal gray matter dopaminergic neurons with 6-hydroxy-dopamine increases daily sleep time by 20%.[33] Release of dopamine in the frontal cortex is higher during wakefulness than during sleep.[34] Dopamine is inactivated primarily through reuptake by the dopamine transporter. Stimulant drugs such as amphetamines and modafinil act primarily through dopamine receptors, particularly by binding to and suppressing the dopamine transporter, reducing reuptake.[35] The degeneration of the nigrostriatal dopamine system is a neuropathologic basis of Parkinson disease, which can be accompanied by excessive daytime sleepiness.[36] Patients with this disease, however, exhibit widespread neuronal loss, including of orexinergic neurons,[37] which also may contribute to their sleepiness. Dopamine agonists used to treat periodic limb movement in sleep and restless legs syndrome do not usually induce arousal, probably because they have effects on both presynaptic and postsynaptic dopamine receptors; presynaptic receptors inhibit transmitter release, counteracting postsynaptic stimulation.

Glutamate

Glutamate is the most widespread excitatory neurotransmitter of the brain. Glutamate-containing neurons are found throughout the brain, including in the core of the pontine and midbrain reticular formation.[38] Extracellular levels of glutamate in the cortex and in the hypothalamus are elevated during waking and REM sleep, compared with NREM sleep.[39,40] Arousal is increased by application of glutamate to

many sites.[41] Its actions are mediated by receptors controlling membrane ion flux, including the *N*-methyl-D-aspartate (NMDA) receptor, and "metabotrophic" receptors controlling intracellular processes. Humans may be exposed to systemic NMDA receptor antagonists in the form of anesthetics (e.g., ketamine) or recreational drugs (e.g., phencyclidine). The effects are dosage-dependent: Low dosages produce arousal, and high dosages produce sedation. In rats, exposure to NMDA antagonists induces a potent long-lasting enhancement of NREM slow wave activity.[42]

SLEEP-PROMOTING MECHANISMS

As noted in the foregoing review of evidence for multiple neurochemically specific arousal systems, the activity of each of these neuronal groups is reduced during NREM sleep. In most groups, the reduction in neuronal discharge precedes EEG changes that herald sleep onset. How is the process of sleep onset orchestrated?

Rostral Hypothalamic Sleep-Promoting System

Sleep-Active Neurons in the Preoptic Area

More than 70 years ago, Von Economo postulated a POA sleep-promoting area on the basis of his observation that postmortem examinations in patients with encephalitis who had severe insomnia showed inflammatory lesions in this area of the brain.[43] Patients with hypersomnia had lesions in the vicinity of the posterior hypothalamus (PH). To von Economo, these observations suggested the concept of opposing hypothalamic sleep-promoting and wake-promoting systems. In rats, symmetric bilateral transections of the POA resulted in complete sleeplessness, and symmetric bilateral transections of the PH caused continuous sleep.[44] Rats that underwent both POA and PH transections exhibited continuous sleep, as with PH transections alone. This finding was interpreted as showing that the POA normally inhibits the PH wake-promoting region. The PH wake-promoting system can now be understood as the rostral extension of arousal-promoting systems and pathways summarized earlier.

The existence of a sleep-promoting mechanism in the POA has been confirmed by a variety of methods. Experimental bilateral lesions of the POA with diameters of 1 to 2 mm in rats and cats induce partial sleep loss. Larger bilateral lesions (3 to 5 mm in diameter) that extend into the adjacent basal forebrain are associated with more severe insomnia (as described in our review of this work[45]). After introduction of POA lesions that result in partial sleep loss, residual sleep is characterized by reduced slow wave (delta) EEG activity.[46] Delta EEG activity in NREM sleep is augmented by POA warming (see later). Because delta activity is recognized as a marker of enhanced sleep drive, this finding suggests that POA output contributes to the regulation of sleep drive. Electrical or chemical stimulation of the POA evokes EEG synchronization and behavioral sleep.

The identification of sleep-active POA neurons has been advanced by the application of the c-Fos immunostaining method.[47] Rapid expression of the proto-oncogene *c-fos* has been identified as a marker of neuronal activation in many brain sites and in multiple cell types.[48] Thus c-Fos immunostaining permits functional mapping of neurons, identifying neurons that were activated in the preceding 30 to 60 minutes. After sustained sleep, but not waking, a discrete cluster of neurons exhibiting c-Fos is found in the ventrolateral preoptic area (VLPO).[47] The VLPO is located at the base of the brain, lateral to the optic chiasm. Sleep-related Fos immunoreactive neurons also are localized within the rostral and caudal median preoptic nucleus (MnPN).[49] The MnPN is a midline cell group that widens to form a "cap" around the rostral end of the third ventricle. Examples of c-Fos immunostaining and the correlations between c-Fos counts and sleep amounts are shown in Figure 7-2. The number of sleep-related Fos immunoreactive neurons in the MnPN is increased in rats exposed to a warm ambient temperature, in association with increased NREM sleep.[49]

The VLPO and the MnPN contain a high density of neurons with sleep-related discharge.[50,51] Most sleep-active neurons in these nuclei are more activated during both NREM and REM sleep than in awake states (Figure 7-3). VLPO neurons typically exhibit increases in activity during spontaneous transitions between waking and sleep and display a progressive increase in discharge rate from light to deep NREM sleep. MnPN neurons often show a gradual increase in firing rates *before* sleep onset, elevated discharge rates during NREM sleep, and a small but significant additional increase in discharge rate during REM sleep.

VLPO and MnPN sleep regulatory neurons are dynamically responsive to changes in homeostatic sleep pressure induced by sleep deprivation. In the MnPN, c-Fos expression in GABAergic neurons is increased after a brief (2- to 3-hour) period of sleep deprivation, even if no opportunity for recovery sleep is permitted.[52] Fos expression in GABAergic VLPO neurons is increased during recovery sleep subsequent to sleep deprivation.[52] When the neuronal discharge of individual sleep-active neurons in the MnPN and VLPO is continuously recorded across baseline sleep-wake, sleep deprivation, and recovery sleep, dynamic responses to changing homeostatic sleep pressure are evident[53] (Figure 7-4). MnPN and VLPO neurons identified as sleep-active during spontaneous baseline sleep exhibit progressive increases in waking discharge rate during sleep deprivation that are correlated with behavioral indices of sleep pressure (Figure 7-4). NREM sleep-related discharge is elevated in comparison with baseline NREM sleep early in the recovery period and then declines in association with the reduction in EEG delta power.[53] Thus sleep-active neurons in the MnPN/VLPO are involved in orchestrating spontaneous wake-sleep transitions (see further on) and function as components of the neuronal circuits that mediate homeostatic responses to sustained wakefulness.

Orchestration of Sleep by Sleep-Promoting Circuits of the Preoptic Area

How do POA sleep-active neurons initiate and sustain sleep? VLPO neurons that exhibit c-Fos immunoreactivity during sleep express glutamic acid decarboxylase, the synthetic enzyme that produces the *inhibitory* neurotransmitter GABA. A majority of MnPN neurons that exhibit sleep-related Fos-immunoreactivity also express glutamic acid decarboxylase.[54] VLPO neurons send anatomic projections to histamine neurons in the TMN.[55] Additional projections of the VLPO include the midbrain dorsal raphe and the locus coeruleus. The MnPN also projects to both the dorsal raphe and locus coeruleus.[56] Both MnPN and VLPO also project to the perifornical lateral hypothalamic area, the location of cell bodies of the orexin arousal system.[57] Thus discharge of VLPO and MnPN

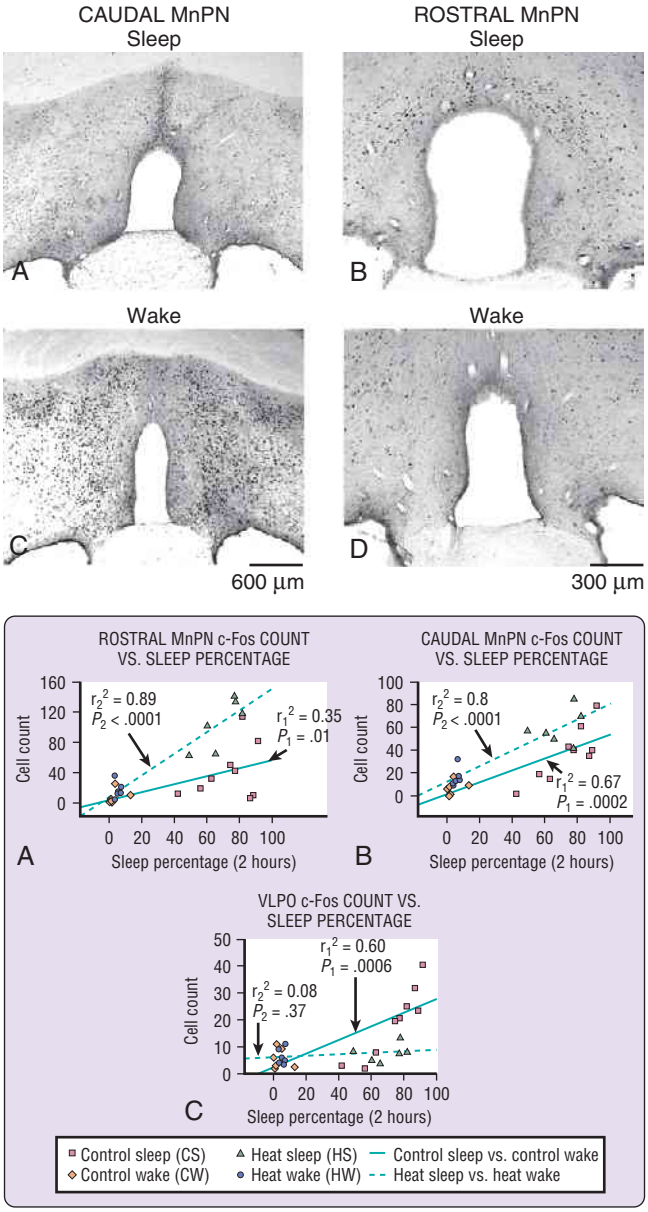

Figure 7-2 *Upper panel:* Examples of c-Fos immunostaining of preoptic area (POA) neuronal nuclei, identified by *dark spots* after either sustained spontaneous sleep or wakefulness. c-Fos immunostaining is a marker of neuronal activation and is a method for mapping the localization of sleep-active neurons in the brain. After sleep, increased staining was seen in the midline **(A)** or around the top of the third ventricle **(B)** relative to the wake samples (**C** and **D**). These sites correspond to the caudal and rostral median preoptic nucleus (MnPN). Similar results were seen in the ventrolateral preoptic area (VLPO). In other POA sites, c-Fos immunostaining was seen after both waking and sleep. *Lower panel:* Regression functions and correlations relating c-Fos counts and sleep amounts before sacrifice among individual animals. In all sites, high correlations were found between sleep amounts and c-Fos counts at a normal ambient temperature. Groups of animals were studied in both normal and warm ambient temperatures. In a warm ambient temperature, c-Fos counts after sleep and correlations between counts and sleep amounts were increased in MnPN sites (**A** and **B**), but they were suppressed in the VLPO **(C)**. (From Gong H, Szymusiak R, King J, et al. Sleep-related c-Fos expression in the preoptic hypothalamus: effects of ambient warming. *Am J Physiol Regul Integr Comp Physiol* 2000;279:R2079-88.)

GABAergic neurons during sleep is expected to release GABA at these sites. Indeed, GABA release is increased during NREM sleep and further increased in REM sleep in the PH, doral raphe, and locus coeruleus.[58-60] Sleep-active neurons in VLPO and MnPN exhibit discharge-rate-change profiles across the wake-NREM-REM cycle that are reciprocal to those of wake-promoting histamine, 5-HT, norepinephrine, and orexin neurons (Figure 7-5). These findings support a hypothesis that POA sleep-active neurons, through release of GABA, inhibit multiple arousal systems.

The PH and LH areas also facilitate both motor and autonomic activation, and these processes are under GABAergic control.[61] Sleep-related GABAergic inhibition of PH and LH provides a basis for sleep-related deactivation of autonomic and motor functions. POA lesions suppress REM as well as NREM sleep. Because sustained NREM sleep normally precedes REM sleep, REM sleep loss after POA damage may be a secondary consequence of NREM sleep disturbance. Alternatively, POA mechanisms may directly facilitate REM sleep as well as NREM sleep.

GABAergic neurons in the VLPO region are inhibited by ACH, 5-HT, and norepinephrine.[62] MnPN neurons are inhibited by norepinephrine.[63] Thus POA sleep-active neurons inhibit arousal systems, and arousal systems inhibit POA sleep-active neurons. These mutually inhibitory processes are hypothesized to underlie a bi-stable sleep-wake switch (see Figure 7-5).[64] Activation of arousal systems inhibits sleep-active neurons, thereby removing inhibition of arousal systems and facilitating stable episodes of waking. On the other hand, activation of sleep-promoting neurons would inhibit arousal-related neurons, thereby disinhibiting sleep-promoting neurons and promoting consolidated sleep episodes. This model provides a mechanism for the stabilization of both sleep and waking states.

Abnormalities in one or more of the components of this "flip-flop" system could result in less stable sleep and wake states, a possible explanation for the fragmentation of sleep in sleep disorders in which insomnia is an element, and for the fragmentation of waking in narcolepsy.

Sleep Regulatory Functions of Melanin-Concentrating Hormone Neurons

Neurons expressing the inhibitory peptide melanin-concentrating hormone (MCH) are located in the PH, where they are intermingled with orexin neurons (reviewed by Bittencourt[65]). A majority of MCH neurons also express the inhibitory neurotransmitter GABA. Rats possess approximately twice as many MCH neurons as orexin neurons, with a more widespread distribution throughout the hypothalamus. MCH groups include a medial cluster found adjacent to the third ventricle, a perifornical cluster, a far lateral cluster located medial to the internal capsule and extending to the zona incerta, and a more posterior-medial group localized in the supramammalary region.[65] MCH neurons have anatomic interconnectivity with hypothalamic and brainstem nuclei implicated in sleep-wake regulation.[65,66]

Intracerebroventricular injection of MCH was found to increase NREM and REM sleep, identifying a potential sleep regulatory role for the peptide.[67] Subsequent work pointed to a role for MCH neurons in REM sleep control. Increased c-Fos immunoreactivity was observed in MCH neurons during REM-enriched sleep after 72 hours of REM sleep

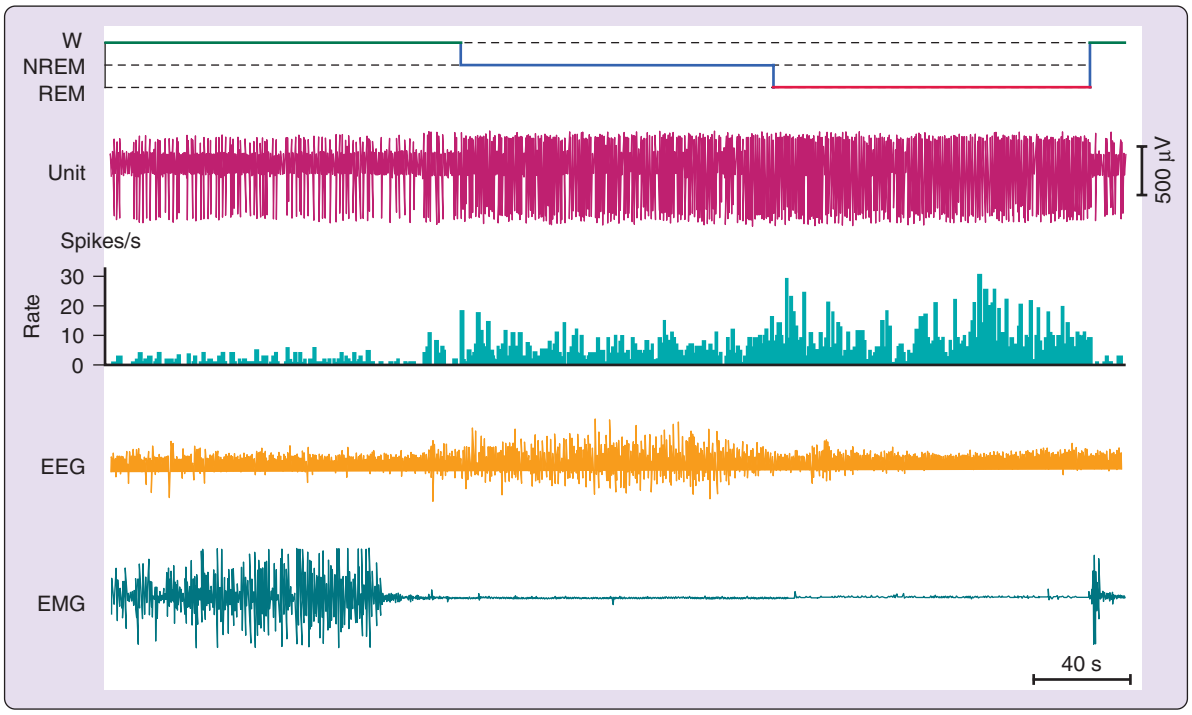

Figure 7-3 Example of sleep-active neurons in the median preoptic nucleus (MnPN). Shown is a continuous recording of discharge of an MnPN neuron during a wake (W)-NREM-REM cycle (*top*). Discharge rate increased at the onset of sleep, as indicated by the increased amplitude of the electroencephalogram (EEG). Discharge rate increased further in association with REM sleep (*right*). Such sleep-active neurons constituted a majority of those encountered in the median preoptic nucleus (MnPN) and the ventrolateral preoptic area (VLPO). The presence of sleep-active neurons is one critical piece of evidence for the importance of a brain region in the facilitation of sleep. EMG, Electromyogram. deprivation.[68] REM sleep–related c-Fos expression was found in MCH neurons with descending projections to critical brainstem nuclei implicated in REM sleep control.[69] In the only published report of sleep-wake discharge pattern in identified MCH neurons, a small sample of neurons located in the perifornical area were activated during REM sleep relative to the status of such neurons during waking and NREM sleep,[70] consistent with a hypothesized REM sleep regulatory role. Targeted optogentic excitation of MCH neurons during NREM sleep was found to promote transitions to REM sleep,[71,72] whereas stimulation at REM sleep onset prolonged REM bout durations.[71] Release of GABA by MCH neurons in response to optogenetic stimulation may be responsible for REM sleep effects.[71] Optogenetic silencing of MCH neurons had no effect on REM sleep measures,[72] indicating that activation of MCH neurons is sufficient but not necessary to promote REM sleep from a background of NREM sleep.

Other selective genetic manipulations of MCH neuronal function point to a key role for these neurons in the control of sleep onset and NREM sleep. Continuous optogenetic excitation of MCH neurons (by light pulses delivered for 1 minute every 5 minutes at 10 Hz) at the start of the dark (active) phase in mice reduced sleep latency, decreased the duration of waking episodes by 50%, and increased NREM and REM sleep time.[73] In the human brain, MCH release, as measured in the amygdala, is maximal at sleep onset.[74] Widespread, conditional ablation of the MCH neuronal population by cell-specific expression of diphtheria toxin A increased wakefulness and decreased NREM sleep without affecting REM sleep.[72] Collectively, the findings suggest a heterogeneity of MCH neuronal function, with some neurons interacting with circuits that control REM sleep and another population of MCH neurons functioning to promote NREM sleep onset and maintenance.

Cortical Sleep-Active Neurons

A population of cortical GABAergic interneurons specifically activated during sleep has been described.[75] In addition to GABA, these neurons colocalize immunoreactivity for neuronal nitric oxide synthase (nNOS) and the substance P receptor, NK1.[75,76] Expression of c-Fos immunoreactivity in these neurons is correlated with time spent in NREM sleep and with NREM EEG delta power. Fos expression during recovery sleep is proportional to the duration of previous time awake, suggesting that sleep-active cortical nNOS neurons are inhibited during waking and activated in response to homeostatic sleep pressure.[76,77] Waking inhibition may be mediated by synaptic input from basal forebrain cholinergic neurons and from monoaminergic inputs arising from the TMN, dorsal raphe nucleus, and locus coeruleus.[76] It is unclear if activation during sleep is due to disinhibition caused by sleep-related silencing of subcortical input, or if sleep-related excitation from neuronal and/or neuromodulatory sources (e.g., adenosine, cytokines) also is involved.

Although sleep-active cortical nNOS neurons are found in multiple cortical areas in rats and mice, the density of these neurons is low. These cortical neurons appear to be a subset of type II nNOS interneurons—that is, those with the largest

cell bodies, which are a source of cortico-cortical and other long-range projections (as reviewed by Wisor and colleagues[77]). In keeping with this anatomic feature, sleep-active nNOS neurons are well suited to organize synchronous discharge across large ensembles of cortical neurons that are characteristic of deep NREM sleep.[76,77] These neurons may be a component of local cortical circuits responsible for use-dependent augmentation of EEG slow wave activity.[77-79] The differential functional roles of GABA versus NOS signaling by cortical sleep active neurons are unknown.

THALAMIC-CORTICAL INTERACTIONS AND GENERATION OF THE SLEEP ELECTROENCEPHALOGRAM

Changes in cortical EEG patterns usually are considered to be the defining feature of NREM sleep in mammals. Briefly reviewed here is the current understanding of thalamocortical mechanisms underlying NREM sleep EEG patterns, and of how modulation of thalamocortical circuits by arousal and sleep regulatory neuronal systems has an impact on key features of the sleep EEG.

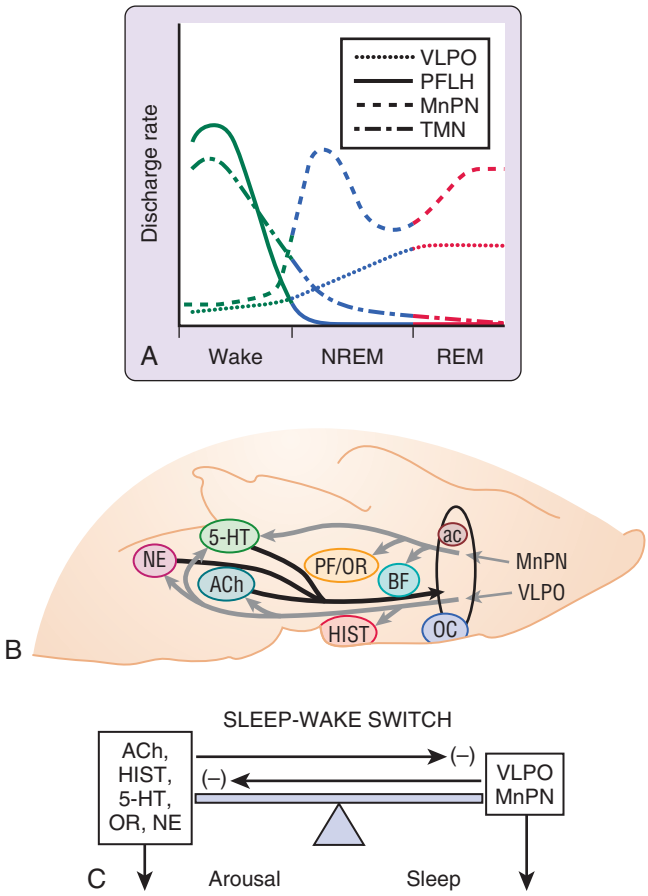

Figure 7-5 Interactions of the preoptic area (POA) sleep-promoting neuronal system with arousal systems that can account for the orchestration of the sleep process. **A,** The neuronal discharge rates across the wake-NREM-REM cycle of sleep-active neurons from the ventrolateral preoptic area (VLPO) and the median preoptic nucleus (MnPN), and from arousal-related (wake-active) neurons in the perifornical lateral hypothalamus (PFLH) and tuberomammillary nucleus (TMN). These neuronal groups generally have reciprocal discharge patterns, although MnPN and VLPO neurons exhibit peak activity at different times during NREM episodes. The wake-active, NREM-diminished, REM-off discharge pattern shown for TMN and a subgroup of PFLH neurons also is characteristic of putative serotoninergic neurons of the dorsal raphe nucleus (DR) and putative noradrenergic neurons of the locus coeruleus (see also **C**). **B,** Sagittal section of the diencephalon and upper brainstem of the rat showing anatomic interconnections of MnPN and VLPO neurons with arousal-related neuronal groups. The MnPN and VLPO distribute projections to sites of arousal-related activity including the (1) basal forebrain, (2) PFLH, which includes orexin-containing neurons, (3) histamine (HIST)-containing neurons of the tuberomammillary nucleus, (4) pontomesencephalic acetylcholine (ACh)-containing neurons, (5) pontomesencephalic serotonin (5-HT)-containing neurons, and (6) noradrenergic (norepinephrine [NE]-containing) neurons of the pons, particularly the locus coeruleus (LC). 5-Hydroxytryptamine (5-HT), NE, and ACh arousal-related neurons provide inhibitory feedback to sleep-active neurons. The arousal-related neuronal groups also have widespread additional ascending and descending projections that control state-related functions throughout the brain. **C,** Wakefulness and sleep are each facilitated by several neurotransmitters and neuromodulators. ACh-, 5-HT-, NE-, histamine (HA)-, and glutamate (Glu)-expressing neurons directly activate thalamocortical and cortical neurons as well as hypothalamic and basal forebrain nuclei to promote waking. Orexin (OR) neurons facilitate arousal through direct effects and through excitation of ACh, 5-HT, NE, and HA neurons. Sleep-promoting neurons expressed in the preoptic area are gamma-aminobutyric acid (GABA)-ergic and act by inhibiting wake-promoting neurons. Other sleep-promoting molecules, adenosine (AD), endoplasmic reticulum (ER) stress signaling molecules, growth hormone–releasing hormone (GHRH), certain cytokines, and signals of oxidative stress such as oxidized glutathione (GSSG) (see text), are thought to act indirectly, by either facilitating sleep-active neurons or inhibiting wake-promoting neurons, or both in the case of AD. Subsets of wake-promoting neurons and sleep-promoting neurons are mutually inhibitory. Accordingly, if one system is more strongly activated, the opposing system is inhibited, with consequent reduced feedback inhibition of the initiating neurons, thereby facilitating sleep-wake state stability, as in an electrical "flip-flop" switch. The circadian clock in the SCN regulates the timing of sleep by exciting arousal systems during the active phase of the day and by exciting or disinhibiting sleep-promoting neurons during the rest phase. Because of the redundancy of both wake-promoting and sleep-promoting systems, deficiency of any one system may have only small effects on the amount of sleep but may reduce the stability of sleep. ac, Anterior commissure. These discharge patterns can be recorded in neurons from isolated slices of thalamus. **C** and **D,** In vitro intracellular recordings of a relay neuron from guinea pig thalamus. In **C,** direct current (DC) injections are labeled 1 and 2, and recordings of intracellular voltage, 3 and 4. Spontaneous resting potential for the cell is indicated by the *dashed line*. A depolarizing current step (1) delivered at resting potential (>–65 mV) evokes a tonic depolarizing response in the neuron (3) that is subthreshold for action potential generation. When membrane potential is rendered more positive by DC injection, the same depolarizing step (2) evokes tonic generation of fast action potentials (*arrow*) that persist for the duration of the depolarizing pulse. In **D,** the neuron has been hyperpolarized below resting potential (<–65 mV) by negative DC injection, and the low threshold Ca^{2+} current (I_t) is activated. When a depolarizing pulse is applied on the background of hyperpolarization, a slow Ca^{2+} spike is evoked (*arrow*), and it is crowned by a high-frequency burst of fast Na^+ action potentials. I_t is inactivated in response to the Ca^{2+}-mediated depolarization, and membrane potential sags toward the hyperpolarized level despite the continuance of the depolarizing current step. Thalamocortical circuits exhibit two fundamentally different modes of operation across the sleep-wake cycle: a state of tonic activation, or desynchrony, during waking and REM sleep and a state of rhythmic, synchronized activity that is characteristic of NREM sleep.[80] The two functional modes of thalamocortical activity are evident at the level of single neurons. During waking and REM sleep, thalamocortical neurons exhibit tonic firing of single action potentials (Figure 7-6, *A*) that are modulated by the levels of excitatory input from thalamic afferents, including specific sensory afferents.[80,81] During NREM sleep, relay neurons discharge in high-frequency bursts of action potentials, followed by long pauses (see Figure 7-6, *B*).

These two modes of action potential generation reflect the expression of intrinsic properties of thalamocortical neurons, and a specialized, voltage-sensitive Ca^{2+} current plays a critical role.[82] This Ca^{2+} current, known as the low-threshold or transient Ca^{2+} current (I_t), is inactivated (nonfunctional) when the membrane potential of thalamic relay neurons is relatively depolarized (less negative than –65 mV). Thus, when depolarizing input is delivered to a relay neuron that is resting at this level of membrane polarization, the cell responds with tonic single-spike firing (see Figure 7-6, *C*). When relay neurons are hyperpolarized (membrane potential more negative than –65 mV), I_t becomes activated, and depolarizing input evokes a slow Ca^{2+}-mediated depolarization (100 to 200 milliseconds in duration) that is crowned by a burst of three to eight fast Na^+-mediated action potentials (see Figure 7-6, *D*). There is a pause in the generation of fast action potentials after the burst, because I_t is self-inactivated by the Ca^{2+}-mediated depolarization, and membrane potential falls below the threshold for action potential generation and is restored back to the resting, hyperpolarized state (see Figure 7-6, *D*). Thus the properties of I_t equip thalamocortical neurons with the ability to generate action potentials in two different modes: (1) tonic firing when stimulated from a relatively depolarized resting state and (2) burst-pause firing from a hyperpolarized resting state.[80,81]

The major NREM sleep EEG rhythms—spindles, delta waves, and slow oscillations—all arise through a combination of intrinsic neuronal properties (e.g., I_t) and the synaptic organization of cortical and thalamic circuits.[83] A schematic of the core circuitry responsible for the generation of sleep rhythms in the EEG is shown in Figure 7-7. Thalamocortical relay neurons receive excitatory input from sensory neurons and from several of the brainstem arousal systems that function to promote depolarization and tonic firing in relay cells during waking. During waking, this excitation is faithfully conveyed by ascending thalamocortical axons to the functionally relevant area of cortex for processing and integration. Thalamic relay neurons also send a collateral projection to the adjacent portion of the thalamic reticular nucleus (RE), which is a thin band of neurons that surrounds most thalamic relay nuclei. RE neurons are GABAergic, and they send an inhibitory projection back to relay neurons. These reciprocal connections between relay and RE neurons are thought to be important for aspects of waking thalamic function.

The final critical piece of the basic circuitry for consideration is the feedback projection from layer VI pyramidal cells in cortex to both thalamic relay neurons and RE neurons. Corticothalamic projections are topographically organized so that each cortical column has connectivity with the same relay neurons from which they derive thalamic inputs, and with the corresponding sector of the RE. In this anatomic/functional scheme, a key feature is the central location of RE neurons, which receive copies of thalamocortical and corticothalamic activity and send an inhibitory projection back to the relay neurons. Although corticothalamic projections have excitatory effects on their postsynaptic targets in the thalamus, corticothalamic inputs to the RE are so powerful that the net response evoked in relay neurons by cortical stimulation often is inhibition.[83]

Sleep Spindles

In humans, EEG spindles are waxing and waning, nearly sinusoidal waves with a frequency profile of 10 to 15 Hz. Spindles are generated in the thalamus, as evidenced by the fact that thalamectomy eliminates spindles in the sleep EEG.[4] At the level of the thalamus, spindles are generated by an interplay between neurons in the RE and the relay nuclei.[80,81,83] RE neurons also possess I_t calcium channels and exhibit high-frequency-burst firing from a hyperpolarized background. A high-frequency burst in RE neurons will

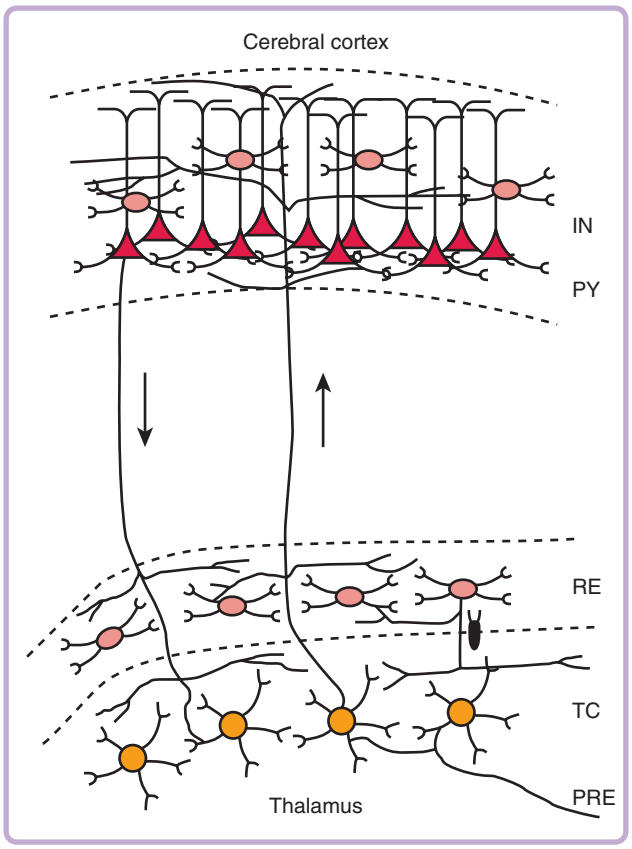

Figure 7-7 Schematic representation of thalamic and cortical cell types involved in the generation of sleep EEG rhythms, and of the synaptic connectivity among the cell types. Four cell types are shown: thalamocortical relay (TC) cells, thalamic reticular (RE) neurons, cortical pyramidal (PY) cells, and cortical interneurons (IN). TC cells receive excitatory inputs from prethalamic afferent fibers (PRE) arising from specific sensory systems and from cholinergic and monoaminergic arousal systems located in the brainstem and posterior hypothalamus. Activity in sensory systems is relayed to the appropriate cortical area by ascending thalamocortical axons *(up arrow)*. TC neurons also send an axon collateral that makes synaptic contact with RE neurons. RE neurons are GABAergic, and they send an inhibitory projection back to TC neurons *(down arrow)*. Corticothalamic feedback is mediated by layer VI, PY neurons that project back to the same relay neurons from which they derive thalamic input, and they send an axon collateral to RE neurons. Corticothalamic projections are excitatory on both RE and TC cells, but cortical stimulation can evoke net inhibitory effects on TC neurons because of activation of GABAergic RE neurons. (From Destexhe A, Sejnowski TJ. Interactions between membrane conductances underlying thalamocortical slow-wave oscillations. *Physiol Rev* 2003;83:1401-53.)

produce strong inhibitory postsynaptic potentials (IPSPs) in relay neurons that are followed by rebound slow Ca^{2+} spikes and a high-frequency burst. This burst of firing in the relay neuron is conveyed back to the RE, evoking an excitatory postsynaptic potential that triggers a calcium spike and a burst in RE neurons. In thalamic slices in which connectivity between the RE and the adjacent relay nuclei is preserved, this disynaptic circuit can generate spontaneous spindle-like oscillations that can propagate across the slice.[81] In the intact brain, the spindle oscillation in the thalamus is conveyed to the cortex by the pattern of burst firing in thalamic relay neurons.[83,84] However, relay of specific sensory information through the thalamus to the cortex is severely compromised during spindle oscillations because of the combination of disfacilitation of relay neurons resulting from loss of excitatory input from arousal systems and the rhythmic IPSPs evoked by RE input. This sensory deafferentation of the cortex is believed to play an important role in maintaining NREM sleep continuity. Although the spindle oscillation originates in the thalamus, cortical feedback to the thalamus and cortico-cortical connections are important in synchronizing the occurrence of spindles over widespread thalamic and cortical areas.[83,84] Phasic activation of layer VI pyramidal neurons excites neurons in the RE and synchronizes IPSP–rebound burst sequences in thalamic relay neurons with cortical activity.

Delta Waves

The delta oscillation of NREM sleep appears to have both cortical and thalamic components. This dual origin is evidenced by the fact that cortical delta activity in the 1- to 4-Hz range persists after complete thalamectomy[4] and by the demonstration that isolated thalamic relay neurons can generate a spontaneous clocklike delta oscillation resulting from the interplay of I_t and a hyperpolarization-activated cation current, known as the h-current.[81] In the intact, sleeping brain, both sources of delta oscillation contribute to the frequency content of the cortical EEG. As discussed previously for spindles, corticothalamic and cortico-cortical connections function to synchronize delta oscillations over widespread cortical areas.

Slow Oscillations

Slow oscillations (with a frequency less than 1 Hz) are a key aspect of the sleep EEG because they function to coordinate the occurrence of other synchronous EEG events (e.g., delta waves, spindles, and K-complexes). Slow oscillations are thought to be primarily of cortical origin. They are absent from the thalamus in chronic decorticate animals and are present in the cortex after thalamectomy as well as in isolated cortical slices.[83] It has been recently reported that cortical deafferentation causes an acute suppression of slow oscillations that recovers over time, indicating a thalamic contribution (as reviewed by David and Schmiedt[85]). Underneath the slow oscillations, fluctuations occur between two states of activity in nearly all cortical neurons.[86,87] "Up" states are characterized by depolarization and generation of trains of action potentials. Up states occur simultaneously in all cell types, including interneurons, and both fast excitatory and inhibitory postsynaptic potentials are characteristic of cortical neuronal activity during this state. Up states are followed by a prolonged period of hyperpolarization and quiescence, referred to as "down" states (see Figure 7-8).

Generation of up states occurs through recurrent excitation in local cortical circuits and depends on excitatory transmission through α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and NMDA receptors.[88] Transitions from up to down states involve a combination of activation of outward K^+ currents and disfacilitation resulting from depression of excitatory synapses.[88,89] Discharge of layer IV corticothalamic projection neurons during up phases can synchronize IPSPs in thalamic relay neurons through activation of RE neurons, causing the expression of EEG spindles and delta activity of thalamic origin on the background of the slow oscillation.[84] Slow oscillations organize the synchronization and propagation of cortical delta activity through cortico-cortical connections. Frequency spectra of the human NREM sleep EEG reflect this dynamic, with prominent spectral peaks in the delta (1 to 4 Hz) and slow oscillation (less than 1 Hz) frequency ranges.[90]

Detection of active and silent states in neocortical neurons from the field potential signal during slow-wave sleep. *Cereb Cortex* 2007;17:400-14.)

By orchestrating the temporal and spatial coherence of rhythmic oscillations in thalamocortical circuits, slow oscillations are thought to be important in promoting the functional sensory deafferentation of the cortex during sleep, which in turn enhances sleep continuity and sleep depth. The transitions between up and down states in cortical neurons have been hypothesized to underlie changes in synaptic plasticity, or synaptic strength, during sleep, and to contribute to sleep-dependent changes in learning and memory.[91]

Spindle and delta oscillations are blocked by stimulation of the rostral brainstem, which activates cholinergic, monoaminergic, orexinergic, and glutamatergic inputs to the thalamus. Activity of cholinergic and monoaminergic neurons facilitates thalamic *depolarization* through inhibition of potassium channels.[92] Accordingly, *inhibition* of these arousal systems facilitates hyperpolarization of thalamic neurons, permitting the activation of voltage-dependent membrane currents underlying spindles and slow waves.

INTEGRATION OF CIRCADIAN RHYTHMS AND SLEEP

The suprachiasmatic nucleus (SCN) of the POA generates the signals that bring about the circadian patterns of sleep-waking.[93] Direct projections from the SCN to areas of the POA implicated in sleep regulation are sparse, but multisynaptic pathways by which SCN signals can control sleep-active neurons have been described. Introduction of lesions of a primary SCN projection target, the subparaventricular zone, like those of the SCN, itself, eliminates circadian rhythms of sleep-waking.[94] The SPVZ projects directly to the MnPN and indirectly to the VLPO, MnPN, and other POA regions through the dorsomedial hypothalamic nucleus.[95,96] Lesions of the dorsomedial hypothalamic nucleus disrupt the circadian distribution of sleep-waking states in rats. In diurnal animals, activity of SCN neurons could inhibit sleep-promoting neurons during the light phase and facilitate sleep-promoting neurons in the dark phase, with the reciprocal pattern occurring in nocturnal animals.

THE PREOPTIC AREA, THERMOREGULATION, AND CONTROL OF SLEEP

Several types of evidence support the hypothesis that sleep onset is coupled to body cooling. Depending on ambient conditions, sleep onset evokes heat loss–effector processes such as cutaneous vasodilation and sweating.[97] In humans, sleep onset occurs soon after vasodilation of the hands and feet, which increases heat loss. Sleep in humans and animals is modulated by ambient temperature. Mild to moderate ambient temperature elevation increases coincident sleep as well as subsequent sleep (as described in an earlier review[98]). An increase in heat production by selective activation of brown adipose tissue, using a beta$_3$ adrenoreceptor agonist, also increases NREM sleep.[99] It is therefore reasonable to hypothesize that one function of sleep is body cooling, particularly after increased body warming during wakefulness.

A circadian temperature rhythm is well documented. In humans, sleep normally occurs on the descending phase of the circadian temperature cycle, but sleep onset evokes a further decrease in temperature, even during continuous bed rest.[100] Self-selected human bedtimes coincide with the time of the maximal rate of decline of core body temperature.[101] The association of sleep onset and the circadian temperature rhythm could represent two independent outputs of the circadian oscillator. However, under certain experimental conditions, including short sleep-wake cycles, internal desynchronization, and forced desynchronization, the interactions of the temperature rhythm and sleep propensity can be studied and partially isolated from effects of prior waking (see Chapter 35). Although sleep may occur at any circadian phase, sleep propensity is increased on the late descending phase of the circadian temperature rhythm and is highest when temperature is low. Awakenings tend to occur as temperature increases, even if sleep time is short. These findings can be interpreted as evidence that the thermoregulatory mechanism that lowers body temperature also promotes sleep.

The coupling of sleep propensity and body cooling is controlled by the POA. The POA is recognized as a thermoregulatory control site on the basis of the effects of local warming and cooling, lesions, local chemical stimulation, and neuronal unit recording studies (reviewed by Boulant[102]). In vivo and in vitro studies have confirmed that the POA contains populations of warm-sensitive and cold-sensitive neurons (WSNs and CSNs), which are identified by changes in neuronal discharge in response to locally applied mild thermal stimuli.

Activation of WSNs induces heat loss mechanisms. Local POA warming promotes NREM sleep and EEG slow wave activity in cats, rabbits, and rats (as detailed in our earlier review of these experiments[98]). NREM sleep is increased for several hours during sustained POA warming.[103] Local POA warming also increases EEG delta activity in sustained NREM. Augmentation of sleep by ambient warming is prevented by coincident local POA cooling.[103] Because POA cooling prevents activation of WSNs, this finding suggests that POA WSN activation mediates the sleep augmentation induced by ambient warming.

Most POA WSNs exhibit increased discharge during NREM sleep compared with waking; most CSNs are wake-active (described in the earlier review[98]). Increases in WSN discharge and decreases in CSN discharge anticipate EEG changes at sleep onset by several seconds. Thus activity of WSNs and CSNs is likely to modulate spontaneous sleep-wake as well as sleep induced by local POA warming. As summarized earlier, POA sleep-active neurons send afferents to putative arousal systems. Local POA warming suppresses the discharge of arousal-related neurons in the PH, dorsal raphe (5-HT neurons), LH orexin neuronal field, and basal forebrain cholinergic field (Figure 7-9).

These studies demonstrate that functional inhibitory regulation of arousal regulatory neurons originates in WSNs located in the POA. Activation of WSNs has two effects: increasing sleep propensity and inducing heat loss, accounting for the coupling of these two processes at sleep onset.

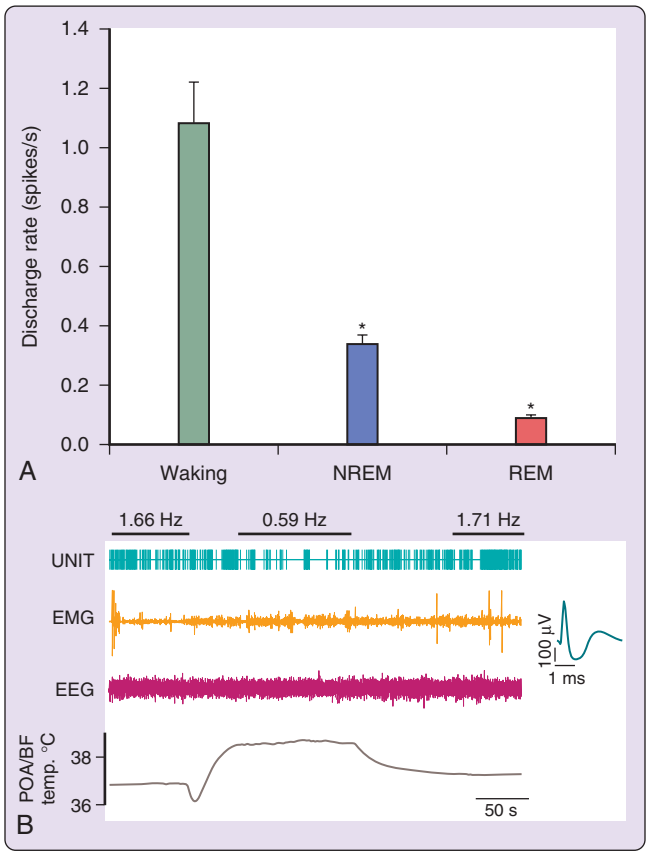

Figure 7-9 Effects of activation of preoptic area (POA) warm-sensitive neurons (WSNs) by local warming on discharge of a putative serotoninergic neuron of the dorsal raphe nucleus (DRN) in the rat. **A,** Pattern of activity of DRN neurons across the sleep-wake cycle. Putative DRN serotoninergic neurons exhibit reduced discharge during NREM compared with waking, and very low discharge in REM sleep. The identification of this pattern of discharge as representing serotoninergic neurons is supported by several types of indirect evidence. **B,** Effects of POA warming on the discharge of a putative serotoninergic REM-off neuron during waking. A POA warming pulse was applied for approximately 100 seconds (*bottom trace*). During POA warming, the discharge was reduced by 64%, to a typical NREM sleep rate. A waking state was maintained during warming, as shown by EEG and EMG recordings. Increased discharge of POA WSNs during spontaneous NREM sleep is thought to contribute to the concurrent reduction of DRN discharge. The central role of temperature-sensitive neurons in sleep control provides a neurologic basis for the coupling of sleep and the circadian temperature rhythm (see text). HIERARCHICAL SLEEP CONTROL MODEL

As reviewed earlier, available evidence supports the existence of sleep-promoting mechanisms at all levels of the neuraxis, both in forebrain, including the neocortex, and in the brainstem. Sleep-like behavior may be generated by an isolated lower brainstem, and sleep is facilitated by midbrain, thalamus, and neocortex. Introduction of lesions encompassing the *ventral* pontomesencephalic reticular formation and adjacent ventral structures in cats produced severe sustained sleep reductions.[104] Both NREM and REM sleep were reduced by approximately 50%. Lesioning of the parafacial area in the medulla of rats causes significant reductions in sleep.[9] However, a central role for the POA in the orchestration of sleep is supported by a variety of findings. To rationalize these diverse findings, it is useful to consider a hierarchical control concept, such as that applied in the context of thermoregulation.[105] In this model, a fundamental behavior such as rest-activity or sleep-waking is organized at all levels of the neuraxis. The POA may act as a master controller, integrating sleep-promoting circuitry with sleep homeostatic processes, other behavioral and hormonal regulatory systems, and circadian signals. The limbic system and neocortex are likely sources of additional controls, related to more complex behavioral contingencies including learning processes, instinctive behaviors, and sensory stimuli. These controls may be conveyed to the hypothalamus through projections from neocortex and limbic system.

SLEEP-PROMOTING NEUROCHEMICAL AGENTS

Conceptions of sleep control based on neuronal circuitry, as outlined earlier, are deficient in that they do not provide explanations for quantitative features of sleep or sleep homeostasis. The control of neuronal activity by neurochemical mechanisms, including the release of GABA, occurs in a time frame of seconds. Sleep regulation and homeostasis operate within a time frame of hours to days, not seconds. In addition, a complete description should account for biologic variations in sleep such as the high daily sleep quotas in some species,[106] higher sleep quotas in infants, sleep facilitation after body heating, and increased sleep propensity during acute infection. The investigation of biochemical mechanisms with sustained actions is needed to address these issues. Presented next is a brief overview of this approach, focusing on neurochemical agents with sleep-promoting properties. (Complete details of the biochemical mechanisms of sleep-wake regulation are available in a review by Obal and Krueger.[107])

Adenosine

Adenosine is recognized as an inhibitory neuromodulator in the central nervous system, whose role in sleep is suggested by the potent arousal-producing effects of caffeine, an antagonist of adenosine A_1 and A_{2A} receptors. Adenosine and its analogues were found to promote sleep after systemic administration by intraperitoneal injection, intracerebroventricular administration, and intra-POA microinjection, and after administration by microdialysis in the basal forebrain (reviewed by McCarley[108]). In the basal forebrain and, to a lesser extent, in neocortex, adenosine recovered through microdialysis increases during sustained waking in cats. No increase is found in thalamus or brainstem sites. Application in the basal forebrain of an antisense oligonucleotide to the adenosine A_1 receptor messenger RNA (mRNA), which blocks synthesis of receptor protein, slightly reduced spontaneous sleep but strongly reduced rebound after sleep deprivation.[109] Adenosine A_1 agonists delivered using microdialysis adjacent to basal forebrain neurons inhibited wake-active neurons during both waking and sleep.[110] A current hypothesis is that the effects of adenosine on sleep-waking are mediated by basal forebrain cholinergic neurons through A_1 receptors.[108] Adenosine could act at multiple sites. Adenosine A_{2A} receptors also are present in restricted brain regions and seem to mediate some sleep-promoting effects of adenosine. Administration of A_{2A} agonist by either intracerebroventricular infusion or infusion into the subarachnoid space ventral to the preoptic area increases sleep amounts and increases c-Fos expression in GABAergic neurons in the MnPN and VLPO.[111] Knockdown of A_{2A} receptors in the shell of the nucleus accumbens significantly attenuates the alerting effects of caffeine.[112]

Brain adenosine levels rise when ATP production is reduced; under these conditions, inhibition of neuronal activity is neuroprotective. Astrocytes as well as neurons are potential sources of adenosine. Genetically inhibiting the release of gliotransmitters, including ATP, by astrocytes diminishes homeostatic responses to sleep deprivation.[113] It has been proposed that increased adenosine is a signal of reduced brain energy reserves that develop during waking, and that sleep is induced as an energy-restorative state.[114] With respect to the brain energy restorative concept, some but not all studies show reduced cerebral glycogen, an energy-supply substrate, after sleep deprivation.[115] Functional evidence that brain energy supply is compromised after sleep deprivation is lacking. This absence of evidence is a critical gap in the theory. Of course, adenosine could be a sleep-promoting signal based on functions other than energy supply limitation.

Proinflammatory Cytokines

Several proinflammatory cytokines have sleep-promoting properties. Summarized next is work on a well-studied and prototypical molecule, interleukin (IL)-1. When administered intravenously, intraperitoneally, or into the lateral ventricles, IL-1 increases sleep, particularly NREM sleep (as reviewed by Krueger et al.[116]). Basic findings have been confirmed in several species. REM usually is inhibited by IL-1. Additional evidence supports a hypothesis that IL-1 modulates spontaneous sleep. Administration of agents that block IL-1 reduces sleep. In rats, IL-1 mRNA is increased in the brain during the light phase, when rat sleep is maximal. Sleep deprivation also increases IL-1 mRNA in the brain.

Increased sleep associated with peripheral infection also may be mediated by responses to circulating IL-1, either through vagal afferents or by induction of central IL-1 or other hypnogenic signals. POA sleep-active neurons are activated by local application of IL-1, and wake-active neurons are inhibited.[117] IL-1 fulfills several criteria for a sleep-promoting signal, and it is likely to be important in facilitating sleep during infection.

Prostaglandin D_2

Administration of prostaglandin D_2 (PGD_2) by intracerebroventricular infusion or by microinjection into the POA increases sleep, but the most potent site for administration is the subarachnoid space ventral to the POA and basal forebrain (reviewed by Huang and coworkers[118]). Sleep induced by PGD_2 administration is indistinguishable from normal sleep on the basis of EEG analysis. The enzyme required for PGD_2 synthesis, lipocalin-PGD synthase (L-PGDS) is enriched in the arachnoid membrane and choroid plexus, but the receptor (the D-type prostanoid receptor) is localized more locally in the leptomeninges under the basal forebrain and the TMN. L-PGDS–knockout mice experienced normal baseline sleep, but unlike the control animals, they exhibited no rebound increase in NREM sleep after sleep deprivation. The PGD_2 concentration was higher in the cerebrospinal fluid during NREM sleep than in wakefulness and was higher in the light phase in the rat (when sleep amounts are high). Sleep deprivation increased the PGD_2 concentration in the cerebrospinal fluid. On this basis, it was proposed that PGD_2 plays a central role in sleep homeostasis. The hypnogenic action of PGD_2 is hypothesized to be mediated by adenosine release acting on an adenosine A_{2A} receptor. Administration of A_{2A} antagonists blocked the effects of PGD_2. A functional basis for the role of PGD_2 in sleep homeostasis or its primary localization in the meninges has not been identified.

Growth Hormone–Releasing Hormone

Growth hormone–releasing hormone (GHRH) is known primarily for its role in stimulating the release of growth hormone (GH). A surge in GH release occurs early in the major circadian sleep period in humans, specifically during the earliest stage 3 or 4 NREM sleep episodes (see Chapter 26). GHRH is a peptide with a restricted localization in neurons in the hypothalamic arcuate nucleus and in the adjacent ventromedial and periventricular nuclei. Neurons in the latter locations are thought to be the source of projections to the POA and basal forebrain. GHRH promotes NREM sleep after intraventricular, intravenous, intranasal, or intraperitoneal administration, or after direct microinjection into the POA (as reviewed by Obal and Krueger[119]). Blockade of GHRH by administration of a competitive antagonist reduces baseline sleep and rebound sleep after short-term sleep deprivation. Mutant mice with GHRH signaling abnormalities have lower amounts of NREM sleep. GHRH stimulates cultured GABAergic hypothalamic neurons; these may constitute the GHRH target in the sleep-promoting circuit.[120] Intracerebroventricular infusion of GHRH activates c-Fos expression in GABAergic neurons in the MnPN and VLPO, whereas intracerebroventricular infusion of a competitive GHRH antagonsist suppresses c-Fos in these neurons.[121] It has been suggested that GHRH may elicit sleep onset in conjunction with release of GH as a coordinated process for augmenting protein

synthesis and protecting proteins from degradation during the fasting associated with sleep. In the brain, protein synthesis increases during sleep, and inhibition of protein synthesis augments sleep.[122] GHRH is proposed to be one element of a multiple-element sleep-promoting system.[107]

Endoplasmic Reticular Stress.

Brain protein synthesis is increased during sleep. The endoplasmic reticulum (ER) is a large cellular organelle that houses the machinery that synthesizes and folds new proteins on instructions from messenger RNA, including proteins needed for neuronal growth, repair, and plasticity. The capacity of the ER, particularly with respect to the process of new protein folding, is limited, and overloading can contribute to cell death. The ER generates a set of signals to prevent overloading, called the unfolding protein response (UPR), that temporarily inhibits new protein synthesis. UPR signals are induced by sleep deprivation.[123] Studies in both *Drosophila*[124] and rats[125] suggest that UPR signals also can facilitate sleep. Neuronal damage from long-term sleep deprivation has been linked to the failure of protection by the UPR.[126]

Sleep as Detoxification or Protection from Oxidative Stress

Reactive oxygen species (ROS) include superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), hydroxyl radical (OH^-), nitric oxide (NO), and peroxynitrite ($OONO^-$). These molecules are generated during oxidation reactions or reactions between O_2^- and H_2O_2 or NO. ROS normally are reduced by constitutive antioxidants such as oxidized glutathione (GSSR), endogenous glutathione (GSH), and different forms of superoxide dismutase (SOD). Oxidative damage ensues when antioxidant mechanisms fail to adequately scavenge ROS, resulting in generation of oxidized lipids, identified by malondialdehyde (MDA), oxidized proteins (carbonyl proteins), and oxidized nucleic acids, identified by 8-hydroxy-deoxy-guanosine.

GSSR was identified as one of four sleep-promoting substances in brain tissue extracted from sleep-deprived rats.[127] Infusion of GSSR into the lateral ventricle of rats during the dark phase increases both NREM and REM sleep (as reviewed by Ikeda and associates[128]). GSH levels were lower in the hypothalamus of rats after 96 hours of sleep deprivation in studies using the platform-over-water method.[129] Sleep deprivation for 5 to 11 days using the disk-over-water method reduces Cu/Zn SOD (cytosolic SOD) as well as glutathione peroxidase in the hippocampus and brainstem.[130] Also in rats, four days of sleep deprivation using the platform-over-water method reduced GSH and increased MDA in hippocampus,[131] and 72 hours of sleep deprivation using the same method reduced GSH in whole-hippocampus and neocortex samples.[132] In mice, 48 or 72 hours of sleep deprivation using the platform-over-water method increased MDA levels in whole-hippocampus samples.[133] These studies suggest that by reducing antioxidant availability, sleep deprivation can increase the risk of oxidative damage, and that sleep is protective against actions of ROS. The possibility that sleep deprivation could cause neuronal damage was suggested by a finding that supraoptic nucleus neurons exhibited signs of subcellular damage after exposure to sleep deprivation.[134] Supraoptic nucleus neurons may be sensitive to sleep deprivation because of their high rate of protein synthesis.[134] In mice, after only 8 hours of sleep deprivation, locus coeruleus neurons were found to lose antioxidant expression (SOD2, CAT) and expression of a key regulator of responses to metabolic stress, Sirt3.[135] Locus coeruleus neurons were reduced in number by 30%.

What are the signaling molecules related to oxidative stress that increase as a function of sustained wakefulness and can promote sleep? In addition to GSSH, as summarized previously, a probable signal is NO, which can be a response to glutamatergic stimulation, to cytokines and inflammation, and to oxidative stress.[136] Activity of an NO-synthetic enzyme, cytosolic nitric oxide synthase (NOS), was increased during the dark phase in rats, most strongly in the hypothalamus (as reviewed by Gautier-Sauvigne and associates[137]), and NO metabolites are increased during waking and decreased during sleep.[138] Intracerebroventricular or intravenous administration of an NOS inhibitor strongly reduced sleep in rabbits and rats and suppressed NREM sleep response to sleep deprivation. Administration of NO donors increased sleep. NO inhibits oxidative phosphorylation and may stimulate the production of adenosine. NO production could therefore be a mediator of several sleep factors.

ROS may play a role in the underlying pathology of obstructive sleep apnea. Affected patients exhibit signs of increased oxidative stress, including increased O_2^- production by neutrophils, monocytes, and granulocytes derived from patients (see Chapter 20). OSA patients exhibit elevated levels of vascular endothelial growth factor that normally is induced by ROS. These changes were reversed by treatment with continuous positive airway pressure. On the basis of these and several additional findings, it has been proposed that the increased cardiovascular disease in patients with obstructive sleep apnea results from oxidative damage to vascular walls. Oxidative stress is hypothesized to play a central role in other forms of vascular disease and in neurodegenerative disease. It is important to recognize that adenosine, ROS, glutamate, and NO have brief lives in the synaptic space—no more than a few seconds. If these molecules regulate sleep, they must have sustained release, or they may regulate the gene expression to generate sustained downstream effects. These mechanisms are the subject of current investigations.

Sleep-promoting molecules are clearly related to the multiple functions of sleep: adenosine to resupply brain energy reserves, cytokines to facilitate immune functions, GHRH to promote anabolic processes, UPR signals to prevent protein misfolding, and GSSR and NO to prevent oxidative stress–induced cell damage.

CLINICAL PEARLS

- Sleep is reduced in the presence of a wide variety of localized brain lesions; this correlation may account for the association of insomnia with various neuropathologic conditions.
- Degeneration of the hypothalamic wake-promoting cell type that expresses the neuropeptide orexin is known to underlie narcolepsy.
- Identification of certain sleep-promoting molecules strongly suggests that sleep serves to restore brain energy reserves, facilitate immune functions, promote macromolecule synthesis, prevent protein misfolding, and curtail oxidative stress–induced cell damage.

SUMMARY

Rapid progress has been achieved in the elucidation of the neural circuitry underlying the facilitation of sleep and the orchestration of NREM sleep, as well as the facilitation of arousal. Wake and arousal are facilitated by several chemically distinct neuronal groups, including groups synthesizing and releasing acetylcholine, serotonin, norepinephrine, dopamine, histamine, orexin/hypocretin, and glutamate. These neuronal groups distribute axons and axon terminals throughout the brain, providing a basis for concurrent changes in physiology associated with arousal. At the center of the sleep-promoting circuitry is the POA of the hypothalamus. The POA sleep-promoting circuitry has reciprocal inhibitory connections with several arousal-promoting systems. A balance between the activities of sleep-promoting and arousal-promoting neuronal systems determines sleep-waking state. The circadian clock in the SCN has both direct and multisynaptic connections with wake and sleep regulatory neurons, providing a neurologic basis for generation of the daily rhythm of sleep-waking. Both sleep-promoting and arousal-promoting neuronal groups are modulated by a host of processes, including sensory, autonomic, endocrine, metabolic, and behavioral influences, accounting for the sensitivity of sleep to a wide range of centrally acting drugs and behavioral manipulations.

The long-term regulation of sleep—sleep homeostasis—is the subject of competing and still incomplete hypotheses. Long-term sleep homeostasis may reflect the actions of several neurochemical processes that express "sleep factors." Some of these sleep factors, including adenosine, PGD_2, IL-1β, and GHRH, are known to act directly on the POA or adjacent basal forebrain neuronal targets. Sleep factors have been linked to distinct functional models of sleep homeostasis, including brain energy supply (adenosine); control of protein synthesis (GHRH and UPR signaling); local sleep, immune protection, and temperature elevation (IL-1); and protection against oxidative or glutamatergic stress (NO, antioxidant enzymes). All of these factors may be involved in sleep homeostasis, but the relative importance of each factor for daily sleep has yet to be established.

Rapid Eye Movement Sleep

Jerome M. Siegel

Chapter Highlights

- Rapid eye movement (REM) sleep was first identified by its most obvious feature: rapid eye movements occurring during sleep. In most adult mammals the electroencephalogram (EEG) of the neocortex is low in voltage during REM sleep. The hippocampus exhibits regular high-voltage theta waves throughout REM sleep.
- The key brain structure for generating REM sleep is the brainstem, particularly the pons and adjacent portions of the caudal midbrain. The isolated brainstem can generate REM sleep, including rapid eye movements, spike potentials linked to eye movements called ponto-geniculo-occipital (PGO) waves, muscle tone suppression (atonia), and autonomic variability. The structures rostral to the caudal midbrain–pontine brainstem cannot generate the forebrain aspects of REM sleep, such as PGO waves or rapid eye movements. The brainstem and the hypothalamus contain cells that are maximally active in REM sleep, called "REM-on cells," and cells that are minimally active in REM sleep, called "REM-off cells." Subgroups of REM-on cells each use a specific transmitter—gamma-aminobutyric acid (GABA), acetylcholine, glutamate, or glycine. Subgroups of REM-off cells use the transmitters norepinephrine, epinephrine, serotonin, histamine, and GABA.
- Destruction of large regions within the midbrain and pons can prevent the occurrence of REM sleep. More limited damage to portions of the brainstem can cause abnormalities in certain aspects of REM sleep. Of particular interest are manipulations that affect the regulation of muscle tone within REM sleep. Early animal work found that lesions of several regions in the pons and medulla can cause REM sleep to occur without the normal loss of muscle tone. In REM sleep without atonia, animals exhibit locomotor activity, appear to attack imaginary objects, and execute other motor programs during a state that otherwise resembles REM sleep. Subsequent work found a similar syndrome in humans that has been termed the REM sleep behavior disorder. Stimulation of portions of the REM sleep–controlling area of the pons can produce a loss of muscle tone in antigravity and respiratory musculature during waking, without eliciting all aspects of REM sleep.
- Narcolepsy is characterized by abnormalities in the regulation of REM sleep. Most cases of human narcolepsy are caused by a loss of hypocretin (orexin) neurons. Hypocretin neurons, which are located in the hypothalamus, contribute to the regulation of the activity of norepinephrine, serotonin, histamine, acetylcholine, glutamate, and GABA cell groups. Hypocretin neurons have potent effects on alertness and motor control and normally are activated in relation to particular, generally positive, emotions in humans as well as in animals.

OVERVIEW

Rapid eye movement (REM) sleep was discovered by Aserinsky and Kleitman in 1953.[1] These workers reported that REM sleep was characterized by the periodic recurrence of rapid eye movements, linked to a dramatic reduction in the amplitude of the electroencephalogram (EEG) signal from that of the higher-voltage activity of the previous non–rapid eye movement (NREM) sleep period. In their study, the EEG pattern in REM sleep closely resembled that in alert waking; and those subjects awakened from REM sleep reported vivid dreams. Dement identified a similar state of low-voltage EEG with eye movements in cats.[2] Jouvet repeated this observation, finding in addition a loss of muscle tone (i.e., atonia) in REM sleep. He used the term *paradoxical sleep* to refer to this state. The "paradox" was that the EEG resembled that recorded during waking, while behaviorally the animal remained asleep and unresponsive.[3-5] Subsequent authors have described this state as "activated" sleep or "dream" sleep. More recent work in humans has shown that some mental activity can be present in NREM sleep but has supported the original finding linking the most vivid dreaming to the REM sleep state. Lesions of parietal cortex and certain other regions prevent dreaming in humans, even in persons continuing to show normal REM

sleep as judged by cortical EEG activity and suppression of muscle tone and rapid eye movements.[6] Children younger than 6 years of age, in whom the amount of REM sleep is greater than in adults, do not typically report dream mentation, perhaps because the cortical regions involved have not yet fully developed.[7] The physiologic signs of REM sleep in both the platypus, the animal showing the most REM sleep,[8] and a related monotreme, the short-nosed echidna,[9] are largely restricted to the brainstem, in contrast with their propagation to the forebrain in adult placental and marsupial mammals. These findings make it questionable whether all or any nonhuman mammals that apparently experience REM sleep, all of which have cortical regions whose structure differs from that in adult humans, have dream mentation.

Surveyed in this chapter are (1) the defining characteristics of REM sleep, including its physiology and neurochemistry; (2) the techniques used to investigate the mechanisms generating REM sleep; (3) the mechanisms responsible for the suppression of muscle tone during REM sleep and the pathologic effects of disruption of these mechanisms; (4) narcolepsy and its link to mechanisms involved in REM sleep control and especially to the peptide hypocretin; and (5) the functions of REM sleep.

CHARACTERISTICS OF RAPID EYE MOVEMENT SLEEP

The principal electrical signs of REM sleep include a reduction in EEG amplitude, particularly in the power of its lower-frequency components (as shown in Figure 8-1, *top*). REM sleep also is characterized by a suppression of muscle tone, called *atonia*, visible in the electromyogram (EMG). In males, erections are more likely to occur.[10] Thermoregulation (e.g., sweating, shivering) largely ceases in most animals, and body temperatures drift toward environmental temperatures, as in reptiles.[11] Pupils constrict, reflecting a parasympathetic dominance in the control of the iris.[12] These changes, which are present throughout the REM sleep period, have been termed its "tonic" features.

Also visible are electrical potentials that can be most easily recorded in the lateral geniculate nucleus of the cat.[13] These potentials originate in the pons, appear after a few milliseconds in the lateral geniculate nucleus, and can be observed with further delay in the occipital cortex, leading to the designation *ponto-geniculo-occipital* (PGO) *spikes*. They occur as large-amplitude, isolated potentials arising 30 or more seconds before the onset of REM sleep as defined by EEG and EMG criteria. After REM sleep begins, they arrive in bursts of 3 to 10 waves, usually correlated with rapid eye movements. PGO-linked potentials also can be recorded in the motor nuclei of the extraocular muscles, where they trigger the rapid eye movements of REM sleep. They also are present in thalamic nuclei other than the geniculate and in neocortical regions other than the occipital cortex.

In humans, rapid eye movements are loosely correlated with contractions of the middle ear muscles of the sort that accompany speech generation and that are part of the protective response to loud noise.[14] Other muscles also contract during periods of rapid eye movement, briefly breaking through the muscle atonia of REM sleep. Periods of marked irregularity in respiratory and heart rates are characteristic of REM sleep, in contrast with NREM sleep, during which respiration and heart rate are regular. No single pacemaker for all of this irregular activity has been identified. Rather, the signals producing twitches of the peripheral or middle ear muscles may lead or follow PGO spikes and rapid eye movements. Bursts of brainstem neuronal activity may likewise lead or follow the activity of any particular recorded muscle.[15-17]

These changes that occur episodically in REM sleep have been called its "phasic" features.

As described further on, certain manipulations of the brainstem can eliminate only the phasic events of REM sleep, whereas others can cause the phasic events to occur in waking; yet other manipulations can affect tonic components. These tonic and phasic features also are expressed to various extents in different species, and not all of these features are present in all species that have been judged to have REM sleep.[18]

The distribution of REM sleep in the animal kingdom is discussed in Chapter 10.

RAPID EYE MOVEMENT GENERATION MECHANISMS

Technical Considerations

The identification of sleep-generating mechanisms can be achieved by *inactivation* or destruction of particular brain regions or neurons, by the *activation* of populations of neurons, or by *observation* of the activity of neurons or measurement of the release of neurotransmitters. Each approach has its advantages and limitations.

Inactivation of Neurons by Lesions, Inhibition, Antisense Administration, or Genetic Manipulation Including Optogenetic Inhibition

More has been learned about brain function and about sleep control from brain damage caused by stroke, injury, or infection in patients and by experimentally induced brain lesions in animals, than by any other technique. However, some basic principles need to be borne in mind when interpreting such data.

Brain lesions can result from ischemia, pressure, trauma, and degenerative or metabolic changes. In animals, experimental lesions most commonly are induced by aspiration, transection of the neuraxis, electrolysis, local heating by radio frequency currents, or the injection of cytotoxins. These substances include certain amino acids, such as *N*-methyl-D-aspartate (NMDA) and kainate, that cause cell death by excitotoxicity, and targeted cytotoxins, such as saporin coupled to a particular ligand, which will kill only cells containing receptors for that ligand. Cytotoxic techniques have the considerable advantage of sparing axons passing through the region of damage, so that deficits will be attributable to the loss of local neurons, rather than interruption of these axons. Injection of inhibitory neurotransmitters, such as muscimol, allows reversible inactivation of neurons in the injection region. DREADDs (designer receptors exclusively activated by designer drugs) also can be used to inactivate or activate groups of neurons. Viral vectors or transgenic mouse models can be used to express the receptors in the desired populations, which can then be manipulated by the locally or systemically applied "designer drug."

If damage to or inactivation of a brain region causes the loss of a sleep state, that region cannot be assumed to be where a "center" for the state resides. Lesion effects usually are maximal immediately after the lesion is created. Swelling and circulatory disruption make the functional loss larger than will be apparent from standard postmortem histologic techniques. The loss of one brain region also can disrupt functions that are organized elsewhere. For example, so-called spinal shock is a well-known phenomenon in which severing the spinal cord's connection to more rostral brain regions causes a loss of functions known to be mediated by circuits intrinsic to the spinal cord.

On the other hand, this sort of denervation-induced shock dissipates with the passage of time. In addition, adaptive changes occur that allow other regions to take over lost functions. This process is mediated by sprouting of new connections to compensate for the loss. A striking phenomenon seen after placement of lesions aimed at identifying the brain regions responsible for REM and NREM sleep is that with even massive lesions targeted at putative sleep-generating "centers," often only a transient disruption or reduction of sleep occurs, presumably as a result of this compensation.[19]

A particularly useful approach to the understanding of REM sleep generation has been the transection technique. In this approach, the brain is cut at the spinomedullary junction, at various brainstem levels, or at forebrain levels by passing a knife across the coronal plane of the neuraxis. Regions rostral to the cut may be left in situ or may be removed. Such a manipulation might be expected to completely prevent sleep phenomena from appearing on either side of this cut. To a surprising extent, however, this is not the case. As reviewed further on, REM sleep reappears within hours after introduction of some of these lesions. When both parts of the brain remain, signs of REM sleep usually appear on only one side of the cut. This kind of positive evidence is much more easily interpreted than loss of function after lesions, because undoubtedly the removed regions are not essential for the signs of REM sleep that survive.

It is increasingly possible to acquire mutant mice in which any one or several of more than 20,000 genes are inactivated. Investigation of two mutants[20,21] led to major insights into the etiology of human narcolepsy.[22-24] Techniques for the postnatal inactivation of genes permit investigation of gene deletions without the developmental effect of these deletions. They can also be used for investigation of the effects of gene inactivation within particular brain regions. A similar inactivation can be achieved by localized microinjections of antisense. Many if not most such mutants can be expected to have some sleep phenotype, such as increases or decreases in total sleep or REM sleep time, altered sleep rebound, altered responses of sleep to environmental variables, or altered changes in sleep with development and aging. The same interpretive constraints long appreciated in lesion studies apply to the interpretation of manipulations that inactivate genes or prevent gene expression, with the additional possibility of direct effects of genetic manipulation on tissues outside the brain.

Activation of Neurons by Electrical or Chemical Stimulation, Gene Activation, Insertion of Messenger RNAs, or Optogenetic Stimulation

Sites identified by lesion or anatomic studies can be stimulated to identify their roles in sleep control. Older studies used electrical stimulation and were successful in identifying the medial medulla as a region mediating the suppression of muscle tone[25] and basal forebrain as a site capable of triggering sleep.[26] Electrical stimulation is an obviously aphysiologic technique, involving the forced depolarization of neuronal membranes by ion flow at a frequency set by the stimulation device, rather than by the patterned afferent impulses that normally control neuronal discharge. For this reason, it has been supplanted for many purposes by administration of

neurotransmitter agonists, either by direct microinjection or by diffusion from a microdialysis membrane placed in the target area and perfused with high concentrations of agonists, and most recently by optogenetic activation.

One cannot assume that responses produced by such agonist administration demonstrate a normal role for the applied ligand. For example, many transmitter agonists and antagonists have been administered to the pontine regions thought to trigger REM sleep. In some cases this administration has increased REM sleep. The only permissible conclusion from this finding, however, is that cells in the region of infusion have receptors for the ligand and have connections to REM sleep–generating mechanisms. Under normal conditions these receptors may not have a role in triggering the state. Only by showing that the administration duplicates the normal pattern of release of the ligand in this area, and that blockade of the activated receptors prevents normal REM sleep, can a reasonable suspicion be raised that a part of the normal REM sleep control pathway has been identified.

Because it is far easier to inject a substance than to collect and quantify physiologically released ligands, many reported studies have implicated various substances as critical for REM sleep control solely on the basis of microinjection techniques. These results must be interpreted with caution. For example, hypocretin is known to depolarize virtually all neuronal types. It should therefore not be surprising to find that hypocretin microinjection into arousal systems such as the locus coeruleus produces arousal,[27] that microinjection of hypocretin into sites known to control feeding increases food intake,[28] that injection into regions known to contain cells that are waking-active increase waking,[29] that injection into regions known to contain cells selectively active in REM sleep will increase the occurrence of this state,[30,31] that injection into regions known to facilitate muscle tone will increase tone, that identical injections into regions known to suppress tone will decrease tone,[32] and that intracerebroventricular injection of hypocretin can increase water intake[33] and can activate other periventricular systems.[30] Such types of findings do not by themselves demonstrate a role for hypocretin (or any other neurotransmitter) in the observed behavior. It is necessary to obtain data on the effects of inactivation of, for example, hypocretin or hypocretin receptors and recording evidence that indicates activity of hypocretin neurons at the appropriate times before seriously entertaining such conclusions.

Genetic manipulations enable activation of neurons or nonneuronal cells of a particular type. A recent example of a genetic approach is the insertion of a light-sensitive ion channel into hypocretin cells using a lentivirus. Fiberoptic delivery of light could then be used to activate just these cells and determine the effect on sleep-waking transitions.[34] The interpretation of optogenetics responses is discussed elsewhere.[26]

Observation of Neuronal Activity

Recording the activity of single neurons in vivo can provide a powerful insight into the precise time course of neuronal discharge. Unit activity can be combined with other techniques to make it even more useful. For example, electrical stimulation of potential target areas can be used to antidromically identify the axonal projections of the recorded cell. Intracellular or "juxtacellular"[35] labeling of neurons with dyes, with subsequent immunolabeling of their transmitter, can be used to determine the neurotransmitter phenotype of the recorded cell. Combined dialysis and unit recording or iontophoresis of neurotransmitter from multiple barrel recording and stimulating micropipettes can be used to determine the transmitter response of the recorded cell, although whether the effects seen are the direct result of responses in the recorded cell or are mediated by adjacent cells projecting to the recorded cell cannot easily be determined. Such distinctions can be made in in vitro studies of slices of brain tissue by blocking synaptic transmission or by physically dissociating studied cells, but in this case their role in sleep may not be readily ascertained.

Although the role of a neuron in fast, synaptically mediated events happening in just a few milliseconds can be traced by inspection of neuronal discharge and comparison of that discharge with the timing of motor or sensory events, such an approach may be misleading when applied to the analysis of sleep state generation. The sleep cycle consists of a gradual coordinated change in EEG and EMG activity and other phenomena over a period of seconds to minutes, as the awake state turns into NREM sleep and then as NREM sleep is transformed into REM sleep.

Despite this mismatch of time courses, the *tonic latency,* a measure of how long before REM sleep onset the activity in a recorded cell changes, has been calculated in some studies. Neurons purported to show a "significant" change in activity many seconds or even minutes before REM sleep onset have been reported. Such a measure is of little utility, however, because at the neuronal level, the activity of key cell groups can best be seen as curvilinear over the sleep cycle, rather than changing abruptly in the way that activity follows discrete sensory stimulation. A major determinant of the tonic latency, calculated as defined earlier, is the level of "noise" or variability in the cell's discharge, which affects the difficulty of detecting a significant underlying change in rate in a cell population. It is therefore not surprising that cell groups initially designated as "executive neurons" for REM sleep control on the basis of their tonic latencies were later found to have no essential role in the generation of REM sleep.[36-38] The more appropriate method of assessment of the unit activity cycle relative to state control is to compare two different cell types to observe the specific phase relation of the peaks or troughs of their activity under similar conditions. This kind of study is difficult, involving the simultaneous long-term recording of multiple cells, and is rarely performed. Even in this case, a phase lead does not by itself prove that the "lead" neuron is driving activity seen in the "following" neuron, but it does indicate that the reverse is not the case. Awakening, however, is a process that can be studied in this way, because it can be elicited by stimuli and appears to be preceded by abrupt changes in the activity of many neuronal groups.[39] A major advantage of unit recording approaches in the intact animal to investigating sleep and other behavioral processes is their high level of temporal resolution.

Observation of the normal pattern of neurotransmitter release and neuronal activity can help determine the neurochemical correlates of sleep states. The natural release of neurotransmitters can be most easily determined by placing a tubular dialysis membrane 1 to 5 mm long in the area of interest and circulating artificial cerebrospinal fluid through it. Neurotransmitters released outside the membrane will diffuse through the membrane and then can be collected.

Each sample is obtained at intervals typically ranging from 2 to 10 minutes. The collected dialysates can be analyzed by chromatography, radioimmunoassay, mass spectroscopy, or other means. The temporal resolution of this technique typically is on the order of a few minutes for each sample.[40-42]

Unit recording and dialysis approaches require a sharp research focus on a particular neurotransmitter or neuronal group. By contrast, histologic approaches can be used to measure the activity of the entire brain at cellular levels of resolution. The most popular such approach in animal studies labels the activation of immediate early genes. These genes are expressed in the nucleus when a neuron is highly active, and their expression is an early step in the activation of other downstream genes mobilizing the response of the cell to activation. Activation of these genes can be detected by immunohistochemistry techniques, most commonly staining for the production of the Fos protein or the mRNA used to synthesize this protein.[43] Neurons can be double-labeled to identify the transmitter they express, allowing investigators to determine, for example, whether histaminergic neurons in the posterior hypothalamus were activated in a particular sleep or waking state. Metabolic labels such as 2-deoxyglucose also can provide an indication of which neurons are active.[43,44] Similar techniques using radioactive ligands in positron emission tomography studies can be used in living humans or animals. In vivo measurements of blood flow can be made throughout the brain with functional magnetic resonance imaging. All of these techniques have in common their ability to make anatomically driven discoveries of brain regions that are active in particular states, independent of specific hypotheses, thereby leading to major advances in understanding. However, another common feature of these types of "recording" techniques is their very poor temporal and spatial resolutions in comparison to neuronal recording approaches. Fos activation can take 20 minutes or more. Positron emission tomography takes a similar amount of time, and functional magnetic resonance imaging can observe events lasting on the order of 1 to 15 seconds. Accordingly, whether areas active during a particular state caused the state or were activated because of the state cannot be determined with certainty.

Summary of Technical Considerations

Clearly there is no perfect technique for determining the neuronal substrates of sleep states. Ideally, all three approaches should be used in concert to reach conclusions. Explored next are the major findings derived from lesion (transection), stimulation, and recording studies of REM sleep control mechanisms.

Transection Studies

The most radical types of lesion studies are those that slice through the brainstem, severing the connections between regions rostral and caudal to the cut. Sherrington discovered that animals in which the forebrain is removed after transection of the neuraxis in the coronal plane at the rostral border of the superior colliculus showed tonic excitation of the "antigravity muscles" or extensors (Figure 8-2, level A). This decerebrate rigidity was visible as soon as anesthesia was discontinued. Bard and Macht reported in 1958 that animals with decerebrate rigidity would show periodic limb relaxation.[45] It is now known that these researchers were observing the periodic muscle atonia of REM sleep.

After the discovery of REM sleep in the cat,[2] Jouvet found that this state of EEG desynchrony normally was accompanied by muscle atonia.[4] Jouvet then examined the decerebrate cat preparation used by Sherrington and by Bard and Macht, with the addition of measures of muscle tone, eye movement, and EEG. One might have expected that REM sleep originates in the forebrain, but Jouvet found something quite different. When he recorded in the forebrain after separating the forebrain from the brainstem at the midbrain level (Figure 8-2, level A or B), he found no clear evidence of REM sleep. In the first few days after transection, the EEG in the forebrain always showed high-voltage activity, but when low-voltage activity appeared, the PGO spikes that help identify REM sleep in the intact animal were absent in traces from the thalamic structures, particularly the lateral geniculate, where they can be most easily recorded. Thus it appeared that activity in the isolated forebrain included slow wave sleep states and possibly waking, but with no clear evidence of REM sleep.

By contrast, the midbrain and brainstem behind the cut showed clear evidence of REM sleep. Muscle atonia appeared with a regular periodicity and duration, similar to that of the intact cat's REM sleep periods. This atonia was accompanied by PGO spikes with a morphology resembling that in the intact animal. The pupils were highly constricted during atonic periods, as in REM sleep in the intact cat.

An interesting feature of REM sleep in the decerebrate animal is that its frequency and duration varied with body temperature. In the decerebrate animal, the forebrain thermoregulatory mechanisms are disconnected from their brainstem effectors. Shivering and panting do not occur at the relatively small temperature shifts that trigger them in the intact animal. For this reason, if the body temperature is not maintained by external heating or cooling, it will tend to drift toward room temperature. Arnulf and colleagues[46] found that if body temperature was maintained at a normal level, little or no REM sleep was seen. But if temperature was allowed to fall, REM sleep amounts increased to levels well above those seen in the intact animal. This observation suggests that REM sleep

facilitatory mechanisms are on balance less impaired by reduced temperature than are REM sleep inhibitory mechanisms. Another way of looking at this phenomenon is that brainstem mechanisms are set to respond to low temperatures by triggering REM sleep, perhaps to stimulate the brainstem, and that high brainstem temperatures inhibit REM sleep. It is unclear whether this mechanism is operative in the intact animal, in which temperature shifts are within a much narrower range.

A further localization of the REM sleep control mechanisms can be achieved by examining the sleep of humans or animals in which the brainstem–spinal cord connection has been severed (Figure 8-2, level C). In this case, normal REM sleep in all its manifestations, except for spinally mediated atonia, is present.[47] These findings support the conclusion that the region between the caudal medulla and rostral midbrain is sufficient to generate REM sleep.

This approach can be continued by separating the caudal pons from the medulla (Figure 8-2, level D or E). In such animals no atonia is present in musculature controlled by the spinal cord, even though electrical or chemical stimulation of the medial medulla in the decerebrate animal suppresses muscle tone.[48] Furthermore, neuronal activity in the medulla does not resemble that seen across the REM-NREM sleep cycle, with neuronal discharge very regular for periods of many hours, in contrast with the periodic rate modulation that is linked to the phasic events of REM sleep in the intact animal[49] (Figure 8-3). This observation demonstrates that the medulla and spinal cord together, although they may contain circuitry whose activation can suppress muscle tone, are not sufficient to generate this aspect of REM sleep when disconnected from the pons and more rostral brainstem structures.

By contrast, the regions *rostral* to this cut show aspects of REM sleep[50] (Figure 8-4; see also Figure 8-1, *bottom*). Within these regions can be seen the progression from isolated to grouped PGO spikes and the accompanying reduction in PGO spike amplitude that occurs in the pre-REM sleep period and the REM sleep periods in the intact animal. Also evident is increased forebrain unit activity, with unit spike bursts in conjunction with PGO spikes, just as in REM sleep.[49,51]

To summarize, this work shows that when pontine regions are connected to the medulla, atonia, rapid eye movements, and the associated unit activity of REM sleep occur, whereas the medulla and spinal cord together, disconnected from the pons, are not sufficient to generate these aspects of REM sleep. When the pons is connected to the forebrain, forebrain aspects of REM sleep are seen, but the forebrain without attached pons does not generate these aspects of REM sleep. Further confirmation of the importance of the pons and caudal midbrain comes from the studies of Matsuzaki and associates.[52] These workers found that when two cuts were placed, one at the junction of the midbrain and pons and the other at the junction of the pons and medulla, periods of PGO spikes were seen in the isolated pons, but no signs of REM sleep were evident in structures rostral or caudal to the pontine "island."

These transection studies demonstrate, by positive evidence, that the pons is sufficient to generate the pontine signs of REM sleep—that is, the periodic pattern of PGO spikes and irregular neuronal activity that characterizes REM sleep. One can conclude that the pons is the crucial region for the generation of REM sleep. The structures within this region that synthesize the core elements of REM sleep are considered in greater detail further on.

Also clear, however, is that the pons alone does not generate all of the phenomena of REM sleep. Atonia requires the activation of motor inhibitory systems in the medulla.[53] In the intact animal, forebrain mechanisms interact with pontine mechanisms to regulate the amplitude and periodicity of PGO spikes,[54] which in turn are linked to the twitches and rapid eye movements of REM sleep. As documented in cases of human REM sleep behavior disorder, the motor activity expressed in dreams is linked to the imagery of the dream.[55]

With extrapolation to dream imagery in normal humans, it can be hypothesized that because the structure of REM sleep results from an interaction of forebrain and brainstem mechanisms, the dream itself is not just passively driven from the brainstem but rather represents the result of a dynamic interaction between forebrain and brainstem structures.

Localized Lesion Studies

The transection studies point to a relatively small portion of the brainstem, the pons and caudal midbrain, as critical for REM sleep generation. Further specification of the core regions can be achieved by destroying portions of the pons in an otherwise intact animal and then seeing which areas are necessary and which are unnecessary for REM sleep generation. An early systematic study by Carli and Zanchetti in the cat[56] and other subsequent studies emphasized that lesions of locus coeruleus[57] and the dorsal raphe[58] nuclei or of simultaneous lesions of locus coeruleus, forebrain cholinergic neurons, and histamine neurons[19] did not block REM sleep. These investigators concluded that lesions that destroyed the region ventral to the locus coeruleus, called the *nucleus reticularis pontis oralis* or *subcoeruleus region*, produced a massive decrease in the amount of REM sleep. These studies used the electrolytic lesion technique, in which a current is passed through brainstem tissue, depositing metal that kills cells and axons of passage. As cytotoxic techniques that allowed poisoning of cell bodies without the damage to axons of passage came into use, these initial conclusions were confirmed and refined. It was shown that neurons in medial pontine regions including the giant cell region were not important in REM sleep control,[53,59,60] because near-total destruction of these cells was followed by normal amounts of REM sleep as soon as anesthesia dissipated.[37,61] However, lesions of the subcoeruleus and adjacent regions with cytotoxins were associated with a prolonged reduction in the amount of REM sleep. According to one study, the extent of this loss was proportional to the percentage of cholinergic cells lost in subcoeruleus and adjacent regions of the brainstem of the cat.[62] In rats, lesioning or inactivation of the same region below the locus coeruleus (called the sublaterodorsal nucleus in the terminology of Swanson[63]) has been found to reduce REM sleep.[64]

Although large lesions may lead to elimination of all aspects of REM sleep, introduction of small, bilaterally symmetric lesions within the pons can eliminate specific aspects of REM sleep. With lesions of lateral pontine structures, muscle atonia during REM sleep is seen. However, PGO spikes and the associated rapid eye movements are absent when lesions include the region surrounding the superior cerebellar peduncle of the cat[65] (Figure 8-5, *top*). This observation points to a role for this lateral region in the generation of PGO waves and the associated phasic activity of REM sleep.

Small lesions confined to portions of the subcoeruleus regions identified as critical for REM sleep by Carli and Zanchetti, or to the medial medulla,[53] result in a very unusual syndrome. After NREM sleep, affected animals enter REM sleep as indicated by lack of responsiveness to the environment, PGO spikes, EEG desynchrony, and pupil constriction. However, they lack the muscle atonia that normally characterizes this state[5,66] (Figure 8-5, *bottom*). During "REM sleep without atonia" these animals appear to act out dreams, attacking objects that are not visible, exhibiting unusual affective behaviors and ataxic locomotion. When they are awakened, normal behavior resumes. More recent studies have

Twenty-second polygraph tracings during REM sleep before and after introduction of lesions, together with a coronal section through the center of the pontine lesions. Electroencephalographic voltage reduction of REM sleep (recorded from motor cortex) was associated with both lesion locations: pediculopontine tegmental (PPT) and subcoeruleus. *Top traces:* Radiofrequency lesions of the PPT region diminished ponto-geniculo-occipital (PGO) spikes and eye movement bursts during REM sleep. *Bottom traces:* Lesions in the region ventral to the locus coeruleus produced REM sleep without atonia without any diminution of PGO spike or REM frequency. (From Shouse MN, Siegel JM. demonstrated that lesions of a system extending from the ventral midbrain to the medial medulla can cause REM sleep without atonia and that activation of this system can suppress muscle tone.[53,67-69]

This subcoeruleus region is under the control of midbrain regions. A midbrain region located just beneath and lateral to the periaqueductal gray (and called the dorsocaudal central tegmental field in the cat) appears to inhibit REM sleep by inhibiting the critical "REM on" subcoeruleus neurons. Muscimol, a $GABA_A$ receptor agonist, injected into this midbrain region silences these cells and increases REM sleep, presumably by blocking the inhibition.[70] The same phenomena have been observed when muscimol is injected into the corresponding region in the guinea pig[71] and the rat[72] (in the rat, this midbrain region has been called the deep mesencephalic nucleus.) The midbrain region of the deep mesencephalic nucleus is the heart of the classic reticular activating system, shown to induce waking when electrically stimulated[73] and coma when lesioned.[74]

Increasing the levels of GABA in the subcoeruleus region (also called the pontine oralis nucleus in the rat and cat) produces an increase in waking, rather than the increase in REM sleep seen with GABA injection into the midbrain regions as previously indicated.[75,76] This finding is another reminder that despite the sleep-inducing effect of systemic administration of GABAergic hypnotic medications (such as benzodiazepines), the effect of GABA on sleep and waking states induced by local manipulation varies across brain regions. Blocking GABA in the subcoeruleus has been reported to increase REM sleep in the cat.[77]

Stimulation Studies

The first study showing that stimulation could elicit REM sleep was carried out by George and colleagues.[78] These investigators found that application of the acetylcholine agonist carbachol to specific regions of the pons ventral to the locus coeruleus could elicit REM sleep in the cat. An impressive proof that a unique REM sleep generation mechanism was being activated was the long duration of the elicited REM sleep periods, which could last hours. Microinjection of acetylcholine into this region in the decerebrate cat produces an immediate suppression of decerebrate rigidity. Later studies showed that, depending on the exact site, either REM sleep or just atonia in a waking state could be triggered by such stimulation.[79-81] When stimulation was applied to the lateral regions with lesions blocking PGO waves, continuous PGO spikes were generated even though the animal was not always behaviorally asleep.

Increased REM sleep has been reported in the rat after microinjection of cholinergic agonists into the subcoeruleus region,[82-84] although this effect is certainly not as robust as it is in the cat.[85]

The first study demonstrating a role for glutamate in the control of REM sleep was done in the cat. The investigators found that a profound suppression of muscle tone could be elicited by the injection of glutamate into the subcoeruleus region or into the ventral medullary region.[48,86,87] Further work has demonstrated that the pontine cells in this inhibitory region receiving cholinergic input use glutamate as their transmitter and project directly to glutamate-responsive regions of the medial medulla.[86,88-90]

Work in the rat has emphasized the strong triggering of REM sleep by glutamatergic excitation of this region.[64,91] Glutamatergic excitation of this region in the cat also increases REM sleep,[92] suggesting that both cholinergic and glutamatergic mechanisms are intimately involved in the triggering of REM sleep, although the evidence points tospecies differences in the relative potency of the effect of microinjection of these two neurotransmitters.

Neuronal Activity, Transmitter Release

The transection, lesion, and stimulation studies all point to the same regions of the pons and caudal midbrain as the critical region for the generation of the REM sleep state as a whole, and to smaller subregions in the brainstem and forebrain in the control of its individual components. The pons contains a complex variety of cells differing in their neurotransmitter, receptors, and axonal projections. Unit recording techniques allow an analysis of the interplay between these cell groups and their targets to further refine dissection of REM sleep mechanisms.

Medial Brainstem Reticular Formation

Most cells within the medial brainstem reticular formation are maximally active in waking, greatly reduce discharge rate in NREM sleep, and increase discharge rate back to waking levels in REM sleep.[15,16,60,93,94] Discharge is most regular in NREM sleep and is relatively irregular in both waking and REM sleep. The similarity of the waking and REM sleep discharge patterns suggests similar roles for these cells in both states. Indeed, most of these cells have been shown to be active in waking in relation to specific lateralized movements of the head, neck, tongue, face, or limbs. For example, a cell may discharge only with extension of the ipsilateral forelimb or abduction of the tongue. The twitches that normally are visible in facial and limb musculature during REM sleep and the phenomenon of REM sleep without atonia suggest that these cells command movements that are blocked by the muscle tone suppression of REM sleep. Lesioning of these cells has little or no effect on REM sleep duration or periodicity[37,38] but does dramatically prevent movements of the head and neck in waking.[95]

Cholinergic Cell Groups

Cholinergic cell groups have an important role in REM sleep control in the cat. As was pointed out above, microinjection of cholinergic agonists into the pons of the cat reliably triggers long REM sleep periods that can last for minutes or hours. Microdialysis studies show that pontine acetylcholine release is greatly increased during natural REM sleep when compared with either NREM sleep or waking.[96] Recordings of neuronal activity within the cholinergic cell population demonstrate the substrates of this release. Certain cholinergic cells are maximally active in REM sleep (REM-on cells). Others are active in both waking and REM sleep.[97,98] Presumably the REM sleep-on cholinergic cells project to the acetylcholine responsive region in the subcoeruleus area.[99]

Cells with Activity Selective for REM Sleep

Cells with activity selective for REM sleep can be identified within the subcoeruleus area in both cats[100] and rats.[72] Anatomic studies using Fos labeling and tract tracing and unit recording studies indicate that these neurons are glutamatergic and GABAergic[98] and that some of them project to the ventral medullary region involved in the triggering of the muscle atonia of REM sleep.[48,64,72,86,88-90]

Monoamine-Containing Cells

Monoamine-containing cells have a very different discharge profile. Most if not all noradrenergic[101,102] and serotoninergic[103] cells of the midbrain and pontine brainstem and histaminergic[104] cells of the posterior hypothalamus are continuously active during waking, decrease their activity during NREM sleep, and further reduce or cease activity during REM sleep (Figure 8-6). As pointed out earlier, these cell groups are not critical for REM sleep generation, but it is likely that they modulate the expression of REM sleep. The cessation of discharge in monoaminergic cells during REM sleep appears to be caused by the release of GABA onto these cells,[105-108] presumably by REM sleep–active GABAergic brainstem neurons.[109,110] Administration of a GABA agonist to target the raphe cell group increases REM sleep duration,[106] demonstrating a modulatory role for this cell group in REM sleep control. Some studies indicate that dopamine cells do not change discharge across sleep states,[42,111,112] other work suggests an increased release of dopamine in REM sleep[113,114] or shows decreased release in REM sleep,[115] and still other work shows selective waking activity in these neurons.[116] These

findings may reflect heterogeneity of firing of different dopamine cell groups and presynaptic control of release in dopamine terminals.

Other Cholinergic Cells in Lateral Pontine Regions

Other cholinergic cells in lateral pontine regions discharge in bursts before each ipsilateral PGO wave.[117,118] These cells may therefore participate in the triggering of these waves. As shown in other studies, PGO waves are tonically inhibited in waking by serotonin input.[119-121] It is likely, therefore, that certain groups of cholinergic cells receive direct or perhaps indirect serotoninergic inhibition in waking and that the decrease of this inhibition in NREM sleep and REM sleep facilitates PGO wave and REM sleep generation.

Fos Labeling

A more global mapping of neurons active in REM sleep can be achieved by using the Fos labeling to identify neurons active within the 20-minute (or longer) period before sacrifice of the experimental animal. Quattrochi and associates demonstrated that microinjections of the cholinergic agonist carbachol that triggered episodes of continuous PGO waves in waking activated neurons within the laterodorsal and pedunculopontine nuclei. Destruction of these nuclei blocks these waves.[121-123]

More extensive Fos mapping has been done to identify neurons activated during REM sleep in the rat. Verret and colleagues[124] found that only a few cholinergic neurons from the laterodorsal and pedunculopontine tegmental nuclei were Fos-labeled after REM sleep. By contrast, a large number of noncholinergic Fos-labeled cells was observed in the laterodorsal tegmental nucleus, subcoeruleus region and lateral, ventrolateral, and dorsal periaqueductal gray of the midbrain. In addition, other regions outside of the brainstem regions critical for REM sleep control were labeled. These included the alpha and ventral gigantocellular reticular nuclei of the medulla, dorsal and lateral paragigantocellular reticular[125] nuclei, and the nucleus raphe obscurus. Half of the cells in the latter nucleus were cholinergic, suggesting that these neurons might be a source of acetylcholine during REM sleep. In a second study, an effort was made to identify the source of the GABAergic input thou ght to cause the cessation of discharge in locus coeruleus cells during REM sleep.[107] Verret and coworkers[87] also showed that the dorsal and lateral paragigantocellular reticular nuclei of the medulla and regions of the periaqueductal gray of the midbrain, regions with large percentages of GABAergic cells, are active in REM sleep. Maloney and associates[109] found GABAergic cells adjacent to the locus coeruleus that expressed Fos during periods of high REM sleep. Because the critical phenomena of REM sleep do not appear to require the medulla, it seems likely that the periaqueductal gray GABAergic neurons and GABAergic neurons adjacent to locus coeruleus and raphe nuclei are sufficient to suppress the activity of noradrenergic and serotoninergic neurons,[106,126] although medullary neurons may participate in the intact animal.

Fos mapping also has been used to identify forebrain regions likely to control REM sleep. The preoptic region, important in NREM sleep control (see Chapter 7), contains neurons that express Fos maximally in REM sleep–deprived animals, suggesting that these neurons may be related to the triggering or duration of REM sleep by brainstem systems.[127] Fos studies also indicate that melanin-concentrating hormone neurons, which are located in the hypothalamus, express Fos during periods with large amounts of REM sleep and that intracerebroventricular administration of melanin-concentrating hormone increases the amount of subsequent REM sleep.[128,129] These results suggest that melanin-concentrating hormone neurons also contribute to forebrain modulation of REM sleep.

Of note, the identity of the cells involved in triggering and controlling REM sleep is not easily determined. The Fos studies do not necessarily identify all cells active during REM sleep; only those of a phenotype that allows them to express Fos during the tested manipulations are so labeled. Certain cell types do not readily express Fos even when very active. In other words, cells not expressing Fos during periods of REM sleep may be involved and may even have a critical role in REM sleep control. Conversely, cells expressing Fos because of their activity during REM sleep may be responding to the motor and autonomic changes characteristic of this state, rather than causing these changes. With neuronal activity recording, identification of the cells responsible for starting the process of REM sleep triggering cannot be easily be achieved without a complete profile of discharge across the sleep cycle and a direct comparison of candidate cell groups, for the reasons just reviewed. Finally, recording from neurons in head-restrained animals, although easier than in freely moving animals, can be misleading, because such restraint can lower the activity of movement-related cells in waking, making them appear to be selectively active in REM sleep.[36] Nevertheless, by comparing the results of multiple recording and stimulation techniques with data on lesions, the evidence thus obtained helps identify the brainstem and forebrain neuronal groups that are the best candidates for controlling the REM sleep state.

CONTROL OF MUSCLE TONE

Abnormalities of muscle tone control underlie many sleep disorders. During REM sleep, central motor systems are highly active, whereas motoneurons are hyperpolarized.[130] The normal suppression of tone in the tongue and laryngeal muscles in REM sleep is a major contributing factor in sleep apnea (see Chapters 109, 110, and 113–118). The failure of muscle tone suppression in REM sleep causes REM sleep behavior disorder[131] (Chapter 103). Triggering of the REM sleep muscle tone control mechanism in waking is responsible for cataplexy.[132]

Early work using intracellular recording and microiontophoresis had shown that motoneuron hyperpolarization during REM sleep was accompanied by the release of glycine onto motoneurons.[130,133] Microdialysis sampling showed that both GABA and glycine are released onto motoneurons during atonia induced by carbachol in the cat.[41] This release occurs in ventral horn motoneurons as well as in hypoglossal motoneurons. The glycinergic inhibition during a carbachol elicited REM sleep–like state was investigated with immunohistochemistry and found to be due to the activation of glycinergic neurons in the nucleus reticularis gigantocellularis and nucleus magnocellularis in the rostroventral medulla and the ventral portion of the nucleus paramedianus reticularis,[133] regions whose activation has been shown to suppress muscle tone in the unanesthetized decerebrate animal.[86] A second population was located in the caudal medulla adjacent to the nucleus ambiguus; these neurons may be responsible for the

REM sleep–related inhibition of motoneurons that innervate the muscles of the larynx and pharynx.

In related work, it has been shown that norepinephrine and serotonin release onto motoneurons is decreased during atonia.[134] Because these monoamines are known to excite motoneurons and because GABA and glycine are known to inhibit motoneurons, it appears that the coordinated activity of these cell groups produces motoneuron hyperpolarization and hence atonia in REM sleep by a combination of inhibition and disfacilitation.

The inhibitory and facilitatory systems are strongly and reciprocally linked. Electrical stimulation of the pontine inhibitory area, located in the subcoeruleus region,[86] produces muscle tone suppression. Even though the pontine inhibitory area is situated within a few millimeters of the noradrenergic locus coeruleus, electrical stimulation in the pontine inhibitory area that suppresses muscle tone will always cause a *cessation* of activity in the noradrenergic neurons of the locus coeruleus and other facilitatory cell groups.[135] Cells that are maximally active in REM sleep ("REM-on" cells) are present in the pontine inhibitory area and also in the region of the medial medulla which receives pontine inhibitory area projections (Figure 8-7).

The release of GABA and glycine onto motoneurons during REM sleep atonia is most likely to be mediated by a pathway from the pontine inhibitory area to the medial medulla.[89,90] The pontine region triggering this release is not only sensitive to acetylcholine but also responds to glutamate[88] (Figure 8-8).[86] The medullary region with descending projections to motoneurons can be subdivided into a rostral portion responding to glutamate and a caudal portion responding to acetylcholine[48,136] (Figure 8-8). The medullary interaction with pontine structures evidently is critical for muscle tone suppression, because inactivation of pontine regions greatly reduces the suppressive effects of medullary stimulation on muscle tone.[137,138] This ascending pathway from the medulla to the pons may mediate the inhibition of locus coeruleus during atonia and also may help recruit other active inhibitory mechanisms. Thus damage anywhere in the medial pontomedullary region can block muscle atonia by interrupting ascending and descending portions of the pontomedullary inhibitory system, as can muscimol injection into the pons,[137]

again indicating that the pons is a key component of the circuit producing motor inhibition.

The studies just reviewed focused largely on ventral horn and hypoglossal motoneurons. However, the control of jaw muscles also is a critical clinical issue. The success of jaw appliances indicates that reduced jaw muscle activity can contribute to closure of the airway in sleep apnea (see Chapters 109, 110, and 113–118). Jaw muscle relaxation is a common initial sign of cataplexy, and tonic muscle activation underlies bruxism. Investigation of the control of masseter motor neurons allows analysis of the regulation of muscle tone on one side of the face, with use of the other side as a control for changes in behavioral state caused by application of neurotransmitter agonist and antagonists.[139] Using this model, it was determined that tonic glycine release reduces muscle tone in both waking and NREM sleep. Blockade of glycine receptors, however, did not prevent the suppression of muscle tone in REM sleep. In a similar manner, blockade of GABA receptors alone or in combination with glycine receptors increased tone in waking and NREM sleep but did not prevent the suppression of masseter tone[140] or of genioglossus tone in REM sleep.[141] Both of these manipulations, however, increased phasic masseter muscle activity in REM sleep.

Further studies showed that a blockade of glutamate receptors reduces the normal enhancement of muscle tone in waking relative to the level in NREM sleep. Glutamate also contributes to the phasic motor activity during REM sleep. Reduction in glutamate alone, however, is not sufficient to account for the suppression of muscle tone in REM sleep, because stimulation of NMDA and non-NMDA glutamate receptors does not appear to restore muscle tone in REM sleep.[142]

A study in the anesthetized rat suggested that activation of norepinephrine receptors, in combination with the activation of glutamate receptors, was sufficient to potently increase muscle tone in the masseter muscles.[143] A study of the hypoglossal motor nucleus in the unanesthetized rat concluded that the suppression of muscle tone in REM sleep was mediated to a large extent by a reduction in norepinephrine release, but not by reduced serotonin release.[144] In the context of previous microdialysis analysis of transmitter release, these studies suggest that the reduction of norepinephrine release may be a key factor regulating muscle tone, along with the aforementioned changes in amino acid release. These conclusions are consistent with earlier work indicating that cataplexy was linked to a reduction in the activity of noradrenergic neurons (see further on).[145] Although the current literature suggests that trigeminal, hypoglossal, and ventral horn motoneurons are subjected to similar neurochemical control across the sleep cycle, direct comparison of these systems has not been made, and it is likely that some aspects of control may differ across systems as well as species.

The role of reduced serotonin release in the suppression of muscle tone has been investigated in the hypoglossal nucleus of the rat. It was found that the modulation of genioglossus activity across natural sleep-wake states was not greatly affected by endogenous input from serotoninergic neurons, although earlier studies in vagotomized and anesthetized rats had shown an effect of serotonin on muscle tone under these aphysiologic conditions.[146-148]

Subsequent work suggested that inhibition of motor output is accompanied by a neurochemically similar inhibition of sensory relays during REM sleep.[149] Such sensory inhibition may be important in preserving sleep and, in particular, in blocking the sensory input produced by twitches breaking through the motor inhibition of REM sleep. The failure of this inhibition may contribute to sleep disruption and increased motor activity in sleep in pathologic states.

In contrast with the norepinephrine, serotonin, and histamine cell groups, it was reported that mesencephalic dopaminergic neurons do not appear to alter their discharge rate across the sleep cycle.[111] Dopamine release in the amygdala measured by dialysis does not significantly vary across the sleep cycle.[150] In disagreement with this finding, a Fos study indicted that dopaminergic neurons within the ventral portion of the mesencephalic tegmentum were activated during periods of increased REM sleep.[151] A unit recording study indicated that dopaminergic neurons in the ventral tegmental area of the midbrain show maximal burst firing in both waking and REM sleep.[113] Other work using the Fos labeling technique identified a wake-active dopaminergic cell population in the ventral periaqueductal gray.[116] In dialysis measurements of dopamine release, dopamine release was reduced in the dorsal horn of the spinal cord during the REM sleep–like state triggered by carbachol. Such a decrease was not seen in the ventral horn or hypoglossal nucleus.[134] These data suggest either heterogeneity in the behavior of sleep cycle activity of dopaminergic neurons or presynaptic control of dopamine release independent of action potentials in the cell somas.

Figure 8-9 illustrates some of the anatomic and neurochemical substrates of the brainstem generation of REM sleep.

NARCOLEPSY AND HYPOCRETIN

Narcolepsy has long been characterized as a disease of the REM sleep mechanism. Narcoleptic patients often enter REM sleep within 5 minutes of sleep onset, in contrast with normal persons, who rarely show such "sleep-onset REM sleep." Most narcoleptics experience cataplexy,[152] a sudden loss of muscle tone with the same reflex suppression that is seen in REM sleep. High-amplitude theta activity in the hippocampus, characteristic of REM sleep, is also prominent in cataplexy as observed in dogs.[145] Further evidence for links between narcolepsy and REM sleep comes from studies of neuronal activity during cataplexy. Many of the same cell populations in the pons and medulla that are tonically active only during REM sleep in normals become active during cataplexy in narcoleptics, including cells in the medial medullary inhibitory region that are selectively active in relation to the atonia of REM sleep.[17,132] Likewise, cells in the locus coeruleus, which cease discharge only in REM sleep in normal animals, invariably cease discharge in cataplexy.[153] However, just as cataplexy differs behaviorally from REM sleep in its maintenance of consciousness, not all neuronal aspects of REM sleep are present during cataplexy. As noted previously, in the normal animal, noradrenergic, serotoninergic, and histaminergic cells are all tonically active in waking, reduce discharge in NREM sleep, and cease discharge in REM sleep.[145,153] Unlike noradrenergic cells, however, serotoninergic cells do not cease discharge during cataplexy, only reducing discharge to quiet waking levels. Histaminergic cells actually increase discharge in cataplexy relative to quiet waking levels[154] (Figure 8-10). These findings allow identification of some of

Posterior hypothalamic histaminergic neurons remain active, whereas dorsal raphe serotoninergic neurons reduced discharge, and locus coeruleus noradrenergic neurons ceased discharge during cataplexy. All of these cell types were active in waking, reduced discharge in NREM sleep, and were silent or nearly silent in REM sleep. the cellular substrates of cataplexy. Medullary inhibition and noradrenergic disfacilitation are linked to cataplexy's loss of muscle tone. By contrast, the maintained activity of histamine neurons is a likely substrate for the maintenance of consciousness during cataplexy that distinguishes cataplexy from REM sleep. Thus the study of neuronal activity in the narcoleptic animal provides insight into both narcolepsy and the normal role of these cell groups in maintaining consciousness and muscle tone.

In 2001 it was discovered that most human narcolepsy was caused by a loss of hypothalamic cells containing the peptide hypocretin[23,24] (Figure 8-11). On average, 90% of these cells are lost in narcolepsy. Subsequently it was discovered that a lesser reduction in the number of hypocretin cells was seen in Parkinson disease, with a loss of up to 60% of hypocretin cells.[155,156] It was found that administration of the peptide to genetically narcoleptic dogs reversed symptoms of the disorder[157] and that nasal administration reversed sleepiness in monkeys,[158] suggesting that similar treatment could be uniquely effective for narcolepsy and perhaps for other disorders characterized by sleepiness.[159-161] Recently it also has been found that in human narcoleptics, the number of detectable histamine cells is increased more than 65%.[162,163] It has been speculated that because this change is not seen in any of four different animal genetic models of narcolepsy, the increase may be related to the presumed immune activation that causes human narcolepsy.[162]

In further work in normal animals, it was determined that identified hypocretin neurons discharge at their highest rates during active waking[35,164] (Figure 8-12). This discharge was reduced or absent during aversive waking situations, even if the EEG indicated high levels of alertness.[35] The hypocretin level in normal dogs is nearly doubled when they are let out into a yard to play with other dogs. By contrast, when these same dogs run at maximal speed on a treadmill, hypocretin levels are unchanged, demonstrating that motor activity and associated changes in respiratory rate, heart rate, and body temperature do not by themselves determine the release of hypocretin. Findings in studies of hypocretin release in the cat[165] also are consistent with this hypothesis. Hypocretin cells send ascending projections to cortical and basal forebrain regions, in addition to their descending projection to locus coeruleus and other brainstem regions. In the absence of hypocretin-mediated facilitation of forebrain arousal centers, waking periods are truncated, resulting in the sleepiness of narcolepsy.[166]

The functions of hypocretin have been investigated in genetic knockout animals lacking the peptide and in their wild-type littermates, using operant reinforcement tasks. Hypocretin-knockout mice are deficient in the performance of bar presses to secure food or water reinforcement. However, they do not differ from their normal littermates in their performance when trained to bar press to avoid foot shock. Periods of poor performance on the positive reinforcement tasks are characterized by EEG deactivation.[167] This deficit is restricted to the light phase, suggesting that hypocretin neurons mediate the arousing and mood-elevating effects of light,[167] effects that are central to the current understanding of depression. Fos labeling studies in normal littermates showed that the positive reinforcement task used in this study is characterized by activation of hypocretin neurons. However, hypocretin neurons are not activated in the negative reinforcement task or during the same positively motivated task in the dark phase, despite high levels of EEG activation, indicating that nonhypocretin systems mediate arousal during these behaviors.

Reduced number of hypocretin neurons in human narcolepsy. *Neuron* 2000;27:469-74.)

The conclusions of these animal studies were extended in the first study of hypocretin release within the human brain. Hypocretin levels were shown to be maximal during positive emotion, social interaction, and anger, behaviors that induce cataplexy in human narcoleptics. This finding is consistent with the hypothesis that release of hypocretin facilitates motor activity during emotionally charged activities of the sort that trigger cataplexy in narcoleptics.[166,168,169] Even normal persons experience weakness at these times, seen in the "doubling over" that often accompanies laughter or the weakness that can result from other strong emotions of sudden onset. In the absence of the hypocretin-mediated motor facilitation of locus coeruleus and other brainstem regions, muscle tone is lost at

these times. By contrast, the release in humans of melanin-concentrating hormone, a peptide produced by neurons intermixed in the hypothalamus with the hypocretin neurons, is minimal during social interaction but is increased after eating. Both peptides are at minimal levels during periods of postoperative pain despite high levels of arousal. Melanin-concentrating hormone levels increase at sleep onset, consistent with a role in sleep induction,[170] whereas hypocretin-1 levels increase at wake onset, consistent with a role in wake induction. Levels of these two peptides in humans are not simply linked to arousal but rather are correlated with specific emotions and state transitions[171] (Figure 8-13).

The findings that hypocretin is released and hypocretin neurons are active only during arousal linked to certain emotions suggests a new approach to the understanding of arousal systems. Hypocretin is clearly related to arousal linked to certain generally positive emotions. Other arousal systems must mediate arousal during aversive situations. An analysis of the differential activation of arousal systems as a function of emotion, light level, and other variables might provide important clinical and basic science insights into the unique roles of each arousal system.

Hypocretin appears to act largely by modulating the release of amino acid neurotransmitters.[172] Systemic injection of hypocretin causes a release of glutamate in certain hypocretin-innervated regions, producing a potent postsynaptic excitation.[139,173] In other regions it facilitates GABA release, producing postsynaptic inhibition.[165,174] The loss of these competing inhibitory and facilitatory influences in narcolepsy appears to leave brain motor regulatory and arousal systems

less stable than the tightly regulated balance that can be maintained in the presence of hypocretin (Figure 8-14). According to this hypothesis, this loss of stability is the underlying cause of narcolepsy, with the result being inappropriate loss of muscle tone in waking and inappropriate increases in muscle tone during sleep, resulting in a striking *increased* incidence of REM sleep behavior disorder in narcoleptics (see Chapters 89, 90, and 103). In the same manner, although a principal symptom of narcolepsy is intrusions of sleep into the waking period, narcoleptic persons sleep poorly at night, with frequent awakenings.[175-177] In other words, narcoleptics are not simply weaker and sleepier than normal subjects. Rather, their muscle tone and sleep-waking state regulation is less stable than in normal persons as a result of the loss of hypocretin function.

THE FUNCTIONS OF RAPID EYE MOVEMENT SLEEP

Research into the control of REM sleep turns into a seemingly infinite regression, with REM-on cells inhibited by REM-off cells, which in turn may be inhibited by other REM-on cells. It is very difficult to identify the sequence in which these cell groups normally are activated because the axonal condition and synaptic delays could not be more than a few milliseconds between these cell groups, yet REM sleep onset occurs over a period of minutes in the human and cat and at least 30 or more seconds in the rat. It also does not completely enlighten researchers with respect to the ultimate functional question: What is REM sleep for? To answer this question requires determining what if any physiologic process is altered over REM sleep periods. Is some toxin excreted or some protein synthesized? If so, how can the widely varying durations of the typical REM sleep be accounted for? In the human, REM sleep typically lasts from 5 to 30 minutes, whereas in the mouse, it typically lasts 90 seconds.[178] What can be accomplished in 90 seconds in the mouse but requires an average of approximately 15 minutes in humans? If a vital process is accomplished, why do drug treatments that abolish REM sleep have no discernable effect on any vital process, even when such drugs are taken continuously for many years? The biologic need that initiates REM sleep remains unknown, as well as the source of the REM sleep "debt" that accumulates during REM sleep deprivation.[179] Why do some marine mammals have no apparent REM sleep (see Chapter 10)?

Why is REM sleep present in homeotherms (i.e., birds and mammals) but apparently absent in the reptilian ancestors of homeotherms?

Great progress has been made in localizing the mechanisms that generate REM sleep. As described previously, many of the key neurotransmitters and neurons involved have been identified. The discovery of the role of hypocretin in narcolepsy serves as a reminder that key cell groups may still need to be identified before fundamental insights into the generation mechanism and functions of REM sleep can be gained. Yet despite this caveat, a substantial amount of information about what goes on in the brain during REM sleep has already been accumulated.

Clearly, increased brain activity in REM sleep consumes considerable amounts of metabolic energy. The intense neuronal activity shown by most brain neurons, similar to or even more intense than that seen during waking, exacts a price in terms of energy consumption and "wear and tear" on the brain. Such a state would be unlikely to have produced a Darwinian advantage and remained so ubiquitous among mammals if it did not have benefits compensating for its obvious costs. But what might these benefits be?

One idea that has received much media attention is that REM sleep has an important role in memory consolidation. However, the evidence for such a role is poor.[180] Although early animal work suggested that REM sleep deprivation interfered with learning, subsequent studies showed that it was the stress of the REM sleep deprivation procedure, rather than the REM sleep loss itself, that was critical.[181] A leading proponent of a sleep and memory consolidation relationship has concluded that sleep has no role in the consolidation of declarative memory,[182] which would exclude a role for sleep in rote memory, language memory, and conceptual memory, leaving only the possibility of a role in procedural memory—the sort of memory required for learning to ride a bicycle or play a musical instrument. However, studies supporting a role for sleep in the consolidation of human procedural learning have made contradictory claims about similar learning tasks, with some concluding that REM but not NREM sleep is important and others stating just the reverse, and still others claiming that both sleep states are essential.[180] Millions of people have taken monoamine oxidase inhibitors or tricyclic antidepressants, often for 10 to 20 years. These drugs profoundly depress or in many cases completely eliminate all detectable aspects of REM sleep. Of note, however, not a single report of memory deficits attributable to such treatment has emerged. Likewise, well-studied patients with permanent loss of REM sleep resulting from pontine damage show normal learning abilities; the best-studied of these patientscompleted law school after his injury[183] and was last reported to be the puzzle editor of his city newspaper. People with multiple systems atrophy can have a complete loss of slow wave sleep and disruption of REM sleep without manifesting any substantial memory deficit.[184] A recent well-controlled study showed that REM sleep suppression with selective serotonin reuptake inhibitors or serotonin-norepinephrine reuptake inhibitors was associated with no significant decrement in memory consolidation on any task and even produced a small but significant improvement in a motor learning (i.e., procedural) task.[185]

Another idea that has been suggested repeatedly is that REM sleep serves to stimulate the brain.[186-188] According to this theory, the inactivity of NREM sleep causes metabolic processes to slow down to an extent that the animal would be unable to respond to a predator, capture prey, or meet other challenges upon awakening. Such alterations would leave mammals functioning like reptiles, with slow response after periods of inactivity. This hypothesis explains the appearance of REM sleep after NREM sleep under most conditions. It also explains the well-documented increased proportion of sleep time in REM sleep as the sleep period nears its end in humans and other animals. Humans are more alert when aroused from REM sleep than from NREM sleep, as are rats[189]—findings consistent with this idea. The very low amounts or absence of REM sleep in dolphins, in which the brainstem is continuously active and which never show bilateral EEG synchrony, can be explained by this hypothesis. If one hemisphere is always active, there is no need for the periodic stimulation of REM sleep to maintain the ability to respond rapidly. However, the brain stimulation hypothesis of REM sleep function does not explain why waking cannot substitute for REM sleep in terrestrial mammals. REM sleep–deprived persons experience a REM sleep rebound even if they are kept in an active waking state for extended periods, although this effect may be a result of stress, rather than REM sleep loss.[181]

A phenomenon that may explain REM sleep rebound is the cessation of activity of histamine, norepinephrine, and serotonin neurons during REM sleep. This cessation does not occur during the awake state, so waking would not be expected to substitute for this aspect of REM sleep.[190] REM sleep rebound may therefore be due to an accumulation of a need to inactivate these aminergic cell groups. Several cellular processes might benefit from the cessation of activity in aminergic cells. Synthesis of these monoamines and their receptors might be facilitated during this period of reduced release. The

receptors for these substances might be resensitized in the absence of their agonist. The metabolic pathways involved in the reuptake and inactivation of these transmitters also may potentially benefit from periods of inactivity. Some but not all studies have supported this hypothesis.[191-195]

Further investigation at the cellular level may lead to an "inside-out" explanation of REM sleep function, deriving a functional explanation from a better understanding of the neuronal basis of REM sleep control.

CLINICAL PEARL

The loss of hypocretin neurons is responsible for most cases of human narcolepsy. It is thought that this cell loss may be the result of an immune system attack on these neurons, but convincing evidence for this explanation is lacking. Administration of hypocretin is a promising future avenue for the treatment of narcolepsy. Because the hypocretin system has potent effects on arousal systems including the norepinephrine, serotonin, acetylcholine, and histamine systems, manipulation of the hypocretin system with agonists and antagonists is likely to be important in further pharmacotherapies for narcolepsy, insomnia, and other sleep disorders, as well as for depression.

SUMMARY

REM sleep was first identified by its most obvious behavior: rapid eye movements during sleep. In most adult mammals the EEG of the neocortex is low in voltage during REM sleep. The hippocampus has regular high-voltage theta waves throughout REM sleep. The tone of the postural muscles is greatly reduced or abolished during this state.

The key brain structure for generating REM sleep is the brainstem, particularly the pons and adjacent portions of the midbrain. Considerable progress has been made in identifying the neurons most closely linked to REM sleep within these regions and the transmitters that they employ. Massive damage to the REM-generating region can abolish REM sleep. Small lesions can cause REM sleep without atonia in animals or REM sleep behavior disorder in humans

Narcolepsy is characterized by abnormalities in the regulation of REM sleep. Most cases of human narcolepsy are caused by a loss of hypocretin (orexin) neurons, a cell group whose somas are localized to the hypothalamus. Hypocretin neurons have potent effects on alertness and motor control and normally are activated in relation to particular, generally positive emotions in humans as well as in animals. In the absence of this cell group, cataplexy, a REM sleep–like loss of muscle tone, occurs.

Novel Techniques for Identifying Sleep Mechanisms and Disorders

John H. Peever; Priyattam J. Shiromani

Chapter Highlights

- In the past decade, new genetically engineered tools have been developed that enable identification of the neural circuits that control sleep-wake behavior.
- Candidate cell circuits can be genetically targeted to determine how they regulate sleep and wakefulness, and specific genes can be transferred into these circuits to determine if they can correct abnormal sleep behaviors (e.g., narcolepsy).
- Novel genetic tools can be used to advance the current understanding of sleep control and sleep disorders such as narcolepsy.

Considerable effort has been directed at identifying the brain circuits that generate wakefulness, non–rapid eye movement (NREM) and rapid eye movement (REM) sleep because their dysfunction contributes to sleep disorders such as narcolepsy and REM sleep behavior disorder.[1,2] The brain structures responsible for sleep control were first identified by transecting or lesioning specific brain areas and determining how these manipulations affect sleep-wake behavior. For example, transection studies were used to show that structures in the pons are responsible for controlling REM sleep, and lesion studies were used to show that regions of the hypothalamus are critical for regulating NREM sleep. Researchers then began to monitor the electrophysiologic activity patterns of individual neurons and discovered that in regions identified by the lesion studies, neurons were active during either wakefulness or NREM or REM sleep. This discovery strengthened the idea that the sleep-wake states were controlled by activity of specific cell groups. However, neurons in these groups have been found to be intermingled with neurons controlling other behaviors. Moreover, astroglial cells are now considered to be important partners with neurons in regulating behavior. In view of the growing complexity of the circuit, the challenge faced by a new generation of sleep researchers is how to disentangle the network to identify the culprit neurons regulating behavior. This chapter surveys some of the new methodologies used to investigate sleep control at whole-organism, regional, and cellular levels.

NOVEL TOOLS FOR STUDYING SLEEP CIRCUITRY

Emerging technologies are changing the way in which sleep researchers ask questions about the functions and mechanisms of sleep. How some of these new tools have been used to dissect the neural circuits that control sleep and wake behaviors in both health and disease is a main focus of this chapter. Although cutting-edge tools have been applied to study rest-activity behavior in fruit flies and worms, this work is not reviewed here; rather, the focus is on advances in mechanisms of mammalian sleep and how such discoveries have led to better understanding of causes and treatments of narcolepsy.

Figure 9-1 outlines some of the new additions to the neuroscience toolkit that have been (or can be expected to be) influential in furthering the current understanding of sleep-wake behaviors. Optogenetics, pharmacogenetics, and gene therapy are three of the most powerful additions to this toolkit and are described in detail in this chapter. Specific aspects include how sleep researchers are using these technologies to determine (1) how individual neuronal populations generate sleep states, (2) the specific neurotransmitter identities of each of these cell groups, and (3) how these "sleep circuits" communicate with one another to facilitate the switching between different sleep states.

Understanding Sleep Control Using Conventional Genetics

By way of background, presented next is a summary of insights gained from more traditional transgenic approaches in which a specific gene of interest has been either deleted (by so-called knockout strategies) or added (using "knockin" methods) to the genome. The animal models that sleep researchers are most familiar with are ones in which the hypocretin (orexin) system has been manipulated. At the outset it is important to acknowledge the enormous impact that William Dement had on the sleep science field by developing a canine model of narcolepsy. He was the first to recognize canine narcolepsy and believed that this model system would unlock the mystery of the disease. He was right because the "dog model" eventually led to the identification of one of the causes of narcolepsy.

In 1999, researchers found that a genetic mutation in the hypocretin-2 receptor causes canine narcolepsy,[3] and targeted deletion of the gene encoding hypocretin induced narcolepsy in mice[4] (Jackson Labs stock 008867). Shortly thereafter, two independent reports showed selective loss of hypocretin neurons in human narcolepsy.[5,6] A transgenic mouse line was created that mimics the degeneration of the hypocretin neurons in human narcolepsy.[7] This was accomplished by fusing ataxin to the hypocretin promoter (called a fusion gene hypocretin:ataxin) so that a polyglutamine cytoxicity accumulates in hypocretin neurons, resulting in loss of 90% of

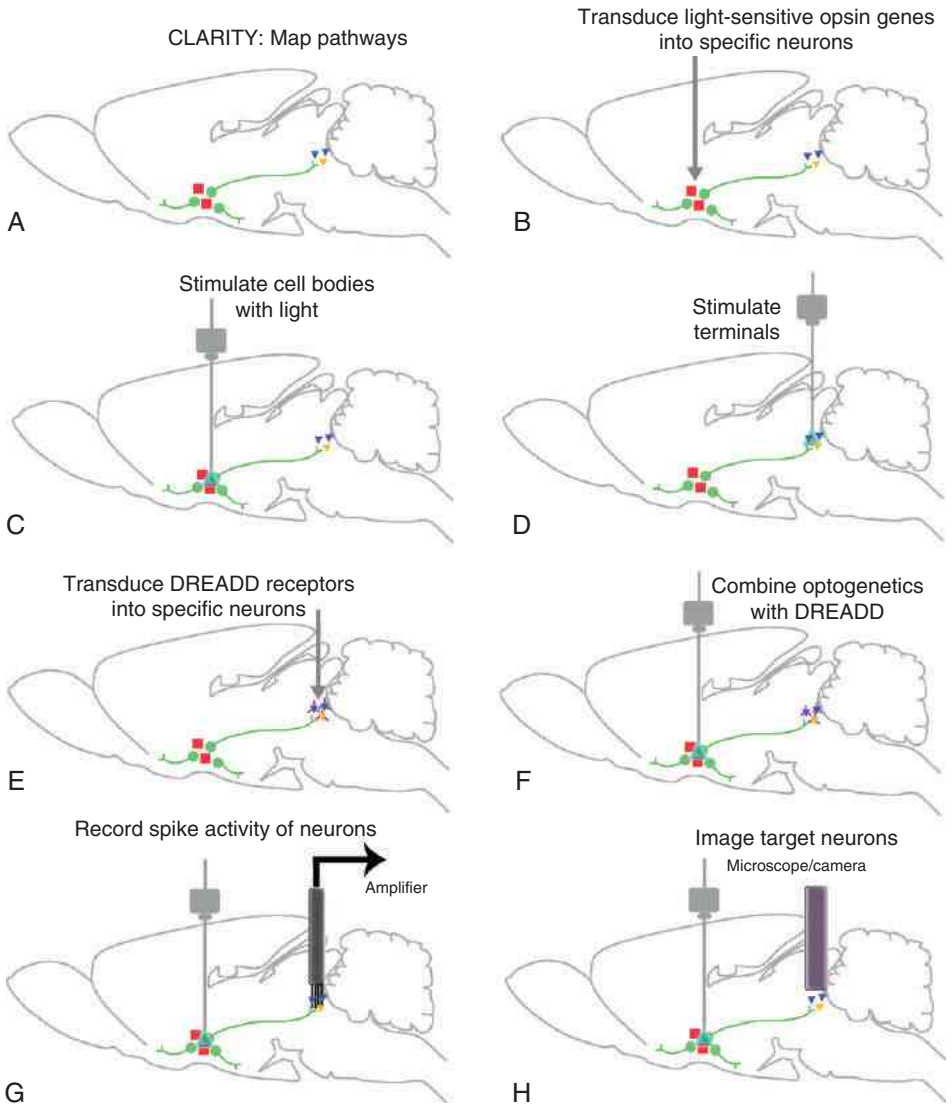

Figure 9-1 New genetically engineered tools to identify the neural circuitry responsible for waking, NREM, and REM sleep. Two areas in the brain, one in the hypothalamus (*green-* and *red-labeled* neurons) and the other in the pons (*triangles*), have been implicated in regulating sleep. These areas were first identified by transection and lesion studies, but now it is necessary to pin down the phenotype of the culprit neurons regulating sleep. To map the circuit, researchers can use CLARITY, a neuroanatomic method that renders tissue such as the brain transparent. The transparent brain is scanned with a confocal microscope allowing visualization of the underlying neurons and pathways **(A).** The activity of specific neurons can be manipulated by introducing light-sensitive genes into these cells **(B)** and using a light source such as a laser or light-emitting diode of a specific frequency to either activate them (via channelrhodopsins) or inhibit them (via halorhodopsin) **(C).** The terminals of these neurons can be manipulated with light to determine whether the target areas are involved in the behavior **(D).** Pharmacogenetic methods such as DREADD also can be used to selectively manipulate a specific phenotype of neurons **(E).** Both optogenetics and DREADD can be applied in the same experimental plan to manipulate specific nodes in the circuit **(F).** Electrophysiologic activity of the neurons can be monitored **(G).** However, to provide definitive evidence about the phenotype of the recorded neuron, a camera attached to a microendoscope can image the behavior of the specific neurons **(H).**

hypocretin cells within 1 month after birth[7] and virtually 100% by 6 months.

In typical gene knockout mice, such as the hypocretin-knockout model, gene deletion is constitutive and starts from conception. Such alterations may produce compensatory responses that could have unexpected effects on behavior, so a potentially better approach is to control the exact timing of gene deletion or cell death. This approach has now been realized by expressing the diphtheria toxin gene in hypocretin neurons and placing it under the control of the Tet-off system[8] (Tet from tetracycline). The use of antibiotics such as doxycycline to control the DNA is referred to as the Tet-off/Tet-on system. This method provides control over gene expression or repression simply through access to tetracycline or doxycycline in the water. In the presence of doxycycline, hypocretin neurons remain intact, but once doxycycline administration (in drinking water) is stopped, diphtheria toxin accumulates in hypocretin neurons, and within 7 days, 80% of hypocretin

neurons die. This approach can be used to determine the time course of development of narcoleptic symptoms as a function of hypocretin neuron loss. In fact, it has been used to show that mice develop cataplexy only when approximately 95% of hypocretin cells are lost.[8]

The Tet-driven system also has been used to study the functional role of neurons containing melanin-concentrating hormone (MCH).[9] Selective loss of MCH neurons produces a selective decrease in NREM sleep without changing either wakefulness or REM sleep.[9]

Cre Recombinase and the Advent of New Genetic Tools

The doxycycline and Tet-off/Tet-on system was made possible by the discovery of an enzyme called Cre recombinase, which was isolated from the P1 bacteriophage. The Cre (cycle recombinase) gene encodes a protein of 343 amino acids, which recognizes two sites called loxP (locus of X-over P1) sites, and the enzyme will very efficiently recombine essentially any DNA substrates that contain these sites. What is remarkable is that the orientation of the loxP sites determines whether the DNA between the loxP sites is deleted, translocated, or inverted. When two loxP sites are oriented in the same direction, Cre excises the DNA flanked by the loxP sites. When the loxP sites are oriented in the opposite direction, Cre flips the flanked DNA into the antisense orientation. Expression of Cre recombinase occurs only in specific cells, which ensures that the gene manipulation (deletion or insertion) is restricted only to cells expressing Cre. Crossing Cre mice with a loxP-flanked (also referred to as floxed sequence) mouse line enables Cre-mediated recombination in the Cre cells of the offspring.

It is no longer necessary to establish breeding colonies to use the Cre-transgenic animals. A new tool has been designed to insert specific genes of interest only in those cells expressing Cre recombinase. This system, developed by Karl Diesseroth's group at Stanford, involves a double-floxed inverse open reading frame (DIO) construct that causes serial recombination in Cre-expressing cells, resulting in the expression of the transgene. The DIO system was designed specifically to express light-sensitive opsins (discussed in a later section) in certain cells in a particular location. The DIO construct comprises a promoter, elongation factor 1 alpha (EF1α) (Table 9-1); DIO, the light-sensitive opsin to be activated (hChR2 or eArch3.0); and a reporter gene, enhanced yellow fluorescent protein (eYFP). These are linked to a viral vector—recombinant adenoassociated virus (AAV), in Table 9-1)—and microinjected into the desired target area. The virus will subsequently infect all of the cells in the area, but only the cells containing Cre recombination will express the transgene (for example, ChR2-eYFP).

It is common to include a reporter gene in the construct because its detection will indicate that the gene insertion procedure was successful. The reporter gene also serves as a proxy for proteins, such as ion channels (ChR2), pumps (halorhodopsin), or receptors that are difficult to detect using immunohistochemical methods. The use of reporter genes as markers of gene expression has been so transformative that Martin Chalfie, Osamu Shimomura, and Roger Y. Tsien were awarded a Nobel Prize for their discovery.

Ready-made viruses that target Cre-expressing cells constitute the most commonly used tool to deliver candidate effector genes (e.g., ChR2). A number of viruses can be used (e.g., adeno-associated virus) for this technology, and a review article[10] has highlighted strengths and weaknesses of each. The choice of a virus depends on the size of the total package of genes, called the cassette, that are going to be transferred into the surrogate cell. The cassette will include the promoter elements (so that the gene is expressed in a specific phenotype of neurons), the gene itself, and the reporter gene (to identify success of the gene transfer).

AAV, Adenoassociated virus infects cells inserting the genes linked to it into the cells; DDO, double-floxed inverse open reading frame; DREADD, designer receptor exclusively activated by designer drug; eArch3.0, enhanced Archerhodopin3.0, inhibitory opsin; EF1a, elongation factor 1 alpha, a promoter; eNpHR, enhanced Natronomonas pharaonis3.0, an inhibitory opsin; eYFP, enhanced yellow fluorescent protein, reporter gene; GCaMP6m, genetically encoded calcium indicator; hChR2(H134R), humanized version of channelrhodopsin-2 that has been mutated to produce larger photocurrents compared to wild-type hChR2; hM3D and hM4D, human M3 muscarinic DREADD receptors; hSyn, human synapsin-1 promoter directs expression of genes into neurons.

THE OPTOGENETIC METHOD

Optogenetics ("opto" for optical stimulation and "genetics" for genetically targeted cell types) uses the light-sensitive proteins channelrhodopsin-2 (ChR2) and halorhodopsin (NpHR) to either activate or inhibit (respectively) the activity of neurons in which they are targeted.[11] ChR2 is a cation channel cloned from green algae, *Chlamydomonas reinhardtii,* that opens in response to blue light (with a wavelength of approximately 473 nm) and allows Na^+ to flow into a cell. Cells expressing ChR2 are depolarized when exposed to blue light (i.e., of the same wavelength). Halorhodopsin is a light-gated chloride pump present in *Natronomonas pharaonis,* a single-celled organism that is abundant in brackish water. Cells expressing NpHR are hyperpolarized when exposed to yellow light (wavelength of approximately 590 nm). The fast temporal kinetics of light-sensitive opsins makes it possible to reliably drive trains of high-frequency action potentials in ChR2-expressing cells or suppress action potentials in NpHR-expressing neurons. These two types of light-sensitive proteins can be inserted into cells, conferring the ability to manipulate the activity of specific cells with millisecond precision. Thus, depending on the wavelength of light, it is possible to control

specific circuits in a neural network. Because cells controlling specific behaviors are intermingled with cells controlling other behaviors, optogenetics empowers researchers to use light to control specific neurons in a neural network.

Optogenetics in Studying Sleep-Wake Control

Optogenetics is currently being used to determine how brain circuitry promotes sleep-wake behaviors. For example, the hypocretin and noradrenergic neurons have been optogenetically manipulated to determine how they control arousal[12-14] (Figure 9-1). In the first use of optogenetics in sleep neurobiology, a lentivirus delivered the gene for channelrhodopsin-2 into hypocretin neurons in mice. Light pulses at a frequency of 1 Hz did not significantly induce waking episodes from either NREM or REM sleep, but stimulation at higher frequencies (5 to 30 Hz) increased transitions from both NREM and REM sleep into wakefulness.[12] Optically induced arousals were blocked with a hypocretin receptor antagonist (almorexant), indicating that hypocretin neurons promote arousal by a hypocretin-dependent mechanism.

Optogenetic methods also have been used to show that hypocretin neurons promote arousal by activating noradrenergic cells in the locus coeruleus (LC). LC neurons were manipulated using channelrhodopsin-2 (activating) or halorhodopsin (inhibiting).[14] The two genes were inserted into LC neurons by injecting a Cre-recombinase-dependent AAV into knockin mice that selectively expressed Cre in tyrosine hydroxylase–expressing neurons. Photostimulation of LC neurons caused rapid transitions from sleep into wakefulness, whereas photoinhibition of these same cells reduced in the length of wake bouts, suggesting that one function of noradrenergic cells is to promote arousal. Of interest, very-high-frequency (5 to 20 Hz) stimulation of LC cells caused "behavioral arrests" that at face value appear similar to cataplexy bouts in narcoleptic mice.[4] One interpretation of this observation is that high-frequency LC stimulation depletes noradrenergic release onto motoneurons, which in turn triggers loss of muscle tone and hence cataplexy-like behavior. This observation is congruent with experiments showing that inactivity of LC neurons and reduced noradrenergic release onto motoneurons are associated with cataplexy.[15,16]

A newer inhibitory opsin, archaerhodopsin, which is more potent in its effects (compared with halorhodopsin), has been used to inhibit hypocretin neurons.[17] One hour of photoinhibition of the hypocretin neurons during the active period (i.e., dark phase) increased total time spent in NREM sleep but had no effect on REM sleep. Of interest, such inhibition did not induce more sleep during the normal inactive period (i.e., light phase) in these same mice, suggesting that optogenetic manipulation of hypocretin neurons has predictable effects on waking behaviors.

Optogenetics also has been used to determine how "sleep-active" neurons participate in sleep control. Although gamma-aminobutyric acid (GABA)/galanin neurons in the median and ventral lateral preoptic area[18,19,20] are hypothesized to induce NREM sleep, their specific role in sleep promotion has not been studied using optogenetic approaches. However, the role of hypothalamic MCH neurons in sleep promotion has been well documented.

MCH neurons are located in the zona incerta, dorsomedial hypothalamus, and lateral hypothalamus.[21] They are intermingled with hypocretin neurons and project to many of the same target regions.[22-25] Electrophysiology studies have shown that MCH neurons are inactive during waking, begin firing during NREM sleep, and become most active during REM sleep.[26] C-Fos studies support these findings.[27,28] Consistent with their sleep activity pattern, MCH release is correlated with sleep onset in both humans and rats,[29,29a] suggesting that MCH could function to initiate sleep. Pharmacologic studies in rodents showed that intracerebroventricular injection of MCH during the dark period increases both NREM and REM sleep in dose-dependent fashion.[29] MCH injection into sleep-promoting areas such as the ventral lateral preoptic area significantly increases NREM sleep,[30] whereas injection into REM sleep-promoting areas such as the nucleus pontis oralis or dorsal raphe increases REM sleep amounts.[31,32]

Because MCH neurons coexpress a variety of transmitters, including GABA,[25] CART (cocaine- and amphetamine-regulated transcript),[33] and nesfatin,[34] it is difficult to determine which neurochemical is responsible for their sleep-inducing effects. In a recent study, however, selectively killing MCH neurons by expressing the diphtheria toxin gene resulted in more wakefulness and less NREM sleep.[9] This finding is supported by observations in MCH-knockout mice, which experience more wakefulness and less NREM sleep,[35,36] suggesting that MCH per se is a sleep-promoting agent.

Optogenetic stimulation provides a direct test of the role of MCH neurons in sleep. In the very first study, Konadhode and coworkers[37] inserted the gene for channelrhodopsin-2 into the MCH neurons in wild-type mice and photostimulated infected neurons with blue-light pulses of 10 milliseconds (for 1 minute on every 5 minutes). These workers found that optogenetic activation of MCH neurons at night reduced the length of waking bouts and increased both NREM and REM sleep amounts. The increase in sleep was most robust when the light pulses were given at 10 Hz than at 5 Hz. The 10-Hz stimulation also increased delta power, which is a marker of sleep intensity. The increase in sleep occurred during the animal's active period, indicating that MCH neurons inhibit the activity of arousal-promoting neurons.

Jego and associates[38] also assessed the role for MCH neurons in sleep control by inserting channelrhodopsin-2 into MCH neurons. These investigators stimulated only during the second half of the normal 24-hour light-cycle and only when the mice entered into REM sleep, and found that such stimulation prolonged REM sleep bouts. They also used light-sensitive halorhodopsin (eNpHR3.0) to inhibit MCH neurons but found no affect on the duration of REM sleep bouts. Their finding broadly supports the hypothesis that MCH function to promote sleep.

Mechanisms generating REM sleep are controversial. One body of data suggests that REM sleep is generated by a cholinergic mechanism originating within the pedunculopontine tegmentum (PPT) and laterodorsal tegmentum (LDT) nuclei, whereas other data suggest that it originates from glutamatergic cells in the subcoeruleus area (synonymous with the SLD). Recently, Van Dort and colleagues aimed to clarify the role of PPT and LDT cholinergic neurons in REM sleep generation.[39] On optogenetically activating cholinergic neurons in the PPT or LDT during NREM sleep, these researchers found that 33% of the time, this intervention triggered REM sleep bouts, but without changing the length of REM sleep episodes. This observation suggests that PPT or

LDT is capable of inducing REM sleep. These workers did not find that optogenetic stimulation of the LDT/PPT cholinergic neurons triggered waking, even though these neurons are active in both waking and REM sleep. Thus NREM sleep may bias these neurons toward REM sleep.

The only other study to assess the functional role of sleep-active neurons using optogenetics is that of Anaclet and colleagues.[40] These investigators showed that optogenetic stimulation of the parafacial zone (PZ) induced NREM sleep, regardless of circadian time. They found that PZ neurons monosynaptically innervate and release GABA onto parabrachial neurons, which in turn project to and release glutamate onto magnocellular basal forebrain neurons. It is therefore hypothesized that GABAergic PZ neurons trigger NREM and slow wave activity by way of this newly identified pathway. Identification of this pathway was made possible by the use of optogenetics, underscoring the important contribution this new technology has made in elucidation of the circuit control of sleep.

THE PHARMACOGENETIC METHOD

Pharmacogenetics, also called chemogenetics, is a complementary technology to optogenetics, but instead of using light to control cell activity, it employs a drug-based approach. The particular branch of pharmacogenetics discussed here is DREADDs (designer receptors exclusively activated by designer drugs). This technology uses two separate types of engineered G protein–coupled receptors to genetically target cells and thereby manipulate their activity. Neurons that are forced to express the hM3Dq muscarinic receptor are excited by a Gαq signaling pathway, whereas neurons expressing the hM4Di muscarinic receptor are inhibited by a Gαi pathway. Both hM3Dq and hM4Di receptors are under exclusive control of the biologically inert compound clozapine-*N*-oxide (CNO) and are unresponsive to endogenous acetylcholine. Because CNO crosses the blood-brain barrier, it can be delivered by intraperitoneal injection. Unlike in optogenetics, which allows rapid, reversible control of neuron activity, manipulation of hM3Dq and hM4Di receptors affects neuronal activity over many minutes (approximately 60 to 120 minutes). However, the drug penetrates a wider area than can be achieved with optogenetics, where neurons only in the immediate arc of light are activated. DREADDs is advantageous for studying phenotypes of neurons that are diffusely scattered.

Pharmacogenetics in Studying Sleep-Wake Control

DREADD technology has been used to determine how manipulating hypocretin neurons affects sleep and wakefulness.[41] In a recent study, CNO-induced activation of hM3Dq receptors on hypocretin neurons increased wakefulness, whereas CNO-induced activation of hM4Di receptors on hypocretin neurons increased sleep.[41] The investigators also have combined both optogenetics and DREADDs to define the brain region in which hypocretin deficiency produces narcoleptic symptoms. They used mice in which both hypocretin receptors were deleted, and then they reinserted either hypocretin receptor 1 or 2 in phenotype-specific neurons in the pons.[42] Cataplexy was suppressed when the hypocretin-2 receptors were restored in the serotoninergic neurons of the dorsal raphe, and waking behavior and sleep fragmentation were rescued only when the hypocretin-1 receptors were restored in the LC. To confirm their findings, the authors used the hypocretin-ataxin-3 mice and selectively activated either the dorsal raphe serotonin neurons or the LC neurons with DREADD technology. DREADDs induced activation of serotonin neurons rescued cataplexy while activation of LC neurons increased waking. This finding suggests that cataplexy results from loss of hypocretin-induced activation of raphe serotonin neurons, and that sleepiness is caused by reduced LC activity.

GENE THERAPY METHODS

Gene therapy is being used to treat some intractable diseases including neurodegenerative diseases (http://www.wiley.com/legacy/wileychi/genmed/clinical/). For instance, in a phase 1 study, eight patients with mild Alzheimer disease were given ex vivo NGF gene therapy, and their rate of cognitive decline was slowed.[43] In another study, motor functions were improved in six patients with Parkinson disease who were given a gene for synthesis of dopamine and serotonin.[44] Because narcolepsy is considered a neurodegenerative disease, it should be feasible to restore network function and hence behavior by transferring the hypocretin gene into surrogate neurons.[5,6]

Mouse models of narcolepsy (see earlier under Understanding Sleep Control Using Conventional Genetics) provide an ideal platform for testing the effects of hypocretin gene therapy on narcolepsy symptoms, namely, sleepiness and cataplexy. One study used the herpes simplex virus to insert the hypocretin gene into neurons in the lateral hypothalamus of hypocretin-knockout mice. This particular mouse model was used because the underlying neuronal network regulating sleep remains unchanged. Liu and associates found that increasing hypocretin expression in the lateral hypothalamus markedly decreased cataplexy.[45]

A second study[46] used the hypocretin–ataxin-3 mouse model,[7] which more closely resembles human narcolepsy in that the hypocretin neurons die. The hypocretin gene (*HCRT*) was inserted into surviving neurons in the lateral hypothalamus, which led to a significant decrease in cataplexy in both number and duration of attacks.[46] Diluted virus produced intermediate effects, and transfer of the hypocretin gene into a control region that is not linked to sleep had no effect on cataplexy. Levels of sleep-wake were not changed by gene transfer in this study.[46]

Another group of investigators injected the hypocretin gene into more ventral regions of the lateral hypothalamus in hypocretin–ataxin-3 mice, and this approach modestly improved waking but not cataplexy.[47] In a fourth study,[48] the hypocretin gene was transferred into pontine neurons on the basis of evidence that they are linked to maintaining muscle tone.[49] Ths strategy produced a significant decrease in cataplexy in hypocretin-knockout mice. Another study combined optogenetics and DREADD to provide a better cellular resolution of the phenotype of neurons in the pons involved in cataplexy.[42] The researchers showed that the hypocretin input onto serotonin neurons reduces cataplexy, whereas hypocretin input onto LC neurons maintains waking.[42] Other sites also regulate waking, however, and hypocretin may exert its action at one of these. One group of workers[50] used mice that could not maintain long waking bouts as a result of a mutation in the hypocretin-2 receptor. They normalized the hypocretin-2

receptor (using Cre recombinase) only in neurons of the posterior hypothalamus including the tuberomammillary nucleus (TMN) and found that the mice could sustain long wake bouts, similar to wild-type mice.[50] The hypocretin-2 receptor is dense on histaminergic TMN neurons, and because the hypocretin ligand is already present in the mice, the normalized hypocretin-2 receptor on the histamine neurons corrected the waking defect. Thus two gene transfer studies show that waking can be sustained by hypocretin action onto TMN or LC neurons.

The conclusions from these gene transfer studies is that hypocretin gene transfer is most successful in decreasing cataplexy and maintaining long waking bouts provided that (1) the surrogate neurons carrying the hypocretin gene or the hypocretin-2 receptor are part of the circuit responsible for the behavior, and (2) the surrogate neurons carrying the ligand in the circuit are active during waking because then they can release hypocretin at target sites to normalize behavior.

CLARITY: Whole-Brain Imaging of Anatomic Pathways

CLARITY is a new neuroanatomic method that makes brain (and other body) tissues transparent. This process allows cells and their neural pathways to be visualized and reconstructed in three dimensions within the intact brain.[51-53] CLARITY has been used to examine cellular and pathway connections within the brain and spinal cord as well as peripheral organs such as the heart and kidney.

CLARITY is achieved by impregnating brain tissue with hydrogel that maintains tissue cellular structure and matrix, including antigenicity of the proteins. After the hydrogel has secured the cellular structure, the lipids in the tissue are dissolved and removed. A third set of chemicals adjusts the refractive index of the tissue to allow light to pass through, rendering it transparent. The entire block of tissue can now be scanned with a light-sheet microscope, and the network visualized in three-dimensional format. Whole-brain clearing methods can be combined with neuronal activity markers, such as c-Fos or Arc, to determine functional activation of the network.[54] CLARITY will be useful in reconstructing visual maps of sleep-wake circuitry to help delineate how and where these circuits are located in the central nervous system. Because CLARITY is largely descriptive in nature, however, functional methods are needed to assess exactly when these pathways become active during specific behaviors. This methodology reconstructs an intact brain in three-dimensional format, so foreseeably, it will prove to be crucial in deconstructing pathways in animal models of narcolepy, restless legs syndrome, or REM sleep behavior disorder.

Optical Live-Cell Imaging in Vivo

One of the newest and still developing technologies in neuroscience is live-cell imaging of neurons in the intact brain during behavior. Initially, only neurons in the cortex or hippocampus could be imaged. Today, however, it is feasible to image neurons deep (5 mm from cortical surface) within brain tissue in freely behaving mice.[55,56]

The target neurons are reached through a microendoscope (only 0.5 mm in diameter) and the optical signals imaged with a miniature fluorescence microscope.[57] Live imaging monitors changes in calcium influx associated with action potentials, and fluorescent calcium sensors, including those contained in the cells of genetically engineered mice, are now available.[58] To image a specific phenotype of neurons, AAVDJ-EF1a-DIO-GCaMP6m can be injected into the target neurons in specific Cre mice, and GCaMP6m fluorescence detected with a fluorescence microscope.

The advantage of this approach is that it allows for monitoring of the activity of individual genetically identified cells (e.g., bone fide hypocretin cells) in real time in the context of specific sleep-wake behaviors. Electrophysiology studies can record activity of single neurons, but this technique is extremely labor-intensive and slow, and it cannot identify the phenotype of the recorded neuron in freely behaving animals. By contrast, with live-cell imaging, a researcher can now "watch" the activity of individual and populations of neurons of known phenotypic origin and rapidly determine their role in behavior. Indeed, the activity of a single neuron can be assessed in this manner to determine whether it is a participant in the behavior. This methodology was recently used to dissect the role of GABAergic neurons in the lateral hypothalamus in appetitive versus consummatory behavior. The investigators found that even within a homogeneous neuronal population, the activity of individual neurons depends on the behavior.[57]

Live-cell imaging also confers the ability to either add or replace genes and to determine how this intervention affects their activity in the context of the intact nervous system during identified behaviors. This approach would be very useful to deconstruct the activity of specific neurons during cataplexy. Previously, electrophysiologic activity of single neurons was monitored during cataplexy in narcoleptic mice,[59] but live-cell imaging could definitively identify the phenotype of the recorded neurons.

CLINICAL PEARL

Technological advances have made it possible for scientists to peer into events at the subatomic level and also allowed humans to gaze out into the universe. The complexity of the human brain also is yielding to technology. In the past decade, new genetically engineered tools have been developed that enable identification of the neural circuits that control sleep-wake behavior. For example, cell circuits can be genetically targeted to determine how they regulate sleep and wakefulness, and specific genes can be experimentally transferred into these circuits to correct abnormal behavior such as in narcolepsy. Clinicians should be aware of these tools because they facilitate developing more rational treatments for sleep disorders.

SUMMARY

Conventional neuroscience tools such as lesions, cell recordings, c-Fos, and track-tracing methodologies have been instrumental in identifying the complex and intermingled populations of sleep- and arousal-promoting neurons that orchestrate and generate wakefulness and NREM and REM sleep. The recent development of new genetic technologies such as optogenetics, DREADDs, and gene therapy, however, has begun to transform the current understanding of sleep-wake regulation to uncover more specific details. These strategies have helped identify how discrete populations of genetically targeted cells (e.g., MCH, hypocretin) function to trigger and shape the timing and transition into and out of

different sleep-wake states. One of the greatest potentials for these new strategies, however, lies in explaining how pathologic activation and inactivation of discrete elements of the sleep-wake circuitry contribute to sleep disorders. For example, optogenetics can be expected to elucidate how (or if) recruitment of the REM sleep circuit contributes to muscle paralysis in cataplexy, and to determine how inactivity in this circuitry contributes to REM sleep without atonia in REM sleep behavior disorder.

Sleep in Animals: A State of Adaptive Inactivity

Jerome M. Siegel

Chapter 10

Chapter Highlights

- In most adult animals sleep is incompatible with mating and feeding. Many researchers view animals as being highly vulnerable to predation during sleep. Why do animals devote from 2 to 20 hours of the day to sleep, in what appears to be a nonproductive state? Why has evolution preserved this state?The presence of sleep in nearly all animals and the enormous variation in sleep time across species are best explained as adaptations to ecologic and energy demands.
- Sleep is not a maladaptive state that needs to be explained by undiscovered functions (which nevertheless undoubtedly exist). Rather, the major function of sleep is to increase behavioral efficiency. Greater waking activity does not necessarily lead to increased numbers of viable offspring and, hence, genetic success. Rather, genetic success is closely linked to the efficient use of resources and to the avoidance of risk. Thus, inactivity can reduce predation and injury. It also reduces brain and body energy consumption. As often stated, energy conservation is not a sufficient explanation for sleep, because the energy saved in a night's sleep in humans is only equivalent to that contained in a slice of bread. In the wild, however, most animals are hungry and are seeking food most of the time they are awake. If ample food is available, the population of a species quickly expands until faced again with food scarcity, a phenomenon that is illustrated by the great increase in the human population.
- The ability of sleep to conserve energy when food is scarce constitutes a major survival benefit even if only a small amount of energy is saved. Conversely, if food is available but is time-consuming to acquire, it is highly advantageous for animals to be able to reduce sleep time without behavioral impairment. Similarly, it is highly advantageous to reduce or eliminate sleep to allow migration and to respond to certain other needs. Several examples of extended periods of elimination or substantial sleep reduction without rebound have recently been documented and appear to be strongly linked to species success.
- Many researchers have assumed that predation risk is increased during sleep—that more animals are killed per hour during sleep than during waking. However there is scant evidence to support this contention. Most animals seek safe sleeping sites, often underground, in trees or in groups that provide communal protection. Those large herbivores that cannot find safe sleeping sites appear to require smaller amounts of sleep and to sleep less deeply. Large animals that are not at risk for predation, such as big cats and bears, can sleep for long periods, often in unprotected sites, and appear to sleep deeply.

ADAPTIVE INACTIVITY

Sleep should be viewed in the context of other forms of so-called *adaptive inactivity*. Most forms of life have evolved mechanisms that permit the reduction of metabolic activity for long periods of time when conditions are not optimal. In animals, this usually includes a reduction or cessation of movement and sensory response. The development of dormant states was an essential step in the evolution of life, and dormancy continues to be essential for the preservation of many organisms. Many species have evolved seasonal dormancy patterns that allow them to anticipate periods that are not optimal for survival and propagation (predictive dormancy, including hibernation). In other species, dormancy is triggered by environmental conditions (consequential dormancy). Many organisms spend most of their lifespan in dormancy, becoming active only when conditions are optimal. A continuum of states of adaptive inactivity can be seen in living organisms including plants, unicellular and multicellular animals, and animals with and without nervous systems.[1]

In the plant kingdom, seeds often are dormant until the correct season, heat, moisture, and pH conditions are present. A documented example of markedly delayed emergence was production of a healthy tree from a lotus seed after a 1300-year period of dormancy.[2] In another, more recent report, a 2000-year-old date palm seed produced a viable sapling.[3] Some forms of vegetation can germinate only after fires that may come decades apart. These include the giant sequoias

native to the U.S. Southwest, as well as many other species of trees and grass. Most deciduous trees and plants have seasonal periods of dormancy during which they cease photosynthesis, a process called abscission. These periods of dormancy enhance plant survival by synchronizing growth to optimal conditions. Clearly this mechanism has evolved to time germination to optimal conditions. Energy savings is not the only reason for dormancy in plants or animals.

Many unicellular organisms (protozoans) have evolved to live in environments that can sustain them for only portions of the year, because of changes in temperature, water availability, or other factors. Their survival requires that they enter dormant states that can be reversed when optimal conditions reappear.

Rotifers, a group of small multicellular organisms of microscopic or submicroscopic size (up to 0.5 mm long), have extended dormant periods lasting from days to months in response to environmental stresses, including lack of water or food.[5,6]

Parasites can become dormant within the host animal's tissues for years, emerging during periods when the immune system is compromised.[7] Some invertebrate parasites have extended dormant periods, defending themselves by forming a protective cyst.[8] In some cases the cyst can be dissolved and the parasite activated only by digestive juices. Many sponges have a similar dormant state that allows them to survive suboptimal conditions by being encased in "gemmules."

Insect dormancy or diapause can be seasonal, lasting several months; anecdotal reports indicate that under some conditions, diapause can last for several years to as long as a century.[9] This can occur in an embryologic, larval, pupal, or adult stage. During diapause, insects are potentially vulnerable to predation, as are some sleeping animals. Passive defense strategies are employed, such as entering dormancy underground or in hidden recesses, having hard shells, and tenacious attachment to substrates. In a few cases, insects have evolved a vibrational defensive response that is elicited when pupae are disturbed. Land snails and slugs can secrete a mucous membrane for protection and enter a dormant state when conditions are not optimal.[10]

Reptiles and amphibia that live in lakes that either freeze or dry seasonally and snakes that live in environments with periods of cold or extreme heat have the ability to enter dormant states (called *brumination* in reptiles). These dormant periods may occur just during the cool portion of the circadian cycle or may extend for months in winter.[11] *Estivation* is a form of dormancy that occurs during warm periods, typically during summer. It allows reptiles, amphibia, fish, and insects[12-16] to emerge with the first rains from what had been a barren, apparently lifeless lakebed.

In the mammalian class, a continuum of states ranging from dormancy to continuous activity can be seen. Small animals that cannot migrate long distances and live in temperate or frigid environments often survive the winter by hibernating. Some bats and many species of rodents, marsupials, and insectivores hibernate. This condition is entered from, and generally terminates in, non–rapid eye movement (NREM) sleep periods. During *hibernation,* body temperature can be reduced to below 10° C, down to as low as –3° C, with greatly reduced energy consumption.[17,18] Animals are quite difficult to arouse during hibernation, with full arousal taking many minutes. Consequently, hibernators are vulnerable to predation and survive hibernation by seeking protected sites. *Torpor*[17] is another form of dormancy that can be entered by mammals and birds daily. Torpor is entered and exited through sleep and can recur in a circadian rhythm or can last for weeks or months. Animals in shallow torpor are less difficult to arouse than hibernating animals but are still unable to respond quickly when stimulated. Some other mammals such as bears enter extended periods of sleep in the winter during which their metabolic rate and body temperature are reduced by 4° to 5° C,[19] but they remain more responsive than animals in torpor.

Sleep can be seen as a form of adaptive inactivity lying on this continuum. What is most remarkable about sleep is not the unresponsiveness or vulnerability it creates but rather its ability to reduce activity and body and brain metabolism but still allow a high level of responsiveness relative to the states of dormancy just described. The often-cited example of a parent's arousing at a baby's whimper but sleeping through a thunderstorm illustrates the ability of the sleeping human brain to continuously process sensory signals during the sleep period and trigger complete awakening to significant stimuli within a few hundred milliseconds. This capacity is retained despite the great reduction in brain energy consumption achieved in sleep relative to quiet waking.[20,21]

Adolescent humans are less responsive than adults to stimuli presented during sleep, as anyone who has lived with teenagers can attest. This trait may have been selected for by evolution, because protection from predators normally is provided by older members of the family group who also tend to the nocturnal needs of infants. The inactivity of children benefits the group by reducing their relatively large portion of the family's food needs and diverting food energy to growth, rather than activity.

Some animals that live in climates with a pronounced seasonal reduction in food or light availability or a periodic increase in threat from predators may need to migrate to survive. Many species of birds do this, as do certain species of marine mammals (see later). Although some may maintain circadian rhythms of activity during migration, others remain continuously active for weeks or months. Some vertebrate species do not ever appear to meet the behavioral criteria for sleep, remaining responsive, or responsive and active, throughout their lifetime.[22]

Humans with insomnia typically are not sleepy during the day despite a reduced (or in many cases normal) duration of nighttime sleep. With respect to their sleep pattern, they may be viewed as falling closer to migrating animals or short-sleeping animals, in contrast with humans with sleep disturbed by sleep deprivation, sleep apnea, or pain, who are sleepy during the day.[23] Patients with restless legs syndrome are similarly unlikely to be sleepy during the day despite low levels of nightly sleep. Conversely, many people with hypersomnia appear to need more sleep and in fact sleep more deeply, rather than being the victims of a shallow or disrupted sleep that is compensated for by extended sleep time. Perhaps such persons may be expressing genes and behaviors that were highly adaptive in distant phylogenetic ancestors needing to reduce energy consumption.

To summarize, evolution has produced a wide range of forms of diurnal or seasonal "adaptive inactivity," some of which are accompanied by a virtual cessation of metabolism and responsiveness. Clearly, evolution rewards judicious

activity, not continuous activity. Sleep often is viewed as a liability because of the associated reduced alertness in comparison with quiet waking. However, seen in the context of adaptive inactivity shown by most species, what is most notable about sleep in humans is its intermediate status, between the highly inactive unresponsive states seen in rotifers, insects, and hibernating mammals (which show little neuronal activity during hibernation) and the virtually continuous periods of activity and wakefulness that have been seen in migrating birds and cetaceans.

QUANTITATIVE ANALYSES OF THE CORRELATES OF SLEEP DURATION IN MAMMALS

Many studies have attempted to correlate the data that have been collected on sleep duration in mammals with physiologic and behavioral variables to develop hypotheses regarding the function of sleep. The data on which these studies are based are not ideal. Only approximately 70 mammalian species have been studied with sufficient measurements to determine the amounts of rapid eye movement (REM) and NREM sleep over the 24-hour period. These are by no means a random sample of the more than 5000 mammalian species. Rather, they are species that are viable and available for study in laboratories or, in some instances, for noninvasive (and less accurate) studies in zoos.

In laboratories, animal subjects for sleep studies typically are fed ad libitum and are housed at relatively invariant, thermoneutral temperatures and on artificial light cycles. These environments differ greatly from those in which they evolved. Digital recording and storage technologies now exist that will enable the collection of polygraphic data on animals in their natural environments,[24] but they have not yet been widely used. Such observations are necessary to determine the variation in sleep times caused by hunger, response to temperature changes, predation, and the other variables that have driven evolution. Very few of these animals have been tested for arousal threshold, the nature and extent of sleep rebound, and other aspects of sleep whose variation across species may potentially contribute to an understanding of sleep evolution and function. An important issue in comparing sleep times in animals is determining sleep depth. In humans, sleep depth, as assessed by either arousal threshold or EEG amplitude, increases after sleep deprivation and often is greater during early stages of development when total sleep time is greatest. Can sleep time be profitably compared across animals without incorporating information on sleep depth? Can it be assumed that animals that sleep for longer periods also sleep more deeply, as is true across human development, or is the reverse more likely—that short-sleeping animals sleep more deeply as has been hypothesized?[25] It would be best not to make either assumption; any conclusions should be based on hard evidence about these dimensions of sleep.

One of the earliest studies comparing REM and NREM sleep durations with physiologic variables found that sleep duration was inversely correlated with body mass.[26,27] A subsequent analysis found that this relationship applied only to herbivores, not to carnivores or omnivores.[28] This study also showed that, as a group, carnivores slept more than omnivores, who in turn slept more than herbivores (Figure 10-1). In an early study, a significant negative correlation was found between brain weight and REM sleep time (but not total sleep time). A point worthy of emphasis is that this latter correlation was extremely small, accounting for only 4% of the variance in REM sleep time (Figure 10-2). The largest correlation emerging from these early studies was that between body or brain mass and the *duration* of the sleep cycle—that is, the time from the start of one REM sleep period to the start of the next, excluding interposed waking. This correlation accounted for as much as 80% of the variance in sleep cycle time between animals and has held up in subsequent studies in mammals. Sleep cycle duration is approximately 10 minutes in mice, 90 minutes in humans, and 120 minutes in elephants. Because sleep is linked to a reduction in body temperature[29] and reduces energy usage, it has been hypothesized that energy conservation may be a function of sleep.[30]

Several studies have reanalyzed the phylogenetic data set with the addition of data on the few more recently studied animals. These studies took a variety of strategies to extract relations from this data set. Lesku and colleagues[31] used a method of "independent contrasts" in an attempt to control for the relatedness of species being compared. Inclusion of many rodent species in earlier analyses would give the data for those animals a disproportionate effect on conclusions. These workers confirmed previous findings of a negative relationship between basal metabolic rate (which is correlated with body mass) and sleep time. In contrast with earlier and subsequent studies of the same data set, they reported a positive correlation between REM sleep and relative brain mass and a negative relationship between REM sleep time and predation risk.

Another study, confining its analysis to studies that met the investigators' more rigorous criteria, found that metabolic rate correlates negatively rather than positively with sleep quotas,[32] in contrast with earlier studies.[27] This result is not inconsistent with some earlier work.[28] They also reported that neither adult nor neonatal brain mass correlates positively with adult REM or NREM sleep times, differing from earlier studies.[27,32] In agreement with earlier analyses, animals with high predation risk were found to sleep less.[28,33] In keeping with the concept of some fixed need for an unknown function performed only during sleep, the researchers proposed that short-sleeping species sleep more intensely to achieve this function in less time, but they presented no experimental evidence for this hypothesis.

A notable feature of the studies by Lesku and Capellini and their coworkers is that both excluded animals that the investigators concluded had unusual sleep patterns. So the echidna, which combines REM and NREM features in its sleep,[34] was eliminated from the analysis. The platypus, with the largest amount of REM sleep of any animal yet studied,[35] also was excluded from this analysis, as it was from another study focusing on brain size relations.[36] The dolphin and three other cetacean species and two species of manatee were excluded from the Lesku et al. study because of their low levels of REM sleep and presence of unihemispheric slow waves. Including these species in such analyses would undoubtedly negate or reverse the positive relationship reported between brain size and REM sleep, because the platypus exhibits the largest amount of REM sleep time of any studied animal and one of the smallest brain sizes and the dolphin, which appears to have little or no REM sleep, has a larger brain size than humans.[37,38] As discussed further on, these "unusual" species that have been excluded from previous

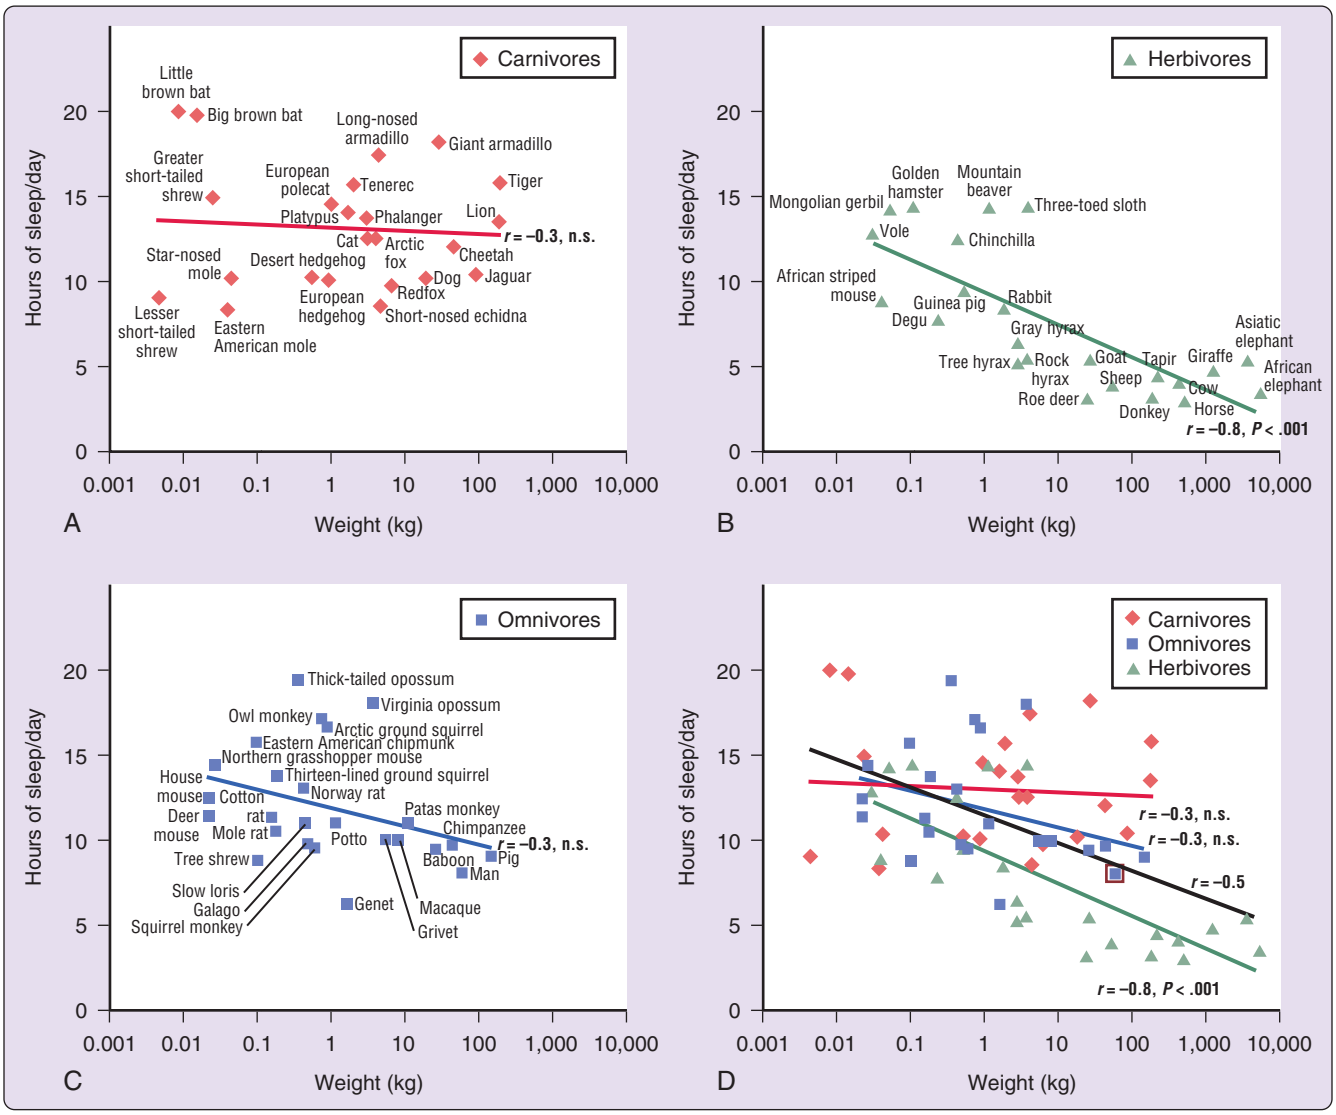

Figure 10-1 Sleep Times in Mammals. Sample data plotted by color: **A,** carnivores, *dark red*; **B,** herbivores, *green*; **C,** omnivores, *blue*; **D,** all data (*red box* indicates human). Sleep times in carnivores, omnivores, and herbivores differ significantly, with carnivore sleep amounts significantly greater than those for herbivores. Sleep amount is an inverse function of body mass over all terrestrial mammals (*black line*). This function accounts for approximately 25% of the interspecies variance (**D**) in reported sleep amounts. Herbivores are responsible for this relation, because body mass and sleep time were significantly and inversely correlated in herbivores but not in carnivores or omnivores. (From Siegel JM. Clues to the functions of mammalian sleep. *Nature* 2005;437:1264–71.)

analyses may in fact hold important clues to the function of sleep across species.

In considering the possibility of universal functions of sleep across species, from humans to *Drosophila*, it is important to appreciate the presence of REM and NREM sleep in birds. A correlational analysis of sleep parameters in birds paralleling the studies done in mammals found no relationship between brain mass, metabolic rate, relative metabolic rate, maturity at birth, and total sleep time or REM sleep time.[39] All values for these parameters were found to be "markedly nonsignificant." The only significant relation found was a negative correlation between predation risk and NREM sleep time (but not REM sleep time), in contrast with the relation reported earlier in mammals between predation risk and REM sleep time (but not NREM sleep time). This lone significant relation explained only 27% of the variance in avian NREM sleep time.

To summarize, a variety of correlation studies reach disparate and often opposite conclusions about the physiologic and functional correlates of sleep time. Of note, with the exception of the strong relationship between sleep cycle length and brain and body mass, all of the "significant" correlations reported explain only a small portion of the variance in sleep parameters, throwing into question whether the correlational approach as currently used is getting at the core issues of sleep function. Despite similar genetics, anatomy, cognitive abilities, and physiologic functioning, closely related mammalian species can have very different sleep parameters, and distantly related species can have very similar sleep parameters. Many such examples exist despite the relatively small number of species in which REM and NREM sleep times have been determined (Figure 10-3). For example, the guinea pig and baboon have the same daily amounts of REM and NREM sleep.[40]

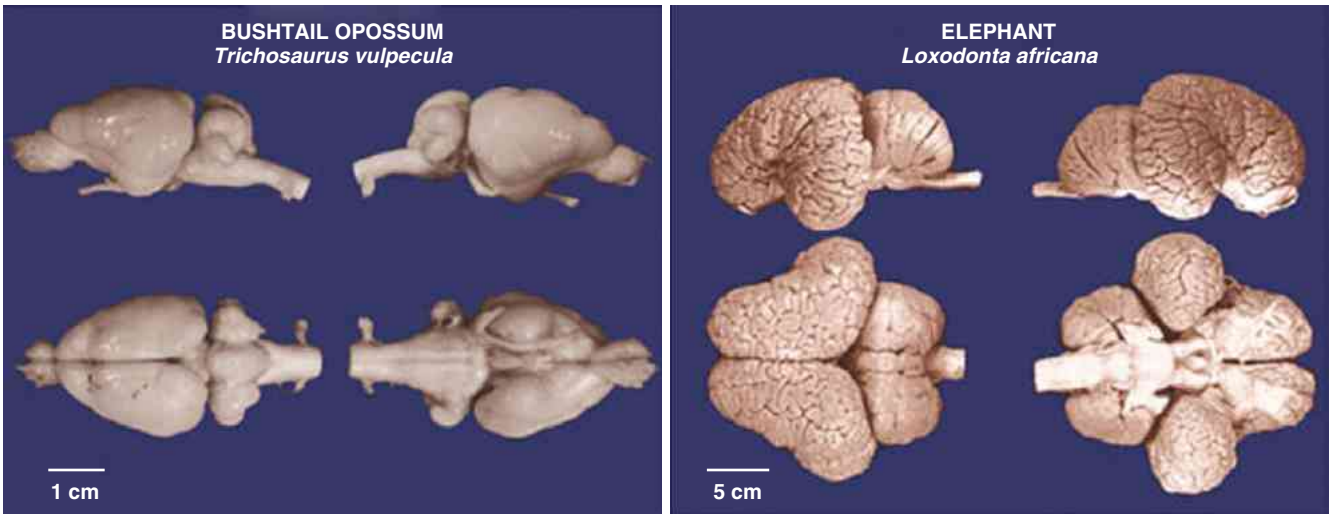

Figure 10-2 Sleep amount is not proportional to the relative size of the cerebral cortex or to the degree of encephalization, as illustrated by these two examples. (From Siegel JM. Clues to the functions of mammalian sleep. *Nature* 2005;437:1264–71.)

THE DIVERSITY OF SLEEP

Overview

On the assumption that sleep satisfies an unknown yet universal function in all animals, some work has been carried out in animals whose genetics and neuroanatomy are better understood and more easily manipulated than in mammals. Much of this work has focused on the fruit fly, *Drosophila melanogaster.* These animals appear to meet the behavioral definition of sleep. Their response threshold is elevated during periods of immobility, but they will rapidly "awaken" when sufficiently intense stimuli are applied. They make up for "sleep" deprivation with a partial rebound of inactivity when left undisturbed. However, major differences between the physiology and anatomy of these organisms and those of mammals make it difficult to transfer insights gleaned from studies of *Drosophila* sleep to human sleep. The *Drosophila* brain does not resemble the vertebrate brain. Octopamine, a major sleep-regulating transmitter in *Drosophila,* does not exist in mammals. Hypocretin, a major sleep-regulating transmitter in mammals, is not produced by *Drosophila.*[40] *Drosophila* flies are not homeotherms, whereas thermoregulation has been closely linked to fundamental aspects of mammalian sleep.[28,29,41] There is no evidence for the occurrence of a state resembling REM sleep in *Drosophila.* Thus the neurochemistry, neuroanatomy, and neurophysiology of sleep must necessarily differ between *Drosophila* and humans and other mammals. Any commonality of sleep phenomena would have to be restricted to cellular level processes. Two studies have shown that *Drosophila* sleep and sleep rebound are markedly impaired by genetic alteration of a potassium current that regulates neuronal membrane excitability.[42,43] Regulation of potassium currents may be a core function of sleep, or it may instead affect the excitability of circuits regulating activity and quiescence, much as such currents affect seizure susceptibility.[44,45]

Caenorhabditis elegans, a roundworm with a nervous system much simpler than that of *Drosophila,* has also been investigated for sleep like behavior.[46] *C. elegans* reaches adulthood in 60 hours and has periods of inactivity during this maturation, called "lethargus," occurring before each of the four molts it undergoes before reaching maturity. Stimulation of *C. elegans* during the lethargus period produced a small but significant decrease in activity during the remainder of the lethargus period but did not delay the subsequent period of activity or increase quiescence overall, phenomena that differ from the effects of sleep deprivation in mammals. It is not clear if adult *C. elegans* shows any aspect of sleep behavior.[47]

Fundamental species differences in the physiology and neurochemistry of sleep have been identified even within the mammalian line. Although many similarities have been recognized, the EEG aspects of sleep also differ considerably among humans, rats, and cats, the most-studied species.[48-50] Human stage 4 NREM sleep is linked to growth hormone secretion. Disruption of stage 4 sleep in children is thought to be a factor in the pathogenesis of short stature. In dogs, however, growth hormone secretion normally occurs in waking, not sleep.[51] Melatonin release is maximal during sleep in diurnal animals, but is maximal in waking in nocturnal animals.[52] Erections have been shown to be present during REM sleep in humans and rats[53]; the armadillo, however, has erections only in NREM sleep.[54] Blood flow and metabolism differ dramatically between neocortical regions in adult human REM sleep,[55] although most animal sleep deprivation and sleep metabolism studies treat the neocortex as a unit. Lesions of parietal cortex and certain other regions prevent dreaming in humans, even in subjects who continue to show normal REM sleep as judged by cortical EEG activity, rapid eye movements, and suppression of muscle tone.[56] Children younger than 6 years of age do not generally report dream mentation, perhaps because these cortical regions have not yet developed.[57] These findings make it questionable whether nonhuman mammals that exhibit REM sleep, all of which have cortical regions whose structure differs from that in adult humans, have dream mentation.

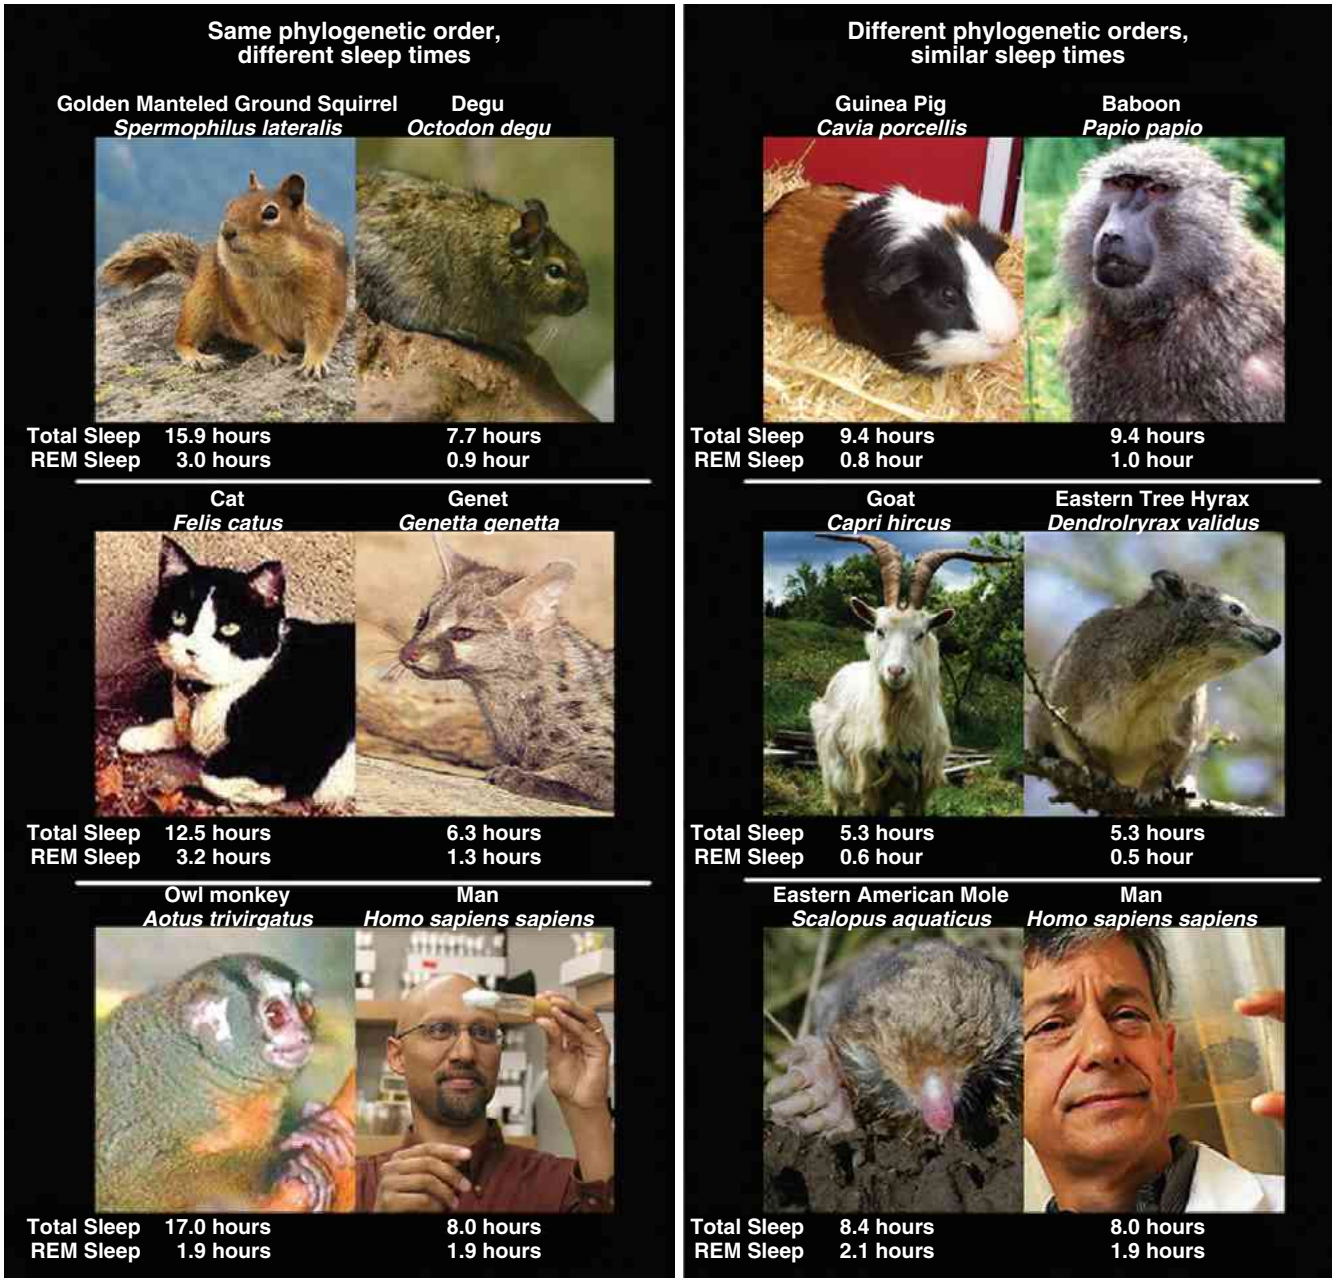

Figure 10-3 Mammalian phylogenetic order is not strongly correlated with sleep parameters. **Left,** Three pairs of animals that are in the same order but have very different sleep parameters. **Right,** Three pairs of animals from different orders with similar sleep amounts. Mammalian sleep times are not strongly correlated with phylogenetic order. (From Allada R, Siegel JM. Unearthing the phylogenetic roots of sleep. *Curr Biol* 2008;18:R670–9.)

Reindeer

Reindeer are ruminants. Like some other ruminants, they appear to remain active over the entire circadian cycle to an extent not seen in most carnivores and omnivores. A study examined the activity of two species of reindeer living in polar regions where they experience periods of continuous darkness in the winter and continuous light in the summer. Activity was monitored for an entire year. It was found that the circadian rhythm of melatonin and circadian rhythms of behavioral activity dissipated in winter and summer. Activity time ranged from 22% to 43% greater in summer than in winter (calculated from data obtained in studies by van Oort and Tyler).[58,59] EEG recording and arousal threshold tests were not done; however, the activity changes suggest that major changes in sleep duration occur seasonally.

Walrus

A study of the walrus revealed that these animals frequently become continuously active for periods of several days even when fed ad libitum and under no apparent stress.[60] Animals living in marine environments may not be as strongly affected by circadian variables because their evolution has been shaped by tidal and weather features that do not adhere to 24-hour cycles.

Sleep in Cetaceans: Dolphins and Whales

REM sleep is present in all terrestrial animals that have been studied, but signs of this state have not been seen in cetaceans, which are placental mammals. These animals show only unihemispheric slow waves (USWs), which can be confined to one hemisphere for 2 hours or longer. The eye contralateral to the hemisphere with slow waves typically is closed, although covering the eye is not sufficient to produce slow waves.[35,61] These animals never show persistent high-voltage waves bilaterally. Sometimes they float at the surface during USW activity. Often, however, they swim while USWs are being produced (Figure 10-4). When they swim during USW activity, no asymmetry in their motor activity is observed, in contrast with the behavior seen in the fur seal (see further on). Regardless of which hemisphere is showing slow wave activity, they tend to circle in a counterclockwise direction (in the northern hemisphere[62]). No evidence has been presented for elevated sensory response thresholds contralateral to the hemisphere that produces slow waves. Indeed, a substantial elevation of sensory thresholds on one side of the body presumably would be quite maladaptive, in light of the danger of collisions while moving. Similarly, brain motor systems must be bilaterally active to maintain the bilaterally coordinated movement that they exhibit during USW activity. As indicated by these findings, forebrain and brainstem sensory and motor activity must differ radically during USW from that seen in terrestrial mammals during sleep (see Chapter 8)[63,64] The one study of USW rebound after USW deprivation in dolphins produced very variable results, with little or no relation between the amount of slow waves lost in each hemisphere and the amount of slow waves recovered when the animals were subsequently left undisturbed.[65] In two other studies it was shown that dolphins are able to maintain continuous vigilance 24 hours/day, responding at 30-second intervals, for 5 and for 15 days with no decline in accuracy. At the end of this period, no detectable decrease of activity or evidence of inattention or sleep rebound, such as would be expected of a sleep-deprived animal, was seen.[22,66,67]

USWs would be expected to save nearly one half of the energy consumed by the brain that is saved during bihemispheric slow wave activity.[20,21] USWs are well suited to the dolphin's group activity patterns. Because dolphins and other cetaceans swim in pods, the visual world can be monitored by dolphins on each side of the pod, and the remaining dolphins merely have to maintain contact with the pod. In routine "cruising" behavior, this can be done with only one eye, allowing the other eye and connected portions of the brain to reduce activity, as occurs in USWs. This hypothesis needs to be explored by electroencephalographic observations of groups of cetaceans in the wild.

In some smaller cetaceans, such as the harbor porpoise[68] and Commerson's dolphin,[69] motor activity is essentially continuous from birth to death—that is, they never float or sink to the bottom and remain still. These animals move rapidly, and it is evident that they must have accurate sensory and motor performance and associated brain activation to avoid collisions. It is difficult to accept this behavior as "sleep" without discarding all aspects of the behavioral definition of sleep.[22]

All studied land mammals have been reported to show maximal sleep and maximal immobility at birth, leading to the conclusion that sleep is required for brain and body development. Newborn killer whales and dolphins, however, are continuously active. In captivity, they swim in tight formation and turn several times a minute to avoid conspecifics in the pool and pool walls. During this period the calves learn to nurse, breathe, and swim efficiently. Although some USWs might be present at these times, the eyes are open bilaterally when they surface, at average intervals of less than 1 minute, indicating that any slow wave pattern could not last longer than this period.[70] Sleep interruption at such intervals can be lethal to rats,[71] and human sleep is not restorative if interrupted on such a schedule.[72] The cetacean mothers also cease eye closure at the surface and during floating behavior and are continuously active during the postpartum period. No loss of alertness is apparent during the "migratory" period. In the wild, mother and calf migrate together, typically for thousands of miles, from calving to feeding grounds. Sharks, killer whales, and other predatory animals target the migrating calves, and a high level of continuous alertness is necessary for both mother and calf during migration. The maternal and neonatal pattern could be described as "sleep" with well-coordinated motor activity, accurate sensory processing, and effective response to threats in the environment, and without the likelihood of any EEG slow waves or prolonged eyelid closure. This designation, however, does not comport with the accepted behavioral definition of sleep.[73] Thus both cetaceans and migrating birds (see later) greatly reduce sleep time during migrations without any sign of degradation of physiologic functions, sluggishness, loss of alertness, or impairment of cognitive function.

Sleep in Otariids: Eared Seals

On land, sleep in the fur seal generally resembles that in most terrestrial mammals. The EEG is bilaterally synchronized, and the animal closes both eyes, appears unresponsive, and cycles between REM and NREM sleep. By contrast, when the fur seal is in the water, it usually shows an asymmetric pattern of behavior, with one of the flippers being active in maintaining body position, while the other flipper is inactive. During these periods, the fur seal has a high-voltage EEG, with slow waves in one hemisphere with the contralateral eye generally closed. The other eye generally is open or partially open, with an activated, waking-like EEG pattern (Figure 10-5). Therefore, unlike in the dolphin, it appears that one half of the brain and body may in some sense be "asleep" and the other half "awake." Microdialysis studies showed that during asymmetric sleep, the waking hemisphere has significantly higher levels of acetylcholine release than the sleeping hemisphere.[74] By contrast, levels of serotonin,[75] histamine, and norepinephrine,[76] transmitters traditionally considered to be linked to arousal, do not differ between the hemisphere with high-voltage EEG activity and the hemisphere with a low-voltage EEG pattern. This work indicates that acetylcholine has a unique role in mediating the waking EEG in this species, and probably in other mammals, including humans.

Sleep in Monotremes

The mammalian class can be subdivided into three subclasses: placentals, marsupials, and monotremes. There are just three extant monotreme species: the short-beaked and long-beaked echidna and the platypus. Fossil and genetic evidence indicates that the monotreme line diverged from the other mammalian lines approximately 150 million years ago and that

Electroencephalogram (EEG) of adult cetaceans, represented here by the beluga, during sleep. All species of cetacean for which sleep EEGs have been recorded so far have demonstrated unihemispheric slow waves. *Top traces* show left and right EEG activity. The spectral plots (*bottom traces*) show 1- to 3 Hz power in the two hemispheres over a 12-hour period. The pattern in the cetaceans contrasts with the bilateral pattern of slow waves seen under normal conditions in all terrestrial mammals, represented here by the rat. (From Siegel JM. Clues to the functions of mammalian sleep. *Nature* 2005;437:1264–1271.)

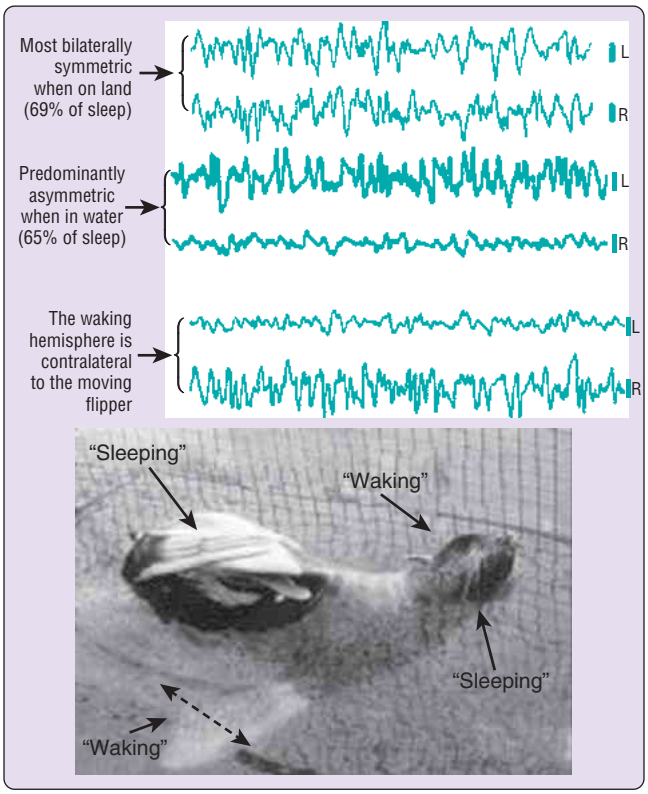

Figure 10-5 **Fur Seal Sleep.** On land, fur seals usually sleep like terrestrial mammals, with bilateral EEG synchrony and REM sleep (*not shown*). When in water, however, they typically show asymmetric slow wave sleep, with a sleep-like EEG pattern in one hemisphere and a waking-like EEG in the other hemisphere. Unlike in the dolphin, the asymmetric EEG of the fur seal is accompanied by asymmetric posture and motor activity, with the flipper contralateral to the hemisphere showing low-voltage activity used to maintain the animal's position in the water and the other flipper and its controlling hemisphere showing "sleep." EEG, Electroencephalogram.

both echidna species are derived from a platypus-like ancestor.[77-80] The monotremes have shown a remarkably conservative evolutionary course since their divergence from the two other mammalian lines. For example, fossil teeth from *Steropodon galmani* dated at 110 million years ago show many similarities to the vestigial teeth of the present-day platypus, *Ornithorhyncus anatinus*.[81] Analyses of fossilized skull remains indicate remarkably little change in platypus morphology over at least 60 million years.[81,82] The low level of speciation throughout the fossil record is another indicator of the uniquely conservative lineage of monotremes. The 150 million years of platypus evolution has produced no species radiation, apart from the echidna line, and only two living and one extinct species of echidna have been documented. Although monotremes are distinctly mammalian, they do display a number of reptilian features, making study of their physiology a unique opportunity to determine the commonalties and divergences in mammalian evolution.[78,83,84]

This phylogenetic history led to an early study of the echidna to test the hypothesis that REM sleep was a more recently evolved sleep state. No clear evidence of the forebrain low-voltage EEG acctivity that characterizes sleep was seen in this study, leading to the tentative conclusion that REM sleep evolved in placentals and marsupials after the divergence of the monotreme line from the other mammals.[85] This issue was subsequently reexamined using single-neuron recording techniques, in addition to the EEG measures employed in the earlier studies. REM sleep is generated in the mesopontine brainstem (see Chapter 8) and is characterized by a highly variable burst-pause activity of brainstem neurons. This activity is responsible for driving the rapid eye movements, twitches, and other aspects of REM sleep. The investigators recorded from these brainstem regions in unrestrained echidnas to see if this activation was absent throughout sleep. Instead of the slow, regular activity that characterizes brainstem neurons in many nuclei during NREM sleep in placental mammals,[63,64] the echidna showed the irregular activity pattern of REM sleep throughout most of the sleep period[34,86] (Figure 10-6). It appeared that the brainstem was in a REM sleep–like state while the forebrain was in an NREM sleep state.

These interesting findings led to the performance of additional electrophysiologic studies of sleep in the platypus. In this work, the platypus was found to have pronounced phasic motor activity typical of that seen in REM sleep (see Video 10-1).[87] This intense motor activity could occur while the forebrain EEG exhibited high-voltage activity,[35] similar to the phenomenon seen in the echidna. Not only was the motor activity during sleep of intensity equal to or greater than than that seen in REM sleep in other animals, but the daily amount of this REM sleep state was greater than that in any other animal. However, unlike in adult placental and marsupial mammals, the signs of REM sleep were largely confined to the brainstem (Figure 10-7). This observation indicates some resemblance to the conditions in most mammals that are born in an immature (altricial) state, which do not show marked forebrain EEG activation during REM sleep early in life. The tentative conclusion reached in the initial studies of the echidna, that the monotremes experienced no REM sleep and that REM sleep was a recently evolved state, had to be reversed. Apparently, a brainstem manifestation of REM sleep probably was present in the earliest mammals, perhaps in very large amounts. It may be the brainstem quiescence of NREM sleep, along with the cortical EEG desynchrony of REM sleep, that are the most recently evolved aspects of sleep in the mammalian line.

Birds

Birds have REM sleep that appears physiologically very similar to that seen in mammals, although REM sleep values tend to be lower than total sleep values in mammals.[39] Many bird species migrate over long distances. The effect of this migratory behavior on sleep has been studied in the white-crowned sparrow (*Zonotrichia leucophrys gambelii*). These birds, even when confined in the laboratory, decrease sleep time by two thirds during the periods when they would normally be migrating.[88] Of note, this is a common feature of cycles of adaptive inactivity. A ground squirrel that normally hibernates in the winter will enter a state of torpor at the appropriate season even when maintained in a laboratory under constant conditions.[89]

During the migratory period, the sparrow's learning and responding were unimpaired or improved. In these birds, sleep was not deeper by EEG criteria than that seen when they were not migrating, despite its greatly reduced duration. Their sleep latency did not differ from that during nonmigrating periods.[88]

A recent study of sleep in birds presented an novel and important example of "adaptive" sleep suppression. It was

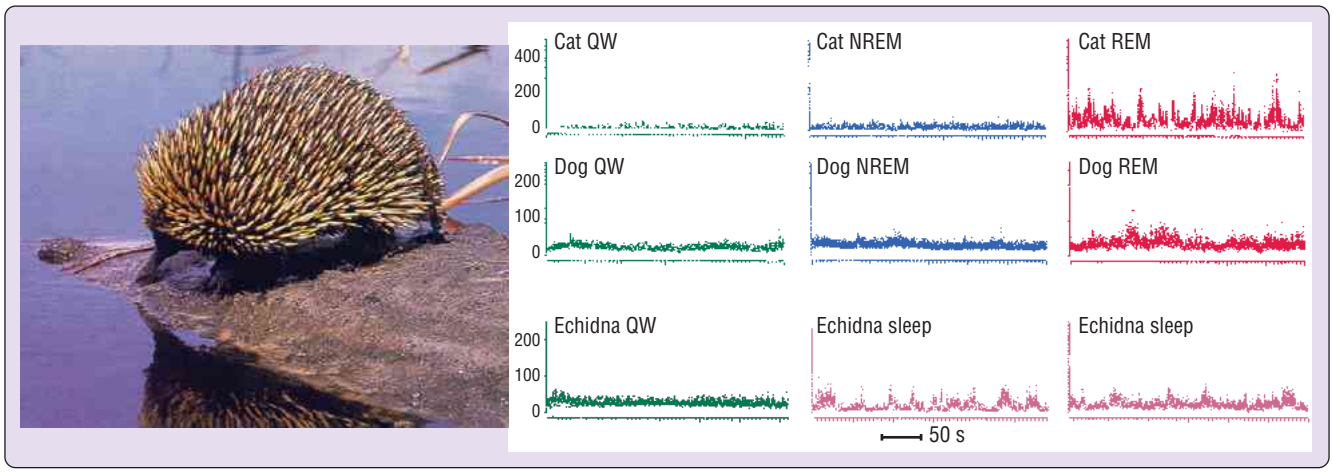

Figure 10-6 **Brainstem Activation during Sleep in the Echidna.** Instantaneous compressed rate plots of representative units recorded in nucleus reticularis pontis oralis of the cat, dog, and echidna. Each point represents the discharge rate for the previous interspike interval. In cat quiet waking (QW) and NREM sleep, the discharge rate is low and relatively regular. The rate increases and becomes highly variable during REM sleep. A similar pattern can be seen in a unit recorded in the dog. In the echidna, sleep is characterized by variable unit discharge rates, as is seen in REM sleep, but this occurs while the cortex is showing high-voltage activity. (From Siegel JM, Manger P, Nienhuis R, et al. The echidna Tachyglossus aculeatus combines REM and nonREM aspects in a single sleep state: implications for the evolution of sleep. *J Neurosci* 1996;16:3500–6.)

found that many polygynous pectoral sandpipers, which breed during a period of continuous summer light, cease sleeping or greatly reduce sleep during breeding. Furthermore, the males with the greatest reduction in sleep sired the most offspring—a unique and dramatic example of adaptive sleep loss increasing genetic propagation.[90] What was most surprising, in view of the strength of this selective benefit, was that *any* males remained sleeping during the breeding period. It was speculated that the continuously active males would be at a competitive disadvantage if their food was scarce after the breeding season relative to those that saved energy by sleeping. In periods of reduced food availability, it is the second group of birds that would survive to mate the next year, leading to a dynamic balance between birds with these two behaviors.[91]

Studies in the ostrich, considered to be in many respects a "primitive" bird, provided novel support for the link between bird and mammalian sleep. It was found that sleep in the ostrich resembles that in the platypus and echidna, with rapid eye movements and muscle tone suppression, brainstem aspects of REM sleep occurring with high-voltage EEG activity, resembling the weak or nonexistent EEG voltage reduction seen in monotremes, whereas their brainstem shows the neuronal activity activation and rapid eye movements that characterize REM sleep.[92]

The observations in monotremes and birds suggest that the reptilian common ancestor of both mammals and birds exhibited REM sleep or a closely related precursor state, rather than the previously advanced speculation that REM sleep must have evolved twice, based on the conclusion that monotremes did not have REM sleep. Although scattered early reports claimed to have identified REM sleep in reptiles, these findings have not been replicated.[28] In the experience of my own research group, when the same recording techniques used in the echidna were appplied in the turtle in a search for evidence of REM sleep, no evidence of phasic brainstem neuronal activity during quiescent states in this reptile was found.[93]

SLEEP REBOUND

The phenomenon of sleep rebound[94] is not always seen. When fur seals go in the water for extended periods, as they do in winter, REM sleep time is greatly reduced. Little or no rebound of lost REM sleep occurs when the animals return to land, even after several weeks in the water.[95] In the cases of the dolphins and killer whales mentioned previously, a near-total abolition of "sleep-like behavior" for periods of several weeks during migration is followed by a slow increase back to baseline levels, with no rebound. The same phenomenon is seen in migrating white sparrows, a migratory species that has been carefully studied under laboratory conditions.[88] In human studies, persons with bipolar disorder in a "manic" phase greatly reduce sleep time for extended periods, and persuasive evidence for progressive degradation of performance, physiologic function, or sleep rebound during this period is lacking. Zebra fish can be completely deprived of sleep for more than three days by placing them in continuous light but show no rebound when returned to a "12-12" light-dark cycle.[96] By contrast, when they are deprived by repetitive tactile stimulation, they do show rebound, suggesting that the deprivation procedure rather than the sleep loss underlies the rebound.

Typically, 30% or less of sleep time lost during deprivation is recovered in the human and rodent, in which the phenomenon has been most extensively studied. A similar percentage of rebound is seen in other species including some invertebrates.[97] One may ask why, if sleep is essentially a maladaptive state, animals that have the ability to regain lost sleep in 30% of the time it would normally have taken have not evolved shorter sleep times to take advantage of the adaptive benefits of increased waking. If sleep is viewed as a form of adaptive inactivity, however, this paradox vanishes. A small sleep rebound may be necessary to compensate for processes that can occur only, or optimally, in sleep, but for the most part,

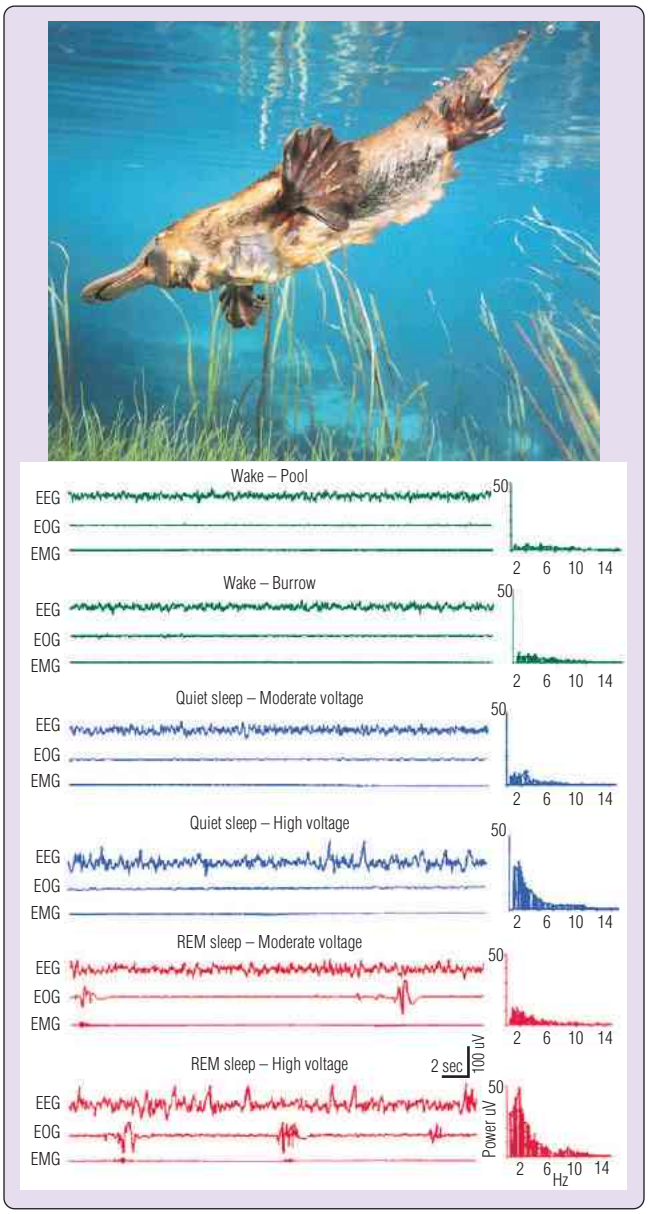

Figure 10-7 **Brainstem REM Sleep State in the Platypus.** Rapid eye movements and twitches can occur while the forebrain is showing a slow wave activity pattern. EEG, EOG, EMG, and EEG power spectra of samples shown of sleep-wake states in the platypus. EEG, Electroencephalogram; EMG, electromyogram; EOG, electrooculogram. (From Siegel JM, Manger PR, Nienhuis R, et al. Sleep in the platypus. *Neuroscience* 1999;91:391–400.)

sleep time is determined in each species by the evolved tradeoffs between active waking and adaptive inactivity.

The variation in rebound within and across species needs to be more carefully studied. Some aspects of rebound have been shown to be due to the deprivation procedure, rather than to the sleep loss itself. For example, stressing rats by restraint can produce increased REM sleep even when no sleep has been lost. This effect is mediated by the release of pituitary hormones.[98,99] It is possible that in some species, other aspects of rebound are driven by changes in hormonal release linked to sleep deprivation,[1] rather than by some intrinsic property of sleep.

CLINICAL PEARL

Although sleep and sleep stages differ in amount between species, human sleep does not appear to be qualitatively unique. This factor makes animal models suitable for the investigation of many aspects of pharmacology and pathology in sleep science.

SUMMARY

Sleep can be seen as an adaptive state, benefiting animals by increasing the efficiency of their activity. Sleep does this by suppressing activity at times associated with maximal predator risk and permitting activity at times of maximal food and prey availability and minimal predator risk. It also increases efficiency by decreasing brain and body metabolism. However, unlike the dormant states employed in plants, simple multicellular organisms, and ectothermic organisms, and the hibernation and torpor employed in some mammals and birds, sleep allows rapid arousal for tending to infants, dealing with predators, and responding to environmental changes. A major function of REM sleep may be to allow rapid awakening with alertness, by means of periodic brainstem activation. Many organisms can reduce sleep for long periods of time without rebound during periods of migration or other periods in which a selective advantage can be obtained by continuous waking.

The big brown bat specializes in eating mosquitoes and moths that are active from dusk to early evening. The big brown bat typically is awake only approximately 4 hours a day.[27] Not surprisingly, this waking is synchronized to the period when its insect prey species are active. It is not likely that this short waking period, one of the shortest yet observed, can be explained by the need for some time-consuming unknown process that occurs only during sleep and requires 20 hours to complete. This extremely brief period of wakefulness can be more easily explained by the ecologicl specializations of this bat. Similarly, "sleep" in ectothermic animals is most likely to be determined by temperature and other environmental variables, rather than any information processing or physiologic maintenance requirement. An approach that takes the environmental conditions in which each species evolved into account can better explain the variance in sleep time among mammals.

Many vital processes occur in both waking and sleep, including recovery of muscles from exertion, control of blood flow, respiration, growth of various organs, and digestion. Some processes may occur more efficiently in sleep but can also occur in waking. It has been claimed that sleep has an essential role in learning, but further investigations have disputed such claims.[100-105] It is highly probable that some functions have migrated into or out of sleep in various animals. Neurogenesis,[106] synaptic downscaling,[107] immune system activation,[108] and reversal of oxidative stress[109,110] may be accomplished in sleep in mammals. It remains to be seen if these or any other vital functions can be performed only in sleep. As suggested by the available evidence, however, such functions cannot explain the variation of sleep amounts and the apparent flexibility of sleep physiology within and between animals. Viewing sleep as a period of well-timed adaptive inactivity that regulates behavior may better explain this variation.

Physiology in Sleep

Chapter 11

Relevance of Sleep Physiology for Sleep Medicine Clinicians

Gilles Lavigne; Meir Kryger

Chapter Highlights

- The physiology section of this book covers a wide spectrum of very specialized concepts, from molecular and behavioral genetics to system physiology (temperature control, cardiovascular and respiratory physiology, immune and endocrine functions, sensory motor neurophysiology), and integrative functions (e.g., mental performance, memory, mood, and daily physical functioning).
- Some chapters are entirely new or have been revised together with new collaborators. For example, new content has been added on the role of opioids in sleep and breathing and on the neurobiology of brain trauma, a topic of major interest owing to its relevance for sleep and wake disorders.
- A deeper understanding of physiologic dysfunctions will help clinicians explain to their patients how to cope with sleep disorders, a process that is instrumental for patient satisfaction and well-being.
- Broader knowledge of physiology will assist sleep science and health stakeholders to clarify new and relevant priorities for basic and clinical research and public health investigations and policy making.
- Bidirectional effective communication and knowledge transfer between clinicians and researchers will benefit patients and, at the same time, will keep clinicians abreast of the latest developments in the field of sleep medicine and better prepare them to cope with the growing challenges in health care systems.

In this new edition of *Principles and Practice of Sleep Medicine,* the chapters on physiology (Section 3) contain a substantial amount of updated knowledge that can be expected to greatly expand the current understanding of sleep disturbances and to help identify and treat persons affected by them. This section includes new, in-depth information that will raise students' awareness of the relevance of the basic sciences and their application to sleep medicine.

New content has been included on how brain imaging has contributed to the understanding of sleep disruption and memory loss, how the cardiac control system regulates sleep and reacts to sleep disruptions, how respiration is related to the heart function as well as the relevance for health, and how the heart and the brain rest and regenerate, as well as the role of altitude in sleep breathing problems; the latest evidence on the interactive effects of insulin and other hormones in normal and deprived or disordered sleep is reviewed as well. Changes in sensory perception and pain during sleep due to the potential deleterious influence of opioids on sleep architecture and breathing also are covered. Finally, sleep-wake disturbances associated with traumatic brain injury are addressed, highlighting the importance of sleep for cognitive functioning and well-being. These chapters contain a wealth of background knowledge and are meant as primers for understanding the broad clinical content of this textbook.

One comment frequently encountered at our lectures on sleep physiology relates to its relevance for the practicing physician or researcher: "Why do doctors need to understand sleep physiology?" First, for doctors, whether in basic or clinical science, a primary objective is to improve public health by promoting and restoring healthy sleep patterns. A thorough knowledge of sleep physiology is essential for developing and validating more accurate diagnostic tools, for developing innovative patient management systems, and for keeping abreast of the latest advancements in sleep medicine. As they read these chapters on sleep physiology, some clinicians may be reminded of their early training days. Nevertheless, physiology is central to many current advances in clinical practice (e.g., breathing and cardiovascular measurements, brain imaging), and it forms the basis for translating genetics and proteomics into innovative diagnostic and therapeutic methods.

Because the adverse impact of poor sleep and a number of sleep disorders as well as overall societal and economic health are interrelated, government health agencies tend to seek discoveries that can improve the public's quality of life and reduce health care costs and mortality. A more thorough understanding of sleep physiology has resulted in innovative pharmaceutical therapies and improved designs for diagnostic and therapeutic devices. These include new recording and scoring systems, continuous positive airway pressure devices and mandibular advancement appliances with intelligent chips to monitor treatment adherence and assess effectiveness, and nerve and brain stimulation techniques to manage sleep-disordered breathing and sleep disturbances. Government agencies generally grant permission to market new products on the basis of epidemiologic data, recognition of the physiologic and pathologic mechanisms involved, and the findings of randomized controlled trials to determine product efficacy and safety. Research agencies are more prone to support pathophysiology-based projects that test hypothesized causes of diseases and disorders to rapidly develop innovative therapies (e.g., to improve mental health in North America). The lack of objective and valid measures to assess sleep improvement or therapeutic efficacy and effectiveness can retard the introduction of innovative developments into sleep medicine practices.

Although questionnaires are used to screen patients for many sleep disorders, physiologic (e.g., oxygen and breathing rate, hormone and endocrine release, electrocardiogram heart rate, electroencephalography brain activity) and psychophysiologic (e.g., reaction time, multiple sleep latency test, sensory perception) measures are used to confirm the accuracy and validity of the responses. Are these physiologic tools perfect? The answer is no. Some need further verification in terms of ecologic validity and the public health consequences of a given physiologic outcome (e.g., morbidity, mortality, cost for payers). Furthermore, it is essential to conduct randomized clinical trials and effectiveness studies with limited sample sizes but with stricter selection criteria, in which questionnaire-based information is combined with clinical findings and genetic findings or physiologic outcomes, and using more powerful analysis methods. These methods would go far beyond the usual Student's *t*-test and analysis of variance (ANOVA). They will require massive calculation capacity to enable finer discrimination of disease states and the most influential variables.

The identification of polymorphic genes associated with specific sleep disorders is another area of intense interest (covered in various chapters in Section 4). With the advent of proteomics, sleep medicine has entered the postgenomic era. *Proteomics* refers to large-scale protein characterization in relation to biologic processes, disorders, and diseases. Most sleep disorders, including sleep breathing disorders (e.g., sleep apnea), parasomnias (e.g., sleepwalking, enuresis, REM behavior disorder [RBD]), sleep-related movement disorders (e.g., restless legs syndrome/periodic limb movements), and circadian rhythm sleep disorders, are associated with genetic and/or molecular deficits that may define potential therapeutic avenues. Genetic epidemiology is a growing field that integrates all aspects of physiology in the aim of identifying further targets (gene loci) along with their individual and environmental variance.

Physiology provides the tools for phenotyping sleep disorders, and genetics advances the clinical domain by identifying risk and vulnerability factors as well as endophenotypes (e.g., interactions with environmental influences). Interindividual trait differences can be identified and phenotypic determinants of vulnerability recognized. Integrated analyses of a disorder's characteristics and outcome variables can form the basis for innovative approaches to sleep therapy, lead to a better understanding of why they work, and explain why some patients are nonresponders.

Large sample size population and genetic study findings using limited physiologic outcomes need to be correlated with the findings of smaller sample size studies, and the variable sets liable to best predict the outcomes of relevance in a given population presenting with a specific condition (e.g., chronic fatigue syndrome) need to be identified.[1,2] Quantitative models also can be applied to assess the strength of sleep medicine hypotheses.[3] Cell to system-wide integration and the reverse, system to cell-wide integration, are among the most promising approaches to track emerging factors and to integrate known factors into the body of knowledge,

leading to innovative diagnostic and therapeutic methods. Research and public health stakeholders have led the movement toward patient-oriented research, which is no longer a debatable issue; it has become a reality and is instrumental in preventing the transition of acute and simple conditions to complex, severe, or chronic conditions that require specialized tertiary care.

What Brain Imaging Reveals About Sleep Generation and Maintenance

Eric A. Nofzinger; Pierre Maquet

Chapter Highlights

- The development of neuroimaging techniques has made it possible to characterize regional cerebral function in humans under a variety of sleep-related conditions. These techniques were first used to characterize brain activity throughout the sleep-wake cycle in normal human subjects.
- Regional brain activity during sleep is segregated and integrated within cortical and subcortical areas differently than during wakefulness.
- Regional brain activity is influenced by incoming stimuli as well as by previous waking experience.
- Functional neuroimaging identified the neural correlates of sleep-wake regulation by homeostatic sleep pressure and the nonvisual effects of light.
- Finally, functional imaging of patients with sleep disorders and in response to treatment interventions indicated reliable changes in neural systems across the sleep-wake cycle.

Functional neuroimaging consists of all techniques that can generate images of brain activity. In humans, such techniques usually include single photon emission computed tomography (SPECT), positron emission tomography (PET), functional magnetic resonance imaging (fMRI), optical imaging, diffusion tensor imaging (DTI), multichannel electroencephalography (EEG), and magnetoencephalography (MEG). Each technique has its own advantages and drawbacks in terms of spatial and temporal resolutions, accessibility, safety, and cost. For instance, EEG and MEG record brain oscillations with an excellent temporal resolution (usually on the order of a millisecond), but their localizing capacity is limited because a method of accurately modeling the electric or magnetic sources of the signal remains unrealized. By contrast, PET and MRI provide excellent spatial resolution (a few millimeters), but they are based on the measure of hemodynamic or metabolic parameters, which reduces their temporal resolution from a few seconds to many minutes. Accordingly, a comprehensive understanding of brain function probably requires human brain function to be characterized using as many techniques as possible.

This chapter summarizes the main advances made using functional neuroimaging in the current understanding of human sleep and its intimate relationships with waking performance and cognition, both in normal healthy sleepers and in patients with sleep disorders. These advances are considered in the context of four main topics: the characterization of regional brain activity during normal human sleep, the neural correlates of the regulation of sleep-wake cycle by circadian influences and nonclassical photoreception, the regional brain function in conditions of increased sleep pressure, and some clinical applications to the management of sleep disorders.

FUNCTIONAL SEGREGATION AND INTEGRATION DURING NORMAL HUMAN SLEEP

Preclinical research has identified the basic circuits in the brain that are responsible for promoting arousal. In general, reduction in activity in these systems is essential for generating and maintaining sleep. A major component of this network is the brainstem reticular core, a diffuse network of predominantly glutamatergic long-projecting neurons and a smaller collection of presumed local circuit gamma-aminobutyric acid (GABA) neurons. Additional components include a collection of nuclei in the brainstem tegmentum dorsal to the reticular formation that include cholinergic and monoaminergic (serotoninergic, noradrenergic, and dopaminergic) neurons. These nuclei send rostral projections that parallel to and are interconnected with those of the brainstem reticular core. Cholinergic nuclei also are clustered rostrally in the basal forebrain, including septal nuclei and the diagonal band of Broca.

Research attention has focused on a significant role for the hypothalamus in arousal and in regulating transitions between sleep and waking states. Specifically, the tuberomamillary histaminergic neurons and the perifornical hypocretin neurons in the posterior hypothalamus have extensive interconnections and interactions with the basic arousal systems (for more information, see Chapters 7, 8, 23, 34, and 39). Activity changes in these primary regulating areas result in profound modifications in activity patterns in thalamocortical circuits and associated structures, such as basal ganglia or cerebellum. A primary aim of functional imaging studies has been to characterize this reorganization of regional brain function during normal human sleep as well as the responses to external stimuli and the influence of previous waking experience on

The images represent the cerebral glucose metabolism measured in a single subject during three different sessions with fluorodeoxyglucose F-18 positron emission tomography (^{18}F-FDG PET). Functional images are displayed at the same brain level and using the same color scale. Similar rates of brain glucose metabolism are measured during wakefulness and REM sleep. Brain glucose metabolism is significantly decreased during slow wave sleep relative to that in both wakefulness and REM sleep. (Modified from Maquet P, Dive D, Salmon E, et al. regional brain activity during sleep. The results of these studies, summarized in Table 12-1, are detailed next (Figure 12-1).

Non–Rapid Eye Movement Sleep

Neurophysiologic recordings in sleeping animals indicate that during non–rapid eye movement (NREM) sleep, the neural activity of the brain is shaped by a slow rhythm (<1 Hz), characterized by a fundamental oscillation of membrane potential made up of a depolarizing phase, associated with important neuronal firing ("up" state), followed by a hyperpolarizing phase, during which cortical neurons remain silent for a few hundred milliseconds ("down" state).[1,2] The slow oscillation occurs synchronously in large neuronal populations in such a way that it can be reflected on EEG recordings as high-amplitude, low-frequency waves.[1,3-5] The slow rhythm entrains other sleep oscillations in a coalescence of multiple rhythms.[6] Among the latter, spindles are associated with burst firing in thalamocortical populations. They arise from a cyclic inhibition of thalamocortical neurons by reticular thalamic neurons, which elicits postinhibitory rebound spike bursts in thalamocortical cells, which in turn entrain cortical populations in spindle oscillations.[7]

At the macroscopic systems level, the measure of brain metabolism or hemodynamics by PET usually requires the integration of the brain activity over extended time periods (from tens of seconds for $H_2{}^{15}O$-PET to 45 minutes for fluorodeoxyglucose F-18 (^{18}F-FDG) PET, resulting in the averaging of brain activity over the up and down states described earlier. Consequently, NREM sleep has systematically been associated with lower brain energy metabolism than that seen in wakefulness.[8] Relative to wakefulness, cerebral glucose and oxygen metabolism, as well as cerebral blood flow, is decreased by 5% to 10% during stage 2 sleep[9,10] and by 25% to 40% during slow wave sleep (SWS)—that is, stage 3 to 4 NREM sleep (see also Chapter 13).[11-13]

These decreases are not homogeneous but show a reproducible regional distribution. It is thought that brain areas with a high proportion of neurons committed in synchronous sleep oscillations are likely to have the lowest regional activity.[8] During light NREM sleep, cerebral blood flow decreases in the pons and thalamic nuclei, as well as in frontal and parietal areas but is maintained in the midbrain.[14] Consistent with the implication of thalamic nuclei in the generation of spindles, thalamic blood flow during stage 2 sleep decreases in proportion to the power density within the sigma frequency range (12 to 15 Hz).[15] During SWS, the most consistent decreases were observed in areas playing a permissive or active role in generating NREM sleep and its characteristic oscillations. These areas are the dorsal pons and mesencephalon, thalami, basal forebrain, and hypothalamus. The topography of the decreases in cortical blood flow during NREM sleep also is very reproducible and encompasses the prefrontal cortex, anterior cingulate cortex, the precuneus, and the mesial aspect of the temporal lobe.

The mechanisms that produce these diminutions in regional blood flow are not completely understood. The frontal and parietal polymodal associative cortices are among the most active brain structures during wakefulness.[8] Consequently, homeostatic sleep pressure locally accrued during a normal waking day generally is thought to be particularly important in these cortical areas, resulting during NREM sleep in a considerable amount of local slow waves, with a substantial decrease in local energy metabolism.[8] Significant decreases in blood flow also were unexpectedly observed in the cerebellum and basal ganglia. It is currently not known whether these changes in blood flow indicate that these two areas have a role in generating and maintaining cortical oscillations or if they are merely entrained by the cortical slow rhythm.

Advances in event-related EEG and fMRI have allowed a finer-grained characterization of brain activities associated with transient events, such as spindles[16] or slow waves. In humans, some evidence suggests the occurrence of two different types of spindles during sleep, slow and fast EEG spindles, which differ by their scalp topography and some aspects of their regulation.[17] Both spindle types trigger significant activity in the thalami, the anterior cingulate and insular cortices, and superior temporal gyri. Beyond the common activation pattern, slow spindles (frequencies of 11 to 13 Hz) are associated with increased activity in the superior frontal gyrus. By contrast, fast spindles (13 to 15 Hz) recruit a set of cortical regions involved in sensorimotor processing and recruit the mesial frontal cortex and hippocampus.

During SWS, human EEG recordings are characterized by high-voltage low-frequency oscillations whose classification is not always clear. The power density in the 0.75- to 4-Hz frequency band, usually referred to as *slow wave activity* (SWA), has proved to be a very useful and popular parameter because it quantifies the dissipation of homeostatic sleep pressure during NREM sleep.[18] However, its frequency bounds do not respect the dichotomy between slow (<1 Hz) and delta rhythms (1 to 4 Hz), which is based on differences in the respective cellular correlates of these oscillations in animals.[6] In the temporal domain, the amplitude of SWS waves is classically larger than 75 μV.[19] However, the largest waves (>140 μV) have been taken as realizations of the slow oscillation (<1 Hz).[20,21] Transient increases in brain activity associated with slow (>140 μV) and delta EEG waves (75 to

*Kety-Schmidt: A method for measuring organ blood flow, first applied to the brain in 1944 by CF Schmidt and SS Kety. A chemically inert indicator gas is equilibrated with the tissue of the organ of interest, and the rate of disappearance from the organ is measured. Blood flow is calculated on the assumption that the tissue and venous blood concentrations of the indicator gas are in diffusion equilibrium at all blood flow rates and that the rate of disappearance of the indicator from the tissue is a function of how much of the indicator is in the tissue at any time; the rate of disappearance is assumed to be exponential.

140 μV) can be detected in the pontine tegmentum (in an area encompassing the locus coeruleus), midbrain, and cerebellum in several cortical areas including inferior frontal, medial prefrontal, precuneus, and posterior cingulate parahippocampal gyrus,[22] areas that have been shown to be current sources underpinning human slow waves.[23]

As compared with baseline activity, slow waves are associated with significant activity in the parahippocampal gyrus, cerebellum, and brainstem, whereas delta waves are related to frontal responses. These findings show that NREM sleep is not a state of brain quiescence but is an active state during which neural activity is consistently synchronized by sleep oscillations (spindles, slow rhythm) in specific cerebral regions. Electrophysiologic and computational evidence from the cortex and thalamus indicates that the tonic firing pattern and fluctuations of the membrane potential during slow oscillation up states are similar to those characteristic of the waking state, suggesting that the up state is a ubiquitous feature of neuronal dynamics in corticothalamic networks reproducing a "micro" wake-like state that facilitates neuronal interactions.[24] The partial overlap between the regional activity pattern related to SWS waves and the waking default mode network is consistent with the hypothesis that the brain responses synchronized by the slow oscillation restore micro wake-like activity patterns[22] (Figure 12-2).

Processing of External Stimuli during NREM Sleep

To date, only a few neuroimaging studies have investigated how the human brain processes external stimuli during sleep, and their results are controversial. In sedated young children, examined with fMRI, visual stimulation elicited a paradoxical decrease in response in the anterior aspect of the medial occipital cortex.[25] Although the neurobiologic significance of this enigmatic finding remains elusive, it has been replicated in naturally sleeping adults during SWS, using fMRI and PET.[26] This response pattern does not seem to be specific to visual stimulations because it also is observed when auditory stimuli are delivered during NREM sleep.[27]

In sharp contrast with these results, other data suggest that the brain still processes auditory stimuli up to cortical areas during NREM sleep.[28] Significant responses to auditory stimuli were detected in bilateral auditory cortex, thalamus,

and caudate nuclei during wakefulness and light NREM sleep. In addition, the left amygdala and the left prefrontal cortex are recruited by stimuli of particular affective significance for the individual subject. (More information on how the brain process sensory input during sleep can be found in Chapter 23.)

REM Sleep

Reorganization of Regional Brain Function during REM Sleep: Relation with Dream Characteristics

The level of energy metabolism recorded during REM sleep is similar to waking levels.[12,13] The distribution of regional brain activity, however, significantly differs from that in wakefulness. In addition to areas known to participate in generation and maintenance of REM sleep (e.g., pontine tegmentum, thalamic nuclei), significant activations of limbic and paralimbic areas (e.g., amygdaloid complexes, hippocampal formation, anterior cingulate cortex, orbitofrontal cortex) are reported during REM sleep[11,29,30] (Figure 12-3).

Although this observation is not reported in all studies, posterior cortices in temporal occipital areas typically are activated during REM sleep.[11] By contrast, the dorsolateral prefrontal cortex, parietal cortex, posterior cingulate cortex, and precuneus are the least active brain regions.[11,29] Although early animal studies had already mentioned the high level of limbic activity during REM sleep, functional neuroimaging in humans highlighted the contrast between the activation of limbic, paralimbic, and posterior cortical areas on the one hand and the relative quiescence of the associative frontal and parietal cortices on the other.

Regional functional integration also is modified during REM sleep relative to wakefulness. For instance, the functional interactions between striate and extra-striate cortices, which are positive during wakefulness, become negative during REM sleep.[31] Likewise, the functional connectivity between the amygdala and temporal occipital areas is tighter during REM sleep than during resting wakefulness.[32]

The organization of human brain function during REM sleep somehow relates to some of the characteristics of dreaming activity.[29,33,34] The perceptual aspects of dreams would be related to the activation of posterior (occipital and temporal) cortices, whereas emotional features in dreams would be related to the activation of amygdalar complexes, orbitofrontal cortex, and anterior cingulate cortex. The recruitment of mesiotemporal areas would account for the memory content commonly observed in dreams. The relative hypoactivation of

the prefrontal cortex might help to explain the alteration in logical reasoning, working memory, episodic memory, and executive functions characterizing dream reports collected from experimentally induced REM sleep awakenings. Activation of the anterior cingulate cortex and surrounding mesial prefrontal cortex has been described, in studies on waking cognitive neuroscience, to be related to self-referential cognition and to the monitoring of performance. Activation of these structures within REM sleep might represent a role for REM sleep in the internal monitoring of aspects of the self, especially those having emotional significance, in keeping with the activation of other related limbic and paralimbic structures.[33]

Brain Imaging and Other Characteristic Features of REM Sleep

Rapid eye movements constitute a prominent feature of REM sleep. Cerebral mechanisms underpinning the generation of spontaneous ocular movements differ between REM sleep and wakefulness in humans. Regional cerebral blood flow changes in the lateral geniculate bodies and in the striate cortex are significantly more correlated with ocular movement density during REM sleep than during wakefulness,[35] a pattern that was later confirmed using fMRI.[36] This pattern of activity is reminiscent of ponto-geniculo-occipital (PGO) waves, prominent phasic bioelectrical potentials associated with eye movements, which occur in isolation or in bursts just before and during REM sleep and are most easily recorded in cats and rats in the mesopontine tegmentum, the lateral geniculate bodies, and the occipital cortex.[37]

Another important feature in REM sleep is the instability in autonomic regulation and especially in cardiovascular regulation. During awake states, the right insula is involved in cardiovascular regulation,[38] but during REM sleep, the variability in heart rate is related to the activity in the right amygdaloid complex.[39] The functional connectivity between the amygdala and the insular cortex, two brain areas involved in cardiovascular regulation, differ significantly in REM sleep as compared with wakefulness.[39] These results suggest a functional reorganization of central cardiovascular regulation during REM sleep (see also Chapter 13).

Experience-Dependent Modifications of Regional Brain Function during NREM and REM Sleep

Waking experience substantially influences regional brain activity during subsequent sleep. For instance, the blood flow of the hippocampus and parahippocampal gyrus during NREM sleep is increased in subjects who were navigating a virtual town (by means of a computer software program) during the previous waking period, as compared with naive participants.[40] The level of hippocampal activity expressed during SWS positively correlates with the improvement of performance in route retrieval the next day, suggesting that hippocampal activity during NREM sleep is related to subsequent "offline" processing of spatial memory.[40] Similarly, several brain areas activated during the execution of a serial reaction time task during wakefulness (brainstem, thalamus, and occipital, parietal and premotor areas) are significantly more active during REM sleep in subjects previously trained on the task than in nontrained subjects.[41] This enhancement of regional brain activity during posttraining REM sleep is observed only when the learning material is presented in a structured manner, versus random presentation.[42] It is then suggested to be associated with significant changes in brain functional connectivity.[43] Collectively, these results support the hypothesis that the memory of a motor sequence is further processed during REM sleep in humans (Figure 12-4). (For more information on memory processing in relation to sleep, see Chapter 23.)

BRAIN IMAGING AND NEURAL CORRELATES OF SLEEP-WAKE CYCLE REGULATION

The timing of sleep and wake episodes is thought to be regulated by the interaction between the homeostatic sleep pressure and an intrinsic circadian oscillation.[44] One study compared regional relative brain glucose metabolism rates for morning and evening wakefulness in healthy humans to define the mechanisms that maintain wakefulness across the day, in relation to the increasing sleep drive that accumulates over the wake period (see Chapter 36 for more information on sleep and wake process). Brain scans, using ^{18}F-FDG PET, were conducted during quiet wakefulness in the morning and in the evening in 13 healthy adults (10 women, 3 men) (mean age, 37 years). As expected, subjective ratings of alertness were lower in the evening than in the morning. Conversely, relative regional glucose metabolism was significantly higher in the evening than in the morning in a large cluster of midline and brainstem structures. More specifically, changes were localized in the pontine and midbrain reticular formation, midbrain raphe, locus coeruleus, and posterior hypothalamus. Of note, evening wakefulness is associated with increased relative metabolism in brainstem and hypothalamic arousal systems and decreased relative metabolism in posterior cortical regions. These patterns might reflect input from the circadian timing system(s) to promote wakefulness, or they might reflect the effects of increasing homeostatic sleep drive (see Chapter 36 and other chronobiology chapters in Section 5).

Using fMRI, two studies capitalized on interindividual differences in sleep-wakefulness regulation to assess the impact of sleep homeostasis and circadian factors on regional brain function. A first study investigated executive responses to a working memory task during a normal sleep-wake cycle and during sleep loss in a population of young healthy volunteers stratified according to homozygosity for a variable-number (4 or 5) tandem-repeat polymorphism in the coding region of the clock gene *PERIOD3 (PER3)*.[45] Homozygosity to the long allele (5/5) is associated with faster buildup of sleep homeostasis and increased vulnerability to sleep-loss.[46] In the less vulnerable genotype (4/4), no changes were observed in brain responses during the normal sleep-wake cycle. During sleep loss, these subjects recruited supplemental anterior frontal, temporal, and subcortical regions, while executive function was maintained. By contrast, in the vulnerable genotype (5/5), activation in a posterior prefrontal area was already reduced in comparison of evening to morning responses during a normal sleep-wake cycle. Furthermore, in the morning after a night of sleep loss, widespread reductions in activation in prefrontal, temporal, parietal, and occipital areas were observed in this genotype. Such differences occurred in the absence of genotype-dependent differences in circadian phase. These findings clearly showed that the allocation of prefrontal resources is constrained by sleep pressure and circadian phase.

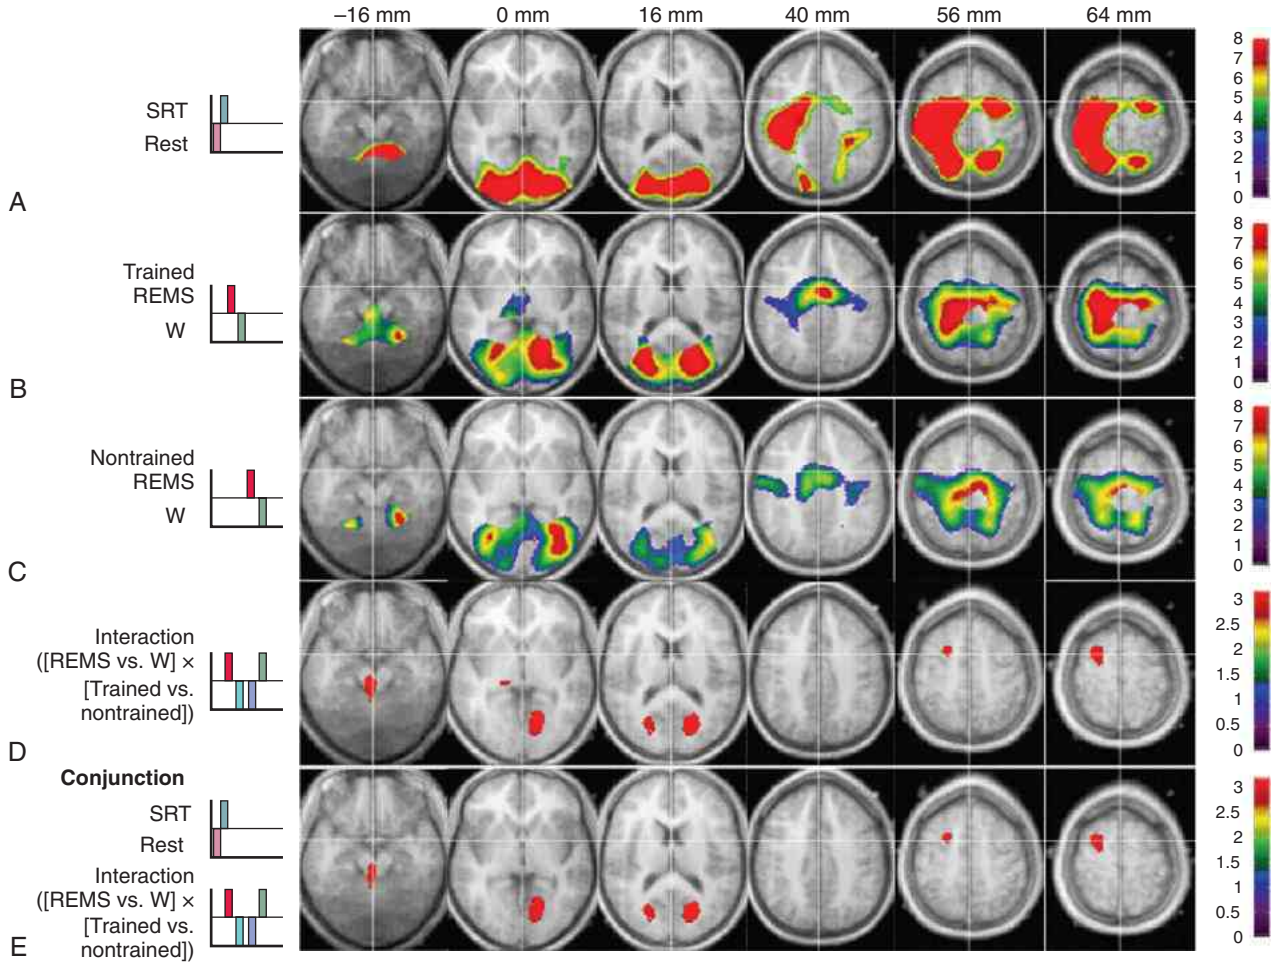

Figure 12-4 Influence of previous waking experience, in this case a procedural motor learning sequence, on the distribution of regional brain activity during subsequent REM sleep (REMS). Statistical parametric maps of different contrasts are displayed at six different brain levels (from 16 mm below to 64 mm above the bicommissural plane), superimposed on the average (coregistered and normalized) magnetic resonance imaging scan of the brain in sleeping subjects. All maps were thresholded at $P < .001$ (uncorrected), except for **A,** which was thresholded at voxel level–corrected ($P < .05$). **A,** Brain regions activated during performance of a serial reaction time (SRT) task during wakefulness (SRT-rest). **B,** Brain regions activated during REM sleep (REM sleep–wakefulness) in subjects previously trained to the SRT task. **C,** Brain regions activated during REM sleep (REM sleep–wakefulness) in nontrained subjects. **D,** Brain regions activated more in trained subjects than in nontrained subjects during REM sleep—that is, the intersection of the condition (REM sleep versus wakefulness) by group (trained versus nontrained). **E,** Brain regions that were both recruited during the execution of motor tasks and more activated in trained than in nontrained subjects scanned during REM sleep—that is, the conjunction of (SRT-rest) with the condition (REM sleep versus wakefulness) by group (trained versus nontrained). (Modified from Maquet P, Laureys S, Peigneux P, et al. Experience-dependent changes in cerebral activation during human REM sleep. *Nat Neurosci* 2000;3:831-6.)

The second fMRI study assessed the cerebral correlates of sustained attention in persons categorized as extreme early and late chronotype individuals, in the morning and in the evening (1.5 and 10.5 hours, respectively, after preferred waking time).[47] Early and late chronotypes are known to differ in terms of circadian phase, but early-morning types also are known to accrue a larger homeostatic sleep pressure buildup during wakefulness than is seen in evening types.[48]

Brain responses differed between chronotypes in the thalamus and areas compatible with the locus coeruleus and suprachiasmatic area. Furthermore, estimated fMRI blood oxygen level–dependent (BOLD) activity in the suprachiasmatic region was negatively related to the slow wave activity recorded during the subsequent first sleep cycle. This finding suggested that the activity profile of the suprachiasmatic nucleus (SCN) master clock acting on the cerebral correlates of sustained attention inherently depends on the status of the sleep homeostat. In other words, whereas evening types can benefit from the increasing circadian alertness signal to achieve optimal performance levels during the evening hours, morning types have to fight against a disproportionally increasing homeostatic sleep pressure at this time of the day and are therefore less able to profit from the beneficial circadian alertness signal to accomplish sustained attention performance.

The activity of the SCN, the master circadian clock, is influenced by external temporal markers (zeitgebers), the most important of which is light. In addition to vision, light profoundly affects human physiology and modulates sleep-wake cycles, body temperature, endocrine functions, alertness, and performance.[44] Animal and human studies demonstrated that

a *nonvisual* photoreception system mediates these effects, which include the synchronization of the circadian system, suppression of melatonin, regulation of sleep, and improvements in alertness and cognition.[49-53] This photoreception system recruits the retinal photoreceptors (rods and cones) and intrinsically photosensitive retinal ganglion cells expressing melanopsin.[54,55] These retinal ganglion cells project to numerous nuclei of the brainstem, hypothalamus, thalamus, and cortical structures; such anatomic connectivity suggests that the nonvisual system can influence many brain functions.

However, light has been shown to enhance cortical and subcortical responses induced by various cognitive challenges. Polychromatic bright white light (>7000 lux) was first shown to enhance responses to attention tasks in subcortical (hypothalamus and thalamus) and cortical areas during the night.[56] Similar results were observed during daytime.[57] These early experiments did not make it possible to specify the relative contribution of the different retinal photoreceptors involved. Monochromatic blue (470 nm) light was then shown to enhance brain responses to a working memory task in areas such as the thalamus and association cortices; it prevented the decline otherwise observed with green (550 nm) light exposure.[58] These results supported the potential involvement of melanopsin in eliciting these nonvisual modifications in brain responses. However, no definite claims could be made concerning the contribution of different photoreceptor classes. Subsequently, the relative contribution of S-cones, melanopsin-expressing ganglion cells, and M-cones to nonvisual brain responses to light was assessed using short-duration monochromatic light exposures of 430 nm (violet), 473 nm (blue), and 527 nm (green) wavelength, respectively.[59] Because light exposures were brief, this protocol allowed the detection of subcortical brain structures involved in early nonvisual responses to light, such as the thalamus and the brainstem.

It also appears that these immediate effects of ambient light on cognition in turn depend on circadian phase, homeostatic sleep pressure, and genotype.[60] An fMRI study showed that in a genotype reported to be more vulnerable to sleep loss (*PER3*$^{5/5}$), exposure to as little as 1 minute of low-intensity ambient blue light in the morning following sleep deprivation increases responses in a left thalamo-fronto-parietal circuit to a larger extent than does green light. By contrast, no impact of ambient light was observed during sleep loss in the genotype reported to be less vulnerable to sleep (*PER3*$^{4/4}$). These results support the view that the impact of light on cognitive brain function is especially present in challenging conditions when endogenous alerting mechanisms are not already active.

Collectively, these findings show that light, and especially blue light, not only can influence the timing of sleep and wake cycles but can also profoundly and swiftly influence regional brain function. The underlying mechanism is more likely to be a modulation of the activity in subcortical structures promoting alertness (e.g., anterior hypothalamus, mesopontine tegmentum, thalamus)[49-53] (Figure 12-5).

BRAIN IMAGING AND NEURAL CORRELATES OF HUMAN SLEEP DEPRIVATION

Sleep generation and maintenance are strongly affected by the homeostatic sleep drive. Accordingly, an understanding of the neural correlates of sleep deprivation, which increases the homeostatic sleep drive, can be expected to provide additional clues from functional neuroimaging about the mechanisms of sleep generation and sleep maintenance.

One study[61] assessed regional cerebral metabolism using the ^{18}F-FDG PET method in healthy subjects before and after 32 hours of sleep deprivation. The investigators noted prominent decreases in metabolism in the thalamus, basal ganglia, temporal lobes, and cerebellum and increases in visual cortex. Whole-brain absolute metabolic rate was not different. Another study[62,63] described the effects of 24, 48, and 72 hours of sleep deprivation on waking regional cerebral metabolism assessed using ^{18}F-FDG PET, as well as alertness and cognitive performance. Sleep deprivation was associated with global declines in absolute cerebral metabolism. Regionally, these declines were most notable in frontoparietal cortex and in the thalamus. These findings are consistent with studies showing that the effects of sleep deprivation on SWS are greatest in frontal EEG leads. Alertness and cognitive performance on a sleep deprivation–sensitive serial addition and subtraction test declined in association with the sleep deprivation–associated regional deactivations.

In other work, blood flow in the thalamus and pontomesencephalic tegmentum, as assessed by $H_2{}^{15}O$ PET, was found to positively correlate with frequency of arousals in sleep,[64] with performance on vigilance tasks,[65] and with loss of consciousness associated with anesthesia.[66] In some instances, this arousal network also included the basal forebrain and anterior cingulate cortex.[65] These findings regarding sleep deprivation support the role for sleep in restoring brain function in thalamocortical networks associated with higher-order cognition.

Another study[67] assessed changes in regional brain function during sleep recovery after sleep deprivation to define the specific neural correlates of the sleep recovery process. Homeostatic sleep need was modulated in a within-subjects design based on sleep deprivation. In four young adult healthy male subjects (mean age, 24.9 years ± 1.2 years), NREM sleep was assessed using ^{18}F-FDG PET after a normal night of sleep and again after 36 hours of sleep deprivation. Both absolute and relative regional cerebral glucose metabolic data were obtained and analyzed. In relation to baseline NREM sleep, the subjects' recovery NREM sleep was associated with increased slow wave activity, global reductions in whole-brain metabolism, and relative reductions in glucose metabolism in broad regions of frontal, parietal, and temporal cortex. These findings demonstrate that the homeostatic recovery function of sleep is associated with global reductions in whole-brain metabolism during NREM as well as greater relative reductions in broad regions of frontal, parietal, and temporal cortex. As indicated by these results, the homeostatic function of sleep in humans involves a reduction of glucose metabolism throughout the cortex. Neurobiologic models of sleep homeostasis, therefore, need to account for the inverse relationship between slow wave activity and cerebral glucose utilization and may suggest that the increased slow wave activity associated with recovery from sleep deprivation is a marker of an increased need for cerebral metabolic restoration.

FUNCTIONAL NEUROIMAGING IN SLEEP DISORDERS

Functional neuroimaging studies in patients with sleep disorders provide additional clues to the role of various brain

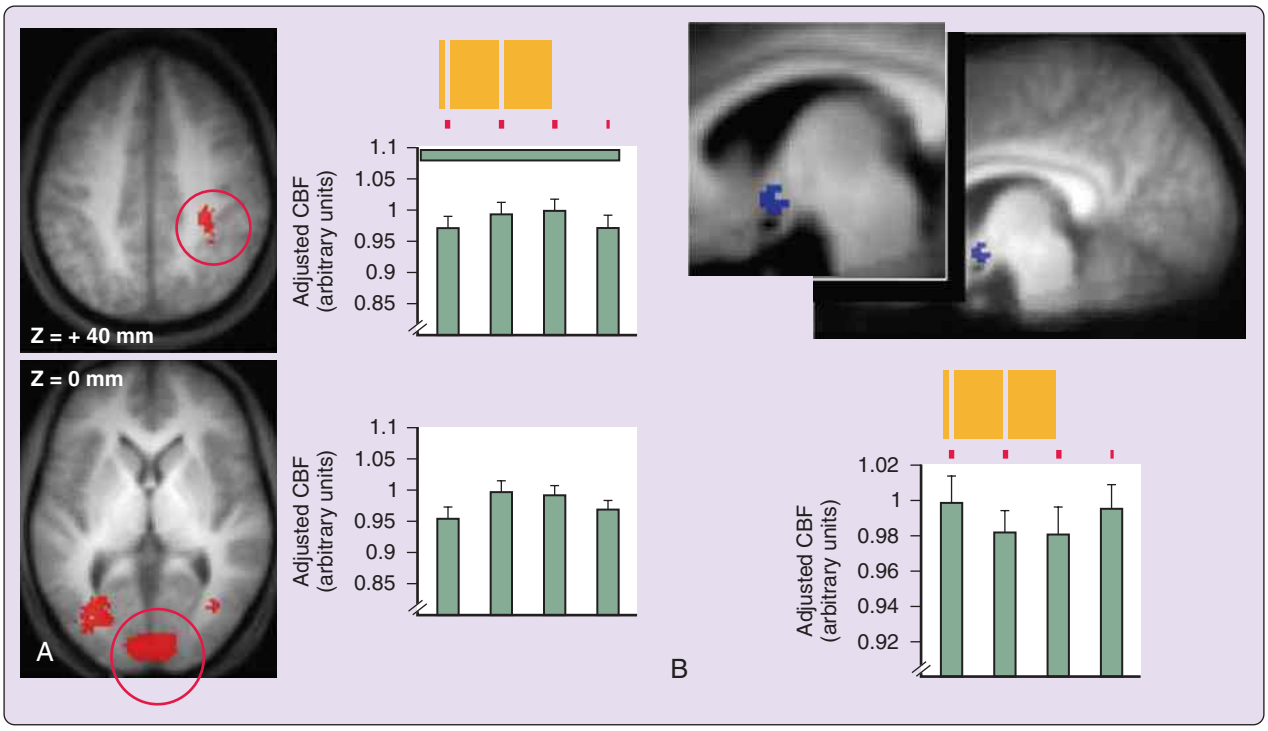

Figure 12-5 Effects on regional brain activity of exposure to bright white light during the night, as assessed with positron emission tomography. structures in generating and maintaining sleep. If the previously stated hypotheses regarding the role of various brain structures in these processes are correct, then these brain structures should function abnormally in some manner in patients who do not sleep well. Insomnia, for example, is a disorder in which patients have difficulty falling asleep or staying asleep or who have nonrestorative sleep along with daytime dysfunction. A survey of the functional neuroimaging findings in this disorder can be expected to provide additional clues, because new data are emerging on a regular basis about the neural mechanisms of sleep generation and maintenance in humans.

Although an overview of all neuroimaging studies in the full spectrum of all sleep disorders would be beyond the scope of this chapter, it bears mention here that extensive studies exist in circadian rhythm disorders, narcolepsy and the hypersomnia disorders, sleep-related breathing disorders, parasomnias, restless legs syndrome (RLS), and periodic limb movement disorder (PLMD) as well as neuroimaging studies reporting the effects of various treatments for sleep disorders on brain function. These findings have been reviewed in more extensive detail in the textbook *Neuroimaging of Sleep and Sleep Disorders,* by Nofzinger, Maquet, and Thorpy (2013), listed in the Selected Readings section of this chapter.

Insomnia and Brainstem and Hypothalamic Arousal Networks

Insomnia is the most prevalent of all sleep problems. *Insomnia* is the subjective complaint of difficulty falling asleep, difficulty staying asleep, poor quality sleep, or inadequate sleep duration despite having an adequate opportunity for sleep. Of importance, EEG sleep alterations in insomnia are not always found in persons with subjective complaints of insomnia. The leading neurobiologic model of insomnia is that of hyperarousal. For instance, people with insomnia have been shown to have elevated temperature and muscle tone at sleep onset, elevated heart rate and elevated sympathovagal tone in heart rate variability, and positive correlations between wake times after sleep onset and urinary norepinephrine and dopamine metabolites.[68-71] Studies of whole-body metabolic rate, assessed by oxygen consumption, show elevated rates for patients with insomnia compared with healthy control subjects, a difference that persists 24 hours per day.[72] The hyperarousal of insomnia is supported by higher rates of self-reported ruminations and intrusive thoughts among insomniac patients.

Perhaps more than for all other sleep disorders, brain imaging studies have been most helpful in elucidating the neural substrates of hyperarousal. An emerging body of evidence exists showing specific regional brain alterations despite

the relative absence of EEG sleep signs of the disorder. These findings hold promise that the use of brain imaging in this disorder can considerably advance the current understanding of the disorder and lead to new mechanisms for treatment in a manner previously unattainable through traditional EEG sleep assessments.

Human sleep neuroimaging studies in insomniac subjects support the involvement of basic arousal networks in disturbances in NREM sleep (Video 12-1). Nofzinger and colleagues[73] investigated the neurobiologic basis of poor sleep in insomnia. Insomniac patients and healthy subjects underwent regional cerebral glucose metabolic assessments during both waking and NREM sleep using ^{18}F-FDG PET. Healthy subjects reported better sleep quality than did those with insomnia. The two groups did not differ on any measure of visually scored or automated measure of sleep. Grouping by state interaction analysis confirmed that insomniac subjects showed a smaller decrease than for healthy subjects in relative glucose metabolism from waking to NREM sleep in the brainstem reticular core and in the hypothalamus. This study supports the concept that persistent activity in this basic arousal network may be responsible for the impaired objective and subjective sleep in insomniac patients (Figures 12-6 and 12-7).

In terms of interventions, the action of sedative-hypnotics may be primarily on these basic arousal systems. For example, one study[74] assessed regional cerebral blood flow, as a correlate of neuronal activity, during NREM sleep in response to triazolam, a short-acting benzodiazepine sedative-hypnotic. They found that blood flow in the basal forebrain was lower during NREM sleep after administration of triazolam than after administration of placebo.

One study aimed to determine if eszopiclone, a nonbenzodiazepine cyclopyrrolone, reversed the pattern of brainstem, hypothalamus, and basal forebrain abnormalities found in insomniac patients.[75] In this study, eight subjects (four women and four men) (mean age, 35 years ± 13 years) completed 2 weeks of open-label eszopiclone treatment, 3 mg at bedtime. Pre- and posttreatment assessments included a sleep diary, three nights of polysomnography, and waking and NREM sleep ^{18}F-FDG PET scans. From pre- to posttreatment, insomniac patients showed improvements in all subjective measures of sleep, sleep quality, mood, and next-morning alertness. The Pittsburgh Sleep Quality Index total was 11.9 ± 2.5 pretreatment and 7.5 ± 2.3 posttreatment; paired $t = 3.86$, $P = .006$. Brain imaging analyses showed that the reduction in relative metabolism in an arousal network from waking to NREM sleep was greater after eszopiclone treatment than before. Specific arousal network regions associated with such reduction included the pontine reticular formation and ascended into the midbrain, subthalamic nucleus, culmen of the cerebellum, and thalamus. Related neocortical areas showing this interaction included the orbitofrontal cortex, superior temporal lobe, right paracentral lobule of the posterior medial frontal lobe, right precuneus, dorsal cingulate gyrus, and portions of the frontal lobe. Comparisons involving only sleep, but not waking states, revealed similar regions of posttreatment reductions in relative metabolism.

These results demonstrate that eszopiclone reverses a pattern of central nervous system hyperarousal in insomniac patients. This effect is most pronounced during NREM sleep, at a time when the concentration of eszopiclone in the brain, when given before sleep, should be highest. The inhibitory actions of eszopiclone, and probably similar nonbenzodiazepine sedative-hypnotics and potentially the benzodiazepine sedative-hypnotics, then, that are likely to be responsible for the sedating properties of these medications appear to be largely on an arousal neural network within sleep that includes the pontine and midbrain reticular activating system. Such studies further corroborate the essential role of these structures in generating and maintaining sleep in humans (Figure 12-8).

Insomnia, Disorders of Emotion, and Limbic and Paralimbic Arousal Networks

Importantly, the basic biology of arousal can be modified by neural systems that regulate emotional and goal-directed behavior. These systems may play an important role in modulating or perpetuating the increased frequency of arousal of insomniac patients. Demonstration of this regulatory effect

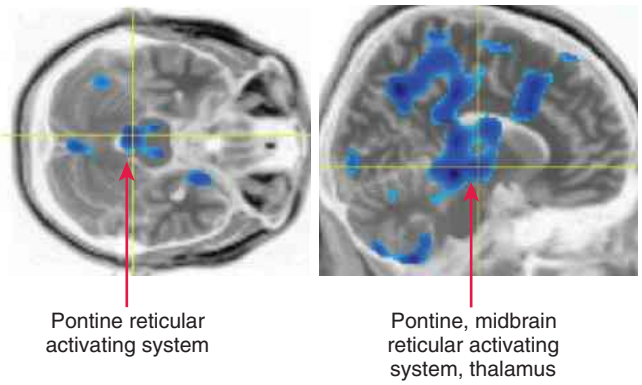

Figure 12-8 Brain structures that show a greater decline in metabolism from waking to NREM sleep in insomniac patients after 2 weeks of medication management with eszopiclone. provides significant support for an essential role for these systems in generating and maintaining sleep. This is especially true given the significant epidemiologic and neurobiologic overlaps between insomnia and mental disorders.

The results of preclinical neuroimaging studies of healthy subjects and depressed persons support the importance of two neural systems in emotional behavior. A more ventrally located system, with important contributions from the amygdala, has been shown to be fundamental to the initial experience of emotions and to the automatic generation of emotional responses. The function of this system is a reactive one in response to emotional stimuli. Other structures related to this system include the anterior insula, ventral striatum, and ventral regions of the anterior cingulate cortex and ventral prefrontal cortex. A more dorsally located system, with important contributions from the dorsolateral prefrontal cortex, has been shown to be fundamental to the conscious, planned regulation of emotional behavior in light of future behavior. The function of this system is one of planning behavior in response to emotional stimuli. Other structures related to this system include the hippocampus and the dorsal regions of the anterior cingulate cortex. A primary structure in the ventral system is the amygdala. It has been shown to participate in the sensory component of emotional behavior and in the initial organization of a reactive emotional response. In humans, the amygdala shows increased activation in response to a variety of emotional stimuli including fearful faces, sad faces, threatening words, and fearful vocalizations. A reactive motor role for the amygdala includes the recruitment and coordinating of cortical arousal and vigilant attention for optimizing sensory and perceptual processing of stimuli associated with underdetermined contingencies.

Recent work shows that the amygdala is anatomically connected with and functionally modulates effects on the brainstem centers involved in arousal and sleep regulation. Similarly, other components of the ventral emotional system such as the ventral striatum, the subgenual anterior cingulate cortex, and the ventromedial prefrontal cortex are known to have anatomic and functional relationships with brainstem centers that are thought to play a role in behavioral state regulation in addition to the primary roles they each play in cortical arousal.

Human sleep neuroimaging studies support the role for components of the *ventral emotional system* in pathologic sleep associated with both depression and insomnia. Nofzinger and colleagues[76] used ^{18}F-FDG PET to define regional cerebral correlates of arousal in NREM sleep in 9 healthy and 12 depressed patients. These workers assessed EEG power in the beta high-frequency spectrum as a measure of cortical arousal. They then correlated beta power with metabolism in NREM sleep. They found that beta power negatively correlated with sleep quality. Further, beta power positively correlated with ventromedial prefrontal cortex metabolism in a group of depressed subjects and a group of healthy subjects. These investigators concluded that elevated function in the ventromedial prefrontal cortex, an area associated with obsessive behavior and anatomically linked with brainstem and hypothalamic arousal centers, might contribute to dysfunctional arousal.

Nofzinger and coworkers[73] also investigated the neurobiologic basis of poor sleep in insomnia. Insomniac patients and healthy subjects completed regional cerebral glucose metabolic assessments during waking and during NREM sleep using ^{18}F-FDG PET. A group-by-state interaction analysis confirmed that insomniac persons showed a smaller decrease than in healthy subjects in relative metabolism from waking to NREM sleep in the insular cortex, amygdala, hippocampus, anterior cingulate, and medial prefrontal cortices. This study supports the notion that persistent overactivity in a limbic or paralimbic level of the arousal system contributes to the nonrestorative sleep in insomnia patients.

Pharmacotherapy for insomnia may entail direction of some component of its mechanism of action to these limbic and paralimbic structures, especially with use of the antidepressant medications. In a study[77] assessing regional cerebral blood flow during NREM sleep in subjects receiving triazolam, blood flow in the amygdaloid complexes, in addition to basal forebrain, was lower than after administration of placebo. Although not always consistent, several neuroimaging studies show that serotoninergic antidepressants tend to lower, or inhibit, brain function (blood flow or metabolism) in ventral limbic and paralimbic cortex including the amygdala,[78,79] perhaps through actions on 5-hydroxytryptamine type 1A (5-HT$_{1A}$) postsynaptic receptors, in keeping with their high density in these areas.[80] Inhibiting hyperarousal in this limbic-paralimbic emotional neural network could be of benefit in insomniac patients.

Recent studies have focused on the role of sleep in memory consolidation utilizing both cognitive neuroscience and brain imaging of the hippocampus. One study[81] compared sleep-related consolidation of procedural memory in 7 patients with primary insomnia and 7 healthy control subjects. Performance on a mirror-tracing task was assessed before and after sleep. Performance measures in the mirror-tracing task before sleep did not differ between the groups. Both groups performed significantly better in the recall condition after sleep. Healthy control subjects showed an improvement of 42.8% ± 5.8% in the mirror tracing draw time, whereas patients with insomnia showed an improvement of 20.4% ± 14.8% (multivariate analysis of variance [ANOVA] test session × group interaction: $F = 10.9$, $P = .002$). These preliminary findings support the view that sleep-associated consolidation of procedural memories may be impaired in patients with primary insomnia.

Another study focused on morphology of the hippocampus in insomniac patients.[82] Morphometric analysis of MRI brain scans was used to investigate possible neuroanatomic differences between patients with primary insomnia and with good

sleepers. MR images (1.5T) of the brain were obtained from both groups of subjects. MRI scans were analyzed bilaterally by manual morphometry for different brain areas including hippocampus, amygdala, anterior cingulate, and orbitofrontal and dorsolateral prefrontal cortex. Patients with primary insomnia demonstrated significantly reduced hippocampal volumes bilaterally in comparison with the good sleepers. None of the other regions of interest analyzed revealed differences between the two groups. Although replication of the findings in larger samples is needed to confirm the validity of the data, these pilot data raise the possibility that chronic insomnia is associated with alterations in brain structure. The integration of structural, neuropsychological, neuroendocrine, and polysomnographic studies is necessary to further assess the relationships between insomnia and brain function and structure.

One study suggested a role for the basal ganglia in the neurobiology of insomnia.[83] Patients with insomnia and good-sleeper control subjects were studied polysomnographically for three nights with a whole-brain SPECT scan of NREM sleep on night 3 of the series. Tomographs of regional cerebral blood flow during the first NREM sleep cycle were successfully obtained. Contrary to expectations, patients with insomnia showed a consistent pattern of hypoperfusion across all eight preselected regions of interest, with particular deactivation in the basal ganglia ($P = .006$). The frontal medial, occipital, and parietal cortices also showed significant decreases in blood flow compared with those in good sleepers ($P < .05$). Subjects with insomnia had decreased activity in the basal ganglia relative to the frontal lateral cortex, frontal medial cortex, thalamus, and occipital and parietal cortices ($P < .05$). These preliminary results suggest that primary insomnia may be associated with abnormal central nervous system activity during NREM sleep that is particularly linked to basal ganglia dysfunction.

Insomnia, Disorders of Emotion, and Neocortical Arousal Networks

Beyond the subcortical brainstem and the hypothalamic and limbic and paralimbic neural systems, the prefrontal cortex might play a role in insomnia in several respects. As noted, significant epidemiologic links have been documented between insomnia and disorders of emotion. The dorsolateral prefrontal cortex is a primary structure in the dorsal emotional neural system. This structure has been shown to play an important role in executive function, including selective attention, planning, and effortful regulation of affective states. The dorsolateral prefrontal cortex maintains the representation of goals and the means to achieve them. It sends bias signals to other areas of the brain to facilitate the expression of task-appropriate responses in the face of competition with other responses.

Left-lateralized prefrontal cortex regions are important in approach-related appetitive goals and the right, in behavioral inhibition and vigilant attention. The dorsolateral prefrontal cortex not only is responsible for recruiting or inhibiting limbic regions as appropriate to performing tasks[84] but also appears to be modulated by early limbic processing. A related component of the dorsal emotional system is the dorsal anterior cingulate cortex. This region has been associated with conflict monitoring (e.g., it is particularly active during conditions requiring swift arbitration quickly between two likely responses). In view of its role in the executive aspects of emotional behavior, an abnormal increase in vigilant functions of the prefrontal cortex could lead to insomnia, whereas deficient executive behavior could be a consequence of inadequate sleep resulting from insomnia.

Nofzinger's group[85] again investigated regional cerebral glucose metabolism in insomniac patients and healthy subjects during both waking and NREM sleep using ^{18}F-FDG PET. Insomniac subjects scored worse on measures of daytime concentration and fatigue, consistent with prefrontal cortex impairment. Insomniac patients showed increased global cerebral glucose metabolism during sleep and wake states, suggesting an increased vigilant or attentive function of the neocortex consistent with hyperarousal. A group-by-state interaction analysis confirmed that insomniac subjects showed a smaller decrease than that in healthy subjects in relative metabolism from waking to NREM sleep in the thalamus, the anterior cingulate, and medial prefrontal cortices, suggesting a persistence of thalamocortical arousal even within sleep in insomniac patients. In comparison with healthy subjects, insomniac subjects, while awake, showed relative hypometabolism in a broad region of the frontal cortex bilaterally; left hemispheric superior temporal, parietal, and occipital cortices; and the thalamus. Their daytime fatigue might reflect decreased activity in prefrontal cortex that results from inefficient sleep.

Several interventions may alter activity in the prefrontal cortex in a beneficial manner for insomniac patients. For example, one study[86] assessed regional brain function associated with yoga nidra, a meditative state characterized by a loss of conscious control and an increased awareness of sensory experience. In this study, the investigators found reduced blood flow during meditation in an attentional network that included the dorsolateral prefrontal cortex and anterior cingulate cortex, as well as increased blood flow in posterior sensory and associative cortex associated with visual imagery. Cognitive approaches to the treatment of insomnia may operate by means of similar mechanisms of action in prefrontal areas.

Serotonergically active antidepressants also increase brain function (blood flow or metabolism) in dorsal paralimbic and dorsolateral prefrontal cortex. Increasing activity in prefrontal cortex might reverse prefrontal deficits in insomnia patients, leading to improved daytime cognitive function. Alternatively, further increase of an already metabolically overactive prefrontal cortex might increase attentive and vigilant functions, thereby producing further insomnia, a not uncommon side effect of selective serotonin reuptake inhibitor (SSRI) therapy in depressed or insomnia patients.

One study has documented prefrontal hypoactivation in insomnia as predicted from the background review previously mentioned. This study investigated functional brain activation differences as a possible result of chronic insomnia, and the reversibility of these differences after nonmedicated sleep therapy. Twenty-one persons with insomnia and 12 carefully matched control subjects underwent fMRI scanning during the performance of a category task and a letter-fluency task. Insomniac subjects were randomly assigned to either a 6-week period of nonpharmacologic sleep therapy or a wait-list period, after which fMRI scanning was repeated using parallel tasks. Task-related brain activation and number of generated words were considered as outcome measures. Compared with control subjects, insomniac patients showed hypoactivation of the medial and inferior prefrontal cortical areas (Brodmann areas 9, 44, and 45); activation function recovered after sleep

therapy but not after a wait-list period. These studies support the hypothesis that insomnia interferes in a reversible fashion with activation of the prefrontal cortical system during daytime task performance.

Another study attempted to explore frontal cortex function in subsets of insomnia patients subtyped as either morning- or evening chronotypes.[87] Although insomnia is a well-established risk factor for the initial onset, recurrence, or relapse of affective disorders, the specific characteristics of insomnia that connote risk remain unclear. Insomniac patients with an evening chronotype may constitute one particularly high-risk group, perhaps owing to alterations in positive affect and its related affective circuitry. This study explored this possibility by comparing diurnal patterns of positive affect and the activity of positive affect–related brain regions in morning and evening types of insomnia. The investigators assessed diurnal variation in brain activity by means of the relative regional cerebral metabolic rate of glucose uptake by using [^{18}F]fluorodeoxyglucose PET during morning and evening wakefulness. They focused on regions in the medial prefrontal cortex and striatum, which have been consistently linked with positive affect and reward processing. As predicted, chronotypes differed in their daily patterns in both self-reported positive affect and associated brain regions. Evening types displayed diurnal patterns of positive affect characterized by phase delay and smaller amplitude compared to those of morning-types with insomnia. In parallel, evening types showed a reduced degree of diurnal variation in the metabolism of the medial prefrontal cortex and the striatum, as well as lower overall metabolism in these regions across both morning and evening wakefulness. Taken together, these preliminary findings suggest that alterations in the diurnal activity of positive affect–related neural structures may underlie differences in the phase and amplitude of self-reported positive affect between morning and evening chronotypes and may constitute one mechanism for increased risk of mood disorders among evening-type insomniac patients.

REM Sleep in Depression

Because REM sleep activates the limbic and anterior paralimbic cortex in healthy subjects, the increased REM sleep in depressed patients may reflect a greater reactivation of these structures in REM sleep. Nofzinger and coworkers[88] tested this hypothesis in 24 depressed patients and 14 healthy subjects, who underwent EEG sleep studies and regional cerebral glucose metabolism assessments during both waking and REM sleep using ^{18}F-FDG PET. Depressed patients showed greater REM sleep percentage. Consistent with the hypothesis that depressed patients would show increased activation in limbic and anterior limbic structures from waking to REM, depressed patients showed greater increases in relative metabolism from waking to REM sleep than those seen in healthy subjects in the midbrain reticular formation, including the pretectal area, and in a larger region of anterior paralimbic cortex. Additionally, depressed patients showed greater increases in relative metabolism from waking to REM sleep than for healthy subjects in a broadly distributed region of predominantly left hemispheric dorsolateral prefrontal, parietal, and temporal cortex. This area included the frontal and parietal eye fields.

Increased activation of the brainstem reticular formation from waking to REM sleep in depressed patients is consistent with the model of an altered balance in brainstem monoaminergic (norepinephrine and serotonin) systems and brainstem acetylcholine neuronal systems in depressed patients. A second important finding in this study was the increased activation of limbic and anterior paralimbic (hippocampus, basal forebrain/ventral pallidum, anterior cingulate, and medial prefrontal) cortex from waking to REM sleep in the depressed patients. The highest density of cholinergic axons is in core limbic structures such as the hippocampus and amygdala. Limbic and anterior paralimbic cortices also exhibit high densities of inhibitory 5-HT$_{1A}$ postsynaptic receptors in relation to other areas of cortex. In terms of behavior, increased activation of limbic and paralimbic cortex in depressed patients may reflect a susceptibility to experiencing stimuli in a more affectively intense, negative context, in keeping with the increased activation of these structures in response to negatively valenced stimuli or increased affective states. A third major finding in this study is the relatively greater activation of executive cortex from waking to REM sleep in depressed patients. This differential effect may reflect a change in modulation of cortical function from monoaminergic during waking to cholinergic in REM sleep, coupled with a monoaminergic or cholinergic imbalance in depressed patients. Behaviorally, this finding also might reflect a greater involvement of executive function during REM sleep in depressed patients, perhaps in response to the increased affective state produced by the abnormal reactivation of limbic and paralimbic cortex during REM sleep in these patients.

Fatal Familial Insomnia

One study[89] by Perani and colleagues assessed cerebral metabolism in four patients with fatal familial insomnia, a prion disease with a mutation at codon 178 of the prion protein gene. Thalamic hypometabolism was found in all cases, and more widespread nonspecific cortical hypometabolism was noted in some. These workers suggested that the thalamic dysfunction is consistent with the neuropathologic findings in the disorder and is a hallmark of the disease.

Another study[90] reported the results of a [^{123}I]β-CIT SPECT study in two cases of fatal familial insomnia. The researchers showed a 57% and 73% reduced availability of serotonin transporters in a thalamus-hypothalamus region in the two patients in comparison with age-expected control values. Although the interpretation is not entirely clear, they suggested that this decrease might reflect altered serotoninergic function in regions of the brain thought to be important in sleep-wake regulation in this patient group.

CLINICAL PEARLS

- Brain imaging technology has helped the field of sleep medicine to explore more precisely the relation between wake-sleep and sleep disturbances and their relation to cognitive function.
- Neural systems related to sleep-wake regulation and the function of sleep overlap extensively with neural systems involved in essential aspects of waking cognitive and emotional behavior.
- Disruptions in sleep in patients with sleep disorders can therefore be associated with alterations in these neural systems, and in turn, altered sleep leads to fundamental changes in these neural systems that impair waking behavior.

SUMMARY

The application of functional neuroimaging methods to the study of sleep in health and disease in human subjects has provided unique insights into the neural mechanisms of sleep generation and maintenance. In many instances, these studies provide secondary support for those mechanisms that have been discovered in preclinical research. They also have shed light on the involvement and interaction of broad neural networks operating at subcortical and cortical levels in a defined and regular manner to produce the final experience of sleep in humans. Brain imaging studies are contributing to the understanding of how wake and sleep networks can behave pathologically to produce various sleep disorders, and to the identification of those cases in which specific treatments, either pharmacologic or behavioral, can reverse these abnormalities.

Cardiovascular Physiology and Coupling with Respiration: Central and Autonomic Regulation

Ronald M. Harper; Richard L. Verrier

Chapter Highlights

- Sleep states contribute to substantial variability in heart rate and coronary artery flow, mediated by pronounced activation and deactivation of parasympathetic and sympathetic components of the autonomic nervous system. Surges in both components of the autonomic nervous system concurrent with electroencephalographic phasic activity during rapid eye movement sleep can significantly alter heart rate and coronary flow, potentially compromising individuals with heart disease or sleep-disordered breathing.
- Sleep-disordered breathing results in significant changes to brain tissue, including cell and axonal loss, and glial alterations indicative of injury. The changes appear in neural structures that serve essential autonomic, hormonal, cognitive, affective, and motor control functions; involve nuclei that are origins of neurotransmitter systems, as well as important medullary cardiovascular sites; and are often lateralized.
- The specificity and asymmetry of injury to autonomic regulatory areas, which include autonomic cortical sites as well as hypothalamic and medullary regions, result in marked functional consequences expressed as pathologic hypertension, potential for cardiac arrhythmia, and altered cerebral perfusion.
- Several syndromes, including those of sudden infant death (SIDS), sudden unexplained death in epilepsy (SUDEP), sudden unexplained nocturnal death syndrome (SUNDS), and sudden death in diabetes, and multiple cardiovascular conditions appear to have sleep-related disturbed autonomic regulation as their basis.

OVERVIEW

Because of the close neurohumoral coupling between central structures and cardiorespiratory function, a dynamic coordination exists between heart rhythm, arterial blood pressure, coronary artery blood flow, and ventilation. Non–rapid eye movement (NREM) sleep is associated with relative autonomic stability and functional coordination between respiration, pumping action of the heart, and maintenance of arterial blood pressure. During rapid eye movement (REM) sleep, surges in cardiac-bound sympathetic and parasympathetic activity provoke accelerations and pauses in heart rhythm, respectively. These surges occur in association with alterations on the electroencephalogram (EEG) indicative of phasic central nervous system activation in REM sleep, so-called phasic REM sleep. Whereas autonomic nervous system perturbations are well tolerated in normal persons, patients with heart disease or sleep-disordered breathing may be at heightened risk for cardiac events, especially due to the exaggerated sympathetic tone of REM sleep. Autonomic regulation often is compromised from injury to central autonomic regulatory sites in obstructive sleep apnea (OSA) and heart failure, resulting in preferentially lateralized high sympathetic nerve output and inappropriate responses to momentary challenges. In patients with severely compromised hearts, NREM sleep is associated with the potential for onset of hypotension, which can in turn impair blood flow through stenotic coronary vessels. During a typical night's sleep, a broad spectrum of autonomic patterns unfolds that provides both respite and stress to the cardiovascular system. These effects result from natural carefully orchestrated changes in central nervous system physiology, as the brain periodically reexcites during REM sleep, from the relative tranquility of NREM sleep.

This chapter surveys central and autonomic nervous system mechanisms that regulate cardiovascular function during sleep and identifies some dysfunctions that can arise in patients with underlying pathologic conditions. Particular attention is focused on cardiac electrical stability and coronary artery blood flow, because disturbances in these factors of cardiovascular function can trigger life-threatening cardiac arrhythmias and myocardial ischemia and infarction in patients with heart disease. Attention also is directed toward central mechanisms underlying the high sympathetic tone found in conditions associated with sleep-disordered breathing, including OSA and heart failure, and with cardiovascular function in infants, particularly because nocturnal regulatory perturbations of these systems may be an important factor in sudden infant

death syndrome (SIDS). The importance of these issues to public health is underscored by the annual toll of nocturnal, sleep-related cardiac events, which account for an estimated 20% of myocardial infarctions (approximately 250,000/year) and for 15% of sudden cardiac deaths (47,500/year) in the United States.[1] For detailed reports and discussion of clinical findings, see Chapters 124 and 125.

SLEEP STATE CONTROL OF CARDIOVASCULAR FUNCTION

The first NREM sleep cycle, from sleep onset, is characterized by a period of relative autonomic stability, with vagus nerve dominance and heightened baroreceptor gain. During NREM sleep, a near-sinusoidal modulation of heart rate variation occurs from coupling of respiratory and cardiorespiratory brain centers, resulting in what is termed "normal respiratory sinus arrhythmia" (Figure 13-1). During inspiration, heart rate accelerates to accommodate increased venous return, increasing cardiac output, followed by progressive rate slowing during expiration. This normal sinus variability in heart rate, particularly during NREM sleep, generally is indicative of cardiac health, whereas absence of intrinsic variability has been associated with cardiac pathology and advancing age.[2] The reflexive cardiovascular changes during breathing, manifested as cyclic heart rate variation, also have a converse relationship seen as transient elevation of arterial blood pressure, which results in slowing, cessation, or diminution of breathing efforts. This cascade of reflex adaptation is enhanced during sleep,[3] when even small reductions in arterial blood pressure increase respiratory rates.[4,5] These breathing pauses and increased rates serve as compensatory mechanisms to normalize arterial blood pressure. Reduced breathing variation and absence of normal breathing pauses, as well as declines in respiration-induced heart rate variation, are characteristic of infants who later succumb to SIDS[6] and may hint at failing compensatory mechanisms in the syndrome. Reduced heart rate variability appears in infants afflicted with congenital central hypoventilation syndrome, a condition characterized by reduced drive to breathe during sleep and compromised autonomic regulation, with high sympathetic tone.[7] Exaggerated heart rate variation appears in children with OSA, coincident with the enhanced bradycardia/tachycardia of apnea, but with lower sinus arrhythmia.[8] Patients with heart failure, who typically exhibit high levels of sympathetic tone, also have diminished respiratory function–related heart rate variation.[9] Thus the common denominator of cardiac risk associated with decreased heart rate variability appears to be enhanced sympathetic activity, together with reduced vagus nerve function.

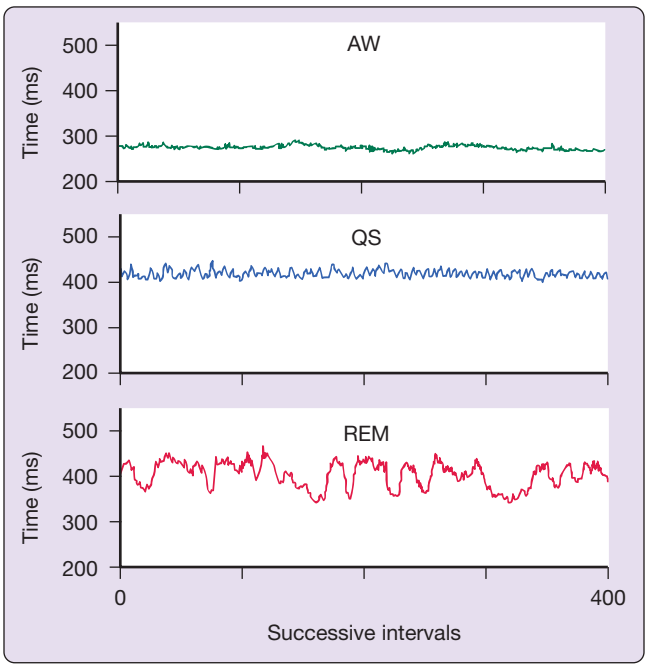

Figure 13-1 The *x*-axis represents successive heartbeats and the intervals between heartbeats from a healthy 4-month-old infant during quiet sleep (QS), REM sleep, and wakefulness (AW). The *y*-axis represents time (in milliseconds) between those heartbeats. Note the rapid modulation of intervals during quiet sleep contributed by respiratory variation. Also evident are lower-frequency modulation during REM sleep and epochs of sustained rapid rate during wakefulness.

Sympathetic nerve activity appears to be relatively stable during NREM sleep, and its cardiovascular input is reduced by more than half from wakefulness to stage N3 of NREM sleep.[10] In general, the autonomic stability of NREM sleep, with hypotension, bradycardia, and reduced cardiac output and systemic vascular resistance, provides a relatively salutary neurohumoral background during which the heart has an opportunity for metabolic restoration.[11] The bradycardias appear to result mainly from increased vagus nerve activity, whereas the hypotension is primarily attributable to reduced sympathetic vasomotor tone.[12] During NREM-to-REM sleep transitions, vagus nerve activity bursts may result in pauses in heart rhythm and frank asystole.[13]

REM sleep is initiated at approximately 90-minute intervals and, in subserving brain neurochemical functions and behavioral adaptations, can disrupt cardiorespiratory homeostasis.[14] The brain's increased excitability during REM sleep can result in major surges in cardiac sympathetic nerve activity to the coronary vessels. Baroreceptor gain is reduced. Heart rate fluctuates strikingly, with marked tachycardia and bradycardia episodes.[15,16] Cardiac efferent vagus nerve tone generally is suppressed during REM sleep,[11] and the highly irregular breathing patterns can lead to lower oxygen levels, particularly in patients with pulmonary or cardiac disease.[14] Neurons serving the principal diaphragmatic respiratory muscles are spared the generalized inhibition (see also Chapter 15),[17] although accessory and upper airway muscles diminish activity.[18] The REM atonia is especially marked in infant thoracic and abdominal muscles,[19] leading to the potential for dangerously low residual tidal volumes from the resulting increased thoracic wall compliance when the rib cage is not yet calcified. During sleep apnea, loss of central respiratory activity and/or airway obstruction may occcur several hundred times each night, with dire consequences for neural structures from the resulting intermittent hypoxia.

CARDIORESPIRATORY INTERACTIONS

Central Mechanisms

Integration of cardiorespiratory function during sleep is achieved at several neuraxis levels. Several pontine and suprapontine, as well as cerebellar mechanisms, can alter cardiorespiratory patterns during sleep and waking, and cerebral cortex sites play major roles, especially in modulating sympathetic and parasympathetic outflow and breathing effort.

Regional pontine roles in REM sleep activation have been documented by imaging studies of REM sleep, which also show preferential activation of limbic and paralimbic regions in REM sleep, compared with waking or with NREM sleep.[20-22] The pontine midline raphe contains serotoninergic neurons exerting significant roles in vascular control[23]; the raphe is damaged in OSA and heart failure (Figure 13-2), probably resulting from altered perfusion and intermittent hypoxia accompanying sleep-impaired breathing in these conditions.[24-27]

The classic sympathetic medullary areas include the rostral and caudal ventrolateral nuclei (RVLM and CVLM) and the nucleus of the solitary tract (NTS); the latter integrates baroreceptor and other sensory signals, relaying information to the CVLM, which in turn projects to the RVLM and then to the spinal cord intermediolateral column for sympathetic outflow. The human RVLM and CVLM are dorsally displaced relative to usual anatomic descriptions in rodents, and their signal changes with muscle sympathetic nerve discharge have been well described.[28] The RVLM shows significant

injury, measured by diffusion tensor imaging, in both OSA and heart failure (see Figure 13-2).[25,26]

The ventral medial frontal, cingulate, and insular cortices, along with portions of the hippocampal formation, mammillary bodies, and hypothalamic structures, are suprapontine structures participating in cardiorespiratory patterning and autonomic control, and all of these structures (see Figure 13-2) are injured in OSA.[26,29-32] The amygdala central nucleus projects extensively to the parabrachial pons, the NTS, the dorsal motor nucleus, and the periaqueductal gray, all areas exerting significant influences on cardiac action.[33] Portions of the amygdala, hippocampus, and frontal and insular cortices help mediate transient arterial blood pressure changes elicited by cold pressor or Valsalva challenges.[34,35] Injury to those areas may contribute to the impaired dynamic blood pressure control and chronic hypertension in OSA.

The insular cortices deserve special attention in cardiovascular regulation during sleep and waking. Both animal and human studies show that these areas modulate sympathetic and parasympathetic action, with the right insula principally affecting sympathetic outflow and the left, parasympathetic action[36] (although both sides interact).[37] The right anterior insula modulates baroreflex action,[37] and a lateralized and anterior-posterior topography of fMRI signals emerges to different autonomic (Valsalva, hand grip, or cold pressor) challenges.[38] The insular topographic organization affects sleep, heart failure, and stroke fields, because the right insula is damaged in OSA and heart failure[24,26,29,39,40] (Figure 13-3, *A*) and can be vascularly compromised from middle cerebral artery stroke. Heart failure and OSA are accompanied by enhanced sympathetic nerve discharge and hypertension, possibly from injury to the anterior insula and its baroreflex modulation roles. That insular damage is accompanied by impaired amplitude and timing of fMRI signals to autonomic challenges and an inability to mount appropriate heart rate responses.[41-44]

Some types of seizure discharge in epilepsy occur during sleep states. A unilateral seizure focus in the insula could exert profound influences on arterial blood pressure and heart rate,[45] which might include exaggerated sympathetic drive from right-sided foci, leading to circumstances underlying sudden unexplained death during sleep in epilepsy (SUDEP) and diabetes.[46,47] The ventral medial frontal and cingulate cortices also exert major roles in vagal and sympathetic control, respectively.[48-51] The cortical influences on subcortical sites carry significant import for cardiorespiratory control.

The cerebellum is especially important for regulating cardiovascular and respiratory control in both sleep and waking states. Although it is not classically considered a component of either breathing or cardiac regulation, that cerebellar role has been known for over half a century[52] and is mediated partially through vestibular/cerebellar mechanisms in blood pressure coordination.[53] Vestibular mechanisms modify arterial blood pressure responses to rapid postural changes, a process familiar to orthostatic hypotensive individuals who suffer syncope on rising rapidly from the horizontal position. Lesions of feline cerebellar fastigial nuclei result in ineffective compensatory responses to hypotension,[54] with ensuing death. Significant gray matter loss occurs in the cerebellar cortex and deep nuclei in heart failure[39] (Figure 13-3, *B*) and in OSA[40] and probably contributes to aberrant cardiovascular control in these syndromes. Abnormal cerebellar development or cerebellar insult contributions to cardiorespiratory disturbances are well described.[55-57]

Cardiorespiratory Homeostasis

An important consideration in preserving circulatory homeostasis during sleep is coordination of control over two systems: the respiratory system, essential for oxygen exchange, and the cardiovascular system, for blood transport. The coordination of two motor systems, one for somatic musculature (i.e., diaphragmatic, intercostal, abdominal, and upper airway musculature) and the other for autonomic regulation (to the heart and vasculature), is a formidable task during sleep and is particularly challenging in patients with diseased respiratory or cardiovascular systems, especially in apnea or heart failure, or in infants, whose developing control systems may become compromised. Respiratory neuron activity varies greatly between sleep states, as does heart rhythm regularity. Tachycardia, polypnea, sweating, and dramatic elevations in arterial blood pressure secondary to intense autonomic activity occur primarily during REM sleep.

Maintaining perfusion of vital organs through adequate arterial blood pressure control is essential for cardiorespiratory homeostasis. Respiratory mechanisms are recruited to support cardiovascular action by assisting venous return and by reflexly altering cardiac rate. REM sleep induces a near-paralysis of accessory respiratory muscles, including upper airway musculature, and diminishes descending forebrain influences on brainstem vasculature and motor control regions.[58,59] This reorganization during REM sleep may interfere with compensatory breathing mechanisms that assist arterial blood pressure management and may lead to removal of protective forebrain influences on hypotension or hypertension. The significant interaction between breathing and arterial blood

pressure appears in the partial normalization of blood pressure by delivery of continuous positive airway pressure in patients with apnea-induced hypertension.[60]

Arterial blood pressure control during sleep is of interest in examining mechanisms of failure in SIDS. Several reports indicate that the fatal sequence in SIDS may originate with a cardiac rhythm failure.[61] Specifically, an arrhythmia, or bradycardia and hypotension, rather than an initial breathing cessation, characterizes the final event.[62,63] Antecedent tachycardia may be present for up to 3 days. The terminal events in SIDS appear to parallel the two stages of shock—namely, an initial sympathoexcitation followed by a sudden, centrally triggered sympathoinhibition and bradycardia, leading to a life-threatening fall in arterial blood pressure. Some monitored SIDS cases show a near-total loss of arterial blood pressure within a minute of onset of the fatal event. Because SIDS deaths occur largely during sleep, some interaction of state and compensatory mechanisms is suspected. The prone sleeping position enhances the risk for SIDS, which may derive from the vestibular and cerebellar contributions to arterial blood pressure control[53] described earlier. Because vestibular and cerebellar mechanisms assist mediation of arterial blood pressure to postural changes, static stimuli, such as those from the prone position, can directly modify cardiovascular responses to blood pressure challenges.[64-67] Sleep effects on vestibular systems must be considered in examination of arterial blood pressure control mechanisms.

Sleep spindles are evident during NREM sleep, eye movements during REM sleep, and gross eye movements on awakening. Surges in heart rate and coronary flow occur during REM sleep. SLEEP STATE–DEPENDENT CHANGES IN HEART RHYTHM

Recent evidence indicates that the pronounced changes in heart rate occurring during REM sleep and transitions between sleep states are attributable to distinct mechanisms associated with specific brain sites, rather than representing a continuum of autonomic change.

Heart Rate Surges

Several investigators have reported REM sleep–induced increases in heart rate in experimental animals.[12,15,68-71] Accelerations consisting of an abrupt, although transitory, 35% to 37% increase in rate that are concentrated during phasic REM sleep were observed in canines (Figure 13-4). These marked heart rate surges are accompanied by a rise in mean arterial blood pressure and are followed by a rate deceleration that apparently is baroreceptor-mediated. Because the sequence is completely abolished by interruption of sympathetic neural input to the heart,[68-70] the acceleration does not appear to be dependent on withdrawal of parasympathetic nerve activity.[15,70]

REM sleep state–dependent heart rate surges also have been observed in felines. The rate accelerations are linked to central nervous system activation as reflected in a concomitant increase in hippocampal theta frequency, ponto-geniculo-occipital (PGO) activity, and eye movements.[71] In cats, the appearance of theta waves is characteristic of arousal, orienting activity, alertness, and REM sleep.[71-75] The surges are abolished by cardioselective beta-adrenergic blockade with atenolol, suggesting, as in canines, that the peripheral effect is attributable to bursting of cardiac sympathetic efferent fiber activity, which directly affects heart rate. The main difference in rate responses between the two species is that in dogs, the rate acceleration is accompanied within seconds by a baroreflex-mediated deceleration. The precise basis for these differences in the pattern of heart rate responses is unclear, but a plausible explanation is that the canine studies were performed in beagles—dogs that are bred for intense physical activity, a factor known to augment baroreceptor responsiveness.

Heart Rhythm Pauses

A complementary finding to centrally mediated heart rate surges is the observation in cats of an abrupt heart rhythm deceleration that occurs predominantly during tonic REM sleep and is not associated with any preceding or subsequent heart rate or arterial blood pressure change[76] (Figure 13-5). The vagus nerve involvement appears to be directly initiated by central influences, as no antecedent or subsequent change in resting heart rate or arterial blood pressure occurs. The primary involvement of central nervous system activation is shown by the consistent, antecedent, abrupt cessation of PGO activity and the concomitant interruption of hippocampal theta rhythm. In normal human volunteers, Taylor and colleagues[77] observed heart rate decelerations during REM sleep that preceded eye movement bursts by 3 seconds and suggested that the phenomenon reflects an orienting response at dreaming onset. The processes underlying the central nervous

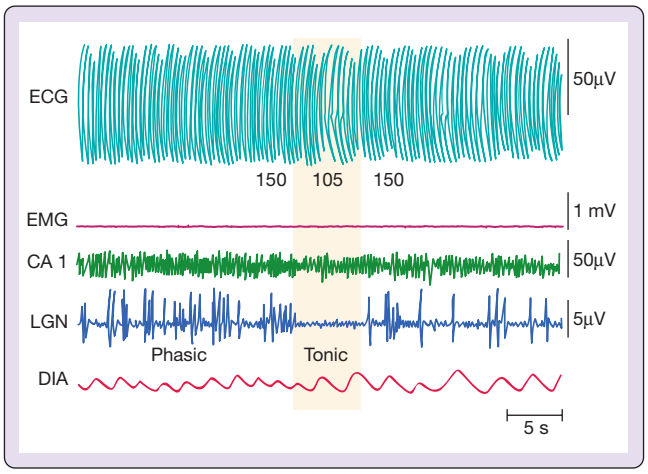

Figure 13-5 Representative polygraphic recording of a primary heart rate deceleration during tonic REM sleep. During this deceleration, heart rate decreased from 150 to 105 beats/minute, or 30%. The deceleration occurred during a period devoid of ponto-geniculo-occipital (PGO) spikes in the lateral geniculate nucleus (LGN) or theta rhythm in the hippocampal (CA 1) leads. The abrupt decreases in amplitude of hippocampal theta waves (CA 1), PGO waves (LGN), and respiratory rate (DIA) are typical of transitions from phasic to tonic REM sleep. system changes accompanying the tonic REM sleep–induced increase in vagus nerve tone, suppressing sinus node activity, remain unknown. Notwithstanding extensive studies of the physiologic and anatomic bases for PGO activity, little is known about its conductivity and functional relationship to heart rhythm control during sleep.

The most likely basis for the abrupt deceleration in heart rate during tonic REM sleep is a centrally induced decline in sympathetic nerve activity or enhanced vagus nerve tone, or both in combination. In felines, cardioselective beta$_1$-adrenergic blockade with atenolol did not affect the incidence or magnitude of decelerations, but muscarinic blockade with glycopyrrolate completely abolished the phenomenon. These observations suggest that the tonic REM sleep–induced decelerations are primarily mediated by cardiac vagus nerve efferent fiber activity. It is well known that enhanced vagal activity can abruptly and markedly affect the sinus node firing rate.[78] Because beta-adrenergic blockade exerted no effect on the frequency or magnitude of decelerations, it does not appear that withdrawal of cardiac sympathetic tone is an important factor in the observed rate changes. Respiratory interplay is not an essential component of the deceleration, inasmuch as the phenomenon often occurs in the absence of a temporal association with inspiratory effort.

This primary heart rate pause phenomenon appears to be distinct from baroreceptor-mediated reductions in heart rate that almost invariably follow accelerations in rate and elevation of arterial blood pressure[13] (Figure 13-6). This second

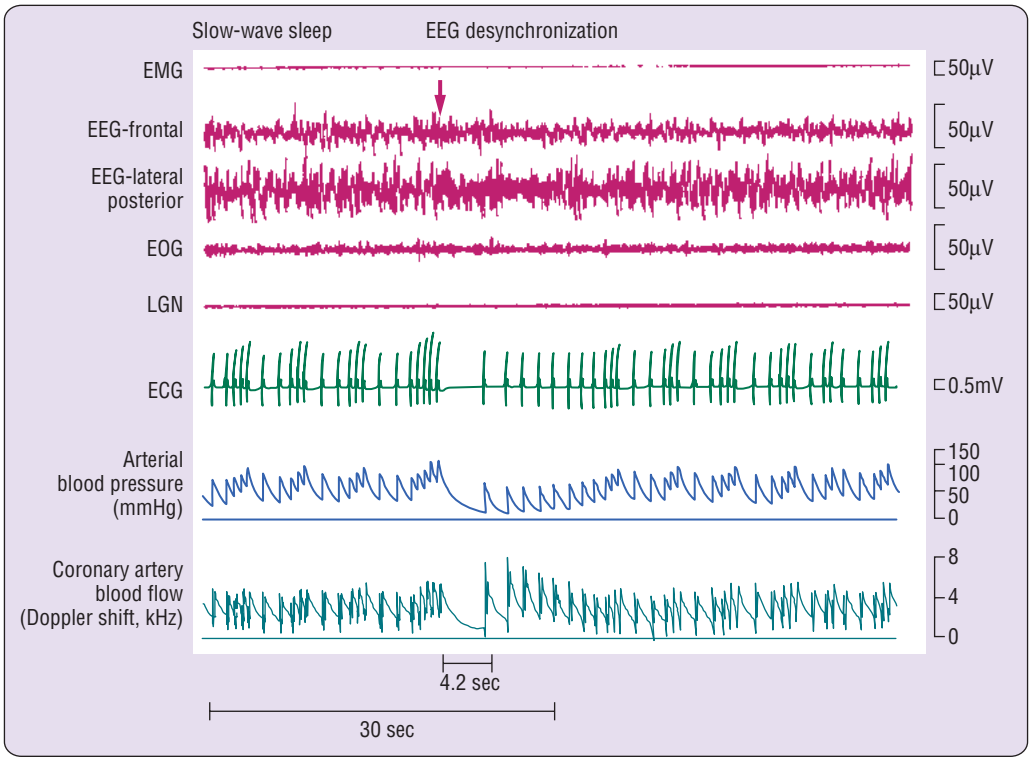

Figure 13-6 Coronary blood flow (CBF) surge during deep NREM sleep interrupted by electroencephalographic desynchronization. This response pattern is common and appears to represent a brief, low-grade arousal. The 4.2-second pause in heart rhythm was followed by a brief increase of 46% in average peak CBF and a decrease of 49% in the heart rate–systolic blood pressure product. group of heart rhythm pauses was observed in canines and occurs mainly during the transition from slow wave sleep to desynchronized sleep and more frequently during phasic than tonic REM sleep. These pauses persist for 1 to 8 seconds and are followed by dramatic increases in coronary blood flow averaging 30% and ranging up to 84%, which are independent of metabolic activity of the heart as reflected in the heart rate–blood pressure product. An intense burst of vagus nerve activity appears to produce the phenomenon, because the pauses develop against a background of marked respiratory sinus arrhythmia with varying degrees of heart block (with nonconducted P waves) and with low heart rate. Moreover, the heart rhythm pauses could be reproduced by electrical stimulation of the vagus nerve. Guilleminault and colleagues[79] documented similar pauses in healthy young adults.

CORONARY ARTERY BLOOD FLOW REGULATION DURING SLEEP

Striking changes in coronary blood flow occur during REM and sleep state transitions.[13,68-70,80] Vatner and coworkers[80] studied the effects of the sleep-wake cycle on coronary artery function in baboons. During the nocturnal period, when the animals were judged to be asleep by behavioral indicators, coronary blood flow increased sporadically by as much as 100%. The periodic oscillations in blood flow were not associated with alterations in heart rate or arterial blood pressure and occurred while the animals remained motionless with eyes closed. Because the baboons were not instrumented for electroencephalographic recordings, no information was obtained regarding sleep stage, nor was the mechanism for the coronary blood flow surge defined.

Concomitant with the heart rate surges of REM sleep found in canines[68-70] as described earlier, were remarkable episodic surges in coronary blood flow, with corresponding declines in coronary vascular resistance. These phenomena occurred predominantly during periods of REM sleep marked by intense eye movement phasic activity.[70] No significant changes in mean arterial blood pressure were seen. Heart rate was elevated during the coronary flow surges, suggesting increased cardiac metabolic activity as the basis for the coronary vasodilation. In fact, the close coupling between rate-pressure product, an index of metabolic demand, and the magnitude of the flow surges indicates that the surges do not constitute a state of myocardial hyperperfusion. These surges in coronary blood flow appear to result from enhanced adrenergic discharge, because they were abolished by bilateral stellectomy, and not from nonspecific effects of somatic activity or respiratory fluctuations.

During severe experimental coronary artery stenosis (with baseline flow reduced by 60%) in canines, phasic decreases in coronary arterial blood flow, rather than increases, were observed during REM sleep coincident with these heart rate surges[69] (Figure 13-7). An increase in adrenergic discharge could lead to a coronary blood flow decrement by at least two possible mechanisms. The first is by stimulation of alpha-adrenergic receptors on the coronary vascular smooth muscle. Such an effect, however, could be only transitory, because alpha-adrenergic stimulation results in brief (10 to 15 seconds) coronary constriction even during sympathetic nerve stimulation in anesthetized animals[81] or during intense arousal associated with aversive behavioral conditioning.[82] The second possible mechanism is mechanical: a decrease in diastolic coronary perfusion time caused by the surges in heart rate. In support of this explanation, a strong correlation ($r^2 = 0.96$) was found between the magnitude of the increase in heart rate and the decrease in coronary blood flow.[69] The link between REM-induced changes in heart rate and the occurrence of myocardial ischemia in patients with advanced coronary artery disease was reported by Nowlin and coworkers.[83]

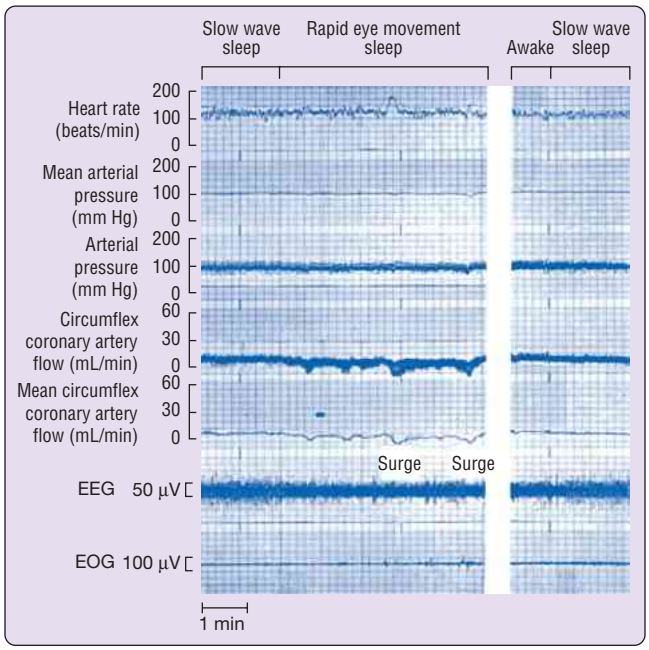

Figure 13-7 Effects of sleep stage on heart rate, mean and phasic arterial blood pressure, and mean and phasic left circumflex coronary artery blood flow in a typical dog during coronary artery stenosis. Note phasic decreases in coronary flow occurring during heart rate surges while the dog is in REM sleep. During REM sleep, the electroencephalogram (EEG) reveals a characteristic lower-amplitude, higher-frequency pattern than in slow wave sleep. The electrooculogram (EOG) tracing indicates the presence of eye movements during REM but not slow wave sleep. (From Kirby DA, Verrier RL. Differential effects of sleep stage on coronary hemodynamic function during stenosis. *Physiol Behav* 1989;45:1017-20.)

Furthermore, nocturnal myocardial ischemia carries significant potential to affect coronary function and cardiac electrical stability in patients with ischemic heart disease, because it has been linked to infarctions, 20% of which occur at night, and arrhythmias (see Chapter 124).

IMPACT OF SLEEP ON ARRHYTHMOGENESIS

Central Nervous System Sites Influencing Cardiac Electrical Stability

Extensive investigation of central nervous system–induced cardiac arrhythmias has provided evidence that triggering of arrhythmias by the central nervous system not only is the consequence of intense activation of the autonomic nervous system but is also a function of the specific neural pattern elicited. Regulation of cardiac neural activity is highly integrated and is achieved by circuitry at multiple levels[84] (Figure 13-8). Higher brain centers operate through elaborate pathways within the hypothalamus, modulated by cortical influences and by medullary cardiovascular regulatory sites. Baroreceptor mechanisms have long been recognized as

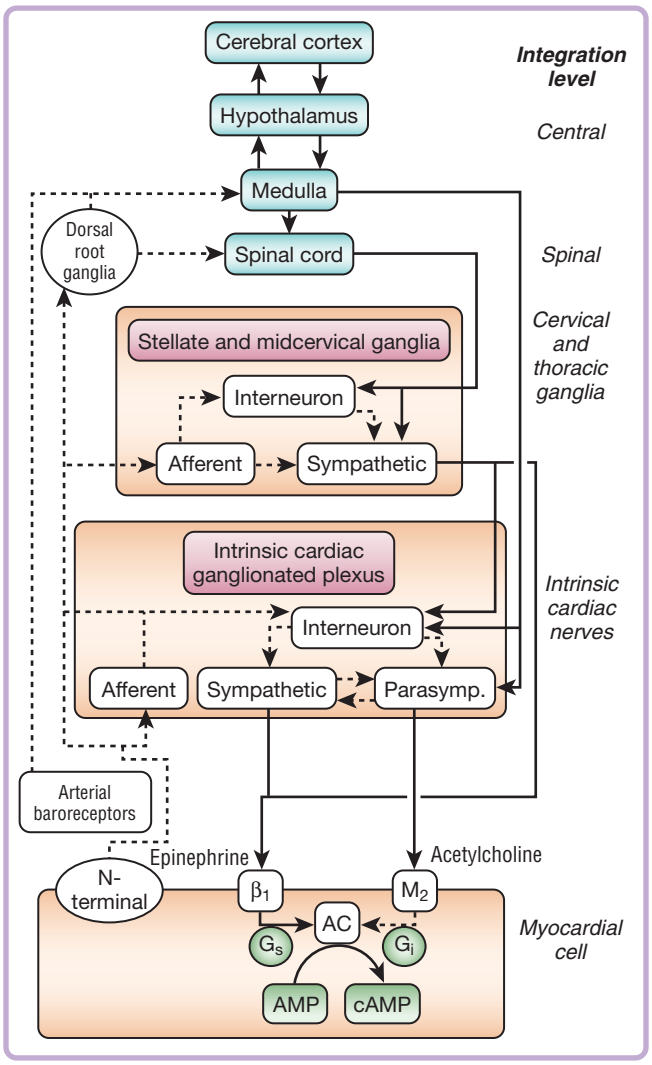

Figure 13-8 Synthesis of new and present views on levels of integration important in neural control of cardiac electrical activity during sleep. More traditional concepts focused on afferent tracts (*dashed lines*) arising from myocardial nerve terminals and reflex receptors (e.g., baroreceptors) that are integrated centrally within hypothalamic and medullary cardiostimulatory and cardioinhibitory brain centers and on central modulation of sympathetic and parasympathetic outflow (*solid lines*) with little intermediary processing at the level of the spinal cord and within cervical and thoracic ganglia. More recent views incorporate additional levels of intricate processing within the extraspinal cervical and thoracic ganglia and within the cardiac ganglionic plexus, where recently described interneurons are envisioned to provide new levels of noncentral integration. Release of neurotransmitters from postganglionic sympathetic neurons is believed to enhance excitation in the sinoatrial node and myocardial cells through norepinephrine binding to beta$_1$ receptors, which enhances adenyl cyclase (AC) activity through intermediary stimulatory G proteins (G_s). Increased parasympathectomy outflow enhances postganglionic release and binding of acetylcholine to muscarinic (M_2) receptors and, through coupled inhibitory G proteins (G_i), inhibits cyclic AMP (cAMP) production. Cyclic AMP alters electrogenesis and pacemaking activity by affecting the activity of specific membrane sodium, potassium, and calcium channels. New levels of integration are shown superimposed on previous views and are emphasized here to highlight new possibilities for intervention. (From Lathrop DA, Spooner PM. On the neural connection. *J Cardiovasc Electrophysiol* 2001;12:841-4, with permission.)

integral to autonomic control of the cardiovascular system, as evidenced by heart rate variability and baroreceptor sensitivity testing in both cardiac patients and normal subjects. The baroreflex is partially modulated by the insular cortex,[37] but intrinsic cardiac nerves and fat pads provide local neural coordination independent of higher brain centers. The phenomenon of electrical remodeling is attributable to nerve growth and degeneration. At the level of the myocardial cell, autonomic receptors influence G proteins to control ionic channels, pumps, and exchangers. The influence of the vagus nerve on ventricular electrical properties is contingent on the level of sympathetic tone, a phenomenon referred to as accentuated antagonism. The underlying mechanism is that acetylcholine, released by vagal activation, exerts its opposing effects by presynaptic inhibition of norepinephrine release from sympathetic nerve endings and through an antagonism of second messenger formation at the cardiac receptor level.[85] Thus the balance in cardiac input from either limb of the autonomic nervous system and their interactions must be considered. Another important concept is that triggering of arrhythmias by central nervous system activity also may depend on several intermediary mechanisms. These include direct effects of neurotransmitters on the myocardium and its specialized conducting system and changes in myocardial perfusion due to alterations in coronary vasomotor tone, enhanced platelet aggregability, or both. The net influence on the heart thus depends on a complex interplay between the specific neural pattern elicited and the underlying cardiac pathology.

More than 100 years ago, Levy[86] demonstrated that ventricular tachyarrhythmias can be elicited in normal animals by stimulating specific areas in the brain, a finding subsequently confirmed in several species. Hockman and colleagues,[87] using stereotactic techniques, demonstrated that cerebral stimulation and hypothalamic activation evoked a spectrum of ventricular arrhythmias. Stimulation of the posterior hypothalamus causes a 10-fold increase in the incidence of ventricular fibrillation elicited by experimental occlusion of the coronary artery.[88] This enhanced vulnerability was linked to increased sympathetic nerve activity, because beta-adrenergic receptor blockade, but not vagotomy, prevented it. These findings are consistent with clinical reports that cerebrovascular disease (particularly intracranial hemorrhage) can elicit significant cardiac repolarization abnormalities and life-threatening arrhythmias.[89,90] Cryogenic blockade of the thalamic gating mechanism or its output from the frontal cortex to the brainstem[91] and of the amygdala[92] delayed or prevented the occurrence of ventricular fibrillation during stress in pigs.

Ventricular arrhythmias also ensue immediately on cessation of diencephalic or hypothalamic stimulation, but the appearance of these arrhythmias requires intact vagi and stellate ganglia.[93,94] The likely electrophysiologic basis for such post–central nervous system stimulation arrhythmias is the loss of rate overdrive suppression of ectopic activity. This phenomenon occurs when the vagus nerve regains its activity after cessation of centrally induced adrenergic stimulation. Accordingly, the enhanced automaticity induced by adrenergic stimulation of ventricular pacemakers is exposed when vagus nerve tone is restored and slows the sinus rate.[94] Although these arrhythmias, including ventricular tachycardia, may be dramatic in appearance, they rarely degenerate into ventricular fibrillation.[95] This proarrhythmic effect of dual autonomic activation has been erroneously interpreted as profibrillatory.

The antiarrhythmic influence of beta-adrenergic receptor blockade may result in part from blockade of central beta-adrenergic receptors. Parker and coworkers[96] determined that intracerebroventricular administration of subsystemic doses of L-propranolol (but not D-propranolol) significantly reduced the incidence of ventricular fibrillation during combined left anterior descending coronary artery occlusion and behavioral stress in pigs. In a surprising turn, intravenous administration of even a relatively high dose of L-propranolol was ineffectual. The latter result may relate in part to a species dependence; unlike canines, pigs do not show a suppression of ischemia-induced arrhythmias in response to beta blockade.[97] It has been proposed that the centrally mediated protective effect of beta blockade results from a decrease in sympathetic nerve activity and in plasma norepinephrine concentration.[96,98,99] Of importance, whereas central actions of beta-adrenergic receptor blockers may play an important role in reducing susceptibility to ventricular fibrillation during acute myocardial ischemia, they are unlikely to constitute the sole mechanism because beta blockers prevent the profibrillatory effect of direct stimulation of peripheral sympathetic structures such as the stellate ganglia.[100] Of note, all three of the beta blockers that have long-term effects on mortality in cardiac patients (propranolol, metoprolol, and carvedilol) are lipophilic[101] and therefore cross the blood-brain barrier readily to affect sleep structure, with significant perturbations of sleep continuity.[102]

Autonomic Factors in Arrhythmogenesis during Sleep

NREM sleep generally is salutary with respect to ventricular arrhythmogenesis, as indicated both by extensive studies of neurocardiac interactions and by clinical experience. Activation of the vagus nerve reduces heart rate, increases cardiac electrical stability, and reduces rate-pressure product, an indicator of cardiac metabolic activity, to improve the supply-demand relationship in stenotic coronary artery segments. In the setting of severe coronary disease or acute myocardial infarction, however, hypotension during NREM can lead to myocardial ischemia as a consequence of inadequate coronary perfusion pressure, thereby provoking arrhythmias and myocardial infarction.[11,103] The abrupt increases in vagus nerve tone that can occur during periods of REM or sleep state transitions can result in significant pauses in heart rhythm, bradyarrhythmias, and, potentially, triggered activity, a mechanism of the lethal cardiac arrhythmia torsades de pointes. Patients with the long QT syndrome who have the type 3 phenotype are more prone to experience torsades de pointes at night rather than during stress or exercise.[64] Tonic control of the vagus nerves over the caliber of the epicardial coronary vessels[104] could be an important factor in dynamic regulation of coronary resistance as a function of the sleep-wake cycle. An important question is whether tonic vagus nerve activity exerts a protective or a deleterious influence on myocardial perfusion and arrhythmogenesis in persons with atherosclerotic disease. In these patients, nocturnal surges in vagus nerve activity could precipitate myocardial ischemia and arrhythmias as a result of coronary vasoconstriction rather than dilation in atherosclerotic segments, because of impaired release of endothelium-derived relaxing factor.[105]

Because of the attendant surges in sympathetic nerve activity and in heart rate, REM sleep has the potential to trigger ventricular arrhythmias.[106,107] The striking variability of heart rate and breathing pattern can exert a significant impact on cardiovascular functioning, as is evident in the development of ischemia and arrhythmias in patients whose myocardium is compromised. Indeed, the only clinical studies in which sleep staging has been employed have identified REM as the state in which arrhythmias occurred.[11,108,109] The increased sympathetic nerve activity that occurs at REM sleep onset[10] provides a potent stimulus for ventricular tachyarrhythmias because of the arrhythmogenic influence of neurally released catecholamines. Sympathetic nerve activation by stimulation of central[86-88,93,94] or peripheral adrenergic structures,[100,110] infusion of catecholamines,[111] or imposition of behavioral stress[112,113] can increase cardiac vulnerability in the normal and the ischemic heart. These profibrillatory influences are substantially blunted by beta-adrenergic receptor blockade.[112] A wide variety of supraventricular arrhythmias also can be induced by autonomic activation.[95]

Enhanced sympathetic nerve activity increases cardiac vulnerability in the normal and in the ischemic heart by complex mechanisms. The major indirect effects include an impaired oxygen supply-demand ratio resulting from increased cardiac metabolic activity and coronary vasoconstriction, particularly in vessels with injured endothelium and in the context of altered preload and afterload. The direct profibrillatory effects on cardiac electrophysiologic function are attributable to derangements in impulse formation or conduction, or both.[95] Increased levels of catecholamines activate beta-adrenergic receptors, which in turn alter adenylate cyclase activity and intracellular calcium flux. These actions probably are mediated by the cyclic nucleotide and protein kinase regulatory cascade, which can alter spatial heterogeneity of calcium transients and consequently increase dispersion of repolarization. The net influence is an increased susceptibility to ventricular fibrillation.[82,114] Conversely, reduction of cardiac sympathetic drive by stellectomy has proved to be antifibrillatory.

Notwithstanding the evidence that autonomic factors can significantly alter susceptibility to arrhythmias, the observation that the heart rate surges of REM sleep are conducive to myocardial ischemia, and the epidemiologic data in humans on the extent of sleep-induced cardiac events,[1] very little information is available on the effects of myocardial infarction on the cardiovascular system during sleep. Ventricular ectopic activity, but not ventricular fibrillation, emerges during NREM sleep in pigs after myocardial infarction.[115] This pattern may be attributable to slowing of heart rate and increased vagus nerve activity during NREM sleep, conditions that can inhibit the normal overdrive suppression of ventricular rhythms by sinoatrial node pacemaker activity and result in firing of latent ventricular pacemakers and triggered activity. Snisarenko[116] found significant elevations in heart rate in both the acute (4 to 10 days) and subacute (3 to 12 months) periods after myocardial infarction in a feline model. In the acute period, these effects were accompanied by increased wakefulness, decreased heart rate variability, and severely disordered sleep. In the intervening weeks, sleep quality recovered fully until, in the subacute period, beta blockade with propranolol led to renewed, pronounced disturbances in sleep structure, with increased wakefulness, reduction in REM sleep, and prolongation of stages N1 and N2 of NREM sleep. Snisarenko attributed these results to reflex activation of adrenergic, noradrenergic, and dopaminergic nerves in several brain structures after coronary artery ligation.[117]

CLINICAL PEARLS

- REM sleep is characterized by surges in sympathetic and vagus nerve activity, which are well tolerated in normal individuals but may result in cardiac arrhythmias, myocardial ischemia, and myocardial infarction in those with heart disease.
- During NREM sleep, systemic blood pressure may fall, potentially reducing flow through stenotic coronary vessels, which may precipitate myocardial ischemia or infarction.
- Sleep-disordered breathing induces significant injury in autonomic regulatory areas.
- In essence, sleep constitutes an autonomic stress test for the heart, and nighttime monitoring of cardiorespiratory function is of considerable diagnostic value.[104]

SUMMARY

Sleep states exert a major impact on cardiorespiratory function, as a direct consequence of the significant variations in brain states that occur in the normal cycling between NREM and REM sleep. Dynamic fluctuations in central nervous system variables influence heart rhythm, arterial blood pressure, coronary artery blood flow, and ventilation. Whereas REM sleep–induced surges in sympathetic and parasympathetic nerve activity, with accompanying significant surges and pauses in heart rhythm, are well tolerated in normal people, patients with heart disease may be at heightened risk for life-threatening arrhythmias and myocardial ischemia and infarction.[83,107] During NREM sleep, in the severely compromised heart, a potential for hypotension exists that can impair blood flow through stenotic coronary vessels to trigger myocardial ischemia or infarction.[11] Cumulative damage incurred as a consequence of sleep-disordered breathing, heart failure, or stroke to the central brain areas that regulate autonomic activity and coordinate upper airway and diaphragmatic action can lead to enhanced sympathetic outflow, increasing risk in heart failure and contributing to hypertension in obstructive sleep apnea. Coordination of cardiorespiratory control is especially pivotal in infancy, when developmental immaturity can compromise function and pose special risks. Throughout sleep, the coexistence of coronary disease and apnea is associated with heightened risk of cardiovascular events[113,118] resulting from the challenge of dual control of the respiratory and cardiovascular systems.

Cardiovascular Physiology: Autonomic Control in Health and in Sleep Disorders

Paola A. Lanfranchi; Jean-Louis Pépin; Virend K. Somers

Chapter Highlights

- Autonomic control of the circulation is pivotal in ensuring an adequate cardiac output to the vital organs through continuous and rapid adjustments of heart rate, arterial blood pressure, and redistribution of blood flow. In the longer term, neural circulatory control appears to be coupled with the circadian rhythm, the sleep-wake cycle, and ultradian rhythms, including rapid eye movement (REM) and non–REM (NREM) sleep processes.
- The cardiovascular autonomic nervous system's primary role is to ensure an adequate cardiac output to the vital organs through continuous and rapid adjustments of heart rate, arterial blood pressure, and redistribution of blood flow.
- Heart rate and blood pressure have a diurnal rhythm characterized by a significant reduction during nighttime hours. This physiologic pattern can be altered by sleep insufficiency and sleep disorders, with important implications for cardiovascular health.
- During NREM sleep, there is an increase in cardiovagal drive and a reduction in cardiac and peripheral sympathetic activity. Baroreflex gain is heightened in response to blood pressure increments rather than decrements during NREM sleep to ensure the maintenance of stable low blood pressure and heart rate during NREM sleep. By contrast, REM sleep is a state of autonomic instability, dominated by remarkable fluctuations between parasympathetic and sympathetic influences.
- Sleep loss, alterations in sleep quality, and sleep disorders are associated with persistence of high sympathetic activity during night and reduction in physiologic nocturnal blood pressure dipping. These effects lead to sustained sympathetic activation with increased blood pressure during the succeeding days.

OVERVIEW

Autonomic circulatory control operates via parasympathetic neurons to the heart and by sympathetic neuronal efferents to the heart, blood vessels, kidneys, and adrenal medulla. Parasympathetic stimulation of the heart, through the activation of cardiac muscarinic receptors, results in bradycardia, whereas sympathetic stimulation of the heart, through activation of $beta_1$-adrenergic receptors, results in tachycardia and increased contractility. Sympathetic activation in the vascular bed induces both vasoconstriction, by stimulating $alpha_1$ adrenoreceptors, and vasodilation, by stimulating $beta_2$ adrenoreceptors. Several reflexes, including the arterial baroreflex, cardiopulmonary reflexes, and chemoreflexes, also are important in the rapid adjustments of circulation that occur in association with postural changes, hypoxemia, temperature changes, and sleep. Heart rate (HR) and blood pressure (BP) have a diurnal rhythm characterized by a significant reduction during nighttime hours, secondary to changes in activity and posture, as well as sleep and circadian influences. This physiologic pattern can be altered by sleep insufficiency and sleep disorders, with important implications for cardiovascular health.

The cardiovascular autonomic nervous system seeks to maintain homeostasis through precise control of numerous hemodynamic variables, including HR, arterial BP, and peripheral blood flow, on a beat-by-beat basis. Neural circulatory control is intimately linked to sleep and circadian physiology, as demonstrated by the disrupted autonomic control that accompanies sleep disruption, for example, with sleep loss and sleep apnea. On the other hand, whether primary alterations in autonomic function may translate into sleep disturbances also needs to be considered.

This chapter begins with a general overview of autonomic cardiovascular regulation and of its central and peripheral controllers, followed by a description of the methods used to explore cardiovascular neural control during sleep in humans and a review of their advantages and limitations. Presented next is an outline of some of the current knowledge of neural circulatory control during normal sleep. Also included is a survey of changes that may occur as a consequence of sleep deprivation, alterations in sleep quality, sleep apnea, and autonomic dysfunction such as may occur in diabetes.

THE CARDIOVASCULAR AUTONOMIC NERVOUS SYSTEM: DEFINITION AND FUNCTIONS

The cardiovascular autonomic nervous system is a highly integrated network that controls visceral functions, which, on a

short timescale (seconds to hours), adjusts the circulation in keeping with behavior, the environment, and emotions. Its primary role is to ensure an adequate cardiac output to the vital organs through continuous and rapid adjustments of HR and arterial BP and redistribution of blood flow. In the longer term, this neural circulatory regulation appears to be coupled with the circadian rhythm, the sleep-wake cycle, and some ultradian rhythms, including rapid eye movement (REM) and non-REM (NREM) sleep processes, as well as hormones implicated in long-term BP regulation.

Neural control of the circulation operates via parasympathetic neurons to the heart and by sympathetic neuronal efferents to the heart, blood vessels, kidneys, and adrenal medulla. Parasympathetic stimulation of the cardiovascular system is mediated primarily by the vagus nerve through the activation of muscarinic receptors and results in bradycardia. Sympathetic stimulation of the heart acts through activation of $beta_1$ adrenoreceptors at the sinoatrial node (the cardiac pacemaker) and in the myocardium (the cardiac muscle) and results in tachycardia and increased contractility. Sympathetic activation in the vascular bed induces vasoconstriction by stimulating $alpha_1$ adrenoreceptors (in the skin and splanchnic regions) and vasodilation by stimulating $beta_2$ adrenoreceptors (in the heart and skeletal muscles). Parasympathetic and sympathetic efferent activity to the heart may also modulate cardiac electrophysiologic properties that can be relevant to the pathogenesis of several types of arrhythmias, particularly in the presence of a pro-arrhythmic substrate.

Central organization of the autonomic nervous system and its relationship with sleep-modulating mechanisms are detailed in Chapter 13. Briefly stated, autonomic impulses to the vasculature and heart originate from the vasomotor center in the brainstem, located bilaterally in the reticular substance of the medulla and pons. The vasomotor center is in turn modulated by higher nervous system regions in the pons, mesencephalon, and diencephalon, including the hypothalamus and many portions of the cerebral cortex. Several cardiovascular reflexes also are important in the rapid adjustments of blood pressure occurring in association with postural changes, hypoxemia, exercise, and moderate temperature changes and, in addition, may be implicated in cardiovascular changes observed during sleep. These mechanisms include the arterial baroreflex, cardiopulmonary reflexes, and chemoreflexes. The renin-angiotensin-aldosterone system, vasopressin, and other vasoactive mechanisms also may contribute to cardiovascular regulation during sleep.

Arterial Baroreflex

The arterial baroreflex is an important regulator of BP in the short term.[1] The baroreceptors are sensory receptors in the aortic arch and carotid sinuses that relay in the medullary regions of the brain. Changes in arterial baroreceptor afferent discharge trigger reflex adjustments that buffer or oppose the changes in BP. For instance, increments in BP stretch the receptors, resulting in heightened afferent traffic to the brainstem neuronal network. This increased trafficking inhibits efferent sympathetic outflow to cardiac and vascular smooth muscle and increases parasympathetic cardiac tone, resulting in slowing of HR, reduction in contractility, and reduced peripheral vasoconstriction, with subsequent compensatory decreases in BP. A decrease in BP has opposite effects: It elicits reflex tachycardia, increased contractility, and peripheral vasoconstriction, with subsequent compensatory increases in BP.

Cardiopulmonary Reflexes

Cardiopulmonary reflexes are triggered by the stimulation of low-pressure receptors located in the atria, ventricles, and pulmonary arteries. The cardiopulmonary receptors are volume receptors that serve to mitigate changes in BP in response to changes in blood volume. The firing pattern of these receptors parallels the pressure changes within the cardiac chambers or vessels and help to regulate blood volume. Cardiopulmonary reflex activation results in peripheral vasodilation, reduction in sympathetic outflow to the kidney, and activation of the posterior pituitary gland to inhibit the release of antidiuretic hormone, resulting in increased urine excretion.

Arterial and cardiopulmonary reflexes are implicated in blood pressure regulation during postural changes. Assumption of the upright position produces a caudal shift in blood volume and acutely reduces stroke volume and blood pressure. The circulatory adjustment to this orthostatic stress is rapid and is characterized by reflex increases in HR and peripheral vascular resistance, followed by enhanced secretion of antidiuretic hormone and activation of the renin-angiotensin system. Recumbency, as during sleep, leads to production of an increased volume load in the cardiac chambers and elicits the opposite effects.

The Chemoreflexes

The chemoreflexes mediate the ventilatory response to hypoxia and hypercapnia and also exert important cardiovascular effects.[2] The peripheral arterial chemoreceptors, the most important of which are located in the carotid bodies, respond primarily to changes in the partial pressure of oxygen. Hypoxemic stimulation elicits an increase in respiratory muscle output, inducing hyperventilation, and an increase in sympathetic outflow to peripheral blood vessels, resulting in vasoconstriction. Hyperventilation in turn activates pulmonary stretch receptors, which buffer the increases in sympathetic and vagal outflow, thereby maintaining homeostasis under normal conditions. During apnea, when hyperventilation is absent or prevented, vasoconstriction is potentiated and occurs simultaneously with activation of cardiac vagal drive resulting in bradycardia, collectively termed the "diving reflex," a protective mechanism that helps preserve blood flow to the heart and brain while limiting cardiac oxygen demand.[3,4]

The central chemoreceptors are located in the brainstem and respond to changes in pH mediated primarily by carbon dioxide tension. Stimulation of central chemoreceptors by hypercapnia also elicits sympathetic and respiratory activation, but without the cardiovagal effects seen with hypoxemia.[2]

MEASURES TO EXPLORE AUTONOMIC CHANGES DURING SLEEP AND THEIR PHYSIOLOGIC SIGNIFICANCE

Heart Rate and Arterial Blood Pressure and Their Variability

The RR interval, the time elapsed between two successive R waves of the QRS signal on the electrocardiogram (and its reciprocal, the HR), is a function of intrinsic properties of the sinus node as well as autonomic influences. BP is a function of vascular resistance (an expression of arterial constriction or

dilation) and cardiac output (the blood volume being pumped by the heart in 1 minute), which is a function of HR, cardiac contractility, and diastolic blood volume, all components controlled in part by the autonomic nervous system.

Autonomic cardiovascular regulation can be investigated through the quantification of average HR and BP as assessed in steady state conditions (wakefulness and sleep, for instance) or in their responses to endogenous or exogenous challenges (e.g., changes in posture, response to respiratory changes, and arousal from sleep).

Both HR and BP exhibit spontaneous fluctuations that can be described by the standard deviation around the mean, or by their rhythmic and nonrhythmic characteristics. When described by the standard deviation over 24-hour ambulatory recordings, high variability of the RR interval is a recognized index of the ability of the cardiovascular system to cope with environmental challenges.[5] By contrast, heightened BP variability is found to accompany aging and hypertension.[6] Among the various cyclic components that characterize 24-hour HR and BP variability, those occurring from daytime wakefulness to nighttime sleep have received great attention. Specifically, HR and BP physiologically decrease during night hours.[7] This diurnal pattern is evident in ambulatory subjects, and even in recumbent subjects maintaining the sleep-wake cycle.[8] The contribution of circadian versus noncircadian factors and how these may be modified in sleep disorders are discussed later in the chapter.

RR and BP also exhibit short-term oscillations, in a frequency range between 0 and 0.5 Hz, which appear to be under the influence of intrinsic autonomic rhythms and of respiratory inputs. Spectral analysis of RR and BP variability provides an estimate regarding how power (i.e., variance) of the signal is distributed as a function of frequency. Indeed, RR and BP variability appear to be organized in three major components: the high-frequency (HF) (>0.15 Hz) respiratory band, the low-frequency band (LF) (around 0.1 Hz), and the very-low-frequency (VLF) band (0.003 to 0.039 Hz) (Figure 14-1 and Table 14-1).[9] The HF components of RR variability primarily reflect the respiration-driven modulation of sinus rhythm, evident as sinus arrhythmia, and have been used as an index of tonic vagal drive. Nonneural mechanical mechanisms, linked to respiratory fluctuations in cardiac transmural pressure, atrial stretch, and venous return, also are determinants of HF power and may become especially important after cardiac denervation such as with heart transplantation.[10] The LF rhythm, which appears to have a widespread neural genesis,[11] reflects in part the sympathetic modulation of the heart,[12] as well as the baroreflex responsiveness to the beat-to-beat variations in arterial BP,[13] but also can be modulated by LF or irregular breathing patterns. Of importance, LF components in respiration confound the interpretation of the LF component of cardiovascular variability in attempts to identify the autonomic characteristics of cardiovascular control. Therefore, in any assessment of the relative contributions of the LF and HF components to any particular physiologic state or disease condition, it is crucial to ensure that the respiratory pattern is limited to the HF component. The LF/HF ratio is used to provide an index of the balance of the

sympathovagal influence on the sinus node,[14] provided that measurements are obtained in strictly controlled conditions. Finally, the VLF component has been hypothesized to reflect thermoregulation and the renin-angiotensin system.[15] Regarding BP variability, LF components in systolic BP variability are considered an index of efferent sympathetic vascular modulation, whereas the HF components reflect mechanical effects of respiration on blood pressure changes.[12] Measurements of HF, LF, and VLF usually are made in absolute (millisecond) values, but LF and HF often are presented in normalized units (nu), which represent the relative value of each power component in proportion to the total power minus the VLF components (see Table 14-1). Normalization allows minimizing the effect of changes in total power on LF and HF components.

Traditional spectral analysis techniques include fast Fourier transform algorithms and autoregressive modeling, which in most instances provide comparable results.[16] These techniques require stationarity of the signal being processed and therefore cannot be applied to processes embodying significant transient activity (e.g., sleep onset, arousals, sleep stage transition and awakening). In addition, such methods have to be used with caution in association with respiratory or motor events (e.g., periodic limb movements, bruxism). More advanced algorithms of signal processing can be used to overcome this limitation and permit the assessment of dynamic changes in autonomic cardiovascular control during transient events (e.g., sleep onset, arousal, bruxism)[17] and help define the temporal relationship between dynamic changes occurring in different systems, such as between the electroencephalogram (EEG) and the electrocardiogram (ECG).[18,19] The most commonly used algorithms include short time Fourier transform, Wigner-Ville distribution, time variant autoregressive models, wavelets, and wavelet-packets.[17]

Finally, in addition to the periodic oscillatory behavior observed in RR interval and arterial blood pressure, a less specific variability occurs with nonperiodic behavior, which can be described by methods based on nonlinear system theory ("chaos theory and fractal analysis").[20] The physiologic basis for this nonharmonic beat-to-beat behavior, which extends over a wide time range (seconds to hours), is still unsettled, although some investigators have proposed that it is under higher central modulation.[21] The application of this type of analysis to sleep cardiovascular physiology is still limited.

Baroreflex Sensitivity

The arterial baroreflex is important in buffering short term changes in BP. The gain of the arterial baroreflex, or baroreflex sensitivity, is measured by the degree of change in heart rate or sympathetic traffic for a given unit change in blood pressure.[22] Two techniques have been mainly used in sleep research to assess spontaneous baroreflex modulation of heart rate: the sequence technique and the spectral analysis technique. The first technique identifies sequences of consecutive beats in which progressive increases in systolic BP are followed by a progressive lengthening in RR (or vice versa). The slope of the regression line between RR intervals and systolic BP within these sequences is taken as the magnitude of the reflex gain. The second technique is based on cross-spectral analysis of short segments of systolic BP and RR and relies on the assumption that a certain frequency band of RR variability, between 0.04 and 0.35 Hz, is modulated by the baroreflex. Baroreflex sensitivity is expressed by the gain of the transfer function relating changes in blood pressure to coherent changes in RR or muscle sympathetic nerve activity (MSNA).

Preejection Period

The *preejection period* (PEP) is the time elapsed between the electrical depolarization of the left ventricle (QRS on the ECG) and the beginning of ventricular ejection and represents the period of left ventricular contraction with the cardiac valves closed. PEP is influenced by sympathetic activity by way of $beta_1$ adrenoreceptors and shortens under stimulation. PEP can be derived noninvasively from impedance cardiography, which converts changes in thoracic impedance (as measured by electrodes on the chest and neck) to changes in volume over time and allows tracking of volumetric changes such as those occurring during the cardiac cycle. This method has been applied, although not intensively, to assess cardiac sympathetic influences in steady state conditions during sleep.[23,24] The application to transient sympathetic responses is unfortunately limited, because errors can occur in interpretation in the presence of blood pressure increases, which can

induce a lengthening of PEP (instead of the expected shortening) owing to the longer time required to overcome the external pressure.

Microneurographic Recording of Sympathetic Nerve Activity

Microneurography provides direct information on sympathetic vasomotor and sudomotor activity to muscle and skin. MSNA, usually measured at the peroneal nerve, induces vasoconstriction and is modulated by the baroreflex.[25] MSNA also increases in response to hypoxic and hypercapnic chemoreceptor stimulation.[1] Skin sympathetic nerve activity reflects thermoregulatory output related to sudomotor and vasomotor activity and is affected by emotional stimuli but not by the baroreflex.

Although microneurography provides a direct measure of peripheral sympathetic drive, it is invasive and technically demanding for both operator and patient. In addition, the information provided is limited to regional sympathetic neural activity. In view of the heterogeneity of system-specific innervations, MSNA and skin sympathetic nerve activity assessments may not necessarily reflect global sympathetic tone.

Peripheral Arterial Tone and Pulse Transit Time

Peripheral arterial tone (PAT), as measured from the finger, provides an indirect index of sympathetic vasoconstrictory mechanisms directed to the peripheral vascular bed. It is based on measurement of the pulsatile volume changes in the vascular bed at the fingertip, which decreases secondary to sympathetically mediated alpha-adrenergic vasoconstriction. Accordingly, PAT amplitude declined less in patients with sleep apnea at end-apnea and arousal after administration of the alpha-adrenergic blocker phentolamine.[26] PAT does not provide absolute values. Only within-subject changes in pulse wave analysis during a limited time interval can be evaluated, but these may be sufficient to assess PAT attenuation related with respiratory events and microarousals.[27] PAT is noninvasive, can be monitored continuously during sleep, has been proposed as a measure of the autonomic changes occurring with arousal in adults and children[28-30] and, in combination with actigraphy and oxymetry, has been used in the diagnosis of sleep apnea. REM sleep is associated with increased and hugely variable sympathetic tone. High sympathetic tone corresponds on the PAT signal to a sustained attenuation that has been reported to help identify REM sleep.[31] Moreover, episodic vasoconstriction associated with the occurrence of rapid eye movements is superimposed on this attenuation. Differences in amplitude of the PAT signal and its variability during REM sleep versus NREM sleep have been reported, and an automatic REM scoring algorithm has been developed and validated for such scoring purpose.[32]

Pulse transit time (PTT) refers to the time required for a pulse wave to travel between two arterial sites.[33] In practice, in a noninvasive estimate of PTT, the R wave in the ECG generally is used to indicate the starting point of the measure, and the peripheral waveform (assessed by photoplethysmography at the finger) to indicate the end of the measure. PTT is sensitive to moment-to-moment sympathetic neural activity and shortens when BP increases and lengthens when BP falls. Of note, PTT encompasses several physiologic components difficult to control for, and intersubject comparison is not recommended. Only intraindividual relative PTT changes from a baseline condition (over several readings) are instead recommended for clinical consideration. Like PAT, PTT also can be monitored continuously and has been used in the assessment of sympathetic responses to arousals[29,34] and respiratory events, especially in children.[35,36] During REM sleep, variations in sympathetic activity are spontaneously very high, so the PTT baseline is highly variable. Thus the recognition of true micro arousals during REM sleep is less specific than in other sleep stages. The heart and large vessels are located in the thoracic cavity and consequently are affected by variations in thoracic volume and pressure. During inspiration, the volume of the thoracic cavity increases, reducing intrathoracic pressure, which in turn reduces the compression of the heart and large vessels (vena cava and aorta), decreasing BP and slowing PTT. The opposite is true for expiration: As the intrathoracic pressure increases, the heart is compressed, and BP increases and PTT quickens. PTT may serve as a noninvasive marker of respiratory effort, especially for defining certain respiratory events (hypopneas, respiratory effort–related arousals [RERAs], and central events).[37,38]

Systemic Catecholamines

Measurement of plasma catecholamines—epinephrine and norepinephrine—provides an estimate of global sympathetic activity. However, blood norepinephrine reflects only a small percentage (8% to 10%) of neurotransmitter release during sympathetic activation. Moreover, the relatively rapid clearance of catecholamines from the bloodstream may limit the ability to detect transient changes in sympathetic activity. Consequently, only frequent sampling through sleep may detect changes related to the sleep-wake cycle and sleep stages.[39] Measurement of urinary excretion of catecholamines and their metabolites is a simpler approach to provide an estimate of the cumulative catecholamine secretion over time and has been used widely in the clinical and sleep research settings. Urinary catecholamine excretion is strictly dependent on renal function. Accordingly, a correction of excreted catecholamine for indices of renal function (urinary creatinine) is recommended.

SLEEP-RELATED CARDIOVASCULAR AUTONOMIC CHANGES

Day-Night Changes in Neural Circulatory Control

HR and BP physiologically decrease during nighttime as compared with daytime in ambulant subjects, as well as in subjects kept in the supine position for 24 hours.[8] Specifically, the normal 24-hour BP pattern consists of a 10% or greater systolic blood pressure reduction during sleep compared with daytime, a reduction that is commonly referred to as "dipping." Posture and activity strongly influence HR and BP during the day,[40] whereas posture and sleep affect HR and BP at night.[8] However, the nocturnal sleep-related cardiovascular dipping is evident even in subjects who maintain the supine position for 24 hours,[8] underscoring the importance of sleep in inducing decreases in nighttime HR and BP. Studies investigating the autonomic changes associated with the wake-sleep cycle noted that indices of parasympathetic function, such as RR interval and HF components of RR variability, begin to change as early as 2 hours before sleep onset,[23] whereas indices of cardiac and peripheral sympathetic activity such as LF/HF ratio, preejection period, MSNA, and catecholamines

start to decrease only after sleep onset and continue to decrease with the deepening of sleep.[23,25,39] Morning awakening induces a stepwise activation of the sympathoadrenal system, with increased HR, BP, and plasma catecholamines, with further increases occurring with postural change and physical activity.[23,41]

Studies conducting 24 hours of sleep deprivation with the subjects supine showed that the nocturnal fall in HR and cardiovagal indices is still present, whereas the fall in nocturnal BP and PEP prolongation (i.e., decreased sympathetic activity) are blunted.[23,42] It may be, therefore, that HR and parasympathetic mechanisms are largely under circadian influences and might be implicated in mechanisms preparatory to sleep, whereas sympathetic drive to the heart and vessels is mainly linked to the wake-sleep cycle. Increasing evidence suggests that the mean nocturnal BP level is a major predictor of *cardiovascular* morbidity and mortality irrespective of the 24-hour BP levels.[43] Any deterioration in sleep quality or quantity may be associated with an increase in nocturnal BP that could participate in the development or poor control of hypertension.[44]

Physiologic Responses to NREM and REM Sleep

In healthy subjects, autonomic cardiovascular regulation varies considerably with sleep stage, and different autonomic patterns dominate in NREM versus REM sleep. As NREM sleep progresses from stages N1 to N3 (Stages 3 and 4 on Figure 14-2), the RR, respiratory-mediated HF components of RR variability and PEP increase, whereas BP, LF components in systolic BP variability, and MSNA significantly decrease, compared with wakefulness. These changes suggest an increase in cardiovagal drive and a reduction in cardiac and peripheral sympathetic activity[8,25,45] (Figure 14-2). Baroreflex sensitivity appears also to be increased during NREM sleep

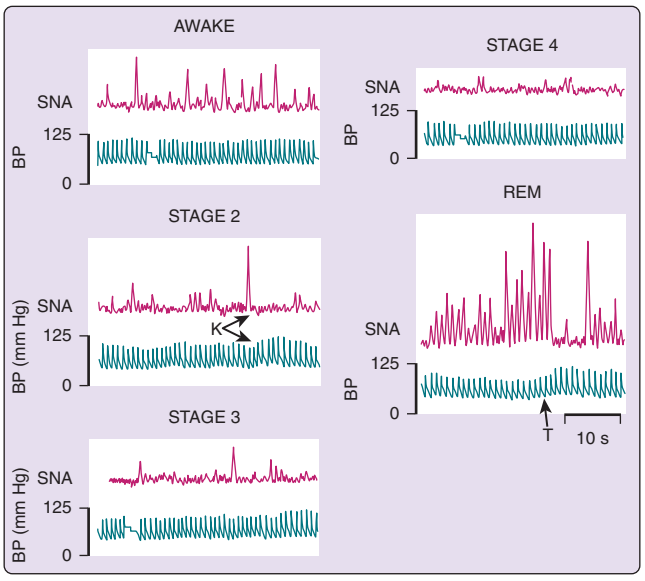

Figure 14-2 Recordings of sympathetic nerve activity (SNA) and mean blood pressure (BP) in a single subject while awake and while in stages 2, 3, and 4 and REM sleep. SNA and BP gradually decrease with the deepening of NREM sleep. Heart rate, BP, and BP variability increase during REM sleep, together with a profound increase in the frequency and amplitude in SNA. over that in wakefulness.[46] However, the response is variable. Namely, compared with that in wakefulness, baroreflex gain is heightened in response to BP increments rather than decrements during NREM sleep. This mechanism probably serves to ensure the maintenance of stable low BP and HR during NREM sleep.

By contrast, REM sleep is a state of autonomic instability, dominated by remarkable fluctuations between parasympathetic and sympathetic influences, which produce sudden and abrupt changes in HR and BP.[47] The average HR and BP are higher during REM than in NREM sleep, as is sympathetic neural vasomotor drive.[25] The cardiovascular excitation of REM sleep also is reflected by a significant increase in the low frequency (LF) components (approximately 0.1 Hz) and a shift of the LF/HF ratio toward sympathetic predominance.[8]

RR Interval Variability and Electroencephalographic Coupling

Studies assessing the overnight relationship between RR variability and electroencephalogrphy (EEG) profiles showed that the dynamic of RR interval variability is closely related to the dynamic of EEG, reflecting the depth of sleep. The presence of an ultradian 80- to 120-minute rhythm in the normalized LF, with high levels during rapid eye movement (REM) sleep and low levels during slow wave sleep, has been described.[48] These oscillations were strikingly coupled in a "mirror image" to the overnight oscillations in delta wave activity, which reflect sleep deepening and lightening. Similarly, it was reported that normalized HF components of RR variability were coherent with all EEG spectral bands, with a maximum gain (the ratio of HF amplitude to EEG amplitude was higher) for delta activity and minimum gain (i.e., HF was lower) with beta activity.[49] The two oscillations were coupled with a phase shift of several minutes, with cardiac changes preceding the EEG changes. Although the mechanisms underlying this coupling are not known, it has been hypothesized that a central generator may act to synchronize the oscillatory process in autonomic and sleep modulation, whereby cardiovascular function may anticipate sleep stage changes.[48]

Autonomic Responses Associated with Arousal from Sleep and with Periodic Leg Movements

Arousals

Electrocortical arousal from sleep (i.e., EEG desynchronization with appearance of a low-voltage, high-frequency EEG pattern), either spontaneous or provoked by an exogenous stimuli, or in the context of sleep-disordered breathing, is associated with sympathetic neural surges, leading to transient increases in HR, BP, and MSNA,[50-52] abrupt PTT dips, and PAT attenuations. The typical cardiac response is biphasic, with tachycardia lasting 4 to 5 seconds followed by bradycardia, with HR increasing before cortical arousals. Using time variant analysis, it appears that the surge in sympathoexcitation as represented by LF components of RR variability and BP variability remains substantially elevated above baseline long after the HR, BP, and MSNA return to baseline values.[18] This finding can be particularly relevant in conditions characterized by frequent arousals across the night, conceivably leading to a sustained sympathetic influence on the cardiovascular system. In sleep apnea, an association between repetitive attenuations in peripheral arterial tonometry (PAT) during

sleep and office blood pressure has been reported independently of age, sex, and body mass index.[53] These results suggest that nocturnal sympathetic activity may represent a direct stimulus to chronically elevated blood pressure in humans, even in the daytime.

Auditory stimuli during sleep may result in autonomic and respiratory modifications even in the absence of overt EEG activation (the so-called *autonomic arousal*), or in association with an EEG pattern different from that for conventional arousal, such as K-complexes or bursts of delta waves not followed by EEG desynchronization (the *subcortical arousal*).[51,52] These observations point to a range of partial arousal responses implicating autonomic responses with EEG manifestations different from classical arousals and even without any EEG response. The different EEG patterns and the associated cardiac responses indicate a hierarchical spectrum of increasing strength from the weaker high-amplitude delta burst to a stronger low-voltage alpha rhythm[52] (Figure 14-3).

Periodic Leg Movements during Sleep

Periodic leg movements (PLMs) are described as a repetitive rhythmic extension of the big toe and dorsiflexion of the ankle, with occasional flexion at the knee and hip. PLM can occur during wakefulness as well as during sleep (PLMS). PLMSs occur frequently in several sleep disorders (such as restless legs syndrome, narcolepsy, REM sleep behavior disorder, and sleep apnea) and in patients with congestive heart failure[54] but also are seen in healthy, asymptomatic subjects, especially with advancing age.[55] In the context of sleep apnea, PLMSs may coexist with (and often are difficult to distinguish from) respiratory response–related leg movements, which are part of the arousal response at the end of airway obstruction (in obstructive sleep apnea [OSA]) or at the peak of ventilation (in central sleep apnea). Approximately 30% of PLMSs are associated with cortical arousal, whereas more than 60% are associated with K-complexes or bursts of delta waves.[56] What causes PLMS is still unknown. However, studies of cardiovascular changes associated with PLMSs and their temporal relationship with EEG events are providing new insights into the physiologic mechanisms of PLMS. A stereotypical autonomic response accompanies PLMS, consisting of a rapid rise in HR and arterial BP[56,57] followed by a significant and rapid bradycardia and a return of BP to baseline values (Figure 14-4). Such cardiovascular changes are present whether or not the PLMSs are associated with arousals. The magnitude of the cardiovascular response is greater, however, when PLMSs are associated with cortical arousals. In addition, the amplitude of cardiovascular responses of PLMS is greater during sleep than that associated with spontaneous or simulated PLMSs during wakefulness. These observations suggest that the intensity of cardiovascular responses observed with PLMS is related to the degree of central brain activation (brainstem to cortical activation) that accompanies PLMS and much less to the somatomotor response (i.e., not a classical sensory motor reflex).

Studies assessing the temporal relationship between the leg motor event and autonomic and cortical activation consistently reported that changes in HR and EEG activity precede by several seconds the leg movement.[56,58] Specifically, HR and EEG delta waves rise first, followed by motor activity, and eventually progressive activation of faster EEG frequencies (i.e., in the alpha, beta, and sigma frequencies). A study assessing the dynamic time course of RR variability changes and EEG changes in association with PLMS confirmed the LF components of RR variability to be the first physiologic change to occur, followed by EEG changes in delta frequencies, and thereafter the leg movement with or without faster EEG frequencies.[19] These data corroborate an original hypothesis suggesting the presence of an integrative hierarchy of the arousal response primarily involving the autonomic responses with sympathoexcitation, then progressing towards EEG synchronization (represented by bursts of delta waves) and finally EEG desynchronization (arousal) and eventually awakening.[56] In this view, leg movements are part of the same periodic activation process that is responsible for cardiovascular and EEG changes during sleep.[58]

The clinical significance of PLMS has been a subject of debate. Recent findings linked the presence of PLMS to poorer cardiovascular health and outcome. Enhanced central sympathetic outflow or the cardiovascular consequences of repetitive BP surges during sleep could be implicated in this association. Restless legs syndrome is characterized by dysesthesia and leg restlessness occurring predominantly at night during periods of immobility. This syndrome is associated in 80% of the cases with PLMS. A systematic review addressing the association between RLS and hypertension identified 17 mainly cross-sectional studies from 12 countries.[59] Only 10 of the 17 studies supported a positive association between restless legs syndrome and hypertension; this association persisted after adjustment for body mass index, smoking, and sleep problems. These inconsistent findings regarding the association between restless legs syndrome, PLMS, and cardiovascular health may be explained by variations in studied populations, presence of confounding factor, and differences in ascertainment of hypertension and restless legs syndrome. Collectively, these studies indicate that restless legs syndrome might be positively related to hypertension when syndrome-related symptom frequency is high, exceeding 15 days per month, and PLMS index is in the severe range.[60]

IMPACT OF AGING ON NEURAL CIRCULATORY RESPONSE TO NORMAL SLEEP

Aging leads to profound morphologic and functional alterations in the cardiovascular system and its autonomic control.[61] Among these changes, basal central sympathetic drive appears

enhanced (increase in resting plasma catecholamines, MSNA, and LF components of RR variability) but the HR responsiveness to sympathetic stimuli is attenuated, at least in part because of a loss of cardiac receptor sensitivity to catecholamines. The increased central sympathetic drive in older persons is reflected during sleep by a reduction of RR variability and relatively lower parasympathetic influences, which appear to be linked to the loss of slow wave sleep.[62]

The cardiac response to EEG arousals and PLMS also is modified by age. Specifically, the HR increments are attenuated and bradycardia is less profound in older than in younger subjects.[63,64] The attenuated tachycardia can be part of the general age-related attenuation in the cardiac response to sympathetic stimuli, whereas impairment in baroreflex mechanisms, encountered in older persons, could be a factor implicated in the blunted bradycardia.

EFFECTS OF DISORDERED SLEEP AND PRIMARY AUTONOMIC DYSFUNCTION ON DAY-NIGHT AUTONOMIC CHANGES

Effects of Sleep Loss and Sleep Disorders on Nighttime Blood Pressure

As mentioned previously, HR and BP physiologically decrease during nighttime as compared with daytime, a reduction commonly referred to as "dipping." The persistence of high nighttime systolic BP and lack of systolic BP dipping are clinically important and have been linked to precursors of atherosclerosis, including inflammation and endothelial dysfunction.[65] Lack of systolic dipping[66] and, more recently, also lack of HR dipping[67] have been associated with increased cardiovascular mortality, after correction for several confounding variables, including daytime values. Sleep loss and sleep disturbances have been invoked as some of the potential factors underlying these abnormalities.[44] Controlled studies show that during partial sleep deprivation/restriction (allowing 4 hours of sleep), nighttime BP and catecholamine levels remain high, while nighttime nocturnal wakefulness is maintained, and then decrease normally in association with subsequent sleep.[68,69] In the same studies, the morning surge in BP and catecholamines appear to be more pronounced after sleep deprivation than in control conditions, particularly in hypertensive subjects.[68,69] A study in male workers showed that relative to a normal working day allowing 8 hours of sleep, working overtime and sleeping 4 hours induced higher daytime BP on the following day, accompanied by higher LF components of heart rate variability and increased urinary excretion of norepinephrine.[70] Hence it appears that sleep loss (1) is associated with persistence of high sympathetic activity and attenuates physiologic nocturnal BP dipping, as long as nocturnal wakefulness is maintained; (2) may enhance sympathetic activation during morning awakening; and (3) induces sustained sympathetic activation, with increased BP during the following day.

In different cohorts of normotensive and hypertensive subjects without sleep disorders, absence of BP dipping was associated with indices of poor and fragmented sleep, including longer wake-time after sleep onset and higher arousal frequency.[71,72] Increased nighttime BP has been reported in subjects with moderate to severe OSA,[73] the degree of BP alteration being proportional to the severity of sleep apnea.

Insomnia

Insomnia is characterized by subjective dissatisfaction with the quality of sleep and daytime consequences that may or may not be explained by a true reduction in sleep duration. Recent studies have used polysomnography to show that insomnia with objective short sleep duration is associated with a significant risk of hypertension. First, a study using 24-hour beat-to-beat blood pressure recordings concurrently with polysomnography reported that normotensive subjects with chronic insomnia had higher nighttime systolic BP and blunted day-to-night systolic BP dipping compared with aged-matched good sleepers.[74] Vgontzas and colleagues[75] have demonstrated an association of insomnia with prevalent hypertension only in the presence of objectively measured short sleep duration. The prevalence of hypertension increased 3.5-fold when sleep duration was between 5 and 6 hours and 5.1-fold when sleep duration was less than 5 hours per night. Accordingly, chronic insomnia with short sleep duration (less than 6 hours of sleep during polysomnography) was associated with an increased risk for incident hypertension (odds ratio, 3.8) in a general population sample of 786 adults within the Penn State Cohort without hypertension at baseline, assessed over a mean follow-up period of 7.5 years.[76]

Narcolepsy-Cataplexy

In narcolepsy-cataplexy (NC), the sleep-wake cycle is disrupted by the frequent occurrence of REM sleep onset episodes during daytime and by numerous awakenings during nocturnal sleep. The disease is characterized by a marked decrease in the number of hypocretin neurons, which are known to play a role in central autonomic and cardiovascular regulation.[77,78] Only a few cardiovascular studies have investigated human narcolepsy, even though NC is classically associated with obesity, type 2 diabetes, and metabolic syndrome—comorbid conditions leading to an increased cardiovascular risk. Recently, a study compared the 24-hour ambulatory BP monitoring pattern for drug-free patients with narcolepsy against that for control subjects.[79] A "nondipping status" was found in one third of patients with NC, versus in only 4.8% of control subjects. Nondipping of diastolic BP was strongly associated with NC by an odds ratio up to 12-fold, with a significant association with the percentage of REM sleep even after adjustment for confounding factors. Grimaldi and coworkers[80] have nicely demonstrated that systolic BP during nighttime REM sleep was increased in narcolepsy. NC is therefore a unique example of increased nocturnal BP mainly during REM sleep. However, in view of the fact that patients with NC will be treated with psychostimulants for the rest of their lives, a therapy that has direct impact on both the autonomic and cardiovascular systems, preliminary studies demonstrating the effects of NC on the dipping pattern of BP might have important clinical implications. Thus further studies addressing longitudinal associations between NC and hypertension as well as further mechanistic studies are clearly warranted.

Loss of Diurnal Variation in Autonomic Function in Diabetes Mellitus: What Comes First?

Cardiovascular autonomic neuropathy is a serious complication of diabetes mellitus and results from damage to autonomic fibers involved in HR and BP control, in the presence

of impaired glucose metabolism.[81] In patients with insulin-independent diabetes (type 2 diabetes), the 24-hour periodicity of HR and RR variability is lost, with attenuated sympathetic control in the daytime and blunted parasympathetic function during the night.[82] In patients with different degrees of glucose abnormalities without overt diabetes, RR variability and its spectral components appear similar to those in control subjects in the daytime but are significantly altered during sleep, with strikingly higher normalized LF and lower HF, proportional to the degree of insulin resistance.[83] Insulin resistance, characterized by a reduced biologic effect of insulin, and sympathetic overactivity are known to be linked and possibly potentiate each other, with insulin increasing sympathetic activity and neuroadrenergic mechanisms acting to increase plasma glucose availability and to reduce peripheral insulin sensitivity. These findings suggest that a primary alteration in the autonomic nervous system may occur during sleep in these subjects before overt diabetes is evident, and may be linked to the level of insulin resistance. However, one study also observed that selectively altered nighttime autonomic function also was present in nondiabetic offspring of patients with type 2 diabetes, whether or not they had insulin resistance,[84] suggesting that nighttime impaired parasympathetic mechanisms, possibly of genetic origin, may precede metabolic abnormalities.

Type 2 diabetes is a complex disease that derives from the interaction of environmental factors on a background of a genetic susceptibility. Chronic sleep debt, either due to sleep restriction or sleep apnea, has been shown to be one factor that can alter glucose handling[85] and increases the likelihood of developing type 2 diabetes.[86] Little is known about the relationship and interactions between these sleep disturbances and early autonomic dysfunction in subjects with differing severities of glucose abnormalities and their healthy offspring. Patients with type 1 diabetes who demonstrated a nondipping pattern of their nighttime blood pressure had shorter sleep duration than those who exhibited a physiologic nocturnal dip of blood pressure.[87,88] More information on insulin and sleep is found in Chapter 20.

SYMPATHETIC ACTIVATION IN OBSTRUCTIVE SLEEP APNEA

The sympathetic nervous system appears to play a key role in the cardiac pathophysiology of sleep apnea. Even when patients with OSA are awake and breathing normally, and in the absence of any overt cardiovascular disease such as hypertension or heart failure, they exhibit evidence for impaired sympathetic cardiovascular regulation. Specifically, they have high levels of muscle sympathetic nerve activity, increased catecholamines, faster heart rates, and attenuated heart rate variability.[89] Furthermore, even though they are normotensive, they show excessive blood pressure variability.[90] In the setting of apnea, the inhibitory effect of the thoracic afferents is absent, resulting in further potentiation of sympathetic activation. The consequent vasoconstriction results in marked surges in blood pressure, as noted earlier. Sympathetic activity abruptly ceases at onset of breathing owing to the inhibitory effect of the thoracic afferents[91] (Figure 14-5). In a minority of patients with OSA, the diving reflex, described earlier, is activated. These patients may therefore develop marked bradyarrhythmias in association with the obstructive apnea, even though they do not have any intrinsic conduction system abnormality.[4] The bradycardia is secondary to cardiac vagal

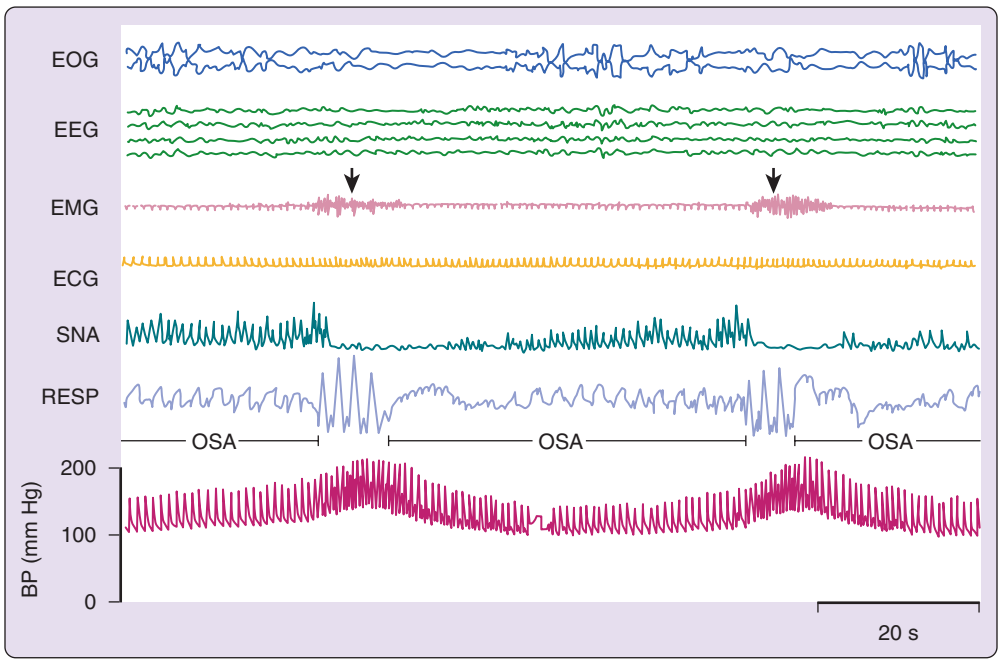

Figure 14-5 Sympathetic nerve activity (SNA) and blood pressure (BP) recordings in association with obstructive sleep apnea (OSA). SNA increases progressively during the apneic episode because of the activation of the peripheral and central chemoreflexes by hypoxemia and hypercapnia. The consequent vasoconstriction results in marked surges in BP, which reaches a peak during the hyperventilation. SNA abruptly ceases at onset of breathing owing to the inhibitory effect of the thoracic afferents. RESP, Respiration. (From Somers VK, Dyken ME, Clary MP, Abboud FM. Sympathetic neural mechanisms in obstructive sleep apnea. *J Clin Invest* 1995;96:1897–904.)

activation owing to the combination of hypoxia and apnea. These acute responses to obstructive apnea may predispose affected persons to longer-term abnormalities in cardiac and vascular structure and function. Several mechanisms have been proposed that could link OSA to cardiovascular diseases through the recurrent nocturnal cycles of hypoxia/reoxygenation. Such changes promote oxidative stress and low-grade inflammation, which are the initiators of a pathophysiologic cascade leading first to sympathetic overactivity. The high vascular sympathetic tone exhibited by patients with OSA results in elevated systemic resistance and hence elevated blood pressure. Impaired arterial vasodilatory capacity may contribute to elevation of blood pressure and lead to vascular disease. Animal models of chronic intermittent hypoxia (CIH) alone or in association with the other stimuli that characterize OSA (i.e., respiratory effort, asphyxia, and arousal from sleep) show elevated blood pressure during the non-CIH portion of the day. These findings suggest that the blood pressure elevation results initially from sympathetic activation. This mechanism requires an intact chemoreflex loop; it also has been demonstrated that in OSA, arterial baroreflex gain is decreased. Although animal models have advanced the current understanding, specific aspects of human physiology may not be adequately represented in such experiments. Accordingly, models of intermittent hypoxia in healthy humans have been developed that induce unstable ventilation and sleep fragmentation similar to those observed in patients with OSA. Healthy humans exposed to 1 or 2 weeks of CIH exhibit an increase in both hypoxic and hypercapnic ventilatory responses, confirming that augmentation of carotid chemoreflex function participates in inducing sustained sympathetic overactivity. After 2 weeks of CIH exposure, MSNA is increased and baroreflex control of sympathetic outflow declines. Consequently, CIH significantly increased daytime ambulatory blood pressure after 2 weeks of exposure (8 mm Hg systolic and 5 mm Hg diastolic)[92] (Figure 14-6).

CLINICAL PEARL

The autonomic nervous system is the mediator of central-cardiovascular interactions occurring during sleep, and its normal function appears to be important in preserving health. Despite the recognized methodologic limitations (the procedure involved is technically demanding, and only cautious interpretation of outcomes of interest, as described in Table 14-1, is possible), broadening sleep polygraphic monitoring to include heart rate and blood pressure recordings may contribute to a better understanding of the physiology and pathology of sleep-related cardiovascular autonomic modulation. This strategy may provide an avenue for innovation in the management of many medical conditions or disorders that are sleep-related (e.g., hypertension, diabetes, metabolic syndrome, periodic limb movements, sleep-disordered breathing).

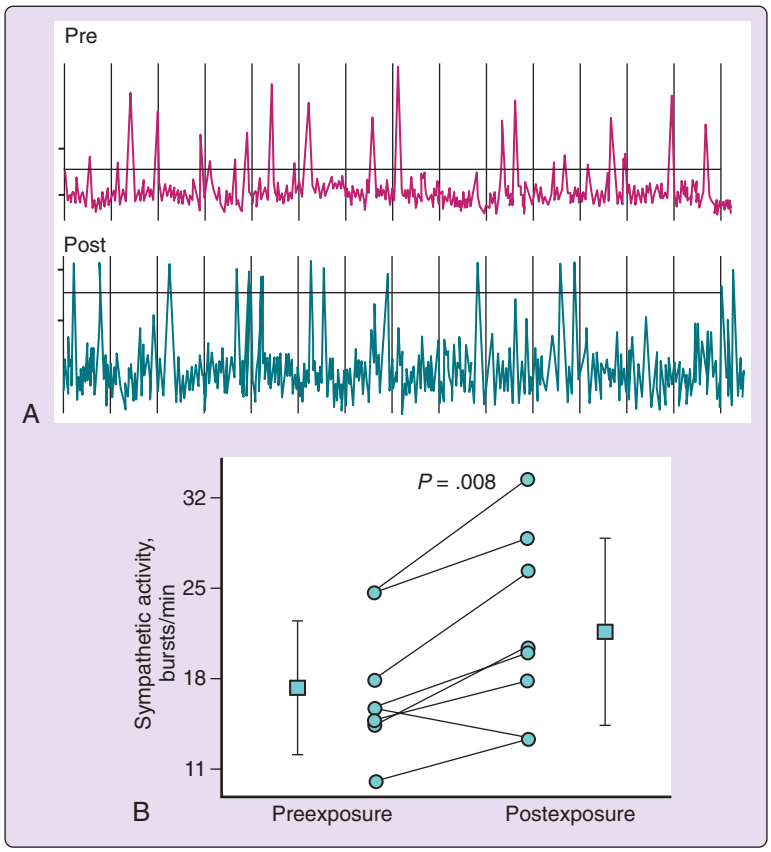

Figure 14-6 Intermittent hypoxia elevates daytime blood pressure and sympathetic activity in healthy humans. **A,** Representative neurograms of muscle sympathetic nerve activity (MSNA) during supine rest while breathing room air before (pre) and after 2 weeks of intermittent hypoxia exposure (post). **B,** MSNA increased across the exposure (17.2 ± 5.1 versus 21.7 ± 7.3 bursts/min; $P < .01$), thus reflecting sympathoactivation.

Data are presented after 1 night, 13 nights, and recovery from exposure to chronic intermittent hypoxia (CIH) as compared with preexposure values. CIH was associated with significantly increased daytime ambulatory blood pressure after a single night of exposure (3 mm Hg for mean and diastolic pressures), with further increased daytime pressures after 2 weeks of exposure (8 mm Hg systolic and 5 mm Hg diastolic). SUMMARY

The autonomic nervous system is intimately linked to central neural state changes. This coupling is especially straightforward for physiologic sleep and sleep disorders. It is clear that although the different stages of physiologic sleep result in structured changes in neural circulatory control, disturbed sleep, such as is seen in patients with OSA, with PLMS, or in sleep deprivation, acts to disrupt the sleep-related physiologic variations in autonomic regulation of heart rate and blood pressure. Current knowledge in this general area is limited by the tools available for comprehensive and direct assessment of the autonomic nervous system in humans. Although microneurography provides a direct measurement of sympathetic neural activity to the peripheral blood vessels, this measurement itself has limitations. The other options available are primarily those that monitor blood and urine levels of catecholamines. Measurements such as heart rate and blood pressure variability, while allowing some insight, provide only indirect information on autonomic cardiovascular control and are of limited usefulness owing to problems with regard to acquisition of data, confounding effects of medications and abnormal breathing patterns, and inconsistencies with regard to interpretation. Rigorous methods in line with standard recommendations[9] are mandatory. Therefore, beyond the body of knowledge regarding neural circulatory control during normal and disordered sleep surveyed in this chapter, the available data are limited, in part because of methodologic shortcomings and also because of the obvious difficulties inherent in nighttime studies of sleep physiology in humans.

Chapter Highlights

- The *wakefulness stimulus* to breathing, and its withdrawal in sleep, is an enduring principle in respiratory medicine because it is the root mechanism for modeling the effects of sleep on breathing. The neural basis for this wakefulness stimulus is identified.
- Central to understanding breathing in sleep has been delineation of the neurobiology of sleep, its impact on central respiratory neurons and motoneurons, and the important role of tonic excitatory (nonrespiratory) drives in contributing to the overall level of excitability in the respiratory system across sleep-wake states.
- Significant developments have contributed to identifying the neural basis for the suppression of pharyngeal muscle activity in sleep, especially rapid eye movement (REM) sleep. Mechanisms of genioglossus muscle suppression in sleep include withdrawal of excitatory inputs from wakefulness-dependent cell groups and active inhibition, a major component of the latter being mediated through a newly identified pathway.
- Mechanisms of respiratory rhythm generation and factors influencing motor excitability are both essential for the manifestation of effective breathing across sleep-wake states. The neurodepressive effects of commonly administered drugs such as opioids and sedative-hypnotics acting at critical sites in the respiratory network can explain the sometimes severe respiratory depression that can occur during sleep with use of such agents.

RESPIRATORY NEUROBIOLOGY: BASIC OVERVIEW

Medullary Respiratory Neurons and Motoneurons

Bilateral columns of neurons present in the medulla show activity patterns that vary in phase with some component of the respiratory cycle. The dorsal respiratory group (DRG) is located in the dorsomedial medulla, specifically in the ventrolateral nucleus of the solitary tract, and contains predominantly inspiratory neurons[1,2] (Figure 15-1). The DRG and the other subnuclei of the solitary tract also are the primary projection sites for vagal afferents from the lung, and for afferents from the carotid and aortic chemoreceptors and baroreceptors, that exert important reflex influences on breathing. These projections indicate that the nuclei of the solitary tract, including the DRG, are key sites of integration of sensory information from the lung, as well as information regarding the prevailing levels of arterial P_{CO_2}, P_{O_2}, pH, and systemic blood pressure. The ventral respiratory group (VRG) extends from the facial nucleus to the first cervical segment of the spinal cord and contains both inspiratory and expiratory neurons (Figure 15-1).[1,2] The nucleus ambiguus also consists of a rostral to caudal column of neurons expressing respiratory-related activity, with subregions regions containing motoneurons that innervate the muscles of the larynx and pharynx that are not considered part of the VRG per se.[3] In addition to the nucleus ambiguus, from rostral to caudal, the VRG is composed of Bötzinger complex (expiratory) neurons, pre-Bötzinger complex (inspiratory) neurons, rostral retroambigualis (predominantly inspiratory) neurons, and caudal retroambigualis (predominantly expiratory) neurons (Figure 15-1).[1,2]

The VRG and DRG contain both bulbospinal respiratory pre-motoneurons (i.e., neurons that project to spinal motoneurons, which in turn innervate the respective respiratory pump and abdominal muscles of breathing), and propriobulbar neurons (i.e., neurons that project to, and influence the activity of, other medullary respiratory neurons but themselves do not project to motoneurons per se) (Figure 15-1).[1,2] The hypoglossal, trigeminal, and facial motor nuclei also innervate muscles important to pharyngeal motor control and the maintenance of upper airway patency[4] (Figure 15-1). An important point, however, is that the expression of respiratory-related activity is not restricted to neurons of the DRG, VRG, and cranial motoneurons innervating the pharyngeal and laryngeal muscles. For example, neurons expressing respiratory-related activity in the pons, such as the pontine respiratory group (PRG) in Figure 15-1, are thought to play an important role in shaping the activity of medullary respiratory neurons during breathing.[3]

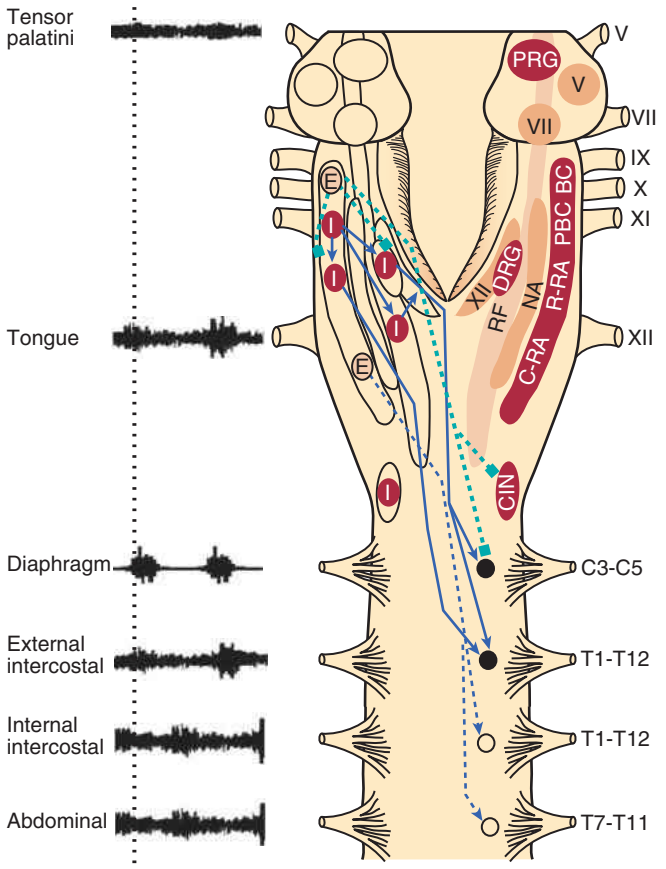

Figure 15-1 Ventral view of the brainstem (with cerebellum removed) showing the main aggregates of respiratory neurons in the dorsal and ventral respiratory groups (DRG and VRG, respectively). The locations of expiratory (E) and inspiratory (I) neurons in the Bötzinger complex (BC), pre-Bötzinger complex (PBC), rostral retroambigualis (R-RA), and caudal retroambigualis (C-RA) are shown. The locations of cervical inspiratory neurons (CIN) and respiratory-related neurons in the lateral reticular formation (RF) projecting to the hypoglossal motor nucleus (XII) also are shown. The projections of inspiratory and expiratory neurons are depicted as *solid* and *dashed lines,* respectively, whereas excitatory and inhibitory synaptic connections are depicted by *arrowhead* and *square symbols,* respectively. The electromyographic activities of various inspiratory-related (e.g., tongue, diaphragm, external intercostal) and expiratory (e.g., internal intercostal, abdominal) muscles are shown. Note that the level of respiratory-related and tonic activities varies for different muscles, with some muscles such as the tensor palatini expressing mainly tonic activity. The onset of muscle activity with respect to the diaphragm is shown by the *dashed line.* The rootlets of cranial nerves V, VII, IX, X, XI, and XII and the cervical (C) and thoracic (T) segments of the spinal cord also are shown, as are the motor nuclei of cranial nerves XII, VII, and V. The locations of the pontine respiratory group (PRG) and the nucleus ambiguus (NA) are shown, although their projections are not included for clarity. See text for further details.

Pre-Bötzinger Complex

Pre-Bötzinger complex neurons have pacemaker-like properties that are thought to be important to the generation of the basic respiratory rhythm, and to the expression of rhythmic neuronal activity elsewhere in the respiratory network[5,6] (Figure 15-1). Respiratory rhythm-generating pre-Bötzinger complex neurons coexpress μ opioid and neurokinin-1 receptors (i.e., the receptors for substance P), which slow and increase respiratory rate, respectively.[6] The development of uncoordinated (ataxic) diaphragm breathing after introduction of lesions of neurokinin-1–expressing pre-Bötzinger complex neurons in animal studies, with this abnormal breathing first appearing in sleep,[7] suggests that pre-Bötzinger complex neurons contribute significantly to normal breathing in vivo. First identified and characterized in rodents, and subsequently in other mammalian species, the pre-Bötzinger complex also has been identified in humans.[8,9] Loss of pre-Bötzinger complex neurons may predispose affected persons to abnormal or ataxic breathing and to central apneas in sleep, such as with aging and in neurodegenerative brainstem diseases.[6,9]

The presence of μ opioid receptors on pre-Bötzinger complex neurons can explain a significant component of the clinically important phenomenon of respiratory rate depression with opioid drugs.[10] The respiratory slowing and central apneas produced by systemically applied opioids are prevented by local application of the μ opioid receptor antagonist naloxone to the pre-Bötzinger complex, showing that this region of medulla is the critical site mediating opioid-induced respiratory rate depression.[10] Moreover, deep non–rapid eye movement (NREM) sleep and general anesthesia are the most vulnerable states for respiratory rate depression produced by opioids at the pre-Bötzinger complex.[10] This observation has significant clinical relevance regarding the potential hazards of administering opioids, for example, in the perioperative setting.

Neuronal Connections

The anatomic connections between the neurons that comprise the essential respiratory network (i.e., respiratory propriobulbar neurons, pre-motoneurons, and motoneurons), and the membrane properties of these cells, are ultimately responsible for the two key components of overall respiratory activity: (1) the generation of respiratory rhythm and (2) the shaping of the central respiratory drive potentials that activate respiratory motoneurons (pattern generation). An analysis of the mechanisms involved in the generation of the basic respiratory rhythm is outside the scope of this chapter; excellent summaries of the concepts underlying pacemaker models (whereby respiratory rhythm is *intrinsic* to some cells, which then drive others in the respiratory network), network models (whereby respiratory rhythm is *dependent* on the inhibitory and excitatory synaptic connections between neurons, and the tonic excitation is derived from both the respiratory chemoreceptors and brainstem reticular neurons), and hybrid models are available in referenced sources.[1,3,6]

With respect to the tonic drive to the respiratory system arising from the respiratory chemoreceptors, this would include both the peripheral and central chemoreceptors, the latter including neurons at the ventral medullary surface such as the retrotrapezoid nucleus, as well as inputs from CO_2-activated sleep state–dependent neurons of the aminergic arousal system (e.g., serotonin and noradrenergic neurons; see the following section).[11] Additional aspects of the organization of the central respiratory network are particularly relevant to understanding the effects of sleep on respiratory neurons and motoneurons, and these concepts are discussed briefly next.

During inspiration the central respiratory drive potential is transmitted to phrenic and intercostal motoneurons via monosynaptic connections from inspiratory pre-motor neurons of the DRG and VRG[1] (Figure 15-1). Bötzinger

complex expiratory neurons have widespread inhibitory connections throughout the brainstem and spinal cord, and these neurons inhibit inspiratory pre-motoneurons and motoneurons during expiration (Figure 15-1). Caudal retroambigualis neurons also increase the excitability of spinal expiratory motoneurons in expiration (Figure 15-1), although this excitation does not necessarily reach the threshold to manifest as expiratory muscle activity.

Of physiologic and clinical relevance, these fundamental aspects of the neural control of spinal respiratory motoneuron activity appear to be different from those for the mechanisms controlling the activity of pharyngeal motoneurons. For example, animal studies show that the source of inspiratory drive to hypoglossal motoneurons is different from the source of drive to phrenic motoneurons, being predominantly from reticular neurons lateral to the hypoglossal motor nucleus (lateral tegmental field) for the former and from bulbospinal VRG and DRG neurons for the latter (Figure 15-1).[1] Of importance, brainstem reticular neurons provide a significant source of tonic drive to the respiratory system, with this drive particularly affected in sleep.[3]

Further differences in the functional control of pharyngeal and diaphragm muscles is shown by the observation that unlike phrenic motoneurons, hypoglossal motoneurons are not actively inhibited in expiration.[1] Accordingly, the activity of the genioglossus muscle in expiration is simply a manifestation of the prevailing tonic inputs. The practical implication of this circuitry is that the overall activation of hypoglossal motoneurons during breathing is composed of an inspiratory drive that adds to a continuous tonic drive that persists in expiration when the inspiratory activation is withdrawn. Moreover, this tonic drive to the pharyngeal muscles, which contributes to baseline airway size and stiffness, is most prominent in wakefulness but withdrawn in sleep, resulting in an upper airspace that is more vulnerable to collapse. Characterization and quantification of this tonic *wakefulness stimulus* have been performed for the pharyngeal muscles in humans.[12] A more detailed analysis of the neural mechanisms controlling the activity of respiratory neurons and motoneurons follows a brief overview of the brain mechanisms modulating the states of wakefulness, NREM sleep, and REM sleep.

SLEEP NEUROBIOLOGY: BASIC OVERVIEW

Although a more detailed discussion of arousal and sleep state regulation is provided in Section 2 of this book, some details are particularly pertinent to the control of respiratory neurons and motoneurons in sleep. Accordingly, a brief overview of the neurobiology of sleep and wakefulness-generating systems is presented next.

Wakefulness

Figure 15-2 shows some of the main neuronal groups contributing to the ascending arousal system from the brainstem that promotes wakefulness. This ascending arousal system includes the cholinergic laterodorsal and pedunculopontine tegmental nuclei that promote cortical activation by way of excitatory thalamocortical projections.[13] The ascending arousal system also incorporates the aminergic arousal system that originates from brainstem neuronal groups principally containing serotonin (dorsal raphe nuclei), norepinephrine (locus coeruleus), histamine (tuberomammillary nucleus), and dopamine (ventral periaqueductal gray). Orexin neurons from the perifornical region of the hypothalamus and cholinergic neurons from the basal forebrain also contribute to this ascending arousal system.[13] Overall, multiple neuronal systems contribute to cortical arousal and wakefulness. These neuronal systems also are positioned to influence respiratory neurons and motoneurons by way of their anatomic projections to the pons, medulla, and spinal cord (Figure 15-2).

NREM Sleep

Sleep is actively generated by neurons in the ventrolateral preoptic area, anterior hypothalamus, and basal forebrain (Figure 15-2).[13] These neurons become active in NREM sleep, an effect influenced by the thermal stimulus that accompanies the circadian rhythm–mediated decline in body temperature at normal bedtime.[14] This circadian-mediated decline in body temperature is mediated by a change in the set-point of hypothalamic temperature-regulating neurons, which initially leads to a relative "warm stimulus" because body temperature is at first higher than the new set-point—that is, before heat loss occurs. This warm stimulus activates NREM sleep-active hypothalamic neurons and so promotes sleep onset. This effect of internal body temperature on sleep is distinct from the influences of ambient environmental temperature on sleep regulation. Activation of ventrolateral preoptic neurons leads to a direct suppression of cortical arousal, this by way of ascending inhibitory cortical projections. Ventrolateral preoptic neurons also promote sleep through descending inhibition of the aforementioned brainstem arousal neurons through release of gamma-aminobutyric acid (GABA) and galanin.[14,15] This effect of GABA explains the sedative-hypnotic effects of barbiturates, benzodiazepines, imidazopyridine compounds, and alcohol, as well as some general anesthetics, all of which enhance GABA-mediated neuronal inhibition through interactions with binding sites on the $GABA_A$ receptor.[16] $GABA_A$ receptors also are strongly implicated in respiratory control and are present throughout the respiratory network,[17] excessive stimulation of which can promote respiratory depression.[18] In summary, sleep onset is triggered by increased GABAergic neuronal activity, and this is accompanied by a massed and coordinated withdrawal of activity of brainstem arousal neurons comprising serotonergic, noradrenergic, histaminergic, and cholinergic neurons. With the widespread projections of these sleep state–dependent neuronal groups, these changes in neuronal activity in sleep also are positioned to influence respiratory neurons and motoneurons (Figure 15-2).[19]

REM Sleep

Decreased serotonergic and noradrenergic activity preceding and during REM sleep withdraws inhibition of the laterodorsal and pedunculopontine tegmental nuclei.[13,15] This effect leads to increased acetylcholine release into the pontine reticular formation and facilitation of transitions into REM sleep.[20,21] Exogenous application of cholinergic agonists or acetylcholinesterase inhibitors (to increase endogenous acetylcholine) into the same region of the pons is used to mimic this process experimentally in animal studies, that is, the "carbachol model" of REM sleep.[20,21] A significant component of the motor suppression of REM sleep is mediated by descending pathways involving activation of medullary

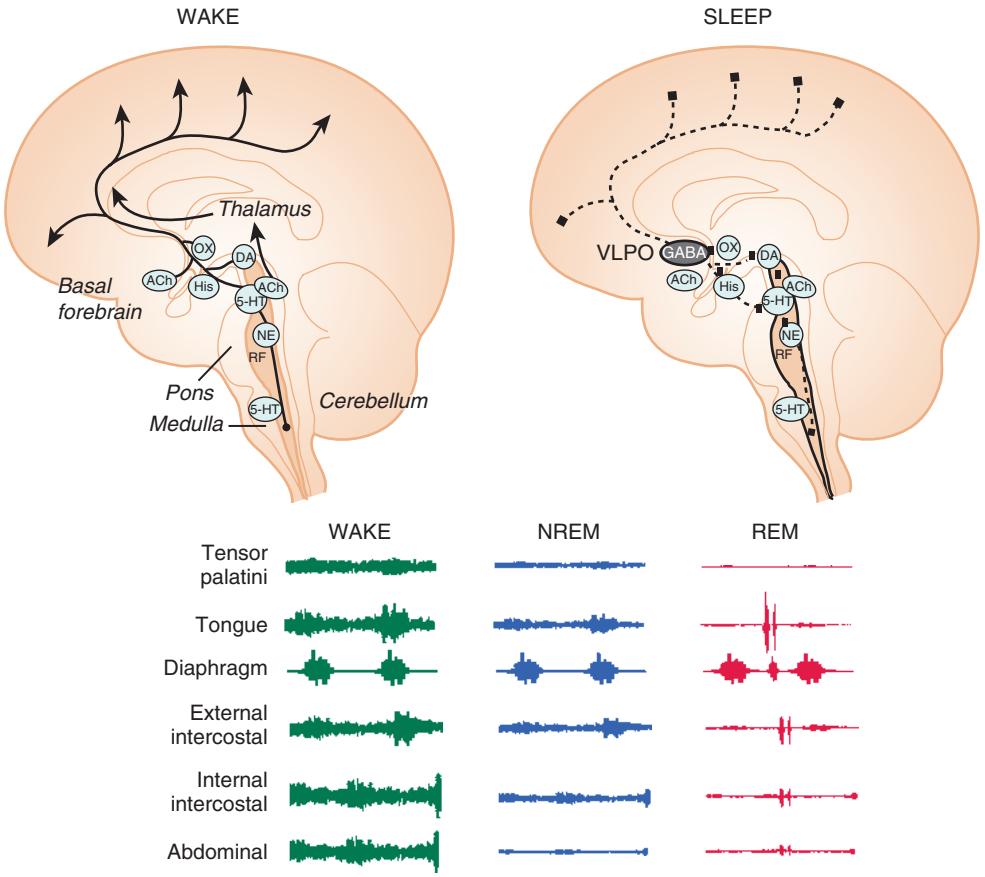

Figure 15-2 Sagittal section of the brain showing the main wake- and sleep-generating neural systems. In wakefulness, acetylcholine (ACh), orexin (OX), histamine (His), dopamine (DA), 5-hydroxytryptamine (5-HT), and norepinephrine (NE) containing neurons contribute to brain arousal (depicted as *black lines* with *arrows*). This ascending arousal system is inhibited in sleep by GABA-containing neurons from ventrolateral preoptic (VLPO) neurons (inhibitory projections shown by *dashed lines* and ■ symbols). By their anatomic projections to the pons, medulla and spinal cord, these wake and sleep-promoting neuronal systems also are positioned to influence respiratory neurons and motoneurons (see Figure 15-1). However, whether the influences of the different arousal-related neurons is excitatory or inhibitory will depend on the receptor subtypes activated (this uncertainty is depicted by the symbol ● in the medulla). Overall, these changes in neuronal activities across sleep-wake states, and their impact on respiratory neurons and motoneurons, mediate the stereotypical changes in the tonic and respiratory components of activity for different respiratory muscles, and their different susceptibilities to motor suppression in sleep. reticular relay neurons[22] that are inhibitory to spinal motoneurons via release of glycine.[23] Despite the strong association and interactions between pontine aminergic and cholinergic neurons in facilitating REM sleep, recent evidence has implicated a glutamatergic-GABAergic mechanism as key to the generation of the REM sleep state per se.[24,25] In addition to the critical contribution of different neural circuits and neuronal interactions to the generation of REM sleep, another key difference between the aminergic-cholinergic and the glutamatergic-GABAergic mechanisms of REM sleep generation is that the motor atonia is produced by different pathways; that is, the latter framework does not require a relay in the medullary reticular region.[25] Rather, in the glutamatergic-GABAergic mechanism of REM sleep induction, the REM sleep-active pontine neurons are thought to lead to suppression of spinal motoneuron activity by way of long glutamatergic projections to the ventral horn of the spinal cord, which then activate local glycinergic interneurons to inhibit motor activity.[25] Such a mechanism is likely to be involved in the strong inhibition of spinal intercostal motoneurons in REM sleep, but whether collaterals from these specific long descending glutamatergic projections also synapse onto glycinergic inhibitory interneurons in the hypoglossal motor pool is not established (see referenced source[19] for further discussion). Recent findings identifying the mechanism of upper airway motor inhibition in REM sleep are discussed later on (see Inhibitory Influences across Sleep-Wake States, under Neuromodulation of Respiratory Motoneurons across Sleep-Wake States). Recent reviews are available for additional details and further discussion.[26,27] In summary, a number of neural systems show changes in activity across sleep-wake states and project to respiratory neurons and motoneurons. Inasmuch as motoneurons are the final common output pathway for the influence of the central nervous system on motor activity, this

chapter initially focuses on the control of respiratory motoneurons across sleep-wake states before addressing the control of the central respiratory neurons that ultimately drive breathing by those motoneurons.

CONTROL OF RESPIRATORY MOTONEURONS

A characteristic and defining feature of mammalian motor activity is that postural muscle tone is highest in wakefulness, decreased in NREM sleep, and minimal in REM sleep, with the hypotonia of REM sleep punctuated by occasional muscle twitches that are associated with vigorous eye movements and "phasic" REM sleep events.[23] Whether *respiratory* muscle activity is affected in the same way as postural muscle activity across sleep-wake states is somewhat complicated by the interaction of the primary influence of sleep state (e.g., producing suppression of muscle tone) and any subsequent respiratory response (e.g., to compensate for any hypoventilation). On balance, however, the overall stereotyped pattern of suppression of postural muscle activity across sleep-wake states also typically occurs in respiratory muscles, with the degree of sleep state–dependent modulation most readily apparent in those muscles that combine respiratory *and* nonrespiratory (e.g., postural and/or behavioral) functions such as the intercostal and pharyngeal muscles.[28] In these respiratory muscles, decreases in activity typically occur immediately at sleep onset,[28] indicating a primary suppressant effect of sleep neural mechanisms on the activity of respiratory motoneurons—that is, before any compensatory increase in activity takes place in response to altered blood gases, mechanical loads, or sleep-disordered breathing. In contrast with those respiratory muscles with both respiratory and nonrespiratory functions, the diaphragm has an almost solely respiratory function and undergoes lesser suppression of activity in NREM sleep and is largely spared the motor inhibition of REM sleep (Figure 15-2).[29] Other chapters in this section provide more detail regarding clinical aspects of the control of breathing and upper airway function during sleep, whereas this chapter describes the fundamental mechanisms underlying these effects of sleep on the respiratory system.

DETERMINANTS OF RESPIRATORY MOTONEURON ACTIVITY

Tonic and Respiratory-Related Inputs to Respiratory Motoneurons

The changes in muscle tone across sleep-wake states ultimately result from the impact of sleep neural mechanisms on the electrical properties and membrane potential of individual motoneurons located in the respective motor pools in the central nervous system. In turn, the excitability of individual motoneurons changes across sleep-wake states because of varying degrees of excitatory and inhibitory inputs to those motoneurons from sleep-wake–related regions in the brain, and from neurons activated during specific behaviors such as purposeful motor acts in wakefulness.[19] At each individual motoneuron, therefore, the relative strengths of and balance between time-varying excitatory and inhibitory inputs ultimately determine net motor output, with neural activity being generated when the membrane potential rises above threshold for the production of action potentials (Figure 15-3). In addition to the excitatory and inhibitory *nonrespiratory* inputs to a motoneuron that alter membrane potential across sleep-wake states, a respiratory motoneuron also receives additional inputs (excitatory and inhibitory) that alter membrane excitability and neural activity in phase with the inspiratory or expiratory phases of the respiratory cycle. In short, a respiratory motoneuron resembles a postural motoneuron in its control and organizational principles except that it receives an additional rhythmic drive related to respiration—that is, the central respiratory drive potential. Figure 15-3 highlights the fact that the electromyographic activity recorded in a given respiratory muscle is critically dependent on the overall sum of the respiratory *and* nonrespiratory (i.e., tonic) inputs to the motoneurons innervating that muscle.

Recognition of the importance of *both* the tonic and respiratory-related inputs to a motoneuron in determining overall motor output is critical to any interpretation of the changes in respiratory muscle activity observed across sleep-wake states. Indeed, periods of hypoventilation, apparent central apnea, and even the sporadic respiratory muscle activations that occur during REM sleep all can result from *independent* effects of sleep neural processes on the tonic and/or respiratory-related inputs to a respiratory motoneuron (Figure 15-3, *A* to *E*). For example, the apparent absence of activity recorded in a respiratory muscle cannot be taken as evidence that the controlling circuitry is inactive; that is, an apparent apnea may not be truly due to a "central" cessation of respiratory drive. Indeed, a simple withdrawal of tonic drive in sleep may be sufficient to take a population of (e.g., otherwise respiratory-related) motoneurons close to, or below, the threshold for the generation of motor activity, such that any excitatory respiratory inputs to the motoneurons are subthreshold for the generation of action potentials and therefore are not revealed as respiratory muscle activity (Figure 15-3, *C*).

In summary, nonrespiratory tonic drives exert important influences on the resting membrane potential of respiratory motoneurons, thereby significantly modulating the excitability of motoneurons in response to the incoming central respiratory drive potential. This significant effect of nonrespiratory tonic drives on the activity of respiratory motoneurons has clear physiologic relevance: When identified experimentally, the tonic drive to respiratory motoneurons typically is reduced from wakefulness to NREM sleep, with consequent important contributions to sleep-related reductions in respiratory muscle activity leading to hypoventilation (Figure 15-3, *A* and *B*).[30,31] Tonic drive to respiratory motoneurons can also be further reduced in REM sleep, although time-varying fluctuations in this tonic drive can produce transient increases or decreases in respiratory muscle activity and contribute to changes in lung ventilation in REM sleep by a mechanism independent of effects on the respiratory-related inputs (Figure 15-3, *E*). Indeed, the presence of endogenous excitatory inputs to respiratory motoneurons in REM sleep (i.e., unrelated to breathing per se and akin to the mechanisms producing phasic muscle twitches in limb muscles), can produce sporadic activation of respiratory muscle and contribute to the expression of rapid and irregular breathing in REM sleep (Figure 15-3, *E*), even in the presence of low CO_2 levels that are otherwise sufficient to produce central apnea in NREM sleep.[30,31]

Electrical Properties of Motoneurons

The electrical properties of the motoneuron membrane also significantly affect the responses of that motoneuron to a

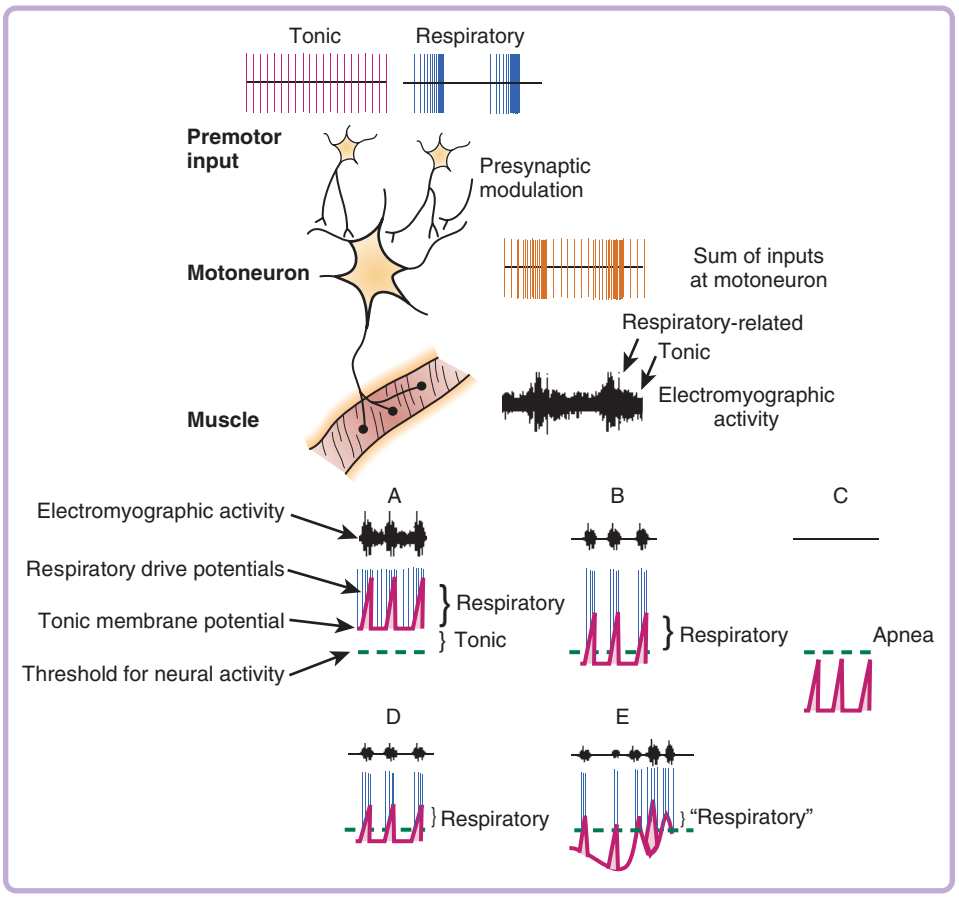

Figure 15-3 Schema depicting how converging tonic (e.g., postural, nonrespiratory) and respiratory inputs to a motoneuron summate to produce the tonic and respiratory components of electromyographic activity. These premotor tonic and respiratory inputs can be excitatory or inhibitory, but here they are shown as excitatory for simplicity. Diagrams **A** to **E** further show how changes in the tonic and respiratory components of respiratory muscle activity can result from *independent* changes in either tonic drives affecting tonic membrane potential (**A, B, C,** and **E**) (such as may occur on transition from wakefulness to NREM and REM sleep) or the magnitude of the respiratory drive potential (**B** versus **D**) (such as may occur in NREM and REM sleep compared with wakefulness). Changes in respiratory drive potential at the motoneuron can result from decreases in the input from respiratory neurons, presynaptic modulation of that input and/or changes in input resistance of the motoneuron membrane per se (see text for further details). In the examples shown in **A** to **E,** respiratory drive is indicated as three depolarizing potentials, each associated with the generation of motoneuron action potentials when the membrane potential exceeds threshold (*dashed line*). Diagram E also shows that time-varying alterations in membrane potential, as occur in REM sleep, for example, can produce respiratory muscle activation unrelated to the prevailing respiratory input (the latter depicted in *gray*). Thus, from peripheral measurements of diaphragm activity or airflow, there appear to be five "breaths," although only three respiratory drive potentials are generated by the central respiratory oscillator.

given synaptic input. For example, reduced motoneuron responses to an incoming respiratory drive potential can be due to the aforementioned effects of reduced tonic drives and consequent membrane hyperpolarization (Figure 15-3), but also to the electrical resistance of the motoneuron membrane itself. The input resistance of a membrane is defined as its voltage response to a given synaptic current, with a decrease in input resistance resulting in less membrane depolarization for a given synaptic drive—that is, a decrease in cell excitability (Figure 15-3). This electrical property of excitable membranes has clear physiologic relevance because a large (~44%) decrease in input resistance of motoneurons occurs in REM sleep compared with NREM sleep and wakefulness.[23] In addition, transient fluctuations in input resistance occur throughout REM sleep episodes, such as the decreased input resistance of somatic motoneurons that occurs in temporal association with the phasic events of REM sleep. Such an effect is likely to contribute to the periods of marked suppression of inspiratory upper airway muscle activity in humans during phasic REM sleep compared with tonic REM sleep.[32]

In summary, a decrease in motoneuron input resistance in REM sleep, especially in association with eye movements, can contribute to decreased motor outflow to the pharyngeal and respiratory pump muscles, leading to periods of increased upper airway resistance and hypoventilation. Moreover, such decreases in respiratory motoneuron activity can occur *despite* the persistence of a continuing, and even heightened, activity of the central respiratory neurons that innervate those motoneurons in REM sleep (Figure 15-4) (see later under Control

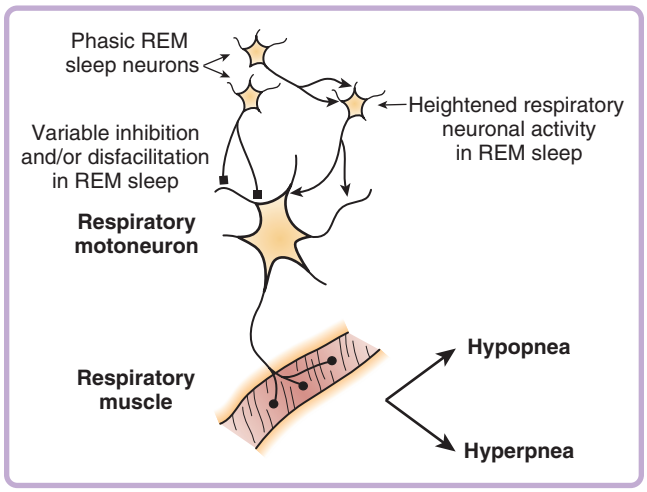

Figure 15-4 Schema depicting how respiratory motoneurons receive competing excitatory (*arrowheads*) and inhibitory (■) drives in REM sleep, the balance of which leads to time-varying increases and decreases in respiratory rate and amplitude, which manifest as hyperpnea and hypopnea, respectively. Additional factors that contribute to this variable lung ventilation in REM sleep are the similar competing excitatory and inhibitory influences at (1) pharyngeal motoneurons in REM sleep that lead to time-varying alterations in upper airway size and resistance, and (2) chest wall and abdominal muscles[23] that modulate resting lung volume and compliance of the chest wall. (Modified from Orem J. Neuronal mechanisms of respiration in REM sleep. *Sleep* 3:251–67, 1980.)

of Respiratory Neurons).[3,31] This observation highlights that a powerful inhibition and/or disfacilitation (i.e., withdrawal of excitation) must be taking place at respiratory motoneurons to explain the periods of reduced motor *output* despite continuing, and even heightened, *inputs* from respiratory neurons in REM sleep (Figure 15-4).[3,33,34]

Presynaptic Modulation

The control of respiratory motoneuron activity by changes in sleep state–dependent neuromodulators and/or inputs from respiratory neurons often emphasizes the postsynaptic effects of released neurotransmitters (see earlier). Such postsynaptic effects do not fully account for the control of motoneuron activity, however, because presynaptic modulation of the prevailing inputs also is important in motor control (Figure 15-3). For example, inhibitory inputs arriving at a nerve terminal before the subsequent arrival of a descending excitatory drive can lead to marked reductions in the release of excitatory neurotransmitters, so leading to the suppression of motoneuron activity. Such presynaptic modulation of neuronal activity is thought to be significant for information processing in neurons innervated by several converging pathways, as is the case for the organization of respiratory motoneurons (Figure 15-3). Accordingly, under specific behaviors, some inputs can be selectively suppressed, whereas others are left unaffected. This presynaptic modulation of specific inputs allows for selective control of motoneuron excitability, an effect that could not be achieved by a generalized postsynaptic modulation that affects the whole cell. This differential control has particular relevance in the control of motoneurons with dual respiratory and nonrespiratory functions, such as hypoglossal motoneurons innervating the genioglossus muscle of the tongue. In hypoglossal motoneurons, the presynaptic inhibition of the incoming central respiratory drive potentials allows for the switching of motor output appropriate for other behaviors such as swallowing, sucking, or speech, without the interference of respiration.[35]

Tonic and Respiratory-Related Activity in Respiratory Muscle

Some respiratory muscles exhibit more respiratory-related activity than others, whereas other muscles are more tonically active and exhibit little respiratory-related activity (Figures 15-1 and 15-2). For example, the genioglossus muscle of the tongue shows both tonic and respiratory-related activity, with the decreased activity of this muscle during sleep strongly linked to the pathogenesis of obstructive sleep apnea.[36] Similarly, the different intercostal muscles show various degrees of respiratory-related and tonic activities related to both the respiratory and postural functions of these muscles, with the expression of this respiratory-related versus tonic activity related to specific anatomic location in the chest wall and ongoing behaviors.[29,37] Suppression of intercostal muscle activity in REM sleep is thought to increase the compliance of the chest wall and to contribute to decreased functional residual capacity, effects that can in turn contribute to hypoventilation, especially in infants because of their already highly compliant chest wall.[29] In contrast with these muscles with respiratory-related activity, the tensor palatini muscle of the soft palate displays mostly tonic activity, which decreases with progression from wakefulness to NREM and REM sleep. The tonic activity in the tensor palatini is thought to enhance stiffness in the segment of the upper airway at the level of the soft palate, a consistent site of airway closure in obstructive sleep apnea.[4] Accordingly, decreases in tonic tensor palatini muscle activity from wakefulness to sleep (Figure 15-2) contribute to increased upper airway resistance and the predisposition to airway occlusion in sleep, with this effect of sleep predominantly affecting breathing by an effect on the tonic (nonrespiratory) inputs to these motoneurons, which receive little or no respiratory input at rest. Ultimately, whether some muscles exhibit respiratory-related activity at rest depends on both the "strength" of the input from respiratory neurons compared with the tonic drives (see Figure 15-5 and later section, Control of Respiratory Neurons)[3] and also the degree of suppression of the respiratory activity by vagal afferents related to lung volume.[4]

NEUROMODULATION OF RESPIRATORY MOTONEURONS ACROSS SLEEP-WAKE STATES

Studies addressing the neurochemical basis for the modulation of respiratory motor activity across natural sleep-wake states, in vivo, have been confined largely to the hypoglossal and trigeminal motor nuclei.[19,20,23,38] This focus on pharyngeal motoneurons is clinically relevant in elucidating the pathogenesis of obstructive sleep apnea, with airway obstructions occurring behind the tongue both at the level of the soft palate and below.[4] In contrast with this focus on pharyngeal motoneurons, similar studies investigating the control of intercostal and phrenic motoneurons in naturally sleeping animals are lacking. Nevertheless, studies of spinal motoneurons have provided important information regarding the control of postural motoneurons across sleep-wake states.[23] Because intercostal motoneurons perform both postural and respiratory functions,

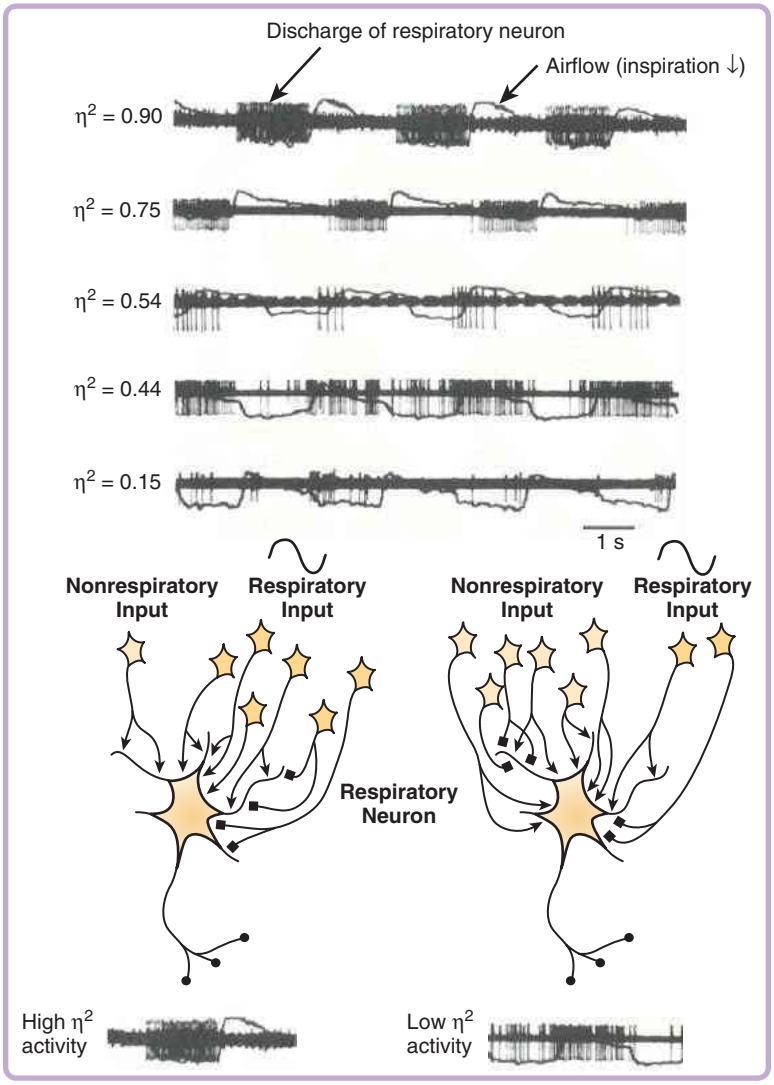

Figure 15-5 Five different medullary respiratory neurons recorded in intact cats in NREM sleep. These neurons vary in the strength of their relationship to breathing, an effect that is quantified by the η^2 statistic with values ranging from 0 (weak relationship) to 1.0 (strong relationship). High η^2 cells are considered to be more strongly influenced by respiratory inputs than nonrespiratory inputs, and vice versa for low η^2 cells. (Modified from Orem J, Kubin L. Respiratory physiology: central neural control. In: Kryger MH, Roth T, Dement WC, editors. *Principles and Practice of Sleep Medicine.* 3rd ed., Philadelphia: WB Saunders; 2000.)

the mechanisms identified at primary postural motoneurons are likely to have close similarities to the mechanisms controlling the nonrespiratory (postural) component of intercostal motor activity. A focus on the control of motoneurons innervating the muscles of the respiratory pump also is relevant within the scope of this chapter because significant hypoventilation can occur in sleep, especially REM sleep, in patients with restrictive lung diseases (e.g., kyphoscoliosis, obesity hypoventilation) and neuromuscular weakness (e.g., postpolio syndrome, muscular dystrophy, amyotrophic lateral sclerosis, partial diaphragm paralysis).[39] Summarized next are the major findings from animal studies addressing the sleep state–dependent modulation of respiratory motor activity. These data derive in large part from studies at the hypoglossal motor nucleus, a model motor pool with dual respiratory and nonrespiratory functions.[19]

Excitatory Influences Across Sleep-Wake States

The concept of a tonic drive activating respiratory muscle in wakefulness but not in sleep (i.e., the wakefulness stimulus for breathing) has been an important and enduring notion in respiratory medicine,[3,29] not least because it is useful in modeling sleep effects on breathing and in elucidating the pathogenesis of sleep-related breathing disorders. Neurons of the aminergic arousal system provide an important source of tonic drive to the respiratory system (Figure 15-2).[3,19,20] Serotonin- and norepinephrine-containing neurons have been of particular attention experimentally because these neurons send excitatory projections to respiratory motoneurons, and because these neurons show their highest activity in wakefulness, reduced activity in NREM sleep, and minimal activity in REM sleep—a pattern that may contribute to reduced

respiratory muscle activity in sleep through withdrawal of excitation.[3,19,20]

Animal studies show that an endogenous noradrenergic drive to the hypoglossal motor nucleus contributes to both the respiratory and tonic components of genioglossus muscle activation in wakefulness, and the residual expression of respiratory-related activity that persists in NREM sleep as the tonic drive is withdrawn.[40] Moreover, this noradrenergic contribution to genioglossus muscle tone was shown to be minimal in REM sleep, thereby explaining, at least in part, the periods of genioglossus muscle hypotonia during REM sleep.[40,41] The identification of an endogenous excitatory noradrenergic drive that contributes to genioglossus muscle activation in wakefulness, but is withdrawn in sleep, is particularly significant because since the first clinical description of obstructive sleep apnea, this was the first identification of a neural drive contributing to the sleep state–dependent activity of a muscle that is central to this disorder. The location of the central noradrenergic neurons that may provide this drive to hypoglossal and other respiratory motoneurons is reviewed elsewhere.[19] As noted previously, with the widespread projections of brainstem aminergic neurons, they also are positioned to provide an endogenous input to other respiratory neurons and motoneurons and thereby influence respiratory pump muscle activity and ventilation across sleep-wake states.[42,43] Recent data also point to a role for endogenous glutamatergic inputs in the tonic excitatory drive that increases pharyngeal muscle activity in wakefulness, the withdrawal of which contributes to reduced activity in sleep.[19,44,45] In contrast with these functionally active tonic inputs, endogenous levels of serotonin at the hypoglossal motor nucleus contribute less to the changes in genioglossus muscle activity in sleeping animals.[19] Whether this minimal influence of endogenous serotonin on genioglossus muscle activity also applies to humans remains to be determined. If so, it may explain (at least in part) the lack of clinically significant effects of selective serotonin reuptake inhibitors on pharyngeal muscle activity and obstructive sleep apnea severity in patients receiving these drugs.[19,46,47]

Local application of serotonergic, noradrenergic, and glutamatergic agonists to the hypoglossal or trigeminal motor nuclei produces robust motor activation in wakefulness and NREM sleep.[19,45] These observations provide "proof of principle" for the notion that it may be possible to develop pharmacologic strategies to increase respiratory muscle activity in sleep—for example, as a potential treatment for obstructive sleep apnea. Of importance, however, a major component of the motor activation observed in response to these agonists in NREM sleep is overcome in REM sleep.[19,45] An important practical implication of this differential modulation of pharyngeal motor responses to otherwise potent excitatory neuromodulators between NREM and REM sleep has been recognized. For example, even if it is possible to effectively target pharyngeal motoneurons with directed pharmacologic manipulations, such as for treatment for obstructive sleep apnea, then different strategies may be required to produce sustained pharyngeal muscle activation throughout both the NREM *and* REM sleep stages, because the neurobiology of motor control is fundamentally different between these two states.[19]

Inhibitory Influences Across Sleep-Wake States

Glycine and GABA are the main inhibitory neurotransmitters in the central nervous system. Glycine and $GABA_A$ receptor stimulation at the hypoglossal motor nucleus in vivo produces the expected depression of genioglossus muscle activity, whereas antagonism of these receptors increases genioglossus activity across all sleep-wake states.[19,26,27] The augmentation of respiratory-related motor activity across *all* sleep-wake states with application of antagonists for these inhibitory neurotransmitters fits best with the notion of a continuous background (i.e., tonic) inhibitory tone that constrains the rhythmic activation via gain modulation.[48] Moreover, any motor-activating effects observed with glycine and GABA receptor blockade at the cranial motor pools are trivial and, of note, are of smallest magnitude in REM sleep compared with wakefulness and NREM sleep. These findings, observed at both the hypoglossal[49,50] and trigeminal[38,51] motor pools, suggest that inhibition by glycine and GABA should not be viewed as a significant mediator of pharyngeal motor inhibition in REM sleep, because the inhibitory tone is present across all sleep-wake states and is weakest of all in REM sleep (see referenced sources[26,27,52] for further details, and see further on for discussion of the strong inhibitory mechanism that operates at the hypoglossal motor pool in REM sleep).

Nevertheless, the tonic inhibitory effects of GABA at respiratory neurons[17] and motoneurons[19] are clinically relevant in view of the widespread use of sedative-hypnotic drugs. For example, benzodiazepine and imidazopyridine drugs commonly are prescribed as sedative-hypnotics (e.g., lorazepam, zolpidem, respectively), and both of these classes of sedatives promote sleep by enhancing GABA-mediated neuronal inhibition through interactions with binding sites on $GABA_A$ receptors.[16] The presence of lorazepam and zolpidem at the hypoglossal motor nucleus also leads to inhibition of genioglossus muscle activity.[19] This inhibitory effect of sedative-hypnotics at respiratory motor nuclei may underlie a component of the respiratory depression observed clinically with excessive $GABA_A$ receptor stimulation, and the predisposition to obstructive sleep apnea in some persons taking sedative-hypnotics and other $GABA_A$ receptor-modulating neurodepressive drugs such as alcohol and certain general anesthetics.[18]

Large inhibitory glycinergic potentials appear to play an important role in the inhibition of spinal motoneuron activity in REM sleep,[23] and this probably explains the inhibition of intercostal respiratory muscle activity in this sleep state.[29] As discussed previously, however, glycine and $GABA_A$ receptor antagonism at the hypoglossal[49,50] and trigeminal[38,51] motoneuron pools fails to reverse the profound *tonic* suppression of genioglossus or masseter muscle activity in REM sleep, although in both cases this antagonism increases the amount and/or magnitude of the sporadic *phasic* motor activations in REM sleep.[19,38] These increases in phasic motor activity during REM sleep with glycine and $GABA_A$ receptor antagonism point to a functional role for sporadic inhibitory neurotransmission in the modulation of hypoglossal and trigeminal motor excitability,[18,25,26] and such inhibitory potentials have been recorded at hypoglossal motoneurons in REM sleep.[53] Based on the findings described here, however, this inhibitory glycinergic and GABAergic mechanism appears not to be as profound as the inhibition demonstrated at spinal motoneurons.[23]

Indeed, the mechanism of hypoglossal motor suppression in REM sleep appears to be different from that for spinal motoneurons. A cholinergic (muscarinic) receptor mechanism

linked to G protein–coupled inwardly rectifying potassium (GIRK) channels mediates the strong inhibition of the tongue musculature in REM sleep.[52] This inhibition is strong enough to counteract the inspiratory excitatory drive to hypoglossal motoneurons that originates from the respiratory network (Figure 15-1), such that respiratory motor activation of the tongue musculature can be abolished during REM sleep even during strong respiratory stimulation with hypercapnia.[54] Moreover, unlike glycine and $GABA_A$ receptor blockade at the hypoglossal motor pool, blockade of this cholinergic-GIRK channel mechanism is capable of reversing the REM sleep–induced hypoglossal motor suppression and of restoring respiratory genioglossus activity throughout REM sleep.[26,52,55]

The degree of suppression observed in a variety of *respiratory pump* muscles in REM sleep appears to be strongly correlated with the muscle spindle density of these different muscles.[37] The diaphragm has few, if any, spindles and little inhibition in REM sleep, whereas different intercostal muscles (especially the external inspiratory intercostals) have significant numbers of muscle spindles and profound suppression of activity in REM sleep, with variation in the degree of suppression in accordance with muscle spindle density.[29,37] Of clinical relevance, *acute* diaphragm paralysis leads to increased reliance on the intercostal and accessory muscles to maintain effective lung ventilation, but this compensation is lost in REM sleep, when the motoneurons innervating these muscles with dual respiratory and postural functions are inhibited.[56] Of interest, however, patients with *chronic* bilateral diaphragm paralysis are able to recruit nondiaphragmatic inspiratory muscle activity during REM sleep, thereby lessening any attendant hypoventilation. This compensation suggests that the central nervous system in these patients is able to functionally reorganize the drives controlling the accessory respiratory muscles such that activity is less suppressed by REM sleep mechanisms in the long term.[57,58]

Mechanisms Operating Across Sleep-Wake States

Current information from experiments in sleeping animals indicates that reduced excitation, largely through withdrawal of endogenous noradrenergic and glutamatergic inputs, is principally responsible for reductions in pharyngeal muscle tone from wakefulness to NREM and REM sleep.[19,20,45] By comparison, an endogenous serotonergic drive plays a lesser role.[19] Increased inhibitory neurotransmission mediated by glycine and GABA also contributes to suppression of pharyngeal motor activity in REM sleep, but the contribution of this mechanism appears to be much less than expected[19,20,45] from studies at spinal motoneurons.[23] Rather, a cholinergic-GIRK channel inhibitory mechanism operates at the hypoglossal motor pool, with the largest inhibitory influence of this mechanism seen in REM sleep and minimal or no effects in waking or NREM sleep. This mechanism is the major cause of inhibition of the tongue musculature in REM sleep.[26,27,52] By contrast, glycine and GABA exert a continuous background (i.e., tonic) inhibitory tone that is present across all sleep-wake states, with constraint of hypoglossal respiratory motor outflow by this tone through gain modulation. Augmentation of this tonic inhibitory GABA tone with commonly administered neurodepressive drugs can lead to further suppression of pharyngeal muscle activity and precipitation of upper airway obstructions in susceptible persons, such as those with anatomically narrow upper airways who already are prone to experience obstructive sleep apnea.

CONTROL OF RESPIRATORY NEURONS

Respiratory Neurons Vary in the Strength of Their Relationship to Breathing

Studies by John Orem and colleagues in sleeping animals led to the fundamental concepts that still best explain the neural basis for the effects of sleep on breathing, including the nature of the so-called wakefulness stimulus, and for the rapid, irregular breathing pattern of REM sleep.[3] Key to this achievement was development of a statistical approach to quantify the consistency and strength of the respiratory-related component of a neuron's activity as related to its overall discharge. The strength of this relationship was quantified by the *eta-squared statistic* (η^2), with η^2 values ranging from 1.0 (strongest relationship) to 0 (i.e., weakest relationship).[3] Of importance, different brainstem respiratory neurons vary in the strength of their relationship to the inspiratory or expiratory phase of the breathing cycle (Figure 15-5).

The interpretation and physiologic meaning of the η^2 value for any given respiratory neuron are best explained in the following quote from Orem, for whom cells with high η^2 values were "quintessentially respiratory . . . , protected from nonrespiratory distortions, perhaps because of rigid sequences of excitatory and inhibitory postsynaptic potentials that preclude activity that is not strictly respiratory."[3] By comparison, the activity of "low η^2-valued cells is the apparent result of mixtures of inputs that have respiratory and nonrespiratory forms."[3] Figure 15-5 further illustrates this concept by showing that the degree of respiratory-related activity of a given respiratory neuron (i.e., its η^2 value) depends on the balance of the respiratory *and* nonrespiratory inputs to that neuron. This is an important concept because respiratory neurons with different η^2 values are differentially affected by sleep-wake state.

Respiratory Neuron Activity in NREM Sleep

The notion that the degree of respiratory-related activity of a particular respiratory neuron depends on the balance of its respiratory and nonrespiratory inputs assumes significant physiologic and clinical relevance with the following experimental observations, made across the sleep-wake cycle:

- Neurons with low η^2 activity—that is, those that are less influenced by the respiratory oscillator but are strongly influenced by nonrespiratory tonic drives—are *most* affected by the transition from wakefulness to NREM sleep, such that their activity can even cease during sleep.
- Neurons with high η^2 activity—that is, those that presumably are strongly coupled to, and controlled by, the respiratory oscillator—are *least* affected by the transition from wakefulness to NREM sleep.

These observations and findings are illustrated in Figure 15-6.[3]

Of note, those respiratory neurons with low η^2 values that become inactive in sleep are not ceasing their activity simply because these neurons lose their respiratory input. That idea is discounted because experimental reexcitation of those low η^2 respiratory neurons that become silenced during NREM sleep restores their rhythmic respiratory activity. This finding shows that the respiratory-related input persists onto those

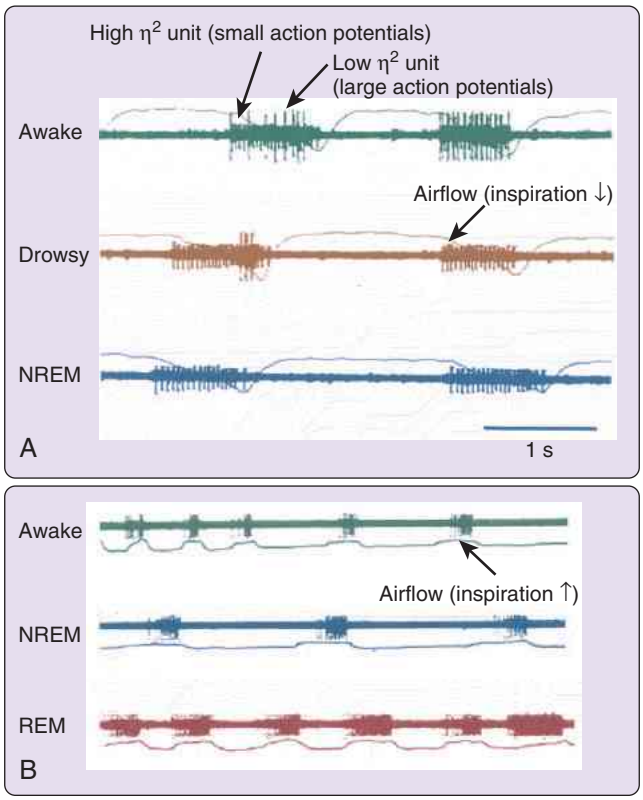

Figure 15-6 A, The activity of high η^2 medullary respiratory neurons is little affected by NREM sleep, whereas the activity of low η^2 cells is significantly suppressed in NREM sleep. This differential effect of NREM sleep on these different classes of respiratory neurons is thought to be due to the particular sensitivity of the tonic nonrespiratory inputs to changes in sleep-wake state, which is the basis of the so-called wakefulness stimulus for breathing. **B,** Electromyographic tracings showing increased and advanced activity of a late inspiratory neuron in REM sleep. inactive low η^2 respiratory neurons in NREM sleep but that this respiratory signal was subthreshold and therefore did not show itself as motor activation (see Figure 15-3, *C,* for comparison and explanation of this principle).[3,59] The major principle here, well articulated by Orem, is that the magnitude of the "effect of sleep on a respiratory neuron is proportional to the amount of nonrespiratory activity in the activity of that neuron," such that the "wakefulness stimulus to breathing is nonrespiratory in form and affects some respiratory neurons more than others.[3] This principle underscores the key importance of tonic drives in the expression of both tonic *and* respiratory neuronal activities.

Respiratory Neuron Activity in REM Sleep

REM sleep is characterized by (1) overall depression of the ventilatory responses to hypercapnia and hypoxia[29]; (2) periods of profound suppression of motor activity in respiratory muscles (e.g., intercostal and pharyngeal)[19,20] and nonrespiratory (i.e., postural) muscles[23]; and (3) occasional periods of slowing of respiratory rate. Periods of sporadic respiratory slowing in REM sleep are associated with increased release of acetylcholine into the pontine reticular formation.[21] It is not correct, however, to consider REM sleep as a state of *overall* depression of central respiratory neurons because, as for most cells in the central nervous system, the activity of brainstem respiratory neurons typically is *greater* in REM sleep than in NREM sleep. As an example, late inspiratory neurons have increased and advanced activity in REM sleep; that is, cells that discharge in the latter part of inspiration in NREM sleep can be active throughout inspiration in REM sleep (Figure 15-6).[3]

A large degree of variability has been observed in the discharge pattern of respiratory neurons in REM sleep; this variability is associated with tonic and phasic REM sleep events.[3] For example, increased medullary respiratory neuronal activity is associated with increased occurrence of ponto-geniculo-occipital waves, these waves being a defining feature of phasic REM sleep events. This finding suggests that the activity of respiratory neurons in REM sleep is strongly influenced by processes and activities that are peculiar to the neurobiology of the REM sleep state per se, rather than being an intrinsic component of the respiratory network.[3] This notion of significant influences on respiratory network activity by nonrespiratory inputs has similarities to the major influence of tonic drives discussed previously in the context of the wakefulness stimulus to breathing. Together, these concepts serve to highlight that the activity levels of central respiratory neurons and motoneurons is determined by the interaction of their component nonrespiratory *and* respiratory inputs, the former having major influences on overall respiratory activity and being particularly sensitive to changes in sleep-wake state.

As discussed previously for respiratory motoneurons, this effect of REM sleep in activating central respiratory neurons can lead to periods of increased respiratory rate and respiratory muscle activity. Of importance, and as mentioned, these periods of increased respiratory network activity in REM sleep are intimately related to the neural substrate for the REM sleep state per se. As a consequence, they also are largely *unrelated* to processes of respiratory control, including homeostatic feedback regulation and responses to prevailing blood gas tensions.[3,30,31] This increased activity of central respiratory neurons in REM sleep also is likely to be responsible for producing the periods of increased respiratory rate and higher respiratory muscle activity at times when the normally time-varying inhibition of respiratory motoneurons is briefly weakened or withdrawn (Figures 15-3 and 15-4). That REM sleep can lead to periods of heightened diaphragm activity unrelated to prevailing blood gas tensions has particular relevance for the clinical observation that hypocapnic central apneas most commonly occur in NREM sleep but can be absent in REM sleep, when breathing is characteristically erratic.[60,61] Figure 15-4 illustrates how this balance of excitatory and inhibitory influences at respiratory motoneurons can underlie the highly variable respiratory activity in REM sleep, including periods of respiratory depression despite activation of central respiratory neurons.

Neuromodulation of Respiratory Neurons across Sleep-Wake States

Unlike the studies performed at respiratory motor pools,[19,20] no studies have been conducted to identify or otherwise characterize the neurochemicals that may mediate the control of respiratory neurons in vivo as a function of sleep-wake states. Nevertheless, it is a reasonable working hypothesis that the neuronal groups involved in the modulation of respiratory

motoneurons across sleep-wake states also are likely to affect respiratory neurons. Accordingly, influences from brainstem reticular neurons (probably glutamatergic) are positioned to provide a source of tonic drive to respiratory neurons, with alteration of this influence from wakefulness to NREM and REM sleep.[3,19,20,45] Brainstem reticular neurons generally show decreased activity in NREM sleep compared with wakefulness, and increased activity in REM sleep[3,22]—a pattern similar to the changes in respiratory neuron activity discussed earlier. Electrical stimulation of reticular neurons in the midbrain converts the activity of several respiratory motor nerves or muscles from a sleeplike pattern to one more like wakefulness.[3] One key source of the tonic (nonrespiratory) input to medullary respiratory neurons in the awake state (i.e., the wakefulness stimulus) is thought to arise from brainstem reticular neurons.[3] The source or sources of the drives activating central respiratory neurons in REM sleep, however, have not been determined.

Neurons of the aminergic arousal system (serotonergic, histaminergic, and noradrenergic), and other sleep state–dependent neuronal groups, also are positioned to provide a source of tonic (i.e., nonrespiratory) drive to respiratory neurons across sleep-wake states. However, whether these tonic drives would be excitatory or inhibitory to respiratory neurons depends on the receptor subtypes activated, and on the pre- or postsynaptic location of these receptors (see Figures 15-2 and 15-3). This lack of knowledge of the sleep state–dependent neuromodulation of respiratory neurons can be addressed by further research, which also may identify specific pharmacologic approaches that can preserve respiratory neuron activity in sleep and in states of drug-induced brain sedation, so as to minimize respiratory depression. The various brain structures that exert behavioral control of the respiratory system also should be considered as a source of the wakefulness stimulus for breathing,[3] but it is not known if this collection of inputs share the same neurochemicals as for the aforementioned inputs from the brainstem reticular neurons and sleep state–dependent neuronal systems.

CLINICAL PEARL

The withdrawal of the wakefulness stimulus to breathing at the transition from wakefulness to sleep is the principal mechanism underlying the major clinical sleep-related breathing disorders. Current evidence identifies neurons of the aminergic arousal system and reticular neurons as providing the key components of this wakefulness stimulus. Withdrawal of this tonic excitatory drive to the muscles of the upper airway is thought to underlie the normal sleep-related increase in upper airway resistance, and the hypoventilation, flow limitation, and obstructive sleep apnea observed in susceptible persons (e.g., those with already anatomically narrow upper airways). Patients with restrictive lung diseases and neuromuscular weakness rely, to various degrees, on the activation of nondiaphragmatic respiratory muscles to help maintain adequate ventilation in the awake state, but this compensation can be reduced or absent in sleep, leading to severe hypoventilation, as the essential tonic excitatory drive that is present in wakefulness is withdrawn. REM sleep mechanisms also lead to inhibition of respiratory motoneurons, thereby explaining the typically increased severity of abnormal breathing events in REM sleep compared with NREM sleep.

SUMMARY

Sleep is a state of vulnerability for the respiratory system. Central to the pathogenesis of a variety of sleep-related breathing disorders is loss of a wakefulness stimulus that sustains adequate breathing in wakefulness. This loss of the wakefulness stimulus is the root mechanism in understanding sleep effects on breathing. Significant developments have helped identify the neurochemical substrates underlying this wakefulness stimulus. Central to this understanding has been delineation of the neurobiology of sleep, its impact on central respiratory neurons and motoneurons, and the important role of tonic excitatory (nonrespiratory) drives in contributing to overall respiratory system activity. Moreover, in parallel with the realization that sleep onset is not simply the passive withdrawal of wakefulness, breathing during sleep is not simply due to the passive withdrawal of the wakefulness stimulus. NREM sleep and REM sleep are fundamentally different neurobiologic states that exert distinct effects on the control of respiratory neurons and motoneurons. Accordingly, NREM and REM sleep modes pose different problems with breathing during sleep in different people with different pathologic conditions. Understanding these mechanisms is necessary for identifying the physiologic basis for the spectrum of sleep-related breathing disorders and their appropriate clinical management.

Chapter 16

Respiratory Physiology: Understanding the Control of Ventilation

Danny J. Eckert; Jane E. Butler

Chapter Highlights

- In the absence of respiratory disease, the process of breathing typically is afforded little conscious thought. Yet it is clearly fundamental to survival.
- Multiple inputs are capable of regulating the rate and depth of breathing. These are regulated by feedforward and feedback mechanisms that control blood gas levels within relatively narrow limits to maintain homeostasis.
- The physiologic capacity to alter breathing is substantial. When metabolic demand decreases during sleep, even very low levels of ventilation can be tolerated. However, the major changes to the control of breathing that occur during sleep can cause breathing disruption.
- This chapter outlines the key neuroanatomic inputs to breathing, describes the changes that occur in the control of breathing during sleep, including differences between men and women, and highlights how abnormal control of ventilation can contribute to sleep-disordered breathing.

OVERVIEW OF THE CONTROL OF BREATHING

Breathing is controlled by means of highly effective feedforward and feedback mechanisms. Conceptually, the functional organization consists of three key elements: (1) brainstem neurons responsible for respiratory pattern generation (*central control*), (2) respiratory muscles that generate force to move airflow in and out of the lungs (*effectors*), and (3) multiple inputs that relay respiratory sensory information (*sensors*) to brainstem respiratory control centers to allow for adjustments according to the prevailing physiologic conditions (Figure 16-1). A breakdown in or damage to any one of these components can lead to breathing abnormalities. During wakefulness, however, additional inputs to breathing can compensate to maintain breathing and blood gas levels within acceptable levels despite damage to key elements that underlie the control of breathing. Accordingly, breathing problems often only emerge (or worsen) during sleep, when wakefulness compensatory mechanisms are either downregulated or absent. This chapter outlines the key components that underpin the control of breathing and highlights the major changes that occur during sleep. This chapter is a synthesis of many elements described in Chapters 15, 17, 18, and 24, plus Section 14 on Sleep Breathing Disorders, with a perspective aimed at translating the information toward a more comprehensive understanding of respiration and sleep disturbances in humans.

CENTRAL CONTROL OF BREATHING

The precise neuroanatomic locations that contribute to respiratory pattern generation within the brainstem are incompletely understood. The central respiratory control network involves both inspiratory and expiratory neurons. Presented next is a brief summary of some of the key brainstem sites and their interconnections, based primarily on animal models.

Central respiratory control and rhythmicity occur within the pons and medulla. Within the medulla, the dorsal and ventral respiratory groups are particularly important (Figure 16-2). The *dorsal respiratory group* contains the nucleus tractus solitarius (nTS). The nTS is a key cardiorespiratory sensory integration site. Afferent information from phrenic, vagus, and peripheral chemoreceptors (by way of the glossopharyngeal nerve) arrive at the nTS. The nTS has numerous outputs contributing to important control of breathing centers, including the nearby retrotrapezoid nucleus[1,2] (see the following section on chemoreceptors). The ventrolateral region of the nTS is believed to be particularly important for inspiratory activity. Major projections also extend to other key respiratory control centers within the ventral respiratory group. Not yet known, however, is whether direct output to respiratory motoneurons occurs.

The pre-Bötzinger complex forms part of the *ventral respiratory group* (see Figure 16-2). The pre-Bötzinger complex is believed to be the major putative respiratory pacemaker. This stems from findings that show persistence of respiratory rhythmicity within these cells in minimal slice preparations.[3] In support of the importance of this region to respiratory control, the pre-Bötzinger complex has multiple projections to other known respiratory control sites within the brainstem.[4] Adjacent to the pre-Bötzinger is the Bötzinger complex. This area plays an active role during expiration by inhibiting respiratory motor neurons to modulate the overall motor output. The rostral ventral respiratory group also includes inspiratory pre-motoneurons such as those located in the nucleus ambiguus. The nucleus ambiguus provides respiratory motor output to the larynx and pharynx by way of the vagi. The nucleus

retroambiguus also may contribute to respiratory rhythm generation.[5]

Although respiratory rhythm generation neurons are located predominantly within the medulla, the *pontine respiratory group* (previously referred to as the pneumotaxic center) also is importantly involved in central respiratory control[6] (see Figure 16-2). The pontine respiratory group includes the nucleus parabrachialis medialis, containing expiratory active neurons. The parabrachialis lateralis and the Kölliker-Fuse nucleus in the upper pons contain inspiratory neurons. Pontine respiratory group activation can decrease inspiratory activity within the dorsal respiratory group, leading to a decrease in inspiratory time. This "inspiratory-expiratory phase transition" can increase breathing frequency.

CHEMICAL CONTROL OF BREATHING

Chemical control is the most important regulator of breathing in healthy persons during quiet breathing. This is true during both wakefulness and sleep. All cells are capable of modifying their activity in response to extreme changes in the chemical environment. Certain cells, however, are highly sensitive to quite minor changes. These chemically sensitive areas can regulate the control of breathing directly or have projections to central control of breathing sites. Accordingly, these groups of cells, known as *chemoreceptors*, are fundamentally important to the control of breathing.

Peripheral versus Central

Chemoreceptors are located peripherally and centrally (Figure 16-3). The main peripheral chemoreceptors lie at the bifurcation of the common carotid arteries. The carotid bodies have long been known to respond to changes in oxygen, carbon dioxide, and hydrogen ion concentration.[7] Detection of these stimuli can lead to rapid alterations in breathing (within 1 or 2 breaths). In addition, recent findings show that the carotid bodies respond to a wide range of other stimuli including potassium, norepinephrine, temperature, glucose, insulin, and immune-related cytokines.[7,8] Repeated exposure to hypoxia can cause plasticity within the carotid bodies.[8] The changes that occur can contribute to pathologic states including an increased propensity for breathing instability during sleep.[7,8] In addition to the carotid bodies, the nearby aortic bodies are also capable of responding to changes in oxygen and other

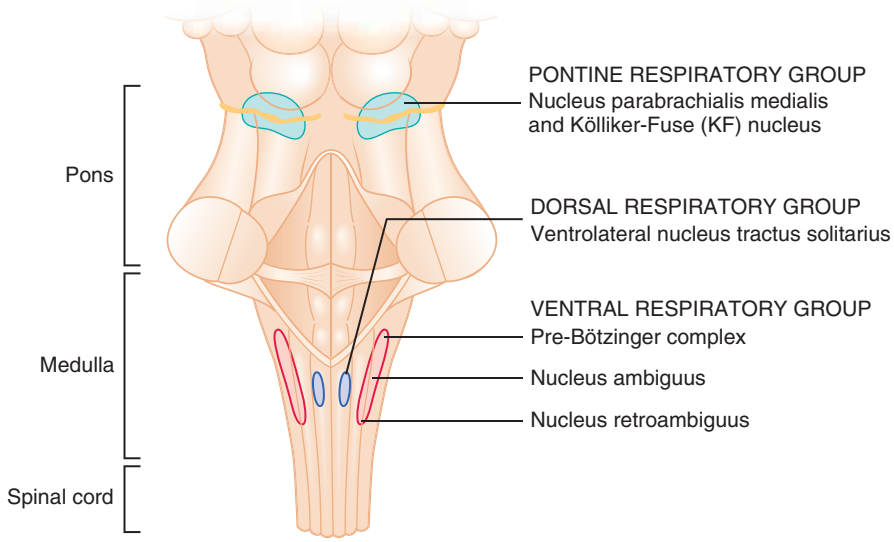

Figure 16-2 Central Control of Breathing. Major regions involved in the central control of breathing lie within the pontine respiratory group, comprising the nucleus parabrachialis medialis and the Kölliker-Fuse nucleus; the ventral respiratory group, consisting of the pre-Bötzinger complex, nucleus ambiguus, and nucleus retroambiguus; and the dorsal respiratory group, comprising the ventrolateral nucleus tractus solitarius. Figure 16-3 Inputs to Breathing. Schematic of the multiple inputs that are capable of regulating breathing. During sleep, many of these inputs are either substantially diminished (*dashed red lines*) or absent (*solid red lines*). Thus the predominant inputs to breathing during sleep are the chemoreceptors, which themselves also are downregulated and affected by state. *Note*: For simplicity, voluntary control of breathing is shown to act by way of the respiratory centers. Whether this is in fact the case or whether voluntary control acts directly on the respiratory motoneurons, however, has not been established. Refer to text for further details. chemical stimuli. Although the peripheral chemoreceptors are important for moment-to-moment modulation of breathing, the most powerful input to breathing during quiet wakefulness is from the central chemoreceptors.

Located on the ventral surface of the medulla, adjacent to the ventral respiratory group, lies the retrotrapezoid nucleus. This region is particularly important for central chemoreception.[9,10] The retrotrapezoid nucleus has major projections to key respiratory control centers including to the nTS within the dorsal respiratory group.[1,2] The central chemoreceptors respond to P_{CO_2} through changes in the pH of the extracellular fluid. CO_2 diffuses across the blood–brain barrier to increase hydrogen ion concentration in the cerebrospinal fluid. Thus, compared with the relatively fast-responding peripheral chemoreceptors, central chemoreceptors can take up to a minute to respond to changes in chemical stimuli. As discussed later, chemoreceptor response delays are critically important in mediating cyclicbreathing instability during sleep.[11-13]

Although the peripheral and central chemoreceptors are anatomically distinct and have different response characteristics, recent findings indicate complex interconnectivity.[7,8,14] Specifically, the activity of the central chemoreceptors is critically dependent on the activity of the peripheral chemoreceptors, and vice versa.[7,8,14]

OTHER INPUTS TO BREATHING

In addition to input from the chemoreceptors, other important inputs and sensors can contribute to the rate and depth at which we breathe (see Figure 16-3). Receptors in the limb muscles and joints can respond to movement to increase minute ventilation. Similarly, when receptors responsible for touch, temperature, and pain are stimulated, breathing increases. An independent stimulus to breathing known as the *wakefulness drive to breathe* also may be recruited.[15] Conversely, overinflation or excess lung stretch can inhibit minute ventilation by means of the Hering-Breuer reflex.[16] Other inputs can either stimulate or inhibit breathing. These inputs include limbic system input in response to emotional stimuli or voluntary cortical control. It remains uncertain, however, if voluntary override of breathing acts indirectly through

changes in central respiratory pattern generation or directly by way of phrenic motoneurons, or by a combination of both.[17] Nonetheless, the physiologic capacity to alter breathing is substantial. As highlighted later, when metabolic demand decreases during sleep, very low levels of ventilation (less than 5 L/minute) can be tolerated. Conversely, during intense exercise, ventilation can increase to greater than 200 L/minute.

STATE-RELATED CHANGES IN THE CONTROL OF BREATHING

Major changes in the control of breathing occur from wakefulness to sleep. The most significant change that occurs from wakefulness to sleep is that a majority of the inputs capable of modifying breathing are either absent or markedly downregulated (see Figure 16-3). Accordingly, chemical control of breathing is the dominant driver of breathing during sleep. In particular, CO_2 is critical in mediating breathing during sleep. Certain disease states adversely affect the chemical control of breathing and can cause sleep-disordered breathing in susceptible persons. This section outlines key state-related changes in the control of breathing that underlie cyclic breathing instability during sleep.

Sleep Onset

Respiratory control is inherently unstable during the transition from wakefulness to sleep.[18] Several factors contribute to respiratory instability at sleep transition. Certain components of respiratory control change rapidly with sleep onset, whereas others require more time. Mismatch in timing combined with downregulation in important respiratory control mechanisms underlies breathing disturbances during the sleep-onset period. Indeed, brief breathing stoppages at sleep onset are very common, even in otherwise healthy persons.

With respect to mechanical factors, the wakefulness drive to breathe and behavioral influences cease with sleep onset.[19] Movement and excitatory input to breathe from other external sensors become minimal or completely absent. Chemosensitivity also decreases[20] (see Figure 16-3). Accordingly, respiratory pump muscle tone is reduced, leading to a reduction in minute ventilation.[21] An abrupt reduction in upper airway muscle tone and protective reflexes also occurs with sleep onset.[21-25] These changes contribute to increased upper airway resistance.[23] The timing and magnitude of these changes vary among individual subjects. Rapid withdrawal of excitatory drive to breathing, in and of itself, can cause respiratory events as a consequence of the delay required to elicit a compensatory response from the chemoreceptors.[26] Patients who experience sleep apnea appear to be more prone than healthy control subjects to major reductions in the wakefulness drive to breathing.[27] As indicated by these findings, sleep onset affects all components of respiratory control and can cause major "state instability."

Stable Sleep

The removal of most excitatory inputs to breathing that occurs with sleep onset is a feature of stable sleep as well. Respiratory load compensation also is reduced during stable sleep compared with wakefulness.[28] Thus minute ventilation decreases during stable sleep, and the control of breathing becomes dominated by chemical input. However, downregulation in chemosensitivity is not isolated to the sleep-onset period. Ventilatory responses to hypoxia are reduced during stage 2 (N2) and slow wave sleep (N3), compared with wakefulness, such that major decreases in oxygen levels are required to stimulate breathing during sleep.[29-31] Accordingly, CO_2 is the main regulator of breathing during sleep. However, ventilatory responses to hypercapnia also are reduced during sleep compared with wakefulness, albeit to a lesser extent than for hypoxia.[32] Consequently, people can tolerate lower levels of minute ventilation and higher levels of CO_2 during sleep than in wakefulness. Typically, depending on the prevailing metabolic conditions, minute ventilation is reduced by 1 to 2 L/minute, and the partial pressure of carbon dioxide in the blood ($Paco_2$) increases by 3 to 8 mm Hg during stable sleep, compared with wakefulness[33] (Figure 16-4, *A*).

In the absence of respiratory disease, breathing is quite regular during stable non–rapid eye movement (NREM) sleep. Rapid eye movement (REM) sleep, by contrast, is characterized by breathing irregularity. Many medullary central control-of-breathing regions exhibit increased activation during REM compared with NREM sleep.[34] In humans, breathing frequency increases, and major variations are seen in breath-to-breath tidal volume. Active eye movements during REM sleep are associated with inhibition of upper airway dilator muscle activity and decreased tidal volume.[28,35] Protective upper airway reflexes also are inhibited.[36] Accordingly, obstructive apnea is common during REM sleep.

Brief Awakenings (Arousal from Sleep)

Brief cortical arousals from sleep lasting less than 15 seconds occur between 10 to 20 times per hour in healthy subjects. Arousal frequency increases with age.[37] Arousals can occur spontaneously or in conjunction with a sleep disorder such as sleep apnea or periodic limb movement disorder. Historically, arousals were believed to be essential for reopening the upper airway during obstructive breathing events.[38] Indeed, arousal can be beneficial in certain circumstances to rapidly resolve blood gas disturbances and to alleviate the increased work of breathing during flow-limited breathing.[39] However, although the initial physiologic changes associated with arousals may be beneficial for respiratory homeostasis, the rapid switch from sleep to wakefulness and the subsequent resumption of sleep can be highly destabilizing for respiratory control.[39] The extent to which arousals destabilize breathing and contribute to central or obstructive breathing events is dependent on two key features: (1) the subject's threshold for arousal—the *arousal threshold*—and (2) the ventilatory response to arousal.

Arousal Threshold

Whether an arousal occurs spontaneously, with a periodic limb movement, or in association with a respiratory disturbance, a person who wakes up easily (i.e., has a *low arousal threshold*) may be susceptible to sleep-state breathing instability. Specifically, a predisposition to sleep-onset breathing instability coupled with a low arousal threshold may lead to repetitive breathing disturbances as the affected person oscillates between wakefulness and sleep.[11] Approximately one third of patients with obstructive sleep apnea arouse to modest levels of respiratory stimuli (negative airway pressure less than 15 cm H_2O).[39,40] This relatively low threshold is likely to contribute to their sleep-disordered breathing.[39] Increasing the arousal threshold in these at-risk patients can stabilize

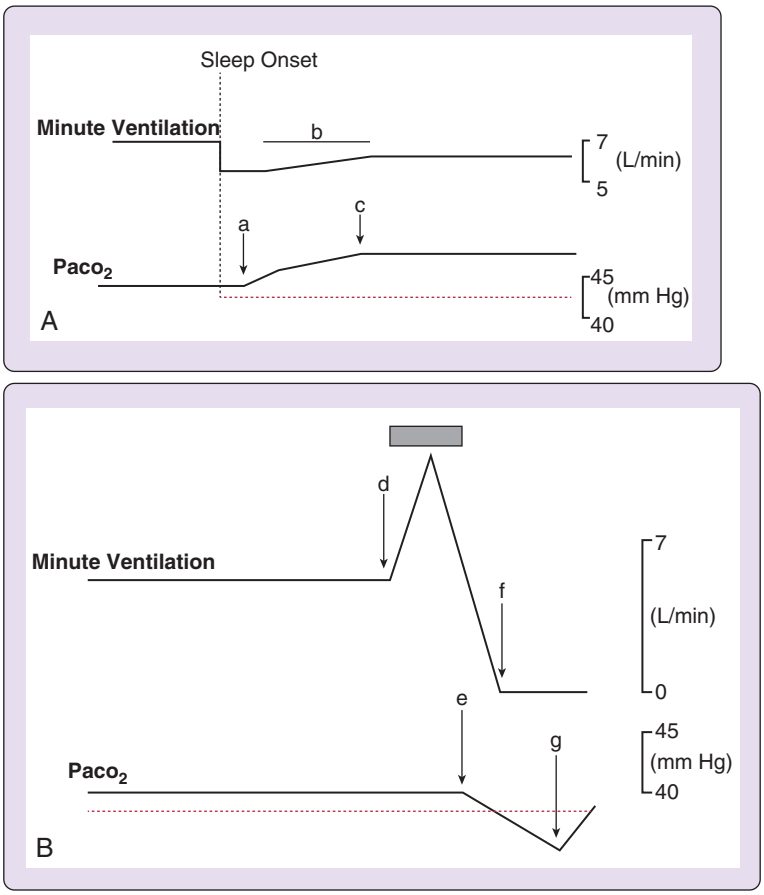

Figure 16-4 Sleep State Changes to the Control of Breathing. **A,** Schema showing typical changes in minute ventilation and $PaCO_2$ from wakefulness to sleep. At sleep onset (*dashed vertical line*), a rapid reduction in minute ventilation (from 7 to 5 L/min) occurs. A delay between the reduction in ventilation and changes in $PaCO_2$ (sleep onset to point a) also is seen. As CO_2 rises, upper airway muscles may be recruited, and minute ventilation may increase somewhat (period b), until a new eucapnic sleeping minute ventilation (5.5 L/min) and $PaCO_2$ (45 mm Hg) are reached (point c). The *horizontal red line* represents the theoretical apnea threshold (in this case, 39 mm Hg). **B,** Schematic representation of a central apnea after an arousal from sleep. At point d, a brief arousal from sleep occurs (arousal duration represented by the *gray box*). Hyperventilation occurs in association with reintroduction of wakefulness stimuli (ventilatory response to arousal). The hyperventilation lowers $PaCO_2$. However, a delay between the change in ventilation and the change in $PaCO_2$ can be seen (point d to point e). As the patient returns to sleep, the reduction in $PaCO_2$, caused by the ventilatory response to arousal, falls below the apnea threshold (which in this example is very close to the eucapnic sleeping $PaCO_2$ level), and apnea occurs (point f). The apnea leads to an increase in $PaCO_2$ until either an arousal occurs, and the cycle is repeated, or the apnea threshold is crossed and breathing resumes. Refer to text for further details. breathing.[41] Indeed, although the precise mechanisms remain uncertain, the arousal threshold and upper airway muscle activity increase in deeper stages of sleep, and sleep-disordered breathing severity decreases.[42-44] Not known, however, is whether deeper stages of sleep are intrinsically more stable in terms of respiratory control or if breathing stability allows sleep to deepen.

Ventilatory Response to Arousal

In much the same way in which rapid changes in respiratory control occur during sleep onset, arousal from sleep causes a rapid change in the homeostatic control of breathing. As highlighted, during stable sleep, lower levels of minute ventilation and higher levels of CO_2, compared with wakefulness (~3 to 8 mm Hg higher), can be tolerated. With arousal, the wakefulness chemical control of breathing is reinstated, and the increased levels of CO_2 that were tolerated during sleep suddenly become excessive. Upper airway motoneurons are activated, and sleep-related upper airway resistance is rapidly resolved.[45] The wakefulness drive to breath also is reintroduced. Accordingly, arousal from sleep is associated with a rapid increase in breathing. The magnitude of the ventilatory response to arousal is dependent on the integrative effects of the various aforementioned factors and may be further augmented by an independent wakefulness reflex.[46] Indeed, this ventilatory arousal response varies substantially among subjects.[47] As outlined next, on the resumption of sleep, the previous ventilatory response to arousal can drive $Paco_2$ levels

below a critical level known as the apnea threshold[48] (see also Figure 16-4, *B*).

APNEA THRESHOLD

Multiple compensatory mechanisms act to oppose breathing cessation even with quite major reductions in $Paco_2$ during wakefulness (see Figure 16-3). During sleep, however, this is not the case. Specifically, if $Paco_2$ falls below a critical level during sleep, breathing ceases. The apnea threshold ranges between 2 and 6 mm Hg below the stable sleep $Paco_2$ level. Evidently, then, the apnea threshold is similar to the wakefulness $Paco_2$ level[49,50] (see Dempsey[51] for details). The difference between the wakefulness $Paco_2$ level and the apnea threshold often is termed the CO_2 reserve. The reduction in $Paco_2$ required to cause apnea is importantly dependent on the peripheral chemoreceptors.[52] Schematic examples outlining important state-related changes in the control of breathing are displayed in Figure 16-4.

Loop Gain

As outlined in this chapter, many inputs contribute to the control of breathing. Loop gain is one approach to conceptualize and quantify the overall sensitivity of the ventilatory control system (see also Chapters 15, 17, and 18 for respiration in high altitude). Specifically, the gain of the ventilatory control feedback loop can be quantified as the ratio of a ventilatory response to a ventilatory disturbance.[11,26,53] Loop gain has three major components: (1) *plant gain* (the efficiency of breathing to remove CO_2, which is determined by the properties of the lungs, blood, and body tissues), (2) *mixing and circulation delays* (the time required for a change in alveolar CO_2 to mix with the blood in the heart and the arteries before reaching the chemoreceptors), and (3) *controller gain* (the sensitivity of the chemoreceptors). Because CO_2 is the predominant modifier of ventilatory control during sleep, determining the loop gain during sleep provides important insight into the overall sensitivity of the ventilatory control system and allows for comparisons to be made between individual subjects and patient groups. Accordingly, techniques have been developed to quantify the steady state loop gain during sleep.[54,55] If certain elements that contribute to loop gain are abnormal (e.g., plant or controller gain), breathing instability can occur. Circulation delay is an integral component of breathing instability; without it, cyclic breathing would not occur. Of note, however, is that although increasing circulation delay increases the length and duration of breathing instability, increased circulation delay alone does not cause breathing instability.

Sex Differences

Sleep-disordered breathing in adults is more common in men than in women. Respiratory control differences between the sexes may contribute to this difference, at least in part. Progesterone is a respiratory stimulant, and sleep-disordered breathing is more common in women after menopause. Although ventilatory responses to CO_2 and hypoxia vary throughout the menstrual cycle, ventilatory responses during sleep to chemical stimuli do not appear to be systematically different between the sexes.[56,57] Consistent with these earlier observations, overall steady state loop gain is not different between men and women.[58,59] In accordance with increased vulnerability to breathing instability, however, important differences in breathing during sleep onset, the ventilatory response to arousal, and the apnea threshold have been observed between men and women.[18,60-62] Whether or not men have systematically lower arousal thresholds remains unclear.

CLINICAL MANIFESTATIONS

Altered respiratory control can contribute to various forms of sleep-disordered breathing. Many causes of abnormal respiratory control have been recognized. These topics are covered elsewhere in this book (Chapters 15, 17, and 24 and Section 14, Sleep Breathing Disorders) and have been the focus of comprehensive reviews.[11-13,63,64] Briefly stated, an abnormality in one or more of the components that importantly contribute to respiratory control as outlined in this chapter can cause breathing instability during sleep. Damage to central respiratory control centers or drugs that impair its function (e.g., certain brain tumors, Chiari type I malformation, morphine) can directly affect central respiratory control.[11-13] Congenital central hypoventilation syndrome is associated with major loss of chemosensitive neurons within the retrotrapezoid nucleus.[12] Heart failure is associated with heightened peripheral chemosensitivity and increased vulnerability to onset of apnea (i.e., crossing the apnea threshold). Conversely, patients with obesity-hypoventilation syndrome have blunted ventilatory responses to chemical stimuli and experience sustained hypoventilation and major blood gas disturbances during sleep.

As indicated by these findings, high and low loop gain can be problematic and can contribute to both obstructive and central breathing instability during sleep.[63] Indeed, approximately one third of patients who experience obstructive sleep apnea demonstrate abnormally high loop gain, which is likely to be an important contributor to the pathogenesis of their obstructive apnea.[40]

CLINICAL PEARL

Sleep is a particularly vulnerable time for respiratory control instability. Many of the potential compensatory inputs to breathing are markedly diminished or absent during sleep. Accordingly, regardless of the underlying cause, abnormality in one or more of the important contributors to respiratory control can cause sleep-disordered breathing. The sleep-related breathing instability that ensues is dependent on the extent to which the respiratory control system is altered and on which of the components of the respiratory control system are involved.

SUMMARY

An understanding of the control of ventilation provides important insight into the causes of various forms of sleep-disordered breathing. Ventilatory control is regulated by means of highly effective feedforward and feedback mechanisms that control blood gas levels within relatively narrow limits to maintain homeostasis. Many inputs have been recognized to regulate ventilatory control. Although these processes are predominantly under autonomic control,

voluntary modulation of breathing also is possible in various circumstances.

The dorsal, ventral, and pontine respiratory groups are key regions within the medulla and pons responsible for central respiratory control. Central (e.g., retrotrapezoid nucleus) and peripheral (e.g., carotid bodies) chemoreceptors provide essential sensory information to modify breathing. Other sensory systems also can provide input to alter the rate and depth of breathing. Most such systems, however, are either downregulated or absent during sleep. Accordingly, the chemical control of breathing—in particular, by CO_2—is the dominant input to ventilatory control during sleep. Sleep onset is particularly destabilizing to ventilatory control. Arousal from sleep and high loop gain can lead to marked fluctuations in CO_2 and to breathing cession during sleep if the apnea threshold is crossed. Abnormalities in one or more of the components that contribute to ventilatory control can contribute to both central and obstructive breathing events during sleep.

Physiology of Upper and Lower Airways

Raphael Heinzer; Frédéric Sériès

Chapter Highlights

- Sleep has an impact on ventilation and gas exchanges mediated through an increase in airway resistance and a decrease in lung volume and thoracopulmonary compliance.
- Upper airway stability can be altered during sleep because of its effects on upper airway muscle control and chest mechanics.
- When upper airway anatomy is compromised, these sleep-related effects can trigger obstructive disordered breathing.

This chapter focuses on the physiologic determinants of respiration used to estimate breathing function in normal persons. The ultimate goal is to allow readers who are not familiar with the field of respiratory medicine to benefit from the more subtle concepts that will help them to better understand sleep-disordered breathing. Chapters 15 and 16 describe the basis of the physiology and applied concepts of respiratory function during wake and sleep.

The dual aim of breathing is to provide oxygen to the different body parts and to eliminate carbon dioxide resulting from cell metabolism. This is achieved through continuous gas exchange between inspired and exhaled air and the blood in the pulmonary circulation. After blood coming from the right side of the heart has been loaded with oxygen, it passes to the left side of the heart, which sends it to every part of the body through the arterial system. The different organs then take up oxygen from the arterial blood and remove carbon dioxide. Blood loaded with carbon dioxide travels through the venous system to reach the pulmonary circulation, where carbon dioxide passively diffuses through the alveolocapillary membrane into the airway, whence it is exhaled. Survival depends on the integrity of this physiologic process, and death can occur if respiratory function stops for more than a few minutes. Maintenance of normal arterial blood gases involves several physiologic systems—control of breathing, thoracopulmonary mechanics, circulatory components, and blood transport—that are intimately linked to one another. This chapter considers only the mechanical properties of the chest and the upper and lower airways, which influence ventilation during sleep (Box 17-1).

ANATOMY AND PHYSIOLOGY

The upper airway, which includes the nasal cavities, pharynx, and larynx, serves to moisten and warm the air and conduct it to the trachea and lungs. Upper airway muscles also are involved in phonation and swallowing. A very subtle regulation of vocal cord tension also allows humans to speak and sing during exhalation. It is hypothesized that the evolution of speech, which requires substantial mobility of the pharynx, led to a loss of the rigid support of the upper airway, which makes it more collapsible in humans than in most mammals.

Breathing is possible through either the nose or the mouth, but nasal breathing is the physiologic breathing route. The lower airway includes the trachea and the lungs (bronchi and alveoli). Thin blood vessels, the capillaries lining the alveoli, allow gas exchange between inspired air and blood. The rib cage provides protection for the lungs and also allows them to change volume from a minimum of approximately 1.5 L to a maximum of 6 to 8 L, depending on the height and sex of the person.[1]

The ribs articulate with the transverse processes of the thoracic vertebrae and have flexible anterior cartilaginous connections with the sternum. The lungs are covered by thin visceral pleura. The inner aspects of each hemithorax are lined with parietal pleura. The virtual space between the visceral and the parietal pleura contains a few milliliters of lubricating fluid, which allows these layers to slide against each other easily during ventilation. Owing to its proximity to the pleural tissue, the esophageal pressure varies in parallel with the changes in pleural pressure and often is used to quantify respiratory efforts.

Respiratory Muscles

The diaphragm is the main muscle of respiration. It is a dome-shaped muscle that separates the thoracic and abdominal cavities. The diaphragm is innervated by the phrenic nerves. During inspiration, the neural outflow coming from the central respiratory centers leads to diaphragm contraction; the shortening of those muscle fibers flattens the diaphragm, with consequent loss of its dome shape, thereby increasing intrathoracic volume. Intercostal muscles also can increase the intrathoracic volume by elevating ribs and increasing the anteroposterior diameter of the thorax (Figure 17-1). Accessory breathing muscles such as the scalene or sternocleidomastoid are not active during normal breathing, but they can be recruited during an effort or in the presence of thoracopulmonary disorders.

Elastic Forces and Lung Volumes

An isolated lung (not surrounded by the thoracic cage) will tend to contract until it eventually collapses owing to the large amount of elastic fibers inside the lung tissue. The lung is thus submitted to a constant recoil force. By contrast, the isolated thoracic cage tends to expand to a volume approximately 1 L more than its natural, in vivo resting position. In a relaxed subject with an open airway and no airflow, the inward elastic recoil of the lungs will be balanced by the outward resting force coming from the thoracic cage. *Lung compliance* or *distensibility* is defined as the change in lung volume per unit change in transmural pressure gradient:

$$\text{compliance} = \Delta V/\Delta P$$

where V is volume and P is pressure.

The lung volume, in the natural resting end-expiratory position, is its *functional residual capacity* (FRC). *Total lung capacity* (TLC) is reached when the thoracic cage and lungs are fully expanded (maximal inspiratory effort). *Residual volume* (RV) represents the volume remaining in the lungs at the end of a forced expiration. *Vital capacity* (VC) is the maximum amount of air that can be expelled after the lungs have been fully inflated. *Tidal volume* (V_T) is the volume of air inspired or expired during each quiet breathing cycle (Figure 17-2). The typical V_T value is 500 mL, but it can dramatically increase during exercise. Only approximately two thirds of inspired air participates in oxygen and carbon dioxide exchange, because the volume corresponding to upper airway, trachea, and bronchi does not contribute to gas exchange; this area is the *dead space* (V_{DS}) of the respiratory tract.[1]

Breathing Cycle and Minute Ventilation

Air always flows from an area of higher pressure to one of lower pressure, to achieve equilibrium. The pressure inside the pleural space is generated by the forces developed during inspiration and expiration and is proportional to the amount of respiratory effort. The pleural pressure represents the driving pressure. During inspiration, the diaphragm and intercostal muscles contract and the pressure inside the thorax decreases below the atmospheric pressure (negative transpulmonary pressure gradient). This gradient is responsible for air movement from the nose (atmosphere) to the tracheobronchial tree down to the alveoli. During expiration, the inspiratory muscles relax, making resting expiration a passive phenomenon. However, during active expiration (volitional or during exercise), the contraction of abdominal and external intercostal muscles enhances the changes in intrathoracic pressure. This causes an abrupt increase in pleural pressure to a less-negative value, with a corresponding rise in alveolar pressure by the same amount. These changes generate a positive pressure gradient from the alveoli to the mouth, which is responsible for exhalation. Lung and chest volume decrease as air flows out, causing lung recoil pressure to fall until a new equilibrium is reached at FRC.

Respiratory rate, or breathing frequency, represents the number of breaths per minute. Average respiratory rate in a healthy adult subject at rest is approximatelyt 12 (range, 10 to

18) breaths/minute. Minute ventilation ($\dot{V}$) can be calculated using the following equation:

$$\dot{V} = V_T \times RR$$

where RR is the respiratory rate. During quiet breathing, a typical value is 6 L/minute, but the volume can rise to 180 L/minute during exercise.

Resistance

Different profiles of airflow may be observed inside the airways, depending on airway anatomy (in accordance with the specific division of the tracheobronchial tree) and mechanical properties (caliber, shape, collapsibility) of the airway structures and on the amount of driving pressure. With a constant laminar flow regimen, the resistance is directly proportional to the pressure gradient along the tube:

$$\text{flow} = \Delta P / R$$

where ΔP is the pressure difference and R is the resistance. Airflow is described as *turbulent* when the pressure drop along the airway is proportional to flow and its square values:

$$\Delta P \propto aV + bV^2$$

where ΔP is the pressure difference and V is the airflow. Airflow along airways is complex and usually consists of a mixture of laminar and turbulent flow. In normal lungs, respiratory resistance depends mainly on airway diameter. The velocity of airflow and airway diameter decrease in successive airway generations, from a maximum in the trachea to almost zero in the smallest bronchioles.

A third flow regimen is represented by flow limitation, whereby flow plateaus once the driving pressure has reached a given level. In this regimen, the flow value depends on the difference between intraluminal and extraluminal pressures, as well as on the compliance of the specific airway. Flow limitation can occur during expiration when the pressure generated by expiratory forces increases intraluminal pressure and induces an external compression of the airway walls at the same time. This pattern of flow is, however, more prone to be seen during inspiration at the level of the upper airway. Upper airway resistance depends on nasal and pharyngeal anatomy, position of the vocal cords, and lung volume (see later).

EFFECTS OF OBESITY AND BODY POSTURE ON LUNG VOLUMES

In an awake normal and healthy subject, a reduction in FRC and TLC is observed in the supine position in comparison with the upright position, both in adults[2] and in children.[3] This reduction is thought to be due to an increase in intrathoracic blood volume or to the gravitational effect of abdominal contents pushing the relaxed diaphragm into a more rostral position.[4] The change in diaphragm position reduces its ability to contract, as suggested by a decreased maximal inspiratory pressure in the supine posture relative to that in the upright and sitting positions.[5] Moreover, this restrictive defect in lung volume increases the work of breathing and deteriorates gas exchange by decreasing the ventilation-perfusion ratio in the dependent parts of the lungs. Decreased lung volume also can increase upper airway resistance by reducing the caudal traction of the mediastinum and trachea on the pharyngeal walls, making them more collapsible during inspiration (as discussed further later on).[6-9]

In obese subjects, a restrictive defect in lung volume also is observed in the sitting position. A further small decrease of 70 to 80 mL from approximately 2.4 L (for an average-sized man) in FRC and TLC occurs when obese subjects lie supine.[2] In view of the effects of abdominal volume on lung function in sitting obese subjects, a greater reduction in lung volume with adoption of the supine position compared with that in lean persons might be expected. However, a lesser decline in FRC and TLC in obese subjects in the supine position has been documented.[2,4,10] One possible explanation is that in sitting obese subjects, the diaphragm is already shifted in a more rostral position and cannot move much farther in the supine position. Two experimental studies also suggest a possible protective or adaptive mechanism against large changes in end-expiratory lung volume during wakefulness[11] and sleep.[12]

Maximal minute ventilation, expiratory reserve volume, FVC, and, to a lesser extent, forced expiratory volume in 1 second (FEV_1) also are affected by obesity.[13] The estimated reduction of FVC is 17.4 mL/kg weight gain for men and 10.6 mL/kg weight gain for women.[14] Men show more impairment of FVC with weight gain than women, possibly because of differential patterns of fat deposition: Waist circumference is negatively associated with FVC and FEV_1. On average, a 1-cm increase in waist circumference was associated with a 13-mL reduction in FVC.[15] All of these effects observed with change from the upright to the supine position and in obese persons may contribute to the exacerbation of respiratory disturbances in the presence of sleep-disordered breathing, as described in later chapters on that topic (Section 14).

EFFECTS OF SLEEP ON LUNG VOLUME

A modest but significant decrease in FRC occurs during sleep in most healthy subjects. FRC decreases by approximately 200 mL in stage 2 non–rapid eye movement (NREM) sleep and by 300 mL during slow wave sleep and rapid eye movement (REM) sleep when measured with a helium dilution technique, in comparison with normal FRC obtained with the subject awake (approximately 2.4 L for an average-sized man).[16] When plethysmography is used to measure differences in lung volume, a 440- to 500-mL decrease in lung volume has been reported in NREM sleep (stages 2 to 4), with a similar decrease in REM sleep.[17] Possible mechanisms of the decrease in FRC during sleep are rostral displacement of the diaphragm secondary to diaphragmatic hypotonia, alteration of the respiratory timing from the central generator of breathing, decrease in lung compliance, decrease in thoracic compliance, and central pooling of blood (see Chapters 15 and 16).

A reduction in tidal volume by approximately 6% to 15% has been reported during NREM sleep (stages N2 and N3), with a further decrease during REM sleep (approximately 25% lower than during wakefulness).[18,19] Minute ventilation is significantly lower during all NREM sleep stages compared with wakefulness and decreases further during REM sleep,

especially during phasic REM (approximately 84% of the level during wakefulness)[18-21] (Figure 17-3). The decrease presumably is due to a faster and shallower breathing pattern in all sleep stages with a lower tidal volume, especially during REM sleep. This explanation is, however, controversial, because another study showed no significant change in V_T between wakefulness and any sleep stage and suggested that the decrease in minute ventilation (8% in NREM and 4% in REM sleep) is due to a decrease in respiratory rate.[22] Nevertheless, most studies agree that during NREM sleep, the rib cage's contribution to V_T increases, in association with an approximately 34% increase in the activity of intercostal muscles.[21-23] There is thus an apparent contradiction between the increase in electromyogram (EMG) activity of thoracic muscles and a decrease in minute ventilation. A possible explanation is that even though muscle activity increases, the actual negative thoracic pressure decreases because of a decrease in the efficiency of muscle contraction during NREM sleep.[24] During REM sleep, the relative contribution of the rib cage and abdomen is not significantly different from that during wakefulness.[21] Age and sex do not seem to significantly alter sleep-related changes in lung volume.

Minute ventilation ($\dot{V}_E$), tidal volume (V_T), and breathing frequency (f) during wakefulness and different sleep stages are illustrated. $\dot{V}_E$ is reduced during NREM sleep, with a further reduction in REM sleep. +, $P < .05$ versus awake; X: $P < .05$ versus REM sleep. EFFECTS OF SLEEP ON BREATHING PATTERN AND BLOOD GASES

During NREM sleep, the decrease in minute ventilation induces a drop in Pao_2 of 3 to 9 mm Hg and an increase in $Paco_2$ and $Paco_2$ levels ranging from 2 to 4 mm Hg.[25,26] During stable NREM sleep, the breathing pattern usually is regular. However, periodic breathing with waxing and waning ventilation commonly is observed at sleep onset (unstable NREM sleep).[27,28] Complete cessation of breathing for more than 10 seconds with respiratory effort (obstructive sleep apnea) or without respiratory effort (central sleep apnea) can even occur at this time in healthy persons. In these circumstances, the transient periodic breathing seems to be due to an unstable ventilatory feedback loop (loop gain). A low arousal threshold during this stage also can induce instability in the sleep-wake cycle and contribute to unstable breathing. Because of the higher CO_2 set point during sleep, arousals are associated with a sudden increase in ventilation, which will then decrease CO_2 level. If the CO_2 level is below the apnea threshold (below which the central respiratory drive is abolished) when sleep resumes, an apneic interval can occur and breathing will resume only when the CO_2 level again reaches the sleep set point. The magnitude and the breathing fluctuation depend on several factors such as chemoreceptor sensitivity (controller gain), lung-to-chemoreceptor circulation delay, and the efficiency of the respiratory system in inducing changes in CO_2 level (plant gain) (see also Chapter 16).[29] The relative effects of each loop gain component can be evaluated using a validated model.[30]

During REM sleep, ventilation is notably variable in both amplitude and frequency. This heterogeneity seems to be directly related to the intensity of phasic activity, as indicated by bursts of eye movements. Specifically, phasic REM activity, characterized by a high density of rapid eye movements and muscle twitches, seems to have an inhibitory influence on ventilation.[19] Overall alveolar ventilation tends to fall by approximately 20% compared with wakefulness, mainly because of a fall in tidal volume.[21]

Upper Airway

Among the mechanical determinants of ventilation just summarized, the upper airway plays a unique role because its mechanical properties are dramatically affected by sleep.

The airway can be divided into intrathoracic and extrathoracic components. These include the upper part of the trachea, the larynx, and the different pharyngeal (nasopharynx, velopharynx, orophrarynx, hypopharynx) segments. The upper airway corresponds to the pharyngeal and laryngeal structures. The airway should remain open throughout the respiratory cycle. The intrathoracic, tracheal, and laryngeal airway structures are supported by cartilaginous structures that prevent them from collapsing during tidal breathing in normal persons. Pharyngeal airways do not have such rigid support and are prone to close in conditions of imbalance between the forces that tend to dilate or close them.

From a mechanical standpoint, the upper airway behaves as a Starling resistor, in which the pharyngeal airway represents the collapsible segment and is situated between two noncollapsible structures (larynx and nasopharynx). The flow

pattern depends on the forces applied inside and outside the collapsible segment. The transmural pressure gradient is the net pressure difference between all of these opposite forces. The collapsing forces are represented by the negative inspiratory transmural pressure gradient and the pressure applied by upper airway tissue (Figure 17-4). The contraction of upper airway stabilizing muscles (upper airway dilators) is the main dilating force, the other being represented by tracheal traction (Figure 17-4). Therefore the amount and timing of the neuromuscular activation process of upper airway stabilizing muscles and the mechanical properties of upper airway tissues play a pivotal role in determining upper airway stability.

According to the Starling resistance model,[31] inspiratory flow increases with rising inspiratory efforts (driving pressure) up to a maximal value and then plateaus independently of respiratory efforts (Figure 17-5, *A*). These features of the flow-pressure relationship characterize a flow limitation regimen. The steepness of the initial rise in flow depends on the resistance upstream and downstream of the collapsing site. The pressure at which flow begins to plateau depends on upper airway mechanical properties. The critical pressure (Pcrit) represents the pressure at which the dilating forces cannot overcome the collapsing ones, leading to upper airway closure. The changes in maximal inspiratory flow with modifying upstream pressure can be used to determine Pcrit and resistance upstream to the collapsing site. A linear positive relationship between these variables can be shown (Figure 17-5, *B*). The slope of the relationship corresponds to the reciprocal of upstream resistance, and the pressure at which flow is zero represents Pcrit. In a given subject, an increase in the propensity for the upper airway to occlude translates the flow-pressure relationship to the right, without changes in slope (i.e., slope a to slope b), making the Pcrit value more positive. In the situation of a decrease in upstream resistance, the steepness of the slope will rise (greater changes in flow occur with changing upstream pressure), but the Pcrit value will remain unchanged (i.e., slope a to slope c on Figure 17-5, *B*).

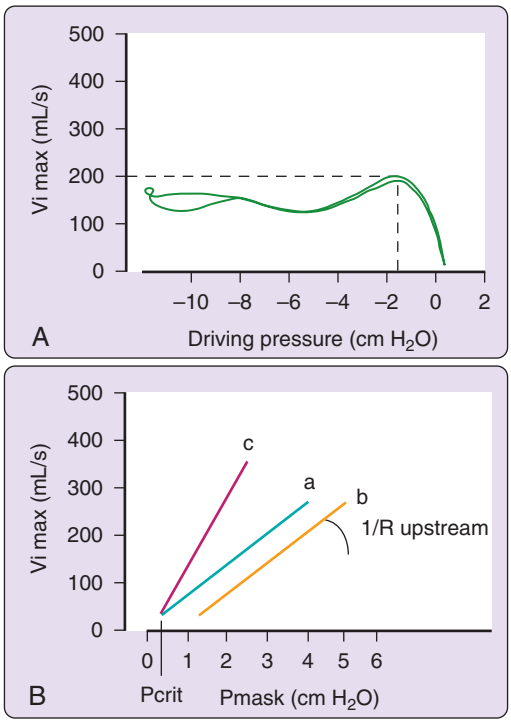

Figure 17-5 **A,** The *upper panel* is a representative example of the relationship between the respiratory flow over the driving pressure during a flow-limited breath. The instantaneous flow value reaches a maximum value and then plateaus despite the continuous decrease in driving pressure. **B,** Typical relationship between flow and upstream pressure during a series of flow-limited breaths. An increase in the instability of the upper airway will be accompanied by a right shift of the flow-pressure curve (slope b). A decrease in upstream resistance will increase the slope of the flow-pressure curve (slope c). Collapsing Forces

The negative intrathoracic pressure generated by diaphragmatic contraction is transmitted to the whole airway, from the alveoli to the nose, to create inspiratory flow. At the pharyngeal level, the difference between intraluminal and peritissue pressures (transmural pressure) represents a suction force that tends to dynamically close the upper airway. According to the Bernoulli principle, the pressure along the walls of a tube drops with the increase in its velocity, making the intraluminal pressure decrease (become more negative) with increasing inspiratory flow. Changes in flow from a laminar to a turbulent pattern increase air velocity near airway walls, which will further reduce intraluminal pressure.

The weight of upper airway tissue significantly influences upper airway stability. In animals, upper airway critical pressure increases proportionally to the weight applied to the hyoid arch.[32] This correlation could account for the fact that positive pressure needs to be applied to open the upper airway during anesthesia with paralysis in patients with sleep apnea,[33] who are known to have large amounts of muscular and adipose tissue surrounding the upper airway.[34] See Chapter 148 for more information on anaesthesia effects in sleep apnea patients. On the other hand, negative pressure applied around the neck significantly unloads the upper airway,[35] and resection of upper airway tissue improves Pcrit in patients with sleep apnea.[36]

Dilating Forces

Contraction of inspiratory muscles—diaphragm, intercostals, and accessory muscles—leads to lung inflation. The downward movement of the diaphragm produces a longitudinal traction of the bronchi and of the trachea. This traction is transmitted to the upper airway, where it contributes to unloading of that region.[37] From a dynamic perspective, tracheal traction improves upper airway stability by unfolding upper airway soft tissue and by decreasing extraluminal airway pressure.[38,39]

Numerous upper airway stabilizing muscles (such as the genioglossus, levator palatini, tensor palatini, geniohyoid, musculus uvulae, and palatopharyngeus) contribute to the maintenance of upper airway patency (Figure 17-6). Activation of masseter and pterygoid muscles also may contribute to stabilizing the upper airway by their influence on the position of the mouth and the mandible.[40] The activation profile of the upper airway muscles is characterized by their tonic activity and the respiratory-related and afferent reflex–mediated phasic activities.[41] This last factor is an important determinant of activity of the upper airway muscles, the negative pressure developed inside the upper airway having a positive feedback on muscle activity through activation of tensoreceptor and mechanoreceptor pathways.[42]

Tonic activity contributes to the maintenance of the upper airway aperture, its obligatory fall during sleep leading to a reduction in upper airway volume.[43,44] Inspiratory phasic activity has an automatic component that is linked with the central respiratory activity through projections of premotor inspiratory neurons to the hypoglossal motor nucleus (as detailed in Chapter 15).[45] Neuromodulators—serotonin, norepinephrine, glutamate, thyrotropin-releasing hormone, and substance P—play a key and complex role in the activity of upper airway muscles.[46–49] In lean animals, resting tonic and phasic activities of the genioglossus muscles mainly depend on endogenous norepinephrine, rather than serotonin drive on hypoglossal motor nucleus,[50,51] but these neuromodulators have similar stimulating effects.[50]

However, the influence of the serotonin drive on upper airway stabilizing muscle activity may be enhanced if upper airway patency is compromised, as demonstrated by the detrimental effects of serotonin antagonists (ritanserine) on upper airway caliber and stability, and on the occurrence on breathing abnormalities in animal models of obstructive sleep apnea.[52,53] Such changes in the balance of the norepinephrine-serotonin drive could result from facilitating hypoglossal nerve activities induced by intermittent hypoxia,[54] or from the relative vulnerability of norepinephrine and serotonin neurons to intermittent severe hypoxia.[55,56] Stimulation of peripheral chemoreceptors by intermittent hypoxia can lead to a prolonged rise in minute ventilation (long-term facilitation)[57,58] and a decrease in upper airway resistance (see also Chapter 16).[59,60] These ventilatory and upper airway facilitation effects are thought to be mediated by the serotonin-driven changes in activity of the phrenic and hypoglossal nerves[54,61] through

plasticity. In humans, posthypoxia upper airway facilitation is observed during sleep in conditions of flow-limited breathing (as in snorers and persons with sleep apnea)[60,62] but is not observed during wakefulness[63-65] unless periodic desaturation is associated with hypercapnia.[66]

Apart from the influence of the extent of phasic activation of upper airway muscles, the dynamic profile of this phasic activity plays a key role in the maintenance of upper airway patency. Phasic activation of upper airway muscles precedes and reaches its peak value earlier than that of respiratory muscles.[67,68] Phasic activity and the preactivation delay increase with increasing central respiratory activity[67,69] and with decreasing upper airway pressure.[70] This activation pattern decreases upper airway resistance and prevents upper airway inspiratory collapse. The occurrence of upper airway obstruction in normal awake subjects when this preactivation of upper airway stabilizing muscles is lost (as with diaphragmatic pacing, phrenic nerve stimulation, or iron lung ventilation)[71] further supports the importance of the upper airway muscle preactivation pattern in maintaining upper airway patency. The link that exists between ventilatory and upper airway stability (see later on) could result from the common activation process of respiratory and upper airway stabilizing muscles originating from the central pattern generator that would be responsible for the fine tuning in the amplitude and activation pattern of these different muscle groups.

Another phasic component comes from the reflex activation of upper airway muscles linked with the decrease in upper airway pressure during inspiration.[70] Upper airway mechanoreceptor afferents contribute to modulation of the different components of upper airway muscle activity, as suggested by the effects of local anesthesia on tonic and phasic activities[72] and on genioglossus reflex–mediated negative pressure response.[73,74] Accordingly, modulating any of these components of the upper airway muscle activation profile can have an influence on upper airway patency[75,76] and stability.[77-80]

EFFECTS OF SLEEP ON UPPER AIRWAY MUSCLE ACTIVITY

The loss of wakefulness stimulus contributes to the sleep-induced decrease in upper airway muscle activity.[81] Tonic and phasic upper airway activities are significantly altered during sleep.[82-84] The impact of sleep on the activation profile of upper airway muscles differs among the various muscles. The tensor palatini has a tonic activity, but the genioglossus, palatoglossus, and levator palatini demonstrate phasic activities. These activity levels are higher during wakefulness, but only tensor palatini activity consistently falls at sleep onset.[85] The decrease in tensor palatini activity correlates with the sleep-induced rise in upper airway resistance, and a compensatory rise occurs in genioglossus activity.[85]

The tensor palatini and genioglossus muscles strongly differ in their response to negative airway pressure during both wakefulness and sleep,[86] with no correlation being found between tensor palatini activity and driving pressure. Even if tensor palatini and genioglossus activities are governed by different efferent motor fibers (trigeminal motor nucleus versus hypoglossal motor nucleus), both activities depend on central neuromodulator drive.[87,88] The preferential decrease in upper airway muscle tonic activity observed during sleep[89] may relate to decrease in central excitatory drive to upper airway motor nuclei stemming from the loss of the awake corticomotor-stimulating drive and from a decrease in the stimulating effects of neuromodulators.[50,51,90,91] Sleep also may compromise upper airway stability by altering the pattern of preactivation of upper airway muscles.[92] The loss of such preactivation is associated with the rise in upper airway resistance and upper airway closure. The reappearance of alpha activity on the electroencephalogram (EEG) restores the normal preactivation pattern with a parallel drop in upper airway resistance and ventilatory resumption.

The neuromuscular activation processes of upper airway and respiratory muscles are closely linked. Tidal inspiration has a facilitating effect—increase in amplitude and reduction in latency of motor response—on diaphragm bulbospinal activity that is enhanced during sleep. This can be attributed to the loss of a wakefulness-related tonic depolarization of phrenic motor neurons, with secondary unmasking of the role of the bulbospinal command on the corticomotor excitability of the diaphragm. It is not known how sleep interacts with the facilitating effect of inspiration on upper airway muscle excitability.[93] On the other hand, some evidence indicates that breathing instability during sleep may promote upper airway closure.

Obstructive breathing disorders are mainly observed during stages N1 and N2 of NREM and REM sleep, when ventilation is physiologically unstable, and rarely during slow wave sleep, when breathing amplitude and frequency are particularly regular.[94] Breathing remains unstable (periodic) after resumption of upper airway obstruction with tracheostomy in patients with obstructive sleep apnea.[95] In normal sleeping subjects, the induction of periodic breathing can lead to partial upper airway obstruction.[96] Ventilatory stimulation with CO_2 decreases the occurrence of obstructed breaths in patients afflicted with sleep apnea.[97] In patients with a moderate increase in upper airway collapsibility, the frequency of obstructive sleep-disordered breathing correlates with the degree of breathing instability.[98]

FACTORS INFLUENCING STABILIZING AND COLLAPSING FORCES

For a given amount of upper airway neuromuscular outflow, the net mechanical effect of the neuromuscular activation process depends on the mechanical effectiveness of the contraction of upper airway stabilizing muscles.[99] Such function depends on factors such as the shape and dimensions of the upper airway. In fact, the amount of phasic activity required to maintain a given upper airway cross-sectional area increases when the upper airway axis converts from a transverse to an anteroposterior orientation.[100,101] Lung volumes influence upper airway dimension, as demonstrated by the decrease in pharyngeal cross-sectional area and the increase in upper airway resistance and collapsibility when lung volume decreases from TLC to residual volume.[102-104] Upper airway dimension also varies throughout the respiratory cycle, being maximal at the beginning of expiration and minimal at end expiration.[105] Vascular tone also interacts with upper airway collapsibility through its effect on upper airway dimension; the decrease in vascular tone or increase in vascular content decreases upper airway caliber but not upper airway collapsibility.[106] In these physiologic situations,

various factors as described can interact with upper airway patency to favor obstruction of the upper airway if upper airway stability is already compromised (i.e., with a highly compliant upper airway).

The mechanical conditions that prevail during muscle contraction also determine the force the involved muscles can develop. The suctioning effect of negative intraluminal pressure can result in a lengthening of upper airway muscles during inspiration (eccentric contraction)[107] that interferes with their ability to dilate the upper airway and leads to upper airway muscle fatigue and structural damage.[108-110] The characteristics of the soft tissues surrounding the upper airway muscles also influence the ability of these muscles to improve upper airway patency, the increase in tissue stiffness impeding the transmission of the dilating force to the upper airway structure.[111]

CONCLUSIONS

Numerous factors are involved in the regulation of normal breathing, including a predominant role of different muscles such as respiratory and upper airway muscles as well as the mechanical conditions that determine the effectiveness of their contraction. Sleep can interfere with several determinants of normal ventilation such as ventilatory control, skeletal muscle activity, and lung volumes. Therefore, because of the influence of thoracopulmonary mechanics on upper airway patency and the close link between respiratory and upper airway muscles, sleep also has a strong impact on upper airway aperture and mechanical properties. Careful delineation of sleep-related changes in respiratory physiology is key to improving our knowledge of sleep-disordered breathing, because these principles are involved in all nocturnal breathing disturbances: hypoventilation, periodic breathing, central apnea, and upper airway closure.

CLINICAL PEARL

Numerous factors contribute to ventilation and mechanical properties of the thoracopulmonary system. Because sleep interacts with several of these factors, it has an impact on ventilation and gas exchanges through its effect on airway resistance, thoracopulmonary compliance, and lung volumes. As a consequence of its effect on upper airway muscle control and chest mechanics, sleep has a strong influence on upper airway stability. Accordingly, persons with compromised upper airway anatomy are at increased risk for development of obstructive sleep-induced disordered breathing, especially during the transition between wakefulness and sleep.

SUMMARY

The respiratory system can be divided into two compartments, the upper and lower airways. The mechanics of both compartments are strongly influenced by sleep. Lung volume, rib cage muscle activity, and minute ventilation tend to decrease during sleep, as does the activity of upper airway stabilizing muscles. The upper airway also plays a critical role in determining ventilation and breathing pattern during sleep. Its patency is influenced not only by pharyngeal and orofacial muscle activity but also by thoracopulmonary mechanics. Sleep therefore has a strong impact on upper airway aperture and mechanical properties. Even though obesity and susceptible pharyngeal anatomy are important contributors to the development of sleep-induced disordered breathing, sleep plays a key role in generating upper airway instability and therefore in determining the underlying pathophysiology.

Respiratory Physiology: Sleep at High Altitudes

Philip N. Ainslie; Keith R. Burgess

Chapter Highlights

- Ventilatory acclimatization to altitude involves cellular and neurochemical reorganization in the peripheral chemoreceptors and central nervous system.
- Sleep at high altitude is disturbed by various factors including a change of sleep environment, snoring, and insomnia; periodic breathing during sleep, however, probably causes the most disturbances and occurs in a majority of people above 3500 m.
- The extent of periodic breathing during sleep at altitude intensifies with duration and severity of exposure and is explained in part by elevations in loop gain. A dimensionless value is a measure of the propensity for a system governed by feedback loops to develop unstable behavior.[1]
- Because periodic breathing may elevate rather than reduce mean arterial oxygen saturation (Sao_2) during sleep, this may represent an adaptive rather than a maladaptive response to altitude.
- Although new mechanical and pharmacologic management techniques are emerging, an oral acetazolamide regimen remains so far the most effective and practical means to reduce periodic breathing in altitude.

OVERVIEW

High altitude can disturb sleep in many ways (see also Chapter 122). Sojourners to high altitude often report restless and sleepless nights. Others describe a feeling of suffocation on awakening from sleep. Additional reported factors include physical discomfort from cold or unsatisfactory bedding and the noise of other people's snoring. At altitudes above 2500 m, a pattern of periodic breathing (as described next) often is seen, and the higher the altitude, the more common it is. Above 5000 m, it is almost universal and becomes the most common cause of sleep disturbance.[2-5]

Periodic breathing is manifested as a pattern of two to four breaths, separated by a brief interval with no breathing from the next burst of two to four breaths, which closely resembles the breathing pattern seen in the premature infant.[6] This periodic breathing during sleep was first described by Mosso[7] in 1886 (Figure 18-1), with further observations by other investigators a few decades later.[8] Of note, periodic breathing at high altitude is different from the typical waxing and waning of tidal volume observed in the periodic breathing of heart failure, or the somewhat chaotic or irregular pattern of apneas associated with opiate use (see Chapter 24 for more information on opioid effects on sleep and breathing).[9] Periodic breathing is more common in male subjects than in female subjects at 5400 m.[10]

During non–rapid eye movement (NREM) sleep, hyperventilation begins immediately on hypoxic exposure and intensifies over time.[11,12] After approximately 10 minutes of hypoxia in the sleeping human, tidal volume begins to oscillate in a waxing and waning pattern. These oscillations keep increasing in magnitude as hypoxia is maintained, and the partial pressure of arterial carbon dioxide ($Paco_2$) falls further to the level of the apneic threshold. Typically an augmented inspiration occurs, and the subject begins overt periodic breathing cycles approximately 15 to 25 seconds in duration, characterized by two to four large (e.g., three to four times higher than normal) tidal-volume breaths followed by an apneic interval of 5 to 15 seconds (Figure 18-2), as well as large swings in blood pressure that drive oscillations in cerebral blood flow (CBF) (Figure 18-3, middle and right panels). During these periodic cycles, arterial hemoglobin oxygen saturation (Sao_2) also oscillates, and often, depending on the altitude, values lie (dangerously) on the steep part of the oxygen dissociation curve. The bursts of breathing (i.e., hyperpneas) are sometimes associated with arousal from sleep and sometimes full wakefulness, which, at least at moderate altitude, may lead to fatigue during the day and cognitive impairment,[13] similar to that from other causes of sleep disruption.

ACCLIMATIZATION

As summarised perfectly by Houston and Riley in 1947, "Acclimatization to high altitude consists of a series of integrated adaptations which tend to restore the tissue oxygen pressure towards normal sea level values in spite of lowered oxygen pressure of the atmosphere."[14] This acclimatization process has two major components: ventilatory adaptation to hypoxia and the renal excretion of bicarbonate, allowing further ventilatory adaptation. Detailed reviews on this topic are available.[15,16]

In brief, acute exposure to high altitude results in the following sequence of physiologic events: (1) Initial changes consist of a decrease in the alveolar partial pressure of oxygen

(Po_2) and, correspondingly, in the partial pressure of arterial oxygen (Pao_2). (2) This decrease in oxygen tension results in stimulation of the peripheral chemoreceptors (predominantly at the carotid sinus), with a resultant increase in ventilation. (3) This initial increase in ventilation (the hypoxic ventilatory response) decreases Pco_2 and increases Po_2 in the alveolar gas according to the alveolar ventilation and gas equations. (4) The decrease in arterial Pco_2 (and consequent increase in arterial pH—defining conditions of respiratory alkalosis) acts to inhibit the peripheral chemoreceptor. In addition, because CO_2 is freely diffusible across the blood-brain barrier, a decrease in cerebrospinal fluid CO_2 occurs, thereby raising cerebrospinal fluid and brain extracellular fluid pH, causing inhibition at the central chemoreceptors. (5) Finally, both of these effects act to return ventilation back toward sea level values. Over a period of hours to days at high altitude, however, the body compensates for the respiratory alkalosis by increasing bicarbonate excretion in the kidney and increasing bicarbonate removal from the extracellular fluid by the choroid plexus. (6) Thus the inhibition at the central and peripheral

chemoreceptors is removed and the ventilation once again increases. A direct influence of hypoxia on the central nervous system also may act to drive these progressive elevations in ventilation (as recently reviewed[16]). As shown in Figure 18-4, acclimatization at high altitude is reflected in reductions in $Paco_2$ and an increase in Pao_2. Although these changes tend to mitigate the deleterious effects of the hypoxic environment, it should be noted that restoration of Pao_2 back to sea level values can never occur.

SLEEP ARCHITECTURE

Sleep architecture has an effect on breathing at high altitude. The effects of altitude on sleep architecture were first reported in 1970 by Joern,[17] who studied only two men in Antarctica at an altitude of approximately 3500 m. Since then, more than 20 studies have been published, which investigated sleep architecture at high altitude. The "sample size" typically has been very small, with only a few subjects each, but two somewhat larger studies included 15 and 19 subjects.[18,19] (A review of the smaller studies is provided in the 19-subject report.[19]) Most of the studies found that duration of light sleep (stage 1 NREM) increased and the duration of slow wave sleep decreased with increasing altitude. The effects on REM sleep were variable. The study with 19 subjects reported no significant change in the percentage of REM sleep with increasing altitude.[19] No differences were found in the percentages of time in slow wave sleep and REM sleep between subjects with periodic breathing and those without. Sleep arousal indices were higher in subjects with periodic breathing than in those without, probably explaining the associated poorer subjective sleep quality. Another observation was that after a cortical arousal, episodes of central sleep apnea (CSA), designated "postarousal centrals," may occur in any sleep stage. These events appear to be more common at high altitude than at sea level, even in subjects in whom sustained CSA did not develop, presumably owing to relatively greater frequency of sleep arousal–related transient hyperventilation. Because sustained CSA occurs only in the lighter sleep stages (stage 1 and stage 2 NREM), the reduced duration of slow wave sleep and increased amount of stage 1 NREM sleep at high altitudes facilitate the onset of CSA.

MECHANISMS CAUSING PERIODIC BREATHING

The mechanisms causing periodic breathing are discussed in a general context in earlier chapters (see Chapters 15 to 17), but some altitude-specific comments are warranted. The principal reason for the occurrence of apnea and periodic breathing during sleep in hypoxic environments is believed to be elevations in controller or feedback gain, as evidenced by the steep increase in the CO_2 response slope above and below eupnea and the greatly narrowed CO_2 reserve.[20-22] These aspects that determine the CO_2 reserve below eupnea are based on mathematical modeling concepts of *plant gain* and *controller gain*.[23-25] Another important factor that has been postulated to influence ventilatory stability and thus periodic breathing is the poststimulus short-term potentiation, or what was initially called the "ventilatory afterdischarge."[26,27] Although these concepts have been described in detail with sleep apnea,[22] a brief review of likely changes experienced at high altitude and the implications for periodic breathing is presented here.

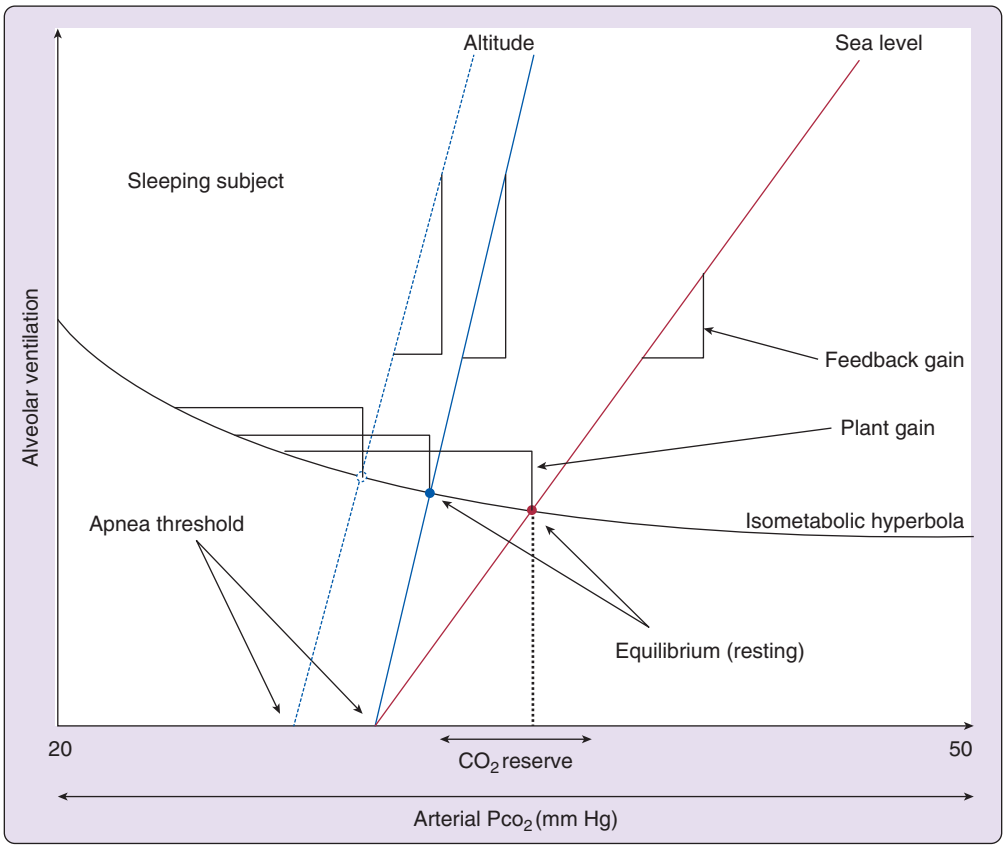

Figure 18-5 Illustration of the relationship between alveolar ventilation and alveolar P_{CO_2} at a fixed CO_2 production (e.g., 250 mL/min). Ascent to altitude increases the chemoreflex slope (*solid blue line*) but does not necessarily change the apnea threshold; the increase in slope moves the equilibrium to an increased ventilation and lower P_{CO_2}, thereby decreasing plant gain. This effect—chronic hyperventilation induced by the high altitude and subsequent reductions in plant gain—indicates that a greater transient increase in alveolar ventilation (V_A) and corresponding reduction in Pa_{CO_2} is required to reach the apneic threshold than would be the case under conditions of normocapnia. Therefore this reduction in plant gain acts to stabilize breathing. Should the apnea threshold also be decreased with acclimatization at altitude (*dotted blue line*), then ventilation increases and P_{CO_2} decreases, and plant gain is further decreased. For a given background Pa_{CO_2}, alterations in the slope of the change in V_E per change in Pa_{CO_2} relationship below eupnea would alter the CO_2 reserve (i.e., the amount of reduction in Pa_{CO_2} required to cause apnea). Changing the slope of the ventilatory response to CO_2 above eupnea would alter susceptibility for transient ventiltory overshoots. Although at altitude the chronic hyperventilation-induced hypocapnia may be "protective" against apnea and breathing instability through reductions in plant gain, the other chemoreceptor (e.g., controller gain) and nonchemoreceptor (e.g., increased pulmonary pressures, behavioral drives, awake-to-sleep transitions, locomotion feedback/forward stimuli) factors may contribute, potentially negating this response. (Modified from Ainslie PN, Lucas SJ, Burgess KR. Breathing and sleep at high altitude. *Respir Physiol Neurobiol* 2013;188:233–56.)

Plant Gain at Altitude

The term *plant gain* is defined as the effectiveness of ventilation in changing the blood gases.[28] This plant gain is determined by the intersection of the chemoreflex response and the isometabolic hyperbola that defines resting conditions of minute ventilation ($\dot{V}_E$) and $Paco_2$ (Figure 18-5). At high $Paco_2$, the equilibrium point is located on a relatively flat portion of the metabolic hyperbola, so the plant gain (i.e., $\Delta Paco_2/\Delta\dot{V}_E$) is high. With the reduced $Paco_2$ with ventilatory accclimatization to hypoxia, the equilibrium point is located on a steeper portion of the isometabolic hyperbola, so the plant gain is low, thereby protecting against instability. What this implies is that hyperventilation per se at high altitude (because of the reduction in $Paco_2$) seemingly "protects" against apnea and ventilatory instability. Therefore, although chronic hyperventilation-induced hypocapnia should theoretically be protective against apnea and breathing instability, other chemoreceptor (e.g., controller gain) and nonchemoreceptor (e.g., increased pulmonary pressures, behavioral drives, awake-to-sleep transitions, locomotion feedback/forward stimuli) factors must contribute, potentially negating this response.

Controller Gain at Altitude

The other mechanism by which the magnitude of the CO_2 reserve decreases to below eupnea is through alterations in the slope or sensitivity (see the blue lines in Figure 18-5) of the reductions in $\dot{V}_E$ below eupnea in response to transient hypocapnia. An increased CO_2 response slope below eupnea during NREM sleep occurs at high altitude.[29] In other words, an elevated chemosensitivity causes a more vigorous response to the rise in $Paco_2$ during the apneic interval (synonymous with a higher controller gain), which is sufficient to overcome the

relatively reduced baseline $Paco_2$ (indicating a lower plant gain), thereby further destabilizing ventilation.[22,30]

Short-term Potentiation and Periodic Breathing

As described previously, another factor that has been postulated to influence ventilatory stability and thus periodic breathing is poststimulus short-term potentiation, or "afterdischarge."[26,27] This short-term potentiation reflects the maintenance of ventilation after cessation of a stimulus despite hypocapnic inhibition. Of note, in a number of human studies it has been reported that short-term potentiation is reduced during hypoxic exposure in the awake state[31] and also in NREM sleep,[32] so that periodic breathing is more likely to occur under these conditions. For the development of periodic breathing during sleep at altitude, however, the combination of transient hypocapnic inhibition and sustained hypoxia presumably overrides or abolishes any meaningful influence from short-term potentiation or after discharge.[28]

Other Factors Influencing Periodic Breathing

Periodic breathing in hypoxia occurs in breath "clusters," with tidal volume increasing from zero to three to four times control levels, almost instantaneously following each apneic interval. This pattern has been suggested to reflect the presence of a transient arousal state at apnea termination that would further augment the responsiveness of the respiratory control system and produce the sudden ventilatory overshoot.[33] Another possibility that also could influence periodic breathing is a direct influence of brain hypoxia.[30] Other evidence, also based on findings in animals,[34,35] supports the notion that breathing instability may also involve pulmonary J receptors. These receptors are stimulated by pulmonary congestion/lung edema at high altitude and evoke reflex inhibition of ventilation which prolongs the apnea. Moreover, acute pulmonary hypertension (as reflected in elevations in left atrial pressure by 5.7 mm Hg in the well-controlled animal model) during sleep results in a narrowed CO_2 reserve and thus predisposes affected subjects to apnea/unstable breathing.[36] It seems likely that the periodic breathing-induced oscillations in CBF also act to destabilize breathing by provoking large swings in brain tissue pH and hence central chemoreflex stimulation and inhibition. Although clear evidence for these complex pathways at high altitude is still lacking, it is known that at sea level, periodic breathing during sleep is more pronounced in patients with pulmonary hypertension than in those without.[37]

Periodic Breathing and Hypoxic Ventilatory Response

If elevations in controller gain are the principal precipitating mechanism for periodic breathing, then, other things being equal, persons with the highest hypoxic and hypercapnia ventilatory responses should have more severe periodic breathing. Although many studies cite the classic Lahiri study[42] to provide evidence of the correlation of hypoxic ventilatory response (HVR) and periodic breathing, this relationship was largely created by the inclusion of a Sherpa group with a blunted HVR. Upon examination, no obvious relationship was found between HVR and periodic breathing within the so-called lowlander population. This absence of a relationship was further confirmed, albeit in a subgroup ($n = 5$), at 6300 and 8050 m.[4] These findings are consistent with those of Masuyama and associates: In their study, two of nine mountaineers did not develop CSA at altitude despite normal values for HVR.[39] More recently, absence of a relationship between HVR and periodic breathing at 5050 m has been reported.[5] By contrast, at 4400 m in a small sample size ($n = 4$), it was shown that the respiratory stimulant almitrine doubled the HVR and elevated periodic breathing compared with acetazolamide or placebo.[40] Nevertheless, the known blunted HVR and diminished periodic breathing in Sherpas[38] lend support to a role for HVR in periodic breathing. A number of potential explanations exist for these discrepant and variable findings, including evidence that the hypoxic and CO_2 response are not always similar above and below eupnea[22]; differences in awake versus sleep respiratory control; variable acid-base status; and methodologic differences (e.g., chemoreflex testing and hence inclusion of CBF using steady state or rebreathing methods, natural versus simulated altitude, or other means). At least on the basis of rebreathing measures in humans at high altitude,[41-43] it is not clear if actual wakefulness chemoreflex gain differs above and below resting equilibrium. Collectively, these findings highlight the multifactorial complexity of characterizing and studying periodic breathing at high altitude.

Periodic Breathing Changes with Both Magnitude and Duration of Hypoxic Stimulus

It was originally considered that the amount of periodic breathing in sleep is greatly reduced over time in normobaric hypoxia.[11,12,44] At least at high altitude, however, recent evidence derived using full polysomnography shows the opposite: that periodic breathing intensifies over time (12 to 15 days) at a given altitude, in all subjects[5] (Figure 18-6). As highlighted in Figure 18-7, it is clear that periodic breathing increases proportionally with altitude, and as illustrated in Figure 18-8, a small but progressive decrease occurs in the average duration of the apnea-hypopnea events at altitude. Because the development of CSA is almost exclusive to NREM sleep (especially during stage 1 and 2 light sleep), collectively, this information allows determination of the theoretical ceiling of CSA at high altitude. Naturally this limit would vary depending on individual differences in cycle duration and percentage of time in REM sleep. Nevertheless, on the basis of this information, it is possible to ascertain when apnea-hypopnea cycling has reached the maximal theoretical value. At this point, which may occur with acclimatization, these calculations are important, because they indicate that the development of CSA becomes independent of key factors affecting its severity (e.g., controller gain, apneic threshold, and cerebrovascular influences; see further on).

A Role of Cerebral Blood Flow in Breathing Stability at Altitude

The supportive evidence for a putative role of CBF and reactivity on breathing stability is now clear. First, pharmacologic blunting of CBF and its reactivity to CO_2 leads to elevations in controller gain, reduced CO_2 reserve, and subsequent increased susceptibility to onset of apnea and breathing instability during sleep.[45] These changes also are evident during wakefulness.[46] Moreover, acute elevations in CBF velocity and reactivity to $Paco_2$, induced by intravenous acetazolamide, have been demonstrated to be related to improvements in breathing stability at high altitude during wakefulness[47] and

sleep.[48] In support, modeling studies have shown that theoretically, doubling of cerebrovascular reactivity to CO_2 leads to a marked dampening of respiratory oscillations in conditions of sleep at high altitude.[49] Conversely, when cerebrovascular reactivity to CO_2 was halved after a sigh transformed a stable breathing pattern into a periodic breathing pattern, restoration of reactivity restored stability.[49] Thus CBF and its related CO_2 reactivity, through its influence on central chemosensitivity, provide an important mechanism in the pathophysiology of CSA. As mentioned earlier, CBF is elevated on initial arrival to high altitude. We speculate that this elevated blood flow provides a protective effect on CSA during initial exposure to high altitude via effective buffering of changes in central P_{CO_2} and hence reductions in controller gain (i.e., chemosensitivity). Moreover, after partial acclimatization, CBF and its reactivity decline, resulting in a further increase in hypercapnic ventilatory response (HCVR) and universally severe CSA at altitude[5] (see arrows in Figure 18-8)—changes ultimately mediated by elevations in controller gain[50] and reduced CO_2 reserve.

The stimulation of the central chemoreceptors is from the CO_2 that is actually produced in the surrounding brain. Arterial blood flow to the brain washes the CO_2 away from the chemoreceptors. This means that CBF during sleep may be very important in ventilatory control. In the absence of the wakefulness drive to breathe, marked oscillations in CBF occur as a consequence of the periodic breathing, similar in nature to that reported in patients who experience sleep apnea at sea level.[51,52] Previous studies[5,53] demonstrated a relation between the decline in CBF from awake to NREM sleep, albeit being only a modest predictor of CSA. Of interest, the relation was stronger after 2 weeks at high altitude, when absolute perfusion was lower (both awake and during sleep), further supporting the idea that reduced $[H^+]$ washout within the brain enhances chemoreceptor activation (see earlier). Moreover, in view of the link between breathing pattern and CBF,[54,55] these oscillations in CBF are likely to be important in the pathophysiology of periodic breathing. Indeed, regardless of the causation of the first apneic episode, that is, whether alterations in basal CBF[56] or in cerebral or arterial P_{CO_2}[57-59] (or a combination of these and other factors) start the apnea cycle, the large swings in CBF that ensue seem likely to exacerbate the under- and overshooting of the ventilatory drive that characterizes the CSA disorder.[30]

The potential role for alterations in CBF during sleep at high altitude in the control of breathing has been further supported by the results of artificially increasing and reducing CBF during sleep by the use of medications. In a group of 12 normal volunteers at 5050 m, the administration of oral indomethacin 100 mg, which reduced CBF by approximately 23%, increased the severity of CSA by 16%. The HCVR also increased by 66%, suggesting that the reduction in CBF may have caused the increase in HCVR, which in turn increased the severity of CSA. Conversely, the administration of intravenous acetazolamide, which increased CBF by 28% without changing acid-base balance in the short term, reduced the severity of CSA by approximately 47%.[60] These results are consistent with modeling studies and suggest that CBF through its influence on the central chemoreceptors, not only in support of ventilation at rest but also in stabilized breathing in situations such as sleeping at altitude.

Role of Arousal from Sleep

Arousal from sleep is a very common feature of CSA, typically occurring during the hyperpneic phase of the cyclic breathing. Traditional thinking was that the hyperpnea of CSA was the cause of such arousals, and that the arousal was crucial in perpetuating the instability of breathing that typifies CSA.[61] In earlier studies at similar altitudes, the arousal index has tracked fairly closely with the increase in apnea-hypopnea index (AHI) with increasing altitude (as summarized in a contemporaneousreview). Although data indicate that benzodiazepines can reduce CSA by reducing arousals,[62] more recent findings indicate that this role has been overemphasized.[5] The cyclic changes in CBF may

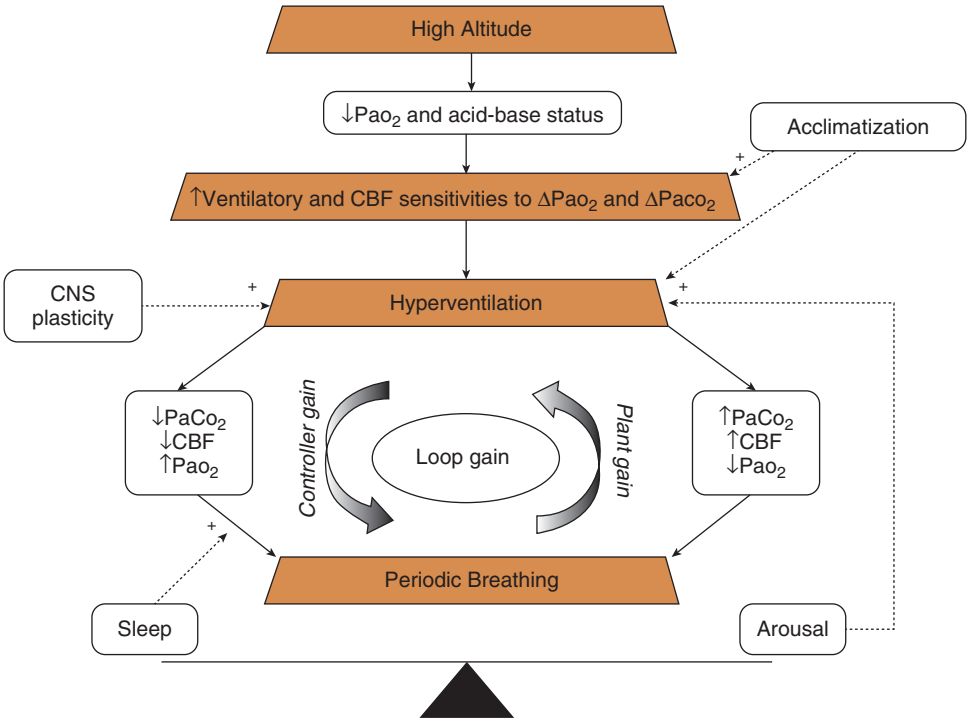

Figure 18-9 Schematic diagram showing various mechanisms by which high-altitude exposure leads to the development of periodic breathing during sleep. Initial effects of high-altitude exposure include a reduction in the partial pressure of arterial oxygen (Pa_{O_2}) and acid-base adjustments. These changes lead to alterations in chemoreflex control and cerebrovascular responses to changes in arterial blood gases. Overall, these complex cellular and neurochemical changes in chemoreflexes, acid-base status, and the central nervous system (CNS) lead to hyperventilation. Acclimatization, at least in lowlanders, magnifies these changes. Elevations in loop gain outweigh the improvements in plant gain caused by the chronic hypocapnia, leading to periodic breathing. Sleep and arousals lead to greater breathing instability. Apnea, which is associated with an increase in Pa_{CO_2} and decrease in Pa_{O_2} (and/or arousal), restimulates the PCRs and consequently ventilation. These changes in blood gases also lead to marked alterations in cerebral blood flow (CBF) (see Figure 18-7), which in turn may result in a sudden elevation (with reduced CBF) or reduction (with increased CBF) in brainstem pH. (Modified from Ainslie PN, Duffin J. Integration of cerebrovascular CO_2 reactivity and chemoreflex control of breathing: mechanisms of regulation, measurement, and interpretation. *Am J Physiol Regul Integr Comp Physiol* 2009;296:R1473–95.)

therefore be more important than repeated arousal from sleep in perpetuating CSA at high altitude. Because arousals without a clear temporal relationship to periodic breathing cycles during sleep also have been reported,[23,63] it seems likely that periodic breathing does not always cause arousal, and is not the only cause of arousals and fragmented sleep at altitude. Figure 18-9 summarizes the various mechanisms that have been outlined by which high-altitude exposure leads to the development of periodic breathing during sleep.

MANAGEMENT OF PERIODIC BREATHING AT ALTITUDE

Because of the strong correlation between absolute altitude and severity of CSA (see Figure 18-7), the obvious treatment would be to reverse that process and descend. If this strategy is not desired or practical, a number of options are available for management of periodic breathing. These can be broadly divided into three different categories: medical gases, pharmacologic interventions, and devices. The evidence of effectiveness of each of these treatment approaches is summarized next.

Medical Gases

Lahiri and associates have shown elegantly the curative effects of supplemental oxygen therapy in a subject with sustained CSA at 5300 m[38] (Figure 18-10). On rapid restoration of normoxic Sa_{O_2} by increasing the fraction of inspired oxygen (Fi_{O_2}), periodic breathing continues with prolonged apneic periods until hyperventilation is gradually reduced and Pa_{CO_2} returns to normal. Stabilizing effects of small incremental increases in fraction of inspired carbon dioxide (Fi_{CO_2}) also have been reported.[11] The mechanism probably involves blunting the degree of fall in Pa_{CO_2} during the hyperpnea phase of the CSA. West has proposed the addition of modest amounts of supplemental oxygen (i.e., using a device; see section on device below) into the sleeping quarters of high-altitude residents as a means of improving sleep quality and daytime performance.[64]

Pharmacologic Interventions

A number of studies have used pharmacologic manipulation at high altitude to decrease the occurrence and severity of periodic breathing, with agents such as acetazolamide, dexamethasone, various hypnotics, and theophylline. (Hypnotics are discussed later with insomnia.)

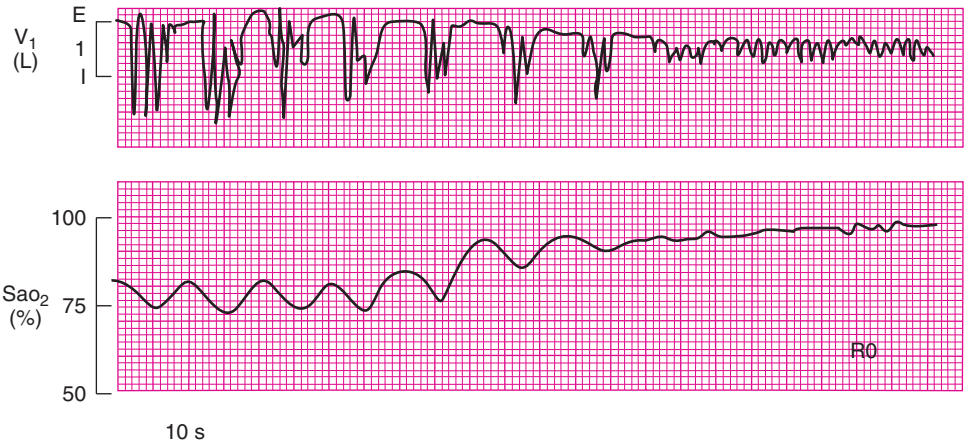

Figure 18-10 Polygraphic tracing. The effect of oxygen on periodic breathing and arterial oxygen saturation during sleep at 5400 m. As oxygen arterial saturation increases, periodic breathing is replaced by shallow and continuous breathing.[38] E, Expiration; I, inspiration. (Data from Lahiri S, Maret K, Sherpa MG. Dependence of high altitude sleep apnea on ventilatory sensitivity to hypoxia. *Respir Physiol* 1983;52:281–301.)

Oral acetazolamide has been shown by a number of investigators to effectively suppress CSA by 50% to 80% at high altitude.[40,65-67] The efficacy of carbonic anhydrase (CA) inhibitors is the result of ventilatory stimulation and better arterial oxygenation driven by the metabolic acidosis and the slight CO_2 retention from vascular CA inhibition and any partial red cell CA inhibition. Depending on the dose and route (intravenous or oral) of administration, CA inhibitors improve ventilatory control instability by increasing the tonic output of the central chemoreceptors and lowering their apneic threshold, thus rendering them less responsive to periodic reductions in $Paco_2$. In addition, inhibition of CA in the peripheral chemoreceptors reduces both the magnitude of hypoxic and hypercapnic sensitivity and the rate at which these signals arrive at the respiratory controller.[68-72] Consistent with this notion, peripheral chemoreceptor stimulants such as almitrine aggravate periodic breathing at high altitude.[40] Other benefits attributed to CA inhibitors in altitude adaptation include mild diuresis, reduced cerebrospinal fluid formation and increased CBF. Although these factors have received little attention at high altitude, studies have shown that acute intravenous acetazolamide induce elevations in CBF velocity and reactivity to $Paco_2$ are related to improvements in breathing stability at high altitude during wakefulness[47] and sleep.[48]

It has recently been reported that, at least in subjects susceptible to high-altitude pulmonary edema (HAPE), dexamethasone (at 8 mg/day in two divided doses) taken before ascent prevents severe hypoxemia and sleep disturbances, while dexamethasone taken 24 hours after arrival at 4559 m increases oxygenation and deep sleep.[73] Whether dexamethasone affects sleep on ascent to high altitude in otherwise healthy persons is unknown, although this seems unlikely. Dexamethasone has been repeatedly studied with regard to its possible beneficial effects on acute mountain sickness (AMS) and HAPE, but rarely with regard to sleep architecture per se. A passing reference suggests that it has no separate effect from acclimatization.[74]

It also has been shown, in a placebo-controlled trial, that low-dose (300 mg/day), slow-release theophylline reduces symptoms of AMS in association with alleviation of events of periodic breathing and oxygen desaturation at 4559 m.[75] In another randomized, double-blind, placebo-controlled study, the effects of theophylline (250 mg/day in two divided doses) on periodic breathing were compared with those of acetazolamide (also at 250 mg/day in two doses) after fast ascent to high altitude (3454 m) (n = 30).[76] Polysomnographic measurements were performed during two consecutive nights, and AMS, pulse rate, oxyhemoglobin saturation, and arterial blood gases were assessed three times a day. Both theophylline and acetazolamide normalized sleep-disordered breathing (median AHI, 2.5/hour versus 4.2/hour; range, 0 to 19, respectively) and reduced oxyhemoglobin desaturations during sleep (median desaturation index, 41.5/hour for placebo versus 6.5/hour for acetazolamide versus 8.5/hour for theophylline; range, 3 to 32). In contrast with theophylline, acetazolamide significantly improved basal oxyhemoglobin saturation during sleep (86% versus 81%). It was concluded that both oral slow-release theophylline and acetazolamide are effective to normalize high-altitude sleep-disordered breathing.[76]

Devices

Recently a number of devices have shown potential to treat periodic breathing at altitude, including bilevel positive airway pressure and the simple addition of dead space using a modified facemask.

A very different treatment, bilevel ventilation, recently was shown in a pilot study to halve the severity of CSA in seven volunteers at 3800 m at the White Mountain Research Center in California.[77] Unfortunately arterial blood gases, ventilatory responses, or CBF measurements were not collected, so the underlying mechanisms for those effects are uncertain. One could speculate that the ventilation further reduced $Paco_2$ and raised Pao_2; however, a further fall in $Paco_2$ would be expected to exaggerate periodic breathing during sleep. Noninvasive positive-pressure ventilation, such as continuous positive airway pressure (CPAP), raises functional residual capacity, which would increase oxygen stores and hence lower loop gain. Indeed, Edwards and colleagues have shown a reduction in loop gain in premature lambs by the application of CPAP, with resolution of CSA.[78] Increasing oxygen stores seems the more likely mechanism.

The simple addition of a 500-mL dead space also has been shown to improve sleep in some subjects at 3500 m.[79] This

study was conducted in 12 unacclimatized persons using full polysomnography. In random order, half of the night was spent with a 500-mL increase in dead space through a custom-designed full face mask and the other half without it. Although the dead space had no effect on individuals with AHI less than 30 events/hour, it did lead to marked reductions in AHI (from 70 to down to 30 events/hour) and oxygen desaturation index (from 73 to 43). Thus a 500-mL increase in dead space through a fitted mask may improve nocturnal breathing in those with severe altitude-induced sleep-disordered breathing.[79] Similar to the aforementioned studies above that have used elevations in $Fico_2$ to improve periodic breathing, the mechanism via elevations in dead space is likely through the stabilizing influence of elevations in $Paco_2$ on the CO_2 reserve.

OTHER SLEEP-RELATED CONDITIONS AFFECTED BY HIGH ALTITUDE

A number of sleep-related conditions are recognized to be influenced by ascent to high altitude, including nasal obstruction, obstructive sleep apnea (OSA), and insomnia.

Nasal Obstruction and High Altitude

Nasal obstruction is known to predispose affected persons to snoring and OSA and poor sleep quality at sea level.[80] Nasal obstruction is common in travelers to high altitude because of the usually dusty environment and the high prevalence of viral infections, at least in newcomers such as trekkers. Snoring is therefore very common at high altitude in sojourners.

OSA in nonnative subjects is recognized to resolve with increasing altitude[81] and the passage of time at high altitude when CSA develops, which has been attributed to increased central respiratory drive. Nasal obstruction and mouth breathing may persist, but snoring seems to lessen with time and increasing altitude regardless—perhaps because of increased central respiratory drive, which tends to stiffen the upper airway, thereby reducing obstruction and making the soft palate and other tissues less susceptible to vibration.[82]

Obstructive Sleep Apnea and High Altitude

Although research into CSA has been substantial, less is known about OSA at high altitude or the effects of altitude on subjects with OSA. It initially was recommended in popular high-altitude medicine publications that persons with OSA should avoid ascending to high altitude because of the likelihood that the condition will worsen.[83] On the basis of pathophysiologic considerations and uncontrolled observations in a small number of patients, a stay at altitude was thought to aggravate sleep-related breathing disturbances in patients with OSA; however, the data reported were elevations in the number of episodes of central apnea and reductions in obstructive apnea, not a worsening of OSA.[84,85] In a recent randomized controlled trial, it was shown that altitude exposure (up to 2590 m) in untreated patients with OSA aggravates hypoxemia, increases sleep-related breathing disturbances due to frequent central apneas/hypopneas, impairs driving simulator performance, and induces cardiovascular stress.[86] Again, the increase in respiratory events was due to an increase in central events, not to a worsening of OSA. It was found that a combination of acetazolamide (750 mg/day) and auto-CPAP therapy, compared with auto-CPAP alone, resulted in improvement in nocturnal oxygen saturation and AHI.[87]

The influence of OSA and optimum treatment approaches at higher elevations are largely unknown. An interesting finding is that mild OSA (approximately 5 events/hour) is abolished at higher altitudes (5050 m) and replaced by CSA.[2] The same effect also has been shown in patients with known OSA, many on CPAP therapy, exposed to a simulated high-altitude environment of 2750 m using normobaric hypoxia.[82]

Treatments for OSA and Snoring at High Altitude

In patients unable to use CPAP, or if electrical power is not available, an optimally fitted mandibular advancement device may be an alternative treatment option (to be confirmed by evidence) that can be combined with acetazolamide during altitude sojourns.[88] Evidently, however, acetazolamide alone also is beneficial and better than no treatment at all, because it improves oxygen saturation, curtails breathing disturbances, and potentially obviates the excessive blood pressure elevation in patients with OSA traveling to altitude.[89]

Insomnia at High Altitude

Part of the disruption to sleep at high altitude is the insomnia (both sleep onset and sleep maintenance) due to repeated arousals and awakenings from the hyperpnic phase of the periodic breathing. Several investigators have studied the effects of hypnotic medications in placebo controlled trials in the field. There is a theoretical risk that sedating medications might suppress ventilatory responsiveness and hence lead to worsened arterial oxygen saturation during sleep, which might also impair sleep quality and exacerbate AMS; however, evidence for this effect is lacking.

The effectiveness of various hypnotics has received attention. Both Dubowitz[90] and Nickol and colleagues[62] have used temazepam at 5400 m and reported a subjective improvement in sleep quality, but with variable effects on saturation and CSA severity. In Dubowitz's study, a group of 11 subjects showed no change in mean arterial saturation but appeared to show a reduction in "desaturation events," probably indicating a reduction in CSA severity linked to arousal from sleep, although no measurements of sleep state were recorded.[90] Nickol and coworkers,[62] on the other hand, demonstrated a modest but significant reduction in CSA index, from 16 to 9 events/hour, in a group of 33 healthy volunteers. Other reported benefits included a small reduction in mean saturation from 78% to 76% and improvement in AMS scores. New nonbenzodiazepine sedative-hypnotics also have been studied at high altitude.[13] Sleep quality was improved, but no direct data were provided about effects on CSA, although no change in oxygen desaturation index was seen.

Headache at High Altitude

Headache is a cardinal feature of AMS; hence it is very commonly experienced by sojourners to high altitude. Anecdotal evidence also suggests that high-altitude exposure increases the frequency of migraine attacks. Administration of paracetamol, with or without codeine, is the usual treatment, but acetazolamide and/or dexamethasone may be required if moderate to severe AMS is present. Opioid medication should be avoided because the possible (in the

most vulnerable subject) depressant effect on the ventilatory responses to both hypoxia and hypercapnia would predispose to lower saturation during sleep (although tending to suppress CSA).

Sleep in High-Altitude Natives

Native populations of the Tibetan and Andean plateaus both are descended from early colonizers. Tibetans arrived approximately 25,000 years ago, whereas the Andean populations arrived much later, around 11,000 years ago. Both populations have therefore been exposed to the opportunity for natural selection for traits to offset the unavoidable environmental stress of severe lifelong exposure to high altitude. The physiologic and genetic consequences of this environmental stress have been elegantly reviewed.[91,92]

CLINICAL PEARL

At high altitudes, say, above 3500 m, the most common cause of disturbed sleep in sojourners is periodic breathing due to the associated hypoxia. Surprisingly, the severity increases over time for at least 1 month at the same altitude, during the ongoing acclimatization. Established treatments, apart from descent to a lower altitude, include regular oral acetazolamide, which reduces CSA severity (as well as improving Pa_{O_2} and thereby decreasing the symptoms of AMS), and hypnotic medications, which reduce sleep disturbance from arousals.

SUMMARY

Sleep at high altitude is disturbed by various factors including a change of sleep environment, snoring, and insomnia; however, periodic breathing during sleep probably causes the most disturbances and occurs in almost everyone above 5000 m. Ventilatory acclimatization to altitude involves cellular and neurochemical reorganization in the peripheral chemoreceptors and central nervous system. The extent of periodic breathing during sleep at altitude intensifies with duration and severity of exposure; this increase is explained in part by elevations in loop gain. Although new mechanical and pharmacologic management techniques are emerging, oral acetazolamide remains the most effective and practical means to reduce periodic breathing. Use of benzodiazepine and other hypnotic agents appears to be a safe way to improve sleep quality at very high altitudes. Dexamethasone is a proven treatment for AMS (and associated sleep disturbance) but probably has no other effect on sleep quality.

Chapter 19

Sleep and Host Defense

Mark R. Opp; James M. Krueger

Chapter Highlights

- That sleep is altered during sickness has been known for millennia. Yet systematic and controlled studies aimed at elucidating the extent to which sleep is altered in response to immune challenge have only been conducted during the past 30 years.
- Substances historically viewed as components of the innate immune system are now known to be involved in the regulation or modulation of physiologic sleep-wake behavior, in the absence of immune challenge. Changes in sleep during immune challenge are actively driven and result from amplification of these physiologic mechanisms.
- Although the precise changes in sleep-wake behavior depend on the pathogen, route of infection, timing of infection, host species, and other factors, altered sleep during immune challenge is generally characterized by periods of increased non–rapid eye movement (NREM) sleep, increased delta power during NREM sleep, and suppressed rapid eye movement (REM) sleep. Infection-induced alterations in sleep are often accompanied by fever or hypothermia.
- Altered sleep has been studied in humans during pathologies and infections with pathogens, including human immunodeficiency virus/acquired immunodeficiency syndrome, rhinovirus (common cold), streptococci, trypanosomes, prions, and sepsis. Laboratory animal models include sepsis, influenza, and other viruses (gammaherpesvirus, vesicular stomatitis virus, rabies, feline immunodeficiency virus), several bacterial species, trypanosomes, and several prion diseases.
- Mechanisms that link sleep to innate immunity involve a biochemical brain network composed of cytokines, chemokines, growth factors, transcription factors, neurotransmitters, enzymes, and their receptors. Each of these substances and receptors is present in neurons, although interactions with glia are critical for host defense responses to immune challenge. Redundancy, feedforward, and feedback loops are characteristic of this biochemical network. These attributes provide stability and flexibility to the organismal response to immune challenge.

Most individuals have experienced the lethargy, malaise, and desire to sleep that may occur at the onset of infection. Further, most have been admonished to "get plenty of rest, or you will get sick." Conventional wisdom and personal experience suggest a connection between sleep and host defense systems; our sleep is perceptively different when sick and insufficient sleep may predispose to getting sick. These beliefs are not new. Indeed, Hippocrates, Aristotle, and many of our predecessors acknowledged such a relationship. But only within the past 30 years have modern science and medicine systematically investigated relationships between sleep and host defense systems. This chapter is organized around four main themes related to sleep and host defense: (1) the acute phase response and host defense, (2) infection-induced alterations in sleep, (3) effects of sleep loss on immune function, and (4) mechanisms linking sleep and immunity. Finally, in the Clinical Pearl section, we briefly present sleep as a recuperative process during sickness.

THE ACUTE PHASE RESPONSE AND HOST DEFENSE

Rapidly after infection, trauma, or during some malignant conditions, a complex response involving many cell types and peripheral organs is evoked that is collectively referred to as the *acute phase response* (APR). Markers of the APR include changes in serum concentrations of acute phase proteins. Measurement of acute phase proteins, such as C-reactive protein, is useful in clinical practice because they indicate inflammation. In addition to changes in serum concentrations of acute phase proteins, the APR includes physiologic changes, such as fever and increased vascular permeability, and other metabolic and pathologic changes. A major theme of this chapter is that altered sleep as a host defense also is part of the APR to inflammatory challenge. Altered sleep during inflammatory challenge is actively driven by multiple mediators and systems, many of which are shared with other facets of the APR.

Recent advances in our knowledge of central nervous system (CNS) innate immunity provide a framework for understanding many of the shared mechanisms underlying the APR in general as well as the specific alterations in sleep that occur during immune challenge. The APR is a critical innate immune response[1] that follows any inflammatory challenge, such as an infection or traumatic injury. Inflammatory challenges that are localized, for example, a minor cut or splinter, may activate a low-level APR that manifests as redness at the site of injury and may not be perceived by the subject. But with increased injury severity or response to an infectious challenge, the full systemic APR develops. The APR to infection by invading pathogens develops within a matter of hours, and the subject feels sick. In the case of infections, the function of the APR is to alert the host to the invasion and mobilize systemic protective responses, isolate and destroy invading pathogens, and remove tissue debris. The systemic inflammatory response activates the brain, liver, and bone marrow to react in a stereotypic manner. The APR includes physiologic and behavioral responses (e.g., fever, excess sleep, anorexia) as well as biochemical responses (e.g., C-reactive protein, serum amyloid A, mannose binding protein). Increased secretion of a broad array of endocrine hormones, including the stress hormones, also occurs. This complex of responses leads to host protective behaviors (e.g., social withdrawal),[2] physiologic responses (e.g., fever, which can increase efficiency of the immune response and inhibit growth of some microorganisms),[3,4] and immune responses (e.g., mobilization of leukocytes and natural killer [NK] cells).[1] Hormonal changes (e.g., prolactin regulation of antimicrobial nitric oxide levels)[5] and biochemical changes (e.g., potentiation of microbial phagocytosis)[6] also contribute to host defense. Although physical barriers (skin, mucosa) are the first line of defense, the APR is the first responder of host defense and is the trigger for acquired immunity, mediated by specific antibodies and cytotoxic T lymphocytes.[7]

A major class of proteins, cytokines, initiates the APR. Cytokines are generally associated with immune cells, but they are made by most cell types. More than 100 of these intercellular signaling molecules have been identified, and the complexity of their interactions rivals that of the CNS. Cytokines induce their own production and the production of other cytokines, and they form biochemical cascades characterized by much redundancy. Cytokines are classified into two major groups: type I cytokines that promote inflammation (proinflammatory) and type II cytokines that suppress it (antiinflammatory).[8] Three proinflammatory cytokines appear to be primary triggers of the APR. These early responder cytokines are interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), and IL-6, each of which is implicated in the regulation and modulation of sleep. The class II cytokines include interferon-α (IFN-α), IFN-β, IL-4, and IL-10. These cytokines damp the APR and may also modulate sleep responses; for example, IL-4 and IL-10 inhibit spontaneous non–rapid eye movement (NREM) sleep (Figure 19-1). Cytokines can act in an autocrine, juxtacrine, paracrine, or endocrine manner to activate numerous APRs through such effectors as nitric oxide, adenosine, and prostaglandins.

A major advance in our understanding of the APR was the recognition that all known microorganisms have one or more biologically stable and chemically unique structural components.[9] These unique structural components are termed

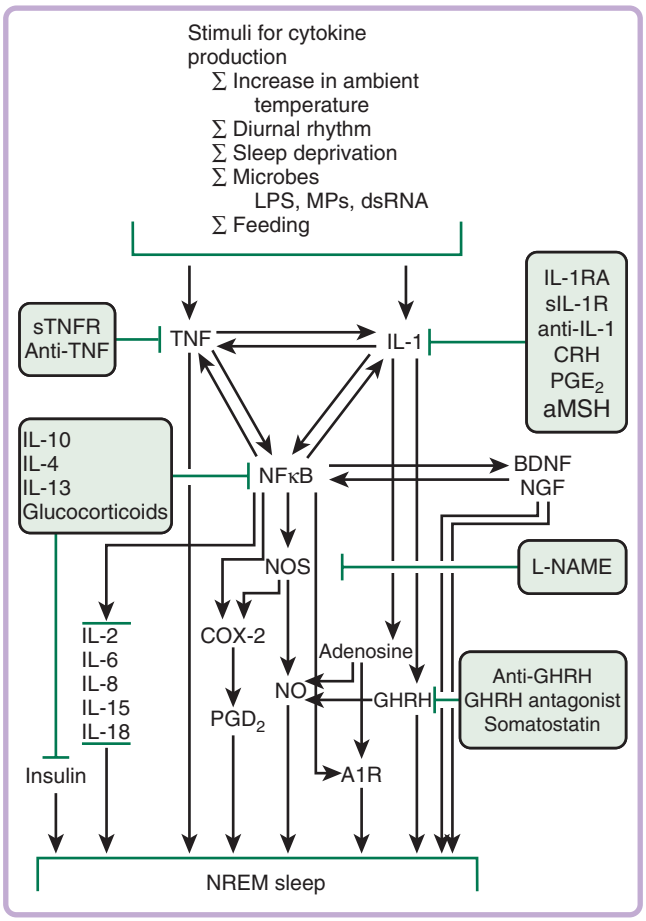

Figure 19-1 Interleukin (IL)-1β and tumor necrosis factor (TNF)-α are part of a brain biochemical network that regulates physiologic sleep and links multiple facets of innate immunity to sleep regulation. Much is known about mechanisms by which IL-1 and TNF directly or indirectly regulate and modulate non–rapid eye movement (NREM) sleep. Less is known about mechanisms of action for the REM sleep–suppressing effects of immune challenge. Current knowledge of the biochemical network that translates information about environmental perturbation into host responses that actively drive changes in sleep-wake behavior is much more complicated than depicted, and sites of action are not indicated (but see[53]). This biochemical cascade included cytokines, chemokines (not included), growth factors, transcription factors, neurotransmitters, and enzymes and their receptors. Because the network is redundant and parallel, inhibition of any single component does not result in complete sleep loss, nor does it block altered sleep in response to immune challenge. Such redundant pathways provide stability to the sleep regulatory system and alternative mechanisms by which sleep-promoting or sleep inhibitory stimuli may affect sleep. Substances in boxes inhibit NREM sleep and inhibit either the production of or the actions of substances in downstream pathways. The receptor and intracellular signaling systems for all these substances are found in neurons. Also not depicted in this schema are interactions of components of this biochemical network with glial cells. Gliotransmission is implicated in the modulation of physiologic sleep, and is likely to play a critical role in brain responses to immune challenge that result in altered sleep-wake behavior (see[100]). The symbol → indicates stimulation or upregulation; ⊥ indicates inhibition or downregulation. A1R, Adenosine A1 receptor; anti-IL-1, anti-IL-1 antibody; anti-TNF, anti-TNF antibody; anti-GHRH, anti–growth hormone–releasing hormone antibody; BDNF, brain-derived neurotrophic factor; COX-2, cyclooxygenase-2; CRH, corticotropin-releasing hormone; dsRNA, double-stranded RNA; GHRH, growth hormone–releasing hormone; IL-1RA, IL-1 receptor antagonist; L-NAME, an arginine analogue; LPS, lipopolysaccharide; MPs, muramyl peptides; αMSH, α-melanocyte-stimulating hormone; NFκB, nuclear factor kappa B; NGF, nerve growth factor; NO, nitric oxide; NOS, nitric oxide synthase; PGD_2, prostaglandin D_2; PGE_2, prostaglandin E_2; sIL-1R, soluble IL-1 receptor; sTNFR, soluble TNF receptor.

pathogen-associated molecular patterns, or PAMPs. The innate immune system recognizes PAMPs using specialized receptors (pathogen recognition receptors, or PRRs) that are either membrane bound or cytoplasmic.[7] These PRRs include Toll-like receptors (TLRs) and nucleotide-binding domain and leucine-rich repeat domain receptors (NLRs; more commonly designated as nucleotide-binding oligomerization domain, or Nod, proteins).[10] The PRR binding of microbial PAMPs induces cytokines, and these cytokines in turn upregulate PRRs and cytokines in neighboring tissues, resulting in amplification of the initial response. Thus in infectious illness, pathogens induce cytokines, then cytokines activate the APR and thereby facilitate host defense through dozens of protective mediators and activated immune cell types.[9] Altered sleep (increased NREM sleep and suppressed rapid eye movement [REM] sleep) is one outcome of this cytokine cascade during infectious illness.

INFECTION-INDUCED ALTERATIONS IN SLEEP

The impact of infection on sleep has been determined for viral, bacterial, and fungal pathogens; prion-related diseases; and protozoan parasites. Most studies to date have used virus and bacteria as the infectious agent, and as such this chapter focuses primarily on altered sleep in response to these pathogens.

Viral Infections and Altered Sleep

Viral diseases that cause CNS lesions or systemic inflammation alter sleep.[11] In von Economo's seminal paper,[12] he related the postmortem location of brain lesions of patients suffering encephalitis lethargica to specific changes in sleep patterns. This work led to the concept that sleep was an active process, not simply the withdrawal of sensory stimuli, and to the idea that there was some degree of localization of neural networks regulating sleep. Although von Economo's encephalitis was commonly thought to have been caused by the 1918 influenza virus pandemic ("Spanish flu"), recent analyses reveal that the disease preceded the 1918 pandemic and was probably an autoimmune complication of streptococcal infections affecting the basal ganglia.[13,14] Despite the importance of von Economo's work, many years passed before the direct effects of viral infections on sleep were experimentally determined.

During the early stages of infection with human immunodeficiency virus (HIV), and before patients are symptomatic for acquired immunodeficiency virus (AIDS), sleep is altered such that excess stage 4 NREM sleep occurs during the latter half of the night.[15] Other CNS viral diseases, such as rabies[16] or viral encephalitis in rodents after vesicular stomatitis virus infection,[17] also are associated with altered sleep. In these CNS infections, it is difficult to know whether sleep is altered by direct actions on sleep regulatory mechanisms or whether altered sleep results from virus-induced brain lesions. One model that has been frequently used to determine effects of viral infections on sleep is influenza. Influenza virus localizes to the respiratory tract during the early stage of disease and does not cause brain lesions. In addition, influenza infections pose tremendous public health burdens owing to the millions of lives lost each year and the threat of pandemics. Smith and colleagues[18] report that low doses of influenza in humans increase sleep and cognitive dysfunction; these symptoms appear after low viral doses that fail to induce the better known characteristics of the APR, such as a fever. However, in that study indexes of behavior, not polysomnography, were used. Drake and colleagues[19] demonstrated in healthy human volunteers that infection with rhinovirus 23 increases total sleep time and impairs cognitive performance. (Rhinoviruses are the predominant cause of the "common cold.") In rabbits, intravenous injections of influenza virus are also associated with large increases in NREM sleep and suppressed REM sleep, even though the virus does not replicate in this species.[11]

Studies in mice infected with influenza virus demonstrate profound changes in sleep through the course of disease progression.[20-22] Changes in sleep of mice during influenza infection share some features of sleep responses to bacterial infections (described later). As a preclinical model, influenza infection of mice is clinically relevant because mouse-adapted strains of this virus can be introduced into the respiratory tract and can fully replicate in the lungs, causing a severe APR. Mice challenged intranasally with influenza virus display profound increases in NREM sleep and inhibition of REM sleep, which last 3 or more days.[20] Macrophages appear to be the critical immune cell type driving increased NREM sleep, whereas NK cells, neutrophils, and T lymphocytes do not play a significant role.[23] There are strain differences in responses of mice to this challenge,[24] indicating a genetic component affecting the sleep response to influenza virus. Genetic regulation of the inflammatory response to influenza in mice and humans has been reviewed elsewhere.[25]

One generic viral PAMP that increases NREM sleep and initiates other facets of the APR is virus-associated double-stranded RNA (dsRNA). All viruses examined to date produce virus-associated dsRNA, which is generally derived from the annealing of viral replication products rather than from the virus itself.[26] Virus-associated dsRNA, recognized by the PRR TLR3, induces numerous cytokines, including IL-1, IL-6, TNF, and IFN. Virus-associated dsRNA can be extracted from lungs of infected mice[27] and is capable of inducing an APR in naïve rabbits that is similar to that of live virus. Similarly, rabbits given short double-stranded (but not single-stranded) oligomers that correspond to a portion of influenza gene segment 3 also exhibit large increases in NREM sleep.[28] Synthetic dsRNA (polyriboinosinic polyribocytidylic acid, or poly I:C), when inoculated into the lungs of mice primed with IFN-α, induces an APR that is virtually identical to that after influenza virus.[26] These observations suggest that virus-associated dsRNA is sufficient to initiate the APRs seen in influenza-infected mice.

Poly I:C administered into rabbits also induces an influenza-like APR, but the corresponding single strands of poly I or poly C are inert. In rabbits, poly I:C can substitute for virus in the induction of a hyporesponsive state to viral challenge.[28] Rabbits challenged with viable virus or poly I:C have increased plasma antiviral activity that occurs concomitantly with the changes in sleep. The antiviral activity is attributed to IFN-α and other cytokines. Injection of IFN-α into rabbits also induces sleep responses similar to those induced by virus, poly I:C, or the double-stranded viral oligomers.[29] High doses of IFN-α increase NREM sleep in other species as well,[30] and low doses that simulate concentrations of IFN-α comparable to those observed during an infection inhibit both NREM and REM sleep in humans.[31]

Interferons play a major role in viral symptoms. Knockout (KO) mice have been widely used to better understand the

role of specific cytokines or hormones in host defense. Mice genetically deficient for the receptor that binds both IFN-α and IFN-β (the type I receptor) respond to poly I:C with altered sleep and a hypothermic response that is similar to that seen in infected wild-type mice. However, in influenza-infected IFN receptor KO mice, the APR occurs earlier,[32] suggesting that type I IFNs may modulate the APR, presumably by regulating proinflammatory cytokine production. Influenza-infected IFN receptor KO mice are less ill later in the infection and recover sooner.[32] Sleep modulatory cytokines, in addition to IFNs, likely mediate the sleep responses to influenza virus. For example, although the duration of altered NREM and REM sleep is the same in both strains after viral challenge, mice deficient in the 55-kd and 75-kd TNF receptors manifest reduced electroencephalogram (EEG) delta power, a measure of sleep intensity, whereas in wild-type control mice delta power increases.[33] IL-1 signaling in brain requires a brain-specific receptor accessory protein.[34] Mice lacking the IL-1 receptor brain-specific accessory protein have higher morbidity and mortality after influenza inoculation and sleep less during the infection than wild-type mice.

Another mediator that plays a role in sleep and host defense is nitric oxide, which is synthesized by multiple nitric oxide synthetases (NOSs). Mice deficient in either neuronal NOS or inducible NOS have attenuated NREM sleep responses to influenza challenge compared with infected wild-type controls.[35]

Mice and rats with natural mutations of the growth hormone–releasing hormone (GHRH) receptor express a dwarf phenotype and altered spontaneous NREM sleep.[36] The GHRH receptor is a candidate gene for regulating NREM sleep increases in response to influenza virus.[37] Dwarf mice with nonfunctional GHRH receptors (called lit/lit mice) fail to respond to influenza virus with increased NREM sleep or EEG delta power.[38] Instead, infected lit/lit mice manifest a pathologic state with EEG slow waves, enhanced muscle tone, and increased mortality.[38] Such results indicate that single genes can substantially modify sleep responses to infectious challenge. Importantly, results from lit/lit mice also demonstrate that the sleep responses forming part of the APR correlate with survival.

Influenza virus is a frequently used model for APR studies, in part because it was assumed that the virus does not invade the brain or lead to the complications associated with the use of neurovirulent viruses. Recent studies, however, demonstrate that the strain of influenza most commonly employed in preclinical studies rapidly invades the olfactory bulb of the mouse brain following intranasal inoculation.[39] The virus activates microglia in the outer layer of the olfactory bulb and upregulates IL-1 and TNF at times that correspond to the postinfection time period when the systemic APR begins. These studies suggest that cytokines made in the olfactory bulb could affect the CNS components of the APR to influenza virus, including sleep responses.

Bacterial Challenge

Altered sleep is also observed after bacterial infection. Indeed, results obtained after inoculating rabbits with the gram-positive bacteria *Staphylococcus aureus* were the first to suggest that NREM sleep responses were part of the APR.[40] In those experiments, rabbits were given *S. aureus* intravenously to induce septicemia; within a few hours of the inoculation NREM sleep was twice the amount as during comparable periods after control inoculation. Associated with the increase in NREM sleep were increases in amplitude of EEG slow waves. EEG slow wave (0.5 to 4.0 Hz) amplitudes are thought to indicate the intensity of NREM sleep. This initial phase of increased duration and intensity of NREM sleep lasted about 20 hours; it was followed by a more prolonged phase of decreased NREM sleep and decreased EEG slow wave amplitudes.[40] During both phases of the NREM sleep changes, REM sleep was inhibited and animals were febrile. Other changes characteristic of the APR, for example, fibrinogenemia and neutrophilia, occurred concurrently with the changes in sleep.[40] In subsequent studies in which gram-negative bacteria and other routes of administration were used, a similar general pattern of biphasic NREM sleep responses and REM sleep inhibition was observed.[41] However, the timing of sleep responses depends on the bacterial species and the route of administration. For example, after intravenous administration of *Escherichia coli,* NREM sleep responses are rapid in onset, but increased NREM sleep lasts only 4 to 6 hours. The subsequent phase of reduced NREM sleep and reduced amplitude of EEG slow waves is sustained for relatively long periods. In contrast, if the gram-negative bacterium *Pasteurella multocida* (a natural respiratory pathogen in rabbits) is given intranasally, a different time course of sleep responses is observed. In this case, the increased NREM sleep responses occur after a longer latency, and the magnitude of the increases in NREM sleep is less than the effects of this pathogen given by other routes of administration.

The intestinal lumen of mammals contains large amounts of many different bacteria species. Bacteria translocate into the intestinal lymphatics under normal conditions. Of importance to this discussion, intestinal permeability is altered after sleep deprivation, resulting in increased release of bacterial products into the lymphatics. Local lymph node macrophages phagocytose and digest these bacterial products,[42] releasing PAMPs that can trigger sleep responses. This mechanism operates at a low basal rate under normal conditions and is amplified during systemic inflammation. The phagocytosis by macrophages of bacterial products is also likely to be involved in sleep responses induced by sleep deprivation and excess food intake. A role for gut bacteria in sleep modulation is also evidenced by observations that reducing bacterial populations in the intestine is associated with reduced sleep.[43]

The first bacterial PAMP demonstrated to alter sleep was a specific muramyl peptide derived from bacterial cell wall peptidoglycans isolated from the brain and urine of sleep-deprived subjects.[44] Peptidoglycan components are recognized by certain NLRs and appear to play a major role in the pathogenesis of inflammatory mucosal diseases. The sleep-promoting activity of muramyl peptides is dependent on their chemical structure.[45] Many muramyl peptides are also immune adjuvants and pyrogenic, although the structural requirements for these biologic activities are distinct from those required for sleep-promoting activity.[45]

Another bacterial product that is involved in sleep responses to gram-negative bacteria is the lipopolysaccharide (LPS) component of cell wall endotoxin. LPS is the dominant PAMP associated with endotoxin, and it binds to TLR4. LPS

has been intensively studied in animal models[46] and humans volunteers[47] with respect to effects on sleep. LPS and its toxic moiety, lipid A, alter sleep in animals and humans.[45,48] The toxic moiety, lipid A, alters sleep, and modification of the lipid A structure alters LPS activity and reduces its sleep-altering properties. Healthy human volunteers injected with LPS manifest sleep changes, fever, cytokine expression, and hormonal changes[47] somewhat similar to those seen in animals. However, the impact of LPS on the human EEG differs from that observed in rabbits or rats, and in humans it requires a higher LPS dose to increase NREM sleep than it does to suppress REM sleep.

Most experimental studies of bacterial infections and sleep have used inoculation of a single pathogen species as the infectious challenge. The gut microbiome, however, is polymicrobial, and many infections result from invasion by multiple pathogen species. Such is the case in sepsis, during which polymicrobial infections are routinely the cause. Clinical studies demonstrate EEG anomalies in patients in the intensive care unit who become septic.[49] The etiology of sepsis is complex, and sepsis may result from many different kinds of insult. As a consequence, several preclinical models have been developed to study sepsis. Although each model used has strengths and limitations, the model currently considered to be the gold standard is cecal ligation and puncture (CLP).[50] CLP produces a polymicrobial infection that is considered clinically relevant because of its time course, because it reproduces the dynamic changes in cardiac function observed in human patients, and because there is a progressive release of inflammatory mediators. The severity of the ensuing infection is readily titrated in this model. Sleep is altered during the acute phase of CLP sepsis, which occurs 1 to 4 days after sepsis induction.[51] In this period, the NREM and REM sleep phases of rats increase during the dark period but are reduced during the light period. These changes in sleep coincide with increased cytokine messenger RNA (mRNA) and protein in the brain.[52] Of interest, effects of sepsis on body temperature and activity rhythms persist long after the animal has recovered and is no longer at risk for dying.[52] These observations suggest that sepsis alters brain function and are in agreement with observations that patients surviving sepsis often suffer severe and debilitating cognitive impairment.

Other microbes, for example, protozoan parasites such as *Trypanosoma brucei brucei,* express their own PAMPs, which bind to specific TLRs and induce sleep responses.[21] Trypanosomiasis in rabbits is associated with periods of increased NREM sleep that occur about every 7 days. Trypanosomes undergo antigenic variations in the host; the proliferating new antigenic variants stimulate new host immune responses, and such periods are accompanied by increased NREM sleep.[21] As with bacteria and viruses, protozoans induce cytokine production by the host.

In summary, infectious challenge is associated with profound changes in sleep. As mentioned in the overview of the APR, PRRs such as the TLR and NLR receptor families detect the various PAMPs capable of altering sleep. Detection of PAMPS by the innate immune system explains, in part, why diverse microbial pathogens activate stereotypic host defense responses such as fever, anorexia, and altered sleep. Microbe-induced alterations in sleep, like the other components of the APR, are adaptive.[53]

EFFECTS OF SLEEP LOSS ON IMMUNE FUNCTION

Sleep is altered during immune challenge, yet whether sleep loss alters immune function has been more difficult to demonstrate. There are multiple systems associated with immunity, each with myriad mediators and modulators. There are positive and negative feedback control mechanisms that interact in complex ways. This complexity of the immune system makes it difficult to determine what measurements one should use to assess immune function. From a functional perspective, the most important question is whether sleep loss renders the animal more vulnerable to infection, tumor formation, or systemic inflammatory diseases. (We already know that sleep loss renders one more vulnerable to accidental injury.) Although few studies have been conducted within the context of sleep, some suggest relationships between sleep and functional immune outcomes. For example, among 12 mammalian species sampled, those with longer daily sleep times have the greatest number of white blood cells and are least susceptible to parasites.[54] Susceptibility to infection has been used as an end point in some studies of human subjects. Shift workers are considered chronically sleep deprived, and a large population study reveals increased incidence of infections in those who experienced the most shift changes.[55] However, sleep time was not quantified in these individuals, and many other variables (including circadian rhythm disruption and stress) confound the interpretation of these results. Self-reports of sleep duration and sleep efficiency before controlled challenge with a "cold" virus suggest that individuals sleeping less than 7 hours per night, or with sleep efficiency of less than 92%, are more likely to develop colds.[56] Although this study was carefully conducted, self-reports may not adequately capture information about sleep duration, and mechanisms underlying these associations cannot be determined.

Vaccinations are effective only when the antigenic challenge (the vaccination) induces a sufficient antibody response (acquired immunity) such that on subsequent exposure to the same or similar pathogen, there is already an immune memory. Some individuals do not respond to vaccination with an antibody response sufficient to confer protection, and factors contributing to nonresponders are not well understood. Several studies of human volunteers have examined the effects of sleep loss on subsequent antibody responses to vaccines. The first of these studies used a protocol in which subjects were restricted to 4 hours of sleep opportunity per night for 4 nights and then given a flu shot.[57] Sleep restriction continued for 2 nights after the vaccination. Subjects then were allowed 12 hours of sleep opportunity each night for the next 7 days. Control subjects were allowed ad libitum sleep but otherwise followed the same protocol. Sleep-restricted subjects 10 days after vaccination produced less than half the antibody titers of control subjects who were allowed 8 hours of sleep opportunity per night. In a different study, subjects were given a hepatitis A vaccination and then deprived of sleep for one night. Antibody titers in sleep-deprived subjects 4 weeks after the vaccination were reduced by about 50% relative to those of control (non–sleep-deprived) subjects.[58] A similar study by the same group demonstrated that effects of a single night of total sleep loss reduced antigen-specific helper T cells and antigen-specific antibody for at least 1 year.[59] Collectively, these aforementioned controlled laboratory studies of healthy volunteers

suggest that sleep loss impairs acquired immunity and that there are functional outcomes. There are few community-based studies relating sleep duration to antibody production after vaccination, but at least one[60] demonstrates a direct relationship between sleep duration (defined by actigraphy) and antibody titers in response to hepatitis B vaccination. This study[60] also demonstrated that short sleep duration was associated with decreased clinical protection from hepatitis B at the conclusion of the three-vaccination series. Studies of clinical populations focused on similar questions are difficult to control and interpret. At least one clinical study failed to demonstrate differences in the antibody response to influenza vaccine in moderate to severe obstructive sleep apnea patients compared with controls.[61]

In contrast to functional studies in which effects of sleep or sleep loss on resistance to parasites or antibody production is the primary outcome, the most widely used approach to determine effects of sleep loss on immune function is to select one or more parameters of interest, for example, NK cell activity or plasma cytokine concentrations, and determine whether sleep loss alters these outcomes. Often such results leave the reader uninformed as to whether the outcome is adverse or beneficial for the host. Sleep deprivation or sleep disruption can be associated with stress, and many factors influence the impact of stress on sleep.[62] The most commonly measured "stress hormone" is cortisol in humans and corticosterone in rodents. Cortisol or corticosterone is a critical negative feedback regulator of cytokine production in brain. As such, nonspecific increases in this hormone could affect the outcome measure of interest. In addition to stressor-induced elevation of cortisol or corticosterone, sleep deprivation protocols often increase locomotor activity, alter feeding patterns, and disrupt normal variation in other hormones and body temperature. Each of these variables is known to affect immune function. Despite these limitations, data derived from human volunteers or laboratory animals suggest that sleep loss does indeed influence the immune system.

Results from studies of laboratory animals subjected to short-term sleep deprivation are consistent with most human studies. Toth and colleagues challenged rabbits with *E. coli* before or after 4 hours of sleep deprivation. They concluded that sleep deprivation failed to exacerbate *E. coli*–induced clinical illness, although the combination of sleep deprivation and bacterial infection altered some facets of sleep responses compared with either manipulation alone.[63] Furthermore, mice immunized against influenza virus and then rechallenged with influenza just before sleep deprivation failed to clear the virus from their lungs.[64] However, in a similar study[65] sleep loss failed to alter preexisting mucosal and humoral immunity in either young or senescent mice. The variation in the effects of sleep loss on outcomes in mice subjected to influenza virus likely results from differences in the sleep deprivation protocols, end points analyzed, and influenza models employed. Little research has focused on sleep deprivation and clinical responses to bacteria, but mortality is greater in mice in which sleep is disrupted after they are made septic by CLP.[66] Collectively, these studies suggest that acute sleep loss impairs or alters host defense.

The effects of long-term sleep loss on host defense in laboratory rodents are more striking. If rats obtain only about 20% of their normal sleep when deprived by the disk-over-water method,[67] they die after a period of 2 to 3 weeks.[68] Yoked control rats, which manage to maintain about 80% of their normal sleep during the protocol period, survive. The experimental rats, but not the yoked controls, develop septicemia.[68] Bacteria cultured from the blood are primarily facultative anaerobes indigenous to the host and environment. These results demonstrate that, using this method, innate host defenses in the rat are compromised by long-term sleep loss. These results suggest that prolonged sleep loss likely amplifies the normally occurring process of gut permeability to bacteria and bacterial products. However, these interactions may be somehow unique to rats because other species do not die when subjected to sleep deprivation by the disk-over-water method.

Sleep disruption may induce low-grade inflammation or may render the animal more susceptible to inflammatory challenge. We recently demonstrated that disrupting daytime sleep of mice for prolonged periods (9 days) exacerbates febrile responses to LPS.[69] The exacerbated febrile response to LPS under the conditions of this study may be due to sleep disruption per se because no other parameters measured (corticosterone, food or water intake, body weight) differed substantially from either home cage control animals or animals housed on the sleep-disruption device but allowed ad libitum sleep.

An independent literature clearly demonstrates that sleep loss is associated with changes in parameters normally associated with inflammation and the immune response. Cytokines such as IFN, IL-1, and TNF are well known for their roles as immunomodulators, and their production is altered by sleep deprivation or sleep disruption.[70] For example, sleep deprivation enhances TNF production in streptococcus-stimulated white blood cells. Other stressors, unlike sleep deprivation, fail to prime for systemic production of TNF, whereas sleep loss increases the ability of LPS-stimulated monocytes to produce TNF. The ability of cultures of whole blood to produce IL-1 and IFN in response to LPS is maximal at the time of sleep onset. In humans or animals, sleep deprivation leads to enhanced nocturnal plasma levels of IL-1–like activity.

Several reports show that in healthy volunteers plasma levels of cytokines are related to the sleep-wake cycle. Such relationships were first described by demonstrating that plasma IL-1–like activity was related to the onset of slow wave sleep.[71] Plasma concentrations of TNF vary in phase with EEG slow wave amplitudes.[72] There is also a temporal relationship between sleep of healthy human volunteers and IL-1 activity.[73] Several clinical conditions associated with sleepiness, such as sleep apnea, chronic fatigue syndrome, chronic insomnia, preeclampsia, postdialysis fatigue, psychoses, rheumatoid arthritis, and AIDS, are associated with enhanced plasma levels of TNF and other cytokines.[70] Only those sleep apnea patients showing elevated TNF activity experience fatigue.[74]

Other facets of the immune response are also linked to sleep. About 40 years ago, altered antigen uptake after sleep deprivation was reported.[75] Studies carried out in the 1970s also showed a decrease in lymphocyte DNA synthesis after 48 hours of sleep deprivation and a decrease in phagocytosis after 72 hours of sleep deprivation.[76,77] Sleep deprivation also induces changes in mitogen responses. Circulating immune complexes fall during sleep and rise again just before getting out of bed, and in mice sleep deprivation reduces immunoglobulin G (IgG) catabolism, resulting in elevated IgG levels. In contrast, one study failed to show an effect of sleep deprivation on spleen cell counts, lymphocyte proliferation, or

plaque-forming cell responses to antigens in rats.[78] In a comprehensive study of human volunteers, 64 hours of sleep deprivation reduced CD4, CD16, CD56, and CD57 lymphocytes after 1 night of sleep loss, although the number of CD56 and CD57 lymphocytes increased after 2 nights of sleep loss.[79] Another group also showed that 1 night of sustained wakefulness reduced counts of all lymphocyte subsets measured.[80]

Sleep and sleep loss are associated with changes in NK cell activity. NK cell activity is reduced in patients with insomnia[81] and decreases after partial night sleep restriction.[82,83] In contrast, increased NK cell activity increases after 64 hours of total sleep deprivation.[79] Circulating NK cell activity, as well as NK cell activity in a variety of tissue compartments, may be sensitive to sleep, although the exact nature of relationships between NK cell activity and sleep likely depend on the specific experimental conditions used to elucidate them.

In summary, determination of sleep deprivation effects on immune function may be confounded by stress and other coincident physiologic responses in animals. Concurrent physiologic changes (other than stress) also complicate sleep deprivation studies in humans. Sleep deprivation protocols are not standardized in animal or human studies, making comparison of results difficult. Despite the problems with available data, collectively the extensive literature on sleep deprivation and immune changes suggests that short-term deprivation potentiates immune function, whereas long-term deprivation leads to functional immune suppression.

MECHANISMS LINKING SLEEP AND IMMUNITY

Substantial evidence now suggests that IL-1 and TNF are involved in physiologic sleep regulation.[70,84] Furthermore, IL-1 and TNF mRNA and protein change during pathologies characterized by altered sleep. Sleep deprivation is associated with enhanced sleepiness, sleep rebound, sensitivity to kindling and pain stimuli, cognitive and memory impairments, performance impairments, depression, and fatigue. Exogenous administration of IL-1 or TNF induces all of these symptoms associated with sleep loss.[46,70] Further, chronic pathologies associated with sleep loss such as metabolic syndrome, chronic inflammation, and cardiovascular disease are also characterized by changes in IL-1 and TNF activity,[46,70] and in some cases these pathologies are attenuated if these cytokines are inhibited.[85-87] Clinically available inhibitors of either IL-1 (e.g., the IL-1 receptor antagonist, anakinra) or TNF (e.g., the TNF-α soluble receptor, etanercept) alleviate fatigue and excess sleepiness in humans with pathologies such as sleep apnea or rheumatoid arthritis.[85,86,88] The IL-1 receptor antagonist and TNF soluble receptor are normal gene products found in blood and brain, and their concentrations are altered by sleep.[46]

In addition to being immunocyte products, the production of which is amplified by viral and bacterial products, IL-1 and TNF are also found in normal brain.[46,70] IL-1and TNF mRNA have diurnal rhythms in the brain, with the highest values being associated with periods of maximum sleep. TNF protein also has a sleep-associated diurnal rhythm in several brain areas, and IL-1 in cerebrospinal fluid varies with the sleep-wake cycle.[89] Cortical expression of TNF is enhanced by afferent nerve activity,[90] which may be part of the process that is responsible for local use-dependent sleep.[46]

Administration of either IL-1 or TNF promotes NREM sleep.[46,48,70] The increase in NREM sleep after either IL-1 or TNF administration is physiological in the sense that sleep remains episodic and readily reversible if animals are disturbed. Further, IL-1 or TNF enhances NREM sleep intensity, as measured by the amplitude of EEG delta waves. The effects of IL-1 on sleep depend on dose and the time of day it is given.[91] IL-1 and TNF inhibit the binding of the BMAL/CLOCK complex in the suprachiasmatic nucleus[92]; this action may be responsible for the differential effects of these cytokines at different times of the day. Finally, knockout strains of mice that lack either the type I IL-1 receptor,[93] the 55-kd TNF receptor,[94] or both of these receptors[95] sleep less than control strains.

NREM sleep increases after sleep deprivation, excessive food intake, or acute mild increases in ambient temperature. The somnogenic actions of each of these manipulations are associated with enhanced production of either IL-1 or TNF. After sleep deprivation, circulating IL-1 increases, brain levels of IL-1 mRNA increase, and the NREM sleep rebound that would normally occur after sleep deprivation is greatly attenuated if either IL-1 or TNF is blocked using antibodies or soluble receptors.

The actions of excessive feeding on NREM sleep and liver and brain production of IL-1 represent physiologic changes, yet they likely involve the actions of bacterial cell wall products. Gut permeability to bacteria and bacterial products is influenced by dietary factors,[96] and the gram-negative bacteria cell wall product, endotoxin, is a normal constituent of portal blood.[97] Endotoxin stimulates IL-1 production in liver and elsewhere. Other bacterial cell wall products, for example, muramyl peptides, also have the capacity to stimulate IL-1 and TNF production[45] and to cross the intestinal wall into lymph. NREM sleep responses induced by muramyl dipeptide are attenuated if animals are pretreated with either blockers of IL-1 or TNF.[45,98] As mentioned previously, prolonged sleep deprivation of rats by the disk-over-water method results in bacteremia. It thus seems likely that the interaction of those bacteria with liver macrophages results in the amplification of the physiologic processes that are also associated with excessive food intake.

IL-1 and TNF act within a biochemical network (see Figure 19-1). For example, IL-1 and TNF stimulate nuclear factor kappa B (NFκB) production. NFκB is a DNA-binding protein involved in transcription. Other sleep-altering cytokines, such as acidic fibroblast growth factor, epidermal growth factor, and nerve growth factor, also stimulate NFκB production. NFκB promotes IL-1 and TNF production and thus forms a positive feedback loop. Sleep deprivation is associated with the activation of NFκB in the cerebral cortex, basal forebrain cholinergic neurons, and lateral hypothalamus. Activation of NFκB also promotes IL-2, IL-6, IL-8, IL-15, and IL-18 production, each of which promotes sleep in rats.[46,48,70]

GHRH is likely involved in IL-1 promotion of NREM sleep. There is an independent literature implicating GHRH in sleep regulation.[31,70] Administration of GHRH promotes NREM sleep, whereas antagonizing GHRH or its receptor inhibits spontaneous NREM sleep and blocks the increase in NREM sleep induced by IL-1. Finally, as mentioned previously, the GHRH receptor seems necessary for an effective response to viral challenge.[38]

The mechanisms by which sleep regulatory substances (SRSs) are regulated and induce sleep are beginning to be understood. TNF and IL-1 neuronal expression is enhanced

in response to afferent nerve activity. For instance, excessive stimulation of rat facial whiskers for 2 hours enhances IL-1 and TNF immunoreactivity in the cortical layers of the somatosensory cortical columns that receive the enhanced afferent input.[90]

What is it about neuronal activity or wakefulness that causes the enhanced SRS activity? Neuronal activity manifests as presynaptic and postsynaptic events that act in both the short and long term. Neuronal activity in presynaptic neurons results in the release of transmitters and adenosine triphosphate (ATP).[99] In turn, some of that ATP is converted to adenosine, and some ATP acts on purine P2X7 receptors on glia to release TNF and IL-1.[46,100] ATP also acts to release cytokines in immunocytes.[101] The extracellular adenosine derived from ATP interacts with neurons through the adenosine A_1 receptor (A1AR). The TNF released in response to ATP activates NFκB in postsynaptic and presynaptic neurons.[46] NFκB enhances the A1AR, thereby rendering the cell more sensitive to adenosine. NFκB also enhances production of a subunit of the AMPA receptor gluR1 mRNA. The time courses of enhanced mRNA for receptors or ligands are much slower than the direct actions of adenosine or TNF; the subsequent production of protein offers a way for the brain to keep track of prior neuronal network activity and translate that activity into a greater sleep propensity. The various time courses of action of the neurotransmitters (milliseconds), the conversions of ATP to adenosine and its actions (seconds), and the actions of ATP-induced release of cytokines and their subsequent effects on gene transcription and translation (minutes to hours) provide a mechanism for activity-dependent oscillations of neuronal assembly sleep.[102]

There is a growing literature demonstrating direct effects of IL-1 and TNF on neural substrates implicated in the regulation of sleep. Some of these mechanisms include interactions with classic neurotransmitters such as glutamate, serotonin, acetylcholine, gamma-aminobutyric acid, histamine, and dopamine.[103] For example, IL-1 increases serotonergic activity in brain regions implicated in sleep regulation,[104] and an intact serotonergic system is required for the full effects of IL-1 on sleep to manifest.[105,106] IL-1 inhibits discharge rates of serotonergic[107,108] and cholinergic[109] neurons in brainstem. Within the hypothalamus, IL-1 increases c-Fos[110] and inhibits wake-active neurons.[111] TNF promotes sleep if microinjected into the anterior hypothalamus, whereas injection of a soluble TNF receptor into this area reduces sleep.[112] TNF also alters sleep if injected into the locus coeruleus,[113] effects likely related to interactions with α_2-adrenergic receptive mechanisms and norepinephrine release.[114] Interestingly, TNF or IL-1, if applied locally onto the surface of the cerebral cortex unilaterally, enhances EEG delta activity on the side to which it is applied but not the contralateral side.[115,116] Conversely, application of the TNF soluble receptor unilaterally onto the cortex of sleep-deprived rats attenuates sleep loss–induced EEG delta activity on the side injected, but not on the opposite side. Further, unilateral application of a TNF siRNA (inhibits TNF) reduces spontaneous cortical TNF expression and EEG slow wave activity on the ipsilateral side. These latter studies suggest that TNF acts locally within the cortex (in addition to its somnogenic actions in the hypothalamus) to enhance EEG synchronization and possibly sleep intensity. In fact, application of TNF directly to the cortex enhances the probability of individual cortical columns entering into a sleep-like state.[90]

CLINICAL PEARL

Although physicians routinely prescribe bed rest to aid in recuperation from infections and other maladies, as yet there is little direct evidence that sleep aids in recuperation. Such studies are difficult to perform because the recovery from an infection, for instance, is influenced by the baseline severity of the infection (i.e., differences in exposure or innate resistance that determine the replication level and clearance of the invading microbe) as well as by what the patient does during the infection. Physicians will continue to prescribe bed rest, and often this is just what the patient desires. It seems likely that such advice is beneficial because enhanced sleep is part of the adaptive APR. The only evidence of which we are aware that is relevant to this issue is consistent with the concept that sleep aids in recuperation; after infectious challenge, animals that have robust NREM sleep responses have a higher probability of survival than animals that fail to exhibit NREM sleep responses.[117] Although strictly correlative, these data suggest that sleep does indeed facilitate recovery. Perhaps our grandmothers' folk wisdom pertaining to the preventive and curative attributes of sleep and sickness is correct, although much additional research is needed before we know whether this admonishment has a biologic basis.

SUMMARY

Sleepiness, like fever, is commonly experienced at the onset of an infection or other cause of systemic inflammation. Changes in sleep in response to microbes appear to be one facet of the acute phase response. Typically, soon after infectious challenge, time spent in NREM sleep increases and REM sleep is suppressed. The exact time course of sleep responses depends on the infectious agent, the route of administration, and the time of day the infectious challenge is given.

There is a common perception that sleep loss renders one vulnerable to infection. Some studies demonstrate that sleep loss impairs acquired immunity, and many studies have shown that sleep deprivation alters selected aspects of the innate immune response. A few studies have combined sleep deprivation with infectious challenge. After mild sleep deprivation, several immune system parameters (e.g., NK cell activity) change, and resistance to a viral challenge is decreased in individuals who spontaneously sleep less. Studies have not yet been done to determine the effects of sleep deprivation on recovery from an infection.

The molecular mechanisms responsible for the changes in sleep associated with infection appear to be an amplification of a physiologic sleep regulatory biochemical cascade. Sleep regulatory mechanisms and the immune system share regulatory molecules. The best characterized are IL-1 and TNF, which are involved in physiologic NREM sleep regulation. IL-1 and TNF are key players in the development of the acute phase response induced by infectious agents. During the initial response to infectious challenge these proinflammatory cytokines are upregulated, leading to the acute phase sleep response. This chain of events includes well-known immune response modifiers such as prostaglandins, nitric oxide, and adenosine. Each of these substances, and their receptors, is a normal constituent of the brain, and each is involved in physiologic sleep regulation.

Endocrine Physiology in Relation to Sleep and Sleep Disturbances

Eve Van Cauter; Esra Tasali

Chapter Highlights

- Sleep and circadian rhythmicity have distinct modulatory effects on endocrine and metabolic function and affect activity of the hypothalamic-pituitary axes, carbohydrate metabolism, appetite regulation, and the hormone control of blood pressure and body-fluid balance.
- Sleep curtailment has become an endemic behavior in modern society. Current evidence from both epidemiologic and laboratory studies suggests that insufficient sleep due to either sleep curtailment or sleep disorders has deleterious effects on hormones, glucose metabolism, and body weight regulation.
- Reciprocally, the most common endocrine disorders, including obesity, diabetes, and polycystic ovary syndrome, are associated with a higher prevalence of and risk for sleep disorders, particularly obstructive sleep apnea.
- This chapter reviews the effects of sleep and sleep disturbances on the endocrine system, the impact of reduced sleep duration and quality on hormonal and metabolic function, age-related alterations in sleep and endocrine function, and the adverse metabolic consequences of sleep disturbances in obesity, type 2 diabetes, and polycystic ovary syndrome.

This chapter is divided in three main sections. We start with a review of the interactions between sleep and endocrine release in the hypothalamic-pituitary axes and the roles of sleep in carbohydrate metabolism, appetite regulation, and hormone control of body-fluid balance in healthy adults. Table 20-1 provides basic information about the hormones that will be discussed in this chapter. We then summarize the growing body of evidence linking decrements of sleep duration or quality that occur with sleep restriction, in sleep disorders, or as a result of normal aging with disturbances of endocrine and metabolic function. Lastly, we review recent evidence linking disorders of sleep-wake regulation with metabolic and endocrine diseases, including obesity, type 2 diabetes, and polycystic ovary syndrome (PCOS). For a review of sleep abnormalities in other endocrine diseases, the reader is referred to other sections in this book.

MODULATION OF ENDOCRINE FUNCTION BY SLEEP-WAKE HOMEOSTASIS AND CIRCADIAN RHYTHMICITY

In healthy adults, reproducible changes of essentially hormonal and metabolic variables occur during sleep and around wake-sleep and sleep-wake transitions. These daily events reflect the interaction of central circadian rhythmicity and sleep-wake homeostasis. Pathways by which circadian rhythmicity and sleep-wake homeostasis affect peripheral endocrine function and metabolism include the modulation of the activity of the hypothalamic releasing and inhibiting factors, the autonomous nervous system control of endocrine organs, and the 24-hour periodicity of circulating glucocorticoids. Findings from genome-wide association and epidemiologic studies also support a role of circulating melatonin levels on specific endocrine targets, including the pancreatic beta cells.[1-4]

Circadian oscillations can be generated in many peripheral organs, including tissues that release endocrine signals such as adipocytes, liver, adrenal glands, and pancreatic beta cells.[5,6] These "local" oscillators appear to be under the control of the central pacemaker in the suprachiasmatic nuclei either directly through neural or endocrine signals, or indirectly through its control of behavioral rhythms such as the sleep-wake cycle and feeding schedule.

To differentiate between effects of circadian rhythmicity and those subserving sleep-wake homeostasis, researchers have used experimental strategies that take advantage of the fact that rhythms primarily under the control of the central circadian pacemaker take several days to adjust to a large sudden shift of sleep-wake and light-dark cycles (such as occur in jet lag and shift work). Such strategies allow for the effects of circadian modulation to be observed in the absence of sleep and for the effects of sleep to be observed at an abnormal circadian time. Figure 20-1 illustrates mean profiles of hormonal plasma concentrations, glucose levels, and insulin-secretion rates (ISRs) observed in healthy subjects who were studied before and during an abrupt 12-hour delay of the sleep-wake and dark-light cycles, for normal-deprived-recovery sleep periods. To eliminate the effects of feeding, fasting, and postural changes, the subjects remained recumbent throughout the study, and the normal meal schedule was replaced by intravenous glucose infusion at a constant rate.[7]

As shown in Figure 20-1, this drastic manipulation of sleep had only modest effects on the wave shape of the cortisol profile, in sharp contrast with the immediate shift of the growth hormone (GH) and prolactin (PRL) rhythms that followed the shift of the sleep-wake cycle. The temporal

organization of thyroid-stimulating hormone (TSH) secretion appears to be influenced equally by circadian and sleep-dependent processes. Indeed, the evening elevation of TSH levels occurs well before sleep onset and has been shown to reflect circadian phase. During sleep, as further described later, an inhibitory process prevents TSH concentrations from rising further. Consequently, in the absence of sleep, the nocturnal TSH elevation is markedly amplified. Both sleep and time of day clearly modulated glucose levels and ISRs. Nocturnal elevations of glucose and ISRs occur even when the subjects are sleep deprived, and recovery sleep at an abnormal circadian time is also associated with elevated glucose level and ISR but at a lower amplitude. This pattern of changes in glucose levels and ISRs reflects changes in glucose use because, when glucose is infused exogenously, as described earlier and illustrated in the study in Figure 20-1 (central section of glucose secretion pattern, pink bar period), endogenous glucose production is largely inhibited.

The Growth Hormone Axis

Pituitary release of GH is stimulated by hypothalamic growth hormone–releasing hormone (GHRH) and inhibited by somatostatin. In addition, the acylated form of ghrelin, a peptide produced predominantly by the stomach, binds to the growth hormone secretagogue receptor and is a potent endogenous stimulus of GH secretion.[8] There is a combined and probably synergic role of GHRH stimulation, elevated nocturnal ghrelin levels, and decreased somatostatinergic tone in the control of GH secretion during sleep. Although sleep clearly involves major stimulatory effects on GH secretion, the hormones of the somatotropic axis, including GHRH, ghrelin, and GH itself, in turn appear to be involved in sleep regulation.[9]

In healthy adult subjects, the 24-hour profile of plasma GH levels consists of stable low levels abruptly interrupted by bursts of secretion. The most reproducible GH pulse occurs shortly after sleep onset.[10] In men, the sleep-onset GH pulse is generally the largest, and often the only, secretory pulse observed over the 24-hour span. In women, daytime GH pulses are more frequent, and the sleep-associated pulse, although still present in most individual profiles, does not account for the majority of the 24-hour secretory output. Sleep onset elicits a pulse in GH secretion whether sleep is advanced, delayed, or interrupted and reinitiated. The mean GH secretion profile shown in Figure 20-1 illustrates the maintenance of the relationship between sleep onset and GH release in subjects who underwent a 12-hour delay shift of the sleep-wake cycle. There is a consistent relationship between the appearance of delta waves in the electroencephalogram (EEG) and elevated GH concentrations, and maximal GH release occurs within minutes of the onset of slow wave sleep (SWS).[10,11] In healthy young men, there is a quantitative correlation between the amount of GH secreted during the sleep-onset pulse and the duration of the slow wave episode.[12] Pharmacologic stimulation of SWS increases in GH secretion.[13,14] Sedative hypnotics that are ligands of the gamma-aminobutyric acid A receptor, such as benzodiazepines and imidazopiridines, do not increase nocturnal GH release, consistent with their lack of stimulation of slow wave activity.[15]

The robust relationship between early sleep and GH release is consistent with a synchronization between anabolic processes in the body and a state when behavioral rest occurs and cerebral glucose use is at its lowest point.[16] There is good evidence to indicate that stimulation of nocturnal GH release and stimulation of SWS reflect, to a large extent, synchronous activity of at least two populations of hypothalamic GHRH neurons.[16] Sleep-onset GH secretion appears to be primarily regulated by GHRH stimulation occurring during a period of decreased somatostatin inhibition of somatotropic activity. Indeed, in humans, GH secretion during early sleep may be nearly totally suppressed by administration of a GHRH antagonist.[17] The late evening and nocturnal hours coincide with the trough of a diurnal variation in hypothalamic somatostatin tone[18] that is likely to facilitate nocturnal GH release. It is also possible that ghrelin plays a role in causing increased GH secretion during sleep because the postdinner rebound of

ghrelin levels results in maximal concentrations during the early part of the night.[19-21]

The upper panel of Figure 20-1 shows that the secretion of GH is increased during sleep independently of the circadian time when sleep occurs and that sleep deprivation results (the pink bar period on the figure) in greatly diminished release of this hormone. However, a slight increase may be observed during nocturnal sleep deprivation, suggesting the existence of a weak circadian component that could reflect, as discussed earlier, lower somatostatin inhibition. Following a night of total sleep deprivation, GH release is increased during the daytime such that the total 24-hour secretion is not significantly affected.[22] Again, the mechanisms underlying this compensatory daytime secretion are unknown, but they could involve decreased somatostatinergic tone or elevated ghrelin levels, as have been observed in experimental studies of partial or total sleep deprivation.[23,24]

Marked rises in GH secretion before the onset of sleep have been reported by several investigators.[25-27] Presleep GH pulses may reflect the presence of a sleep debt because they occur consistently after recurrent experimental sleep restriction.[28] The short-term negative feedback inhibition exerted by GH on its own secretion may also explain observations of an absent or reduced GH pulse during the first slow wave period, when a secretory pulse occurred before sleep onset. Awakenings interrupting sleep have an inhibitory effect on GH release.[29,30] Thus sleep fragmentation generally decreases nocturnal GH secretion.

The Corticotropic Axis

Activity of the corticotropic axis—a neuroendocrine system associated with the stress response and behavioral activation—may be measured peripherally through plasma levels of the pituitary adrenocorticotropic hormone (ACTH) and of cortisol, the adrenal hormone directly controlled by ACTH stimulation. The plasma levels of these hormones decline from an early morning to maximal level throughout the daytime and are near the lower limit of most assays in the late evening and early part of the sleep period. Although the rhythm of ACTH reflects a circadian variation in corticotropin-releasing hormone (CRH) activity, itself under control by the central circadian pacemaker, a peripheral clock in the adrenals enhances the rhythm of glucocorticoid release, one of the

largest and most robust rhythms in humans.[31,32] Sleep is normally initiated when corticotropic activity is quiescent. Reactivation of ACTH and cortisol secretion occurs abruptly a few hours before the usual waking time.

The mean cortisol secretion profile shown in Figure 20-1 illustrates the remarkable persistence of this diurnal variation even when sleep is manipulated. Nonetheless, modulatory effects of sleep or wake have been clearly demonstrated. Indeed, a number of studies have indicated that sleep onset is reliably associated with a short-term inhibition of cortisol secretion,[7,33] although this effect may not be detectable when sleep is initiated at the time of the daily highest corticotropic activity, that is, in the morning.[34] Under normal conditions, because cortisol secretion is already quiescent in the late evening, this inhibitory effect of sleep, which is temporally associated with the occurrence of slow wave sleep,[35-37] results in a prolongation of the quiescent period. Therefore under conditions of sleep deprivation (pink bar period, Figure 20-1), the nadir of cortisol secretion is less pronounced and occurs earlier than under normal conditions of nocturnal sleep. Conversely, awakening at the end of the sleep period is consistently followed by a pulse of cortisol secretion.[7,30,38]

During sleep deprivation, the rapid effects of sleep onset and sleep offset on corticotropic activity are obviously absent, and, as may be seen in the profiles shown in Figure 20-1 (left side of cortisol secretion pattern), the nadir of cortisol level is slightly higher than during nocturnal sleep (because of the absence of the inhibitory effects of the first hours of sleep), and the morning maximal peak is slightly lower (because of the absence of the stimulating effects of morning awakening). Overall, the amplitude of the rhythm is reduced by about 15% during sleep deprivation compared with normal conditions. In addition to the immediate modulatory effects of sleep-wake transitions on cortisol levels, nocturnal sleep deprivation, even partial, results in an elevation of cortisol levels on the following evening (not shown in Figure 20-1).[39] Sleep loss thus appears to delay the normal return to evening quiescence of the corticotropic axis.

The Thyroid Axis

Daytime levels of plasma TSH are low and relatively stable until the initiation of a rapid elevation in the early evening resulting in maximal concentrations around the beginning of the sleep period.[37,40] The later part of sleep is associated with a progressive decline in TSH levels, and daytime values resume shortly after morning awakening. The first 24 hours of the study illustrated in Figure 20-1 are typical of the diurnal TSH rhythm. Because the nocturnal rise of TSH occurs well before the time of sleep onset, it probably reflects a circadian effect. A marked effect of sleep on TSH secretion may be seen during sleep deprivation (as shown in Figure 20-1), when nocturnal TSH secretion is increased by as much as 200% over the levels observed during nocturnal sleep. Thus sleep exerts an inhibitory influence on TSH secretions, and sleep deprivation relieves this inhibition.[37,41]

Interestingly, when sleep occurs during daytime hours, TSH secretion is not suppressed significantly below normal daytime levels, indicating once again the interaction between the effects of circadian time and sleep effects. When the depth of sleep at the habitual time is increased by prior sleep deprivation, the nocturnal TSH rise is more markedly inhibited, suggesting that SWS is probably the primary determinant of the sleep-associated fall.[37] Awakenings interrupting nocturnal sleep appear to relieve the inhibition of TSH and are consistently associated with a short-term TSH elevation.

Circadian and sleep-related variations in thyroid hormones have been difficult to demonstrate, probably because these hormones have long half-lives and are bound to serum proteins. Thus their peripheral concentrations are affected by diurnal variations in hemodilution caused by postural changes. However, under conditions of sleep deprivation, the increased amplitude of the TSH rhythm may result in a detectable increase in plasma triiodothyronine (T_3) levels, paralleling the nocturnal TSH rise.[42] If sleep deprivation is continued for a second night, the nocturnal rise of TSH is markedly diminished compared with that occurring during the first night.[42,43] It is likely that following the first night of sleep deprivation, the elevated thyroid hormone levels, which persist during the daytime period because of the prolonged half-life of these hormones, limit the subsequent TSH rise at the beginning of the next nighttime period. Data from a study of 64 hours of sleep deprivation suggest that prolonged sleep loss may be associated with an upregulation of the thyroid axis, with lower levels of TSH and higher levels of thyroid hormones.[44] Findings of elevations in free thyroxine (T_4) index and of peripheral levels of free T_3 and free T_4 in subjects submitted to experimental sleep restriction or total sleep deprivation are consistent with this hypothesis.[45-48]

Prolactin Secretion

Under normal conditions, PRL levels undergo a major nocturnal elevation starting shortly after sleep onset and culminating around midsleep. Decreased dopaminergic inhibition of PRL during sleep is likely to be the primary mechanism underlying this nocturnal PRL elevation. In adults of both sexes, the nocturnal maximum is about twofold higher than mean daytime levels.[42] Morning awakenings and awakenings interrupting sleep are both consistently associated with a rapid inhibition of PRL secretion.[42]

Studies of the PRL profile during daytime naps or after shifts of the sleep period have consistently demonstrated that sleep onset, irrespective of the time of day, has a stimulatory effect on PRL release. This is well illustrated by the profiles shown in Figure 20-1, in which elevated PRL levels occur both during nocturnal sleep and during daytime recovery sleep, whereas the nocturnal period of sleep deprivation was not associated with an increase in PRL concentrations. However, the sleep-related rise of PRL may still be present, although with a reduced amplitude, when sleep does not occur at the normal nocturnal time. Maximal stimulation is observed only when sleep and circadian effects are superimposed, suggesting that circadian rhythm is not the main driver of PRL release.[49-51] A close temporal association between increased PRL secretion and slow wave activity is apparent.[52] However, in contrast to the correlation between slow wave activity and amount of GH release that has been evidenced in men, no such "dose-response" relationship has been demonstrated for PRL in either men or women.

Benzodiazepine and imidazopiridine hypnotics taken at bedtime may cause an increase in the nocturnal PRL rise, resulting in concentrations near the pathologic range for hyperprolactinemia for part of the night.[53,54] A potential mechanism is a greater suppression of dopaminergic activity under zolpidem versus placebo because dopamine has been

identified as a PRL-inhibiting factor. This is illustrated for triazolam and zolpidem in Figure 20-2. Neither triazolam nor zolpidem has any effect on the 24-hour profiles of cortisol, melatonin, or GH. Chronic treatment of insomnia with the melatonin receptor agonist ramelteon increases PRL release in women, but not in men.[55]

There is evidence from animal studies that PRL is involved in the humoral regulation of REM sleep.[56] The primary effect is a stimulation of REM sleep, which appears to be dependent on time of day. PRL-deficient mice have decreased REM sleep.[57]

The Gonadal Axis

The relationship between sleep and the 24-hour patterns of gonadotropin release and gonadal steroid levels varies according to age and sex (for review, see Copinschi and Challet[42]). Before puberty, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are secreted in a pulsatile pattern, and an augmentation of pulsatile activity is associated with sleep onset in a majority of both girls and boys. The increased amplitude of gonadotropin release during sleep is one of the hallmarks of puberty.

During the transition from puberty to adulthood, the amplitude of daytime LH pulses increases, and in adult men, the day-night variation of plasma LH levels is dampened or even undetectable. During the sleep period, LH pulses appear to be temporally related to the rapid eye movement (REM) sleep and non–rapid eye movement (NREM) sleep cycle.[58] Despite the low amplitude of the nocturnal increase in gonadotropin release, a marked diurnal rhythm in circulating testosterone levels is present, with minimal levels in the late evening, a robust rise following sleep onset, and maximal levels in the early morning.[59,60] Thus the robust circadian rhythm of plasma testosterone may be partially controlled by factors other than LH. The nocturnal rise of testosterone appears temporally linked to the duration of the first NREM period[61] because plasma levels continue to rise until the first REM episode occurs. A robust rise of testosterone may also be observed during daytime sleep, suggesting that sleep, irrespective of time of day, stimulates gonadal hormone release.[62]

Experimental sleep fragmentation in young men resulted in attenuation of the nocturnal rise of testosterone, particularly in subjects who did not achieve REM sleep.[63] Androgen concentrations in young adults decline significantly during periods of total sleep deprivation and recover promptly after the sleep of the subjects is restored.[62,64] In contrast, pharmacologic suppression of testosterone in healthy men appears to have no effect on the total amount and overall architecture of nighttime sleep.[65] In older men, the amplitude of LH pulses is decreased, but the frequency is increased and no significant diurnal pattern can be detected.[66-68] With aging, the circadian variation of testosterone persists, although it is markedly dampened.[68] The sleep-related rise is still apparent in older men, but its amplitude is lower and the relationship to REM latency is no longer apparent.[69] It is likely that decreases in slow wave activity as occurs in aging as well as in sleep disorders (e.g., obstructive sleep apnea [OSA]) plays a role in the dampening of the sleep-related testosterone rise. In otherwise healthy older men, morning testosterone levels are partly predicted by the amount of nighttime sleep, whether measured at home or in the laboratory,[70] suggesting that habitual sleep duration should be taken into account in the diagnosis of androgen deficiency.

In women, the 24-hour variation in plasma LH is markedly modulated by the menstrual cycle.[71,72] In the early follicular phase, LH pulses are large and infrequent, and a marked slowing of the frequency of secretory pulses occurs during sleep, suggestive of inhibitory effect of sleep on pulsatile GnRH release. Awakenings interrupting sleep are usually associated with a pulse of LH concentration.[73] In the midfollicular phase, pulse amplitude is decreased, pulse frequency is increased, and the frequency modulation of LH pulsatility by sleep is less apparent. Pulse amplitude increases again by the late follicular phase. In the early luteal phase, at the opposite, the pulse amplitude is markedly increased, the pulse frequency is decreased, and nocturnal slowing of pulsatility is again evident. In the mid and late luteal phase, pulse amplitude and frequency are decreased and there is no modulation by sleep. In postmenopausal women, gonadotropin levels are elevated, but they show no consistent circadian pattern.[74] A recent well-documented study has demonstrated a causal relationship between the elevation of gonadotropin levels, hot flashes, and decreases in objective and subjective sleep quality.[75] A number of studies[76-78] have indicated that estrogen replacement therapy has modest beneficial effects on subjective and objective sleep quality, particularly in the presence of environmental disturbance[79] or sleep-disordered breathing.[76,77,80]

Glucose Regulation

The consolidation of human sleep in a single 7- to 9-hour period implies that an extended period of fast must be maintained overnight. Despite the prolonged fasting condition, glucose levels remain relatively stable across the night. In contrast, if subjects are awake and fasting in a recumbent position, glucose levels fall by an average of 0.5 to 1.0 mmol/L (±10 to 20 mg/dl) over a 12-hour period.[81] Thus a number of mechanisms that operate during nocturnal sleep must intervene to maintain stable glucose levels during the overnight fast.

The lower panels of Figure 20-1 show profiles of blood glucose and insulin ISRs obtained in normal subjects who were studied under conditions of constant glucose infusion, a condition that results in a marked inhibition of endogenous glucose production. Thus changes in plasma glucose levels illustrated in the figure mainly reflect changes in glucose use. A marked decrease in glucose tolerance (reflected in higher plasma glucose levels under this condition of continuous challenge by the exogenous glucose infusion) is apparent during nighttime as well as daytime sleep. A smaller elevation of glucose and insulin also occurs during nocturnal sleep deprivation, indicating an effect of circadian-dependent mechanisms. Recovery sleep was associated with a robust increase in glucose and insulin, owing to the release of GH linked to sleep onset.

During nocturnal sleep, the overall increase in plasma glucose ranged from 20% to 30%, despite the maintenance of rigorously constant rates of caloric intake, that is, constant glucose infusion. Maximal levels are reached around the middle of the sleep period. During the later part of the night, glucose tolerance begins to improve, and glucose levels progressively decrease toward morning values. The mechanisms underlying these robust variations in set-point of glucose regulation across nocturnal sleep are different in early sleep and late sleep.

It is estimated that about two thirds of the fall in overall body glucose use during early sleep is due to a decrease in brain glucose metabolism[82] related to the predominance of slow wave stages, which are associated with a 30% to 40% reduction in cerebral glucose metabolism compared with the waking state (see Chapter 18).[83] The remainder of the fall would then reflect decreased peripheral use, including diminished muscle tone and rapid hyperglycemic effects of the sleep-onset GH pulse. Furthermore, the nocturnal elevation of melatonin levels could contribute to the nocturnal decrease in glucose tolerance because of an inhibitory effect of melatonin on insulin release from beta cells.[2,84] During the later part of the sleep period, glucose levels and insulin secretion decrease to return to presleep values, and this decrease appears to be partially due to the increase in wake and REM stages.[85] Indeed, glucose use during the REM and wake stages is higher than during NREM stages.[83] In addition, several other factors may also contribute to the decline of glucose levels during late sleep. These include an increase in insulin sensitivity due to a delayed effect of low cortisol levels during the evening and early part of the night.[86]

Sleep and Appetite Regulation

Sleep plays an important role in energy balance. In rodents, food shortage or starvation results in decreased sleep[87] and, conversely, total sleep deprivation leads to marked hyperphagia.[88] The identification of hypothalamic excitatory neuropeptides, referred to as hypocretins or orexins, that have potent wake-promoting effects and stimulate food intake has provided a molecular basis for the interactions between the regulation of feeding and sleeping.[89,90] Orexin-containing neurons in the lateral hypothalamus project directly to the locus coeruleus and other brainstem and hypothalamic arousal areas, where they interact with the leptin-responsive neuronal network involved in balancing food intake and energy expenditure. Orexin-containing neurons are active during waking and quiescent during sleep. Orexin activity is inhibited by leptin, a satiety hormone, and stimulated by ghrelin, an appetite-promoting hormone. Multiple peptides derived from the gut and adipose tissues participate in the control of hunger and satiety. A relationship with sleep has

been demonstrated in some studies for two of them, leptin and ghrelin.[91,92]

Leptin, a hormone released by the adipocytes, provides information about energy status to regulatory centers in the hypothalamus.[93] Circulating leptin concentrations in humans show a rapid decline or increase in response to acute caloric shortage or surplus, respectively. These changes in leptin levels have been associated with reciprocal changes in hunger. The 24-hour leptin profile shows a marked nocturnal rise.[94] The upper panel of Figure 20-3 shows a typical 24-hour profile of plasma leptin levels in a normal man. The nocturnal elevation of leptin has been thought to suppress the hunger during the overnight fast. Although daytime food intake plays a major role in the nocturnal rise of leptin, a study using continuous enteral nutrition to eliminate the impact of meal intake showed the persistence of a sleep-related leptin elevation, although the amplitude was lower than during normal feeding conditions.[95] Prolonged total sleep deprivation results in a decrease in the amplitude of the leptin diurnal variation.[96]

Ghrelin, a peptide produced predominantly by the stomach, is also involved in regulating energy balance[8] and stimulates appetite.[97] Daytime profiles of plasma ghrelin levels are primarily regulated by the schedule of food intake: levels drop sharply after each meal intake and rebound in parallel with increased hunger until the initiation of the following meal.[98] The 24-hour profile of ghrelin levels shows a marked nocturnal rise, which is only modestly dampened when subjects are sleep deprived.[19] The nocturnal ghrelin rise partly represents the rebound of ghrelin following the dinner meal. Despite the persistence of the fasting condition, ghrelin levels do not continue to increase across the entire sleep period and instead decrease during the later part of the night, consistent with an inhibitory effect of sleep on ghrelin release.[21] The lower panel of Figure 20-3 illustrates a representative 24-hour profile of ghrelin from a normal subject who ingested three carbohydrate-rich meals.

Water and Electrolyte Balance during Sleep

Water and salt homeostasis is under the combined control of vasopressin, a hormone released by the posterior pituitary, the renin-angiotensin-aldosterone system, and the atrial natriuretic peptide. Urine flow and electrolyte excretion are higher during the day than during the night, and this variation partly reflects circadian modulation. In addition to this 24-hour rhythm, urine flow and osmolarity oscillate with the REM-NREM cycle. REM sleep is associated with decreasing urine flow and increasing osmolarity.

Vasopressin release is pulsatile but without apparent relationship to sleep stages.[99] Levels of atrial natriuretic peptide are relatively stable and do not show fluctuations related to the sleep-wake or REM-NREM cycle.[100] Whether the levels of plasma atrial natriuretic peptide exhibit a circadian variation is still a matter of controversy.[100]

Figure 20-4 illustrates the 24-hour rhythm of plasma renin activity (PRA) in a subject studied during a normal sleep-wake cycle and following a shift of the sleep period.[101] The initiation of sleep, irrespective of time of day, is associated with a robust increase in PRA. In contrast, the nocturnal elevation

of PRA does not occur when the subject is sleep deprived (lower panel of Figure 20-4). A well-documented study[102] has delineated the mechanisms responsible for the elevation of PRA during sleep. The initial event is a reduction in sympathetic tone, followed by a decrease in mean arterial blood pressure and an increase in slow wave activity. The rise in PRA becomes evident a few minutes after the increase in slow wave activity. During REM sleep, sympathetic activity increases, whereas renin and slow wave activity decrease and blood pressure becomes highly variable. This pattern of changes in PRA during sleep drives the nocturnal profile of aldosterone levels.[103,104] Acute total sleep deprivation eliminates the nocturnal PRA rise, dampens the nighttime elevation of plasma aldosterone, and increases natriuresis.[105] A close relationship between the beginning of REM episodes and decreased activity has been consistently observed for both PRA and aldosterone.[99,101,106-108] This relationship was confirmed in studies with selective REM-sleep deprivation in healthy subjects.[109] Increases in PRA parallel increases in slow wave EEG activity.[104] In conditions of abnormal sleep architecture (e.g., narcolepsy, sleeping sickness), the temporal pattern of plasma renin activity faithfully reflects the disturbances of the REM-NREM cycle.[99]

RECURRENT SLEEP RESTRICTION: IMPACT ON ENDOCRINE AND METABOLIC FUNCTION

Voluntary sleep curtailment has become a very common behavior in modern society. Data from the 2008 "Sleep in America" poll indicate that although working adults report a sleep need of an average of 7 hour and 18 minutes to function at best, 44% of them sleep less than 7 hours and 16% sleep less than 6 hours on a typical weeknight.[110] Sleep times in European countries appear to follow a similar trend.[111] For a substantial portion of the adult population, the cumulative sleep loss per workweek may correspond to as much as 1 full night of sleep deprivation. Several laboratory studies involving extension of the bedtime period for prolonged periods of time have provided evidence that the "recommended 8-hour night" does not meet the sleep need of healthy young adults, who may carry a substantial sleep debt even in the absence of obvious efforts at sleep curtailment.[112-114]

The following subsections review, respectively, the laboratory evidence supporting an adverse impact of recurrent partial sleep restriction on pituitary and pituitary-dependent hormones, glucose metabolism, the neuroendocrine control of appetite, food intake, and energy expenditure. The epidemiologic evidence for an adverse impact of short sleep on the risk for diabetes and obesity is then summarized.

Laboratory Studies of Experimental Sleep Restriction

Figure 20-5 summarizes the hormonal and metabolic findings of the first "sleep debt study,"[45] which examined the impact of 6 days of sleep restriction to 4 hours per night compared with 6 days of sleep extension to 12 hours per night in a group of healthy young men.[28,45,46] The findings suggested that sleep restriction has adverse effects on multiple endocrine axes as well as on glucose metabolism. Multiple observational studies and randomized controlled trials have since been conducted to further examine the hormonal and metabolic consequences of insufficient sleep. It is not possible to provide an exhaustive description of all studies in the present chapter. For excellent recent reviews, the reader is referred to references.[91,92,115-117]

Pituitary and Pituitary-Dependent Hormones

As may be seen in the upper panel of Figure 20-5, sleep restriction results in an alteration in nocturnal GH release such that a GH pulse occurs consistently before sleep onset. There was a negative correlation between presleep GH secretion and sleep-onset GH release. This profile of GH release is quite different from that observed during acute total sleep deprivation (back to top panels of Figure 20-1), where minimal GH secretion occurs during nocturnal wakefulness and GH secretion rebounds during daytime recovery sleep.

When compared with the fully rested condition, the state of sleep debt was associated with alterations of the 24-hour profile of cortisol, including a shorter quiescent period and elevated levels in the evening (Figure 20-5, second panel shaded areas). This alteration was similar to that observed after 1 night of acute total or partial sleep deprivation[39] and may reflect decreased efficacy of the negative feedback regulation of the hypothalamic-pituitary-adrenal axis.[45] Several studies that have assessed the profile of plasma or saliva cortisol levels across the daytime period in individuals submitted to 2 to 7 days of sleep restriction by 4 to 5 hours per night have similarly observed an elevation of cortisol concentrations,[118-121] but there have been well-documented negative studies as well.[122,123] The severity and duration of sleep restriction may play a role in the discrepancies. Recovery sleep after one workweek of mild sleep restriction was shown to reduce daytime cortisol levels relative to baseline.[124]

Restriction and extension of sleep duration were also associated with clear changes in thyrotropic function. The nocturnal elevation of plasma TSH was dampened and thyroid hormone levels were higher in the sleep debt state.[45] Previous studies have demonstrated that total sleep deprivation is initially associated with a marked increase in TSH secretion (see Figure 20-1), which becomes smaller when sleep deprivation continues, presumably because of negative feedback effects from slowly rising levels of thyroid hormones. Similar mechanisms are likely to underlie the alterations in thyrotropic function after recurrent partial sleep restriction. Findings of elevations in free T_4 index and of peripheral levels of free T_3 and free T_4 in subjects submitted to experimental sleep restriction or total sleep deprivation are consistent with this hypothesis.[45-48] In middle-aged overweight adults exposed to moderate sleep restriction over a 14-day period, TSH and free T_4 levels were lower after 14 days of sleep restriction compared with normal sleep.[125]

Evidence implicating an adverse impact of insufficient sleep on the gonadal axis has been obtained for testosterone levels in men. One week of partial sleep restriction (5 hours in bed) in healthy young men has been shown to result in a 10% to 15% decrease in afternoon and evening testosterone levels (Figure 20-6), concurrent with increased levels of subjective sleepiness.[123] A similar trend was observed in a study of 5 nights of sleep restriction to 4 hours in bed.[120] In a study examining morning testosterone levels after 1 night of total sleep deprivation or following sleep restricted to the first 4.5 hours of the night, testosterone levels were also reduced by about 20%.[126] Taken together, these findings suggest that obtaining an estimation of habitual sleep duration as well as sleep duration during the night before testosterone testing

may be important in the diagnosis of androgen deficiency. Because prescriptions for exogenous testosterone replacement for complaints of low energy, fatigue, and reduced libido in adult men have increased dramatically in the past few years, the possibility that partial sleep restriction, a condition that can produce these symptoms, may be involved in producing or exacerbating the condition should be considered.

Glucose Metabolism

In the original "sleep debt" study,[45] 5 days of bedtime curtailment resulted in a higher glucose response to breakfast despite similar insulin secretion (see Figure 20-5, lower panels). The difference in peak postbreakfast glucose levels between the sleep debt and fully rested conditions (i.e., ±15 mg/dL) is consistent with a state of impaired glucose tolerance. Intravenous glucose tolerance testing confirmed this deterioration in glucose tolerance.[45] Reduced glucose tolerance was found to be the combined consequence of a decrease in glucose effectiveness, a measure of non–insulin-dependent glucose use, and of a reduction in the acute insulin response to glucose despite decreased insulin sensitivity. The product of insulin sensitivity and acute insulin response to glucose, that is, the disposition index, a validated marker of diabetes risk,[127] was decreased by nearly 40% in the state of sleep debt, reaching levels typical of populations at an elevated risk for diabetes.[128,129] Of note, the impact of recurrent sleep restriction was only seen on the responses to meals, and intravenous glucose fasting levels were unchanged.

These findings were confirmed in a number of subsequent randomized control trials that involved recurrent sleep restriction in the laboratory and included assessments of glucose tolerance and insulin levels or sensitivity during a glucose challenge.[119,122,130-132] In a randomized crossover study[132] comparing 4 days of 4.5 hours in bed versus 8.5 hours in bed, biopsies of subcutaneous abdominal fat were obtained from each participant at the end of each sleep condition. Adipocytes were exposed in vitro to incremental insulin concentrations to examine the ability of insulin to increase the phosphorylation of Akt, a crucial step in the insulin-signaling pathway. The insulin concentration needed to achieve the half-maximal phosphorylation of Akt response was nearly threefold higher when subjects had restricted sleep compared with normal sleep, indicating that sleep is an important modulator of energy metabolism in this peripheral tissue. A 2010 study involving 23 young men submitted to either 5 nights of sleep restriction to 4 hours per night or 8-hour bedtimes observed an increase in the ratio of insulin to glucose under fasting conditions.[133] This study further suggested that this metabolic alteration was partly corrected after 2 nights of recovery sleep.

Two randomized crossover design studies have examined the impact of repeated sleep restriction versus normal sleep in subjects submitted to caloric restriction who lost weight over the course of both short and long sleep interventions.[134,135] The findings were consistent in that daytime glucose levels were unchanged in either study. The study that had the most severe caloric restriction and the longest period of sleep loss found lower insulin levels in the short sleep condition, suggestive of an improvement rather than a deterioration of systemic insulin sensitivity.[134] Findings from intravenous glucose tolerance testing in the same subjects were, however, in the opposite

direction, with a 26% decrease in insulin sensitivity in the short versus normal sleep condition. Differences in the counterregulatory responses of cortisol, GH, and epinephrine during the ivGTT were proposed to explain the inconsistency.[134] A putative role of sleep restriction to lower incretin responses and thus postprandial insulin release is another possibility. Clearly, the interaction of insufficient sleep and dietary restriction is worthy of additional research because millions of individuals are attempting to follow a weight loss diet without consideration of the potential impact of their habitual sleep duration. In a randomized crossover laboratory study of 14 days with extended or restricted sleep and moderate caloric restriction, insufficient sleep resulted in a decrease in the proportion of weight lost as fat and an increase in the loss of fat-free mass.[136] Consistent findings were reported in a study including 123 overweight and obese adults who underwent a weight loss intervention involving caloric restriction, in which a significant relationship between self-reported sleep duration and loss of body fat was detected, after adjusting for age, sex, baseline body mass index (BMI), length of the intervention, and change in energy intake.[137] Recently, a change in sleep duration from 6 hours or less to between 7 and 8 hours was found to be associated with less visceral fat accumulation over 6 years.[138]

Individuals with a family history of type 2 diabetes have a greater than twofold increased risk for developing diabetes themselves. A 2011 study[139] showed that among adults with a parental history of diabetes, those who have habitual sleep duration of 6 hours or less have increased insulin resistance, making them more susceptible to develop diabetes.

Neuroendocrine Control of Appetite

In the sleep debt study mean levels of the satiety hormone leptin were reduced by 20% to 30% under sleep restriction compared with extension (see Figure 20-5, lowest panels), and the amplitude of the circadian rhythm was decreased.[46] This effect size of sleep restriction is comparable to that occurring after 3 days of dietary restriction by approximately 900 kcal/day under normal sleep conditions.[140] Further, there was a clear dose-response relationship between sleep duration and characteristics of the leptin profile.[46] Importantly, these differences in leptin profiles occur despite identical amounts of caloric intake, similar sedentary conditions, and stable weight. Four independent studies examining the leptin profiles after sleep restriction in lean young adults (mostly male) under conditions of controlled caloric intake also found a reduction of leptin levels or amplitude after sleep restriction.[24,96,141,142] In the most recent study, sleep loss was associated with circadian misalignment.[142] Findings regarding the impact of sleep restriction on leptin profiles or on isolated leptin levels in research participants who were exposed to ad libitum food intake or in whom body weight changed across the study period have been inconsistent, as summarized in several recent reviews.[91,92,117,143] Findings of epidemiologic cross-sectional studies examining the relationship between sleep duration and leptin levels have been similarly inconsistent.[92]

In a randomized crossover study of 2 nights of 4 hours in bed versus 2 nights of 10 hours in bed, in which the only source of caloric intake was a constant glucose infusion, daytime profiles of the hunger hormone ghrelin were measured, and the subjects completed validated scales for hunger and appetite for various food categories.[24] Daytime ghrelin levels were increased by 28% and the ghrelin-to-leptin ratio increased by more than 70%. Hunger showed a 23% increase, and appetite for nutrients with high carbohydrate content was increased by more than 30% when sleep was restricted. There was an excellent correlation between the change in the ghrelin-to-leptin ratio and the increase in self-reported hunger. Subsequent studies examining ghrelin levels in response to partial sleep restriction had variable findings, with no change detected in several studies. Differences in the demographics of the participants, length and severity of sleep restriction, nutritional status, sampling frequency, and assay methodology make it difficult to clearly summarize the current literature.[91,92,143]

Two epidemiologic studies reported reduced leptin levels, after controlling for BMI or adiposity, in habitual short sleepers.[144,145] Higher ghrelin levels have also been also associated with short sleep.[144] A subsequent study involving only postmenopausal women did not confirm the link between sleep duration, leptin, and ghrelin levels,[146] but very few participants had short sleep durations. Lastly, an ambulatory study of 80 obese adults found no cross-sectional association between fasting leptin levels and measures of adiposity.[147]

A reasonable conclusion regarding the roles of leptin and ghrelin as mediators of appetite dysregulation under conditions of insufficient sleep is that both pathways have been shown to be operative under certain experimental conditions but not uniformly. Sleep loss is likely to alter multiple other pathways involved in the control of energy intake.

Hunger, Satiety, and Food Intake

As summarized by Morselli and colleagues,[91] findings of laboratory studies that have examined hunger, satiety, or food intake under ad lib conditions have been more consistent than those focusing on alterations of the neuroendocrine control of appetite. A randomized crossover study of overweight middle-aged adults who were submitted to 2 weeks of 1.5 hours of sleep extension or restriction was the first to clearly demonstrate an increase in food intake from snacks during sleep restriction.[148] A subsequent study of 5 days with 4-hour bedtimes compared with 5 days of 9-hour bedtimes found that participants consumed on average nearly 300 kcal more when sleep restricted, mostly from fat.[149] As in previous studies of recurrent partial sleep restriction, short bedtimes resulted mainly in a loss of stage 2 and REM sleep. Linear mixed model analysis revealed a positive association between stage 2 duration and resting metabolic rate. Greater loss of stage 2 or REM sleep was associated with more hunger, more appetite for sweet as well as salty foods, and more energy consumed.[150] One recent study has addressed the possibility that extending sleep in short sleepers may decrease appetite.[151] In this home-based 2-week intervention, young adults obtained 1 hour and 36 minutes more sleep per day on average and reduced their overall rating of appetite by 14%, whereas the desire for sweet and salty foods was decreased by 62%.[151]

In the past few years, four studies used functional magnetic resonance imaging to examine brain function in subjects after normal sleep, 1 night of total sleep deprivation, or repeated partial sleep deprivation.[152-155] These studies have been consistent in showing that sleep loss increases neuronal activity in brain areas involved in the reward system in response to presentation of food stimuli or decreases neuronal activity in cortical regions involved in food choices.

Energy Expenditure

A logical explanation to the increased hunger and food intake associated with sleep restriction is that they occur in response to the caloric needs of extended wakefulness. Several studies used the doubly labeled water method to assess changes in energy expenditure during sleep restriction. Surprisingly, all three studies failed to detect an increase in energy expenditure.[148,149,156] However, when the subjects were confined to a calorimetry room to monitor minute-to-minute energy expenditure during normal sleep and total sleep deprivation, the caloric cost of wakefulness under recumbent conditions compared with sleep averaged only 17 kcal/hour.[157] A recent study involving 5 days of partial sleep restriction, similar to a workweek, under controlled laboratory conditions observed that the approximate 5% increase in daily energy expenditure was overcompensated by energy intake, particularly at night.[158] Another calorimetry room study comparing 3 nights of 4 hours in bed versus 3 nights of 8 hours in bed found that energy expenditure per 24-hour period was increased by 92 kcal in the 4-hour bedtime condition, thus 23 kcal/hour of extended wakefulness.[159] Taken together, these whole-room indirect calorimetry studies suggest that the stimulation of hunger and food intake far exceeds the caloric needs of extended wakefulness. Additionally, there is evidence that individuals who have insufficient sleep have lower levels of physical activity.[160,161]

Epidemiologic Studies Linking Habitual Short Sleep and the Risk for Obesity and Diabetes

Over the past 10 years, a large number of studies have examined associations between sleep duration and the prevalence and incidence of obesity and type 2 diabetes. Nearly all these studies explored existing data sets that included self-reported sleep duration, and none of them determined whether short sleep was the result of bedtime curtailment or was due to the presence of a sleep disorder or other comorbidities. Further, self-reported sleep duration is strongly dependent on demographics (sex, age, race or ethnicity), socioeconomic factors (income, occupation, education), and mental health status.[162] Nonetheless, by mid-2012, more than 60 epidemiologic studies, most with a cross-sectional design, had examined the relationship between sleep duration and obesity, BMI, or weight gain in adults, and most had found significant associations. In longitudinal studies in adults, the findings have been more mixed, and systematic reviews found either 8 out of 13 positive studies[163] or 8 out of 10 positive studies.[92] Findings from prospective studies in children have been more consistent in indicating that insufficient sleep increases the risk for weight gain or obesity.[163]

To date, 14 prospective studies in adults including a total of 583,263 participants have examined the relative risk (RR) of developing type 2 diabetes associated with short sleep duration,[164-177] and 8 of them reported significantly elevated RR for short sleep (≤5 hours; RR range: 1.51 to 2.94) relative to normal sleep (7 to 8 hours). A meta-analysis published in 2010 that included 10 of the 14 currently available studies concluded that short sleep increases the risk for type 2 diabetes by 28%.[178] Of note, the risk was significantly higher in men (RR: 2.07) than in women (RR: 1.07), and long sleep (≥9 hours) was also found to be associated with a higher risk for incident diabetes (RR: 1.48). All studies relied on self-report of sleep duration, and it is highly likely that different factors mediate the association of diabetes with short versus long sleep.

This body of epidemiologic evidence supports the hypothesis that sleep curtailment may be a nontraditional lifestyle factor contributing to the epidemics of obesity and type 2 diabetes.

REDUCED SLEEP QUALITY AND SLEEP DISORDERS: IMPACT ON ENDOCRINE AND METABOLIC FUNCTION

Experimental Reduction of Sleep Quality

Early studies have been consistent in showing that experimentally induced full awakenings interrupting nocturnal sleep consistently trigger pulses of cortisol secretion.[30,179,180] Furthermore, in an analysis of cortisol profiles during daytime sleep, it was observed that 92% of spontaneous awakenings interrupting sleep were associated with a cortisol pulse.[180]

The initiation of SWS is associated with a decrease in cerebral glucose use, stimulation of GH secretion, inhibition of cortisol release, decreased sympathetic nervous activity, and increased vagal tone. All these correlates of SWS affect total body glucose regulation, suggesting that low amounts of SWS may be associated with reduced glucose tolerance. Our group tested this hypothesis by selectively suppressing SWS (using acoustic stimuli) in healthy young adults and examining the impact on the response to intravenous glucose injection.[181] The amount of SWS was reduced by nearly 90%, similar to what occurs over the course of four decades of aging. Such low levels of SWS are also typical of moderate to severe OSA. Importantly, this intervention did not reduce total sleep duration. Slow wave activity was markedly reduced in each experimental night compared with baseline (left panels of Figure 20-7). After 3 nights of SWS suppression, insulin sensitivity was decreased by about 25% (right panels of Figure 20-7), reaching the level reported in older adults and in populations at high risk for diabetes.[182] This decrease in insulin sensitivity was not compensated for by an increase in insulin release because acute insulin response to glucose remained virtually unchanged. Consequently, diabetes risk, as assessed by the disposition index, was lower, and glucose tolerance was reduced, reaching the range typical of impaired glucose tolerance. These laboratory findings demonstrate that reduced sleep quality, without change in sleep duration, may adversely affect glucose regulation. In this study where SWS was suppressed while carefully avoiding full awakenings, cortisol levels were not affected at any time of the day or night.[181] An increase in daytime sympathic-vagal balance, as assessed by spectral analysis of heart rate variability, was identified as one of the possible mechanisms mediating the adverse impact of SWS suppression on glucose metabolism. In another study, nonselective sleep fragmentation for 2 nights by acoustic stimuli was associated with a decrease in insulin sensitivity and non–insulin-dependent glucose disposal.[183] Notably, nonselective sleep fragmentation resulted in marked reductions in slow wave sleep, whereas other sleep stages were minimally affected.[183] The importance of SWS for the maintenance of glucose homeostasis has also been confirmed by a more recent experimental study in healthy adults.[184]

A randomized crossover study with 1 night of either fragmented or nonfragmented sleep found decreased subjective

fullness with reduced REM sleep and preservation of SWS.[185] In another study, 2 nights of fragmented sleep with reductions in both REM sleep and SWS were associated with unchanged total energy expenditure, increased carbohydrate oxidation, and decreased fat oxidation, which may predispose to weight gain.[186]

Prospective Epidemiologic Studies Linking Poor Sleep Quality to Diabetes Risk

Multiple epidemiologic studies have provided evidence for an association between self-reported poor sleep quality and the prevalence or incidence of diabetes, after controlling for age, BMI, and various other confounders. Of note, in six of seven prospective studies that examined self-reported problems (e.g., difficulty initiating or maintaining sleep, use of sleeping pills, or insomnia complaint), poor sleep quality was associated with an increased risk for diabetes.[166,170,173,187-190] Meta-analysis of these studies found that self-reported difficulty in initiating sleep was associated with an increased risk for diabetes (RR: 1.57; ~18,000 participants), and self-reported difficulty in maintaining sleep also predicted the development of diabetes (RR: 1.84; ~24,000 participants).[178]

Insomnia

There have been remarkably few studies of hormonal and metabolic variables in subjects with physician-diagnosed insomnia. A well-documented study[191] in patients with insomnia revealed that those with decreased total sleep time have higher cortisol levels across the night (Figure 20-8). A few other studies have also shown that insomnia is associated with increased levels of cortisol and norepinephrine.[192-194] It is unclear whether this relative hypercortisolism is the result of sleep fragmentation and the associated sleep loss or, alternatively, whether hyperactivity of the corticotropic axis is causing

hyperarousal and insomnia. Recent views on chronic insomnia propose that it is a disorder of hyperarousal during both the night and the daytime, with associated hyperactivity of the hypothalamic-pituitary-adrenal axis.[195,196] A population-based study involving a total of 1741 men and women found that insomnia with short sleep duration was associated with increased odds of diabetes.[197] A small study involving 14 patients with insomnia found decreased nocturnal ghrelin levels, providing evidence for a possible dysregulation of energy balance in this patient population.[198]

Obstructive Sleep Apnea

There is substantial evidence linking OSA to abnormalities of glucose metabolism, including insulin resistance, glucose intolerance, and increased risk for type 2 diabetes. For a summary of the present state of knowledge, the reader is referred to Section 14 of the present volume as well as to recent reviews.[199,200]

OSA is also associated with disturbances in the control of weight and neuroendocrine regulation of appetite. Indeed, patients with OSA appear more predisposed to weight gain than similarly obese subjects without OSA.[201] Ghrelin levels were found to be increased in patients with OSA compared with controls in most,[202-204] but not all,[205] studies. Elevated leptin levels in OSA, after controlling for BMI, were reported in earlier studies,[201,206] whereas more recent studies found no difference between apneic patients and BMI-matched controls.[205] Hyperleptinemia in OSA is thought to reflect leptin resistance.[201]

Although most studies have shown reduced ghrelin levels after continuous positive airway pressure (CPAP) treatment of OSA,[204,207,208] one study found no difference in ghrelin levels after CPAP.[209] Leptin levels were also consistently found to be decreased after CPAP treatment.[204,209] However, the findings on the effect of CPAP on body weight or visceral adiposity are mixed. Weight loss was reported in one study after 6 months of CPAP,[210] whereas other studies found weight gain after CPAP use.[208,211] In a randomized controlled multicenter trial, the greatest weight gain was found in those most compliant with CPAP.[212] CPAP therapy added to a weight reduction program has not resulted in greater weight loss.[213,214] If weight loss is important, loss of visceral fat is by far more relevant from a metabolic point of view. Again, the studies have yielded conflicting results.[215-219]

Age-Related Sleep Alterations: Implications for Endocrine Function

Normal aging is associated with pronounced age-related alterations in sleep quality, which consist primarily of a marked reduction of SWS (stages 3 and 4), a reduction in REM stages, and an increase in the number and duration of awakenings interrupting sleep (see Chapter 3). There is increasing evidence that these alterations in sleep quality may result in neuroendocrine disturbances, suggesting that some of the hormonal hallmarks of aging may partly reflect the deterioration of sleep quality.[220]

Growth Hormone Axis

There are mutual interactions between somatotropic activity and sleep that are evident both in young and older age. Sex and age differences are illustrated in the upper panels of Figure 20-9. In normal young men, there is a dose-response relationship between SWS or slow wave activity and GH secretion, and the sleep-onset GH pulse is often the largest pulse observed over the 24-hour span. In normal young

women, daytime GH pulses are more frequent, and the sleep-onset pulse, although generally present, is smaller.[221,222] In healthy older adults, in both gender groups, a significant amount of GH secretion occurs in the late evening, before habitual bedtime, at a time when GH secretion is usually quiescent in young adults.[223] Such presleep GH pulses may appear in young subjects when studied in a state of sleep debt.[28] In older men, but not women, the quantitative relationship between SWS/delta activity and sleep-onset GH release persists. In contrast, in older women, presleep GH release inhibits both the amount of GH secreted during sleep and sleep consolidation, as evidenced by negative correlations between presleep GH secretion and sleep maintenance.[223]

The impact of aging on the amount of SWS and on GH release in healthy men occurs with a similar chronology characterized by major decrements from early adulthood to midlife (Figure 20-10).[224] Reduced amounts of SWS were found to be a significant predictor of reduced GH secretion in middle life and late life, independently of age. The observation that in older adults, levels of insulin-like growth factor I, the hormone secreted by the liver in response to stimulation by GH, are correlated with the amounts of SWS[225] is consistent with this finding. The relative GH deficiency of elderly adults is associated with increased fat tissue and visceral obesity, reduced muscle mass and strength, and reduced exercise capacity. The persistence of a consistent relationship between SWS and GH secretion in older men suggests that drugs that reliably stimulate SWS in older adults may represent a novel strategy for GH replacement therapy.

Prolactin Secretion

In both men and women, most of the daily release of PRL occurs during sleep, irrespective of age. The lower panels of Figure 20-9 illustrate typical profiles in healthy nonobese young and older men and women. The sex difference is apparent both during daytime and nighttime in young adulthood, but in older age only nighttime levels are affected. A nearly 50% dampening of the nocturnal PRL elevation is evident in elderly men and women.[226] This age-related endocrine alteration may partly reflect the increased number of awakenings (which inhibit PRL release) and decreased amounts of REM stages (which stimulate PRL release).[223]

Besides its role in the control of lactation and parental behavior, PRL has multiple actions, including on metabolism and immunoregulation. Age-related alterations in sleep architecture and their impact on nocturnal PRL release could thus impact healthy aging.

Pituitary-Adrenal Axis

There are highly consistent, sex-specific alterations in the diurnal pattern of basal cortisol secretion across the lifetime.[227] Figure 20-9 shows 24-hour profiles typical of young and older men and women. In young adulthood, overall cortisol levels are lower in women than in men because the female response to the early morning circadian signal is slower and of lesser magnitude and the return to quiescence is more rapid. In men the nocturnal quiescent period is shorter, and the early morning elevation is higher and more prolonged. During aging there seems to be a progressive decline in the endogenous inhibition of nocturnal cortisol secretion in both men and women, as reflected by a delay of the onset of the quiescent period and higher nocturnal cortisol levels.

In contrast to the rapid decline of SWS and GH secretion from young adulthood to midlife, the impact of age on REM sleep, sleep fragmentation, and evening cortisol levels does not become apparent until later in life. As illustrated in Figure 20-10, REM sleep, wake after sleep onset, and evening cortisol levels follow the same chronology of aging, that is, no alteration until midlife and then a steady rise from midlife to old age.[224] There is a significant negative relationship between the loss of REM sleep in old age and the inability to achieve or maintain the quiescence of the corticotropic axis. Both animal and human studies have indicated that deleterious effects of HPA hyperactivity are more pronounced at the time of the trough of the rhythm than at the time of the peak. Therefore, modest elevations in evening cortisol levels could facilitate the development of central and peripheral disturbances associated with glucocorticoid excess, such as memory deficits and insulin resistance, and further promote sleep fragmentation.

Pituitary-Gonadal Axis

A progressive decline in testosterone levels occurs with aging in normal men. Starting at 30 to 40 years of age, testosterone concentrations decrease by 1% to 2% per year. In elderly men, the diurnal variation of testosterone is still detectable, but the nocturnal rise is markedly dampened.[59] A recent study indicated that the considerable interindividual variability of testosterone levels in healthy elderly men might be partly related to differences in sleep quality.[70] Indeed, both total and free (i.e., biologically active) morning testosterone levels were significantly correlated with total sleep time achieved during a night of laboratory polysomnography. A difference in total sleep time between 4.5 and 7.5 hours translated into a clinically meaningful difference in total testosterone levels because concentrations around 200 to 300 ng/dL are considered to be borderline-low for older men, and concentrations around 500 to 700 ng/dL represent mid-normal values typical of healthy young adults. A similar robust correlation was found with the usual amount of nighttime sleep monitored by actigraphy at home.[70] Thus it is important to enquire about poor or insufficient sleep in the interpretation and management of low testosterone levels in older men.

Sleep Disturbances in Metabolic and Endocrine Disorders

Obesity

Obesity is a major risk factor for OSA.[228] Complaints of daytime sleepiness may be present in obese subjects even in the absence of OSA.[229-232] In obese subjects without OSA, there may be disturbances in sleep architecture, including lighter and more fragmented sleep compared with nonobese controls.[230] Severely obese patients without OSA may have significantly shorter sleep latencies than lean age-matched controls.[229] Excessive daytime sleepiness has been found in 35% of obese subjects (BMI: 40 ± 6 kg/m^2) without OSA compared with 2.7% in age-matched nonobese controls.[232] It has been proposed that excessive daytime sleepiness and fatigue (i.e., tiredness without increased sleep propensity) in obese individuals without OSA could be due to a disruption of sleep homeostasis caused by elevated levels of somnogenic proinflammatory cytokines released by visceral fat (interleukin-6 and tumor necrosis factor-α).[233] In a cohort of 1300 middle-aged men and women who had 1 night of laboratory polysomnography, 47% of obese subjects reported

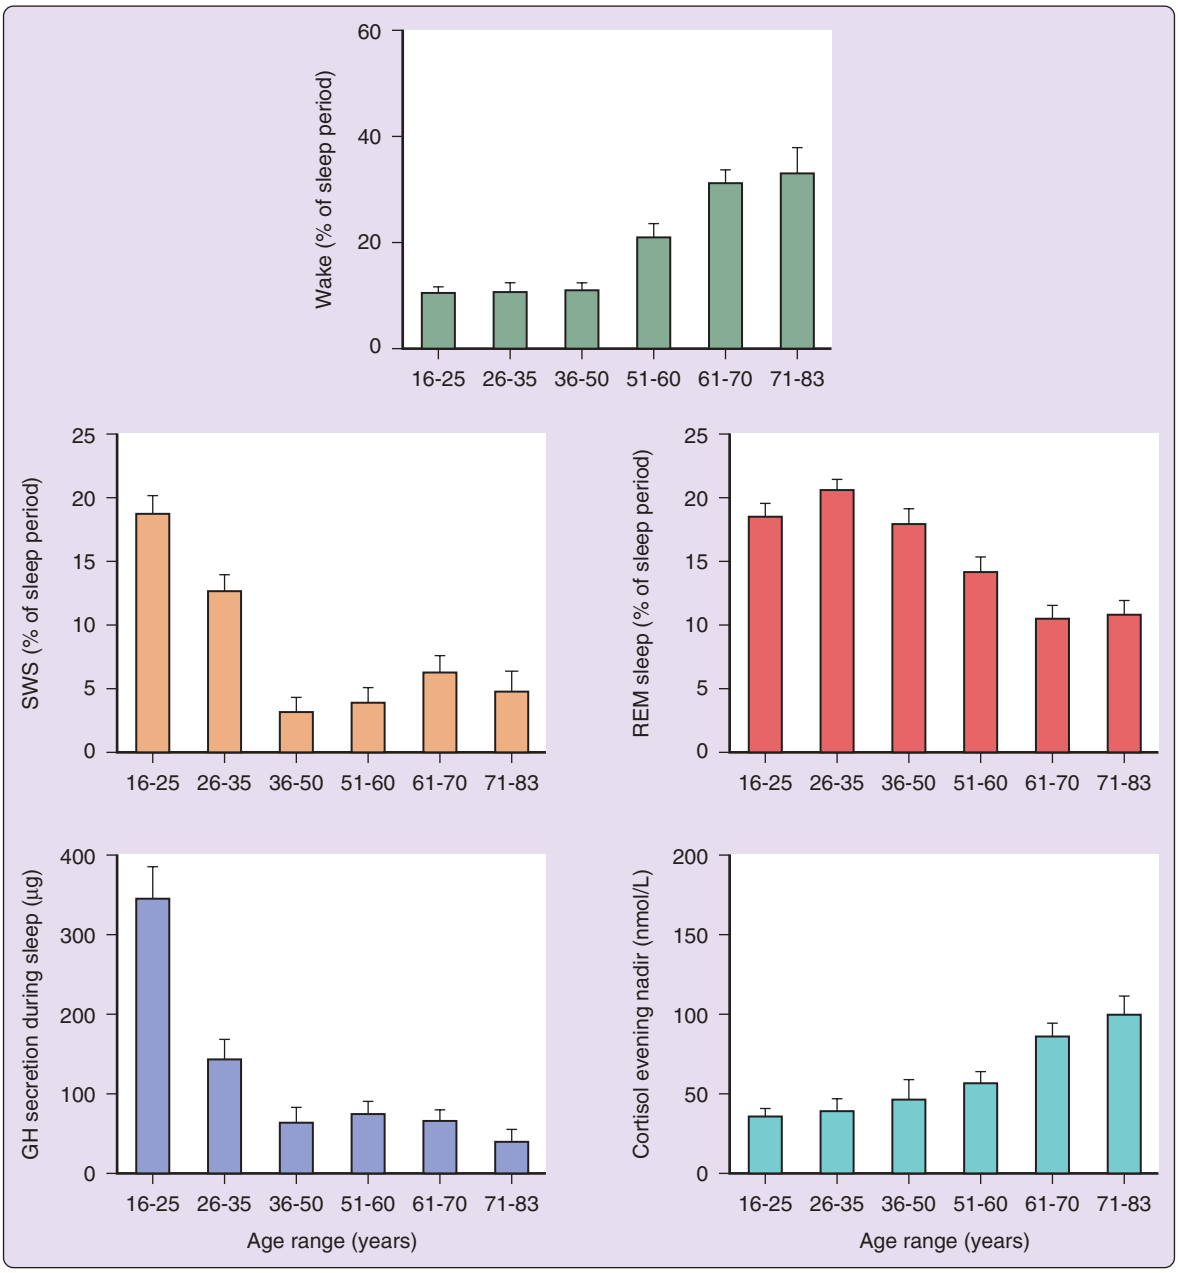

Figure 20-10 Mean (SEM) amounts of wake after sleep onset (*top panel*), slow wave sleep (stages III and IV, *middle left panel*), REM sleep (*middle right panel*), growth hormone (GH) secretion during sleep (*lower left panel*), and nadir of plasma cortisol concentrations (*lower right panel*) by age group in 149 healthy nonobese men. Sleep stages are expressed as a percentage of the sleep period, defined as the time interval between sleep onset and final morning awakening. (From Van Cauter E, Leproult R, Plat L. subjective sleep disturbances (insomnia, sleep difficulty, excessive daytime sleepiness) compared with 26% of nonobese individuals. Thus the association between short sleep and high BMI evidenced in multiple epidemiologic studies may partly reflect the high prevalence of sleep disturbances and emotional stress.[234]

Type 2 Diabetes

Two clinic-based studies have examined the relationship between sleep duration and quality and glycemic control in type 2 diabetes. The first study administered the Pittsburgh Sleep Quality questionnaire to 161 African American diabetic patients.[235] Higher perceived sleep debt or lower sleep quality were associated with poorer glycemic control after controlling for age, sex, BMI, insulin use, and the presence of complications.[235] Importantly, the magnitude of these effects of sleep duration or quality was comparable to that of commonly used oral antidiabetic medications. The second study used actigraphy in 47 diabetic patients and 23 nondiabetic controls under free-living conditions. After adjusting for age, gender, and

schooling, measures of sleep fragmentation were significantly higher in the patients with diabetes, and glycemic control correlated inversely with sleep efficiency.[236]

In patients with type 2 diabetes, the prevalence of OSA as assessed by polysomnography was found to be high, ranging from 58% to 86% (Figure 20-11).[237-244] A retrospective analysis of a total of 16,066 diabetic patients from 27 primary care practices found that only 18% were diagnosed with OSA, suggesting that OSA may remain untreated in most diabetic patients.[245] There is also evidence to suggest that the presence and severity of untreated OSA may be associated with poor glucose control in type 2 diabetic patients.[199,239,243,246,247] In the CARDIA Sleep Study, participants with type 2 diabetes who had more fragmented sleep or insomnia had higher fasting glucose and insulin levels.[246] A recent study indicated that obstructive events in REM sleep rather than NREM sleep may have more adverse metabolic effects in diabetic patients.[247] A number of interventional studies have examined whether CPAP treatment of OSA has beneficial effects on glycemic control in type 2 diabetic patients. Although uncontrolled studies were generally positive,[248-252] one randomized controlled trial found no beneficial effects of CPAP on glycemic control in patients with type 2 diabetes.[253] Notably, this negative study reported an average nightly therapeutic CPAP use of only 3.6 hours.[253]

Polycystic Ovary Syndrome

PCOS, the most common endocrine disorder of premenopausal women, is characterized by hyperandrogenism, obesity, insulin resistance, and an elevated risk for type 2 diabetes. Insulin resistance is often referred to as a "hallmark" of PCOS. OSA is present in at least 50% of PCOS women.[254-259] In one study about two thirds of PCOS women were found to have poor sleep quality, and 45% had chronic daytime sleepiness.[258] In a study involving 52 women with PCOS and 21 women without PCOS of similar age and BMI, OSA was found to be an important determinant of insulin resistance, glucose intolerance, and type 2 diabetes in PCOS.[257] Both the prevalence of impaired glucose tolerance and the degree of insulin resistance increased in direct proportion to the severity of OSA.[257] Eight weeks of CPAP treatment of OSA in obese women with PCOS led to improvement in insulin sensitivity and decreased sympathetic output as assessed by 24-hour profiles of plasma catecholamines.[260] The magnitude of these beneficial effects was modulated by the hours of CPAP use and the degree of obesity.[260] Although the current evidence points to the importance of systematic identification and treatment of OSA in the management of PCOS patients, most clinicians who treat PCOS today are not yet aware of the high risk for OSA in this patient population.[261]

CLINICAL PEARL

Sleep exerts marked modulatory effects on most components of the endocrine system and has an important impact on glucose regulation. There is rapidly accumulating evidence from both laboratory and epidemiologic studies indicating that sleep loss and poor sleep quality are associated with hormonal disturbances and an increased risk for obesity and diabetes. Sleep disorders may also exacerbate the severity of an existing condition. Findings suggest that part of the constellation of hormonal and metabolic alterations that characterize normal aging may reflect the deterioration of sleep quality. Strategies to improve sleep quality may have beneficial effects on endocrine and metabolic function.

SUMMARY

Sleep exerts important modulatory effects on the endocrine system. Sleep timing, duration, and quality may also affect the circadian system and its control of hormone release and action. Pathways mediating the impact of sleep on endocrine function and metabolism include the activity of the hypothalamic releasing and inhibiting factors on pituitary hormone release and the autonomous nervous system control of endocrine organs. Modulatory effects of sleep are not limited to the

hormones of the hypothalamic-pituitary axes; these effects are also observed for the hormones controlling carbohydrate metabolism, appetite regulation, and water and electrolyte balance. Sleep loss is associated with disturbances of hormone secretion and metabolism, which may have clinical relevance, particularly as voluntary partial sleep curtailment has become a highly prevalent behavior in modern society. Reduced sleep quality also adversely affects endocrine release and metabolism. Major metabolic diseases such as obesity, type 2 diabetes, and polycystic ovary syndrome are all associated with sleep disturbances, which may promote the development or exacerbate the severity of the condition. Strategies to reverse decrements in sleep duration or quality may have beneficial effects on endocrine and metabolic function.

Thermoregulation in Sleep and Hibernation

Kurt Kräuchi; Tom Deboer

Chapter Highlights

- Despite the long-term awareness that thermoregulation and sleep are intimately coupled, there is still a lack of knowledge about the crucial mechanisms. Based on the fact that sleeping pills exhibit undesirable side effects, there is an increasing need for nonpharmacologic therapies such as thermal interventions.
- This chapter describes normal sleep in humans in relation to circadian regulation of core body temperature. Based on this correlation, human and animal experimental intervention studies changing ambient temperature or sleep pressure are described to gain information about more causative mechanisms.
- In addition to sleep, the torpid state in animals is described. Because this state is entered through normal sleep, it may be a valuable model to further investigate the relationship between thermoregulation and sleep.

The objective of this chapter is to cover the physiology of the relationship between the thermoregulatory system and the sleep regulatory system. Both are driven, independently, by two interacting physiologic principles, homeostasis and circadian regulation. The chapter is divided into three main sections: (1) a brief introduction into the circadian regulation of core body temperature (CBT); (2) the interaction of sleep and thermoregulatory mechanisms; and (3) hibernation, a special condition displayed by a limited number of mammalian species.

Animals increase survival by residing in a safe sleeping site and have used sleep to maximize energy savings by reducing body and brain energy consumption and to conduct a variety of recuperative processes.[1,2] Knowledge about thermophysiology and its relation to sleep leads to the hope that temperature-related interventions can alleviate sleep disturbances and be helpful to cure certain aspects of sleep and alertness problems in the general population.

A vast amount of knowledge is found in the literature on the variability in rest and sleep states and on thermophysiology across the animal kingdom.[1,2] To limit the scope of this chapter, only findings from humans, rats, ground squirrels, and hamsters are reviewed.

CIRCADIAN REGULATION OF CORE BODY TEMPERATURE

More than 50 year ago, Aschoff[3] showed that the human body consists of two thermophysiologic compartments: the heat-producing, homeothermic core; and the heat-loss-regulating, poikilothermic shell. The size of the latter is largely dependent on environmental temperature. In a warm environment, the shell is small; in a cool environment, it is large and thus acts as a buffer to protect the core from dangerous cooling. All peripheral tissues, such as fat, the skin, and in particular the skeletal muscles of the legs and arms, can contribute substantially to the size of the shell, provided that peripheral blood flow is low. Therefore rates of blood flow through muscles and skin are the main determinants of shell size variability and hence of peripheral insulation. The distal skin regions, in particular fingers and toes, are the main thermoeffectors to lose core body heat because they possess the physical and physiologic properties to best serve the function of heat loss. They have ideal surface shapes (round, small radius) for good heat transfer to the environment; the surface-to-volume coefficient increases from proximal to distal skin sites. The distal skin temperatures therefore provide a good measure of the shell size.

CBT comprises the temperature of the brain and the abdominal cavity, including inner organs (e.g., liver, heart, kidney).[3] In most placental mammals CBT is regulated around 37° C, whereas the brain is the main target for homeothermy, allowing control of all behavioral and physiologic processes over a broad environmental temperature range. A detailed description of the thermoregulatory system can be found elsewhere.[4]

CBT is regulated between thermoeffector thresholds, which are subject to circadian oscillations.[5] Circadian rhythms in mammals are generated by the self-sustaining central pacemaker localized in the suprachiasmatic nuclei (SCN) of the hypothalamus and are usually entrained to the 24-hour solar day mainly by the synchronizer light.[6] A rostral projection from the SCN to the preoptic anterior hypothalamus (POAH) conveys the circadian signal to the thermoregulatory system.[6] The regulation of CBT results from the concerted action of the homeostatic and circadian processes. In humans, the daily decline of CBT in the evening results from a regulated decline in the thermoregulatory thresholds of heat production and heat loss; the inverse happens in the morning. When heat production surpasses heat loss, body heat content increases and

vice versa. Depending on environmental temperature, about 70 to 90% of body heat content is located in the body core. Therefore changes in CBT reflect to a great extent changes in body heat content. Heat production and heat loss are modified by activities such as muscular exertion and fluid and food intake that are not randomly distributed over the circadian cycle. These behaviors induce so-called masking effects and differentially modify the endogenous rhythm of CBT.[7]

To disentangle circadian effects and influences from masking effects of an overt diurnal activity pattern, the constant routine (CR) protocol was developed in humans.[8] With this protocol it was shown that the time course of heat production precedes heat loss and that CBT varies as an intermediate resultant.[8] Heat production and heat loss are separated not only in time but also in space in the body.[3] Under resting conditions, about 70% of heat production depends on the metabolic activity of inner organs, whereas body heat loss is initiated by heat redistribution from the core to the shell through blood flow to the distal skin regions.[3] Thermoregulatory distal skin blood flow is regulated by the autonomic nervous system by constriction or dilation of arteriovenous anastomoses. These are shunts between arterioles and venules, exclusively found in nonhairy distal skin regions such as the toes and fingers.[3] When they are open, warm blood flows rapidly and directly from arterioles to the dermal venous plexus, enabling an efficient heat exchange from the core to the distal skin. Sympathetic nerve activity seems to be crucial for peripheral vasoconstriction, but the exact neural process by which this regulation is achieved is still a matter of debate.[9] The endogenous time course of distal skin temperatures (hands and feet), measured during a CR, exhibits an inverse circadian rhythm in comparison with CBT, with a phase advance of about 100 minites[8] (i.e., in the evening, distal skin temperatures rise before CBT declines).[8] The amplitude of these distal skin temperature rhythms is about three times larger than that of CBT.[8,10] In contrast, temperatures of proximal skin regions (e.g., thigh, infraclavicular region, stomach, forehead) change in parallel with CBT, and the amplitudes are of similar magnitude.[8,10] This inverse relation between distal and proximal skin temperature rhythms reflects the differences in thermophysiologic regulatory mechanisms, as described earlier.[3] The distal minus proximal skin temperature gradient (DPG) therefore provides a selective measure of distal skin blood flow and hence body heat loss through the extremities.[3]

Nocturnal secretion of the pineal hormone melatonin, which is under control of the SCN, plays a crucial role in the endogenous downregulation of CBT in the evening.[11] Administration of melatonin in the afternoon, when endogenous melatonin levels are low, provokes exactly the same thermophysiologic effects, as observed naturally in the evening.[11] Whether melatonin induces distal vasodilation in humans by acting directly on blood vessel receptors, indirectly through modulation of sympathetic nerve activity, or both, remains to be determined.[11] In addition, both subjective ratings of sleepiness and the level of activity in the electroencephalogram (EEG) theta and alpha rhythms as an objective outcome of the sleep-wake state are increased.[11] Moreover, it is noteworthy that rise in melatonin secretion in the evening belongs to a well-orchestrated circadian physiologic regulation controlled by the SCN, which in turn downregulates CBT, increases sleepiness, and promotes sleep.

RELATIONSHIP BETWEEN THE SLEEP REGULATORY AND THE THERMOREGULATORY SYSTEM

The most evident explanation for whether and why the sleep regulatory and thermoregulatory systems are interrelated is a teleologic one: sleep is for energy conservation.[2,12,13] All species sleep or rest when their energy expenditure is low. Rest or quiet wakefulness is a prerequisite for sleep in all species.[1,12,13] These observations represent the starting point of all energetic explanations of the function of sleep. Human sleep evolved from ancestral sleep, and it is quite possible that earlier forms of sleep were linked to energy conservation in ancestors with a smaller body size.[14]

There are two mechanisms that explain how sleep can conserve energy. One is that sleep reduces energy expenditure indirectly by reducing activity. This mechanism would also work when animals only exhibit quiet wakefulness. Alternatively, sleep induces an additional decline in energy expenditure below that accomplished by quiet wakefulness by a change in physiology. Human sleep is only accompanied by a modest additional decline in energy expenditure.[13,15,16] However, energy conservation through sleep may be particularly important in small animals and infants.[2,13,17] Their high surface-to-body mass ratio is ideal to dissipate heat and renders energy conservation achieved by sleep highly adaptive.[13] When body size increases and sensory-motor systems mature, in the course of infant development a parallel decrease in sleep time occurs.[2,17]

COVARIATION OF SLEEP AND THERMOPHYSIOLOGIC VARIABLES

In the following subsections, two lines of evidence are presented to clarify the relationship between sleep and thermoregulatory systems: at baseline thermal comfort condition and after various conditions such as circadian, temperature, and sleep pressure changes. Furthermore, recent research has provided new insights into the relationship between thermoregulation and sleep on the basis of neuroanatomic studies showing significant interaction of the two systems.

Baseline Conditions

To compare the sleep and thermoregulatory systems, it is crucial to separate circadian from masking components of an overt diurnal pattern. This is much more easily accomplished in humans than in animals. Despite this advantage, the most neglected factor in human research is the so-called laying down effect. A change from standing to supine body position induces redistribution of blood, together with heat, from the core to the periphery, thereby increasing skin temperatures, decreasing CBT, and increasing sleepiness.[18] This effect lasts about 1 to 2 hours[18] and significantly confounds the endogenous time course of CBT in a classic human sleep recording protocol where laying down occurs about 20 to 30 minutes before lights off. The temporal relationship between thermophysiologic variables, heart rate, subjective ratings of sleepiness, and salivary melatonin secretion under CR conditions before habitual bedtime and for the following sleep episode is summarized in Figure 21-1. The only thing that changed during this protocol was that the low-intensity lights were switched off with the implicit permission to fall asleep. Before

lights off, the previously described endogenous pattern of CBT downregulation is already visible. In the evening, heart rate (an indirect measure of intrasubject variation of heat production) declined first, followed by heat loss and finally by a decrease in CBT. Subjective ratings of sleepiness increased in parallel with DPG and salivary melatonin levels. The proximal skin temperature exhibited a similar pattern as CBT. Immediately after lights off and before sleep stage 2, the distal and proximal skin temperature increased and heart rate declined.[19] In addition, an increase in sweating is often observed, depending on CBT.[20]

The typical increase in distal skin temperature, as shown in Figure 21-1,[21] is caused by redistribution of heat from the core to the shell. Similar findings at sleep onset have been described in the lower leg.[22] However, CBT exhibited only a slight but significant increase in the rate of change after lights off,[3,21] leading to approximately 0.3°C lower CBT values during sleep compared with quiet wakefulness.[23] In contrast to the fast changes in skin temperature, the decline in CBT is slow, which can be explained by the reduced cardiac output during sleep initiation impeding a faster heat loss during the sleep episode under thermoneutral conditions.[19] The magnitude of the decrease in CBT is negatively correlated with environmental temperature.[24] A distal minus proximal skin temperature gradient (DPG) of 0°C indicates that during sleep the thermoregulatory shell has disappeared, resembling a state similar to that of the human body in the awake state in a warm environment (e.g., 35°C).[3] Heat redistribution from the core to the shell is completed within about 1 hour after lights off. Such a completely relaxed one-compartment body, when core and shell are fused, is prone to a fast cooling when sleep occurs in a cool environment. Under normal conditions, CBT is protected because humans and animals try to occupy a sleep berth in a comfortable thermal environment.[13] When humans initiate sleep outside the natural temporal niche by taking an afternoon nap, similar thermophysiologic changes occur right after lights off and before the initiation of sleep stage 2.[25] There are subjects, mostly women, who exhibit a proneness to cold hands and feet and therefore to having a large shell.[26,27] These subjects show alteration in some of the macrostructure variables of sleep such as a significant prolonged sleep onset latency to stage 2 (SOL2).[26,27] In fact, it has been shown that subjects with sleep onset insomnia respond well to a mild heating with reduced thermoregulatory heat loss from their fingers.[28] Within this context recent studies have shown that wrist skin temperature best predicts thermal sensation, especially in women, and therefore seems useful as a physiologic parameter to thermoregulatory behavior[29] such as using thermophysiologic remedies (e.g., bed socks).[22]

At the end of sleep, the transition to waking is accompanied by an inverse thermophysiologic pattern.[25,30] This period is named *sleep inertia;* after awakening it takes a certain time interval to recover all physiologic and cognitive functions.[25,30] During that time, a similar but inverse time course in distal vasoconstriction is observed.[25,30] It is noteworthy and of clinical relevance that similar thermophysiologic effects as seen during sleep initiation can be observed after administration of benzodiazepines[31] and with certain relaxation techniques like yoga, autosuggestion of warmth, autogenic training, and meditation without falling asleep.[3,31-33] These techniques induce a withdrawal in muscular and cutaneous sympathetic nerve activity, which leads to increased distal skin temperature, and to a reduction in heart rate, energy expenditure, and CBT.[31,32] Inverse effects were induced after caffeine administration with elevated CBT, distal vasoconstriction, and disturbed daytime recovery sleep and prolonged sleep onset latency after night sleep deprivation.[34] Therefore distal vasodilation followed by a drop in CBT appears to be a thermophysiologic event, which is primarily related to relaxation occurring before sleep onset,[35] and the opposite is true for vasoconstriction.

Studies carried out in humans to describe changes in thermophysiologic variables show that changes in CBT and proximal and distal skin temperature related to the non–rapid eye movement (NREM)–rapid eye movement (REM) sleep cycle are very small.[36,37] Heart rate is clearly increased shortly before and during REM sleep relative to NREM sleep, which is, however, reflected only in a minor increase in energy expenditure during REM sleep.[16] Extensive studies on thermophysiologic alterations regarding the NREM-REM sleep cycle concluded that changes in brain heat production are practically not relevant for changes in brain temperature.[38] To our knowledge, only one human study recorded brain temperature together with sleep EEG data, but no significant systematic changes regarding the NREM-REM sleep cycle were found.[39]

One of the advantages of animal research is the parallel recording of body and brain temperature. In many small mammals (rabbit, rat, Djungarian hamster), NREM sleep is associated with a decrease in brain temperature, whereas REM sleep and waking are associated with an increase[40,41] (Figure 21-2).

In an elegant study performed in the rat, it was shown that heat is redistributed across the body when vigilance states change.[42] At the initiation of NREM sleep, the brain and intraperitoneal temperature decreased, whereas the tail skin temperature increased. The opposite occurred at the transition from NREM sleep to wake. At transitions from NREM to REM sleep, brain temperature rose slightly, whereas intraperitoneal and tail temperature did not change. These data are in accordance with those obtained in humans. Heat is redistributed from the core to the shell at the onset of sleep. Humans thermoregulate by vasodilation and vasoconstriction of blood vessels within the skin of extremities; in rats similar changes are observed in the tail. The main difference lies in the timing of the redistribution of heat relative to the onset of sleep and waking. In humans changes are visible several hours before sleep onset; in the rat the same changes occur at the immediate onset of sleep. This difference is probably related to the smaller body size and to the shorter and repetitive ultradian sleep-wake pattern in the rat, which renders a time lag of several hours to be nonfunctional.

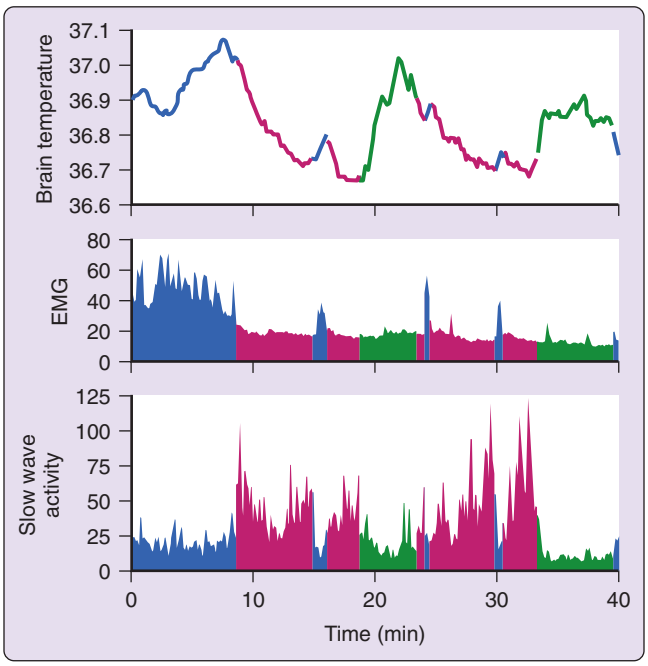

Figure 21-2 A 40-minute record of brain temperature measured at the parietal cortex, integrated electromyogram (EMG) activity from the neck muscles, and electroencephalogram (EEG) slow wave activity (SWA; mean EEG power density between 0.75 and 4.0 Hz) of a Djungarian hamster (*Phodopus sungorus*). *Blue*, Waking; *red*, NREM sleep; *green*, REM sleep. Values are plotted for 8-second epochs. Note the decrease of brain temperature at the entrance into NREM sleep and the increase during REM sleep and waking.

Applying a CR in rodents is not possible. However, on the basis of the relationship between brain temperature and vigilance states, it was possible to subtract the influence of vigilance state changes on brain temperature, rendering a mathematical CR.[43] This study concluded that, in the rat, about 90% of the variance in brain temperature is caused by changes in vigilance. A recent study confirmed that vigilance state–related changes in brain temperature are independent of the functioning of the circadian clock because they remained intact after removing the SCN.[44]

Taken together, there are robust thermoregulatory effects induced by lying down and the relaxing sleep behavior; however, the NREM-REM sleep cycle seems to have minor thermoregulatory function in humans. The thermoregulatory mechanisms, which are active during the wake-sleep transition, redistribute heat from the core to the shell and induce a decline in heart rate, energy expenditure,[15,16] and CBT.[37] Relaxing behavior before sleep in humans and animals belongs inseparably to sleep, and therefore these data do not contradict the energy conservation hypothesis of sleep.[14] The accompanying thermoregulatory effects in humans may be a remnant of their evolutionary past.[14]

Changed Circadian Conditions

It has been observed that subjects living under normal conditions choose their bedtime (lights off) at the maximal rate of decrease in their CBT rhythm.[45] However, when subjects are living on self-selected sleep-wake schedules in a time-free environment, bedtime is phase-delayed close to the CBT minimum, which is an indication that the sleep-wake cycle and the circadian rhythm of CBT are separate but usually entrained (synchronized) oscillatory systems.[46] Unfortunately, neither direct nor indirect measurements of heat loss and heat production were carried out in parallel in these studies. Therefore it is possible that CBT is not the crucial variable for sleep induction, but rather is one of its determinants (i.e., heat loss). Because heat loss seems to be closely linked to sleep initiation, it may be speculated that the circadian rhythm of heat loss is phase-delayed under free-run conditions. The duration of sleep episodes was maximum when initiated at the time when CBT reached its maximum, and at the opposite, minimal sleep lengths occurred when sleep was initiated during the rising phase of the CBT rhythm.[17]

Under most experimental conditions, REM sleep propensity exhibits a strong circadian pattern with a peak about 1 to 2 hours after CBT has reached its circadian minimum.[37,47] There is also a reproducible and robust circadian rhythm in SOL2, which is closely related to the circadian CBT rhythm and thermoregulatory effects described previously.[48] In forced desynchrony studies (i.e., living on a scheduled 28-hour day including a 9.3-/18.7-hour sleep-wake cycle), it was shown

that SOL2 is longest at the circadian phase where CBT reaches its maximum, that is, 1.5 hours before CBT starts to decline and melatonin secretion rises.[47] At this circadian phase, named the *wake-maintenance zone*,[49] inner heat conduction is lowest as indicated by the largest difference between CBT and distal skin temperature and the largest negative DPG values. Thereafter, SOL2 declines rapidly and is minimal around the time when CBT reaches its circadian trough, when inner heat conduction is largest (distal skin temperature is highest and the difference between CBT and distal skin temperature is lowest). However, it remains to be determined whether thermal interventions, like lower leg warming, at the wake-maintenance zone are successful to reduce SOL2, as was shown for melatonin administration.[50]

Taken together, self-selected sleep timing, SOL2, REM sleep latency, REM sleep propensity, and sleep duration are closely associated with CBT. Even though these variables are not fully in phase with CBT, it is possible that one of the determinants of CBT (e.g., heat production, heat loss) is directly interrelated. It still remains to be established whether these rhythms are independently governed by the SCN or causally linked directly to measured thermophysiologic outcomes. These correlative findings lead to the question of how is sleep affected by thermoregulatory challenges.

INTERVENTION STUDIES IN HUMANS

Effects of thermal interventions (heating or cooling) on sleep are not easy to investigate. Thermal interventions, applied either passively or actively by physical exercise, induce significant changes in skin temperatures and CBT.[15,17,37,51,52] The intensity of a thermal intervention is crucial, as are the skin region selected and the time of application. During sleep only passive thermal loads can be applied. It has been shown that sleep reduces the thresholds and gains of the autonomic temperature defense mechanisms and expands the inter-threshold zone (the temperature range for activation of metabolic heat production or evaporative heat loss).[17,52,53] These threshold changes are modest in slow wave sleep (SWS) but much stronger in REM sleep.[17,52] As a consequence, CBT and skin temperatures are more sensitive to changes in environmental temperature during sleep. Maximal total sleep time (TST) is found in the thermoneutral zone (the range of ambient temperature at which temperature regulation is achieved solely by vasomotor responses), whereas REM sleep is more vulnerable to thermal interventions than SWS.[17,52] Too intense thermal interventions induce arousals and awakenings, which in turn can induce thermoregulatory effects, such as elevating CBT.[52] When a thermal load is applied repeatedly, the thermoregulatory system can adapt and the effects on sleep are changed; for example, the arousing effects are reduced. Aborigines in the Central Australian desert and nomadic Lapps in Arctic Finland were experiencing comparable degrees of cold exposure during the night, and both showed lower thermoregulatory thresholds for shivering before modern technology arrived.[54,55] As a consequence, in these subjects CBT was more reduced during sleep, and undisturbed sleep occurred at a lower environmental temperature. Among limitations in actual knowledge is the fact that too many modalities of thermal interventions on sleep are understudied and, in addition, the effect of thermal interventions on sleep may differ between normal and sleep-disturbed subjects.

Changing Temperatures

Ambient temperature, especially in combination with high humidity, is important for both the quantity and quality of sleep.[52] When sleep occurs in a warm environmental temperature (31 to 38°C), duration of wakefulness increases, and at the opposite, duration of REM and NREM sleep decreases.[15,17,51,52] Also, cold exposure (21°C) induced more awakenings, less time in sleep stage 2, and less TST but did not affect the duration of the other sleep stages. Marked thermoregulatory effects were induced under such manipulations.[15] The decrease in CBT observed during the night episode was larger at 21°C compared with the thermoneutral 29°C condition. During REM sleep, forehead temperature and oxygen consumption increased and feet temperature decreased compared with SWS with cold exposure. Therefore cold-exposed humans may not exhibit a complete inhibition of thermoregulation during REM sleep as has been observed in small mammals.

When ambient temperature was gradually decreased during sleep, an earlier CBT nadir and an advanced peak for REM sleep propensity was obtained.[56] Duration of sleep stage 4 increased when the normal nocturnal decrease of CBT was augmented by a constant and mild reduction in ambient temperature, despite decreased sleep efficiency.[56] Similarly, after a 2°C reduction in ambient temperature during sleep, it was observed that the increase in SWS occurred simultaneously with the rise in slow wave activity (SWA; EEG power density ~1 to 4 Hz) without any change in sleep efficiency or reduced amount of REM sleep.[57] The thermal manipulation reduced not only leg skin temperature but also CBT and heart rate. Taken together, the augmentation of heat loss leading to reduced CBT during sleep seems to be the crucial variable for increased SWS.

In humans, body heat content and hence CBT can also be effectively manipulated by body immersion in warm or cold bathes. For instance, as a result of rapid conductive heat loss in a cold bath, CBT decreases faster compared with the drop observed in air at the same temperature. Rewarming of the cool shell after cool bathing leads to a characteristic after-drop in CBT.[58] Several studies showed effects of positive heat load on sleep,[15,51,52] but no study examined effects on sleep after a cold bath. In general, passive body heating (40° to 43°C for 30 to 90 minutes; CBT increase of 1.4° to 2.6°C) has a positive effect on many aspects of sleep in healthy young adults and in older and sleep-disturbed subjects. It was found that warm bathing in the evening shortened sleep onset latency, enhanced SWS duration, and sometimes reduced REM sleep duration. The increase in SWS, however, is not dependent on a reduction in REM sleep. Bathing performed in the morning or early afternoon had no effect on sleep architecture.[15,51] In principal, actual levels of CBT at sleep onset or the decline in CBT afterward could be related to the amount of SWS after warm bathing.[15,51] Additionally, a phase delay of the CBT nadir during the night sleep episode has been described after evening hot bathing, which correlates with increased SWS.[59] All these CBT characteristics could be correlated because directly after a positive heat load the velocity of CBT decline is larger, the CBT level is elevated before sleep onset, and the overt CBT nadir during sleep may be delayed. However, phase shifting effects of passive heat loads in humans have not been studied systematically. Other variables than CBT, such as skin

temperature, may play a role. The available findings are inconsistent because of the diversity in study designs and methodology and the low statistical power of many studies. In a study in which hot full-body and hot foot bathing were performed 35 minutes before lights off,[60] CBT increased by about 1°C only during full-body bathing. Both conditions, however, increased mean skin temperatures and reduced sleep onset latency and movement during sleep. These findings indicate that elevated skin temperature is crucial for a rapid onset of sleep, but not changes in CBT. Older sleep-disturbed subjects responded to hot foot bathing with slightly reduced sleep onset latency to stage 1 (SOL1) and significantly decreased wakefulness in the second NREM sleep period.[61] In these older subjects not only DPG but also CBT were elevated after hot foot bathing during the first hour of sleep. However, the same authors recently reported that warming the feet may improve sleep only for those who have cold feet.[62]

Of clinical relevance are the data describing that REM sleep duration and TST are reduced when electric heat blankets are used throughout the night,[63] suggesting that heat load exerted through the blanket is too strong an intervention and disturbs rather than supports sleep. In a series of experiments with a thermal suit, the effects of small changes in skin temperatures of only 0.4° to 2°C within the thermal comfort zone, without significantly altering CBT, were investigated on several sleep parameters.[64] It was demonstrated that intermittent elevation in skin temperature during the sleep episode suppressed nocturnal awakenings and triggered shifts to deeper sleep in young and older healthy subjects and in insomniac patients.[64] Whole-night studies are needed to confirm that a sleep depth–enhancing effect of mild skin warming can indeed be sustained. Nevertheless, these findings emphasize the importance of skin temperatures, primarily proximal skin temperatures (including the trunk), but also more distal skin region temperatures such as of the legs and arms, for these effects. Other studies revealed that subtle skin temperature warming was associated with a faster onset of sleep in young and older subjects and in older insomniac and narcoleptic patients.[64-66] At present, it cannot be concluded which thermophysiologic correlate represents the causal factor to increase SWS and reduce sleep onset latency. Nevertheless, heat load before sleep seems to increase the duration of SWS.

Intense exercise is a manipulation that can also raise CBT by 2°C or more. Subsequently, CBT declines as a result of the thermoregulatory heat loss drive through increased vasodilation and sweating. A number of reproducible changes on sleep have been identified after exercise in the evening: shortened sleep onset latency, increased TST and SWS, longer REM sleep onset latency, and less REM sleep.[67,68] Exercise exhibits negative effects on sleep when performed close to sleep onset; the optimal temporal positioning of physical activity is thought to be 4 to 8 hours before bedtime.[68] Chronic exercise studies have not provided much stringent evidence of a sleep-promoting effect. Conversely, with reduced exercise load in trained athletes, SWS and REM sleep onset latency were reduced and REM sleep duration and sleep onset latency were increased.[69] Taken together, after intense exercise, sleep appears to commence faster and is deeper.

In conclusion, warm distal skin temperatures induced either by endogenous circadian heat loss regulation in the evening, homeostatic downregulation of CBT after passive and active heat load, or selective skin warming predispose to a rapid onset of sleep. More sophisticated studies with respect to skin regions are necessary to show whether warming of shoulder, stomach, legs, hands, or feet, for example, exhibits the strongest effects on sleep initiation and sleep architecture. The increase in skin temperatures could be the causal factor for the acceleration of sleep onset and the increase of SWS. Further studies must investigate the optimal time interval between thermal intervention and bedtime and which physiologic mechanisms are involved in the observed effects. It is possible that thermal afferents provide a signal for the sleep-inducing brain regions in the hypothalamus.[31,70]

Changing Sleep Pressure

The studies of sleep deprivation effects on the thermoregulatory system cannot be understood without considering the circadian time at which the deprivation occurs. All thermophysiologic variables undergo significant circadian changes. Additionally, the effects of an experimental overnight sleep deprivation on the thermoregulatory system have to be controlled for changes in body position, locomotor activity, food intake, and light intensity. Using the CR protocol, it was shown that 40-hour total sleep deprivation does not change CBT, distal and proximal skin temperatures, heart rate, and energy expenditure despite the huge increase in sleepiness.[8] A comparison with a sleep pressure–reducing protocol, including regularly scheduled naps, provided evidence that changes in sleep pressure do not influence the thermoregulatory system.[12] Additionally, the nocturnal 8-hour sleep episodes before and after the two protocols revealed that CBT and distal and proximal skin temperatures did not differ even though a large difference in SWA was observed.[12] Taken together the circadian modulation of sleepiness is primarily related to the circadian regulation of distal vasodilation and hence to heat loss and circadian CBT reduction, whereas the homeostatic regulated increase of sleep pressure does not influence the thermoregulatory system,[19] contrary to earlier suggestions.[71] To be more conclusive, longer sleep deprivations may need to be performed to test whether the thermoregulatory system remains independent of sleep pressure.

INTERVENTION STUDIES IN RODENTS

Changing Temperature

The main interventions applied in rodent studies are manipulation of ambient temperature and brain temperature. In the rat, a general decrease in the daily percentage of REM sleep was seen when ambient temperature decreased,[42,72] indicating that REM sleep is very sensitive to changes in temperature and incompatible with low ambient temperature in the rat. Djungarian hamsters enter REM sleep more easily when brain temperature is relatively low,[73] but probably also in this species REM will disappear first when ambient temperature is lowered. In this context, low ambient temperatures are applied as a tool to investigate REM sleep regulatory mechanisms.[74,75]

In general the impression exists that increasing ambient temperature increases sleep pressure. In rats, when ambient temperature was increased to 33° to 35°C for 3 hours, resulting in a brain temperature of approximately 40°C, subsequent NREM sleep displayed more slow waves than in sleep-matched controls.[76] The amount of REM sleep did not change

compared with controls, and brain temperature was significantly decreased in the first 5 hours of recovery. Under these conditions animals slept less during the heating compared with baseline, indicating that too high ambient temperatures override sleep demand.

In two separate experiments in rats in which ambient temperature was increased to 30° to 32°C for 24 hours, cortical brain temperature was significantly increased by 0.3° to 1.0°C but hypothalamic temperature did not change.[77,78] This treatment resulted in one case in increased NREM sleep and in both experiments in an increase in SWA in NREM sleep in the dark period. These data indicate that changes in sleep can be induced by increasing ambient temperature without changing hypothalamic temperature.

Another approach is heating the POAH, increasing hypothalamic brain temperature locally, without changing ambient temperature. This approach resulted in increased SWA and NREM sleep during 1 hour of warming (1.0°C above baseline) in cats.[79] One hour of cooling (2.0°C below baseline) did not elicit a response. The data suggest that an acute increase in ambient or brain temperature (0.3° to 1.0°C) can increase NREM sleep and possibly increase the occurrence of SWA in the NREM sleep EEG.

Changing Sleep Pressure

During sleep deprivation, brain temperature is higher compared with baseline, and subsequent recovery is characterized by a decrease in brain temperature below baseline and an increase in NREM sleep and in SWA in NREM sleep.[41,78,80,81] This result was interpreted as a heat load incurred during the sleep deprivation that was subsequently recovered by increasing NREM sleep and SWA.[71] One of the clear results obtained from these experiments is a negative correlation between the amount of NREM sleep and the level of brain temperature.[73,80] There is no significant correlation, however, between SWA in NREM sleep and brain temperature,[73,80] ruling out the possibility that the depth of sleep determines brain temperature directly. Moreover, in Djungarian hamsters well adapted to a short winter photoperiod with a brain temperature 1°C below summer photoperiod brain temperature, recovery sleep after sleep deprivation is accompanied by an increase in brain temperature.[73] This is in contrast to the long photoperiod during which sleep deprivation is followed by a decrease in brain temperature.[41,73] A correlation between SWA and brain temperature, combining these data, supported the notion that brain temperature after sleep deprivation is set to the same temperature in both conditions,[73] suggesting that there may be an optimal temperature for high-amplitude slow waves in NREM sleep during recovery.

Two experiments in rats, in which ambient temperature was raised to 32°C during a sleep deprivation of 2.5 hours[78] or 3 hours,[81] did not result in similar outcomes. Short-lasting increases in SWA and NREM sleep were observed after a 2.5-hour sleep deprivation,[78] but not after a 3-hour sleep deprivation.[81] In contrast, a short-lasting increase in REM sleep was observed after a 3-hour sleep deprivation,[81] but not after a 2.5-hour sleep deprivation.[78] It can be questioned whether consistent results can be obtained in the rat with these short sleep deprivation durations. Probably a more systematic approach of scanning different ambient temperatures with longer sleep deprivations is needed to resolve these differences.

Brain Temperature, Electroencephalogram, and Thermosensitive Neurons

The EEG is influenced by changes in brain temperature as well. From analysis of the EEG of the Djungarian hamster during spontaneous entrance into the hypothermic state of torpor (see Hibernation, later) and from experiments in which either rats, cats, or humans were cooled, it was found that the amplitude and frequency of the EEG changes when brain temperature decreases. The amplitude becomes smaller, and prominent frequencies in the EEG slow down with decreasing temperature.[82] Recently the slowing down of the EEG was confirmed in rats in which hypothermia was induced pharmacologically by inhibiting neurons in the central nervous pathways for thermoregulatory cold defense.[83] This relation between EEG frequency and brain temperature was shown to follow a Q_{10} of approximately 2.5,[84] which means that the frequency became 2.5 times slower when brain temperature decreased by 10°C. Under influence of euthermic changes this effect is relatively small, but it can be significant even for frequencies below 5 Hz.[82] Faster frequencies like the theta rhythm (6 to 9 Hz) in rodents[82,85] and frequencies above 10 Hz[82] are significantly influenced by these daily changes in brain temperature.

Measuring the electrical activity of neurons in the POAH revealed the activity of two distinct types of neurons that either increase or decrease firing rate when brain temperature increases. The latter are called *cold-sensitive neurons,* whereas the first group is called *warm sensitive*. A biochemical process (i.e., neuronal firing) that slows down when temperature is increased is quite unique and therefore cold sensitive neurons, when observed, can be considered to be genuine. In contrast, a biochemical process that speeds up when temperature is increased is quite normal and was theoretically explained at the end of the nineteenth century.[82] Many processes, ranging from the firing rate of SCN neurons,[86] to the frequency of prominent EEG waves,[82] to muscle contraction,[87] double or triple when temperature is increased by 10°C ($2 < Q_{10} < 3$).

To identify warm-sensitive neurons, two criteria are applied in the literature. The first determines that an increase in firing rate needs to be more than double when temperature is increased by 10°C ($Q_{10} > 2$).[88] The second says that the increase in firing rate needs to be more than 0.8 impulses per second per 1°C of warming.[89] Both are insufficient. The criterion of a Q_{10} above 2 ignores the fact that most biochemical processes have a Q_{10} somewhere between 2 and 3. Therefore, a Q_{10} of at least 3 needs to be reached before one can be relatively sure that the change in firing rate can be distinguished from the passive biochemical response of the temperature insensitive neurons. With the second criterion, fast firing neurons have a relatively large chance of being included even when they follow the passive biochemical Q_{10} rule of doubling firing rate when temperature is increased by 10°C. Nevertheless there are genuine warm-sensitive neurons in the POAH[90] and other brain areas, such as the diagonal band.[91]

The firing rate of warm- and cold-sensitive neurons in the POAH is known to be vigilance state dependent. Most warm-sensitive neurons increase their activity at the onset of NREM sleep. On the other hand, most cold-sensitive neurons are more active during waking.[90,91] Those results emphasize the importance of simultaneous polysomnographic recordings to be able to disentangle the vigilance state–related changes in firing rate from temperature-related changes.[92] Noradrenergic

afferents from sleep-wake regulatory centers like the locus coeruleus and the lateral tegmental system are also involved in the change in firing rate observed in the POAH.[93] The changes in firing rate of the ensemble of neurons are thought to shape the sleep-wake response to thermoregulatory demands encountered by the animal.

HIBERNATION

The hypothermic state observed during the hibernation season may be a valuable model to investigate the relationship between thermoregulation and sleep and may generate relevant data to the understanding of human physiology. Most hibernating mammals are small and weigh between 10 and 1000 g.[94] During the hibernation season these animals spend a considerable amount of time in a torpid state with body temperature below euthermia (i.e., <30° to 32°C). This sustained hypothermic state is entered voluntarily and can be terminated by the animal. Body temperature can drop by more than 35°C,[95] and the metabolic rate is only a fraction of that during normothermia.[96]

In hibernators the torpid state can last for several days or weeks. A group of smaller mammals with body weights between 5 and 50 g display daily torpor in which body temperature is dropped for a couple of hours during the rest phase but returns to euthermia during the active phase.[94] Both hibernation and daily torpor result in substantial energy savings[97,98] and are therefore considered to be adaptive mechanisms that permit the conservation of energy during unfavorable environmental conditions.

Whether circadian rhythms continue during hibernation is unclear. In hibernating ground squirrels, rest-activity rhythms only slowly reappeared a couple of days after termination of torpor bouts, and this correlated with the number of vasopressin-containing neurons in the SCN.[99] Also, sleep-wake distribution in hibernating ground squirrels did not show a circadian modulation.[100] In contrast, responses to, for instance sleep deprivation, temperature changes, and other homeostatic regulatory processes, are still functioning.[101-105] Under certain circumstances a small circadian modulation of body temperature can be observed during hibernation[106]; however, it is possible to conclude that the contribution of the circadian clock is reduced, whereas homeostatic regulation seems to be virtually identical to its regulation outside the hibernation season.

THERMOREGULATION AND METABOLIC RATE REDUCTION

The mechanism by which the animals reach the reduction in metabolic rate is still controversial. The traditional view was that metabolic rate falls as body temperature decreases at torpor entry. The Q_{10} of metabolic rate between euthermia and torpor is often close to 2, which is typical for biochemical processes[82]; therefore the reduction in metabolic rate seems to be explained solely by the temperature effect on biochemical processes in the body.[107,108]

However, Q_{10} values above 3 for metabolic rate have been observed during torpor entry and during torpor at relatively high temperatures. It was proposed that an additional phy siologic inhibition must be involved in the reduction of metabolic rate.[109,110] Metabolic rate is downregulated before torpor entry, and the decrease in body temperature is the consequence and not the cause of the metabolic rate reduction.[111-113] As an alternative hypothesis it was proposed that metabolic rate is a function of the difference between ambient temperature and body temperature, similar to that during euthermia.[111] Because this difference is generally very small during torpor, metabolic rate is equally reduced.

Inhibition of metabolic rate during torpor may be caused by reduced pH, which slows down metabolic processes.[114] In hibernating ground squirrels the respiratory quotient drops during entrance into torpor and rises during subsequent arousal, suggesting CO_2 storage, which may result in decreased pH. In contrast, in Djungarian hamsters, who display daily torpor, respiratory quotient increases during entrance into torpor and decreases before emergence from torpor. Changes in enzyme activity are other candidates for metabolic rate reduction. Mitochondrial respiration is reduced by 50% during torpor in hibernating ground squirrels compared with euthermic individuals.

The previous data support the notion that the mechanism of metabolic rate reduction differs between hibernators and animals that use daily torpor.[114] The reduction in metabolic rate in animals who display daily torpor is largely determined by the decrease in body temperature, whereas hibernators seem to apply some kind of extra reduction in metabolic rate.

For some essential but unknown reason, deep torpor in hibernators is interrupted on a regular basis by short (<24 hours) euthermic periods.[115,116] Above 0°C body temperature, torpor bout length correlates negatively with ambient temperature,[117] and metabolic rate depends on ambient temperature and therefore body temperature. The timing of the euthermic period (also called *arousal*) correlates with the ambient temperature and the metabolic rate of the animal during the preceding hibernation bout.

More recent experiments indicate that the arousal is probably not induced by a process accumulating in the course of a multiday torpor bout but that there exists a separate arousal process of which the onset is more susceptible at higher body or ambient temperatures.[118] Although the mechanism of the arousal is not known, it appears to be totally endogenous in its origin.

The question of the reason for the arousal is important. The function of hibernation is energy conservation, and energy expenditure during the hibernation season is reduced to less than 15% of that the animals would have expended if they remained euthermic throughout the winter season.[96] However, there is still room for improvement because the energetic costs of the periodic arousals constitute 64% to 90% of the total energy expenditure during the hibernation season.[96,119,120] It has been proposed that arousals are required to eliminate metabolic waste products, to replenish blood glucose levels, or to restore cellular electrolyte balance. All these hypotheses have not survived critical experimental testing.[121] Based on EEG observations it was proposed that animals terminate torpor and return to euthermia to restore a sleep debt.[122,123] NREM sleep was deepest at the beginning of a euthermic period, and most of the euthermic period was spent in sleep. The putative restorative function of NREM sleep was thought to be incompatible with torpor.

Torpor and Sleep

Animals in torpor appear to be sleeping. They remain in their nest in a sleeplike posture with elevated arousal thresholds.

Based on several behavioral and physiologic findings it is generally accepted that torpor has evolved as an extension of sleep. When the animals enter torpor, analysis of the EEG shows that rodents are mainly in NREM sleep and that REM sleep is reduced or not present.[124,125] Recordings of neuronal activity in the hypothalamus of hibernators with brain temperatures of 10° to 20°C indicate that these animals keep alternating between long NREM sleep bouts and short waking bouts.[126] Below 10°C it is not possible to determine vigilance states with electrophysiologic methods.[126] These findings supported the hypothesis that NREM sleep is an adaptive behavior for energy conservation, which function is strengthened during torpor.[12,98,127]

However, when the animals subsequently emerge from torpor they immediately enter deep NREM sleep, irrespective of whether animals emerge from deep hibernation[122,123] or daily torpor.[125] This observation suggests that during deep torpor the function of sleep cannot be fulfilled completely and animals have to return to euthermia to recover from a sleep deprivation incurred during the hypothermic state. In the Djungarian hamster the hypothesis was confirmed by combining daily torpor with sleep deprivation experiments.[101] In contrast, similar experiments in hibernating ground squirrels resulted in rejection of the sleep deprivation hypothesis.[103,104] Recently, after recovering from pharmacologically induced hypothermia in rats, the increase in deep sleep was also observed.[83]

There appear to be fundamental differences between animals that display daily torpor and hibernating animals that display multiple-day torpor bouts. The mechanisms of metabolic rate reduction seems to differ.[114] Another fundamental difference between the two groups of animals is the effect of torpor on subsequent sleep. In hibernating animals who display deep torpor similar to ground squirrels or hamsters, regulation of temperature and sleep seems to be reduced to a level that currently cannot be measured reliably. In contrast, animals who display daily torpor appear to make use of the same processes, although applied in an extreme way, which reduces body temperature at the onset of sleep in humans. This latter similarity may provide an opportunity to investigate the relationship between sleep and body temperature with much larger variability.

CLINICAL PEARL

Humans with cold hands and feet are predisposed to difficulties initiating sleep. Better knowledge about sleep thermophysiology may help to develop evidence-based thermal interventions to alleviate sleep disturbances and to manage certain aspects of sleep and alertness problems in the general population. Therefore to assess dysfunctional thermoregulation, clinicians can use objective skin temperature measurements (e.g., wrist and instep seem promising sites for gender-related cold sensation assessment in relation to sleep) in conjunction with patient self-reports about thermal discomfort (e.g., sensation of cold hands and feet) to diagnose, monitor, and advise patients on their sleep disturbances or thermal discomfort–related complaints.

SUMMARY

The human sleep-wake cycle is tightly coupled to the circadian time course of core body temperature. The evening increase in heat loss through distal skin regions and reduction in heat production is associated with sleepiness and the ease to fall asleep, whereas the homeostatic increase in sleep pressure does not influence the thermoregulatory system. After sleep initiation, ultradian NREM-REM sleep cycle fluctuations seem to have minor thermoregulatory functions, especially in humans.

From experimental data it can be concluded that mild warming can increase sleep propensity, sleep consolidation, and the duration of SWS. More reproducible systematic investigations applying temperature levels within the thermoneutral zone on different skin regions are needed to develop applicable thermal therapeutic strategies for sleep disturbances.

The preoptic anterior hypothalamus integrates input from brain areas involved in circadian, temperature, and sleep-wake regulation and in turn influences vigilance states and body temperature in response to that input.

In animals, the torpid state may be a valuable model to investigate the relationship between thermoregulation and sleep. During daily torpor, similar physiologic processes occur as during normal entrance into sleep, but this is observed in a more extreme way, providing an excellent opportunity to investigate these processes in more detail.

Chapter 22

Chapter Highlights

- Sleep contributes to memory consolidation in the long term.
- Sleep stages and specific sleep features (e.g., brain oscillatory activity, spindles) exert different functions in memory consolidation processing.
- Disturbed and reduced sleep affect cognitive functions, especially learning and memory.

In 1867, Hervey de Saint Denys, fascinated by his dreams since the age of 14, published *Les Rêves et les Moyens de les Diriger*.[1] In his book, he reported a series of ingenious experiments showing that experienced events are incorporated into our dreams, in which they can be combined to create original associations between "memory images" of the past. Hence he opposed the idea that sleep may be a sudden drop in a state of cognitive nonbeing in which our resting brain is disconnected. On the contrary, he claimed that "sleep without dreams cannot exist, just as wake without mentation does not exist." Besides dreaming activity however, already addressed in this book, we now know that the sleeping brain houses a great variety of cognitive processes, including, to name a few, the ongoing processing of external stimuli, the revival of past experiences, and last, but not least, the consolidation of new information into memory. Interestingly, recognition that persistence of mental activity in the sleeper may be an integral part of the physiologic processes that subserve memory consolidation only arose in the last quarter of the twentieth century. It is now widely accepted that the sleeping brain is highly active and dynamic, but until recently it was not well understood to what end this heightened activity may serve, beyond the initiation and maintenance of sleep itself.

This chapter aims at introducing issues surrounding the role that sleep may play in memory consolidation, focusing on studies in humans. Reviews in which relationships between sleep and memory in animals are addressed can be found elsewhere.[2-4] We outline here key findings and milestones in probing the sleep for memory hypothesis, as well as ongoing debates and thoughtful questions that remain to be solved. First, we briefly introduce the concepts of memory consolidation and memory systems in humans. Indeed, previous chapters have shown that sleep is a multidimensional state of vigilance, composed of rapid eye movement (REM) and non–rapid eye movement (NREM) sleep states characterized by distinctive features and relying on specific neuroanatomic substrates.[4-5] It is these biologic markers of the various sleep states, rather than the categorical stages of sleep per se, that have been the focus of much of the recent investigation of the role of sleep for memory and are discussed in the following sections. Likewise, it must be kept in mind that memory is not a unitary phenomenon, both from cognitive and neurophysiologic perspectives. Rather, *memory* should be seen as a generic concept for information storage, encompassing a series of specific subdomains. Consequently, the interaction between multidimensional states of sleep and distinctive memory systems makes it logical that not all sleep manipulations will affect performance to the same extent, depending on the nature and demands of the memory task. Hereafter, we examine the growing number of behavioral studies that have enlightened our understanding of the role played by sleep episodes in memory consolidation. Besides, the rapid evolution of neurophysiologic techniques and analytical approaches now allow scrutiny of the complex relations between cognitive processes and their underlying neural substrates. Therefore it is timely to focus part of this chapter on the neurophysiologic mechanisms acting in sleep to support, or at least favor, memory consolidation processes. The relationship between consolidation of newly formed memories and sleep is a crucial issue because memory is at the root of most of our daily behaviors, such as simple skill acquisition (e.g., typewriting), sophisticated operational procedures (e.g., using computer-based systems), or keeping track of personal events and relationships, but is also an integral component of mental health therapeutic interventions.[6]

MEMORY SYSTEMS AND MEMORY CONSOLIDATION

Humans are able to learn, store, and remember various types of information in different ways and for variable periods of time, from conscious acquisition strategies to incidental detection of environmental events. Cerebral damage can selectively alter some of these processes while leaving others undisturbed. These simple observations have led to the proposal that memory is not a unitary phenomenon, but rather should be seen as a complex construct of more or less specialized memory subdomains that interact in ways that remain to be elucidated. Long-term memories in humans may further belong to multiple systems, primarily delineated between declarative and nondeclarative memories (Figure 22-1). Distinguishing features of declarative memory are that information is easily accessible to verbal description and that encoding or retrieval is usually carried out explicitly; that is, the subject is aware that the stored information exists and is being accessed. Declarative memory further comprises semantic and episodic

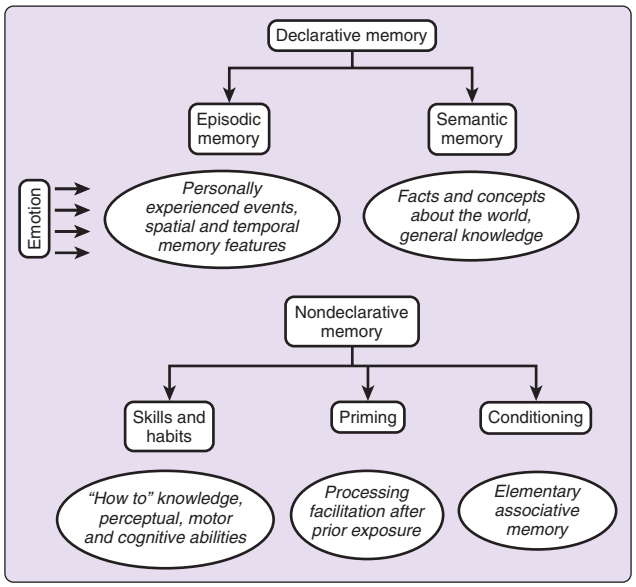

Figure 22-1 Schematic organization of long-term memory systems.

memory components. Semantic memory is the receptacle for our general knowledge about the world, regardless of the spatiotemporal context of knowledge acquisition. Conversely, episodic memory refers to the system that stores events and information along with their contextual location in time and space. On the other hand, distinctive features of nondeclarative memories are that they are not easily accessible to verbal description and can be acquired and reexpressed implicitly. It means that our behavioral performance can be affected by the new memory even if we are not necessarily consciously aware that new information has been encoded or is retrieved. Importantly, memory abilities aggregated under the nondeclarative label also include skills, habits, priming, and conditioning. Although grouped under the nondeclarative label, these various processes are subtended by distinct neuroanatomic substrates both in humans and animals, further suggesting their relative independence.

In addition to the transverse division between long-term memory subsystems proposed by these influential models, it is important to emphasize that newly acquired information is not immediately stored at the time of learning in its final form, if such a stable state exists. Rather, memories undergo a series of transformations over time periods ranging from hours to days, maybe even years, during which they are gradually incorporated into preexisting mnemonic representations[7-9] or are subjected to forgetting.[10] This dynamic longitudinal process refers to the concept of *memory consolidation*, which can be defined as the time-dependent process that converts labile memory traces into more permanent or enhanced forms.[11] Eventually, time-dependent processes of consolidation and the ensuing robust memory trace will enduringly adjust behavioral responses to the recent environmental changes, thereby expanding the organism's behavioral repertoire.[12,13]

In this framework, scientific evidence suggests that sleep and associated processes of brain plasticity[4] are major players in time-dependent processes of memory consolidation, acting as key constituents in the chain of transformations that help integrate information for the long term. Furthermore, these studies have suggested that the electroencephalogram (EEG) features of sleep and their respective sleep states that they characterize may have distinct memory-related functions, which has been interpreted in two different but nonexclusive manners. According to the *dual-process hypothesis*, REM and NREM sleep act differently on memory traces depending on the memory system or process to which they belong. For instance, it has been proposed that slow wave sleep (SWS) facilitates consolidation of declarative and spatial memories, whereas REM sleep facilitates consolidation of nondeclarative memories[14,15] (but see an alternative interpretation of sleep and declarative memory consistent with Tulving's serial-dependent-independent [SPI] model,[16] or an alternative explanation of the relationship between sleep states and nondeclarative memory[17]). Other models hypothesized that memory processing during sleep takes place in a sequential manner whereby particular transitions from one sleep state to another each handle particular aspects of memory consolidation.[18-21] Both approaches assume that it is sleep on the first posttraining night that is important for memory consolidation. Notwithstanding, it would be inappropriate to claim that *only* sleep may achieve the necessary conditions to consolidate novel memories in the nervous system because both sleeplike cognitive and neural processes of memory consolidation have also been observed during wakefulness.[22-24] The precise nature of the relationship between online and off-line consolidation processes remains to be fully elucidated.

MAIN METHODS FOR STUDYING THE ROLE OF SLEEP FOR MEMORY CONSOLIDATION

Three broad classes of experimental approaches have been used to test the hypothesis that sleep exerts a favorable or promoting effect on memory consolidation: (1) effects of posttraining sleep deprivation on memory consolidation and on the reorganization of the neural substrates of long-term memories, (2) effects of learning on posttraining sleep and reexpression of behavior-specific neural patterns during posttraining sleep, and (3) effects of within-sleep stimulation on sleep patterns and overnight memories.

Posttraining Sleep Deprivation

The first and likely earliest type of investigation has probed the putatively detrimental effect of sleep deprivation on the night following learning, based on the assumption that memory performance over the long term will be better if participants are allowed to sleep after learning, compared with sleep-deprived subjects. In classic experimental procedures, subjects learn new material. Afterward, some participants are allowed to sleep normally, whereas others either do not sleep at all (total sleep deprivation), or awakened at the onset of occurrences of the sleep stage under study (selective sleep deprivation), are kept awake during the period of the night in which the sleep stage is predominant (partial sleep deprivation), or have a shortened sleep duration (sleep restriction). Finally, prenight and postnight memory measures are compared between sleeping and sleep-deprived subgroups, either the next day or several days later. This approach was first used more than 80 years ago[25] and revealed that the normal forgetting curve for newly learned verbal material was significantly dampened by the presence of an intermediate period of sleep.

Notwithstanding, investigators did not interpret this effect as a specific role of sleep per se in memory processing but merely as a protective role that sleep may have against "interference, inhibition, or obliteration of the old by the new."[25] However, this hypothesis of a purely passive role for sleep in memory processes has been challenged by selective sleep deprivation studies attributing a specific role to REM sleep in memory storage and consolidation, both in human and animal species.[26] Also, it was demonstrated that memory over an interval with relatively high amounts of SWS was superior to memory over an interval with relatively high amounts of REM sleep.[27] This seemingly apparent contradiction was resolved later with the demonstration that recall of paired-associate lists was significantly better after sleep than wakefulness in the SWS-rich first part of the night only, whereas consolidation of mirror-tracing skills specifically benefited from sleep in the REM-rich second part of the night.[14] Other experimental manipulations inferred a specific role for stage 2 sleep in the second part of the night for the consolidation of motor memories.[28,29] Hence, sleep deprivation studies have suggested that all stages of human sleep (REM, SWS, and stage 2 sleep) might be actively involved in distinctive ways in learning and memory consolidation processes.[30,31]

In the recent past, brain imaging investigations have complemented these findings using neuroimaging techniques, especially functional magnetic resonance imaging (fMRI). As in behavioral paradigms, subjects are trained to the task and then either sleep deprived or allowed to sleep on the following night. A few days later, cerebral activity is recorded during memory retrieval and contrasted between the two posttraining sleep conditions. One or two additional nights of regular sleep are usually allowed after the posttraining night before testing in the scanner to avoid different arousal states that may confound neural activity associated with memory retrieval between sleeping and sleep-deprived subjects. For similar reasons day (wake) versus night (sleep) comparisons[32] or daytime napping protocols[33,34] have been used. These neuroimaging studies have yielded two important contributions. First, they have demonstrated that sleep deprivation during the posttraining night eventually impedes the reorganization and optimization of the cerebral activity subtending delayed retrieval of consolidated memories during wakefulness.[35-38] Second, they have shown that sleep-dependent changes in memory-related brain activity patterns may be present even in cases in which similarity in behavioral performance between posttraining sleep conditions suggests an absence of sleep-related effect on memory.[36,38,39] The latter results further indicate that long-term memory performance can be achieved using different cerebral strategies initiated as a function of the status of sleep during the posttraining night.

Posttraining Sleep Modifications

This second type of investigation stemmed from the reasoning that if newly acquired information underwent an ongoing process of consolidation during sleep, then this should be reflected in neural and physiologic features of posttraining sleep.[40-72] These changes in the characteristics of sleep provide a window into the processes that underlie sleep-dependent memory consolidation.

Numerous EEG studies have demonstrated that both the architecture of sleep and distinctive features of sleep stages can be affected by prior learning experience. For instance, postlearning sleep modifications have been observed by looking at absolute or proportional (i.e., relative to total sleep time) increases in the duration of REM sleep,[21,30,42-44] stage 2 sleep,[45] and SWS[46] episodes. Other studies have reported increased density of rapid eye movements[29,47] and stage 2 spindle activity in the sigma frequency band,[48-55] as well as increases in REM sleep theta power.[56] Many found relationships between quantitative parameters of sleep and overnight performance improvements[21,44,48-50,53-55] or levels of performance at the end of learning,[57] suggesting a close link between changes in sleep physiology and memory consolidation. In support of the double-step hypothesis described previously, others studies demonstrated relationships between performance changes and the organization of NREM-REM sleep cycles.[58,59] Hence these investigations, mostly based on noninvasive electrophysiologic techniques, have consistently demonstrated that prior learning during the day influences the physiology of sleep.

Noninvasive neuroimaging studies, initially using positron emission tomography (PET) measurements and more recently fMRI studies, have taken advantage of their superior spatial resolution and whole brain coverage to complement this picture, in looking more precisely at the neural correlates of postlearning modifications during sleep. Most important, they have provided evidence that neural activity occurring during memory task practice in learning-related cerebral structures can be reexpressed or continued during both REM[63,64] and NREM[65] stages of sleep as well as during posttraining wakefulness.[22] More recently, advances in simultaneous EEG-fMRI recordings have enabled investigating functional activations in brain regions associated with sleep EEG features. These studies showed that activity in brain regions active during learning and then during subsequent sleep is time-locked to phasic events, such as sleep spindles.[66,67] These data are in close agreement with intracerebral recording studies in animals, which demonstrated neuronal reactivation during sleep,[68,69] although these seminal animal studies did not seek to establish a link to memory consolidation or behavioral relevance of this reactivation per se. In this context, a significant contribution of human neuroimaging data was to show that experience-dependent reactivations of local (hippocampal) activity during SWS correlated with overnight gains in memory performance after spatial navigation.[65] Conversely, levels of implicit procedural learning achieved before sleep correlated with the amplitude of reactivation in cortical areas during REM sleep,[64] when connectivity patterns between learning-related areas were additionally reinforced.[70] Functional MRI studies also revealed reactivation of hippocampal activity time-locked to sleep spindles following both declarative[66] and procedural[67] learning. Moreover, procedural learning-dependent reactivation recruited other task-relevant structures, including the putamen,[67] which correlated with overnight improvement. Taken together, human reactivation studies have suggested that there is neuronal replay of previous experience during sleep and that posttraining sleep activity in brain areas involved during the learning episode represent a neural signature of memory-related cognitive processes, possibly linked with phasic sleep events such as spindles. An alternate but not exclusive hypothesis is that learning at wake induces local synaptic changes which themselves induce local changes in slow wave activity (SWA), the main marker of

sleep homeostasis, and that these changes are ultimately beneficial to imprinting novel memories.[71,72]

Within-Sleep Stimulations

Finally, a third approach using more causal manipulations to demonstrate enhanced (or diminished) sleep-dependent memory consolidation has consisted of providing specific stimulations during sleep with the aim to investigate whether meaningful stimuli could be recognized or new associations formed or whether presleep learning can be modified by nonawakening stimulations.[73-94] Indeed, evidence for such phenomena would be indicative that active plastic processes are taking place during sleep.

Demonstrating an active and potentially causal role for sleep in memory consolidation processes, several studies have established that stimulations within the posttraining sleep period may enhance performance compared with a normal, unmodified posttraining night.[84-88] Indeed, presentation of nonawakening auditory stimulations during REM sleep after Morse code learning[84] or re-presentation during REM sleep of sounds heard in the background while learning a complex logic task[85] increased overnight memory performance. Importantly, the effect was only present when auditory stimulations were displayed in coincidence with the bursts of rapid eye movements that reflect phasic ponto-geniculo-occipital (PGO) activity in humans, further suggesting that the characteristics of sleep are important markers and perhaps are even tied to cellular mechanisms of memory consolidation processes but reflected at a macroscopic level. Likewise, presentation during SWS of odors that were used as contextual cues during the learning episode triggers hippocampal responses and improves overnight retention of declarative memories.[88] Reactivation of memory traces is not merely an epiphenomenon of sleep, but rather is highly specific to the previously learned task. Indeed, in subjects trained to produce two musical melodies by following sequences of movements, motor sequence accuracy was significantly more enhanced for the melody that was replayed during sleep,[89] and improvement correlated with the amount of posttraining SWS and sleep spindles. Likewise, transcranial direct current stimulation that modulates excitability in cortical areas improves declarative memory when applied during SWS,[87] especially when application of oscillating potentials at about 0.75 Hz induced slow oscillation-like potential fields that mimic the slow oscillations of deep NREM sleep.[86] Finally, artificially maintaining high levels of cortisol feedback and cholinergic tone during SWS impairs hippocampus-dependent declarative memory formation,[90-92] suggesting that the natural shift in central nervous system cholinergic tone from high levels during acquisition-related wakefulness periods to minimal levels during SWS optimizes declarative memory consolidation.[93] Conversely, preventing natural increases in cortisol during REM sleep periods appears to enhance amygdala-dependent emotional memory.[92] These studies have demonstrated the beneficial (or detrimental) effects of various stimulations and manipulations within the posttraining sleep periods on overnight gains in performance and therefore have provided stimulating evidence that sleep does not merely play a passive role in memory processing by protecting novel memories from interference. Rather, they support the hypothesis that sleep acts in a complex manner in providing optimal conditions for the consolidation of novel memories in the nervous system.

SLEEP AND DECLARATIVE MEMORY

As described previously, long-term declarative memory comprises (1) semantic and (2) episodic memory components. Experimental data indicate that the role of sleep in consolidating these two memory components may be dissociated to a certain extent and that (3) emotional variables play a modulatory role in episodic memory consolidation. These aspects are covered in the following section.

Semantic Memory

Few studies have looked at the role of sleep for consolidation of semantic information per se, although event-related potential studies have demonstrated that semantic processing of externally presented stimuli is possible during REM and stage 2 sleep, but not during SWS.[76,81,82] Also, it has been shown that semantic priming (i.e., the facilitating processing effect resulting from prior presentation of semantically related material) qualitatively differs on awakening from stage 2 and REM sleep.[95] Sleep also enhances the creation of semantically related false memories (i.e., "theme words" associated with lists of semantically related words[96]; but see Fenn and colleagues[97] for an alternative view). Furthermore, both accurate and illusory recollections have been associated with increased hippocampal activity after sleep, although behavioral effects were similar.[98] Despite evidence for residual semantic processing, attempts to create novel semantic associations using direct auditory stimulation during sleep have been unsuccessful.[75] One possible explanation for this is that transfer of novel information from hippocampus-dependent episodic memory stores to neocortical semantic, decontextualized memory representations is a gradual, slow process that may take years to complete.[7] Therefore protocols in which initial encoding, posttraining sleep periods, and retrieval are temporally close are probably not best suited to segregate the semantic component of memory from other constituents. One promising approach used to address this issue[99] is to investigate the integration of novel words that were part of either densely or sparsely populated networks of semantic memory. Results showed that sleep spindles and SWA (0.5 to 4 Hz) increased more after learning sparsely than densely semantically integrated words, suggesting the involvement of these NREM sleep parameters in the integration of new information into existing semantic networks.

In this respect, a few neuroimaging studies have investigated the cerebral correlates of declarative memory retrieval after extended periods of up to 6 months using paired-associates list of words[37] or pictures of landscapes.[100] Although these experiments were not specifically designed to probe whether the memorized material was "semanticized" at the time of retesting, neuroimaging results clearly indicated a transfer from activity in hippocampal locations, observed early after learning, toward activity in medial prefrontal cortical sites recorded 6 months later during memory retrieval.[37,100] Furthermore, total sleep deprivation on the postlearning night hindered this gradual process of consolidation. Indeed, 6 months after learning verbal material, memory retrieval more strongly activated the medial prefrontal cortical when initial encoding was followed by a night of sleep than by sleep deprivation, suggesting that sleep leads to long-lasting changes in the representation of memories at the neuroanatomic level.[37] These results may be consistent with the hypothesis that sleep

exerts an effect on the gradual semantic integration of the learned material.

Episodic Memory

The effect of sleep on episodic memory has been extensively studied using a series of declarative memory paradigms encompassing learning of verbal material such as lists of words or paired-associates words[14,15,37,48,49,55,56,86,87,101-107,108-109] and sentences or prose passages,[110] but also explicit encoding of landscapes,[100] objects locations[88] and faces,[111] or visuospatial memory[15,54] and navigation within virtual[36,38,65,112] or natural[113] environments.

Among these, most studies using partial behavioral[14,15,37,103] or pharmacologic[91] sleep deprivation have consistently found that SWS, or at least the first half of the night of sleep, which is rich in SWS, is beneficial for the consolidation of novel declarative memories, particularly when the to-be-remembered material is of future importance.[114] Moreover, the benefit of sleep to episodic recall is greater for young than for older subjects and correlated with sleep duration,[115] and long-term forgetting is correlated with sleep disruptions in this population.[116] It suggests that age-related changes in sleep contribute to deterioration of episodic memory with age. Additionally, consolidation of declarative learning was linked to increased spindle activity during posttraining stage 2 sleep,[48,49,53-55] as well as to the alteration of SWS[117] and spindles[118] in schizophrenia. Spindles are strong candidates to subserve memory consolidation processes during NREM sleep because they are thought to support neural plasticity.[119] As well, declarative learning abilities have been linked with increased spindle activity during stage 2 sleep[50,120] and periodic arousal fluctuations during NREM sleep[121] in healthy subjects. Conversely, declarative memory deficits are associated with decreased sleep spindle activity in patients with Alzheimer disease[122] and with NREM sleep duration and number of cycles in patients with chronic nonrestorative sleep.[123] On a different note, others reported that overnight performance gains on declarative verbal memory primarily depend on preserved organization of sleep cycles (i.e., sleep continuity), rather than on the integrity of a specific sleep stage per se.[59] Also, a more recent study found that REM sleep deprivation specifically impairs recall of spatial and temporal features of memories, as well as the subject's confidence in his or her own remembering,[107] these parameters being considered as genuine components of episodic memory, as opposed to general recall, which may partially rely on semantic, decontextualized memories.[16] Accordingly, it has been reported that consolidation during sleep enhances explicit recollection in recognition memory[124] and strengthens the original temporal sequence structure for lists of triplet words.[125] Taken together, these studies provide compelling evidence that sleep is important for the formation of novel episodic experiences and the preservation, integration, and recollection of episodic memory. When sleep is adversely affected by age, by psychiatric and neurodegenerative conditions, or more simply by sleep disruption or deprivation, episodic memory is impaired.

Emotion in Episodic Memory

The role of emotional variables in sleep-dependent processes has been a focus of recent interest.[92,110,126-135] Emotion can be seen as an important contextual cue in retention of episodic memories. Notwithstanding, emotional material was better recalled after REM than NREM sleep[110] and was altered after sleep deprivation,[126] although more for the emotional content than the context of the information.[129] Others have found that emotional memories were preserved, or at least less disrupted than neutral memories, after total sleep deprivation.[92,131] These latter results suggest that consolidation of emotional memories also occurs efficiently during wake periods, an effect that may be explained by the important ecologic value of rapidly acquiring emotional stimulus-response associations. Moreover, a lack of behavioral effect does not guarantee that sleep was without any consequence on memory consolidation processes because the underlying patterns of brain activity at retrieval were effectively altered by sleep deprivation on the posttraining night.[36,38,131]

From another perspective, it has been proposed that sleep may play an instrumental role in dissociating memories from their emotional context,[132] contributing to the regulation and integration of emotional experiences. Accordingly, mood-dependent memory effects (i.e., better recall for neutral material in the same than in a different mood during learning) were attenuated when tested after 3 days of normal sleep, but not when sleep deprivation took place on the postlearning night.[133] However, mood-dependent memory effects were equally preserved after 4 hours of sleep dominated either by NREM or REM sleep,[134] or after a night of sleep,[135] suggesting that emotional decontextualization of neutral memories takes place over several nights of sleep, the process being initiated on the first posttraining night. Further studies are needed to ascertain whether this effect is specifically emotional in nature or merely related to contextual information in general.[136]

SLEEP AND NONDECLARATIVE MEMORIES

As previously mentioned, memory abilities aggregated under the nondeclarative category comprise various heterogeneous subtypes. These may be relatively independent from both cognitive and neuroanatomic standpoints but are collectively considered procedures for "how" to perform various tasks that are often divorced from explicit knowledge of the experiences where these skills were acquired. Skills and habits that refer to the gradual acquisition of novel perceptual, motor, and cognitive abilities through repeated practice (e.g., discriminating figures, playing piano, riding a bicycle, or detecting environmental regularities) have been the most widely investigated in relation to sleep. In this respect, numerous studies have found that posttraining sleep boosts acquisition levels on nonverbal motor,[32,42,51,137-144] perceptual,[61,145-154] and perceptual-motor[28,35,57,63,64,70,72,155-163] procedural learning tasks. Sleep was also shown to reinforce proactive interference effects in motor learning in children,[158] a population in whom procedural memory effects are typically not observed using direct measures.[159] Additionally, a few studies have found that pharmacologic enhancement (e.g., using nonbenzodiazepine hypnotics) of sleep spindles restores sleep-dependent motor memory consolidation in schizophrenia.[160] Also, sleep particularly enhances procedural memory performance in brain-damaged individuals,[162] but not in patients suffering from degenerative Parkinson disease.[163] Age-related changes in sleep spindles may also underlie age-related reduction in striatal activation and the related deficits in motor memory consolidation.[33] In the following section we further describe the

role of sleep on (1) perceptual, (2) motor, and (3) perceptual-motor learning and on (4) priming.

Sleep and Perceptual Learning

One of the most consistent findings in the literature is the prominent role of sleep in the development of visual discrimination abilities. Most studies have used the texture discrimination task,[164] in which learning is retinotopic, that is, specific to the trained visual quadrant.[145,149-154] It was initially found that selective REM sleep deprivation, but not SWS deprivation, abolishes overnight performance improvement during visual perceptual learning, whereas no or only feeble improvements occur over episodes of wakefulness.[164] However, another study using the same task found that improvement in visual discrimination skills was mostly disrupted by early sleep deprivation (i.e., rich in SWS) and even more so by total sleep deprivation.[145] This apparent contradiction was partially resolved with the finding that overnight improvement was a direct function of both the amount of SWS in the first fourth of the night and the amount of REM sleep in the last fourth of the night,[21] suggesting that SWS and the predominance of slow—frequency EEGs prompt memory formation, which is possibly, but not necessarily, consolidated during REM sleep. There is further evidence of the complementary role of sleep in the off-line (i.e., occurring outside of actual practice) processes of consolidation for visual perceptual learning. Indeed, others have found that repeated practice on the task within the same day does not lead to any improvement, and can even result in performance deterioration for the trained visual quadrant, unless there is an intervening sleep episode.[152] But most important, they demonstrated that the duration of the sleep episode and its constituent phases are crucial in this process because 30-minute daytime naps merely discontinued performance deterioration over repeated sessions,[152] 60-minutes naps reverted performance to its original level,[152] and 90-minutes naps yielded improvement in discrimination performance.[151] The main differences were more time spent in NREM sleep in the 60-minute versus the 30-minute nap and the occurrence of REM sleep in the 90-minute nap. Other studies confirm the importance of posttraining sleep in the consolidation of coarse visual discrimination[148] as well as the effect of visual adaptation paradigms on subsequent sleep parameters,[61] thus demonstrating the importance of both REM and NREM sleep states for consolidation of procedural abilities in the visual system.

Interestingly, visual perceptual skill performance transfer to the untrained eye also tends to generalize to the untrained visual quadrant following sleep, suggesting that sleep contributes to the generalization of perceptual skill learning beyond the primary visual cortex.[165] However, sleep-dependent improvements cannot yet be fully generalized across modalities because contradictory results have been reported in the auditory domain.[146,147,166-169] Regarding more sophisticated auditory discrimination abilities, however, it has been shown that integration of newly learned spoken word forms, which must be discriminated from similar-sounding entries during auditory word recognition, requires an incubation-like period containing sleep.[170]

Sleep and Motor Learning

The time-dependent evolution of motor learning has been mostly investigated using a simple sequential thumb-to-fingers opposition task.[171] Skilled performance on this task is acquired across an initial, within-session fast learning phase, followed by a slow phase of consolidation and optimization that can extend for several weeks of repeated practice.[171] Using the same task or a keyboard-presses variant, others subsequently found that posttraining sleep significantly enhances performance in the absence of further practice compared with the same amount of time elapsed awake.[51,138,140,141] However, contrary to the observations made using perceptual visual discrimination tasks described in the prior section, it cannot be claimed here that posttraining time spent awake prevents the formation of long-term motor memories because performance merely stabilizes at the level achieved at the end of learning and does not deteriorate, but rather modestly improves over repeated practice sessions. Still, a transitory boost in performance is observed 5 to 30 minutes after the end of learning,[172] which disappears if tested without an intermediate sleep period more than 4 hours later.[51,51,172] Interestingly, performance improvement over the 5- to 30-minute boost predicts performance levels after a night of sleep.[172] This precocious posttraining period appears important for the initial stabilization of motor memories[22] because it has been shown that learning another sequence during that time can interfere with the initial sequence,[143,173] unless a nap is allowed.[143] When a night of sleep occurs after initial training, off-line gains in performance and increased activation in the putamen are observed using fMRI 12 hours later compared with an equivalent period of wake.[32,137] Sleep spindle density, particularly for fast frequency (~13 to 15 Hz) spindles at parietal regions, is correlated with both sleep-dependent behavioral changes[174] and neural changes that occur.[175] With age, the beneficial impact of sleep on motor sequence consolidation is reduced, along with an age-related reduction in the activation of the putamen, in turn correlated with spindle density.[33] Noteworthy, a role of sleep for motor memory consolidation extends beyond a genuine motor component because training-related changes in sleep architecture are observed after practice of a sequence of finger movements but not after random key presses,[139] as well as after acquiring new and complex motor patterns such as trampolining[42,144] but not after the familiar and well-known motor activities of soccer or dancing.[144] These latter results are in line with the demonstration that sleep provides maximal benefit for motor skill procedures that proved to be most difficult during learning.[142] Motor learning-related changes in posttraining sleep parameters were mostly observed during stage 2 sleep,[51,139,140] although others have reported links with REM sleep[144,176] or both SWS and REM, resulting in a lengthening of the ultradian sleep cycle.[42] Taken together, these results suggest that the sleep may strengthen the initially labile memory trace formed during learning, possibly through a reactivation process. This hypothesis was tested using combined EEG-fMRI during sleep following acquisition of a motor sequence task.[33] Results revealed that sleep spindle activity in the same brain regions that were active during practice correlated with overnight improvement in performance. Moreover, slow and fast spindles were associated with activation in hippocampal and striatal regions, respectively, suggesting that different types of spindles may serve to consolidate different aspects of the memory trace. Indeed, hippocampus and striatum have been found to interact whereby a competitive interplay between

these structures was correlated with improved performance at retest in participants who slept after learning compared with sleep-deprived participants.[177] Further studies are needed to delineate precisely the role and benefit of sleep on various types of motor learning and the neurophysiologic mechanisms involved.

Sleep and Perceptual-Motor Learning

The motor learning tasks described previously have definite features. They are self-initiated, and acquisition is initially carried out in an explicit, almost declarative manner because the motor sequence of movements to be generated is already known and can even be verbalized. In this respect, motor procedural learning reflects the optimization of predefined motor forms possibly created with the contribution of episodic memory processes. By contrast, perceptual-motor procedural learning entails a motor performance triggered by external stimulations, but the organization of the material to be learned is not necessarily obvious to the subject, although it affects their performance. These features should allow us to distinguish the role of sleep for consolidation of covertly versus overtly formed memories. We review this aspect at the end of this section after reviewing perceptual-motor studies.

It was initially found that performance improvement on the pursuit rotor task was blocked by total sleep deprivation and by sleep deprivation of the second part of the night, but not by selective REM sleep deprivation.[28] Task improvement was also associated with increased sleep spindle activity,[57,178] together suggesting that consolidation of motor adaptive memories is mostly dependent on stage 2 sleep. Functional MRI additionally showed that posttraining total sleep deprivation hampered both performance improvement and the reorganization of brain activity on a visuomotor pursuit task with hidden regularities in the target's trajectory.[35] However, mirror-tracing skills were reported to improve more during the late part of the night[14] and to be associated with REM sleep increases in well-performing individuals,[56] suggesting that this latter task is rather REM sleep dependent. Still, performance improvement on mirror tracing was also found to occur after naps dominated by stage 2 sleep[155] and to correlate with stage 2 sleep spindle activity. This apparent discrepancy between sleep stages and task associations within the perceptual-motor learning domain might be explained by differences in initial skill levels of participants. Indeed, an association was reported between performance improvement on the pursuit of rotor task and stage 2 spindle activity in highly skilled subjects, whereas a similar relationship was established with REM density in lower skilled subjects,[57] in line with the proposal that motor skills tasks involving REM and stage 2 sleep might be dependent on two separate but overlapping neural systems.[29]

This interpretation may be consistent with neuroimaging data that have established a relationship between posttraining REM sleep activity and the consolidation of higher order perceptual-motor cognitive skills. Indeed, subcortical and neocortical areas already activated during practice on a probabilistic sequence learning task[179] (i.e., a paradigm of implicit sequence learning) were reactivated during posttraining REM sleep in subjects previously trained to the task.[63,64,70] It was further demonstrated that these reactivations were not merely activity dependent but rather occurred specifically because a rules-based sequence was implicitly learned during prior practice,[64] supporting the hypothesis that REM sleep might be deeply involved in the reprocessing and optimization of the higher order information contained in the material to be learned (as in the mirror-tracing and Tower of Hanoi tasks), as opposed to its motor component alone.

Notwithstanding, further studies using sequence-learning tasks have raised several issues, and some of these remain to be resolved. Indeed, it has been claimed that sleep is beneficial for sequence learning only when acquisition of the sequential regularities practiced during the task was explicit, with time alone being sufficient for the consolidation of implicitly acquired sequences.[24,180] These results appear to contradict the above findings of REM sleep dependency for higher order probabilistic sequence learning, in which learning was undoubtedly implicit.[64,179,181] However, one overlooked difference between these studies and those claiming a sleep dependency exclusively for explicit sequential material is that the latter have used deterministic, repeated sequences, whereas the probabilistic sequences used in the former studies are much more ambiguous. Accordingly, neural responses to nonpredictable elements in the probabilistic serial reaction time were attenuated over sleep, suggesting better integration of the learned structure.[39] It is therefore possible that sleep (and especially REM sleep) mostly supports the consolidation of implicitly acquired complex relationships. This interpretation may be in line with the proposal that different aspects of a procedural memory are processed separately during consolidation; for example, that the movement sequence (e.g., a repeated, deterministic sequence) improves over daytime wakefulness periods independently of sleep whereas its goal (e.g., the complex, abstract rules for items succession in a probabilistic sequence) improves after a night of sleep.[182] How and whether off-line processes of memory consolidation do actually benefit from posttraining sleep may also be a function of the circadian moment of the day when the material is acquired,[157] as well as the nature of the complex interactions between declarative and procedural memory systems.[23] The complexity of these interactions is further illustrated by the demonstration that learning-related cerebral responses in cerebral structures linked to procedural (i.e., striatum) and declarative (i.e., hippocampus) memory systems are both correlated to an overnight gain in performance in an implicit oculomotor sequence learning task[183] and the finger-tapping task.[177]

Sleep and Priming

Perceptual priming refers to the facilitation or bias in the processing of a stimulus as a function of a recent encounter with that stimulus.[184] The few studies that have investigated a role for sleep in consolidating the memory representations subtending priming[15,185,186] or priminglike[185,187] effects have yielded discrepant results.[186,187] Although studies have found that intervening deprivation of sleep, especially REM sleep, alters priming effects in word stem completion[15] as well as face processing[185,187] and enhances reactivity for emotional pictures,[188] another study failed to disclose sleep-dependent effects using better controlled tachistoscopic identification of drawings,[186] and total sleep deprivation was found to affect priminglike performance in the right hemisphere only, suggesting interhemispheric differences in sleep-dependent processes of memory consolidation.[187]

SLEEP-DEPENDENT MECHANISMS OF BRAIN PLASTICITY AND MEMORY CONSOLIDATION

In this section, we provide an overview of specific mechanisms viewed as particularly important to support sleep stage–related processes of brain plasticity and memory consolidation: (1) PGO waves, (2) hippocampal rhythms, and (3) sleep spindles.

Ponto-Geniculo-Occipital Waves

PGO waves are prominent phasic bioelectrical potentials, closely related to rapid eye movements, that occur in isolation or in bursts during the transition from NREM to REM sleep or during REM sleep itself. PGO waves are a fundamental process of REM sleep in animals, playing a significant role in central nervous system maturation.[189] In humans, intracerebral recordings in epileptic patients[190] and noninvasive PET,[191] fMRI,[192] and magnetoencephalography (MEG)[193] scanning in healthy volunteers indicate that the rapid eye movements observed during REM sleep are generated by mechanisms similar or identical to PGO waves in animals. Most important, animal data indicate that PGO activity during REM sleep is associated with learning and memory consolidation,[189] suggesting that activation of this generator during REM sleep may represent one of the natural physiologic processes of memory, possibly through the synchronization of fast oscillations that would convey experience-dependent information in thalamocortical and intracortical circuits.[194]

Despite the evidence from animal studies, a direct demonstration of the association between PGO activity and memory consolidation during REM sleep in humans has yet to be done. Nonetheless, the hypothesis is supported by studies showing an increase in the density of rapid eye movements during REM sleep following procedural learning[29,195] and intensive learning periods,[47] and correlations between declarative memory performance[196] or retention levels after learning a Morse code[44] and rapid eye movements during posttraining REM sleep.[44] Also, presenting sounds in the background while learning a complex logic task at wake enhanced next-morning performance when the same sounds were presented again during REM sleep. Most interestingly, however, enhancement was found only when sounds were coincident with the bursts of posttraining rapid eye movements that reflect PGO activity,[85] further suggesting its association with memory consolidation processes. Also, it has been proposed that during human phasic REM sleep, propagation of PGO activity in the parahippocampal and hippocampal areas is linked with verbal learning performance and mnemonic retention values.[197]

Hippocampal Rhythms

The theta rhythm (i.e., regular sinusoidal oscillations in the frequency range of 4 to 7 Hz recorded in the hippocampal EEG) constitutes a prominent signature of REM sleep in mammals, including humans.[198] Theta represents the "online" state of the hippocampus, believed to be critical for temporal coding and decoding of active neuronal ensembles and the modification of synaptic weights.[198] Additionally, population synchrony of pyramidal cells is maximal during quiet wakefulness and SWS associated with sharp waves (i.e., sharp waves of SWS are the consequence of synchronous discharge of bursting CA3 pyramidal neurons) and fast ripples (140 to 200 Hz). Sharp waves and ripples during SWS constitute good candidates to induce neuronal plasticity.[199] Hence, the alternation between both REM sleep and active wake theta activity and SWS and quiet wakefulness sharp waves and ripples could contribute to brain plasticity. According to the two-stage model of memory formation,[199] neocortical information activates the entorhinal input, which causes synaptic changes to occur in the hippocampal CA3 system during learning associated with active waking and REM sleep theta rhythmic activity in the hippocampus. In the subsequent non-theta state (i.e., SWS but also possibly quiet wakefulness), previously activated neurons are reactivated during sharp waves bursts, and the memory representation transiently stored in the CA3 region can be transferred to neocortical targets for the long term.

Also, animal[52] and human studies have shown increases in theta rhythms during REM sleep following learning in declarative memory tasks,[56] as well as correlations between theta during REM sleep and memory facilitation for emotional tasks.[200] Human brain imaging studies have demonstrated after spatial navigation in a virtual town the experience-dependent reactivation of hippocampal activity during SWS, but not during REM sleep.[65] Additionally, intracerebral recordings in humans suggest that slow EEG frequencies in the hippocampus during NREM sleep contribute to the consolidation of spatial memories.[201] Similarly, an odor-cued activation in hippocampus-related memory areas was observed during SWS,[88] eventually leading to overnight performance improvement. These studies also found long-term transfer of hippocampal memories toward neocortical stores,[37,100] an effect disturbed by sleep deprivation on the posttraining night.[37] In parallel, neuroimaging data have suggested the off-line persistence of memory-related cerebral activity during active wakefulness and its dynamic evolution in the hippocampus.[22] Although this model is well supported by the previous data and may account for the off-line processing of declarative material, the fact that reactivations have been observed during both posttraining REM sleep[63,64] and wakefulness[22] after procedural, nonhippocampal learning suggests that other routes for consolidation exist, which should likewise be investigated.

Sleep Spindles and Slow Waves

Traditionally, the sleep spindle has been defined as the presence of rhythmic, about 12- to 14-Hz, activity lasting a minimum of about 0.5 second and displaying an increasing, then decreasing amplitude envelope. This definition has expanded to 12 to 16 Hz and includes both slow (~11 to 13.5 Hz) and fast (~13.5 to 16 Hz) spindles, which may reflect two separate spindle generators with different brain topographies,[202,203] and modern automated detection methods are capable of reliably identifying shorter duration spindles, even during SWS. Although spindles occur most frequently in stage 2, they also appear to a lesser extent in SWS but are obscured by delta activity. Spindles are considered to be caused by the intrinsic properties and the connectivity patterns of the thalamic neurons and are regulated by slow oscillations.[204-206] Spindle generation seems an ideal mechanism for neural plasticity.[119] Therefore spindles may play an important role in the processes of memory consolidation during sleep.

Accordingly, several studies have reported links between the consolidation of verbal declarative memory and increases

in spindle density during nocturnal and diurnal sleep that follows learning.[48-50,53] Verbal memory association with spindle density increased in the left frontocentral scalp location at night, whereas memory for faces did not elicit this effect.[53] Similarly, postlearning increases are observed during daytime napping in low sigma frequency spectral power (11.25 to 13.75 Hz), particularly in the left frontal scalp region. Additionally, these increases are positively correlated with learning performance for difficult word associations, but not easy word associations,[49] and the integration of new verbal learning with existing knowledge is correlated with sleep spindles.[207] Recent studies have attempted to causally manipulate spindles to investigate memory enhancement processes. One such study observed that increasing sleep spindle density improved verbal memory.[160] Functional neuroimaging investigation found hippocampal reactivation during sleep following declarative learning, time-locked to the onset of sleep spindles, modulated by spindle amplitude and correlated with memory performance.[66] Taken together, these studies suggest that sleep spindles are important for the overnight consolidation of declarative memories and that the occurrence of sleep spindles in brain structures recruited during initial learning contributes to reactivation and consolidation processes.

Similarly for procedural memory, posttraining stage 2 sleep deprivation impaired memory for a perceptual-motor task,[28] and the amount of stage 2 sleep correlated with learning progress on the finger-tapping task.[138,140] Also, intensive training on perceptual-motor learning tasks results in marked increases in number and density of spindles during subsequent stage 2 sleep,[56] as well as an increase in average spindle duration.[56] Posttraining increases in slow sigma power (12 to 14 Hz) have been observed in frontal and occipital regions, with no changes in high-frequency sigma.[56] Napping studies using the same task provided similar results: subjects that take naps regularly showed positive correlations between postnap performance and stage 2 spindle density.[208] In this case, low-frequency spindle activity (12 to 14 Hz) was correlated with performance at frontal sites, whereas high-frequency spindle activity (14 to 16 Hz) was correlated with performance at central and parietal sites. Moreover, subjects who did not nap on a regular basis did not benefit from the nap.[208] In another study using a longer (60 to 90 minute) nap after motor performance for the finger-tapping task, it was found that subjects with the most significant increases in motor performance also had the largest increases in stage 2 sleep, with a significant correlation between spindle density and postnap performance that was confined to the learning hemisphere.[51] Finally, a marked increase in stage 2 spindle densities was observed following acquisition of the finger-tapping task, but not after a control motor task, indicating that the changes were not a result of general motor activity.[139] Neuroimaging studies also revealed that similar to declarative memory, activation time-locked to sleep spindles in brain regions (e.g., hippocampus, putamen) recruited during practice of a motor procedural task was correlated with overnight gains in performance.[67] The fact that spindles have been related to consolidation both for declarative and nondeclarative memories indicates their prominent role in sleep-dependent memory processes, although it remains to be investigated whether spindles subserve the same process across declarative and procedural memory.

Finally, spindle oscillations may not act in isolation because they are grouped and regulated by slow waves[206] that are thought important for memory consolidation and synaptic plasticity, as discussed previously. Indeed, experience-dependent regional increases in delta activity have been observed during NREM sleep,[72] suggesting the existence of local homeostatic mechanisms for memory consolidation.[209] Furthermore, coherence was found to increase after learning in the depolarizing phase of the slow oscillations below the 1-Hz frequency.[206] Conversely, transcranial direct current stimulation, which may contribute to modulation of cortical excitability, was found to improve the overnight retention of declarative memories when applied during NREM sleep at a slow rhythm whose frequency (<1 Hz) approximates slow oscillations.[86] Further, reducing SWA during NREM sleep with transcranial direct current stimulation reduces verbal declarative memory retention,[210] suggesting a causal relationship between slow waves and declarative memory. Taken together, available data suggest that slow oscillations during NREM sleep may play a facilitating role in neuronal plasticity and the ongoing transformations and consolidation of memory traces, either in concert with spindles or perhaps contributing in some unique way to memory consolidation processes. Further study is required to better dissociate the unique roles that these two interrelated aspects of non-REM sleep may have in memory consolidation.

CONCLUSIONS

Although elusive at times, studies supporting the proposal that sleep is an integral component in the off-line processes that subtend memory consolidation have now substantially flourished. Still, when compared with other domains of cognition, the field obviously remains underdeveloped. Indeed, there is an urgent need of replication and validation of studies to confirm or disprove a series of hypotheses regarding the type of memories that can benefit from sleep and in which circumstances it can occur. Furthermore, the mechanisms that support these processes remain to be fully elucidated or fully understood. Most important, it remains to be understood how sleep disorders and the numerous pathologies accompanied by sleep disturbances affect cognitive processes and especially learning and memory in humans.

CLINICAL PEARL

In the long term, patients with inadequate REM sleep may be expected to experience more difficulty learning novel cognitive procedures than same-age individuals with healthy sleep. Patients exhibiting little or impaired SWS may be impaired in declarative learning, for example, in memorizing large amounts of factual material. Those with specific stage 2 sleep disturbances (e.g., reduced spindles) may be expected to have trouble refining and performing reasonably simple motor skill tasks and exhibit declarative memory deficits. Finally, those patients with poor sleep quality or pathologies affecting all sleep stages would be expected to have deteriorated long-term memory performance pervasively on all types of memory. Because sleep is only a part of memory consolidation processes, however, these deficits may manifest in a subtle manner and be compensated to a certain extent by alternate consolidation strategies. In-depth clinical investigation of memory problems should always be performed by a trained neuropsychologist.

SUMMARY

Although the utmost importance of sleep for the quality of everyday life is empirically recognized, the functions of sleep have long remained shrouded in mystery. Beyond its putative physiologic functions, there is now growing evidence that sleep plays a prominent role in brain plasticity and memory consolidation processes. According to this proposal, memory traces formed during a learning episode are not immediately stored in their ultimate form. Rather, they initially remain in a labile, fragile state during which they can be easily disrupted or interrupted. Over time and especially during sleep, memory traces subsequently undergo a series of transformations during which they will be consolidated and fully integrated into long-term memory. In this chapter, we present experimental data that provide support for the hypothesis that sleep exerts a promoting effect on plastic processes of memory consolidation. Several sources of support for this hypothesis are described in this chapter, including studies that have assessed (1) the effects of posttraining sleep deprivation on memory consolidation and on the reorganization of the neural substrates of long-term memories; (2) the effects of learning on posttraining sleep and reexpression of behavior-specific neural patterns during posttraining sleep; and (3) the effects of within-sleep stimulation on sleep patterns and overnight memories. Despite advances that have refined the understanding of the relationships between sleep and cognitive processes, the underlying mechanisms still remain to be fully elucidated. Further steps are now required to understand how sleep disorders and pathologies accompanied by sleep disturbances affect cognitive functions, especially learning and memory consolidation in humans, eventually leading to remedial interventions.

Sensory and Motor Processing During Sleep and Wakefulness

Chapter 23

John H. Peever; Barry J. Sessle

Chapter Highlights

- Sensory and motor processing are reduced during sleep, and their integration is differentially affected during different sleep states. For example, respiratory reflexes are reduced during non–rapid eye movement (NREM) sleep but are virtually abolished during rapid eye movement (REM) sleep. Such observations suggest that discrete NREM and REM sleep mechanisms modulate and control sensory and motor processes in a sleep state–dependent manner.
- Changes in sensory processing during sleep affect the somatosensory pathways that transduce and relay nociceptive signals to and within the central nervous system. Sensory mechanisms are affected by sleep, and sleep is in turn affected by nociceptive processes. The interaction between pain and sleep is common in patients suffering from chronic pain such as cancer.
- Abnormal sensory and motor functions during sleep underlie common sleep disorders. For example, reduced chemical control of breathing during sleep plays a role in congenital central hypoventilation syndrome, and pathologic motor control during REM sleep underlies REM sleep behavior disorder. Abnormal motor control and sensory processes also are associated with periodic limb movement disorder, narcolepsy, and sleep apnea.

Sleep has a profound impact on the mechanisms by which the central nervous system (CNS) transduces and expresses sensory and motor commands. Transmission of sensory information to the CNS is markedly attenuated during sleep, which enables sleep continuity; in certain circumstances, however, some sensory inputs such as pain may influence sleep patterns. Sleep mechanisms not only modulate the pathways that relay sensory commands to the central nervous system but also affect the manner in which regulatory brain centers such as the thalamocortical circuits relay afferent inflow to appropriate sensory and motor control centers, including somatic motoneurons. The neurocircuits that generate sleep-wake states also affect the fundamental integration and expression of sensorimotor processes.

This chapter comprises three main topics: (1) pathways and mechanisms of sensory processes, especially those related to pain; (2) the integration of sensory and motor processes; and (3) respiratory reflexes. As appropriate, each of these various functions is considered during both sleep and wakefulness, to highlight the contributions of changes in sensory and motor processes and their integration during sleep to both normal and abnormal physiology. Also discussed are the mechanisms by which sleep influences the central processing of nociceptive information and how pain itself may affect sleep. Although all sensory and motor systems are affected by sleep, a primary focus in this context is on how sleep affects the sensorimotor processes of spinal reflexes and the respiratory responses to chemical (e.g., CO_2) and mechanical stimuli (e.g., airway pressure). An appreciation of these physiologic systems is important for the clinician to realize that sleep-related changes in sensory-motor processing and their integration have a direct impact on human health and disease and can underlie common and serious sleep-related disorders.

MODULATION OF SENSORY PROCESSES DURING SLEEP AND WAKEFULNESS

Sensory Pathways and Mechanisms

The body's peripheral tissues—skin, mucosa, muscles, and joints—are supplied by small-, medium-, and large-diameter primary afferent nerve fibers. The medium- and large-diameter afferents are myelinated and comprise A beta and A delta afferents, most of which terminate in the tissues as sense organs (receptors) detecting tactile or proprioceptive stimuli applied to the tissues. However, some of the A delta afferents, along with unmyelinated C-fiber afferents, terminate in the tissues as free nerve endings, many of which act as nociceptors—that is, they are the sense organs that respond to noxious stimulation of the peripheral tissues; other A delta or C-fiber afferent terminals function as thermoreceptors responding to warming or cooling stimuli. The activation of nociceptors may result in the elicitation of action potentials in the A delta or C-fiber afferents, and these action potentials are conducted along the afferents into the CNS and thereby provide the brain with sensory-discriminative information about the location, quality, intensity, and duration of the noxious stimulus.[1-4]

In some cases, a prolonged increase in excitability of the nociceptors may occur after tissue injury or inflammation, to the stage at which they become more responsive to noxious

stimulation or even start responding to stimuli that normally are innocuous. Thus this process of "peripheral sensitization" may contribute to the hyperalgesia (increased sensitivity to a stimulus that is normally painful) and allodynia (pain resulting from a stimulus that typically does not provoke pain) that occur in certain pain conditions. Numerous chemical mediators are involved in peripheral sensitization of nociceptive endings, as well as in their activation by noxious stimuli, including several that also have actions in the CNS, such as glutamate, serotonin (5-hydroxytryptamine [5-HT]), and norepinephrine.[5-7]

The primary afferents in spinal nerves supplying skin, viscera, and musculoskeletal tissues of the limbs, trunk, and neck project to the spinal cord and synapse on second-order neurons that are predominantly located in the spinal dorsal horn and the dorsal column nuclei.[3,4] The afferents innervating orofacial tissues project mainly to the trigeminal brainstem sensory nuclear complex (V-BSNC). This structure is subdivided into the main or principal sensory nucleus and the spinal tract nucleus, which from rostral to caudal comprises three subnuclei: oralis, interpolaris, and caudalis.[2,8,9] The subnucleus caudalis has many anatomic and physiologic features that are analogous to those of the spinal dorsal horn.[8] Another brainstem region receiving primary afferent inputs is the solitary tract nucleus (NTS); it contains second-order neurons on which respiratory and alimentary tract afferents, taste afferents, and cardiovascular and chemoreceptor and baroreceptor afferents synapse, and it plays an important role in autonomic (e.g., respiratory, cardiovascular) functions, taste, and reflexes evoked from the respiratory and alimentary tracts (e.g., cough, swallow).

The spinal primary afferents conducting actions potentials evoked by tactile or proprioceptive stimuli terminate principally in the spinal dorsal horn and dorsal column nuclei, where they may activate second-order nonnociceptive neurons (e.g., low-threshold mechanoreceptive [LTM] neurons). Analogous trigeminal (V) afferents terminate at all levels of the V-BSNC. The primary afferents carrying thermoreceptive or nociceptive information predominantly terminate in the spinal dorsal horn (Figure 23-1) and subnucleus caudalis (Figure 23-2). The main excitatory neurotransmitters or neuromodulators released from the central terminals of the nociceptive afferents are glutamate and substance P.[4,8] In addition to LTM and thermoreceptive neurons, there are nociceptive neurons that are of two main types: nociceptive-specific (NS) neurons, which are excited only by noxious stimuli (e.g., pinch, heat) applied to a localized receptive field in peripheral tissues (e.g., skin), and wide-dynamic-range (WDR) neurons, which are excited by nonnoxious (e.g., tactile) stimuli as well as by noxious stimuli.

Nociceptive afferent inputs relayed toward many neurons in the spinal dorsal horn and subnucleus caudalis appear to derive exclusively from superficial (e.g., cutaneous) tissues and endow these neurons with coding properties, suggesting that they are critical neural elements for the detection and discrimination of superficial pain. However, nociceptive information from deep tissues (e.g., muscle, joint, viscera) is processed predominantly by subsets of these cutaneous nociceptive spinal dorsal horn or caudalis neurons that receive extensive convergent afferent inputs from these tissues. These convergence patterns appear to underlie the CNS mechanisms contributing to deep pain and also may explain the poor

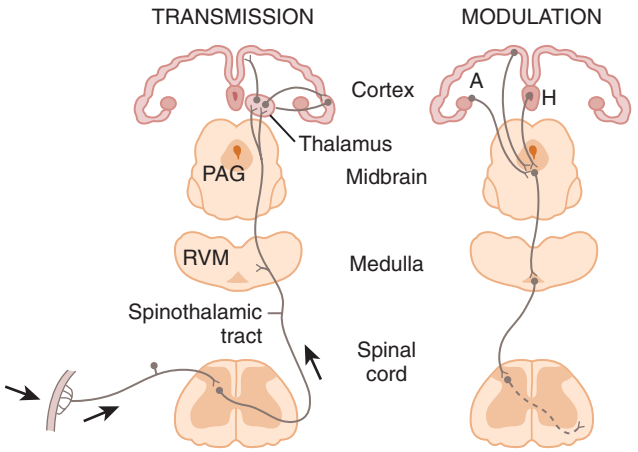

Figure 23-1 Major nociceptive pathways from spinal tissues. This schematic shows the ascending and descending pathways that transmit and modulate nociceptive signals from spinally innervated tissues. Nociceptive afferents synapse onto spinothalamic neurons in the spinal dorsal horn, which in turn relay afferent signals to the thalamus and then to the cortex (e.g., anterior and posterior cingulate cortex). Ascending spinothalamic neuronal inputs also are modulated by descending pathways located in higher brain centers such as the cortex, amygdala (A), and hypothalamus (H). Such descending pathways converge in the periaqueductal gray (PAG) and then in the rostral ventral medulla (RVM) before synapsing onto spinothalamic neurons. (From Price DD. *Psychological mechanisms of pain and analgesia.* Seattle: IASP Press; 1999, p. 250–71.)

localization, spread, and referral of pain that are typical of pain conditions involving deep tissues. Some of the convergent afferent inputs also may be "unmasked" in pathophysiologic situations and become more effective in exciting the nociceptive neurons.

Neuroplastic changes can be manifested in caudalis and spinal dorsal horn (and thalamocortical) nociceptive neurons as a result of nociceptive afferent inputs evoked by injury or inflammation.[4,8] This neuroplasticity results from the release from the nociceptive afferent terminals of neurochemicals, such as glutamate, that act by way of *N*-methyl-D-aspartate receptor mechanisms to induce a cascade of intracellular events in the nociceptive neurons. These events can result in an increase in neuronal excitability, reflecting what has been termed a "central sensitization" of the nociceptive neurons. Central sensitization has been documented in both acute and chronic pain models and involves glutamatergic mechanisms as well as nonneuronal (i.e., glial cells) processes. The neuroplastic alterations in the nociceptive neuronal properties, and in the reflex neuromuscular changes and other behavioral activities that may be induced by injury or inflammation, represent mechanisms that along with peripheral sensitization (discussed previously) can explain the allodynia and hyperalgesia as well as pain spread and referral that characterize several pain conditions.

Some neurons in the spinal dorsal horn, dorsal column nuclei, NTS, and the V-BSNC give rise to axons that ramify within that structure and serve to modulate the activity of other neurons. Nevertheless, many neurons in these various structures project to other spinal cord or brainstem regions including the reticular formation, raphe nuclei, and spinal ventral horn or cranial nerve motor nuclei. Such connections provide the central circuitry underlying autonomic and muscle

Trigeminal primary afferents project by way of the trigeminal ganglion to second-order neurons in the trigeminal brainstem sensory nuclear complex. These neurons may project to neurons in higher levels of the brain (e.g., thalamus) or in brainstem regions such as cranial motor pools or the reticular formation (RF). *Not shown* are the projections of some cervical nerves and cranial nerve VII, X, and XII afferents to the trigeminal complex and the projection of many VII, IX, and X afferents to the solitary tract nucleus. reflex responses to peripheral stimuli or provide sensory inputs to neurons in some of these structures that contribute to descending modulatory systems (discussed hereafter). In view of the role that the raphe and reticular formation areas play in wakefulness and sleep, projections to these areas also may provide neural substrates by which noxious stimulation may influence sleep and consciousness.[10]

Many neurons in the spinal dorsal horn, dorsal column nuclei, NTS, and V-BSNC also (or instead) project to the contralateral thalamus (see Figures 23-1 and 23-2), either directly or along multisynaptic paths. The main regions of the thalamus that receive and relay this sensory information are the ventrobasal complex (or ventroposterior nucleus in the primate) as well as the medial thalamus and the posterior nuclear group.[3,11,12] These thalamic regions contain LTM and thermoreceptive neurons that project to the overlying somatosensory cerebral cortex, where their relayed signals are processed by analogous neurons to provide for the detection and localization of tactile and nonnoxious thermal stimuli. In addition, NS and WDR neurons are present in these thalamic regions, and most have spatiotemporal coding properties and connections to NS and WDR neurons in the overlying somatosensory cortex that indicate a role for them in defining the spatiotemporal features of peripheral stimuli and hence in the sensory-discriminative dimension of pain. By contrast, the spatiotemporal coding properties of most nociceptive neurons in the medial thalamic nuclei and posterior nuclear group and their connections to areas such as the anterior cingulate cortex are more suggestive of a role in the motivational or affective dimensions of pain. These features generally are consistent with brain imaging findings in humans that noxious stimuli activate several cortical regions, including the somatosensory cortex and the anterior cingulate cortex.[13,14] It also is noteworthy that neurons at brain higher levels (e.g., somatosensory thalamus, sensorimotor cortex) also are subject to neuroplastic changes reflecting central sensitization.

Modulation of Sensory Processes Including Those Related to Pain

In addition to its role in transferring to the cortex neural signals used for sensory, affective, and motivational functions, the thalamus also is the site of modulatory influences involved in the state of consciousness. The thalamocortical transfer of sensory information is subject to modulation or "gating" as a result of facilitatory and inhibitory processes exerted by local neural circuits or inputs to the thalamus and cortex from other CNS regions such as the reticular formation.[15-17] These gating processes are especially apparent during changes in behavioral state and consciousness, such as during non–rapid eye movement (NREM) sleep. For example, there is marked attenuation during NREM sleep, which may function to maintain sleep continuity.

Nonetheless, modification of somatosensory transmission also can occur at spinal and brainstem levels and, in addition, may be operational in various degrees during different behavioral states and indeed may contribute to specific features of these states—for example, the hypotonia of rapid eye movement (REM) sleep. These modulatory mechanisms may involve neural circuits within the spinal dorsal horn, V-BSNC, and NTS and adjacent regions, as well as inputs from primary afferents and descending inputs from reticular formation, raphe nuclei, locus coeruleus (LC), and cerebral cortex, to name a few. Various neurochemicals are used by these circuits and inputs, including gamma-aminobutyric acid (GABA), norepinephrine, 5-HT, and opioids.

In the case of nociceptive transmission, the variety of inputs and interconnections in spinal dorsal horn and subnucleuscaudalis noted earlier provide the basis for considerable interaction between the various afferent inputs derived from peripheral tissues (e.g., so-called segmental or afferent inhibition) or from intrinsic brain regions (e.g., descending inhibition). Examples are the interneuronal system within the substantiagelatinosa of the spinal dorsal horn and subnucleuscaudalis, and the descending inputs to these structures from the periaqueductal gray/raphe nuclei, reticular formation, cerebral cortex, and several other brain centers (see Figure 23-1). Several neurochemicals, including GABA, 5-HT, norepinephrine, dopamine, hypocretin, cholecystokinin, prolactin, melatonin, and opioids (e.g., enkephalins), provide a neurochemical substrate by which many of the afferent and descending inputs can exert their modulatory

actions on nociceptive transmission. Of note, many of these neurochemicals and descending influences also are involved in sleep mechanisms.[15,16] Inhibitory influences exerted by many of these inputs on nociceptive neurons have been implicated as intrinsic mechanisms contributing to the analgesic effects of several procedures used to control pain, including deep brain stimulation, acupuncture, and opiate-related (e.g., morphine) and 5-HT agonist (e.g., amitriptyline) drugs. Some, instead, have a role in facilitating nociceptive transmission (e.g., in the central sensitization process noted earlier).[4,8]

Processing Related to Pain during Sleep and Wakefulness

As noted previously, sensory transmission through the spinal cord and brainstem, as well as thalamus and cerebral cortex, may be modulated during sleep and thereby may contribute, for example, to the decreased responsiveness to external stimuli during NREM sleep to favor sleep continuity. The modulatory influences on nociceptive neurons of behavioral factors, including state of alertness, attention, and distraction, are just some examples in which the higher brain centers involved in these states give rise to descending influences operating at these levels and thereby contribute to the influence of these behavioral factors on pain. Unfortunately, although much has been learned independently about pain and sleep, investigation of how sleep affects pain, and vice versa, has been limited (see Chapter 133).

Available evidence indicates that sensory processing, including that related to pain, is reduced in sleep states compared with wakefulness, but the underlying processes are still unclear. Nonetheless, with the advent of studies in chronic (awake and sleeping) animal preparations as well as more conventional anesthetized preparations, as well as some correlated studies in humans, it has been shown that somatosensory transmission through several ascending pathways originating in the spinal dorsal horn is tonically diminished during REM sleep. Apparently, however, the gating process is quite complex during REM sleep, because modulation of somatosensory transmission may be different between phasic and tonic REM sleep.[18] Other evidence of complex gating during NREM sleep includes findings that sensory transmission through some ascending tracts may be attenuated in some stages of NREM sleep and that this is reflected in reduced thalamic and cortical activity in these stages.[16-20] Recent studies also suggest that the modulation of spinal sensory transmission during REM sleep appears to involve presynaptic inhibition as well as postsynaptic inhibitory mechanisms, supporting earlier findings that presynaptic regulatory processes are important in REM sleep and contribute to the reduction in motor activity during this sleep phase (discussed further on). In addition, the presynaptic inhibitory processes in the spinal cord utilize GABA, and the postsynaptic inhibition utilizes glycine. Several other neurochemicals released from neurons in higher brain centers also have been implicated in the sleep-dependent modulation of spinal cord neurons or their thalamic targets; these include 5-HT, norepinephrine, acetylcholine, and hypocretin.[16,18-20]

A complex gating mechanism also has been documented in the rostral components of the V-BSNC that is state-dependent; for example, the activity of many rostral V-BSNC neurons and their responses to sensory inputs, including those evoked by noxious (tooth pulp) stimuli, may be presynaptically and postsynaptically inhibited during REM sleep through, respectively, GABA and glycine-based modulatory processes.[16,18-20] Comparable investigations, however, have not been made in more caudal V-BSNC nociceptive (e.g., caudalis) neurons, which as noted previously have many features analogous to those of spinal dorsal horn nociceptive neurons and play crucial roles in trigeminal nociceptive transmission; thus, if and how sleep stages affect their properties constitute an important area of future study. Of note, the state-dependent processes on spinal and V-BSNC nociceptive transmission that have been revealed have been studied only in acute sleep models, and it is unclear what neural modulatory processes are involved in the more clinically challenging sleep-pain interactions that may occur in chronic pain conditions (discussed later). Furthermore, if nociceptive afferents inputs do reach cortical levels and result in the conscious feeling of pain, then sleep may be disrupted to alert the subject to the noxious event.

Clinical Correlates

When healthy subjects are sleeping in conditions favoring good sleep quality (e.g., a quiet, comfortable environment), low-intensity stimuli may have little or no effect on sleep quality, whereas a loud noise or a sudden pain attack during sleep can produce awakening that may potentially trigger anxiety or concern that impedes subsequent sleep.[21] Nonetheless, several other factors in addition to pain can influence sleep quality (e.g., past experiences, psychological variables, anxiety, mood, life style, health status, and any concomitant pain-sleep interactions).

In the case of so-called pain patients, they may experience long delays in falling asleep, as well as sleep-stage shifts, frequent sleep arousals, and undesirable body movements; furthermore, some analgesic drugs (e.g., opioids) may affect sleep patterns (see Chapter 24). Although the majority of patients with chronic pain report that pain occurred before or at the onset of poor sleep, suggesting that pain may have a direct effect on sleep quality, studies using experimental noxious stimuli have revealed only minor sleep disturbance in healthy subjects.[22,23] However, these studies have elicited acute pain, and it remains unclear the mechanisms by which chronic pain may negatively influence sleep quality. Nonetheless, as noted earlier, chronic pain can be associated with neuroplastic changes in spinal dorsal horn, V-BSNC, and thalamocortical relays, so these or other pain-related changes may potentially have effects on sleep; however, how these changes influence the brainstem and thalamocortical circuits involved in sleep is largely unknown.[16]

The reverse situation, that poor sleep might be a significant cause of pain, also is unclear. According to some reports, experimental sleep deprivation or fragmentation can lead to pain, and restoration of sleep quality (continuity and duration) can reduce this pain in humans. Likewise, in animals, sleep limitation leads to a reduction in nociceptive threshold during wakefulness that is reversed once sleep is restored. Some studies, however, suggest that other factors (e.g., fatigue, mood changes, cognitive impairment) may be involved,[24] thereby raising doubts about whether poor sleep is indeed a dominant or a pathognomonic cause of pain. Accordingly, further investigations into the relationship between chronic pain and poor sleep quality are needed.

MODULATION OF SENSORIMOTOR PROCESSES DURING SLEEP AND WAKEFULNESS

Sleep mechanisms markedly affect sensorimotor functions. Sleep not only suppresses basal muscle tone but also attenuates and, in some cases, even abolishes motor reflexes (see later section on Specific Reflexes). Sensory and motor processes and their integration are also differentially affected by prevailing behavioral states. For example, during wakefulness, chemical and mechanical stimulation of laryngeal tissues evokes coughing; during sleep, however, the same stimulus elicits only a brief expiration. Such observations suggest not only that sensorimotor processes are suppressed by sleep but also that sleep mechanisms themselves control the integration and expression of sensorimotor processes.

Sensorimotor Pathways and Mechanisms

The afferent inputs that provide access to the spinal cord, brainstem, thalamus, and cerebral cortex are involved not only in perceptual processes but also in sensorimotor integration and control.[1,9,25,26] The neuromuscular system is reflexively influenced by receptors that signal pain, touch, joint position, and muscle stretch or tension. In the case of muscles of the trunk, neck, and limbs, afferents from spinally innervated tissues enter the dorsal root and project into the spinal cord, where they can excite or inhibit motoneurons that innervate skeletal muscles. Motoneurons that innervate craniofacial muscles (e.g., jaw, soft palate, laryngeal, tongue) reside in motoneuron pools in the brainstem, most notably the trigeminal, facial, ambiguus, and hypoglossal nuclei.

One source of afferent input that reflexively influences motoneurons is derived from the muscle spindle, a stretch-sensitive receptor signaling muscle length. The group Ia primary afferents innervating muscle spindles monosynaptically excite motoneurons to produce contraction of the stretched muscle. This monosynaptic circuitry is the neural substrate for the H-reflex and jaw-closing reflex. Muscle spindle afferents are a fundamental motor control mechanism in limb, neck, and trunk muscles; however, because there are insignificant numbers of muscle afferents in most craniofacial muscles (e.g., anterior digastric, facial, pharyngolaryngeal muscles), other receptor systems, such as the receptors in tooth-supporting tissues and in the pharyngeal and laryngeal mucosa, play a significant role in the control of these muscles.[1,9,25]

Some afferent inputs trigger either excitatory or inhibitory reflexes by affecting the activity of interneurons, which are located in the spinal dorsal horn, V-BSNC, or NTS, or within motor pools themselves. Both interneurons and motoneurons also are modulated by the descending neural systems that regulate somatosensory transmission such as the reticular formation, limbic system, lateral hypothalamus, basal ganglia, LC, red nucleus, cerebellum, and sensorimotor cerebral cortex.[25,26] Some of these systems also are involved in the initiation and guidance of movements such as the sensorimotor cortex, which contributes to the learning of novel sensorimotor skills through neuroplastic changes in sensory and motor representations in the sensorimotor cortex. Others are involved in the control and guidance of movements and their integration with other sensorimotor functions (e.g., basal ganglia; spinal or brainstem pattern generators for locomotion, chewing, or swallowing), and yet others in the regulation of sleep-wake states themselves (e.g., periaqueductal gray, lateral pontine tegmentum, lateral hypothalamus).[27]

Processing of Somatic Reflexes during Sleep and Wakefulness

Sleep influences the processing of sensory-motor responses such as the withdrawal reflex, jaw-closing reflex, jaw-opening reflex, and other H-reflexes. Because changes in somatic reflex responses are linked to movement disorders, such as PLMD and restless legs syndrome (RLS),[28] it is important to consider how such reflexes normally are affected by sleep and to identify mechanisms by which these reflexes are modulated during sleep, as reviewed next. Also discussed is how H-reflexes are affected during periods of cataplexy, because such changes provide valuable insight into understanding how brain function is affected by narcolepsy.

The withdrawal reflex (also known as the flexion reflex) is a polysynaptic multisegmental spinal reflex that triggers withdrawal (flexion) of the stimulated limb. It functions to remove the affected limb from potentially noxious stimuli that could cause tissue damage. The withdrawal reflex is composed of two excitatory responses. The first component, termed RII, is considered a tactile response and is characterized by muscle activation (e.g., biceps femoris muscle) that occurs 40 to 60 ms after nerve stimulation (e.g., sural nerve). The second component, termed RIII, occurs 85 to 120 ms after stimulation and is considered a nociceptive polysynaptic reflex.[29] The first and second components probably represent, respectively, the activation of A-beta and A-delta cutaneous afferent fibers. Because a robust correlation has been found between the RIII threshold and subjective pain thresholds, the primary focus here is on the effects of sleep on this component of the reflex.

Sleep has a marked impact on the expression of the withdrawal reflex in humans. Compared with wakefulness, a significant increase in the stimulus intensity is required to activate the reflex during both NREM and REM sleep.[30] The polysynaptic jaw-opening reflex (a reflex analogous to the withdrawal reflex) also is suppressed during NREM sleep in monkeys; reduced trigeminal motoneuron excitability is one factor that may cause suppression of this reflex during NREM sleep.[10,31] Although stimulus thresholds are elevated during sleep, the withdrawal reflex, like other somatic reflexes, is most reliably activated and most stable during NREM sleep. An increase in the latency to the RIII component also is observed during both NREM and REM sleep,[30] suggesting that sleep reduces nociceptive reflex excitability and acts to filter sensory inputs in order to preserve sleep continuity. However, there is an increase in both the magnitude and duration of the RIII reflex during REM sleep. This second finding is paradoxical, because monosynaptic reflexes are maximally suppressed during this state,[32] and somatic motoneurons are hyperpolarized during REM sleep in cats.[33] The mechanism(s) underlying RIII reflex facilitation during REM sleep is unknown.

Unlike the RIII nociceptive component, the RII tactile reflex is absent during sleep.[30] This observation is physiologically important because it suggests that sleep differentially affects the individual components of the sensory pathways that mediate this two-part reflex, which implies that sleep mechanisms do not affect all physiologic systems equally. This concept is of clinical relevance because it suggests that sleep suppresses tactile responses (i.e., RII), which if activated by body repositioning, for example, could cause unwanted arousal,

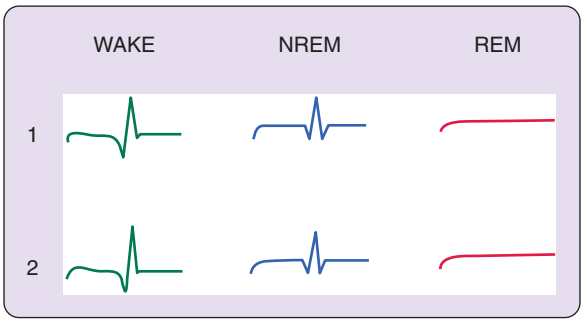

Figure 23-3 Magnitude of the H-reflex during sleep and wakefulness. The H-reflex of the calf muscle was triggered by electrical stimulation of the tibial nerve in a 22-year-old man during wakefulness, NREM sleep, and REM sleep, with reflex responses obtained on two separate measurements (1 and 2). Relative to that in wakefulness (WAKE), the H-reflex is depressed in NREM sleep and abolished in REM sleep. (From Shimizu A, Yamada, Y Yamamoto J, et al. Pathways of descending influence on H reflex during sleep. *Electroencephalogr Clin Neurophysiol* 1966;20:337–47.)

whereas nociceptive reflexes (i.e., RIII) and their motor component remain active during sleep. Preservation of this protective reflex would therefore ensure that painful stimuli elicit appropriate motor responses and if necessary arousal from sleep.

Sleep also has powerful effects on the expression of monosynaptic reflexes such as the masseteric jaw-closing reflex and the classic H-reflex. In humans, a progressive reduction in the magnitude of the H-reflex amplitude is seen during stages 1 to 4 of NREM sleep, along with a near-complete loss of the reflex during REM sleep[32] (Figure 23-3). Animal studies also show that the stimulus intensity needed to trigger the masseteric reflex is increased in sleep and that reflex responses are reduced during NREM sleep, minimal during tonic REM sleep, and maximally suppressed during periods of active REM sleep (i.e., during rapid eye movements). Because trigeminal motoneurons, which ultimately mediate the masseteric reflex, are inhibited by GABA and glycine during both NREM and REM sleep,[31] such inhibitory mechanisms may act to shunt the excitatory afferent inputs onto motoneurons during sleep. The available evidence, however, suggests that presynaptic inhibition of Ia afferents onto spinal motoneurons also may function to suppress monosynaptic spinal reflexes during REM sleep.[34] Therefore descending inhibitory inputs acting on both motoneurons and Ia afferents contribute to reduce monosynaptic reflexes during sleep.

Clinical Correlates

Sleep Bruxism

Sleep bruxism, classified as a sleep-related movement disorder, is characterized by tooth grinding and jaw clenching that can lead to destruction of teeth or dental restorations and cause jaw and head pain (see Chapters 144 and 145).[35,36] It occurs in 8% to 10% of the adult population and is characterized by rhythmic episodes of involuntary jaw muscle activity occurring primarily during NREM sleep and less frequently in REM sleep. Sleep bruxism is characterized by phasic contractions of jaw muscles, with three or more muscle bursts, although it also can manifest as tonic jaw muscle activity lasting 2 seconds or more or a mixture of the phasic and tonic activities. Because rhythmic jaw activity also occurs in most healthy subjects during sleep, sleep bruxism may represent an extreme manifestation of this normal pattern. Although the etiology and pathophysiology of sleep bruxism are not fully understood, abnormal sensorimotor processing within the CNS level, rather than an abnormal processing of peripheral sensory feedback (e.g., from the teeth), is recognized to underlie the genesis of sleep bruxism.[10]

Brainstem structures (e.g., reticular formation, LC, raphe nuclei) that influence sleep-wake control and sensorimotor processes also influence the mechanisms underlying sleep bruxism, and involve many of the same neurochemicals (e.g., 5-HT, GABA, acetylcholine, dopamine). In addition, the rhythmic movements appear secondary to CNS events related to "arousals," with increases in autonomic (cardiac and respiratory) and brain activity reflecting reactivation of the reticular formation arousal system preceding the movements.[35] The activity of noradrenergic cells in the LC also may contribute to the pathogenesis of sleep bruxism (see Chapter 144).

Descending cortical pathways, producing rhythmic masticatory movements during wakefulness, also may be involved in bruxism. Recent findings comparing cortically induced jaw movements in the awake and sleep states of awake versus sleeping primates indicate that cortical influences are suppressed during NREM sleep.[10] These findings suggest that corticobulbar excitatory influences are deactivated during sleep to preserve sleep continuity, providing indirect support for the importance of brainstem structures in the genesis of sleep bruxism.

Periodic Limb Movement Disorder and Restless Legs Syndrome

RLS is a common neurologic disorder that results from pathologic sensory and motor processing (see Chapter 95). It is characterized by unpleasant, uncomfortable, or painful sensations in the limbs, most often the legs, that lessen or disappear following limb movement.[36] Symptoms of RLS worsen during the night and can cause sleep disturbances that underlie the excessive daytime sleepiness and somnolence that typify RLS. Most affected patients also experience periodic limb movements (PLMs), which occur mainly during NREM sleep. PLMD is a sleep disorder characterized by the occurrence of brief (0.5 to 5 seconds), repetitive limb movements, typically involving the legs, every 5 to 90 seconds, arising periodically throughout the night. Common physiologic mechanisms probably underlie both RLS and PLMD, because 80% of patients with RLS also experience PLMs, and both RLS and PLMD are treated with dopaminergic drugs.[28]

Abnormal sensorimotor processing contributes to both RLS and PLMD. For example, marked hyperexcitability of both monosynaptic and polysynaptic reflexes is a feature of these two disorders.[28] The threshold required to activate the withdrawal reflex is lower and the response magnitude is larger during sleep in patients with RLS and PLMD than in healthy control subjects.[28] Changes in the response attributes of the soleus H-reflex in patients with RLS and PLMD also are seen—specifically, an increased late facilitation and a decreased late inhibition of the reflex response.[37] Reduced inhibition of either spinal motoneurons or presynaptic mechanisms may underlie the facilitation of motor responses and could explain why patients with RLS and PLMD exhibit hyperexcitability of spinal reflexes. Brain imaging studies show changes in thalamic, cerebellar, and pontine activity in both patient populations,[38] suggesting that these regions may

affect spinal reflex activity and hence contribute to RLS and PLMD.

Narcolepsy

Cataplexy is characterized by a sudden loss of skeletal muscle tone (i.e., atonia) despite maintenance of consciousness, and it is a pathognomonic symptom of narcolepsy. It generally is triggered by strong positive emotions (see Chapters 89 and 90). Because motor atonia is a defining feature of both cataplexy and REM sleep, similar neurocircuits may mediate both motor phenomena. In human and canine narcolepsy, the atonia of cataplexy can last from several seconds to several minutes. In both dogs and humans, the monosynaptic H-reflex is either absent or minimal during cataplectic attacks.[39] This observation demonstrates that the "wakefulness drive," which has been proposed to cause loss of muscle tone in sleep,[40] does not mediate motor suppression during cataplexy because wakefulness is preserved during this state. Loss of excitatory noradrenergic drives onto motoneurons may mediate the loss of muscle tone and the H-reflex during cataplexy, because noradrenergic cells in the LC project to motoneurons, and they cease firing during cataplectic attacks in narcoleptic dogs[41] (Figure 23-4). Furthermore, because LC neurons reduce their discharge activity in NREM sleep and virtually stop firing during REM sleep,[41] loss of noradrenergic drives onto motoneurons also may explain why motor reflexes and muscle tone are reduced in NREM and REM sleep.[42]

RESPIRATORY REFLEXES DURING SLEEP AND WAKEFULNESS

Sleep not only affects the processing of spinal and craniofacial sensorimotor activities but also changes how the respiratory system responds to both mechanical and chemical stimuli (see Chapters 15 to 17). The focus of this section is on sensory-motor integration in upper airway and craniofacial muscles, because sleep-dependent changes in these reflexes can cause respiratory instability during sleep. Airway reflexes, including coughing, swallowing, laryngeal closure, apnea, and the negative-pressure reflex, function to protect the airway from inhalation of inappropriate substances and to preserve airway patency during vulnerable periods such as during anesthesia and sleep. A multitude of afferent nerve endings in the upper alimentary and airway mucosa and muscles that detect changes in muscle tone, pressure, airflow, temperature, and chemical status (e.g., acidic fluids) are able to respond to and thus trigger appropriate respiratory reflexes. Presented next is a summary of how two important airway reflexes are affected by sleep; the potential mechanisms underlying state-dependent regulation of such reflexes are then reviewed.

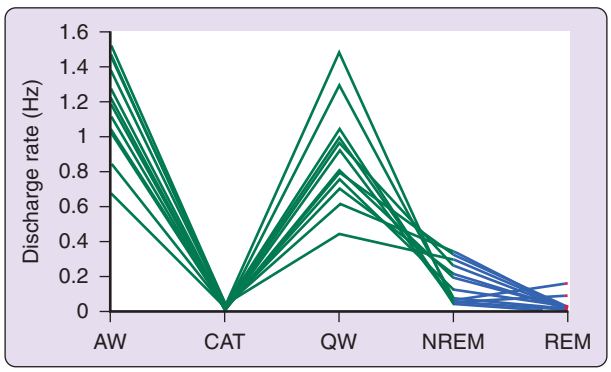

Figure 23-4 Discharge activity of putative noradrenergic cells in the locus coeruleus of narcoleptic dogs during wakefulness, sleep, and cataplexy. The discharge rate for locus coeruleus neurons is tightly correlated with behavioral state. Cell activity is maximal during active and quiet wakefulness (AW and QW, respectively), reduced during NREM sleep, and minimal or absent when motor hypotonia/atonia is present, that is, during REM sleep and cataplexy (CAT). Specific Reflexes

Airway Negative-Pressure Reflex

One of the most clinically relevant reflexes is the airway response to negative pressure. The airway negative-pressure reflex is characterized by increased upper airway muscle tone in response to the negative suction pressures generated by diaphragmatic contraction. During normal breathing, the reflex is inactive because airway pressure is below the stimulus threshold required to trigger it; however, during sleep, particularly REM sleep, reductions in airway muscle tone cause airway narrowing and increased resistance, which increases negative pressure, and this triggers the pressure reflex. The primary function of the negative-pressure response is to increase upper airway muscle tone when airway pressures threaten to occlude the airspace. This reflex response plays an important role in obstructive sleep apnea (OSA) (see the following Clinical Correlates section and various chapters in Section 14).

The negative-pressure reflex is typified by short-latency activation of a variety of craniofacial and pharyngeal muscles (e.g., tensor palatini and genioglossus) when airway pressure drops below a variable threshold. Studies using resistive loading, which approximates the effects of sleep on airway pressure, show that the negative-pressure reflex is reduced in sleep and indeed often is absent, except in the presence of hypercapnia or hypoxia.[43] Studies in both animals and humans show that the magnitude of pharyngeal dilator activation is reduced during NREM sleep and further reduced during REM sleep[44] (Figure 23-5).

The mechanisms mediating the airway negative-pressure reflex are not fully understood (see Chapter 15). Changes in pressure probably are detected by mechanoreceptors located within both airway mucosa and airway muscles themselves; whether both mechanisms operate at all levels of the airway is unknown. Trigeminal nerve afferents play a particularly important role in detecting upper airway pressure changes because not only do they respond to pressure changes, but the pressure reflex also is diminished when regions of the airspace innervated by trigeminal afferents are locally anesthetized.[45] Reductions in the negative-pressure reflex during sleep could be mediated, at least in part, by changes in the excitability of trigeminal pathways. Neuronal activity in the rostral V-BSNC is reduced during REM sleep[18]; because some of these neurons relay their excitatory signals to the respiratory centers and motoneurons that trigger reflex expression, reductions in their activity could function to reduce reflex responses in sleep, particularly during REM sleep.

Changes in airway pressure also are detected by mechanoreceptors supplied by the superior laryngeal nerve; such afferent signals are relayed to the NTS before reaching respiratory centers. Because excitatory (e.g., serotonergic raphe neurons,

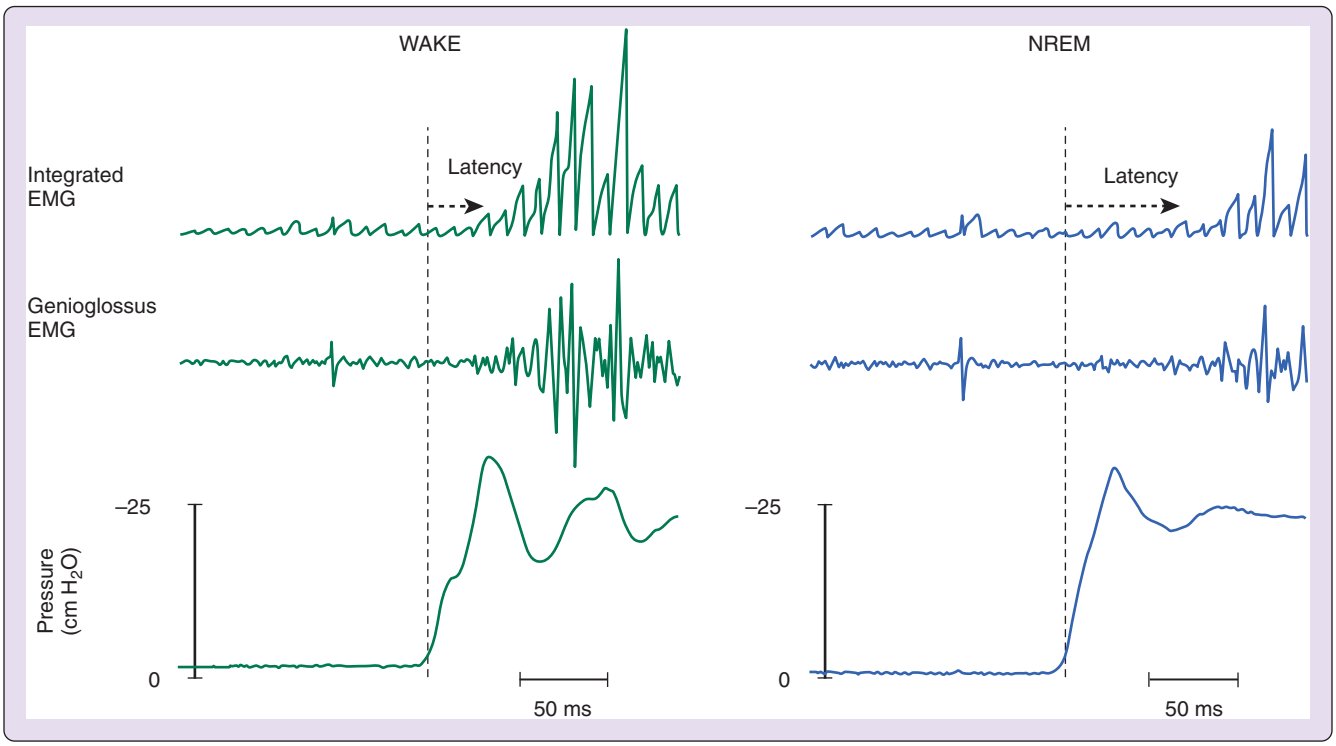

Figure 23-5 The airway negative-pressure reflex is suppressed during sleep, as seen in this typical example of an electromyogram (EMG) recorded in a human subject during wakefulness and sleep. *Top two traces,* Integrated and raw EMG activity recorded from the genioglossus muscle; *bottom trace,* changes in airway pressure. During waking, negative airway pressure (–25 cm H_2O) triggers a short latency activation of genioglossus muscle tone; during NREM sleep, however, the reflex magnitude is suppressed, and a significant increase in response latency is evident. (From Horner RL, Innes JA, Morrell MJ, et al. The effect of sleep on reflex genioglossus muscle activation by stimuli of negative airway pressure in humans. *J Physiol* 1994;476:141–51.)

hypocretin cells) and inhibitory (GABAergic in the ventrolateral preoptic nucleus) components of the sleep-generating circuitry also project to and synapse onto NTS neurons, reduced excitation and increased inhibition of NTS neurons could act to reduce the negative-pressure reflex during sleep.[27] In addition, GABAergic and glycinergic inhibition of upper airway motoneurons during NREM and REM sleep[31] may function to shunt the excitatory signals arising from pressure afferents; this effect also would limit the expression of the negative-pressure reflex during sleep.

Laryngeal and Bronchopulmonary Reflexes

Chemoreceptors in the nose, mouth, pharynx, larynx, and lower airways (e.g., trachea) detect various chemical stimuli that elicit protective upper airway reflexes. Stimulation of the larynx with acidic liquids or mechanical forces causes the laryngeal reflex, which during wakefulness in adults triggers swallowing or coughing. During NREM and REM sleep, however, the laryngeal reflex is not simply suppressed (and the stimulus threshold increased); it is transformed into a fundamentally different motor response. Compared with the waking reflex, which triggers coughing, laryngeal stimulation during sleep often initiates apnea and bradycardia[46] (Figure 23-6). Activation of bronchopulmonary receptors also elicits different respiratory motor responses during waking and sleep. Mechanical activation of the bronchopulmonary receptors that detect changes in airflow and/or lung stretch triggers the cough reflex during wakefulness but elicits reflexive apnea during both NREM and REM sleep.[47] Such an observation implies that sleep circuits inhibit the expression of these reflex responses or that activation of wake-generating circuits is required to trigger these reflexes.

The mechanisms responsible for reversing laryngeal and bronchopulmonary reflexes during sleep have not been determined. This type of response reversal, however, previously has been identified and studied in other motor pathways. During wakefulness, auditory stimuli (e.g., sudden loud noises) or skeletal muscle stimulation (e.g., muscle stretch) cause reflexive activation of somatic motoneurons with subsequent facilitation of skeletal muscle tone; during REM sleep, however, identical stimuli, albeit at greater intensities, cause the opposite effect—that is, motoneuron inhibition and reduced muscle tone. This type of state-dependent response reversal is mediated, at least in part, by the pontomescencephalic reticular formation (PMRF) that participates in sleep-wake regulation.[48] Stimulation of the PMRF causes excitatory postsynaptic potentials (i.e., excitation) in trigeminal motoneurons when the jaw-closing masseteric reflex is evoked during waking, but PMRF stimulation during REM sleep triggers inhibitory postsynaptic potentials (i.e., inhibition) in motoneurons and reduced masseteric reflex output.[48] The PMRF may therefore function to gate sensory-motor reflexes during different sleep-wake states; during wakefulness, it allows sensory stimuli to produce appropriate motor facilitation such as coughing, whereas during sleep, when motor activation could elicit inappropriate arousals, such stimuli trigger motor

inhibition (e.g., apnea). Whether this type of response reversal underlies state-dependent changes in laryngeal and bronchopulmonary reflexes is unknown.

Processing of Chemoreflexes during Sleep and Wakefulness

During wakefulness, respiratory control mechanisms are acutely sensitive to changes in blood and tissue carbon dioxide (CO_2) levels, with subtle increases in CO_2 levels causing potent increases in ventilation. However, sleep has profound effects on the respiratory sensitivity to CO_2, which influences the control of breathing during sleep. During sleep, ventilation decreases even though CO_2 levels increase. The decrease in ventilation is paradoxical in that increased CO_2 levels trigger potent increases in ventilation during waking. These changes are of physiologic importance because during waking, an increase of 1 mm Hg in the partial pressure of CO_2 (P_{CO_2}) causes a 20% to 30% increase in ventilation; during sleep, however, CO_2 levels can increase by 2 to 6 mm Hg without affecting breathing. Therefore, during sleep there is a change in the relationship between ventilation and the mechanisms that detect CO_2 levels; this change reflects the fact that sleep dramatically affects the processing of respiratory chemoreflexes.

The hypercapnic ventilatory response undergoes two important changes during sleep. First, the P_{CO_2} threshold that normally triggers increased ventilation during wakefulness is significantly increased during sleep. This sleep-related change indicates that higher CO_2 levels are required to increase ventilation during sleep, which could partially explain why ventilation decreases below waking levels during NREM sleep. Second, the sensitivity of the ventilatory response to CO_2 during sleep is significantly reduced from that in awake states. For example, decreases of 25% to 75% have been reported in the hypercapnic ventilatory response during NREM sleep compared with waking.

REM sleep also has a profound impact on the ventilatory sensitivity to CO_2. Compared with NREM sleep, there is a further reduction in the hypercapnic ventilatory response during REM sleep. In fact, CO_2 sensitivity often is suppressed to such a degree that high levels of CO_2 have negligible effects on breathing during REM sleep. In dogs, even high levels of CO_2 have minimal effects on breathing, and despite potent CO_2 stimulation, the irregular breathing patterns (e.g., rapid fluctuations in tidal volume and breathing frequency) that predominate during REM sleep still persist.[49] This is a notable observation because such levels of CO_2 normally would cause breathing to become deep and regular during waking and NREM sleep. The persistence of irregular breathing during REM sleep indicates that REM phenomena override the sensory control of breathing.

CO_2 sensitivity is different during tonic (i.e., no eye movements) versus phasic (i.e., eye movements) REM sleep. Compared with either waking or NREM sleep, the ventilatory response to CO_2 is potently suppressed during periods of phasic REM sleep. By contrast, the CO_2 response during tonic REM sleep is no different than during NREM sleep; however, CO_2 sensitivity remains below waking levels during this state.[50] This important observation underscores the fact that CO_2 sensitivity is differentially affected by NREM and REM sleep and also is subject to intrastate variability. Such findings suggest that behavioral states have a marked impact on the sensory mechanisms by which the CNS detects and responds to changes in CO_2.

Sleep also affects the manner by which different respiratory muscles respond to CO_2. In both humans and animals, hypercapnia causes marked increases in both diaphragmatic and upper airway (e.g., the genioglossus muscle) muscle activity; compared with waking, however, a marked reduction in levels of muscle activity is seen during both NREM and REM sleep. Although hypercapnia increases diaphragmatic muscle tone during NREM and REM sleep, the sensitivity of genioglossus upper airway muscle tone is severely blunted during REM sleep.[51] Therefore, although hypercapnia can trigger increased diaphragm activity in REM sleep, it has comparatively minimal effects on recruiting upper airway muscles whose activation is required for keeping the airspace open and for overcoming OSA (see the following Clinical Correlates section).

Sleep-dependent suppression of respiratory muscle function could limit the expression of the hypercapnic ventilatory response. Although respiratory muscle tone is reduced in

NREM sleep, it is unlikely that this change explains reduced CO_2 sensitivity, because hypercapnic exposure during this state increases ventilation and respiratory muscle tone (e.g., diaphragm and genioglossus) to within waking levels. During REM sleep, however, upper airway muscle tone is minimal and virtually unresponsive to hypercapnia; these effects could mask the ventilatory response to CO_2. Bypassing the upper airway by means of chronic tracheotomy can prevent the stereotypical loss of the ventilatory responses to CO_2 during REM sleep in cats,[52] which suggests that loss of upper airway muscle tone is, at least in part, responsible for the suppression of CO_2 sensitivity during REM sleep. Nevertheless, it is unlikely that REM sleep muscle atonia fully accounts for suppression of the hypercapnic ventilatory response, because CO_2 responses are minimal or absent during phasic REM sleep, when skeletal muscles are transiently activated, and CO_2 responses are present during tonic REM sleep, when skeletal muscle tone is lowest.[50]

Two mechanisms by which the nervous system detects changes in CO_2 levels are recognized. First, sensory cells (glomus cells) in the carotid body chemoreceptors respond to changes in arterial P_{CO_2} (and O_2). It is unknown how this sensing mechanism contributes to sleep-related changes in CO_2 sensitivity; however, because glomus cells relay their afferent signals to the brain via the NTS, sleep mechanisms that affect the activity of NTS neurons presumably could affect CO_2 sensitivity. Second, intrinsic CO_2-sensing mechanisms also are located within the brain itself. These CO_2 sensors, termed central chemoreceptors, consist of neurons that respond to local tissue changes in CO_2, which in turn trigger ventilation. The primary areas that detect changes in CO_2 are the NTS, LC, raphe nuclei, and retrotrapezoid nucleus (RTN).[53] Hypocretin/orexin neurons in the lateral hypothalamus, which form part of the neurocircuitry underlying arousal, also respond to and detect changes in CO_2. Focal acidification (i.e., increased CO_2) of hypocretin neurons causes them to depolarize and increase their firing frequency.[54] Genetic deletion of hypocretin neurons reduces the ventilatory response to CO_2 in awake mice and promotes respiratory instability during NREM and REM sleep,[55] suggesting that hypocretin neurons act as central CO_2 sensors that function to maintain normal respiratory reflexes during both sleep and waking.

Animal research demonstrates that some CO_2 sensors are able to detect changes in CO_2 only during waking, whereas others are able to detect CO_2 changes *only* during sleep. For example, local increases in CO_2 within the retrotrapezoid nucleus activates breathing only during waking; the same stimulus has no effect on breathing during sleep[53] (Figure 23-7). Although CO_2 stimulation of the NTS triggers increased ventilation during both waking and sleep, the response is significantly larger during waking than in sleep. Therefore the RTN and NTS could serve as the primary CO_2 sensors during wakefulness; loss of their CO_2 sensitivity during sleep may explain why the hypercapnic ventilatory response is suppressed during sleep. Although CO_2 sensitivity is reduced in sleep, it is not abolished; therefore other CO_2 sensors must continue to monitor tissue CO_2 levels during sleep. The serotoninergic raphe nucleus is one potential candidate, because local increases in CO_2 levels in this brain region increase breathing only during sleep; it does not affect

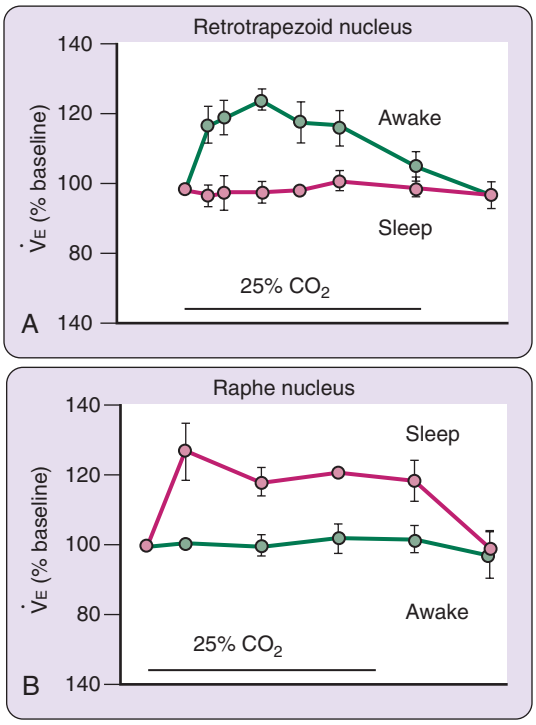

Figure 23-7 Some CO_2 sensors function only during wakefulness, whereas others function only during sleep. **A** and **B,** Plots of data for changes in $\dot{V}_E$ triggered by activation of CO_2 sensors in the retrotrapezoid nucleus RTN **(A)** or raphe nucleus **(B)** during wakefulness (*green line*) and sleep (*red line*) in behaving rats. To activate CO_2 sensors, 25% CO_2 (in saline) was perfused directly into either the RTN or raphe nuclei; this CO_2 concentration has physiologically relevant effects on CO_2 sensors. Activation of CO_2 sensors in the RTN increases ventilation only during waking; it has no effect during sleep (see **A**). Conversely, activation of CO_2 sensors in the raphe nucleus increases ventilation only during sleep; ventilation is unaffected during wakefulness (see **B**). (From Nattie EE. Central chemosensitivity, sleep, and wakefulness. *Respir Physiol* 2001;129:257–68.)

breathing during wakefulness (see Figure 23-7).[53] The raphe nucleus may therefore be the primary CO_2 sensor during sleep. This concept is supported by the fact that mice lacking functional serotonin neurons have abnormal arousal responses to CO_2 stimulation during sleep.

The neurocircuits that regulate sleep may also influence the ability of CO_2 sensors to transmit their excitatory drives to respiratory centers, thus limiting the expression of the hypercapnic ventilatory response during sleep. For example, because monoaminergic (e.g., noradrenergic in the LC; see Figure 23-4) and hypocretin neurons reduce their discharge activity during sleep and because these neurons also project to CO_2 sensors (e.g., RTN), then reduced excitatory drive from these sites would limit the ability of CO_2 sensors to relay their afferent signals to respiratory motor pools and to the respiratory centers that trigger the CO_2 response. Conversely, increased inhibitory drives from the GABAergic neurons in the ventrolateral and median preoptic nuclei that regulate NREM sleep could function to suppress CO_2 sensitivity during this state, because such inhibitory regions also project to CO_2 sensors and respiratory centers. Therefore both reduced excitation and increased inhibition during sleep may curtail CO_2–sensing mechanisms such that the hypercapnic ventilatory response is reduced in sleep.

Clinical Correlates

Although breathing continues without respite during wakefulness, it becomes fragile during sleep, and in approximately 2% to 5% of the adult population, it is punctuated by transient apneic episodes, which can manifest clinically as sleep-disordered breathing (see Section 14). OSA is the most common and serious respiratory-related sleep disorder. Its prevalence is growing, in keeping with its recognized link with obesity and the current obesity epidemic. A defining feature of OSA is that it occurs exclusively during sleep—patients with OSA breathe normally while awake but not while asleep. Changes in both chemical and mechanical processing during sleep account for the drastic changes in respiratory control that contribute to OSA. Reduced upper airway muscle tone during sleep, particularly REM sleep, is the primary cause of OSA; it causes either airway narrowing or complete airway obstruction, both of which lead to hypoventilation and subsequent asphyxia. Under waking conditions, these respiratory stimuli (i.e., airway narrowing and asphyxia) trigger an increase in upper airway muscle tone, which reopens the airspace by activating both the negative-pressure reflex and the hypercapnic ventilatory responses. Because these reflexes are suppressed during sleep, however, they are only partially reactivated, so airway muscle tone does not cause airway reopening. Accordingly, the airway remains occluded, and asphyxia worsens until it finally triggers awakening from sleep. Although wakefulness reinstates and reactivates the respiratory reflexes that increase muscle tone and thus causes airway reopening, it also causes hyperventilation, which in turn leads to hypocapnia. Hypocapnia then reflexively triggers a brief apneic episode, coincident with reentrance into sleep; this timing is problematic because sleep reduces the sensitivity of the mechanoreflexes and chemoreflexes needed to overcome apnea. Therefore apnea continues until the accompanying asphyxia produces arousal from sleep. This vicious circle occurs repeatedly throughout the night and underlies the sleep fragmentation, excessive daytime sleepiness, and related comorbid conditions (e.g., hypertension) that typify OSA.

CLINICAL PEARL

Determining how sleep controls sensory and motor processes is of notable importance in sleep medicine because some sleep disorders result from disturbances in sensory or motor control. As indicated by the available evidence, nociceptive transmission in the CNS is affected by sleep, and acute pain causes some sleep disturbance, but the extent and mechanisms by which chronic pain influences sleep, and vice versa, are largely unexplored. Clinicians need to be mindful that there is no simple relationship between chronic pain and sleep quality. Abnormalities in motor control during sleep underlie most of the major sleep disorders, including OSA, narcolepsy-cataplexy, RLS and PLMD, and sleep bruxism. Identifying the underlying mechanisms of motor regulation during sleep is a prerequisite for developing more rational treatments for such sleep disorders.

SUMMARY

Sensory and motor processing are reduced during sleep, and the integration of these processes is differentially affected during different sleep states, suggesting that discrete NREM and REM sleep mechanisms modulate and control sensory and motor processes in a sleep state–dependent manner. Changes in sensory processing during sleep affect the somatosensory pathways that transduce and relay nociceptive signals to and within the CNS. Sensory mechanisms are affected by sleep, and sleep is in turn affected by nociceptive processes. The interaction between pain and sleep is common in patients suffering from chronic pain such as that associated with cancer. Abnormal sensory and motor functions during sleep underlie common sleep disorders. For example, reduced chemical control of breathing during sleep plays a role in congenital central hypoventilation syndrome, and pathologic motor control during REM sleep underlies REM sleep behavior disorder.

Opiate Action on Sleep and Breathing

Chapter Highlights

- Opiates are not commonly prescribed for primary disorders of sleep, but with widespread use and increasing misuse of this class of drugs, opiate-related problems of respiratory depression, addiction, neuropsychiatric disorders, and optimal versus inadequate pain control, will be encountered with increasing frequency in sleep medicine clinics.
- Sleep disruption caused by opiates is consistently documented by studies using objective, polysomnographic measures. The effects of opiates on sleep are complex and vary as a function of the particular opiate administered, dose, and acute versus chronic administration. In the absence of data demonstrating significant, deleterious effects of opiate-induced sleep disruption, a prevailing view is to focus on the positive role that opiates play in acute pain management.
- Wakefulness is blunted by opiates, and chronic administration of opiates to manage chronic pain causes a dose-dependent torpor that is characterized by decreased physical and mental vitality. Drugs currently deployed to counter opiate-induced torpor and sedation are used off-label.
- The chapter concludes by emphasizing gaps in knowledge as opportunities for research on how to achieve both pain reduction and a restorative, sleep-like state that is as similar as possible to normal, nondrugged sleep.

Opiates have been briefly considered in previous editions of this book. Opiates can be useful for treating restless legs syndrome in some patients,[1] but these agents have the unwanted side effects of sleep disruption[2,3] and exacerbation of sleep-disordered breathing,[4] in concert with significant abuse potential.[4] Therefore, opiates are indeed relevant for practitioners of sleep medicine. The complex relationship among opiates, pain, and sleep means that sleep medicine clinicians will increasingly be confronted by problems of addiction, neuropsychiatric disorders, and pain. For example, deaths caused by overdose of prescription opiates have been described as an ongoing public health crisis.[5] Insomnia is the most common presenting condition in sleep medicine and often is a comorbid feature of posttraumatic stress disorder and opiate dependence.[6] This chapter updates and expands previous reviews of opiates and sleep,[7-9] and confirms that polysomnographic data repeatedly demonstrate that opiates disrupt sleep. This confirmed association should not be construed as indicating that the relationship between sleep and opiates has been thoroughly studied. Reviews of the literature reveal few objective polysomnographic studies that quantitatively describe how opiates, independent of pain, illness, or addiction, influence the temporal organization of sleep. This issue is directly relevant for a scientific approach to sleep disorders because although self-assessment of sleep quality is clinically valuable,[10] the data obtained using such assessments can differ significantly from measures provided by objective polysomnography.[11] To date, no polysomnographic studies in humans characterizing how the effects of opiates on sleep vary as a function of age, sex, body habitus, or race have been published. Furthermore, human polysomnographic data systematically comparing effects on sleep across multiple opiates, or across the variety of pain modalities are lacking. These gaps in knowledge represent important opportunities for sleep research. Studies also are needed to address the paradox that opiate-induced sleep disruption can contribute to increases in the doses of opiates that are needed to achieve pain relief, and to examine the putative role of opiates in causing hyperalgesia.[12]

This chapter is organized into four main topics: (1) the historical context for ongoing social and medical issues concerning opiates, (2) the mechanisms of sleep disruption caused by opiates, (3) the clinical relevance of opiate-induced respiratory depression, and (4) emerging opportunities for research on opiates and sleep. Not included here is the important topic of acute pain management by anesthesiologists in the perioperative setting. For more information on sleep and pain interactions, see Chapters 23 and 133.

HISTORICAL CONTEXT FOR ONGOING SOCIAL-MEDICAL ISSUES CONCERNING OPIATES: OPIOPHILIA AND OPIOPHOBIA

Efforts to promote patient access to pain management[13] and consensus statements on safe and effective treatment guidelines[14] have not resolved the longstanding debate regarding legitimate prescriptions for opiates, with both pros ("opiophilia") and cons ("opiophobia") well described.[15-17] Calls for a "balance between treating legitimate pain patients and mitigating opiate abuse, overdoses, and related deaths" reflect this

reality.[18] The increase in prescriptions for opiate analgesics[19,20] means that practitioners of sleep medicine commonly will confront the challenge of how to preserve the human right of pain relief while protecting patients against opiate side effects. The difficulty of this challenge is emphasized by the lack of consensus regarding prevalence and incidence of addiction associated with long-term use of opiates for chronic pain.[21-23]

Data selected from a large body of literature on substance abuse provide statistics showing that analgesic-induced overdose fatalities in New York City increased almost 700% during the interval from 1990 to 2006.[24] In September 2014, the National Institutes of Health (NIH) Office of Disease Prevention sponsored a workshop entitled "The Role of Opioids in the Treatment of Chronic Pain."[25] The NIH announcement also noted that chronic pain is a major public health problem affecting about 20% to 30% of the world's population. This statistic is emphasized by data from the Centers for Disease Control and Prevention showing that the problem of prescription opiate abuse is exacerbated by a 300% increase over the past 20 years in clinical prescriptions written for opiates. The number of deaths due to prescription opiates has exceeded the total number of deaths caused by cocaine and heroin.[25] Since 2005 in the state of Massachusetts, annual deaths attributed to opiate overdose have outnumbered those caused by motor vehicle accidents.[19] This crisis continues to receive extensive media coverage in North America and also is a concern in other parts of the world experiencing increased access to opiates.[26]

Figure 24-1 illustrates opium-induced states of torpor as a historical predecessor of contemporary opiophobia. During the opium wars of the early 19th century, the British foisted upon China the use of opium, with the drug serving as a form of currency intended to reduce a British trade deficit.[27] The Chinese administration fought this and sought to ban the sale of opium. The Chinese leadership understood that the state of torpor caused by highly addictive opium was a threat to the Chinese economic and social structure.

Figure 24-1 Photograph from the late 1890s showing persons in opium-induced torpor, characterized by diminished physical and mental activity, eyelid closure, and recumbency. This constellation of traits accounts for the mislabeling of opioid-induced torpor as sleep. One neuronal substrate for the opioid-induced blunting of wakefulness is suggested by the finding that mu opioid agonists depress the discharge of arousal-promoting hypocretin-containing neurons. (Li Y, van den Pol AN. μ-opioid receptor-mediated depression of the hypothalamic hypocretin/orexin arousal system. *J Neurosci* 2008; 28:2814–9.)

SLEEP MEDICINE, PAIN MEDICINE, AND HEALTH POLICY

The association between sleep disorders medicine and pain medicine has been slow to develop. More than 10 years ago the National Sleep Disorders Research Plan[28] documented the importance of achieving an understanding of the mechanisms by which opiates disrupt sleep. Opiates remain a key component of acute and chronic pain management[29,30] despite slow progress in overcoming unwanted side effects.[31] The U.S. Congress declared the years 2001 to 2010 as the Decade of Pain Control and Research (Public Law 106-386-OCT). The Pain Care Policy Acts of 2003 (HR 1863) and 2005 (HR 1020) were bills calling for establishment of a Center for Pain and Palliative Care Research within the NIH. These mandates were encouraged by data on the prevalence of clinically significant pain and by evidence that pain often is inadequately managed. For example, adequate postsurgical relief of acute pain is provided to only approximately 25% of patients.[32,33] Some studies report that only 40% of patients with chronic pain can obtain adequate relief.[33] More recent studies also question the efficacy of long-term opiate administration for treating nonmalignant chronic pain.[34] In 2001, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), since renamed "The Joint Commission," mandated that health care organizations comply with the agency's Pain Assessment and Management Standards in order to receive accreditation.[33] Compliance includes documenting the efficacy of pain treatment plans and educating patients and their families, as well as health care providers, about pain.[35] The 2010 Patient Protection and Affordable Care Act mandated the U.S. Department of Health and Human Services to "increase the recognition of pain as a significant public health problem in the United States."[13] In 2011 a report from the Institute of Medicine indicated that at least 116 million adults in the United States suffer from chronic pain resulting in an economic cost of up to $635 billion, exceeding the combined costs of cancer, diabetes, and heart disease.[13] Thus, nearly 40% of the U.S. population experiences chronic pain, a disease prevalence that is significantly greater than that for sleep disorders, affecting 50 to 70 million people.[36]

OPIATES AND OPIOID PHARMACOLOGY

The nomenclature used in this chapter is that recommended by the International Union of Basic and Clinical Pharmacology (IUPHAR), which distinguishes between exogenous opiate drugs and receptors that are activated by endogenous opioid peptides[37] including enkephalins, beta-endorphins, and dynorphins.[38] The IUPHAR review, summarizes nomenclature for the four opioid peptide receptors (mu, delta, kappa, and nociceptin/orphanin FQ), their nonapproved monikers, and the presumed endogenous ligands for each opioid receptor.[37] The mu opioid receptor was named for morphine, and the clinical management of both acute and chronic pain commonly involves administration of mu opiates. Mu opioid receptor activation closes voltage-gated calcium channels and opens potassium channels, thereby hyperpolarizing neurons

and decreasing neuronal excitability.[39] Opioid receptors are part of the family of G protein–coupled receptors, and the complexity of opioid signaling is illustrated by the identification of multiple splice variants of the mu opioid receptor throughout brain and spinal cord.[40,41] In addition, distinctly different opioid receptors can combine to form dimers and/or oligomers with unique functional roles.[42] Opiates also interact with multiple receptor systems. Adenosine is a sleep-promoting molecule, and the potential relevance of the foregoing details for sleep is demonstrated by evidence of interaction between mu opioid and adenosine A_1 receptors. For example, mu opiates enhance G protein expression in sleep-regulating regions of the brainstem, where opiates and adenosinergic agonists can additively activate G proteins.[43]

Despite the incontrovertible evidence of unwanted opiate side effects, it is important to acknowledge that opiates make a significant, positive contribution to the management of pain. Sleep disorders medicine and pain management are linked by a shared focus on states of consciousness.[32] States of pain are composed of complex psychophysiologic events that include nonnociceptive variables such as alterations in affect, cognition, and autonomic physiology,[44] each of which varies as a function of sleep and wakefulness. Finally, the problem of polypharmacy clearly complicates efforts to delineate the effects of opiates on sleep and wakefulness. Clinical efforts to manage cancer pain can involve a complex array of pure mu agonists, partial agonists such as buprenorphine, and opiates with multiple mechanisms of action.[45] At present, studies characterizing opiate effects on sleep-wake states using polysomnography are not available for a majority of 20 opioid medications considered in the context of managing cancer pain.[45] Readers are referred to cited references[46-48] for reviews of opiates and opioid pharmacology.

Systemically administered opiates alter cell excitability throughout the nervous system (Figure 24-2). These anatomically distributed effects cause diverse alterations in physiologic traits including cortical electroencephalogram (EEG) activity, breathing, and motor control, as well as in more global behavioral states. At present, it is not possible to selectively achieve the desired opiate effect of diminishing states of pain and anxiety without causing the unwanted side effects of disrupting breathing and states of sleep and wakefulness. The subsequent sections emphasize the persisting lack of data regarding unwanted opiate side effects.

Opiates Disrupt the Temporal Organization of Sleep and Wakefulness

Sleep disruption has long been recognized as a major complaint of patients experiencing pain.[49] Unfortunately, opiates used in the clinical management of acute pain also can cause sleep disruption. This paradoxical effect associated with systemic administration of opiates has been consistently documented in studies using objective, polysomnographic measures of sleep (Table 24-1). Considered as a group, the studies summarized in Table 24-1 distinguish between disruptions in sleep that are caused by opiates and sleep changes that are caused by pain, disease, or addiction. Administering clinically relevant doses of opiates to otherwise healthy people increases light (stage N1) non–rapid eye movement (NREM) sleep, decreases deeper NREM sleep (stages N3, N4), and inhibits rapid eye movement (REM) sleep.[50-55] Sleep and EEG data recorded from rodents fit well with clinical evidence showing that opiates increase EEG power in the delta (0.35 to 3.5 Hz) and theta (3.5 to 8 Hz) frequency ranges.[56,57] Many studies have shown that even in pain-free subjects, sleep disruption promotes hyperalgesia.[58-61] The pronociceptive effects of sleep disruption are likely to be mediated by many neurochemicals in multiple brain regions. Available evidence indicates that gamma-aminobutyric acid (GABA)-ergic transmission in the pontine reticular formation contributes to hyperalgesia caused by sleep disruption.[62]

The effects on sleep of acute opiate administration in people who are pain-free are complex and also vary as a function of the particular opiate administered, dose, and route of administration. Remifentanil, for example, is a synthetic opioid that is delivered by intravenous infusion, rapidly reaches a steady state level in plasma, and has an elimination half-life of less than 4 minutes.[55] When delivered to pain-free subjects, remifentanil disrupted the temporal organization of sleep and inhibited REM sleep.[54,55] Buprenorphine, an agonist at mu opioid receptors and an antagonist at kappa opioid receptors, was discovered in 1966, and its role in the search for addiction therapeutics has been reviewed elsewhere.[63] Buprenorphine is advocated by some researchers as an agent for treating opiate addiction.[64] Survey data also indicate a large increase in buprenorphine use for nontherapeutic purposes.[65] The first study[66] showing that an antinociceptive dose of buprenorphine significantly disrupts sleep was published as recently as 2011. Systemic administration of buprenorphine to rats delayed sleep onset (Figure 24-3) and caused a significant increase in wakefulness and a significant decrease in both NREM sleep and REM sleep (Figure 24-4, *A-E*).[66] To date, no polysomnographic data that quantify the effects of buprenorphine on the sleep of healthy, pain-free, nonaddicted

humans are available. The ideal clinical goal is to achieve both pain reduction and a restorative, sleep-like state that is as similar to normal, nondrugged sleep as possible. The potential to achieve this dual goal is suggested by the results of preclinical studies showing that buprenorphine-induced disruption in the temporal organization of sleep can be diminished by coadministering the sedative-hypnotic eszopiclone (Figure 24-4, *F-J*).[66]

Opiates Promote Torpor-like States

Tissue injury and some pain-producing diseases are accompanied by inflammation. The signs of inflammation were recognized in the First century by Celsus to be heat, pain, redness, and swelling (*calor*, *dolor*, *rubor*, and *tumor*).[67] The use of opiates to provide pain relief adds a fifth cardinal sign of "torpor." The clinical manifestations of torpor are expressed as lethargy and a reduced ability to sustain physical and mental activity. (Additional information on sleep and torpor is provided in Chapter 21.) Opiates blunt wakefulness and slow cortical EEG activity.[68-72] Systemic delivery of morphine to rodents significantly increases low-frequency EEG power.[73,74] EEG slow wave activity is characteristic of the postmorphine state and is accompanied by behavioral torpor and muscle rigidity.[72,74] The action of opiates to blunt wakefulness is relevant because the duration and quality of wakefulness significantly modulate subsequent sleep[75,76] and global brain states.[77] The torporlike state experienced by some patients receiving opiates for pain on an acute basis, in whom a rapid return to health is anticipated, is commonly regarded as an equitable exchange for relief from pain. For patients experiencing chronic pain, however, the decreased physical and mental vitality characteristic of torpor can significantly diminish the quality of life. Inflammation alone can produce fatigue,[78] which may interact with the sedating effects of opiates to induce a state of torpor. Studies on the neurobehavioral effects of opiates are available,[79-81] but the psychophysical characteristics of torpor associated with chronic administration of opiates remain poorly understood. A 1-year retrospective chart review of findings in adult patients with nonmalignant pain who were identified by the Epworth Sleepiness Scale as experiencing opiate-induced sedation suggested that treatment with modafinil diminished sedation.[82] By contrast, a retrospective examination of the 1996 to 2004 MEDLINE database provided limited support for the view that methylphenidate, donepezil, and modafinil can offset the torporlike state caused by opiates.[83] The study authors emphasized the limitations of their review[83] and provided a useful summary (Table 24-2) that can inform the design of prospective clinical studies aiming to achieve opiate-induced pain relief while minimizing a torpor-like blunting of wakefulness. The drugs shown in Table 24-2 include a three-pronged approach of enhancing hypocretinergic transmission (modafinil), decreasing the degradation of acetylcholine (donepezil), and enhancing sympathomimetics (methylphenidate and dextroamphetamine). For all of the listed drugs, recommended uses are off-label.

CLINICAL RELEVANCE OF OPIATE-INDUCED RESPIRATORY DEPRESSION

Although many nonanalgesic effects of opiates have been documented,[84,85] the most notorious side effect is opiate-induced respiratory depression. This section focuses on the intersection of opiate-induced respiratory depression and sleep medicine and on how the overlap affects specific patient populations. For a more comprehensive review of opiate-induced respiratory depression, readers are referred elsewhere.[86-95]

A complex association has been recognized between sleep-disordered breathing, being overweight or obese, and pain. For example, sleep-disordered breathing is common in overweight or obese persons.[96] Obesity itself is associated with increased pain,[97,98] and among patients with sleep-disordered breathing, increased reports of pain are typical.[99] The neurochemical mechanisms modulating the foregoing associations remain unknown. Preclinical studies show that an adenosine A_1 receptor agonist is antinociceptive only in the presence of the satiety factor leptin.[100] The hypothesis that nocturnal (or recurrent) hypoxia somehow causes pain is currently being studied. When nocturnal hypoxemia was examined independently of sleep fragmentation in patients with obstructive sleep apnea (OSA), it was found that pain reported by the participants on awakening significantly increased.[99] These findings, along with the discovery that use of continuous

Medication	FDA Indication	Typical Use(s)	Potential Adverse Effects	Dosing Range*	Advantages	Disadvantages
Methylphenidate	CNS stimulant	Narcolepsy, ADHD	Agitation, anxiety, psychosis, anorexia, hypertension, tremor, tachycardia, diaphoresis	10–15 mg/day	Most clinical trial support, rapid onset in responders, inexpensive	Significant adverse effects, schedule II prescribing restrictions, abuse potential, diversion potential, stigma associated with use
Dextroamphetamine	CNS stimulant	Narcolepsy, ADHD	Agitation, anxiety, psychosis, anorexia, hypertension, tremor, tachycardia, diaphoresis	5–30 mg/day	Few compared with methylphenidate	Similar to methylphenidate
Donepezil	ACh esterase inhibitor	Alzheimer's disease, dementia	Nausea, vomiting, diarrhea, headache	2.5–15 mg/day	Generally well tolerated, once-daily dosing, nonscheduled, promotility effect may relieve constipation, safe in patients with cognitive dysfunction, no abuse potential	Limited clinical trial support, expensive
Modafinil	CNS stimulant	Narcolepsy, shift work sleep disorder	Agitation, anxiety, dizziness, psychosis, diarrhea, nausea, hypertension, tachycardia	100–600 mg/day	Generally well tolerated, schedule IV some prescribing restrictions, low abuse potential	Limited clinical trial support, expensive, multiple CYP450 enzyme system effects
Caffeine	CNS stimulant	Headache	Agitation, insomnia, GI upset, nervousness, restlessness	Unknown	Readily available, generally well tolerated, inexpensive	No data to support efficacy, variable patient tolerance

positive airway pressure decreased the pain experienced by patients with severe OSA,[101] are consistent with the interpretation that intermittent hypoxia may be one source of pain experienced by patients with OSA. Conversely, subsequent work has shown that both adult and pediatric patients with recurrent hypoxia and severe OSA require less opiate administration postoperatively to obtain adequate analgesia.[102,103] On the basis of the available literature, it is not possible to unequivocally resolve the association between sleep-disordered breathing and pain.[99,102] Mu opioid receptor upregulation occurs in the developing rat in response to intermittent hypoxia.[104] Humans with high levels of endogenous opioids display less analgesia when administered morphine.[105] Thus hypoxia-associated pain and decreased opioid requirement may not always be mutually exclusive.[106]

During both REM sleep and NREM sleep, the ventilatory response to carbon dioxide is reduced, minute ventilation decreases, and a mild to moderate hypoxemia prevails.[90] Similarly, opiates induce central nervous system depression by blunting the chemoreceptive response to both carbon dioxide and hypoxia, prolonging exhalation time, and suppressing tidal volume, while also increasing upper airway resistance.[90,107-109] Thus, sleep and opiates both impair breathing by reducing respiratory rate and decreasing tonic respiratory drive.[90,108] These additive effects contribute to opiate-induced respiratory depression.

Opiates and Sleep-Disordered Breathing

Sleep-disordered breathing is a term that encompasses OSA, central sleep apnea, and upper airway resistance syndrome (snoring).[107] In the general population, men are twice as likely to be diagnosed with OSA as women are, with middle-aged obese males identified as the most susceptible.[91,110–112] Many persons with OSA remain undiagnosed preoperatively.[112] This is problematic because these patients are at increased risk for upper airway collapse,[110] and because accumulating evidence suggests that administration of mu opioid analgesics in this population has been associated with an increased risk of respiratory complications in the postoperative period.[102] The evidence also points to an increase in endogenous opioids in the cerebrospinal fluid of patients with sleep apnea syndrome, which can in turn increase sensitivity to opiates.[113] Additionally, a dose-dependent relationship has been confirmed between chronic opiate use and sleep-disordered breathing regardless of the presence or absence of a preexisting condition.[9,90,91,114-118] Thus, a preoperative condition of sleep-disordered breathing can intensify opiate-induced respiratory depression, and opiates alone can lead to sleep-disordered breathing.[109] Patients with pure OSA who also are being treated with opiates are at increased risk for development of complex sleep apnea, characterized by central as well as obstructive apneic events.[119–121]

Occurrence of central apneas during NREM sleep is the most common effect of chronic opiate use on breathing and sleep.[87,109,122,123] Seventy percent of patients chronically using opiates developed ataxic breathing and central apneic episodes during NREM sleep, compared with 5% of control subjects.[91] By contrast, central sleep apnea was reported in 30% of patients undergoing methadone maintenance therapy.[124] Data on the occurrence of sleep apneas after surgery also are available: An increase in the apnea index has been found to be most severe in the first 24 to 48 hours postoperatively.[110,125] Understanding the degree and timing of postoperative changes in sleep-disordered breathing and sleep architecture can be expected to help develop strategies for postoperative monitoring and treatment.[110] A recent innovation is development of a new mode of minute ventilation–targeted servoventilation for central apneas associated with opiate use. This approach was significantly more effective than bilevel ventilation with back-up respiratory rate (bilevel-ST) in decreasing both the apnea-hypopnea index and the central apnea index.[126]

Considered next are specific populations known to be vulnerable to opiate-induced respiratory depression.

Obesity and Opiate-Induced Respiratory Depression

Obesity has become a worldwide epidemic.[127] In the United States, the incidence of obesity has doubled over the past 20 years, yielding frequencies three times higher than for some European countries, with the greatest relative increase in the subpopulation with a body mass index greater than 50 kg/m^2.[112,128] Paralleling this increase in obesity over the past decades has been an eightfold increase in the occurrence of OSA, with as many as 50% of morbidly obese patients experiencing sleep apnea.[111,119] Obesity functions as a comorbid condition for OSA by exacerbating airway obstruction through anatomic factors, thereby increasing the risk of life-threatening respiratory complications induced by opiates.[112,125] Affected patients need to be closely monitored postoperatively, and therapies such as continuous positive airway pressure, bilevel positive airway pressure, or auto-titrating positive airway pressure should be considered.[112]

Geriatric Population Is Vulnerable to Opiate-Induced Respiratory Depression

The geriatric community represents the fastest-growing sector of society, and older patients undergo surgery four times more frequently than other age groups.[129] A combination of age-related physiologic changes and increased risk of disease augments the potential for negative disease-drug and drug-drug interactions. Furthermore, the complex association between sleep-disordered breathing, pain, and postoperative outcome is exacerbated by the fact that the prevalence rates for both sleep-disordered breathing and pain increase with age.[130,131] Adequate postoperative analgesia in elderly patients is of particular importance because insufficient pain control is associated with unfavorable outcomes.[129] As a consequence of aging, the pharmacokinetics and pharmacodynamics of drug action change, leading to increases in mean elimination half-life and brain sensitivity with decreases in volume of distribution, clearance, and protein binding.[129] In addition, normal reduction in renal function occurring as a consequence of aging hinders the elimination of many drugs and their metabolites.[132] Simultaneously, a drug's EC_{50}, the concentration producing half of the maximal effect, linearly decreases with age.[132] The major morphine metabolite, morphine-6-glucuronide, is more potent than morphine. Accumulation of morphine-6-glucuronide, in concert with its increased potency, can lead to heightened sensitivity to opiates and increased risk of respiratory depression.[132] These effects may be especially pronounced in geriatric patients in the seventh to ninth decades of life, in whom the risk of critical ventilatory depression is between 2.8 and 8.7 times higher than that in younger patients.[132] Owing to these natural physiologic changes, it is

important to adopt the "start low and go slow" approach for titrating the opiate dose prescribed to elderly patients.[129]

Opiates Alter Breathing in Children

One of the most common procedures performed in response to pediatric OSA is adenotonsillectomy, for which postsurgical administration of opiates often results in respiratory complications similar to those that occur in adults.[103] A prospective, stratified, and blinded study found that "the postsurgical total analgesic morphine dose required for children with a history of significant recurrent hypoxemia is lower than that in children who have not experienced such hypoxemia."[103] (See also Chapters 148 and 149 on perioperative use of opiates in patients with obstructive sleep apnea.) Additionally, this study identified a twofold difference in the calculated total analgesic morphine dose required between children with severe versus mild hypoxemia.[103] These results are supported by recent preclinical studies showing that respiratory sensitivity to opiates is enhanced by recurrent hypoxic episodes.[133] Finally, similar to the geriatric population, the pediatric cohort demonstrates age-related physiologic patterns that affect the metabolism of opiates. Some of these differences in pediatric patients include a potentially underdeveloped renal pathway and *CP2D6*-dependent conversion of codeine to morphine in infants (before 6 months of age).[133] These findings further emphasize the significance of individual dose titration, encouraging clinicians to determine the level of hypoxemia in each child diagnosed with OSA before surgery.[103]

Chronic Pain

The number of patients experiencing chronic pain has been steadily on the rise, with 100 million Americans suffering from the condition as of 2011.[13] Prevalence of chronic pain is higher in patients with a body mass index of 27 or greater, women, and the elderly; the chronic pain patient population is thus likely to grow along with the aforementioned cohorts.[134,135] Fifty percent to 90% of patients with chronic pain are estimated to report poor sleep quality, including sleep disturbances, difficulty falling and staying asleep, and less restful sleep.[134,136] Additionally, chronic pain is known to alter sleep architecture.[9,58,134] Chronic pain disrupts sleep, and sleep disruption worsens pain.[9,58,93,134,136,137] This vicious circle can contribute to a diminished quality of life by inflicting emotional, physical, economic, and social distress on the patient.[9,136,138] Treatment for some forms of chronic pain may involve around-the-clock administration of long-acting opiates, supplemented by short-acting opiates for breakthrough pain.[9,93,139] It is hypothesized that by utilizing extended-release opiates, the plasma levels of the analgesic can be maintained at a constant level, thereby improving sleep by eliminating gaps in analgesic action and blocking the associated breakthrough pain.[134] A study in which patients with chronic pain were treated with extended-release morphine resulted in significant improvements to several sleep measures compared with placebo.[134] These improvements in the quality of sleep for patients with chronic pain who are on extended opiate therapy[136] are tempered by the finding that chronic opiate use has been associated with increased risk of central sleep apnea in this population.[90,109,115,134,136] Additionally, it is a common occurrence during opiate therapy for patients with chronic pain to experience a loss of treatment effect, necessitating an increase in opiate dose to obtain adequate analgesia.[140,141] Some researchers suggest that this increased need is attributable to opiate-induced hyperalgesia, in which exposure to opiates results in an increased sensitivity to pain.[140] Owing to variability in experimental methods and inconsistent results, however, tolerance and acute withdrawal cannot be ruled out as potential causes of opiate dose escalation; accordingly, further investigation is required.[141]

Substance Abuse, Opiates, and Respiratory Control

Sleep disorders are 5 to 10 times more common in substance abusers than in nonabusers.[142] Oral administration of methadone to persons addicted to heroin has become the international standard for treatment.[143] This approach has proved to be successful in keeping heroin-dependent patients in treatment programs while reducing their risk of relapse by preventing or reducing withdrawal symptoms.[143] Because of these results, enrollment in methadone maintenance programs has been on the rise, with more than 160,000 enrollees in the United States.[144] Unlike previously discussed cohorts, methadone-maintained patients have been found to develop tolerance to respiratory depression caused by the opiate over a period of 5 to 8 months, although the reduction in hypoxic drive does not fully reverse during this time.[144] Patients undergoing methadone maintenance therapy exhibited significant changes in sleep architecture compared with control subjects, including decreases in total sleep time, slow wave sleep, and REM sleep, with an increase in stage 2 sleep.[144] Similar to patients with chronic pain, methadone-maintained patients experienced hyperalgesia when pain tolerance was tested using cold pressor techniques.[145] Additionally, a weak but significant correlation between methadone blood concentration and central sleep apnea was found.[144,146] As the number of patients undergoing methadone maintenance therapy increases, the likelihood that these patients will require treatment for either acute or chronic pain also increases. This duality of diagnosis can pose a problem because drug tolerance in these patients is not limited to methadone but extends to different opiate medications, such as morphine.[145,147] These changes in pain sensitivity and tolerance require clinicians to administer a larger quantity of drug more frequently to effect adequate pain control, thereby increasing the risk of respiratory complications.[145,147] In these patients, careful titration of dosage, with concomitant close monitoring of respiratory function, is essential.

The foregoing overview illustrates that opiate-induced respiratory depression varies for subgroups of patients. The acknowledged limitations of such studies, and the ethical challenges to performing such studies, also can be read as opportunities for future research. As summarized by Orlov and associates[117]:

> [O]ur findings underscore the need for large, prospective, observational studies that incorporate validated screening tools, reliable diagnostic tests, homogeneous sample populations, standardized monitoring for operationally defined complications, and faithful recording of adverse events in order to reliably quantify risk.

EMERGING OPPORTUNITIES FOR RESEARCH ON OPIATES, SLEEP, AND PAIN

A unifying theme throughout this chapter is insufficient interaction between pain medicine and sleep medicine. For example,

the word *pain* does not appear in an otherwise excellent 2014 consensus statement[36] on how best to achieve the goals of the 2011 NIH Sleep Disorders Research Plan. In 2011 the Society for Anesthesia and Sleep Medicine (SASM)[148] was incorporated in the United States "to promote interdisciplinary communication, education and research in matters common to anesthesia and sleep."[149] This SASM mission aims to address the estimated 15 million to 20 million cases of surgical anesthesia in the United States per year[150] and the relevance of postsurgical pain disrupting sleep.[151] SASM has recently partnered with the International Anesthesia Research Society (IARS), and the IARS journal *Anesthesia and Analgesia* has established an editorial board position focused specifically on respiration and sleep.[152]

A better understanding of endogenous opioids may provide mechanistic insights into the neurobiology underlying states of hibernation[153] and opiate-induced torpor. Just as sleep and anesthesia are different states sharing some similar traits, states of torpor and states of hibernation share an intimate link with thermoregulation and energy balance. (Chapter 21 provides additional information on hibernation and seasonal triggering of torpor.) The opiate antagonist naloxone can prevent entry into and reduce the duration of hibernation.[154,155] As reviewed elsewhere,[156] hibernation-inducing factor is an 88-kDa polypeptide found in ground squirrels that binds to the delta opioid receptor. Induction of hibernation mediated by hibernation-inducing factor activation of delta opioid receptors was confirmed by the finding that the delta opioid agonist (D-Ala 2, D-Leu 5) enkephalin (DADLE) did induce hibernation.[156] Studies of hibernating, nonhuman primates also indicate an interaction among sleep, thermoregulation, and metabolic rate.[157] These findings encourage future research aiming to determine the extent to which opioid receptors modulate sleep, thermoregulation, and metabolic rate in human and nonhuman primates.

Substantial progress has been achieved in identification of the multiple brain regions and molecules regulating sleep and in elucidation of how levels of these neurotransmitters are altered by opiates.[7,158] Additional work is needed to characterize the effects of an extensive number of molecules including cannabinoids, oleamides, and resolvins/protectins,[159-161] which show promise for treating chronic pain[162,163] and altering states of sleep and wakefulness.[164,165]

CLINICAL PEARL

Opiates significantly alter states of sleep and wakefulness as well as control of breathing. The variety of opiate receptors and endogenous opioid neurotransmitters within numerous tissues emphasizes the myriad physiologic functions that are modulated by opiates. Opiates acting primarily through G protein–coupled receptors also have an impact on non–G protein–related functions, underscoring the potential synergy of opiates with a vast array of nonopioid compounds. Clinical syndromes requiring long-term narcotics are not cured but are managed. To minimize untoward side effects, changes in prescriptions for sedating or wakefulness-promoting medications must be made in concert with the prescriber of narcotic medications.

SUMMARY

Opiates are vital for the clinical management of acute and chronic pain. Avoiding the potential for addiction, respiratory depression, blunted wakefulness, and sleep disruption makes use of opiates a nexus for efforts to optimize patient care. Opiate-induced sleep disruption has been documented by studies using objective, polysomnographic measures of sleep. Opiates disrupt the temporal organization of sleep, and even in pain-free persons, sleep disruption promotes hyperalgesia. Opiates also blunt wakefulness and can produce dose-dependent states of torpor. Opiates blunt the ventilatory response to hypercarbia and hypoxia, prolong expiratory time, and suppress tidal volume, while increasing upper airway resistance. Opiate-induced respiratory depression can be synergistic with comorbid conditions commonly encountered in sleep medicine. Increased vigilance on the part of health care providers is indicated when opiates are part of a treatment plan for obese patients and for patients with obstructive and central apnea. In geriatric as well as pediatric patients, age-specific pharmacokinetics can enhance opiate potency and decrease opiate elimination. Among patients with chronic pain and with a history of substance abuse, a significantly increased incidence of sleep disorders has been documented.

Pathophysiology of Sleep-Wake Disturbances After Traumatic Brain Injury

Nadia Gosselin; Christian R. Baumann

Chapter Highlights

- Sleep-wake disturbances (SWDs), particularly fatigue, excessive daytime sleepiness, and pleiosomnia (an increased sleep need per 24 hours), are very common after traumatic brain injury (TBI), but their pathophysiology is poorly understood.
- The bulk of animal studies consistently show that TBI leads to modification in sleep-wake patterns, which suggests that the TBI itself causes a proportion of SWDs.
- Brain dysfunction, in animals and humans, includes impaired neurotransmitter signaling, changes in gene expression, altered circadian rhythms, cerebral hypometabolism, neuroinflammation, and hypopituitarism; all have been identified as potential contributors to the emergence and persistence of posttraumatic SWD.
- Other factors that may occur in association with TBI in humans are pain and psychiatric comorbidity, which can independently affect sleep-wake pattern after TBI. Prolonged use of sedatives/analgesics also was found to exacerbate SWD.
- The role of sleep in cognition, neuroplasticity, and neurogenesis is now well recognized, but increasing evidence suggests that sleep and its abnormalities after TBI influence recovery, on both a clinical and a neuropathologic level. Improving the current understanding of factors involved in posttraumatic SWD could lead to more specific and efficient interventions in this clinical population.

Traumatic brain injury (TBI) is the leading cause of death and disability among young adults in industrialized countries.[1] Incidence is estimated at up to 600 per 100,000 in the general population, and a majority of victims are young men entering their most productive years. TBIs often result in short- and long-term impairments that interfere with the return to normal life. Fatigue, excessive daytime sleepiness, pleiosomnia (an increased sleep need per 24 hours), and insomnia are among the most persistent and the most disabling symptoms after TBI. Chronic SWDs are reported by at least 50% of patients with TBI, but despite their high prevalence, the emergence and evolution of SWD are still poorly understood and probably involve interaction aong multiple causal factors.

This chapter is organized into three main sections, as follows: (1) an introduction to the diagnosis and the pathophysiology of TBI; (2) a survey of recent animal models that were specifically developed to characterize posttraumatic sleep-wake patterns; and (3) an update on human neuropathology data giving insights into potential pathophysiologic causes, physiologic factors, and influences of comorbid conditions that may contribute to SWD onset or maintenance. Other important sleep-wake disorders associated with TBI, not covered in this chapter, include insomnia, narcolepsy, sleep-disordered breathing, and sleep-related movement disorders; these are discussed in Chapter 99 and other subsequent chapters.

INTRODUCTION TO TRAUMATIC BRAIN INJURY

According to the definition proposed by the Demographics and Clinical Assessment Working Group of the International and Interagency Initiative, TBI is an alteration in brain function, or other evidence of brain pathology, caused by an external force.[2] In turn, alteration in brain function is defined as one of the following signs: any period of decreased level of consciousness, any loss of memory for events immediately before (retrograde amnesia) or after the injury (posttraumatic amnesia), neurologic deficits (e.g., weakness, loss of balance, change in vision, aphasia), or any alteration in mental state at the time of the injury (e.g., confusion, disorientation). Other evidence of brain pathology may include visual, neuroradiologic, or laboratory confirmation of damage to the brain. The diagnosis of TBI involves a severity assessment.[3] Generally, mild TBI is characterized by a short loss of consciousness (<30 minutes), a Glasgow Coma Scale (GCS) score between 13 and 15, and a short period of posttraumatic amnesia (<24 hours). Moderate TBI typically is associated with a loss of consciousness of 30 minutes to 24 hours, a GCS score between 9 and 12, and posttraumatic amnesia lasting 1 to 14 days.

Severe TBI generally is characterized by a loss of consciousness of more than 24 hours, a GCS score between 3 and 8, and posttraumatic amnesia persisting during several weeks.

Pathophysiology of Traumatic Brain Injury

Cerebral damage after TBI results from primary and secondary insults.[4] Primary insults result when the application of biomechanical forces causes local lesions (i.e., skull fracture, intracranial hematoma, lacerations, and contusions) or diffuse axonal injury. Secondary insults occur in the hours or days after the initial trauma as a consequence of neuronal hypoxia caused by several dysfunctions that alter the cerebral oxygen and glucose supplies.[5] Intracranial hypertension is the most common form of secondary insult. Both primary and secondary insults lead to neurochemical changes, such as an increase in extracellular excitatory amino acids (glutamate and aspartate),[6] which provokes excessive intracellular calcium influx, leading to free radical production, mitochondrial dysfunction, apoptosis, and inflammatory response.

Brain CT scan typically is performed in patients who present with TBI, particularly those with moderate or severe TBI, and is considered a good clinical tool for detecting focal lesions[7] that are mostly localized in the ventral and polar frontal regions and in the anterior temporal lobes.[8] However, TBI often is associated with diffuse axonal injury,[9] which is difficult to quantify by conventional imaging techniques. Rapid acceleration-deceleration of the brain generates traumatic shearing forces, ultimately leading to diffuse axonal injury. Diffusion tensor imaging, which allows the measurement of microstructural white matter integrity, showed white matter injuries in the corpus callosum and the internal capsule, as well as a global white matter loss, within 2 weeks after TBI that were mostly attributed to axonal swelling.[10,11] Neuroimaging findings in the acute stage of TBI are extremely variable from one patient to another in terms of severity and localization of lesions, with mild TBI generally causing no acute white matter lesions.[12]

TBI also may lead to permanent pathologic modifications of brain structures, which can explain some of the neuropsychiatric and cognitive dysfunctions observed in this population. In patients with chronic TBI, reduced gray matter may be observed, particularly in the hippocampus, but also in the frontal and temporal cortex, the thalamus, the basal forebrain, the anterior cingulate, the caudate nucleus, and the insula.[13,14] This long-term decrease in gray matter density is more severe in patients with lower initial GCS score or in those who presented with intracranial hypertension in the intensive care unit.[15] In these TBI subgroups of more severely affected patients, white matter degeneration can be observed in all of the major fiber tracts, including the corpus callosum, the cingulum, the superior and inferior longitudinal fasciculus, the uncinate fasciculus, and the brainstem. More severe disruptions in cortical and cortical-subcortical pathways were found to correlate with poorer cognitive functioning.[10,14]

Traumatic Brain Injury and Neurodegenerative Diseases

Several studies have drawn a parallel between a history of TBI and the later development of a neurodegenerative disease. The first evidence comes from epidemiologic studies, which showed that TBI increases the risk of developing Alzheimer disease or another dementia later in life by 50%, with more severe TBI associated with greater risk.[16] The link between TBI and Alzheimer disease is particularly important. Healthy axons contain amyloid precursor protein in high concentrations, and amyloid precursor protein markedly accumulates in damaged axons, most likely through impaired axonal transport, which in general leads to the production and accumulation of toxic proteins and peptides including amyloid-beta plaques and neurofibrillary tangles after TBI.[17] Other posttraumatic processes leading to brain network dysfunction and abnormal information processing also play a role in the generation of neurologic and neuropsychological impairment after TBI.[18]

Chronic traumatic encephalopathy, or dementia pugilistica, is a tauopathy caused by repeated TBI, most often sports concussion, that has recently emerged as a postmortem entity,[19] confirming the link between TBI and subsequent risk of neurodegenerative disease. Increased levels of alpha-synuclein protein, which is known to play an important role in the development of Parkinson disease and other neurodegenerative disorders, also have been detected in brain tissue samples from persons with a history of TBI.[20] In view of the probable role of TBI in the development of later neurodegenerative disease, it is not surprising that such injuries are reported to have chronic and long-term impact on brain functioning, including sleep-wake and circadian regulation.

Behavioral and Cognitive Consequences of Traumatic Brain Injury

After moderate and severe TBI, an alteration in the level of consciousness, followed by a period of delirium, confusion, agitation, and posttraumatic amnesia, generally is apparent when patients are in the awakening stage in the intensive care unit. Neurobehavioral impairments such as impulsivity, irritability, disinhibition, mutism, and apathy may be noted.[21] With regard to neuroimaging findings, the extent of functional and cognitive deficits observed in the post-acute period is highly variable among patients with TBI and depends on several factors, such as brain injury severity, location of focal lesions, severity of diffuse axonal injury, duration of posttraumatic amnesia, age, level of education, and preexisting conditions. Despite the variability of cognitive deficits, certain deficits are common, including arousal and alertness impairments, reduced information processing speed, impaired memory, executive dysfunctions, impaired language, and reduced self-awareness. Unfortunately, these impairments persist for longer than 1 year in 50% of patients with moderate and severe TBI, also may be observed in chronic mild TBI, and may lead to dependency in activities of daily living and problems with return to work or school.[22]

Biomarkers of Outcome after Traumatic Brain Injury

Several TBI studies have searched for sensitive and reliable markers of short- and long-term neurologic and functional outcome. The first group of studies supports that genetic factors influence functional outcome after TBI. Among the most-studied polymorphisms in the TBI population is the apolipoprotein (APOE) ε4 allele that was associated with poor outcome at 6 month after injury and with greater risk of later cognitive decline.[23] Preliminary evidence also suggests that functional polymorphisms of the brain-derived neurotropic factor (BDNF) and the catechol-*O*-methyltransferase (COMT) genes, involved, respectively, in brain

plasticity regulation and dopamine modulation, influence cognitive recovery after TBI.[24,25] Moreover, BDNF polymorphisms contribute to the regulation of slow wave sleep oscillations and hence non-rapid eye movement (NREM) sleep intensity in humans possibly explaining variability in SWD after TBI.[26] Other potential genetic biomarkers may potentially be related to circadian disorders. For instance, the expression of bone morphogenetic protein 6 (BMP6) coincides with melatonin levels.[27]

The second group of studies investigated proteomic markers of outcome. The serum level of the S100B protein is among the most extensively studied marker among the TBI patient population. It is known to predict unfavorable outcome in severe TBI[28] and also is sensitive and specific for intracranial lesions in mild TBI,[29] but changes in S100B serum concentration are not specific for TBI and can be observed in several other conditions, such as infection and with orthopedic injuries. Glial fibrillary acid protein (GFAP) is a protein specifically expressed in astrocytes and is a well-known marker of central nervous system pathology. In a study that included 94 patients with mild TBI, GFAP serum level at admission predicted return to work and functional outcome.[30] A study in mice suggested that GFAP expression and microglial cell activation are increased in the reticular thalamic nucleus preceding sleep disturbance, 4 weeks after TBI.[31] No sufficient evidence, however, is available on how these proteins might affect sleep-wake behavior after TBI.

PATHOPHYSIOLOGY OF POSTTRAUMATIC SLEEP-WAKE DISTURBANCES

Surveyed in this section are recent animal models that were specifically developed to improve the current understanding of posttraumatic sleep-wake patterns. Also reviewed are potential pathophysiologic causes, physiologic factors, and influences of comorbid conditions that may contribute to SWD onset or maintenance. Figure 25-1 presents an integrative model of potential contributors to posttraumatic SWD.

Experimental Models of Traumatic Brain Injury and Studies of Sleep-Wake Behavior in Animals

So far, only few animal studies have explored posttraumatic SWD. This limitation might be explained by at least two main reasons: apart from the fact that posttraumatic SWD have not been a focus of major interest for many years, combining trauma and electrophysiologic recordings in animals is challenging. In addition to the scarcity of systematic studies in animals, the few available studies applied different TBI models that lead to different pathologic mechanisms and to different lesions at cortical and subcortical levels. A summary of findings in animal models of posttraumatic SWD is presented in Table 25-1. Models of injury included fluid percussion and weight drop with acceleration and deceleration. Both mice and rats were studied, and outcomes were evaluated using different methods (electroencephalography [EEG]/electromyography [EMG] or automated locomotor rhythm analyses) and observed within different time windows.

Fluid Percussion

One group of investigators used a midline fluid percussion injury model in male mice.[32] In this model, craniotomy is performed, and then the insult is inflicted by application of a fluid pressure pulse to the dura. It has been shown that midline fluid percussion injury leads to bilateral cortical alterations associated with direct axial movement of the lower brainstem, along with changes in blood pressure, brief respiratory arrest, increased craniocerebral pressure, decreased cerebral perfusion pressure, reduced cerebral blood flow, and increased cerebral vascular resistance, and has therefore been interpreted as a good model for human TBI.[33] Midline fluid percussion injury led to a marked increase in sleep within the first 6 hours after trauma, as assessed by a noninvasive, piezoelectric cage system.[32] In a subsequent study and by applying the same methods, these investigators could not identify persistent SWD 2 to 5 weeks after injury.[34] EEG recordings were not available.

Lateral fluid percussion injury belongs to the most established and commonly used models to evaluate mixed focal and diffuse brain injury, because it is reproducible and recapitulates many injuries observed in humans.[35] EEG/EMG recordings after lateral fluid percussion injury in mice were performed by another group.[36] The behavioral data from days 8 to 12 after trauma indicated that TBI persistently impairs the ability to sustain wakefulness. The brain-injured mice exhibited more wake to NREM, NREM to wake, and rapid eye movement (REM) to wake transitions in comparison with sham injury control animals, indicating a higher fragmentation of behavioral states. In a recent study that used a similar protocol in rats, moderate TBI led to a decreased ability to maintain consolidated wake bouts during the active phase, and this observation was made for 6, 9, 19, and 29 days after injury.[37]

Controlled Cortical Impact Model

One study performing EEG/EMG recordings within the first 3 days after controlled cortical impact injury in mice reported a reduction in wakefulness and shorter wake bouts during the active period after trauma but not in control animals.[38] This TBI model permits better control over mechanical factors because a controlled impact is delivered to the intact dura by a strictly controlled compressed air-driven metallic piston, causing deformation of the underlying cortex.[33] It leads to diffuse axonal injury and other pathologic alterations in subcortical areas, cerebellar structures, midbrain, and brainstem.

Weight Drop Model

In a recent study,[39] a closed-head mouse TBI model using a weight drop system was applied in adult mice, compared with mice subjected to sham surgery. Sleep was recorded by EEG/EMG starting 14 to 16 hours after injury. Results showed that mild TBI decreased long bouts of wakefulness in the first 24 hours after mild injury, similar to findings reported independently by other studies,[38] suggesting an altered capacity to sustain wakefulness after TBI. In addition, some studies adopted a closed-impact acceleration TBI rodent model with a physical hit to the skull with subsequent acceleration-decelerations mechanisms, which also allowed for EEG/EMG recordings (Noain et al., unpublished results). Briefly summarized, a blow from a falling metal rod onto the exposed rat skull, which is placed on a thick foam pad, led to acceleration mechanisms similar to those in human TBI and to brain compression, with subsequent widespread histopathologic changes including diffuse axonal injury, particularly in the corpus callosum, midbrain, cerebral and cerebellar

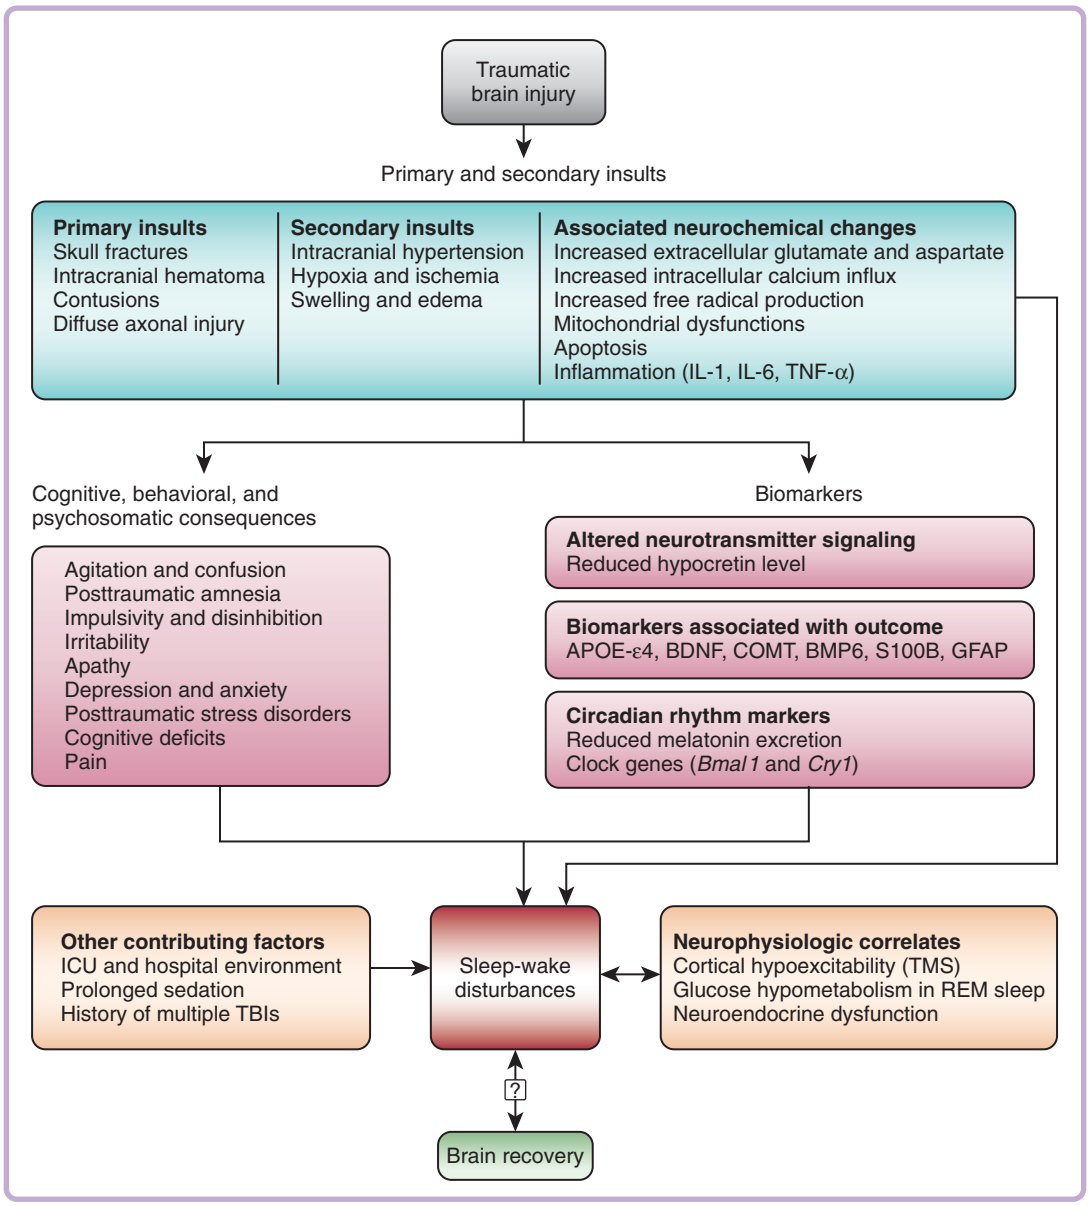

Figure 25-1 Integrative model of potential contributors to sleep-wake disturbance (SWD) after traumatic brain injury (TBI). All potential contributors to SWD after mild, moderate, or severe TBI are included. TBI causes primary and secondary insults that may directly influence sleep-wake patterns, but these injuries also have cognitive, behavioral, and/or psychosomatic consequences known to increase the risk of SWD. Several biomarkers have been associated with outcome, and an increased risk of SWD has been identified for certain of these markers. Other significant contributing factors are environment, medication, and history of multiple TBIs. SWDs have been associated with physiologic changes in patients with TBI, more specifically, cortical hypoexcitability, reduced glucose metabolism in rapid eye movement (REM) sleep, and neuroendocrine dysfunction. Posttraumatic SWDs possibly influence brain recovery after TBI. peduncules, and brainstem.[33] In the Noain et al. study, rats that were subjected to TBI exhibited an increase in NREM sleep at 1 month after injury, and in contrast with the latter study, sleep was less fragmented.

In conclusion, different models of rodent TBI have been used to examine posttraumatic SWD, both behaviorally and by means of EEG/EMG recordings. This heterogeneity of applied methods probably is responsible for the somewhat inconclusive results so far. Nevertheless, most studies found an increased amount of sleep and a reduction of the capability to maintain wakefulness in the first few days, but also 2 to 4 weeks after TBI. Issues to be investigated in the future include whether this observed increase in sleep after TBI is a mere reaction to the trauma and consecutive disturbed signaling within sleep-wake modulating pathways, or whether sleep is critical for recovery.

Inflammation Mediators from Animal Studies

Mediators of inflammation that are secreted as a result of TBI are important potential contributors to SWD. Acute inflammatory response occurring after TBI is characterized by an increase in interleukin 1 (IL-1), interleukin 6 (IL-6), and tumor necrosis factor alpha (TNF-α). Proinflammatory cytokines IL-1β and TNF-α are known to increase sleepiness, prolong duration of slow wave sleep, and increase EEG delta power.[40] TNF-α also is known to inhibit melatonin synthesis and hypocretin (orexin) activity in rats,[41,42] which can have a significant impact on sleep and wakefulness. To date, only one mouse study has suggested an association between proinflammatory cytokine IL-1β level and increasing sleep duration in the hours following a mild TBI.[32] The investigators argued that increased sleep in their TBI mice may result from the inflammatory response associated with the secondary injury, but this association needs to be confirmed in future studies.

Impaired Neurotransmitter Signaling in Animal Models of Traumatic Brain Injury

Brain structures, especially the hypothalamic, midbrain, and brainstem networks that are involved in sleep, wake, and circadian rhythmicity, can be impaired or damaged in a

proportion of patients with TBI, potentially explaining some forms of SWD observed in this population. In this line of thought, consecutive impairment of neurotransmitter signaling would contribute to altered regulation of behavioral states.

Some studies performed intracerebral microdialysis after controlled cortical impact in mice (as described earlier) and found that hypothalamic hypocretin levels were depressed.[38] Furthermore, the associations between hypocretin levels and wakefulness were diminished. Abnormal hypocretin dynamics were not associated with acute loss of hypocretin neurons but with hypothalamic astrogliosis. Lim and colleagues, who performed fluid percussion injury in mice (see earlier), measured c-Fos protein in the lateral hypothalamus, where the hypocretin neurons reside.[36] Mice with TBI exhibited significantly decreased hypocretin neuronal activation during wakefulness but, again, normal hypocretin neuron numbers, suggesting that nonfatal injury in these animals primarily affects hypocretin physiology rather than marked cell loss.

In addition, one study investigated the immunoreactivity of hypocretin-1 receptors after murine TBI, and the reporting authors found transiently increased immunoreactivity in the surrounding penumbra of the injury.[43] Again, all of these results suggest that that hypocretin and its receptors may play a role in behavioral abnormalities after TBI, but the exact nature of dysfunctional hypocretin signaling and its pathophysiologic impact remain elusive thus far.

As suggested by the experience of the Noain group of investigators, mentioned previously (Noain et al.; see earlier), additional observations in post-TBI rats point toward a critical role of the histamine system in pathologic sleep-wake behavior after trauma. Stereologic cell counts in these animals revealed fewer histaminergic neurons in the tuberomammillary nucleus, and the number of histamine-producing neurons was inversely correlated with the total amount of sleep per 24-hours period. These findings might be among the first initiatives for delineating the mechanisms behind sleep disturbances after TBI.

Impaired Neurotransmitter Signaling in Human Traumatic Brain Injury

For obvious reasons, human data on neurotransmitter signaling after TBI are sparse. The first hint toward dysfunctional hypocretin signaling after TBI appeared in the supplementary data of a publication on hypocretin levels in neurologic disorders, showing pathologically decreased hypocretin levels in the cerebrospinal fluid (CSF) of some brain-injured patients.[44] A systematic approach in prospectively assessed CSF from patients with TBI within the first 4 days after trauma confirmed a massive decrease in hypocretin levels, similar to that in narcolepsy patients.[45] Several months later, however, hypocretin levels mostly had recovered to normal (Figure 25-2).[46] Altogether, these CSF-based results suggested that impaired signaling of wake-promoting hypocretin neurons may at least contribute to decreased arousal after TBI.

A pilot study in four deceased patients with fatal TBI reported a significant 27% loss of hypocretin neurons in the hypothalamus.[47] Similarly, in 12 brains from patients who died of fatal TBI, a significant 21% loss of hypothalamic hypocretin neurons was documented.[48] The most marked cell loss (41%), however, involved the wake-maintaining histamine-producing neurons in the tuberomammillary nucleus. Again, these data suggest that damage to this susceptible and exposed posterior hypothalamic area might be involved in the SWD we often see after TBI.

Levels were measured 1 to 4 days after trauma (acute phase; $n = 27$) and 6 months later (follow-up; $n = 21$). *Lines* connect hypocretin values from the same patient ($n = 15$). Many patients had undetectable levels in the acute phase (plotted as 0). In all patients, levels recovered toward normal, but in some patients, they remained low. Cortical Hypoexcitability and Transcranial Magnetic Stimulation

As suggested earlier, lesions to midbrain or brainstem structures presumably could lead to posttraumatic SWD. One group of investigators used transcranial magnetic stimulation (TMS) in humans to determine whether SWDs after trauma are linked to pathologic excitability of the cerebral cortex.[49] The study included patients with TBI demonstrating excessive daytime sleepiness, fatigue, or increased sleep need and appropriate control subjects. Only in those patients with objective excessive daytime sleepiness (as confirmed by multiple sleep latency tests) were correlates of cortical hypoexcitability found. The investigators concluded that this finding on a cortical level might reflect the deficiency of the excitatory hypocretin system. In fact, earlier functional imaging studies showed that brain perfusion abnormalities, as assessed by single photon emission computed tomography (SPECT), are present predominantly in the midbrain structures and less so in cortical areas.[50]

Neuroimaging of Sleep

Functional neuroimaging comprises noninvasive techniques that allow exploring patterns of brain activation during wakefulness and sleep in humans. Although some studies using functional neuroimaging during sleep that included normal control subjects were published in past years, only one study was recently performed in persons with mild TBI.[51] That study included five consecutive in-laboratory polysomnographic recordings in 14 military veterans with a history of blast exposure and/or mild TBI (42.6 ± 26.9 months after injury) using [^{18}F]-fluorodeoxyglucose positron emission tomography (FDG-PET) during wakefulness, REM sleep, and NREM sleep. After controlling for effects of posttraumatic stress disorder, it was found that these patients exhibited

decreased glucose metabolism during wakefulness and REM sleep in the amygdala, hippocampus, parahippocampal gyrus, thalamus, insula uncus, culmen, visual association cortices, and midline medial frontal cortices when compared with control subjects (other veterans). Hypometabolism was found despite normal sleep architecture. These findings suggest that blast exposure and/or mild TBI may produce long-lasting neural effects that can be observed during both wakefulness and REM sleep, but further studies are needed to understand how these brain metabolic changes may explain persistent SWD.

Circadian Rhythms

One factor potentially contributing to SWD is the presence of alteration in the circadian timing system. Specifically, irregular circadian rhythms are known to be translated into increased daytime sleep, reduced nocturnal sleep, and fragmented sleep.[52] Circadian disruption may occurs when the main biologic clock of the hypothalamus is not synchronized to the 24-hour day and/or when it produces a circadian signal too weak to entrain the peripheral clocks of the brain and body. Short (acute phase) and long-term studies were conducted after TBI, and it is obvious that the paucity of literature necessitates caution in interpreting the following data.

Circadian Studies in Acute Traumatic Brain Injury

Thus far, only a few studies have investigated melatonin, cortisol, and body temperature rhythms, three well-known markers of circadian rhythms, in analgosedated patients with TBI while they were hospitalized in intensive care units. In a study performed in three patients with TBI and eight patients with other acute neurologic injuries, an absence of circadian rhythms was found for plasmatic melatonin, plasmatic cortisol, and body temperature.[53] When results were compared with those for critically ill patients without neurologic injury, alteration in circadian rhythms was greater in patients with brain lesions. These results suggest that brain injuries are in part responsible for altered circadian rhythms in intensive care units. In another study,[54] reduction in serum melatonin concentration was observed in addition to irregular circadian cycles in eight sedated patients with TBI, and these alterations were correlated with brain injury severity. Using microdialysis, an absence of cortisol circadian rhythm also was found in 10 patients with severe TBI under analgosedation.[55] Among mechanisms that may explain the absence of circadian rhythms in critically ill brain-injured patients is a cerebral lesion in the suprachiasmatic nucleus, because this region is known as the master clock that synchronizes most endogenous circadian rhythms.[56] Other possible causes include an altered pattern of light exposure (such as with too-little contrast between day and nighttime light exposure),[57] hypoxia,[58] and anesthesia/sedation.[53]

Circadian Studies in Post–Acute Traumatic Brain Injury

In a preliminary study performed in an intermediate care unit, actigraphic sleep-wake cycle and urinary melatonin circadian rhythm (measured hourly for 26 consecutive hours) were evaluated in nine nonsedated patients with severe TBI.[59] Nocturnal 6-sulfatoxymelatonin excretion showed an increased nighttime concentration (13.0 ± 17.9 ng/mL) beyond daytime concentration peaks (3.0 ± 5.2 ng/mL). Despite the presence of melatonin circadian rhythm, only two of the nine patients exhibited a consolidated sleep-wake cycle, which suggests that a nonconsolidated sleep-wake cycle is not due to an absence of melatonin circadian rhythm. Such study design is an example of a method that could be used for future investigations of circadian rhythm alterations in acute and postacute TBI.

Circadian Studies in Chronic Traumatic Brain Injury

Several case studies reported circadian rhythm disturbances associated with chronic TBI (see Chapter 99 for more details), and two studies specifically investigated salivary dim-light melatonin onset in patients with chronic TBI. The first study reported no group difference in the timing of nighttime melatonin onset, but a high variability among the subjects was noted.[60] A second study conducted by the same investigators found lower levels of evening melatonin production in patients with mild to severe TBI than in control subjects, but again, no changes were found for dim-light melatonin onset[61] (Figure 25-3). Because saliva melatonin concentration was measured only for 6.5 consecutive hours during the evening (i.e., from 6:00 PM to 12:30 AM) in this latter study, it was not possible to determine whether a phase delay of melatonin secretion could explain the reduced melatonin production in the TBI group.

Clock Genes

More recently, it has been hypothesized that circadian rhythm disruption after TBI is mediated by changes in expression of clock genes in the suprachiasmatic nucleus and hippocampus. It was found that in rats with fluid percussion–induced TBI, in comparison with sham-operated ones, the circadian expression of two key clock genes (i.e., *Bmal1* and *Cry1*) was altered in both the suprachiasmatic nucleus and the hippocampus.[62] In this study, altered daily rhythm of locomotor activity coincided with the deregulation of clock genes. The investigators suggested that a disturbance in the transcriptional-translation

feedback loops that modulate circadian timing could be induced by TBI. Obviously, the role of these genes needs to be confirmed in humans (see Chapters 26 to 31 for more information on genes in relation to sleep and circadian rhythms).

Neuroendocrine Dysfunctions

Neuroendocrine dysfunctions, mostly hypopituitarism, are common in patients after TBI. The prevalence is estimated at 15% to 68% in the acute phase of TBI, with the highest prevalence among persons with moderate and severe TBI, but tends to decrease over the first year after the injury.[63] Chronic hypopituitarism may lead to growth hormone and gonadotropin deficiency and to hypothyroidism. These alterations in neuroendocrine functioning are important to consider in the pathophysiology of SWD after a TBI, because bidirectional interactions between hormonal secretion and sleep are well documented.[64] Among the most important hormonal disturbances in this context is the growth hormone deficiency that was found to be closely associated with increased slow wave sleep and EEG delta power but with worsened subjective sleep quality and sleepiness. To date, few studies have investigated neuroendocrine changes in relation to sleep alterations and fatigue after TBI, and no clear evidence exists for a role of hypopituitarism and SWD or fatigue in the TBI population. In one study, patients with TBI reporting fatigue exhibited an overall higher prevalence of growth hormone deficiency than that for patients not reporting fatigue.[65] In another study, however, no correlation was observed between abnormal endocrine function and fatigue in a sample of 119 patients with TBI tested at least 1 year after injury.[66] In these two studies, sleep was assessed with questionnaires, and no objective measures of sleep were performed. Further studies are indicated to investigate whether neuroendocrine dysfunctions among patients with TBI explain not only subjective evaluation of sleep quality but also abnormal polysomnographic findings in this population.

Effects of Prolonged Sedation

Sedative and analgesic agents are commonly administered to patients with severe TBI admitted to the intensive care unit for prolonged periods regardless of the patient's specific circadian rhythm. These agents are used to prevent agitation, facilitate mechanical ventilation, and reduce pain and also may improve intracranial pressure and cerebral perfusion pressure. Still not clear, however, is whether sedation and analgesia share the restorative properties of sleep. Some studies have shown that prolonged sedation with propofol does not result in sleep deprivation: After a 12-hour infusion of propofol followed by withdrawal, rats did not show the typical increase in slow wave activity that occurs in response to sleep deprivation.[67] Controversial results, however, were reported for isoflurane anesthesia and its recovery effect.[68,69] In any case, sedation and analgesia have adverse effects on circadian rhythms, particularly when these agents are not administered during biologic night—that is, when they are given during the day, they impair the sleep-wake cycle mechanism more potently than when they are administered during the night.[70] How sedative and analgesic agents interact with an injured brain to promote the development of sleep and circadian rhythm disorders is still not well understood, but one study reported greater alteration in circadian rhythms among patients with neurologic injury (traumatic and nontraumatic injuries such as stroke) under analgosedation than among those without neurologic injury.[53] For more information on mechanism and effects of opioid analgesia on sleep, see Chapter 23.

Repetitive Traumatic Brain Injury

In many people with TBI, a presumed underlying pathologic process involves multiple lifetime traumatic injuries, particularly among military personnel and contact sports athletes. Repetitive acceleration and deceleration forces directed to the brain may cause chronic traumatic encephalopathy, but the underlying pathophysiology is unknown.[71] Increasing evidence indicates that repetitive TBI accentuates residual symptoms; for instance, multiple TBIs have been found to be associated with a higher risk for suicide.[72] Using patient self-report measures and clinical interviews, a recent study showed that repetitive TBI increases the severity of posttraumatic SWD, namely, insomnia.[73]

To characterize more fully the clinical entity of chronic traumatic encephalopathy and its consequences, a novel mouse model was introduced whereby a series of 6 concussive impacts were delivered daily, for 7 days. This model allowed the comparison of groups of single-injury and sham-injury control animals.[74] EEG/EMG was recorded at 1 month after injury for a period of 24 hours; animas in the single- and repetitive-TBI groups exhibited a reduction in NREM sleep, more NREM sleep fragmentation, and an increase in wake time in comparison with control animals. Moreover, EEG spectral analysis during NREM sleep demonstrated reduced power for very low frequencies (1 to 2 Hz) and increased power in the theta band in single- and repetitive-TBI groups compared with the control group. Still needed are larger studies to support these human and animal observations that repeated trauma leads to a higher SWD burden, not only in relation to insomnia but also in association with other SWDs.

Pain

A case–control study showed that both pain and SWD are prevalent after TBI, and that pain was strongly associated with insomnia.[75] Anxiety, depression, and pain influence sleep quality; however, only anxiety and pain seem to explain 32% of the variance in the sleep quality assessments.[76] Conversely, after multiple stepwise analyses controlling for many factors, another study reported that depression mainly accounts for the poor sleep quality complaints as assessed by the Pittsburgh Sleep Quality Index.[77] Such discrepancy in findings is not surprising, because chronic pain is multifactorial; it is a frequent comorbid accompaniment of TBI and is reported to be independent of posttraumatic stress disorder and depression in brain-injured patients.[78] The interaction between pain and mood on the one hand and long-term outcome on the other deserves studies with larger sample sizes, taking into account the heterogeneity of the population under investigation. It is likely that many factors in addition to pain contribute to the different patterns of SWD within the first weeks after trauma, with more insomnia at the acute phase and a higher prevalence of disorders of arousal such as sleepiness or increased sleep need in the chronic post-TBI phase.[79]

In view of the probable impact of pain on sleep quality, one group of researchers aimed to identify how pain affects sleep quality and sleep microstructure using quantitative and high-temporal-density EEG analysis.[77] Compared with patients with TBI not afflicted by pain, those with pain

showed increased rapid EEG frequency bands (9 to 50 Hz), mostly during REM sleep, and beta bands (16 to 30 Hz) in NREM sleep. The specificity of this phenomenon remains to be demonstrated, because intrusion of fast EEG activity in sleep of TBI patients with pain is not an exclusive phenomenon. Such differences also might reflect altered nociceptive processing at the central nervous system level, exacerbation of hypervigilance, and presleep cognitive arousal, as seen in the sleep of chronic pain patients.

Psychiatric Comorbid Illness

Approximately 65% of patients with TBI suffer from at least one psychiatric disorder, with depression, anxiety, and posttraumatic stress disorders being among the most common.[80] The associations between these psychiatric disorders and sleep disturbances, mostly insomnia, have been well described in the non-TBI population.[81] In agreement with this strong association, sleep-wake disturbances are included among the diagnostic features of major depressive disorder, generalized anxiety disorder, and posttraumatic stress disorder.[82]

For instance, most studies that investigated the prevalence of comorbid SWD and psychiatric syndromes among patients with TBI consistently found a higher burden of psychiatric disorders among those with sleep complaints than among those without sleep complaints. For example, in two different cohort studies of chronic TBI, depression and anxiety symptoms were found to be among the variables that significantly contributed to the prediction of the presence of insomnia syndrome.[83,84]

Still poorly understood, however, is how psychiatric disorders interact with TBI in the emergence and/or the persistence of SWD. Recent studies point to the predictive role of SWDs in the emergence of mental health problems. One retrospective study in 443 patients with mild TBI showed that reporting sleep complaints at 10 days after injury is associated with a 9.9- and 6.3-fold increased risk of feeling depressed at 10 days and 6 weeks, respectively.[85] Similarly, it was observed that onset of sleep disturbances within 3 months of injury predicted emergence of symptoms of depression and anxiety 12 months after TBI.[86] The role of sleep disturbances in the development of posttraumatic stress disorder and depression was recently confirmed by a large cohort study of 29,640 U.S. Navy and Marine Corps men, in whom sleep problems mediated 26% of TBI's effect on development of posttraumatic stress disorder and 41% of its effect on development of depression.[87] The specific mechanism underlying the link between sleep disturbances and the development of depression, anxiety, or posttraumatic stress disorder remains to be investigated.

SLEEP AND BRAIN RECOVERY

The role of sleep in memory and neural plasticity is now increasingly recognized.[88] In fact, sleep is known to optimize the consolidation of memory by strengthening new synapses. More recently, sleep has been shown to have a crucial role in neurogenesis.[89] Indeed, chronic sleep deprivation or fragmentation (>3 days) in rodents was associated with a 30% to 80% reduction in hippocampal cell proliferation and with a decrease in the percentage of cells that mature and develop into adult neurons.[90,91]

Extrapolation of the significance of these findings to human TBI suggest that chronically restricted or disrupted sleep in persons with acute TBI should reduce learning abilities, cerebral plasticity, and generation of new neurons in their brain, particularly in the hippocampus. This association is particularly important in the context of brain injury, where recovery is dependent specifically on new learning, cerebral plasticity, and neurogenesis. In humans, SWDs have been associated with worse functional outcome in the acute stage of TBI, whereby consolidated sleep-wake cycle predicted resolution of posttraumatic amnesia,[92,93] and in the chronic stage of moderate and severe TBI.[94]

The question remains whether sleep abnormalities in the acute phase after TBI influence recovery, on both a clinical and a neuropathologic level. In a recent animal study, the impact of acute 6-hour sleep disruption after TBI was investigated in adult mice; no effect on recovery of neurologic and cognitive functions was found.[95] This study suggests that short-duration sleep disruption after relatively mild TBI does not affect functional outcome. Other studies, however, found that 24 hours of sleep deprivation in rats before TBI results in faster recovery.[96] Also, 24 hours of sleep deprivation after TBI was reported to reduce morphologic damage and to improve behavioral recovery in rats.[97] Furthermore, unpublished evidence suggests that both sleep induction and sleep deprivation immediately after TBI in rats improve functional recovery and histologic outcome (Morawska et al., unpublished results).

In an animal study, the reverse association between sleep disruption and recovery was found.[39] Genes associated with sleep regulation and neuronal plasticity were investigated in adult mice with mild TBI before and after two consecutive 6-hour periods of sleep deprivation during the light period of the day-night cycle. Quantification of messenger RNA levels was performed in the cerebral cortex and the hippocampus, and in a region incorporating the thalamus and the hypothalamus. In the hippocampus, sleep deprivation decreased the expression of *Arc* and *EfnA3* only in mice with mild TBI. In the thalamus-hypothalamus, sleep deprivation decreased *Homer1a* only in mice with mild TBI. These results point to an accentuated effect of sleep deprivation on sleep- or plasticity-related genes after mild TBI.

In addition, an EEG and magnetoencephalographic study in humans showed that sleep spindles may reflect recovery of consciousness and cognitive function after diffuse axonal injury, suggesting that some aspects of sleep—that is, pharmacologically induced sleep or sleep rebound—might underlie neuronal plasticity and clinical recovery after TBI.[98]

Altogether, and despite contradictory results in the previous literature, the possibility remains that some aspects of sleep may potentially influence recovery after TBI, and the challenge is to define the mechanism and how such an improvement would be mediated.

CLINICAL PEARLS

- Both TBI and comorbid conditions, such as pain and psychiatric disorders, are potential causes of posttraumatic SWD in the acute and chronic phases of injury.
- Acute SWD may adversely influence brain recovery after TBI, as well as contributing to comorbid posttraumatic symptoms.
- Identifying mechanisms associated with the pathogenesis of posttraumatic SWD and factors that contribute to the persistence of TBI can be expected to lead to improved management in the chronic phase.

SUMMARY

Fatigue, excessive daytime sleepiness, and pleiosomnia are common SWDs after TBI. Recently developed animal models have conferred new understanding of posttraumatic SWD; the translation of animal findings to human TBI suggests that specific factors are associated with the pathophysiology of TBI and contribute to emergence of SWDs. Consistent with animal models, an important decrease in hypocretin occurs in acute human TBI, which is reversed in the months after the injury. Prolonged use of sedative and analgesic in the intensive care unit, altered circadian timing, comorbid pain, anxiety, depression, and posttraumatic stress disorder are among the factors associated with the emergence and/or persistence of SWD after a TBI. How acute sleep disturbances and sleep disruption improve or impede brain recovery after TBI needs further investigation, but interesting preliminary observations suggest a role for an accentuated effect of sleep deprivation on sleep and/or the plasticity related to some specific genes after TBI. The differences observed between acute and chronic phases suggest that studies should be conducted within a longer time frame to elucidate TBI and SWD pathophysiology and derive best management strategies.

Genetics and Genomic Basis of Sleep

Chapter 26

Introduction: Genetics and Genomics of Sleep

Fred W. Turek; Ravi Allada

A section on the "Genetics of Sleep" was an important addition to the preceding edition of the *Principles and Practices of Sleep Medicine,* and inclusion of this new topic was heralded as signifying that the genetic control of the sleep-wake cycle had become an active area for sleep research, both for characterizing regulatory mechanisms underlying the control of the sleep-wake cycle and for elucidating the function(s) of sleep. The inclusion of the term "genomics" in the title of this section in the sixth edition of the book is a heralding event as well, in confirming that sleep researchers are beginning to take a systemwide genomic approach for investigating this interplay of genes and gene networks regulating the multiple phenotypes or traits that constitute the sleep-wake cycle. Indeed, as genetic and genomic approaches are being used for the study of sleep in diverse species from flies to mice to humans (see Chapters 28 to 30), the evolutionary significance of the many functions of sleep that have evolved over time is becoming a tractable subject for research as many investigators are bringing the tools of genetics and genomics to the sleep field. The complexity of the sleep-wake phenotypes and the difficulty in collecting phenotypic data on a large enough number of animals or humans to begin to unravel genetic mechanisms have been partly responsible for why few comprehensive attempts have been made to identify "sleep genes" beyond the circadian clock genes regulating the timing of sleep (see Chapter 27).

The focus on genetic and genomic approaches to sleep is predicated in large part on the notion that the mechanisms of sleep regulation are conserved from simple organisms highly amenable to genetic analysis such as the fruit fly and zebrafish to conventional rodent models and even humans (see Chapters 28 to 30). The best example of such evolutionary conservation comes from the discovery of the core circadian clock genes that regulate the diurnal sleep-wake cycle, as well as most, if not all, 24-hour behavioral, physiologic, and cellular rhythms. These core clock genes were first identified in fruit flies, employing mutagenesis and the screening of thousands of flies for mutant phenotypes, eventually leading to the finding of the same genes in mice and humans. Indeed, similar screens in rodents leveraging the simplicity and ease of monitoring a representative "output rhythm" of the central circadian clock from literally thousands of rodents in a single laboratory, such as the precise rhythm of locomotor activity or wheel running in rodents, also was a major factor in uncovering conserved molecular transcriptional-translational feedback loops that give rise to 24-hour output signals (see Chapter 27). The discovery of the core clock genes controlling the timing of sleep-wake cycles represents one of the great triumphs of behavioral genetics and serves as a road map to uncover the mechanisms of sleep homeostasis. The relatively recent search for sleep genes in flies has been an active area of study for only the past decade or so, and this approach is uncovering new sleep-related genes with clear mammalian orthologs.

In addition, substantial evidence has now accumulated demonstrating that deletion or mutations in many canonical circadian clock genes can lead to fundamental changes in other sleep-wake traits including the amount of sleep and the response to sleep deprivation.[1] The recent finding that different alleles of a core circadian gene, *per,* first identified in flies, can affect the homeostatic response to sleep deprivation and/or the amount of slow wave sleep (Chapter 30) argues that

uncovering sleep genes in flies will lead directly to changes in sleep-wake traits in mammals. As discussed in Chapter 29, on sleep genetics in rodents, one can argue that many circadian clock genes are also "sleep genes." As noted by Dijk and Landolt (Chapter 30), sleep is a rich phenotype that can be broken down into a wide variety of sleep-wake traits based on the electroencephalogram and electromyogram. Furthermore, the "genetic landscape" for regulating multiple sleep-wake traits clearly is going to involve hundreds of genes and integrated molecular neurobiologic networks.[2,3] Although early work by Valtex and colleagues using inbred strains of mice[4] and early human twin studies[5] provided considerable evidence of a strong genetic basis for some sleep-wake traits, little has been done to unravel the complex network of genetic interactions that must underlie this universal behavior in mammals. The fact that the environment and the subject's own volition also can have major effects on sleep-wake traits, particularly sleep duration in humans, also makes it difficult to uncover the underlying genetic control mechanisms. Indeed, although a large number of genome-wide association studies in humans have identified multiple genetic loci and genes involved in the regulation of a wide variety of physiologic systems and disease states, only recently has this approach been used to uncover sleep-wake genes (Chapters 30 and 31). Franken and colleagues pioneered the use of quantitative trait loci in recombinant inbred mouse strains, which has led to the identification of a small number of genes that are associated with specific sleep-wake properties[6] (see Chapter 27). More recently, the first attempt to record sleep in a large genetically segregating population of mice revealed considerable complexity to the genetic landscape for multiple sleep-wake traits.[2,3] Uncovering these loci and elucidating how gene-environment interactions contribute to different sleep-wake states are expected to not only reveal the molecular events underlying the sleep-wake cycle but also identify new targets for drug discovery. New therapies based on the genetic control of sleep may be particularly important for treating both genetically and environmentally based disorders of sleep (Chapter 31).[7]

Genetics and Genomics of Circadian Clocks

Chapter Highlights

- Circadian (near-24-hour) rhythms can be produced by individual mammalian cells in a self-sustaining manner. These rhythmic patterns result from coordinated daily oscillations in the transcription and translation of key clock component genes. The positive elements CLOCK and BMAL1 regulate transcription of the *Per* and *Cry* genes, forming the core feedback loop of the timekeeping mechanism.
- Interactions between these genes and their products, as well as other proteins, tune the clock and link it to other cellular pathways. The genetic clock also regulates a tissue-specific circadian program of gene expression.
- Rhythms in histone acetylation/deacetylation, chromatin modifications, and posttranslational changes are beginning to be explored, adding epigenetic elements to the circadian clock network.
- Signals from the suprachiasmatic nucleus and from behavioral states (sleep/wake or feed/fast) can also influence clocks in peripheral tissues.

Over the past three decades, remarkable progress has been made in elucidating the molecular substrates that underlie the generation of 24-hour rhythms in mammals. A major finding that has emerged over the past decade is that most cells and tissues of the body contain and express the core 24-hour molecular clock mechanism. Although normally coordinated, individual tissues and even cells are capable of producing sustained rhythms in isolation. These rhythms result from oscillatory expression of a core set of interrelated circadian genes. This chapter describes the genes expressed in cells of the hypothalamic suprachiasmatic nucleus and other oscillators and reviews the current understanding of the roles they play in this daily rhythmicity. In addition, in view of the homology of mammalian clock genes with those in the fruit fly, where appropriate, a discussion of the discovery of fly and mammalian genes is provided.

THE MAMMALIAN CELLULAR CIRCADIAN CLOCK

Several lines of evidence pointed to the suprachiasmatic nucleus (SCN) as the site of the master circadian "pacemaker," beginning in the 1970s. (For a discussion of central and peripheral circadian clocks see Chapter 38.) Destruction of the SCN abolishes circadian oscillations in the plasma concentration of cortisol[1] and in locomotion and drinking.[2] These oscillations are independent of inputs from the eye,[1] although an autonomous circadian clock had been demonstrated to exist within the eye that controls, among other functions, the shedding of rod outer segment disks.[3] Normal circadian rhythms can be restored to an SCN-lesioned animal by transplantation of fetal SCN tissue, but not by transplantation of fetal tissue from other regions of the brain.[4] Transplant into an SCN-lesioned animal of fetal tissue from the SCN of a circadian-mutant animal confers the short period of the donor,[5] indicating that the properties of the rhythm are determined by the SCN, rather than by other tissues or brain regions. Thus several lines of evidence point to the SCN as the site driving or controlling circadian behavior for mammals. More recent studies of rhythms in gene expression indicated that persistent rhythms can be observed in tissues throughout the organism, even in tissue explants kept in culture for extended periods.[6,7] The phase of these peripheral tissue rhythms differs from that of the SCN but nonetheless appears to be coordinated by the SCN. In SCN-lesioned animals, these peripheral rhythms persist but no longer exhibit the consistent phase seen in intact animals.[7] Some environmental manipulations, such as temperature cycles or restricted feeding, can alter the phase of peripheral rhythms.[8,9] In addition, studies confirm the presence of oscillations in gene expression throughout the body, with different phases in different tissues.[10-13] Loss of many of these rhythms is reported with SCN lesions. Of note, however, these studies cannot discriminate between a loss of rhythmicity by individual cells and a loss of synchronicity among the cells. Thus the roles of the SCN and of the peripheral oscillators in the mammalian circadian system continue to be defined.

CIRCADIAN CLOCK PROPERTIES AND CLOCK GENES

More than half a century ago, the formal properties of the circadian "clock" function had been well characterized. Among the 16 "empirical generalizations about circadian rhythms" defined by Colin Pittendrigh[14] were the following: Circadian rhythms are ubiquitous in living systems; they are endogenous; they are innate; they are not learned from or impressed by the environment; they occur autonomously at both cellular and whole-organism levels of organization; the free-running period of circadian rhythms is so slightly temperature-dependent that it is proper to emphasize its near-independence

of temperature; and the rhythms are surprisingly intractable to chemical perturbation. These six observations already suggest what is now definitely known to be the case: A cell-autonomous program of gene expression makes up the mammalian circadian "clock" that produces these rhythms.

How do individual cells generate rhythmic activity with a period of approximately 1 day? Many pacemaker neurons generate oscillatory activity, such as rhythmic patterns of action potentials, and these relatively rapid oscillations can be explained by the concerted action of a small number of ion channels. The much slower oscillations of the individual SCN neurons, however, are not likely to involve the same mechanisms. Pittendrigh's observations that circadian rhythms are not sped up or slowed down by changes in temperature and that they are relatively impervious to chemical perturbations similarly argue against such a neuronal mechanism underlying the generation of 24-hour oscillations. In fact, the finding that nonneuronal tissues (Pittendrigh's cell autonomy) can produce sustained circadian rhythms, as well as the prevalence of circadian rhythms in plants and unicellular organisms (Pittendrigh's ubiquity), argue against a neural process underlying circadian rhythm generation.

Indeed, it appears that the synthesis of proteins by each oscillatory cell is central to the mechanism for the generation of 24-hour rhythms. The initial evidence for this role is that application of protein synthesis inhibitors in the region of the SCN shifts the circadian phase of activity of animals by an amount and in a direction that depends on the time at which the inhibition is imposed.[15,16] A similar shift in the phase of vasopressin release from explanted SCN also results from inhibition of protein synthesis.[17] Thus gene expression is central to the generation of circadian oscillations.

As discussed in detail further on, gene expression profile studies, in which expression levels are sampled at regular time points in constant darkness (free-running conditions) focusing on the SCN and on peripheral tissues, reveal that approximately one third of the transcriptome is rhythmically expressed, even in peripheral tissues.[18-21] Reporter gene constructs combining genes known to be rhythmically expressed with luciferase (thereby allowing visualization of expression in culture by means of the luciferase-induced glow) demonstrated in rats and in mice that peripheral tissues are capable of self-sustained rhythms.[6,7] With so many genes exhibiting circadian expression, and with competent oscillators present in such a variety of tissues, one cannot assume that either rhythmic expression or expression in the SCN constitutes a valid criterion for a "clock gene." Identification of which genes are central to the generation and maintenance of circadian cycles thus represents a challenge.

A potential solution to the challenge of identification of clock genes (versus clock-controlled genes) is to refocus attention on the formal properties of the circadian system. Arnold Eskin and others promoted this conceptual framework in the late 1970s by characterizing rhythm properties as arising from the input pathway, the clock itself, or the output pathway[22] (Figure 27-1). As articulated for pharmacologic approaches (but equally valid for genetic ones), manipulations that produce phase-dependent shifts in the rhythm (a phase response curve), or changes in the phase response curve or the free-running period, are likely to be affecting the clock, or at least not affecting an output process.[23] Applying this logic, a genetic perturbation that alters the free-running period in constant darkness, or the phase response curve to light pulses, or the persistence of rhythmicity in constant conditions may be likely to be a perturbation in a clock gene, although no one alteration alone is necessarily a clock change (as opposed to input or output).

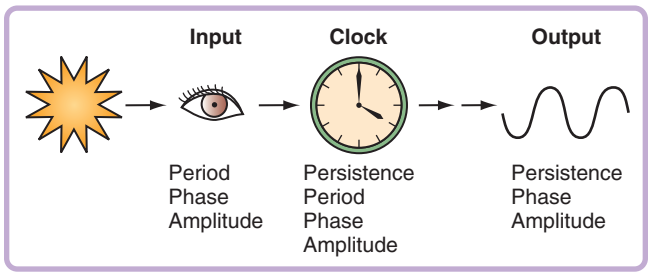

Figure 27-1 Classical View of Circadian System and Circadian Clock Properties. At minimum, the circadian clock system would have an input pathway by which entraining signals are received (light in this example), a clock mechanism, and output pathways. No single property of observed circadian rhythms is necessarily determined by the clock mechanism; these properties may be affected by changes in the input or output. However, when a mutation is observed to affect multiple properties of circadian rhythms, then that genetic change may most parsimoniously be attributed to a change in the clock mechanism itself.

Zatz[24] and Aronson[25] and their colleagues proposed more restrictive criteria: Null mutations should abolish rhythmicity; the gene's protein product level or activity should oscillate and be reset by light pulses; changes in amount or activity should result in phase shifts; and prevention of oscillation of protein levels/activity should result in loss of rhythmicity.[24] In the parlance of the field, these criteria would define a "state variable"—a rate-limiting element that itself defines the phase of the core oscillation. A self-sustaining clock would require at least two state variables,[26] although more clearly are possible. To date, no single gene in the mammalian system has satisfied all of the criteria for a state variable. Indeed, a hallmark of the mammalian circadian clock seems to be the multiple homologs of many genes that appear to play distinct but partially redundant roles. It may thus be that so-called state variable status is actually shared by related groups of genes in the mammalian system.

POSITIVE ELEMENTS

Clock

In the early 1990s, no genes in mammals had been identified as even possible candidate circadian clock genes, leading us to undertake a mutagenesis and screening in mice in an effort to identify mammalian circadian clock genes. For this, we used the C57BL/6J mouse strain, in which wild-type mice show robust entrainment to a light-dark cycle and exhibit a circadian period between 23.6 and 23.8 hours under free-running conditions in constant darkness (DD). In a screen for mutations of more than 300 progeny of mutagen-treated mice, one animal was found to have a free-running period of approximately 24.8 hours—more than 6 standard deviations longer than the mean.[27] In the homozygous condition, this mutation results in a dramatic lengthening of the period to approximately 28 hours, which usually is followed by the eventual loss of circadian rhythmicity (i.e., arrhythmicity) after 1 to 3 weeks in DD. The affected gene was mapped to mouse chromosome 5 and named *Clock*.[27,28] The *Clock* gene was cloned using a

combination of genetic rescue and positional cloning techniques. *Clock/Clock* mutant mice were phenotypically rescued by a bacterial artificial chromosome (BAC) transgene that contained the *Clock* gene, allowing for functional identification of the gene.[29] The *Clock* gene encodes a transcriptional regulatory protein comprising a basic helix-loop-helix DNA-binding domain, a PAS dimerization domain, and a Q-rich transactivation domain. The mutant form of the CLOCK protein (CLOCK Δ19) lacks a portion of the activation domain found in wild-type protein; thus, although it is capable of protein dimerization, transcriptional activation is diminished or lost. The PAS domain is named for the genes originally identified with this protein dimerization domain: ***p****er* (a fly clock gene), ***ARNT,*** and ***sim.*** *Clock* mRNA is expressed in the SCN as well as other tissues, but it has not been found to oscillate in a circadian fashion.[30]

Bmal1

The presence of the PAS dimerization domain in CLOCK protein suggested that it may form a heterodimer similar to that of PER and the protein product of another *Drosophila* clock gene, TIM.[31] A screen for potential partners for the CLOCK protein using the yeast two-hybrid system revealed that a protein of unknown function, BMAL1 (Brain and Muscle ARNT-Like 1), was able to dimerize with the CLOCK protein.[32] Creation of mice harboring a null allele of *Bmal1* (also referred to as *MOP3*) demonstrated the critical role of this gene in circadian rhythm generation. These mutant mice, while displaying light-dark–responsive differences in activity level, lose circadian rhythmicity immediately upon release in constant darkness.

Recently, additional actions of the CLOCK:BMAL1 heterodimer have become clear. Whereas *Clock* mRNA does not oscillate, its protein's nuclear versus cytoplasmic localization does so.[33] By studying the intracellular localization of CLOCK and BMAL1 in cultured fibroblasts of mouse embryos with mutations in different clock genes, and ectopically expressing the proteins, it was found that nuclear accumulation of CLOCK was dependent on formation of the CLOCK:BMAL1 dimer, as was phosphorylation of the complex and its degradation.[33] Other PAS domain–containing proteins failed to affect the localization of CLOCK, indicating that these posttranslational events are specific to the CLOCK:BMAL1 dimer.

NEGATIVE ELEMENTS

The *Period* Genes

The first identified gene (defined as a *Mendelian gene* as opposed to a sequenced, cloned gene) that encodes a clock component, *period,* denoted by the symbol *per*, was discovered in 1971 in *Drosophila* using a forward genetics approach consisting of chemically inducing random mutations in the genome, and detecting those mutations that affect circadian rhythms by screening the progeny of the mutagenized individuals for altered rhythmicity.[34] This approach has the advantage that no assumptions are made about the nature of the genes or gene products involved but is based on the presumed existence of genes that, when mutated, will alter rhythms in a detectable manner. At the time, this presumption of the existence of genes that regulate a complex behavior was considered radical but has proved to have been a field-defining moment.

Initially, three alleles of the *per* gene were identified by the process of mutagenesis and screening. Flies carrying these alleles had no apparent rhythm in either eclosion (emergence from the pupal case) or locomotion, or had either long (e.g., 29 hours) or short periods (e.g., 19 hours) for the rhythms of eclosion and locomotor activity.[34] It is important to note that the finding of three alleles with three different phenotypes made it possible to have confidence in the conclusion that the *per* gene encodes a protein that is a clock component. Had only an arrhythmic mutant been found, then the alternative explanation could be proposed that the lack of circadian behavior was secondary to another primary defect that did not lie in a clock component, such as in a clock output process. This approach of mutagenesis and screening also has been successful in identifying circadian clock genes in other organisms such as *Neurospora crassa*,[35] plants,[36] and cyanobacteria,[37] as well as mice. A discussion of these important findings, however, is outside the scope of this chapter.

Confirmation of the importance of the *per* gene as a central circadian clock component was made by the rescue of the mutant phenotype after introduction of the wild-type allele of the *per* gene into mutant flies.[38,39] The level of the mRNA transcript encoded by the *per* gene was shown to oscillate in a circadian fashion[40] as a result of transcriptional regulation,[41] and the levels of the PER protein were shown to lag the *per* mRNA levels.[42] In fact, shifts in the circadian phase can be evoked by the induction of PER protein under the control of a noncircadian promoter.[43] Thus many lines of evidence indicate that the *per* gene encodes a protein that is a clock component. Three orthologs of the *per* gene, *Per1, Per2*, and *Per3*, have now been identified in the mouse, and the levels of their mRNA also have been shown to oscillate with a circadian period.[44-48]

After the identification of CLOCK:BMAL1 dimerization, the ability of this heterodimer to regulate transcription was tested using a reporter construct based on the upstream regulatory elements of the *per* gene. The *per* gene of *Drosophila* contains an upstream regulatory element, the "clock control region," within which is contained a sequence needed for positive regulation of transcription, the E-box element (CACGTG).[49] CLOCK-BMAL1 heterodimers were found to activate transcription of the *Per1* gene in a process that requires binding to the E-box element.[32] The CLOCK-Δ19 mutant protein, however, was not able to activate transcription, consistent with the finding that exon 19, which is skipped in *Clock* mutant animals,[30] is necessary for transactivation. Thus CLOCK protein interacts with the regulatory regions of the *per* gene to allow transcription of the *per* mRNA and eventual translation of PER protein. A similar activation of transcription of the *tim* gene by the CLOCK-BMAL1 heterodimer also occurs in flies.[50] This positive regulation alone, however, will not produce an oscillation in *per* mRNA levels, which is known to be responsible for the oscillation in PER protein levels.[41] Findings that the *Clock* mutation dramatically decreases *per* gene expression also confirm the positive regulation of CLOCK:BMAL1 on *per* transcription in situ.[51,52] Mice with null mutations of *Per1, Per2,* or *Per3* alone display altered circadian periods,[53,54] whereas mice with both *Per1* and *Per2* null mutations lose circadian rhythmicity. *Per3* null mutant mice exhibit only a subtle alteration in rhythmicity, and *Per1/Per3* or *Per2/Per3* double mutants are not substantially distinct from the *Per1* or *Per2* single mutants. These

findings suggest there may be some compensation of function among the different mammalian *per* genes and raise the question of the significance of *Per3* for the generation of mammalian circadian rhythms.

Cryptochromes

Cryptochromes are blue light–responsive flavoprotein photopigments related to photolyases, so named because their function was cryptic when they were first identified. In mammals, two cryptochrome genes, *Cry1* and *Cry2,* have been identified and were found to be highly expressed in the ganglion cells and inner nuclear layer of the retina as well as the SCN,[55] and their messenger RNA (mRNA) expression levels oscillate in these tissues. Targeted mutant mice lacking *Cry2* exhibit a lengthened circadian period, whereas mice lacking *Cry1* have a shortened circadian period; mice with both mutations experience immediate loss of rhythmicity on transfer to constant darkness.[56-58] Thus, like the mammalian *period* genes, the cryptochrome genes appear to have both distinct (given their opposite effects on circadian period) and compensatory (given that either gene can sustain rhythmicity in the absence of the other) functions.

Because of their expression pattern, the cryptochromes were thought to be the long-unidentified mammalian circadian photoreceptors (see later); accordingly, light responses were examined in characterizing the null mutants. *Cry2* mutant mice exhibit altered phase-shifting responses to light pulses.[56] *Cry1/Cry2* double mutants exhibit impaired light induction of *Per1* in the SCN, whereas light induction of *Per2* in double mutants remains intact.[57,59] Neither *Per1* nor *Per2* exhibits persistent oscillations in expression in the SCN in constant conditions in *Cry1/Cry2* double mutants.[57,59] Thus, although the cryptochromes are not the mammalian circadian photoreceptor, they do appear to play a central role in the generation of circadian signals.

Further evidence for a central clock function is the finding that the cryptochromes appear to share a number of regulatory features with the *period* genes. In *Clock* mutant mice, the mRNA levels of *Cry1* and *Cry2* are reduced in the SCN and in skeletal muscle,[60] suggesting that the *cryptochrome* genes also are induced by CLOCK:BMAL1 transactivation. In experiments using mammalian (NIH 3T3 or COS7) cell lines, CRY1 and CRY2 were found by coimmunoprecipitation techniques to interact with PER1, PER2, and PER3, leading to nuclear localization of the CRY:PER dimer, as indicated by cotransfection assays with epitope-tagged proteins.[60] Luciferase assays indicate that CRY:CRY or CRY:PER complexes are capable of inhibiting CLOCK:BMAL1 transactivation of *Per1* or *vasopressin* transcription.[60] Thus the CRYs as well as the PERs are capable of a negative feedback function, inhibiting CLOCK:BMAL1-induced transcription.

MODULATORS AND OTHER COMPONENTS OF THE CLOCK

Timeless

How is the level of the PER protein regulated by the circadian clock? The first hint came from the identification of the *timeless* gene *tim*, which when mutated produces abnormal circadian rhythms in *Drosophila*.[61] The levels of the mRNA encoded by the *tim* gene oscillate with a time course that is indistinguishable from those of *per* mRNA.[62] The levels of the TIM protein lag behind those of *tim* mRNA by several hours,[63] similar to the finding with *per* mRNA and PER protein. The PER and TIM proteins form heterodimers[64] that are transported to the nucleus.[65] The finding that the heterodimer is transported to the nucleus suggested that it might be involved in the regulation of transcription of the *per* or *tim* genes. Indeed, recent experiments have shown that the transcription of the *per* and *tim* genes is repressed by the PER-TIM protein heterodimer.[50] This finding is very important because it demonstrates that the production of mRNA encoded by a clock component gene, the delayed accumulation of the encoded protein, and later feedback to the clock gene's promoter in the nucleus are able to explain the basic features of the circadian clock in *Drosophila*.

PER-TIM interactions are not sufficient, however, and the basic mechanism does not become clear until interactions with other clock genes are considered. In experiments using a luciferase reporter assay, the luminescent luciferase protein was expressed under the control of the promoter regions of the *Drosophila per* and *tim* genes. It was found that the fly homolog of *Clock*[66] was capable of driving expression of luciferase[50] in cells that have high endogenous levels of the *Drosophila* homolog of BMAL1, CYC (encoded by the *cycle* gene). The effect of the PER-TIM heterodimer on the ability of the CLOCK-CYC heterodimer to drive the transcription of the *per* and *tim* genes was tested by cotransfecting the encoding genes into the cells that expressed the luciferase reporter gene. Indeed, it was found that the expression of both the *per* and *tim* genes was reduced by their own protein products. This negative feedback has recently been found for a mammalian heterodimer consisting of homologs of the TIMELESS and PER1 proteins.[67]

Whether the mammalian *tim* homolog identified[67,68] actually represents an orthologous gene has been called into question.[69] This issue has been difficult to resolve, because gene targeting to create a null mutant resulted in early embryonic lethality. Differences in results obtained by different groups of researchers examining the oscillation of *Tim* expression could result from existence of both a full-length and a truncated protein, with only the full-length form oscillating.[70] Using antisense oligodeoxynucleotides directed against *Timeless* in rat SCN slice preparations results in a disruption of neuronal oscillations in vitro, suggesting a role in rhythmicity.[70] True functional homology of *Timeless* in mammals, however, remains to be demonstrated in vivo.

The *CASEin Kinase 1* Gene

The *tau* mutation of the hamster arose spontaneously in a laboratory stock.[71] The mutation is semidominant and shortens the period from 24 to 22 hours in heterozygotes and 20 hours in homozygotes. This mutation has been of great importance for several reasons. First, the *tau* mutation predated the *Clock* mutation and demonstrated that single-gene mutations could profoundly alter the circadian clock in mammals, just as in flies and *Neurospora*. Second, *tau* mutants display several other physiologic phenotypes such as alteration of the responses of males to photoperiod length[72] and effects of the estrous cycle in females,[73] which gave further insights into the importance of the circadian clock for other biologic cycles. Finally, the evidence that the SCN is indeed the site of the master circadian oscillator (see earlier) was demonstrated unequivocally using transplantation of the SCN that employed

the *tau* mutation. These manipulations also gave rise to the evidence necessary to conclude that the *tau* mutation encodes a protein that is a clock component. Unfortunately, the genetic tools needed for cloning this important and interesting gene were not available for the hamster, so its molecular identity could not be determined by conventional genetic mapping/positional cloning approaches.

Lowrey and colleagues were able to identify a genomic region of conserved synteny (a grouping of genes together on a chromosome), in hamsters, mice, and humans, that encompassed the *tau* mutation.[74] *Tau* was thus identified as being a mutation in the *Casein Kinase 1, epsilon* gene (*CK1e*), the mammalian ortholog of the *Drosophila doubletime* gene. Sequencing of the gene identified a point mutation that leads to altered enzyme dynamics and autophosphorylation state. In vitro assays demonstrated that CK1e can phosphorylate PER proteins, and that the *tau* mutant enzyme is deficient in this ability. Thus CK1e may lead to degradation of PERs, slowing the accumulation of PER in the nucleus and thus repression of CLOCK:BMAL1. The *Casein Kinase 1, delta* gene (*CK1d*) also has been implicated in mammalian circadian rhythmicity.[75-78]

Rev-erb alpha and *ROR*

Whereas the negative feedback of PER and CRY proteins on their own CLOCK:BMAL1-induced may be sufficient to explain the oscillations in expression of *Per* and *Cry* genes, the rhythmic expression of *Bmal1* with an opposite phase is not explained by this feedback. What regulatory elements produce the rhythmic transcription of *Bmal1*, with an antiphase relationship to the *Per*s? *Rev-erb alpha,* an orphan nuclear receptor, may act as the missing link. Its promoter region contains three E-boxes, and transcription is therefore positively regulated by CLOCK and BMAL1.[79] Its transcription is negatively regulated by PER and CRYs; *Rev-erb alpha* mRNA is at a minimum when PER2 is at a maximum, and it is constitutively expressed at intermediate levels in *Cry1/Cry2* or *Per1/Per2* double knockouts. REV-ERBa protein appears to drive the circadian oscillation in *Bmal1* transcription: The *Bmal1* promoter includes two RORE sequences (enhancer sequences that recognize members of the REV-ERB and ROR orphan nuclear receptor families), and *Bmal1* expression is drastically reduced in *Rev-erb alpha* null mutants.[79] Thus *Rev-erb alpha* may act to link the positive and negative regulatory signals of other clock genes to the transcription of *Bmal1*. In view of the importance of orphan nuclear receptors in regulating cellular metabolic properties,[80] interaction with circadian clock genes may, at the molecular level, form the links between circadian clocks and metabolic regulation, with important implications for health and disease. Such molecular links between circadian clocks and cellular metabolism also include a clock-metabolism feedback loop. CLOCK:BMAL1 activity is suppressed by a NAD^+-dependent deacetylase SIRT1, which is in turn regulated by the circadian control of NAD^+ biosynthesis.[81-84] See Bass (2012) in Selected Readings for more detail.

Rev-erb alpha also contributes to the differences between the phase of *Cry1* mRNA rhythms and that of other clock genes whose transcription is enhanced by CLOCK:BMAL binding to E-boxes. The *Cry1* gene has three candidate REV-ERB/ROR binding sites[85]; in vitro assays indicate that REV-ERBa binds to two of these sites. Luciferase reporter assays indicate that REV-ERBa protein can inhibit transcription of *Cry1* through binding at these two sites. REV-ERBb also appears to share some functional redundancy with REV-ERBa.[86]

Fbxl3 and *Fbxl21*

In addition to *Rev-erb* modulation of *Cry* genes (described earlier), other genes appear to modulate the activity of the Cryptochromes. The *Overtime* mutation in mice was identified in a mutagenesis screen based on a lengthened free-running circadian period.[87] The responsible mutation was ultimately localized to a known gene encoding the F-box protein *Fbxl3* but previously unknown to be involved in circadian rhythmicity. $Fbxl3^{OVTM}$ mutants appear to be functionally comparable to null mutants. FBXL3 protein leads to degradation of CRY1; the OVTM mutant protein is less effective in this capacity. Thus the period lengthening may be a direct result of a delay in degradation of CRY, effectively preventing the core cycle from restarting. Recently, the closely related protein FBXL21[88] has been found to function in a similar manner.[89,90]

NPAS2

NPAS2 (neuronal PAS family member 2) shares the closest homology with CLOCK of all identified bHLH-PAS family members. Null mutants for this gene exhibit altered circadian activity patterns, notably the absence of a "siesta" in later subjective night, but no dramatic alterations in circadian free-running period or persistence.[91] However, when *Clock* null mutants showed less dramatic phenotypes than for the Δ19 mutant,[92] the role of NPAS2 was reexamined. In the absence of functioning CLOCK, NPAS2 appears to be able to partially compensate.[93]

Dec1 and *Dec2*

Like other clock genes, *Dec1* and *Dec2* encode basic helix-loop-helix transcription factors that bind to E-boxes. DEC1 and DEC2 have been found to inhibit transactivation of Per by CLOCK and BMAL1.[94] DEC1 and DEC2 form dimers.[95] The inhibition of CLOCK and BMAL1 transactivation may be related to interactions with BMAL1 but also can be attributed to binding to (and thus possibly competition for) E-boxes.[96]

Recently, a human allelic variant in DEC2 has been linked with total sleep time.[97] This functional relationship has been confirmed in transgenic mice expressing the human *Dec2* allele.

Other Regulators of the Clock

The discovery of the core molecular machinery of the circadian clock has allowed identification of additional regulators of the circadian clock by characterizing proteins that interact with known clock components. For example, an RNA- and DNA-binding protein NONO and a subunit of histone methyltransferase complexes WDR5 were identified as interacting proteins and modulators of PER1. Knockdown of *NONO* using RNA interference (RNAi) in mammalian cells and *NONO* mutant in flies both disrupt circadian rhythms.[98] Another study later showed that NONO and PER1 are involved in the regulation of circadian gating of cell cycles via controlling the circadian expression of a cell cycle checkpoint gene *p16-Ink4A*.[99] Similarly, RACK1 (receptor for activated

C kinase 1) and PKCα (protein kinase C alpha) were found interacting with BMAL1 and modulating CLOCK-BMAL1 transcriptional activity. Knockdown of either PKCα or RACK1 by RNAi shortens circadian period.[100] Clock modulators identified by studying proteins interacting with known clock components also include E3 ligases Arf-bp1 and Pam, which are involved in the regulation of the degradation of REV-ERBa.[101]

Furthermore, high-throughput screening studies using the combination of luciferase reporter assays in cell-based systems with large-scale RNAi libraries also have identified many other genes that modulate the circadian oscillation of core clock genes. One study focused on known and predicted kinases as well as phosphatases and F-box proteins and identified 22 kinases, 7 phosphates (or regulatory subunits), and 6 F-box proteins as potential components of the clock.[102] Among those, casein kinase 2 (CK2) was shown to phosphorylate PER2 and regulate its nuclear accumulation and stability. Using a similar RNAi screening approach, Zhang and colleagues searched the entire genome and identified more than 200 candidates that strongly affected the circadian period or amplitude when knocked down.[103] As indicated by protein interaction network analysis, most of these identified candidates are directly or indirectly connected with the core clock components, suggesting that large-scale and complex interactions among the molecular clock mechanisms are likely to be involved in the regulation of circadian timing.

Finally, along with the accumulation of "-omic" (i.e., genomic, proteomic, interactomic, metabolomic) data sets, it recently became possible to predict clock components using in silico modeling approaches. The first computer-assisted study to identify clock components was performed by Anafi and colleagues.[104] These authors collected a number of genomewide data sets and established metrics that describe key features of core clock components, including (1) 24-hour oscillatory expression, (2) disruption of circadian rhythms when mutated or knocked down, (3) interaction with other core clock proteins, (4) ubiquity expressed in multiple tissues, and (5) conservation between vertebrates and flies. Although these clock features are not absolute, the core clock metrics allowed the investigators to use a machine learning algorithm to identify genes that share similar metrics with known core clock genes. The top identified genes include many that have already been implicated in the circadian clock machinery. In addition, a previously uncharacterized gene, *Gene Model 129* (*Gm129*), also was among the top candidate clock genes, and the investigators renamed it *Chrono*, for "*c*omputationally *h*ighlighted *r*epressor *o*f the *n*etwork *o*scillator." Validation experiments show that *Gm129* expression exhibits strong circadian rhythms in the liver, heart, and adipose tissue. GM129 protein interacts with the carboxyl terminus (C-terminus) of BMAL1 and suppresses CLOCK/BMAL1 transcriptional activity. Finally, free-running periods of activity are lengthened in *Gm129*-knockout mice. Of interest, the role of *Gm129* in the circadian clock network also was independently discovered using conventional biochemical approaches,[105] at roughly the same time of this in silico–assisted study. With the rapid growth of bioinformatics techniques and databases, it can be expected that computational approaches will be highly complementary to traditional biochemical approaches, contributing to a full understanding of the circadian clock network.

An important point is that many regulators of the clock also are key regulators in other cellular processes, including metabolism and redox homeostasis (such as *Rev-erb alpha* and *Sirt1*), cell cycle (such as *NONO*), cell signaling (such as *PKCα*), and many others. The interactions between clock and other cellular pathways are further supported by results from large-scale RNAi screen studies because pathway analysis suggests that the identified clock modulators are overrepresented for genes involved in insulin and Hedgehog signaling, the cell cycle, and folate metabolism.[103] Many of these pathways and key regulators that influence the circadian clock are themselves regulated by the clock. Taken together, these findings suggest that the molecular clock machinery is hardwired to diverse cellular processes and pathways, providing a basis for functional coordination of multiple pathways by the circadian clock.

OUTPUT REGULATION

Transcriptional Output of the Clock

As described earlier, the core clock components form a transcriptional and translational feedback loop, which produces a program of oscillatory gene expression involving roughly one third of the transcriptome. Much effort has been devoted to clarifying the details of how circadian transcriptome is regulated by the clock. Bioinformatics analyses of promoter regions of oscillatory genes in multiple tissues suggest enrichment of classical enhancer elements such as E-box and D-box.[106,107] Many of the clock-controlled, E-box–containing genes are themselves transcription factors, which are thought to be important for expanding the repertoire of clock-regulated transcription to a wide range of genes. Of interest, bioinformatics studies also have suggested that rather than a single E-box, an arrangement of two closely spaced (six to seven base pairs apart) E-box–like elements—namely, E1 and E2 elements—are critical for robust oscillations in many of the clock-regulated genes in both flies and mice.[108,109] Using chromatin immunoprecipitation (CHIP) combined with deep sequencing (CHIP-seq), one study characterized direct DNA-binding targets of BMAL1 in mouse liver.[110] A total of 2049 BMAL1 target–binding sites were identified, 60% of which exhibited rhythmic binding. Sequence analysis suggests that 13% of the BMAL1–binding sites consist of a pair of E1-E2 elements, and these E1-E2 sites are associated with more robust rhythmic BMAL1 binding, whereas a single E-box alone is sufficient for rhythmic CLOCK:BMAL1 binding.[110] Another study using CHIP-seq compared the binding targets of seven clock components, CLOCK, BMAL1, NAPS2, PER1, PER2, CRY1, and CRY2, in mouse liver.[111] Remarkably, although more than 1400 target sites were found to be common to CLOCK, BMAL1, PER1, PER2, CRY1, and CRY2, distinct target profiles also were apparent for each of these components. Targets of all clock components commonly are enriched with E-boxes; sites that are specifically bound by PER2, CRY1, or CRY2, however, show a reduction in E-boxes, as well as an enrichment for nuclear hormone receptors—consistent with known partnerships between the negative elements of the clock and nuclear receptors.[112,113] Finally, an interesting finding is that E-box elements can be occupied by other transcription factors. For example, Usf1, a suppressor of the $Clock^{\Delta 19}$ mutant phenotype, competes with CLOCK:BMAL1 for E1 sites, modulating the circadian transcriptome.[114]

Many other mechanisms are likely to be involved in the regulation of the circadian transcriptome. For example, multiple lines of evidence have supported a role for rhythmic histone modification and chromatin remodeling in the regulation of circadian transcription. P300, a histone acetyltransferase, immunoprecipitates together with CLOCK in liver nuclear preparations, with a peak at CT 6 and minimum at CT 18.[85] P300 enhances CLOCK:BMAL1-mediated transcription of reporter gene, and this increase in expression is inhibited by CRY1 and CRY2, suggesting a potential mechanism by which CRY proteins can preclude CLOCK:BMAL1 transactivation of target genes. It also has been demonstrated that CLOCK protein itself also can function as a histone acetyltransferase.[115] Indeed, genome-wide circadian chromatin modifications have been extensively described in a number of studies.[110,116,117] Remarkably, the binding of CLOCK:BMAL1 to target DNA promotes removal of nucleosomes, which leads to chromatin opening at the binding site, allowing for rhythmic binding of other transcription factors.[118] Finally, a recent study has reported clock-controlled long-range chromosomal interactions, suggesting a genomic configuration that is coordinated with the rhythmic gene expression.[119]

In addition to direct transcriptional activation and chromatin remodeling, posttranscriptional mechanisms are likely to be involved in shaping output programs of the clock (as described by Lim and Allada[120]). By separating intronic and exonic signals in whole-genome RNA-seq data, Koike and coworkers were able to infer the oscillatory patterns of pre-mRNA from total mRNA.[111] Of interest, genes that exhibited both exonic and intronic cycling signals account for only 22% of the exonic cycling genes and 30% of the intronic cycling genes, suggesting that de novo transcription contributes to only a relatively small portion of circadian program of the transcriptome. Similar results were observed on comparing rhythmic expression pattern of nascent and total mRNA using RNA-seq in both mice and flies,[121,122] indicating significant contributions of posttranscriptional mechanisms in regulating circadian transcriptome.

A complex profile of rhythmic gene expression arises from clock-dependent transcriptional, epigenetic, and posttranscriptional regulations. Early microarray studies have suggested that up to a third of the expressed genes exhibit circadian oscillations.[18-21] More recent studies with higher temporal resolutions have added a great amount of detail to the overall picture of the circadian transcriptome, including transcripts that exhibited clock-controlled harmonic oscillations (i.e., 12-hour and 4-hour rhythms)[123] as well as rhythmically expressed noncoding regulatory RNAs.[117,124] Of interest, only a small fraction of rhythmically expressed genes commonly are found in SCN and liver,[20] in liver and heart,[21] as well as in liver and skeletal muscle[125] (Figure 27-2). Adding together all oscillatory genes from all the tissues that have been examined thus far, a total of 43% of protein-coding genes oscillate in the body.[124,126] At least in flies, tissue-specific programming of circadian gene expression is correlated with a tissue-specific preference in *cis*-regulatory motifs of genes that are bound by CLOCK and other partner transcription factors.[127] Gene ontology suggests that rhythmically expressed genes are involved in diverse pathways and cellular functions. In addition, the tissue specificity of circadian gene expression is tightly related to the specific functions of the tissue. For example, genes cycling in the SCN include those involved in protein or neuropeptide synthesis, processing, and degradation, as well as genes known to be important for circadian locomotor activity, whereas genes cycling in the liver are involved in nutrient metabolisms and regulation of metabolic intermediates.[20] Nonetheless, expression of genes involved in essential cell functions, such as redox homeostasis, appear to be under circadian regulation across different tissues. Remarkably, a recent study suggests that the targets of best-selling drugs and World Health Organization (WHO)-designated essential medicines are highly enriched with oscillating genes.[124] This finding has significant clinical implications, in that the treatment outcome drugs with short half-lives could potentially be improved by circadian-timed administration.

Figure 27-2 Rhythmic Gene Expression Varies among Cells and Tissues. Gene expression profiling studies[124,126] have revealed that up to a third of genes expressed in any given tissue may do so rhythmically. Although the core circadian clock genes that constitute the transcription-translation feedback loop are rhythmically expressed in all tissues, and some common regulatory factors may be expressed in multiple tissues, the vast majority of these rhythmic transcripts are specific to the cell type and functions of the particular tissue. Still to be delineated are the contributions of various regulatory mechanisms in determining the tissue specificity. (Data from Miller BH, McDearmon EL, Panda S, et al. Circadian and CLOCK-controlled regulation of the mouse transcriptome and cell proliferation. *Proc Natl Acad Sci U S A* 2007;104:3342–7; McCarthy JJ, Andrews JL, McDearmon EL, et al. Circadian transcriptional output in the SCN and liver of the mouse. *Novartis Found Symp* 2003;253:171–80.)

Of note, the oscillatory gene expression pattern observed outside of the SCN is driven by both local cell-automatous clock machineries as well as system cues originating from the SCN. Using an inducible hepatocyte-specific *Rev-erb alpha* transgene, Kornmann and associates were able to arrest the liver clock by suppressing *Bmal1* expression on activation of the transgene.[128] Of interest, 10% of the liver circadian transcriptome, including the transcript of core clock gene *Per2*, remained cycling when the hepatocyte clock was arrested. Circadian expression of these genes are thus attributed to the output signals from the master clock, including direct neural and humoral signals from the SCN as well as indirect cues such as those associated with clock-controlled sleep-wake, feed-fast, and body temperature rhythms. In particular, sleep-wake affects the expression of at least 5% of the genes,[129] and large-scale interactions between circadian rhythms and sleep-wake have been recently documented[130,131] (for detailed discussion, see Chapter 29). Recent studies also suggest that

the circadian transcriptome can be reprogrammed by environmental conditions. For example, compared with normal-chow feeding, feeding with a high-fat diet suppressed cycling of more than 1000 genes (including those involved in insulin signaling) while eliciting rhythmic expression of hundreds of other genes.[132] In addition, of the genes cycling under both conditions, 66% exhibited significant shifts in circadian phase. These findings suggest that the circadian program of gene expression is highly plastic in response to environmental conditions and associated functional challenges.

Output from the Suprachiasmatic Nucleus

Both neural and humoral mechanisms are likely to be involved in the output of the master clock. The molecular clock controls a firing rhythm in SCN neurons, and the SCN neurons project to many other brain areas.[133] On the other hand, encapsulated SCN grafts are capable of rescuing the circadian locomotor activity in SCN lesion animals,[134] suggesting that secreted factors are also involved in SCN output. To date, a few proteins, such as PK2, TGF-α, CLC, and VIP, have been implicated in the SCN humoral outputs.

Prokineticin 2 (PK2) is rhythmically expressed in the SCN,[135] and infusion of PK2 into the cerebral ventricles inhibits locomotor activity. Mice with a null mutation in the PK2-encoding gene exhibit dramatically reduced levels of activity[136] with reduced circadian amplitude. These mice also exhibit attenuated rebound in non–rapid eye movement, rapid eye movement, and delta wave power on electroencephalogram after sleep deprivation.[137]

The peptide transforming growth factor alpha (TGF-α) was identified in a screen for SCN factors that might inhibit locomotor activity; when infused into the third ventricle, this peptide inhibits locomotor activity. Mice with targeted mutations of the epidermal growth factor receptor (the receptor likely to bind TGF-α) also display disruption of activity rhythms.[138] These effects are attributable to actions on the epidermal growth factor receptors.

Mice that lack the peptide receptor VPAC2 show abnormal entrainment and disrupted rhythms, indicating that VIP signaling in the SCN may be necessary for normal expression and coordination of rhythms.[139]

Cardiomyotrophin-like cytokine (CLC) also is expressed in the SCN in a rhythmic manner in vasopressin neurons. Infusion of CLC into the third ventricle (near the SCN) dramatically inhibits locomotor activity, whereas infusion of antibodies to the CLC receptor increases activity.[140]

INPUT REGULATION

Melanopsin

The circadian rhythms of many humans who are blind, with no conscious perception of light, are nevertheless able to be entrained by light.[141] This intriguing observation led to studies of the circadian light input pathway and the photoreceptors and photopigments in mammals.

In experiments using mouse mutations that result in degeneration of rods[142] or both rods and cones,[143] light entrainment of the circadian rhythm was preserved.[144] However, the eye must be the site of the light-entraining pathways in mammals because enucleated mammals are not capable of light entrainment.[142] Indeed a morphologically distinct set of retinal ganglion cells projects to the SCN via the retinohypothalamic tract.[145] Ablation of the SCN abolishes circadian rhythmicity and ablation of the retinohypotalamic tract abolishes light entrainment.[146] Thus the light signal responsible for light entrainment enters the SCN via a unique axonal pathway from the eye.

Melanopsin, a member of the opsin family of photopigments, was first identified in the inner retina[147] and later found to be expressed in the somata and dendrites of retinal ganglion cells of the retinohypothamamic tract.[148] Neurons that contribute axons to the retinohypothalamic tract were found to express the marker pituitary adenylate cyclase–activating polypeptide (PACAP).[148] PACAP was used as a marker for rat retinohypothalamic tract neurons; every PACAP-positive neuron was found to express melanopsin, and every melanopsin-positive neuron was PACAP-positive.[148]

Further evidence confirming the role of melanopsin as the phase-shifting pigment has come from genetically engineered mice in which the gene encoding melanopsin was disrupted.[147,149,150] Two behavioral measures of circadian rhythm responses to light were altered in these mice. The *phase-shifting response* to a discrete light pulse was of lesser amplitude in the knockout mice than in wild-type mice, and the *free-running periods* of the knockout mice were lengthened less by exposure to constant light than the periods of wild-type mice. Hence it appears that melanopsin represents a primary photopigment with other photopigments also having input to the circadian system.

Rab3a

The *Rab3a* gene was identified in a mutagenesis screen (*earlybird*) based on an advanced phase angle of entrainment and shortened circadian period. Null mutant mice display a similar phenotype.[151] Furthermore, both the *Rab3a* null and *earlybird* mutants exhibit alterations in the homeostatic response to sleep deprivation,[151] as well as alterations in emotional behavior.[152]

CONCLUSIONS AND FUTURE DIRECTIONS

The core circadian oscillator is autonomous to individual neurons of the SCN and is the result of the daily oscillation in the levels of several clock component proteins. The basis for this oscillation in mammals, as in other organisms, lies in rhythmic feedback regulation of transcription of the genes encoding these proteins. The levels of the PER and CRY proteins alter the rate of transcription of their own genes. This alteration is achieved by inhibition of the enhancement of transcription that results from binding of the CLOCK-BMAL1 heterodimer to the E-box element of the promoter region of the *Per* and *Cry* genes. Additional interactions between circadian clock proteins may slow the time course of this feedback, achieving the near-24-hour interval. The phosphorylation of PER by CKIε may lead to its degradation, and the association with BMAL1 apparently is needed for CLOCK to be present in the nucleus. Rhythmic transcription of *Bmal1* appears to result from regulation mediated by REV-ERBα, itself regulated by E-box elements. Finally, rhythms in histone acetylation evidently contribute to the circadian expression pattern of some core circadian genes. Additional genes have been identified on the basis of altered circadian rhythms in mutants, although the roles of these genes in the circadian system remain to be determined.

It is of interest that a majority of the core genes have been identified in mice or in flies by forward genetics, in which mutations were induced in the genome randomly, and those mutations that specifically affect the circadian oscillator were identified with carefully crafted circadian phenotypic screens. Now that these clock component proteins have been identified, it will be easier to find the proteins that serve the input and output pathways of the circadian oscillator, and to identify the components that are out of order in disease states affecting circadian rhythms. Furthermore, with the great advances achieved thus far in genomic, proteomic, and metabolomic techniques, future studies are expected to integrate and depict the circadian program at a multiscale level. Such studies will eventually facilitate a comprehensive understanding of how the clock is coupled with other cellular and physiologic functions. It is fortuitous that the unraveling of the molecular basis for circadian rhythmicity is occurring at a time when the general public is becoming aware of the importance of normal circadian timekeeping for human health, safety, performance, and productivity.

CLINICAL PEARL: How Many Levels of Genetic Regulation of Clocks Exist?

The developing picture of the molecular genetic clock is becoming many-layered and complex. At its core is a transcriptional-translational feedback loop of CLOCK:BMAL1 and PER:CRY. This loop interacts intimately with a cellular metabolism loop, by way of NAD and SIRT. The genetic circadian clock regulates rhythms of gene expression through direct transcriptional regulation, mediated by histone acetylation/deacetylation, chromatin modifications, and possibly posttranscriptional modifications as well. These modifications may be tissue-specific but can be influenced by the SCN.[153] Rhythms or behaviors (driven by the SCN) such as melatonin levels,[154] body temperature,[155] feeding,[156] or sleep[131,157] also can influence gene expression rhythms in the periphery. It thus seems that the so-called cell-autonomous genetic circadian clock is subjected to a wide array of modulators ranging from the intracellular to nutritional, endocrine, and behavioral. How cell-autonomous is the human circadian clock? Whether such disruptions in physiology and behavior are due to altered circadian information from the SCN or to local tissue-specific changes in the molecular circadian clock is not known. Regardless of the mechanisms, such results point to a very central role of circadian clock genes in regulating biochemical, metabolic, and physiologic processes at many different levels of organization.

SUMMARY

The cell-autonomous circadian clock found in all mammalian cells and tissues has, at its core, a feedback loop of transcription and translation of a key set of "clock genes." Identification of clock genes has been guided by examining the effects of gene alterations on clock properties. A substantial proportion of expressed genes exhibit circadian variation; however, distinct cell types appear to have their own unique sets of "clock-controlled genes," while the core clock genes remain the same. The transcription-translation feedback loop is subject to regulation at multiple levels, including histone, chromatin, and posttranscriptional modifications. Signals from the suprachiasmatic nucleus of the hypothalamus and from behavioral states such as sleep/wake or feed/fast also can influence clocks in peripheral tissues.

Genetics and Genomic Basis of Sleep in Simple Model Organisms

Chapter 28

Ravi Allada; Mark Wu

Chapter Highlights

- The availability of simpler animal model systems, such as nematodes, flies, and fish, has greatly facilitated the genetic analysis of sleep.
- These simpler animal models exhibit the defining features of sleep, including behavioral quiescence, reduced responsiveness to sensory stimuli, and homeostatic regulation.
- Genetic studies in these simpler models have revealed both circuit and molecular pathways involved in sleep regulation, including many that are conserved with rodents and even humans.

The complexity of sleep in mammals has led to a movement toward examining related phenomena in simpler organisms, such as nematodes, flies, and fish, that exhibit sleep (or sleep-like states), with development of model systems that harbor technical advantages not present in more conventional rodent, feline, or primate models. One such system is that starring the fruit fly *Drosophila melanogaster,* best known for its use in genetic studies. Remarkably, the mammalian homologues of many *Drosophila* genes have been found to function in a manner similar to that observed in flies. Indeed, most human disease genes have clear fly homologues. In view of the notable genetic similarity between *Drosophila* and mammals, it is not surprising that fruit flies exhibit many of the defining features of sleep, including circadian-dependent quiescence, reduced responsiveness to sensory stimuli, and homeostatic regulation. Furthermore, preliminary indications are that even the genetic and pharmacologic underpinnings of sleep are conserved between flies and mammals. Primary topics addressed in this chapter are (1) use of the *Drosophila* model for sleep studies, (2) the available evidence on the circadian regulation of behavior, and (3) recent insights into sleep regulation. Also discussed are the unique features of both the zebrafish and nematode *Caenorhabditis elegans* models of sleep, along with relevant technological advances. Both experimental observations in reported studies and the insights they engender could prove to be important in elucidating the genetic basis of human sleep and, ultimately, answering the question of why organisms sleep.

In contrast with studies of naturally occurring genetic variation, it is possible to induce mutations in animal models to test whether a given gene is important for sleep. One strategy to investigate the molecular basis of complex behaviors such as sleep is classical or *forward genetics*.[1] Here a population of animals is randomly mutagenized using DNA-alkylating agents, such as ethyl methane sulfonate (EMS), or mobile DNA transposable elements. This mutagenized population is screened for a mutant phenotype of interest, such as altered sleep. Molecular genetics techniques can then be applied to identify the mutant gene responsible for the mutant phenotype. Thus forward genetics can be used to establish causal relationships between the function of individual genes and otherwise complex phenotypes. Forward genetics is unbiased and does not require any previous knowledge about the genetic basis of the phenotype of interest and is therefore an ideal approach for studying sleep. By contrast, *reverse genetics* starts with a disrupted gene in search of a phenotype. The finding of a gene can provide insight into biochemical and cellular pathways that are important for sleep, perhaps even providing novel diagnostic tests or targets for drug development for sleep disorders.

DROSOPHILA AS A MODEL SYSTEM FOR GENETICS

Many of the "genetic" model organisms, such as zebrafish (*Danio rerio*) and the nematode (*C. elegans*), recently have been adopted for the study of sleep because they are highly suited to the forward genetics approach.[2] One of the premier model systems for genetics is that of the fruit fly, *D. melanogaster* (Figure 28-1). The fruit fly has been a workhorse for genetic studies since the pioneering work of Thomas Hunt Morgan in the early 20th century.[3] A major advantage of *Drosophila* over mammalian model systems is the ability to grow and handle large numbers relatively easily and cheaply.[1] A single female can produce hundreds of offspring. In addition, it has a short generation time, approximately 10 to 12 days from fertilized egg to fertile adult at room temperature. Because of these traits, *Drosophila* has been a model par excellence for high-throughput screening of mutants with altered phenotypes. The facility of genetic mapping, gene disruption using transposable elements (mobile DNA), and the full genome sequence allows rapid identification of mutant genes responsible for mutant phenotypes.[4] Remarkably (to some researchers), the mammalian versions (i.e., homologues) of *Drosophila* genes have been found to function in a manner similar to that for their *Drosophila* counterparts. Indeed, entire signaling pathways are shared between *Drosophila* and their mammalian counterparts. For example, most human disease genes have

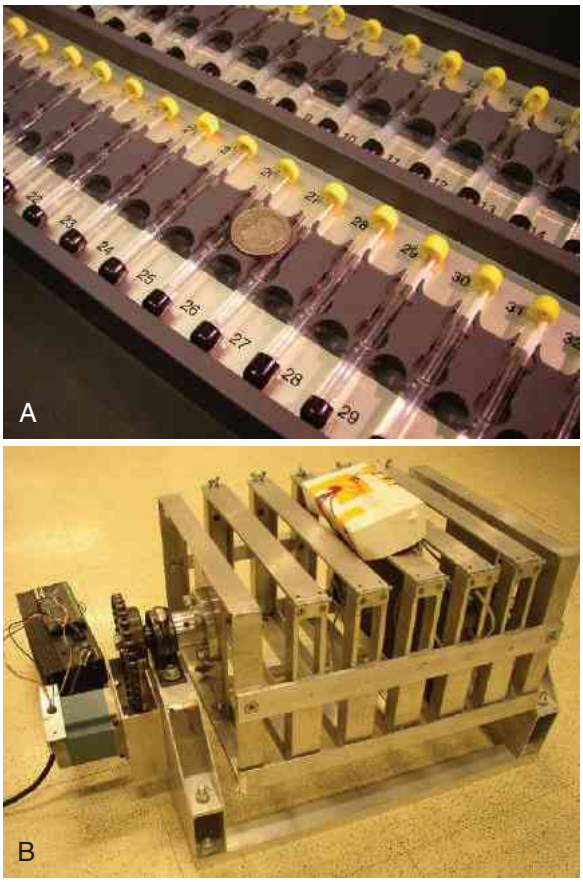

Figure 28-2 The *Drosophila* Activity Monitoring (DAM) System and Rotating Sleep-Depriving Box. **A,** The DAM system. clear fly homologues.[5] Thus genes identified in flies are likely to serve comparable functions in more complex mammalian systems, including that of humans.

The conservation between flies and mammals extends to the nervous system. Although flies have approximately 1/1,000,000th the number of neurons in humans (10^5 versus 10^{11}), the fly and human genomes are surprisingly similar in gene number (14,000 and approximately 22,000, respectively), with differences largely due to gene duplication.[6] In fact, the fly brain uses comparable neuronal machinery, including neurotransmitters, ion channels, receptors, and signal transduction pathways. Consequently, flies have been used as valuable nervous system models for olfaction,[7] vision,[8] hearing,[9] sexual behavior,[10] synaptic transmission, axon guidance,[11] and learning and memory.[12] Flies also have been exploited as models for numerous human diseases and conditions including diabetes,[13] aging,[14] pain,[15] Alzheimer and Parkinson diseases,[11] epilepsy,[16] and fragile X mental retardation.[17] Finally, flies have been successfully used to study the response to clinically important drugs such as ethanol,[18] cocaine,[18] and general anesthetics.[19] In many of these cases, genes identified in *Drosophila* serve similar functions in mammalian systems.

DROSOPHILA AS A MODEL FOR STUDIES OF SLEEP

Studies of *Drosophila* sleep have been predicated on a small but noteworthy literature examining sleep-like states in other invertebrate models such as mollusks[20] and insects including cockroaches[21] and honey bees.[22,23] These classical descriptions of sleep behavior formed the basis for pursuing similar studies in *Drosophila*.

Sleep in the fruit fly typically is measured behaviorally using the *Drosophila* Activity Monitoring (DAM) System (developed by Trikinetics Inc., Waltham, Massachusetts) (Figure 28-2), which allows for high-throughput analyses. Single flies are placed into a small transparent glass tube plugged on one end by agar food and the other end by a porous cap, allowing air passage. Each tube is placed into a monitor that contains a series of 32 infrared emitter-detector pairs, one for each tube. An awake fly will move back and forth in the tube, periodically breaking the infrared beam. Independent methods indicate a close correlation between infrared beam breaks and overall activity. A 5-minute period of inactivity (i.e., no beam breaks) has been found to be a reliable indicator of sleep. Video-based monitoring also has been coupled to measurements of beam breaks to provide higher spatial resolution analysis of fly sleep behavior.[24,25] The use of consolidated inactivity to measure sleep in flies is similar to the use of actigraphy to measure sleep in humans.[26]

In view of the remarkable similarity between *Drosophila* and mammals, it is not surprising that fruit flies exhibit many of the defining features of sleep. Flies exhibit extended periods of behavioral quiescence that can last for hours, and a majority of the sleep-like episodes typically occur in bouts

longer than 30 minutes.[24] In addition, sleeping flies exhibit reduced responsiveness to sensory stimuli.[2,24,27-29] Indeed, *Drosophila* sleep studies do not rely solely on measures of spontaneous movement but also assess responsiveness to sensory stimuli. Arousal threshold is assayed by application of a stimulus and measuring a behavioral response, typically induction of locomotor activity. During periods of extended immobility, flies are less likely to respond to a range of sensory stimuli, including social, mechanical, vibratory, thermal, and visual.[24,27,30,31] Although this responsiveness typically is measured behaviorally, it also can be uncoupled from movement using electrophysiologic measures.[32] The typical fly demonstrates an increase in arousal threshold, reaching a plateau after 5 minutes.[27,31] The 5-minute criterion for fly sleep is in part based on this observation. More recent analysis suggests that like mammals, flies exhibit deeper stages of sleep, characterized by more elevated arousal thresholds after more than 10 minutes of inactivity.[33] Nonetheless, quiet wakefulness can be distinguished from sleep by assessing arousal threshold.

Of importance, fly sleep is under homeostatic regulation—that is, flies deprived of sleep will exhibit increases in sleep duration and intensity (the latter as measured by sleep bout length or arousal threshold) the following day. Flies typically are deprived of sleep mechanically using automated devices or by tapping the flies by hand[24,27,31,34] (see Figure 28-2). Sleep rebound is not observed, or is much less evident, if similar deprivation protocols are applied to flies that are already awake, arguing strongly against nonspecific stress effects of mechanical disruption.[24,27,31] Continuous sleep deprivation ultimately results in premature death,[34] as it does in some mammals.[35] Thus sleep is essential for life in the fly.

Although flies do not display the precise electroencephalographic signatures of mammalian sleep (that is, the synchronous changes in neural activity seen as slow waves on the electroencephalogram [EEG] that are seen in mammalian sleep have not been observed in *Drosophila*),[30] they do exhibit electrical correlates of sleep behavior, providing behavior-independent state markers. In vivo electrical correlates in behaving flies have relied on the development of novel approaches to study the fly brain. In this approach, recording electrodes are inserted into the center of the *Drosophila* brain and into the optic lobes of a tethered fly[30] (see Figure 28-1). Local field potentials (LFPs) are measured, reflecting neural activity near the electrode. Leg movement in the tethered fly is simultaneously monitored. There is a general-but-not-perfect correlation between spike-like potentials recorded from the central brain and waking movement. If flies are exposed to a rotating stripe, LFPs in the 20- to 30-Hz frequency are observed, reflecting attention to the stimulus, but these LFPs are reduced when the fly is asleep.[32] In addition, periods of poor correlation between LFPs and movement are associated with increased arousal threshold and precede behavioral quiescence.[32] These approaches clearly demonstrate that differences in arousal states can be characterized using electrophysiologic correlates as they are in more complex organisms. The differences between fly and mammalian neuroanatomy are likely to account for the differing electrical manifestations of sleep even if the underlying molecular and cellular mechanisms are similar. Studies of eye development provide some precedent for the idea that common genetic mechanisms can underlie anatomically distinct but functionally analogous structures.[36]

In addition to the core features of sleep, flies also display age-related changes in sleep architecture similar to those in aging mammals. Directly after emergence from the pupal case, young flies exhibit increased amounts and depth of sleep, as in their mammalian counterparts.[27,37] With increasing age, sleep becomes more fragmented and less consolidated.[38] In addition, drugs that increase oxidative stress can induce changes that mimic these effects.[38] Thus the fruit fly has the potential to become a valuable model for the analysis of aging effects on sleep.

Mammalian sleep enhances various aspects of memory consolidation.[39] Similarly, flies also display sleep-loss related deficits in learning and memory, using a number of different learning paradigms. For example, flies normally exhibit phototaxis but can be trained to avoid light using aversive stimuli. However, flies that have experienced reduced sleep perform more poorly on this task.[40] In courtship conditioning, male flies learn to stop courting females that have already mated. Under the appropriate conditions, males can remember this experience for longer than 24 hours; however, if flies are subjected to sleep deprivation after training, that is, during the period of presumed memory consolidation, they fail to retain this memory.[41] Finally, waking experience, in particular, social experience, can increase subsequent sleep amount, a process that may utilize dopamine and cyclic adenosine monophosphate (cAMP) pathways.[41] Taken together, these data implicate a reciprocal relationship between sleep-wake regulation and plasticity and memory in *Drosophila,* as is proposed for mammals.

DROSOPHILA CIRCADIAN BEHAVIOR REVEALS CONSERVED MECHANISMS BETWEEN FLIES AND HUMANS

The best case for the argument that *Drosophila* genetics will illuminate the genetics of human sleep has emerged from studies of circadian behavior. As in most (but not all) organisms, sleep is under temporal control of a circadian clock in *Drosophila.*[24,27] The first-identified fly circadian mutants displayed short- and long-period rhythms in constant conditions and phase-advanced and delayed activity in light-dark conditions, analogous to human advanced and delayed sleep phase syndromes.[42,43] Cloning of the genes responsible for these fly phenotypes led to breakthroughs in the understanding of the core biochemical mechanisms of circadian timing. These studies also provide an experimental roadmap for elucidating basic mechanisms of sleep homeostasis. Although circadian clocks often have been viewed solely as timekeepers, both circadian genes and their accompanying neural circuits extensively regulate sleep-wake, perhaps independent of their timing functions (see later). Thus a deeper molecular understanding of the circadian system should provide insights into the control mechanisms for sleep.

Most aspects of the fly molecular clockwork are conserved with mammals, including humans (Table 28-1).[44,45] People affected by familial advanced sleep phase syndrome exhibit an advanced phase of sleep-wake rhythms and shortened circadian period that is inherited in a mendelian dominant manner.[43] Mutations in the human *PER2* and *CK1delta* genes, orthologues of fly circadian genes *period* and *double-time,* respectively, are responsible for this advanced sleep phase.[46,47] These data argue that the basic architecture and

core components of circadian clocks can be traced back to the shared ancestor of flies and humans hundreds of millions of years ago. In view of the close association of circadian with sleep behavior, the basic mechanisms of sleep homeostasis presumably also may be conserved with flies.

CELLULAR AND MOLECULAR BASIS OF *DROSOPHILA* SLEEP

As described earlier, considerable evidence indicates that fruit flies display the core characteristics of sleep. Substantial progress has been made in identifying discrete molecular and neural circuits that convey signals to time sleep and wake behavior. Presented next is an overview of the neural circuits that contribute to sleep-wake behavior, along with the genes that regulate sleep and that are regulated by sleep. The emerging picture (and "take-home message") is that the molecular mechanisms governing *Drosophila* sleep may be shared with animals with more complex nervous systems.

Specific Neural Circuits Are Important for Sleep-Wake Regulation

A theme of mammalian sleep studies is the notion that discrete neural circuits are important for initiating and maintaining sleep and wake states. Using genetics-based tools to study such circuitry in live animals, distinct neural circuits have been identified that regulate sleep in *Drosophila*. Thus far, several anatomically defined loci have been implicated in sleep-wake regulation: the mushroom bodies, the dorsal fan-shaped body (dFB), the pars intercerebralis (PI), and the circadian pacemaker neurons—the small and large ventral lateral neurons (sLNv and lLNv neurons) (Figure 28-3). In addition to these loci, other circuits have been defined according to their specific neurotransmitter (e.g., dopamine). These circuits are discussed further later on. To discover novel circuits involved in sleep regulation, an approach akin to forward genetics has been employed with the modification that, instead of screening for genes, circuits are screened in an unbiased manner for behavioral functions.

A cornerstone of this approach is the binary GAL4/UAS system.[48,49] In one parental strain, the yeast transcription factor GAL4 is placed under the control of a tissue-specific promoter. In the second strain, the upstream activating sequence (UAS) bearing GAL4-binding sites is fused to an effector gene of interest. In the progeny of these two strains, the effector gene is expressed in the distribution specified by the tissue- or circuit-specific promoter driving GAL4. A plethora of GAL4 lines are available that provide a nearly limitless display of temporal and spatial expression patterns.

In addition to the multitude of GAL4 lines, numerous UAS effector lines have been generated, including those

engineered to alter specific cellular properties such as membrane excitability or synaptic transmission. Although these approaches are well developed in *Drosophila,* they have inspired even more sophisticated strategies in mammalian models.[50] A number of cellular effectors have been successfully utilized for *Drosophila* sleep studies. One tool that has been used to conditionally block synaptic transmission is the UAS-driven *shibire*^{ts1} (*shi*^{ts1}) transgene.[51] This transgene encodes a multimeric guanosine triphosphatase (GTPase) required for vesicle scission, a process that is in turn required for synaptic vesicle recycling and hence the maintenance of fast synaptic transmission. UAS-driven expression of the *shi*^{ts1} allele in a wild-type neuron can block synaptic transmission at an elevated restrictive temperature (e.g., 29° C) but not at the permissive temperature (e.g., 21° C). Using the GAL4/UAS system, and given the fact that flies are not homeotherms, it is possible to specifically manipulate synaptic transmission in discrete neural circuits in a live-behaving animal, with temperature acting as a remote control, and then assay the behavioral consequences of circuit modulation. Tools to manipulate cellular excitability also have been developed and applied using ectopically expressed constitutive and conditionally active ion channels that can activate or silence neuronal activity. For example, a bacterial depolarization-activated sodium channel, NaChBac, and the thermosensitive TrpA1 channel have been used to increase cellular excitability, the latter in a temperature-dependent manner.[52,53] Conversely, a variety of engineered potassium channels have been employed to silence neurons.[54,55]

The use of these transgenic tools in combination with various GAL4 drivers led to the discovery of a sleep regulatory role for the mushroom bodies (MBs), paired (bilateral) neuropil wells known for their role in learning and memory.[12,56,57] The MBs are analogous to the mammalian cerebral cortex and hippocampus.[58,59] Conditional inhibition of the MBs using *shi*^{ts1} as well as chemical ablation reduces overall sleep levels,[56,57] and in both cases the sleep decrease was largely due to reduced sleep bout length, that is, an inability to maintain sleep.[56] In addition, flies with impaired or absent MBs exhibited a reduced lifespan consistent with a loss of restorative sleep.[56] Thus these flies are analogous to insomniac patients who are unable to maintain sleep and who may suffer adverse consequences as a result. Other data using a different MB-GAL4 line that can be conditionally activated in adult flies[60,61] in combination with activating and silencing tools[57] suggest that the MBs also may promote wakefulness. One possibility is that different subsets of MB neurons play opposing roles in sleep regulation. Sleep and memory functions may overlap in the MBs, an important site for the function of adenylate cyclase in short-term memory[62] and cAMP-dependent protein kinase A (PKA) activity in sleep.[57] The connection between sleep and memory is particularly intriguing in view of the proposed function of sleep in regulating synaptic plasticity.

Flies that lack MBs demonstrate both spontaneous sleep (albeit reduced) and a robust homeostatic response, indicating that other brain loci promote sleep. Decades of research in mammals has led to the identification of discrete sleep and arousal centers in the brain.[63] For example, the gamma-aminobutyric acid (GABA)-ergic ventrolateral preoptic nucleus (VLPO) located in the anterior hypothalamus promotes sleep, whereas monoaminergic and acetylcholinergic nuclei in the brainstem and posterior hypothalamus enhance wakefulness.[63] The dFB in *Drosophila* appears to be an analogue of VLPO in mammals because activation of the dFB using TrpA1 induces sleep (see Figure 28-3).[64] In addition, in a manner similar to how VLPO activity is increased with sleep deprivation in mammals,[65] sleep deprivation in flies enhances the excitability of dFB neurons.[66] These data suggest that VLPO in mammals and the dFB circuit in flies act downstream of sleep-homeostatic mechanisms to regulate sleep. Of interest, inducing sleep by activation of the dFB circuit facilitates memory consolidation, further emphasizing the intimate relationship between sleep and memory.[64]

Another sleep regulatory locus is the PI, a neuroendocrine cluster considered genetically analogous to the mammalian hypothalamus, an important player in sleep regulation.[67] Targeted decreases in epidermal growth factor (EGF) function in the PI result in reduced sleep.[68] EGF and its related set of ligands (e.g., transforming growth factor alpha) appear to serve similar functions in promoting sleep in *C. elegans*[69] and mammals,[70,71] suggesting an ancient sleep function for EGF.

As discussed further on, specific PI neurons act downstream of monoaminergic circuits to promote arousal.[72] In addition, the PI may be a direct target of circadian pacemaker neurons. The dorsal projections of a subset of circadian pacemaker neurons, the sLNv neurons, terminate in close proximity to the PI neuron soma (see Figure 28-3), and loss of the key peptide transmitter of these neurons, pigment-dispersing factor (PDF), affects molecular circadian rhythms in PI neurons.[73]

In addition to sleep-wake circuits in the MBs, dFB, and PI, the circadian pacemaker LNv neurons also regulate wakefulness and sleep (see Figure 28-3). The *Drosophila* clock circuit comprises approximately 150 neurons,[74] which together are analogous to the mammalian circadian pacemaker, the suprachiasmatic nucleus. Within this network are the two subgroups of LNv neurons mentioned earlier, the large (lLNv) and small (sLNv) clusters, which have opposite roles in regulating sleep. The lLNv neurons promote arousal, whereas the sLNv neurons induce sleep. Excitation of the lLNv using NaChBac or TrpA1 reduces sleep, especially at night.[75-77] Selective ablation of the lLNv results in increased sleep.[76] The vigilance effect is similar to that observed in animals in which the mammalian circadian pacemaker, the suprachiasmatic nucleus, is ablated.[78] The activity of these arousal-promoting neurons appears to be inhibited by GABA,[77] a relationship that is reminiscent of a similar organization of mammalian sleep circuits.[79] By contrast, the sLNv neurons appear to enhance sleep by inhibiting the lLNv cells through the action of short neuropeptide F (sNPF) (which is related to mammalian NPY).[80] These studies demonstrate that distinct clock subcircuits can promote wake or sleep, implying that similar principles may apply to the mammalian suprachiasmatic nucleus.

Arousal Neurotransmitters: Monoaminergic Arousal Pathways

A number of different neurotransmitters and neuromodulators have been shown to play important roles in sleep regulation. Whereas the anatomic organization of the *Drosophila* brain is distinct from that in mammals, flies use a similar system of neurotransmitters and receptors. Indeed, it appears that the transmitters used by flies to regulate sleep are similar to those used by mammals. In mammals, monoamine transmitters,

such as dopamine, histamine, and norepinephrine, generally promote wake-arousal.[81] Similarly, in flies, these monoamines, or their fly counterparts, also promote wakefulness, suggesting that the nervous system of the common ancestor of flies and mammals used similar arousal transmitters.

The monoamine most strongly linked to arousal in *Drosophila* is dopamine. Flies with mutations of the dopamine transporter gene *fumin* exhibit dramatically reduced sleep duration (approximately 50%).[82,83] Of note, mutations in this gene also were identified in a large-scale unbiased genetic screen for sleep mutants.[83] The psychostimulant methamphetamine, which is thought to increase dopaminergic neurotransmission, also reduces sleep.[84] When awake, flies with enhanced dopamine neurotransmission display increased spontaneous locomotor activity as well as hyperresponsiveness to mechanosensory stimuli, suggesting that these flies were hyperaroused.[82-84] In addition, although its mechanism of action remains unclear, the clinically prescribed wake-promoting drug modafinil may operate by enhancing dopaminergic neurotransmission.[85] Of importance, modafinil has similar wake-promoting properties in *Drosophila.*[86]

In mammals, the predominant model for how sleep and wake circuits intersect involves mutually inhibitory interactions, promoting fast switching between bistable states.[63] Of interest, in flies, arousal-promoting dopaminergic neurons project to and inhibit the sleep-promoting dFB circuit.[87,88] This dopaminergic (DA-dFB) circuit also plays a critical role in age-dependent effects on sleep. This circuit is hypoactive when flies are very young (0 to 1 days old) compared with that in adults (approximately 8 days old).[37] Finally, the dopamine-dFB circuit also is involved in mediating the effects of a volatile anesthetic on arousal in flies,[89] which parallels the finding in mice of increased activation of the VLPO circuit by volatile anesthetics.[90] Dopaminergic neurons densely innervate the MBs,[91] and type D_1 dopamine receptor (dDA1) activation in the MB may mediate the wake-promoting effects of caffeine[92] and can mitigate the effects of sleep loss in an MB-dependent learning paradigm.[40] Taken together, these data indicate that dopamine is an important transmitter for arousal and cognitive function in *Drosophila*.

Two other monoaminergic transmitters implicated in fly arousal are octopamine and histamine. Octopamine is thought to serve as a functional homologue of mammalian norepinephrine. Genetically reduced octopamine synthesis or octopamine neuron activity results in increased sleep which can be rescued in the former case by pharmacologically restoring octopamine.[93] These effects require PKA but do not operate through the MB.[93] Instead, specific wake-promoting octopamine cells send projections to the PI circuit discussed earlier.[72] Octopamine acts to inhibit the function of a Ca^{2+}-dependent potassium channel and also increases cAMP signaling in these PI neurons to promote wakefulness.[72] Histamine has been implicated principally by pharmacology-based studies. The histamine H_1 receptor antagonist hydroxyzine induces sleep and reduces sleep latency in flies,[27] suggesting conserved functions for histamine. A large-scale small-molecule screen was performed in adult flies that identified reserpine, which is an inhibitor of vesicular monoamine transporter (VMAT), as causing an increase in sleep.[94] In light of the fact that the function of VMAT is to load monoaminergic neurotransmitters in vesicles, these data further reinforce the importance of monoamines in promoting arousal in flies. It should be mentioned that not all monoamines are arousal-promoting in *Drosophila* (e.g., serotonin).[95] Nonetheless, the role for monoamines in promoting arousal in mammals is largely preserved in *Drosophila*.

Sleep Neurotransmitters: Gamma-aminobutyric Acid and Adenosine Sleep Pathways

A crucial neurotransmitter for sleep promotion in both flies and mammals is the inhibitory neurotransmitter GABA. Many of the most commonly prescribed hypnotics act at ionotropic GABA receptors, promoting GABAergic neurotransmission.[96] Silencing of GABAergic neurons reduces sleep, a finding consistent with a sleep-promoting role.[97] In *Drosophila*, a mutation in one $GABA_A$ receptor subunit gene is responsible for resistance to the dieldrin insecticide; hence its name, *Resistant to DieLdrin* (*Rdl*). These receptors rapidly desensitize on GABA activation, and this process is reduced in insecticide-resistant *Rdl* mutants, prolonging GABA-activated currents.[97] In these *Rdl* mutants, the latency to sleep after lights-off is increased, an observation consistent with an important role for GABA in promoting sleep in *Drosophila.*[97] *Rdl* may promote sleep in part by reducing the activity of PDF arousal-promoting neurons (see earlier; Figure 28-3).[77,98,99] In view of the conserved role for ionotropic GABA receptors in sleep regulation, it will be of interest to determine whether flies respond to many clinically used hypnotics that target this receptor class.

Adenosine is thought to play a key role in sleep homeostasis in mammals.[100] Adenosine also has been implicated in the promotion of sleep in *Drosophila.* Adenosine, a metabolic product of adenosine triphosphate, acts through specific G protein–coupled receptors.[100] In mammals, the stimulant effects of caffeine are thought to operate by antagonizing adenosine receptors.[101] Flies fed caffeine exhibit reduced sleep, whereas flies administered cyclohexyladenosine, an adenosine agonist, exhibit increased sleep.[24,27] However, caffeine may function differently in flies versus mammals. Besides antagonizing adenosine signaling, caffeine, like other methylxanthines, has been shown to inhibit cAMP phosphodiesterase activity.[101] Deletion of the single adenosine receptor in flies did not block the wake-promoting effects of caffeine.[102] Instead, reduction of neuronal PKA activity largely suppressed the effects of caffeine on sleep.[102]

GENETICS AND PHARMACOLOGY OF SLEEP: WHICH MOLECULES REGULATE SLEEP?

The power of the *Drosophila* system lies in the ability to identify genes whose function is important for sleep. One strategy is to manipulate the function of genes and assay the consequences on sleep. In addition, traditional pharmacologic approaches have complemented genetics to identify pathways whose function is important for sleep. Finally, genomic approaches have been applied to identify genes whose expression is regulated by sleep-wake state. The discovery of novel sleep genes in *Drosophila* using genetics has relied on a combination of candidate gene approaches and classical forward genetics. In addition, the molecular identification of quantitative trait loci contributing to sleep using inbred strains also

has identified numerous candidate sleep genes.[103] Of note, unbiased large-scale screens are especially powerful because they tend to identify the strongest contributors to a process among thousands of mutagenized candidates. Not surprisingly, identified genes play a role in various aspects of neural function, including genes involved in the circadian system, stress and immune responses, signal transduction, neurotransmitter/neuromodulator signaling, and cellular excitability. These findings suggest that many sleep pathways are conserved between flies and mammals and support the notion that studies in *Drosophila* should yield insights into the molecular basis of sleep in more complex systems.

Circadian Clock Pathway

As in many mammalian species, sleep is under the control of a circadian clock in *Drosophila.*[24,27] Mutations in the core clock transcription factors Clock (Clk) and cycle (cyc) result in reduced sleep.[99,104] However, in certain arrhythmic mutants, such as *per*^{01}, sleep homeostasis is intact, as is consistent with the two-process model.[24,27] Some of these clock gene effects are likely to be mediated by the PDF neuropeptide through its function in the arousal promoting lLNv[76,77] (see Figure 28-3).

Although a detailed molecular understanding of the nature of the core circadian oscillator has emerged, the mechanisms by which this core clock regulates sleep is poorly understood. A novel molecule named Wide Awake ("WAKE") is a likely candidate for a key clock output molecule that specifically regulates the timing of sleep onset.[99] WAKE exhibits cycling expression in the lLNv clock neurons, peaking in the evening, when it acts to silence these arousal-promoting cells by upregulating GABA transmission. Strikingly, a single homologue of WAKE has been identified in mice, which is enriched in the suprachiasmatic nucleus, the master circadian pacemaker in mammals, suggesting that its function in mediating circadian regulation of sleep is conserved.[99]

Unbiased genetic screens often uncover unexpected molecular pathways in sleep regulation. Using in vivo RNA interference, the essential cell cycle gene, encoding cyclin A, functions in nondividing neurons to regulate sleep duration and homeostasis.[105] Of note, this cyclin is expressed in a small number of adult brain neurons that are in proximity to clock neurons.[105] As supported by the extensive understanding of both molecular and circuit basis of circadian behavior that has been achieved, elucidating the clock links to sleep should continue to be a fruitful area of research.

Dopamine Arousal Pathways

Dopamine is a major arousal-promoting neuromodulator in flies (see earlier). A key player in this process is protein ubiquitination, mediated by the E3 ubiquitin ligase cullin-3 (Cul3) and the BTB Cul3 substrate adaptor insomniac (inc). Post-translational covalent modification of proteins by ubiquitin polypeptides typically targets these proteins for degradation but also influences diverse processes like receptor trafficking. Loss of either *Cul3* or *inc* dramatically reduces sleep levels and sleep bout lengths and suppresses homeostatic responses to sleep loss.[106,107] Inhibition of DA synthesis can reverse these sleep phenotypes.[106]

BTB protein-protein interaction motifs also have been implicated as a genetic contributor to restless legs syndrome (RLS). Loss of the *Drosophila* homologue of the RLS gene *BTBD9* (*dBTBD9*) results in fragmented sleep and increased locomotor activity, which parallels the clinical disorder.[108] The dBTBD9 protein appears to function in dopaminergic neurons and is important to maintain dopamine levels, consistent with the established role for dopamine in RLS.[108] These data provide important validation of using fly models for human sleep disorders.

Stress and Immune Pathways

Studies of the role of the circadian clock gene *cyc* (*Bmal1* in mammals) led to the discovery of a role for heat shock stress response genes in sleep homeostasis. Female, but not male, *cyc* mutants display an exaggerated sleep rebound.[34,104] In addition, *cyc* mutants, both male and female, but not other clock mutants, are hypersensitive to the lethal effects of sleep deprivation.[34] These effects appear to be due to inadequate expression of heat shock proteins, protein chaperones important in the cellular response to stresses, such as elevated temperature.[34] This study suggests that the heat shock stress response is an important pathway for defending against the adverse consequences of sleep loss (e.g., death).

In addition to the heat shock stress pathway, endoplasmic reticulum (ER) stress responses also may be important for sleep homeostasis. The ER stress pathway is both regulated by and regulates sleep. The ER chaperone BiP is upregulated during wake and sleep deprivation.[27,109] In addition, the amount of rebound sleep after sleep deprivation is dependent on BiP levels.[109] BiP plays an important role in the stabilization and translocation of newly synthesized secretory proteins from the cytosol to the ER. BiP also is upregulated as part of the unfolded protein response (UPR), which is activated in response to an abundance of unfolded proteins in the ER. The UPR is itself upregulated in mammals subjected to sleep deprivation.[110] These data suggest that the UPR response, and subsequent BiP activation, may occur as a consequence of extended wakefulness and support a significant role for ER stress pathways in sleep homeostasis.

Another important regulator of *Drosophila* sleep is the immune response. Infection resistance and immune response genes, including the immune system master regulator nuclear factor-kappaB, Relish, are upregulated in response to sleep deprivation.[111] Decreased Relish function in the fat bodies, a key immune response tissue in *Drosophila,* results in reduced sleep.[111] Of note, the immune-related cytokines are important regulators of sleep in mammals.[112]

Membrane Excitability

A role for membrane excitability in sleep regulation is evident from studies using engineered heterologous ion channels that regulate membrane excitability (see earlier); however, these studies leave open the question of which specific channels normally underlie sleep function. Studies in *Drosophila* have highlighted the function of the voltage-gated potassium channel *Shaker* (*Sh*). The *Sh* mutant was discovered several decades ago as a mutant whose legs shake under ether anesthesia.[113] Positional cloning of this mutant led to the identification of the first voltage-gated potassium channel and subsequently several similar channels in mammals, highlighting the similarity in fly and mammalian nervous system components.[114-116]

Independent unbiased mutagenesis screens identified mutants in the Sh potassium channel and a novel SH regulator, called Sleepless (SSS), that exhibit dramatically reduced sleep amounts, with loss of as much as 80% of total sleep in a *sss* mutant.[117,118] The gene *sss* encodes a glycosylphosphatidyl-linked membrane protein,[118] and strikingly it was found that SSS directly regulates the levels, localization, and function of Sh channels.[119] In addition, mutants of an Sh regulatory subunit, *Hyperkinetic* (*Hk*), also exhibit a reduced sleep phenotype.[120] Short-sleeping *Sh* and *Hk* mutants display reduced memory in a short-term memory paradigm, providing a genetic link between reduced sleep and cognitive function.[120] The function of Sh in sleep is highly conserved as genetic inactivation of mammalian Sh orthologues also results in reduced sleep.[121,122] Of importance, severe insomnia is a prominent complaint in persons with Morvan syndrome and other autoimmune disorders characterized by antibodies to voltage-gated potassium channels,[123,124] which further highlights the conserved role of Sh and membrane excitability in sleep regulation. Another molecule recently shown to regulate sleep through changes in excitability is the rho-GTPase–activating protein Crossveinless-C (CV-C).[66] CV-C acts specifically in the dFB circuit to regulate its excitability and appears to influence sleep amount in response to homeostatic inputs, although precisely how CV-C modulates excitability remains unknown.[66]

Signal Transduction

Components of the cAMP signaling pathway also play conserved roles in sleep regulation. Various neurotransmitters act at cell surface G protein–coupled receptors to activate intracellular signal transduction cascades via metabotropic receptors (e.g., dopamine). Activation of G protein–coupled receptors such as dopamine receptors leads to an increase or decrease in adenylate cyclase activity, which modulates cAMP levels. Cyclic AMP in turn activates PKA, which phosphorylates a number of targets, including the transcription factor CREB (cAMP response element–binding protein). Mutants affecting this pathway that increase activity (e.g., increase cAMP or PKA activity) result in increased wake, whereas mutants that decrease cAMP levels generally reduce wake.[57,125] Furthermore, CREB activity is linked to sleep homeostasis. A CRE reporter gene is upregulated in response to sleep deprivation, and reduced CREB activity results in an elevated sleep rebound.[125] In addition to a wake-promoting role for this pathway in *Drosophila,* the cAMP pathway serves similar functions in both nematodes and mice.[126,127] Many of the mutations that affect the cAMP pathway were originally isolated in unbiased genetic screens for mutations that disrupt learning and memory. Thus signaling important for sleep and memory may intersect at cAMP pathways.

In mammals, a substantial body of evidence has demonstrated that acetylcholinergic signaling, originating from the lateral dorsal and pedunculopontine tegmental nuclei, promotes wakefulness and also REM sleep. Recent work in flies suggests that nicotinic acetylycholine receptors play a role in the sleep homeostatic output pathway. The *redeye* (*rye*) gene, which encodes a nicotinic acetylcholine receptor alpha subunit,[128] recently has been shown to be required for normal amounts of sleep in flies. What was unusual about Rye, however, is that levels of this protein cycle in response not to circadian time but rather to sleep need, suggesting that it acts as a sleep homeostatic output molecule. At present, however, the circuits that Rye regulate remain unclear, and it is unknown whether Rye itself acts in dFB neurons or elsewhere to modulate sleep.

WHICH GENES ARE REGULATED BY SLEEP-WAKE?

Although the focus of classical genetics is to identify those genes whose function is important for a process of interest, it also is of interest to determine how sleep-wake may in turn regulate gene function or expression. A number of sleep-wake–sensitive changes in gene expression have been described, including the activity of a CRE reporter,[125] upregulation of the ER chaperone BiP,[109] and immune system genes.[111] The most extensive attempts at identifying sleep-wake–regulated genes have used DNA microarrays to assess genome-wide gene expression under conditions of sleep, wake, and sleep deprivation.[129,130] To control for circadian regulation of gene expression, sleep-deprived and spontaneously asleep animals are analyzed at the same circadian time. By identifying the genes that correlate with a behavioral state, one is presumably identifying both factors that sustain and/or reflect that state. In addition, one can monitor gene expression linked to homeostatic drive by screening for genes whose expression increases with the duration of wakefulness. These changes in gene expression may provide clues to the molecular processes occurring during sleep and thus may reveal its underlying function.

One of the most compelling theories for the function of sleep relates to its role in homeostatic control of synaptic strength, the so-called synaptic homeostasis hypothesis. Sleep deprivation and also waking experience in *Drosophila* are accompanied by elevated expression of synaptic proteins throughout the brain,[131] as well as in larger and more numerous synapses.[132] In addition, social experience increases sleep levels and synaptic proteins in a subset of clock pacemaker neurons, the PDF^+ large LNv, which in turn mediate social experience–induced effects on sleep.[133] A number of plasticity-related genes have been implicated in mediating the sleep-plasticity link.[132,133] These observations indicate that the fly model will be a valuable platform to reveal the molecular links between sleep and plasticity.

SUMMARY: *DROSOPHILA*

The fruit fly *Drosophila melanogaster* is now well established as a genetic model organism for studying sleep. The track record of *Drosophila* genetics in unraveling the molecular mechanisms underlying the circadian clock supports the idea that this approach will yield key insights into sleep as well. The neural circuitry regulating sleep in flies remains less well characterized than in mammals, where these circuits have been studied for more than 50 years. In view of the ever-expanding technological resources available in fly model systems, however, rapid progress in delineating the circuits regulating sleep-wake is expected. Reflecting the intersection of sleep with multiple biologic processes, a number of pathways and genes have been identified that affect sleep. A current challenge is to integrate these findings to determine how these molecules fit into a hierarchical framework within the context of specific circuits in the regulation and function of sleep.

NEWER GENETIC MODEL SYSTEMS FOR STUDYING SLEEP

The success of the fruit fly as a model for sleep and circadian research has in part motivated the development of other genetically tractable animal models for studying sleep. Discussed next are the advantages and disadvantages of two such models, the zebrafish *Danio rerio* (Figure 28-4) and the nematode worm *C. elegans* (Figure 28-5), and how these newer models are providing insights into the molecular and cellular basis of sleep.

ZEBRAFISH AS A MODEL SYSTEM FOR GENETICS

In the 1970s, seminal work by George Streisinger and colleagues laid the groundwork for the use of the zebrafish *Danio rerio* as a model system for the genetic analysis of vertebrate development.[134] Zebrafish are particularly well suited for these studies owing to their small size (approximately 0.5 cm for larvae and 2.5 cm for adults), ease of maintaining large collections, rapid development, and transparent body (during embryonic and larval stages), which facilitates visualization of internal structures. After hatching, zebrafish spend approximately 1 month in a larval stage and can live up to 2 to 3 years as adults. Zebrafish mating pairs can yield hundreds of progeny, but one relative disadvantage is that their generation time approaches 3 months, which is similar to that for mice and much longer than for flies (approximately 10 days).

Large-scale chemical mutagenesis screens for developmental mutants have been carried out in zebrafish,[135-137] illustrating their suitability for powerful forward genetics approaches. In addition, generating transgenic zebrafish is routine. However, unlike with flies and worms, other genome-wide genetic technologies remain less developed, such as large libraries of transgenic lines for Gal4/UAS binary expression systems, mutation-causing transposon insertions, or RNA interference (RNAi) knockdown (to study the function of genes in specific neural circuits). Another disadvantage for genetic analysis is that the genome of zebrafish is relatively large. Members of a given gene family often are more numerous than in mammals, which can obscure analysis of mutant phenotypes.[138,139]

In contrast with other commonly used genetic model systems such as flies and worms, zebrafish are vertebrates and accordingly have a nervous system whose organization and neuropeptides and hormones are more similar to those in humans.[140-142] Moreover, the nervous systems of zebrafish are much simpler than in mammals (approximately 100,000 neurons in larvae), which facilitates fine-grained dissection of neural circuits. For example, mice have approximately 5000 hypocretin/orexin (Hcrt/Orx) neurons, whereas larval and adult zebrafish have approximately 10 and 50 such neurons, respectively.[143-145] Another advantage of zebrafish models is the ease of performing large-scale drug screens in these animals, which can then be used to inform mechanisms of action of drugs or dissect molecular pathways underlying a behavior of interest, as well as to discover novel potential pharmaceuticals.[146,147] Finally, the transparency of larval zebrafish (and in adults of certain strains) makes possible powerful in vivo imaging approaches to study the activity of neural circuits in real time.

ZEBRAFISH AS A MODEL SYSTEM FOR STUDYING SLEEP

Like fruit flies and humans, zebrafish are diurnal, with elevated locomotor activity during the day as compared with the night. Sleep in zebrafish has been characterized during two developmental stages: larval and adult stages.[140,141,144,148,149] Zebrafish sleep was first characterized in midstage larvae[148] and later in early larvae[144] and adults.[149] As in fruit flies and other nonmammalian models, sleep is defined in larval and adult zebrafish using behavioral criteria.[140,141] In both stages, zebrafish exhibit periods of quiescence under circadian control, during which they are less responsive to external stimuli (manifested as increased arousal threshold). Furthermore, in general, this behavior is under homeostatic control and associated with postural changes. High-resolution video tracking is employed to measure sleep in zebrafish, and utilizing changes in arousal threshold as criteria, immobility for 1 minute (for larvae) or 6 seconds (for adults) is used to identify a minimum bout of sleep. Also, as in most other organisms, sleep amount in zebrafish changes throughout the lifespan—sleep amounts are higher in larval fish than in adults.[150]

Sleep behavior in zebrafish is under circadian control, as indicated by persistence of its variation throughout the day in the absence of environmental cues. Molecular components of the core circadian oscillator are well conserved in zebrafish,[151] although only one mutation has been identified in a core clock gene (*Clock1*^{dg3}).[152] It is unclear whether zebrafish have a suprachiasmatic nucleus, and even if present, it may not have the central importance in organizing rhythms as in mammals. Instead, because zebrafish are largely transparent and have many light-entrainable cells throughout their body,[153,154] there may not be a need for a single "master clock."

Zebrafish sleep also is under homeostatic control. To examine these phenotypes, sleep deprivation typically is performed using mechanical perturbation or mild electric shock.[148,149] In larval zebrafish, sleep deprivation induced using mechanical vibration led to an increase in "rebound sleep" (i.e., reduced locomotor behavior associated with an increase in arousal threshold).[148] However, homeostatic regulation may not be as pronounced in adult zebrafish. Although shorter periods of deprivation for several hours led to an increase in sleep behavior in adults,[149] the data have been described to be less consistent with more prolonged sleep deprivation.[140] In addition, sleep deprivation induced by prolonged exposure to light does not result in an increase in sleep rebound,[149] although the absence of rebound may reflect the effect of light on other processes, such as circadian clock function.

Signaling Mechanisms Regulating Sleep in Zebrafish

As discussed earlier, a number of monoaminergic and cholinergic cell groups in the brainstem and hypothalamus promote wakefulness in mammals. A majority of these groups—namely, the tuberomamillary nucleus (histamine), the raphe nucleus (serotonin), and locus ceruleus (norepinephrine)—are well conserved in zebrafish.[155] In terms of sleep-promoting centers, zebrafish have a cluster of GABAergic neurons in the anterior hypothalamus,[149] which may be analogous to VLPO in mammals, although the function of this circuit has not yet been tested. In addition to these neuromodulatory transmitters, zebrafish sleep also is regulated by the hormone melatonin and the neuropeptide hcrt/orx, discussed in more detail further on.

Melatonin Promotes Sleep

In mammals, melatonin is produced by the pineal gland and is released at night in both diurnal and nocturnal animals.

Similarly, melatonin is secreted by the pineal gland of zebrafish under circadian control, with higher circulating levels at night. Also as in mammals, direct projections from Hcrt neurons to the pineal gland have been identified in zebrafish, suggesting that the melatonin/pineal gland system probably can be modulated by noncircadian neuromodulatory circuits.[156] However, unlike in mammals, where circadian release of melatonin is driven by the suprachiasmatic nucleus, in zebrafish, the pineal gland is thought to function as an independent circadian oscillator able to generate rhythmic melatonin release.[157,158] This distinction may reflect anatomic differences, whereby the pineal gland can be directly entrained by light in zebrafish, whereas it is not subject to direct light exposure in mammals. In zebrafish, melatonin has significant sleep-promoting effects. Administration of melatonin to larval zebrafish during the daytime leads to a marked increase in sleep time.[148] These effects appear to be more pronounced than those seen in humans, in whom sleep time is only mildly increased with administration of melatonin.[159-161] However, this difference may reflect administration of melatonin during the night done in a majority of studies, when sufficient levels of melatonin are already present.[159] Indeed, if melatonin is administered to humans during the daytime, significant effects of sleepiness can be observed.[162] These studies in zebrafish highlight the role of melatonin as a sleep-promoting factor, which is regulated by circadian timing mechanisms. Of interest, melatonin does not promote sleep in nocturnal rodents,[163,164] and commonly used laboratory mouse strains (e.g., C57BL/6 and 129/Sv) do not synthesize melatonin.[165] Thus zebrafish may be a better model organism than mice for studying the effects of melatonin on sleep.

Hypocretin Stabilizes Sleep-Wake States

Impairment of Hcrt signaling is the key pathogenic mechanism underlying narcolepsy. To gain further insights into Hcrt function and circuitry, investigators have turned to the zebrafish system. As in mammals, a single pre-pro-Hcrt protein is differentially cleaved to yield two distinct peptides, Hcrt-1 (i.e., orexin-A) and Hcrt-2 (orexin-B). However, only a single Hcrt receptor exists in the zebrafish proteome (HcrtR2), in contrast with mammals with their two receptors. Because of the simplicity of the zebrafish nervous system, the number of Hcrt neurons is substantially smaller (approximately 10 per brain hemisphere in larvae and 50 per hemisphere in adults). In larvae, these cells are located in the lateral hypothalamus[143] and have been shown to send extensive projections to multiple arousal centers, including noradrenergic cells of the LC.[144,145] Consistent with this observation, Hcrt2 is broadly expressed and found in monoaminergic arousal centers.[144] Of interest, however, another team of investigators reported that in 2-day-old larvae and adults, Hcrt2 expression was detected not in these monoaminergic cells but rather in GABAergic cells.[149] The difference in these findings may reflect the use of fluorescence versus chromogenic in situ hybridization assays, but as discussed later, the balance of evidence currently favors the model that Hcrt neurons in zebrafish promote wakefulness by signaling to arousal-promoting monoaminergic neurons.

To address the function of Hcrt in zebrafish, one group of workers overexpressed the Hcrt pre-propeptide in larval zebrafish using an inducible heat-shock promoter and observed an increase in wakefulness and arousal.[144] Inducible ablation of Hcrt neurons in larval zebrafish increases daytime sleep and the number of sleep-wake transitions, supporting the notion that Hcrt promotes wakefulness and sleep-wake stability.[166] Moreover, as discussed later, monitoring Hcrt neuronal activity in vivo reveals that these neurons are active during periods of robust locomotor activity, when larvae presumably are highly aroused.[167] By contrast, another group of investigators found that a null mutation in the Hcrt2 receptor led to a reduction in sleep time during the night, with increased fragmentation, in adult zebrafish,[149] which on the surface would suggest that Hcrt signaling promotes sleep. Differences may be due to inducible versus constitutive manipulations. Although it is well recognized that mouse models of narcolepsy as well as human subjects so affected exhibit sleep fragmentation during the night,[168,169] the primary clinical feature in patients with narcolepsy is their profound sleepiness during the day.[170] In summary, these studies suggest significant conservation of the neuronal circuitry and function of Hcrt between zebrafish and mammals and point toward the promise of the zebrafish system in unraveling molecular and cellular mechanisms that regulate this pathway.

Neuropharmacology Regulating Sleep

As is the case for other genetic model organisms for sleep, including mice and fruit flies, zebrafish sleep is responsive to sleep- and wake-promoting drugs. GABA receptor agonists such as diazepam and pentobarbital promote sleep,[148] whereas modafinil promotes wakefulness.[171] However, a clear strength of the zebrafish system is the ease of performing drug-feeding assays in a high-throughput manner. Drugs can be added to the water, and because zebrafish larvae are approximately 0.4 mm long, individual animals can be monitored in 96-well plates.[172] Furthermore, zebrafish larvae readily take up small molecules and lack a functional blood-brain barrier.[147] Recently, a large-scale screen of approximately 4000 unique compounds was carried out using zebrafish larvae to assay the effects of these drugs on sleep-wake behavior.[147] By profiling and comparing the behavioral responses to each compound, this study found conservation of known molecular pathways regulating sleep in other animals, such as monoamines, GABA, adenosine, and Shaker-type potassium channels. Moreover, novel roles for ether-a-go-go–related gene (ERG) potassium channels and L-type calcium channels in sleep-wake regulation were identified. Finally, such drug profiling screens have the potential to reveal mechanisms of action for compounds that are poorly characterized.[147]

In Vivo Analysis of Circuit Function in Zebrafish

As mentioned previously, the transparency of zebrafish embryos and larvae facilitates live imaging approaches in intact animals. Coupled with their useful genetic traits and their relatively simple neural networks, zebrafish hold tremendous potential for the analysis of long-term in vivo imaging as well for systems neuroscience. A growing body of evidence suggests that synaptic structure is regulated by circadian- and sleep-dependent processes.[132,133,173-175] For example, the *Drosophila* PDF^+ sLNv neurons exhibit circadian-dependent changes in their terminal projections.[176,177] To address this issue in larval zebrafish, a recent study utilized repeated two-photon imaging of the same Hcrt neurons over a 24-hour period. This study reported an increase in synaptic terminal

number of Hcrt neurons projecting to the pineal gland during the daytime, suggesting that Hcrt synaptic terminal structure is under circadian control.[178]

Besides neuronal structure, investigations into the function of neural circuits have been revolutionized by the use of the genetically encoded neuronal activity reporters including GCaMP, which measures Ca^{2+} levels.[179] For example, zebrafish researchers have used GCaMP to monitor real-time dynamics of brainwide circuit function underlying optomotor behavior.[180] One drawback for the use of GCaMP for studying sleep-wake circuits is that the light used for excitation will affect behavior, so this technique may not be suitable until the development of Ca^{2+} reporters with excitation spectra in the infrared range. In addition, the identification of which specific cells are active will require the generation of more cell-specific transgenic driver lines. Until then, bioluminescence approaches, which do not require excitation and can measure neuronal activity over longer time scales (minutes to hours), can be used to measure neuronal activity in vivo in freely behaving zebrafish. To examine Hcrt neuron activity in freely behaving zebrafish larvae, the Ca^{2+}-activated bioluminescent reporter green fluorescent protein (GFP)-apoAequorin was expressed in these neurons. The aggregate activity of these neurons, as assessed by total neuroluminescence, was continuously measured and found to be increased during periods of arousal,[167] similar to results obtained in rodents.[181,182] At present, these bioluminescence techniques lack the spatial resolution to distinguish changes in activity in distinct cells. Ultimately, however, the use of genetically encoded reporters should allow researchers to probe brainwide dynamics of sleep-wake circuits in zebrafish, yielding critical information about how these networks function and interact under different circadian and sleep homeostatic conditions.

SUMMARY: ZEBRAFISH

The zebrafish *Danio rerio* has a well-established history as a powerful genetic model system for the study of vertebrate development and has more recently been utilized to study sleep. Advantages of this system include (1) the ability to study the molecular and cellular mechanisms underlying sleep in a vertebrate animal with a relatively simple nervous system; (2) a higher degree of conservation (compared with invertebrates) of sleep-related neuropeptides and hormones; (3) the ability to perform high-throughput behavioral assays; (4) transparency of early stage zebrafish which facilitates in vivo neuronal imaging; and (5) the ease of performing large-scale drug screens. Disadvantages include (1) a long generation time, which can hinder outcrossing to control for genetic background; (2) a relative dearth (in comparison to *Drosophila* and *C. elegans*) of genome-wide transgenic reagents; and (3) a relatively large genome, with a significant number of paralogs, which can inhibit genetic analysis. Until now, sleep studies in zebrafish have largely focused on determining basic characteristics of sleep behavior as well as confirming the function and circuits of previously identified molecules underlying sleep, such as melatonin and Hcrt. With respect to future investigations, the two main strengths of this system relate to the power of large-scale drug screens and the ability to perform in vivo imaging activity of neural networks regulating sleep at a systems level.

CAENORHABDITIS ELEGANS AS A MODEL SYSTEM FOR GENETICS

At first glance, the nematode worm *C. elegans* would seem to be an unlikely candidate for a model organism to study sleep behavior. Adult animals are small (approximately 1 mm long) and have a very simple nervous system, comprising only 302 neurons.[183] Recent work, however, has indicated that *C. elegans* is the simplest animal that exhibits a sleep-like state, termed *lethargus*. As described next, studying this quiescent behavior in worms can reveal shared mechanisms underlying sleep and potentially identify novel genetic mechanisms.

Since the 1970s, when Sydney Brenner first established *C. elegans* as a model system for the genetic analysis of developmental biology and neurobiology,[184] the nematode worm has been a workhorse for the identification of important molecular mechanisms underlying processes such as apoptosis, cell fate decisions, RNA interference, and the neural circuitry underlying simple behaviors. *C. elegans* shares some advantages with zebrafish in that the worms also can be easily cultivated in large numbers (approximately 10,000 in a single petri dish) and are transparent. In contrast with zebrafish, however, adult *C. elegans* nematodes live only 2 to 3 weeks and have a short generation time (approximately 3 days), during which they develop through four larval stages before becoming an adult. Furthermore, the *C. elegans* genome is compact, with approximately 100 million base pairs, and a number of genomewide transgenic reagents are available in worms, including RNA interference libraries and knockout strains. However, one of the most appealing features of the worm system for studying neuroscience is the presence of a complete "connectome." The entire neural network of *C. elegans* has been mapped, with every connection between each of the 302 neurons in their nervous system identified at the ultrastructural level.[183,185] This comprehensive circuit atlas is a great boon for researchers studying how neural circuits regulate behavior in worms.

CAENORHABDITIS ELEGANS AS A MODEL SYSTEM FOR STUDYING SLEEP

As discussed previously, behavioral criteria have been used to define sleep in small nonmammalian animal models.[186] On the surface, worms do not meet the traditional criterion of "behavioral quiescence under circadian control." That is, these worms do not undergo daily cycling of rhythmic behavioral quiescence. It has long been appreciated, however, that the *C. elegans* nematode exhibits consolidated episodes of behavioral quiescence during development.[187] During larval development, these worms undergo a stage termed "lethargus" that precedes each larval molt, in which the animals generally do not move or feed. An important clue linking lethargus to sleep was the finding that the Period homologue in worms, *lin-42,* did not exhibit a daily cycling rhythm as seen in other animals but rather showed episodic expression, coordinated with the timing of lethargus.[188] In further support of *lin-42* regulating rhythmic timing of this behavior, loss of *lin-42* causes arrhythmic molting.[189] Lethargus is thus a behaviorally quiescent state under control of a molecule best known for its role in regulating the circadian clock. Moreover, quiescence during lethargus meets all other criteria for sleep and was

thus suggested to represent a sleep-like state.[126] First, during lethargus, worms assume a specific posture with reduced body curvature.[190] Second, quiescent animals during lethargus exhibit an increased arousal threshold. Third, depriving *C. elegans* of lethargus behavior leads to an increased drive for this behavior, indicating that it is under homeostatic control. Furthermore, bouts of quiescence are longer in duration in the early part of a lethargus period.[190] Strikingly, as is the case for rats and flies,[34,35] complete deprivation of this sleep-like behavior is associated with lethality in worms.[191] Finally, as discussed further on, a number of molecular pathways that have been shown to modulate sleep in other organisms also do so in worms. Because lethargus is associated with molting behavior, an important point is that this relative immobility is not simply due to physical constraints related to the molting process.[126,190]

As is the case for larval zebrafish, measurement of lethargus quiescence in worms uses high-resolution video analysis. These studies typically focus on the lethargus state occurring during the fourth larval stage and have mainly used a frame-subtraction algorithm for image analysis.[25,126,192] Lethargus is a relatively brief state, lasting 2 to 3 hours, and within this period, hundreds of bouts of quiescence, each lasting approximately 30 seconds and seen predominantly during the early part of this stage, are interspersed with bouts of activity. As discussed previously, measurements of sleep in fruit flies and zebrafish use a specified duration of inactivity, associated with a change in arousal threshold, as the minimum bout length for sleep. By contrast, worm researchers measure the fraction of time a worm is quiescent in a moving 10-minute window during the lethargus state, which is easily recognized owing to both developmental time and the absence of feeding activity (pharyngeal pumping). Because these quiescence bouts during lethargus states are relatively brief, and because adult worms do not exhibit this behavior, certain aspects of sleep, including the effects of aging on sleep, probably cannot be addressed using this model system. Nonetheless, the power to perform genetic and neural circuit analyses is nearly unrivaled in worms and makes this system a compelling one to address specific aspects of conserved quiescent behaviors and potentially ancient functions of sleep.

Shared Molecular Mechanisms between Lethargus and Sleep in Other Animals

The worm system is a relative newcomer to the study of sleep, but already molecular pathways are being identified in *C. elegans* that demonstrate conservation of these sleep-regulating pathways in other animals. These studies support the notion that the developmental lethargus stage is analogous to a sleep state in other animals.

Protein Kinase Signaling Can Promote or Inhibit Sleep-Like States

Two kinases have been implicated in regulating lethargus behavior in worms. The cyclic guanine monophosphate (cGMP)-dependent protein kinase (PKG) has been shown to promote behavioral quiescence, whereas the cAMP protein kinase (i.e., PKA) inhibits quiescence during lethargus. For example, loss-of-function mutation in *egl-4,* a worm homologue of PKG, leads to a decrease in lethargus behavior, suggesting that PKG signaling promotes sleep; similar observations were subsequently made in flies.[126,193] In mice, reduced PKG activity is associated with decreased power in the delta band of the electroencephalogram, suggesting a reduced drive to sleep.[194] By contrast, PKA signaling has been shown to promote wakefulness in flies and mice.[57,125,127] In *Drosophila*, overexpression of PKA reduces sleep time, whereas increasing cAMP levels (in the cAMP phosphodiesterase mutant *dunce*) and decreasing cAMP levels (in the adenylate cyclase mutant *rutabaga*) cause a decrease and an increase in sleep time, respectively.[125] In worms, increasing PKA activity through a loss-of-function mutation in the PKA regulatory subunit *kin-2* or a gain-of-function mutation in the adenylyl cyclase *acy-1* reduces the amount of quiescent behavior during lethargus.[190,195]

Growth and Differentiation Pathways Modulate Sleep

Two signaling pathways with broad roles in development and cellular differentiation—EGF and Notch signaling[196,197]—also have been shown to regulate lethargus in worms. The first signaling pathway identified to regulate lethargus was the EGF pathway.[69] In mammals, EGF signaling had previously been implicated in circadian regulation of locomotion and sleep.[71] Further work in flies revealed that EGF signaling enhanced sleep amount.[68] Similarly, ectopic overexpression of the EGF homologue, Lin-3, induced behavioral quiescence, as seen in lethargus.[69] Finally, Notch signaling recently has been shown to regulate sleep-like behavior in both worms and flies. In worms, overexpression of the Notch coligand OSM-11 induces lethargus behavior,[198] and this phenotype depends on Egl-4/PKG as well as the ALA interneuron.[198] Furthermore, double mutants bearing mutations in OSM-11 and another related protein, OSM-7, display a reduction in quiescence during lethargus. In flies, Notch signaling has been implicated in regulation of "rebound" sleep, the increased sleep seen after sleep deprivation. Overexpression of the Notch ligand Delta in the MBs reduces sleep rebound, which also is seen in a Notch gain-of-function mutation.[199] These data thus demonstrate that classical growth and differentiation signaling pathways also can play a role in modulating sleep-like states.

Neuromodulatory Signaling and Lethargus

The activity of neural circuits often is subject to regulation by neuromodulators, which tunes the function of a circuit in response to internal states of the organism or the environment. These neuromodulators include monoaminergic neurotransmitters, GABA, and neuropeptides and modulate a wide range of behaviors and physiologic processes, including sleep.[200-202] As discussed earlier, dopamine signaling promotes wakefulness in flies.[82,87,88,203] A similar arousal-promoting function for dopamine also has been found in *C. elegans* lethargus. A loss-of-function mutation in the dopamine transporter *dat-1* (which leads to excess dopamine in the synaptic cleft) reduces lethargus quiescence, whereas reduced activity of the dopamine receptor *dop-1* results in increased lethargus quiescence.[204] Neuropeptides also play a key role in regulating sleep behavior.[202,205] These neuropeptides typically activate G protein–coupled receptors and, unlike classical neurotransmitters, can act on multiple neurons at once.[201] In *Drosophila*, the neuropeptide PDF plays a key role as a neuromodulator that synchronizes circadian clock circuits and promotes wakefulness.[77,98,99,206,207] Two homologues of PDF exist in *C. elegans*, PDF-1 and PDF-2, and PDF-1 has been shown

to promote arousal.[208] The release of PDF is itself regulated by neuropeptidergic signaling. The FMRF-like peptides FLP-18 and FLP-21 are ligands for the neuropeptide receptor NPR-1, and this signaling pathway inhibits PDF release during lethargus.[208]

Another neuropeptide recently shown to regulate quiescence behavior during lethargus is the neuropeptide-like protein NLP-22.[209] The expression of NLP-22 mRNA cycles, reaching a peak a few hours before the onset of a lethargus period, and can be regulated by Lin-42/PERIOD. Overexpression of NLP-22 during the normally active adult stage induces behavioral quiescence, while loss of NLP-22 function decreases quiescence during lethargus. Of interest, this neuropeptide bears some similarity to neuromedin-S, which is produced in the mammalian suprachiasmatic nucleus and has been suggested to play a role in regulating circadian phase.[210] Thus the finding that NLP-22 is a rhythmic molecule that mediates behavioral quiescence in worms raises the possibility that neuromedin-S may similarly regulate clock-dependent regulation of sleep. Collectively, these findings from kinase, growth/differentiation, and neuromodulatory signaling pathways suggest that lethargus behavior is regulated by similar mechanisms that modulate sleep in other organisms and support the notion that lethargus in *C. elegans* is a sleep-like state.

Simple Neural Circuits Regulating Lethargus

As mentioned previously, every neuron in the *C. elegans* nervous system has been identified and characterized in terms of its connections to other neurons. Thus studying the circuits that mediate lethargus holds significant potential for precisely dissecting the minimal circuits required for a sleep-like state, as well as how these circuits are modulated according to changes in internal or external states.

Individual Neurons that Regulate Behavioral Quiescence in Caenorhabditis elegans

Recent studies have led to the identification of individual neurons required for lethargus behavior in worms. The first neuron shown to regulate lethargus was the ALA interneuron, which receives the Lin-3/EGF sleep-promoting signal.[69] Elimination of the ALA neuron by laser-induced cell ablation suppressed the lethargus-promoting effect of Lin-3 overexpression. More recent data suggest that one of the key functions of the ALA interneuron is to mediate stress-induced quiescence behavior.[211,212] Exposure of *C. elegans* to treatments that induce cellular stress (e.g., heat) lead to behavioral quiescence resembling that seen during lethargus. This stress-induced quiescence behavior has protective effects, suggesting the possibility that one of the ancient functions of sleep may be for recovery from cellular stress.[212] Of interest, stress-induced quiescence behavior depends on a neuropeptide, FLP-13, which shares some homology with the sleep-promoting sNPF neuropeptide in flies.[211]

Another neuron regulating quiescence during lethargus was identified from a forward genetic screen. From a screen of approximately 4,000 mutant strains, a mutation in an AP2 transcription factor homologue, *aptf-1,* was identified that exhibited strongly reduced quiescence during lethargus.[213] Characterization of this gene led to the identification of a single neuron—the RIS neuron—that promotes quiescence during lethargus. Using GCaMP imaging, the RIS neuron was found to exhibit a sharp increase in activity near the onset of quiescent behavior, and laser-mediated ablation of this cell markedly reduced quiescence behavior during lethargus. Moreover, optogenetic activation of the RIS neuron using Channelrhodopsin-2 (a light-activated ion channel) induced behavioral quiescence, which was reversible, and appeared to do so by suppressing the activity of downstream locomotor command neurons.[213] These properties of the RIS neuron resemble that of the sleep-promoting center VLPO in mammals. Thus the identification of these neurons that promote quiescence in worms may provide an entry point to elucidate how various mechanisms such as homeostatic regulation act to influence sleep.

Gating of Sensory Stimuli Is an Important Mechanism Regulating Behavioral Quiescence

An important mechanism involved in regulating sleep is "sensory gating." In mammals, the thalamus is thought to gate sensory input, such that sensory information is processed at a subcortical level during sleep and wakefulness.[214] Such mechanisms would protect sleep continuity as stimuli from minor noises would be filtered out and not reach the cortex to disturb sleep. Emerging studies using genetic and electrophysiologic approaches are addressing these circuit mechanisms in mammals,[215] but studying lethargus in the nematode *C. elegans* also should provide insights into the mechanisms underlying sensory gating. For instance, the effects of Egl-4/PKG and Notch signaling on lethargus depend on their function in sensory neurons.[126,198] Ca^{2+} imaging studies using GCaMP have supported the notion that the activity of sensory neurons is inhibited during lethargus. For example, the ALM mechanosensory neuron exhibits calcium transients in response to gentle mechanical stimulation, and these calcium transients are substantially reduced in amplitude during lethargus.[216] Another sensory neuron that exhibits state-dependent changes during lethargus is the ASH neuron, which responds to aversive mechanical and olfactory stimuli.[217] Functional imaging of the ASH sensory neuron demonstrates reduced activation after exposure to aversive chemical stimuli during the lethargus state. Also during lethargus, the activity of interneurons downstream of ASH also becomes asynchronous, and synchronizing the activity of these neurons promotes arousal.[217]

An additional example of a sensory gating mechanism regulating lethargus is the PDF-1 neuropeptide discussed previously. During lethargus, the release of PDF is inhibited by NPR-1, a neuropeptide receptor that has sequence similarity to the neuropeptide Y (NPY) receptor in mammals. Outside of lethargus, PDF-1 acts on its receptor PDFR-1 in mechanosensory neurons to enhance their sensitivity to touch stimuli, thus promoting arousal. PDFR-1 is required for the increased touch-evoked calcium transients in these neurons in *npr-1* mutants.[208] Collectively, these data suggest that NPR-1 inhibits PDF-1/PDFR-1 signaling during lethargus, which dampens the response of sensory neurons to external stimuli. Such sensory gating mechanisms would promote sleep by inhibiting its interruption by external stimuli. Despite the many advantages of studying a small and simple neural network for sleep, such as in worms, there are also potential disadvantages. Owing to their small size and small numbers, the firing patterns of neurons in *C. elegans* are distinct from those in mammals and even flies. For example, the current

evidence suggest that neurons in *C. elegans* fire classical action potentials; rather, they appear to produce "plateau potentials," with prolonged depolarized or hyperpolarized states.[218,219] Thus how neural circuits in worm encode information may differ significantly from that in other organisms.

SUMMARY: CAENORHABDITIS ELEGANS

The advantages of using *C. elegans* to study sleep include the powerful molecular genetic techniques available for this system, as well as the simple nervous system with a fully defined wiring diagram for its 302 neurons. In support of the hypothesis that lethargus represents a sleep-like state, previous work has established that a number of signaling mechanisms known to regulate sleep in other animals also regulate lethargus in *C. elegans*. Disadvantages of this system include the question of how closely related lethargus is to sleep behavior in other animals. Just as these worms do not have typical 24-hour behavioral and physiologic rhythms, it may be that an animal with so few neurons and whose lifespan is only 2 weeks long may not have the same requirements for specific functions of sleep. In view of current knowledge on this topic, however, it is likely that many genetic and molecular pathways underlying sleep will be conserved in worms, and in future investigations, the major strengths of this system will be the identification of novel molecules and how they act within a precisely defined neural circuit to regulate sleep.

CLINICAL PEARL

Chronic sleep loss can lead to adverse health consequences. Indeed, sleep deprivation in the fruit fly leads to premature death.

SUMMARY

Over the past 15 years, the fruit fly model of sleep has been validated as an important model for the study of sleep. The fly has many of the core features of sleep in common with mammalian systems. Many features of *Drosophila* sleep are independent of changes in spontaneous movement and include elevated arousal threshold, homeostatic regulation, electrophysiologic correlates, and conserved responses to sleep-wake regulatory drugs. In addition, genetic screens have identified shared genes/pathways of sleep control with their mammalian brethren. Zebrafish and *C. elegans* have more recently joined the fruit fly as established nonmammalian genetic model organisms for dissecting the molecular and cellular mechanisms underlying sleep, and each system has intriguing advantages for such study. Future work exploiting the power of genetics in these model organisms promises to reveal the underlying molecular and cellular mechanisms of sleep regulation and ultimately provide some clues to the function of sleep.

Genetics and Genomic Basis of Sleep in Rodents

Chapter Highlights

- Sleep, the genome, and the brain are all well conserved across mammalian orders. Rodents, and especially the house mouse, *Mus musculus*, offer the ability to dissect the role of genes in multiple pathways including those that regulate, influence, or underlie sleep and wake.
- A number of these genes, or potential candidate genes, have been identified by a wide variety of genetic and genomic approaches, including studies of gene expression that differ in sleep versus wake, alterations or "knock out" of genes by mutagenesis or directed approaches, and the use of many well-characterized mouse strains that differ in multiple sleep traits and can be crossed to map the causative gene alleles that contribute to this variation.
- Knowledge of these genes and gene alleles has suggested both known and new pathways that influence sleep, including the so-called clock genes that may underlie both circadian rhythms and sleep homeostasis, which occurs most likely in forebrain structures such as the cerebral cortex.
- Genetic and genomic approaches have also been useful as markers of neural activity or used to identify key brain regions involved in arousal state control.

Genetic approaches and gene manipulation have recently added to our understanding of genes involved in sleep architecture and function, identified new brain regions involved in regulation of sleep, and characterized genes associated with sleep disorders and disease-related sleep aberrations. New sleep-related discoveries made by integrating classical and newer genetic methods have validated the utility of genetic approaches for identifying and understanding genes involved in sleep in both health and disease. At this time, the mouse represents the best animal model for such studies, which can take advantage of the rich genetic resources that have already been established in this species, including many genetically modified lines and genetic reference populations that can be used for a wide range of biomedical research. Given the similarities in physiology and genetics across eutherian mammals, it is likely that genes influencing sleep traits in mice also influence sleep traits in humans, and genetic studies of sleep using mouse models will continue to help identify critical molecular pathways and networks underlying sleep functions and regulation.

Genes and their allelic variants are important for an understanding of sleep for a number of reasons. For example, genetic approaches have identified critical functions and the core molecular pathways involved in normal sleep and in sleep disorders. Although the biologic need for sleep itself has been more difficult to study, identification of key regulatory genes involved in sleep homeostasis provides a mechanism to study the fundamental question of the function of sleep. This includes exploring the possible substrates of the restorative function of sleep, such as energy state, protein levels, and synaptic optimization, as well as examining the importance of sleep for mental and physical health. Genes and gene regulation may or may not be directly critical to the regulation of sleep-wake transitions; nevertheless, genes still code for the proteins that are critical to all biologic functions, and genetic analyses may still provide the keys for finding these functions. For example, although changes in gene expression are probably too slow to directly underlie sleep-wake transitions, one could imagine that general levels of gene expression could influence the probability of transitions between non–rapid eye movement (NREM) sleep, rapid eye movement (REM) sleep, and wake. Such genes could encode proteins involved in post-translational changes in ion channels or other proteins that alter membrane potential, and their allelic variants could thus contribute to variations in sleep-wake behavior in mouse and human populations.

This chapter addresses various approaches to find genes and allelic variants that influence sleep behavior. As the functions of sleep are still not completely understood, genetic approaches have been most valuable in identifying genes that affect measurable sleep traits, such as the time spent asleep and its distribution over the day. The genes that regulate sleep may or may not be different from those that are involved in the functional restorations that sleep may provide. Similarly, some genes that alter traits related to specific electroencephalography oscillations may or may not be central to the understanding of the function of sleep. In addition, a large group of genes vary their expression across sleep and wake, some of which are probably important to downstream functions relevant to sleep and wake even if they themselves are not "core" sleep-regulating genes. To help understand the current state of the art in these various approaches toward understanding

sleep, this chapter is divided into sections based on the most important general methodologies used to identify genetic mechanisms:

- Changes in gene expression, or more precisely, changes in steady-state–specific messenger RNA (mRNA) levels, during sleep and wake. The majority of these genes may simply be responding to arousal state, but some of these genes could be critical components in the regulation of sleep-wake traits.
- Identification of "naturally occurring" allelic variants that underlie individual differences or strain differences in sleep-related traits. Some of these genes are likely to be important in sleep regulation or functional aspects of sleep, although many may represent pleiotropic genes that only indirectly alter sleep. Nevertheless, such genes and associated genetic networks may still be important to understanding of the underlying physiologic and pathophysiologic mechanisms that underlie normal sleep as well as sleep disorders. We highlight the quantitative trait loci (QTL) approach in uncovering the natural allelic variants influencing sleep-wake phenotypes.
- Identification of genes that regulate sleep or influence sleep-related traits by mutagenesis and transgenic strategies. These approaches artificially alter or knock out genes to find those that influence sleep.

Although these three methodologies differ in their approach, they complement each other, and to ensure progress in identifying the genes and gene networks important to sleep, they are often used in parallel. For example, transgenic approaches are used as follow-up studies for candidate genes located within QTL. Moreover, the QTL approach is now more and more integrated with genome-wide expression profiling to model gene networks and key regulatory pathways that underlie multiple interrelated sleep phenotypes. Such multiscale systems approaches have revealed intriguing gene functional organizations not only important for sleep but also linking sleep to other major functions of the brain.

GENE EXPRESSION, mRNAs, AND MICROARRAY STUDIES

The investigation of variation in gene expression patterns between sleep and wake began with targeted investigation of single genes of interest and later used microarrays and now RNA sequencing to compare global expression changes between sleep and wake in brain and other tissues to identify genes with no prior assumptions about their functional involvement in sleep. The first class of genes that was clearly shown to vary across sleep and wake were rapid response genes, often called immediate early genes (IEGs), such as c-*fos* (FBJ osteosarcoma oncogene).[1-3] Changes in IEG expression are of interest for at least two reasons. Because most IEG mRNAs and proteins increase with neuronal activity, they can be used to identify brain regions activated by changes in arousal state. Second, because most IEGs are transcription factors, they may represent "master-switch" genes that initiate a complex of molecular signaling cascades.[4] These pathways may be important for longer term homeostatic control or restorative functions critical to sleep and wake.

Most brain regions are more active during wake than during sleep and thus show higher levels of expression of IEGs during wake.[1-3] Exceptions to this expression pattern point to brain regions that are active during sleep and may play regulatory roles in sleep. In the cerebral cortex, a small subset of GABAergic neurons that express neuronal nitric oxide synthase (nNOS) increase c-*fos* expression during NREM sleep.[5] This finding led to subsequent studies that further characterized cortical sleep-active nNOS neurons and their role in NREM sleep homeostasis. Specifically, these cortical nNOS neurons coexpress the NK1 receptor (or *Tacr1*, tachykinin receptor 1), and the activities of these neurons regulate the amount of NREM sleep, NREM sleep bout duration, and electroencephalogram (EEG) delta power during NREM sleep.[6,7] The last measure quantifies the amplitude and prevalence of delta or slow waves (1 to 4 Hz) characteristic of the NREM sleep EEG and is widely used to estimate homeostatic sleep need. Another interesting region where c-*fos* is higher in sleep than in wake is the ventrolateral preoptic area (VLPO) of the anterior hypothalamus, consistent with the VLPO's being a "sleep-active" region.[8] Neuroanatomic tracings linked this sleep-active region containing inhibitory GABAergic neurons to wake-active structures, including histaminergic neurons in the posterior hypothalamus, suggesting a reciprocal interaction between these two structures.[9] Later, other hypothalamic nuclei were integrated into a model indicating that several hypothalamic regions combine to play a critical role in sleep-wake regulation.[10] Among these other regions are the hypocretin/orexin neurons that are central to our growing understanding of narcolepsy. The exciting breakthrough that led to the elucidation of a critical role for the hypocretin/orexin neurons in narcolepsy came from a combination of dog genetics,[11] mouse knockouts,[12] human pathology and pathophysiology,[13] and, earlier, subtractive hybridization and rat neuroanatomy.[14] Research on the role of hypocretin/orexin in narcolepsy is described in Chapter 89. Expression of IEGs has also been used to support and to extend our understanding of the dorsolateral pontine region in the control of REM sleep[15] and the locus ceruleus in wake.[16] Mapping of sleep-active neurons by increased c-*fos* expression was first used to identify potential sleep-active neurons in the brainstem that respond to REM sleep perturbations.[17] More recently, c-*fos* expression was used to identify a sleep-active region of the brainstem, called the parafacial zone; loss of the sleep-active neurons in this region causes increased daily wakefulness and reductions in both NREM and REM sleep.[18] A recent follow-up study demonstrates that projections from sleep-active parafacial neurons inhibit wake-promoting neurons in the medial parabrachial nucleus, which in turn send glutaminergic innervations to cortical-projecting magnocellular regions of the basal forebrain, suggesting a neural circuit that may be important in triggering NREM sleep and promoting cortical EEG synchronization.[19]

Other studies have shown interesting regional differences throughout the brain for the expression of specific IEGs during sleep deprivation and recovery sleep[20] and similarly for some of the so-called heat shock or stress response genes.[21] The results from studies in rats and mice are consistent with each other,[22] suggesting an important generalizability across rodents and probably all mammals. In addition, diurnal squirrels have peaks of IEG expression and heat shock protein 70 during the day (instead of the night, as in nocturnal rodents), consistent with high levels of mRNA correlating with wake.[23,24] Although it is still unclear what role these IEGs and

heat shock mRNAs and proteins play, their consistent increase during periods of wake and neuronal activity suggests the possibility of some restorative role or, more specifically with IEGs, the need for transcriptional activation during wake. It is possible that transcription is preferentially activated during wake while translation into proteins is increased during sleep. This is supported by some earlier protein work using ^{14}C-Leu autoradiography in both rat and monkey, which showed that the rate at which labeled leucine was incorporated into the brain was positively correlated with the occurrence of slow wave sleep, suggesting the exciting possibility that one function of sleep might be the restoration of proteins through increased synthesis.[25,26] In general, protein data across sleep and wake periods have been limited in part because of the greater difficulty of identifying and quantifying proteins (see[27] for review) compared with measuring mRNA levels. For example, microarray technology allows hundreds or thousands of mRNAs to be compared across conditions and has generally supported these results.[22,28]

The first large-scale microarray study investigating sleep versus wake was done in rats.[28] Several interesting observations were made in this extensive survey that compared transcripts derived from sleeping (undisturbed) versus sleep-deprived rats killed at 6 PM (sleep deprivation was for 8 hours) as well as from rats sacrificed at 6 AM that had spent the majority of the night awake. More than 15,000 transcribed sequences were found to be present in the cerebral cortex. Of these 15,000, about 10% differed between day and night, and about half of these, 5%, varied between sleep and wake regardless of time of day. The cerebellum, a structure not generally associated with sleep, had similar changes. Again, about 5% of the detectable transcripts were differentially expressed between sleep and wake. Although the cerebellum does not display the electrographic signs of sleep comparable to EEG recordings of the cerebral cortex, this result is consistent with the idea that all or most neurons in the brain may require similar cellular restoration during sleep. The few areas of the brain that have higher activity during sleep, such as the VLPO, could potentially perform these tasks during wake. Different brain regions are likely to express a different constellation of genes. As discussed before, the hypothalamus alone has many different nuclei that appear to play central and counterbalancing roles in sleep and sleep regulation during sleep and wake. In keeping with this diversity, the hypothalamic gene expression changes across sleep and wake appear to be greatly different relative to the cerebral cortex and basal forebrain[22] and to have a smaller number of significant mRNA changes,[29] perhaps owing to its functional diversity.

The nature of the restorative or other biologically important processes occurring during sleep is not well understood. During wake, there is a notable increase in certain categories of mRNAs, including those involved in oxidative phosphorylation (e.g., mitochondrial genes) and other energy-related processes (e.g., *Glut1*). Other genes showing increased activity during wake involve transcription factors such as the IEGs noted before and some of the clock-related genes (e.g., *Per2*, discussed in detail later), stress response factors (e.g., heat shock proteins), glutamatergic neurotransmission–related genes (e.g., *Narp*, *Homer1*), and mRNAs related to activity-dependent neural plasticity and long-term potentiation (e.g., *Arc*, *Bdnf*).[28] In contrast, during sleep, different categories of mRNAs appear to be upregulated, including those involved with translational machinery (e.g., initiating factor 4A-II), membrane trafficking (e.g., *Rab*s, *Arf*s), promoting hyperpolarization (e.g., *Trek-1*, *Task-1*), and synaptic plasticity related to memory consolidation (e.g., *Camk4*, *Calcineurin*). An issue in this and many other studies is how to define the sleep-wake state for each group of animals from which tissues are collected for microarray analysis. For example, whereas mice and rats spend the majority of the day sleeping and the majority of the night awake, they are often awake one third of the day and sleeping one third of the night (with sleep and wake periods typically alternating over periods of minutes or even seconds). In rats and mice, one cannot assume that the animals are "sleeping" during the light or daytime or are "awake" during the dark or nighttime at the time of sample collections. Also, some mRNAs may change rapidly, in which case the prior hour or two before collection of expression data may be of paramount importance, whereas other mRNAs may be influenced over many more hours. Last, it is not clear in sleep deprivation versus control studies whether a gene is sleep induced or goes down during prolonged waking. Incorporating recovery sleep periods after sleep deprivation can partially address this issue, especially if multiple recovery time points are examined (e.g., 1 hour, 2 hours, and 4 hours after sleep deprivation). This has been done for several clock-related genes, such as *Per1*, *Per2*, and *Dbp*,[30,31] which generally return to baseline levels after recovery sleep. *Per1*, *Per2*, and other clock genes are central to the circadian pacemaker located in the suprachiasmatic nuclei (SCN) of the hypothalamus, as discussed in Chapter 27. However, in other brain regions, these genes appear to be responsive more to sleep, wake, and activity state rather than to their internal clock-time.[30-32] Mutations and knockouts of these genes in mice produce not only the expected circadian disturbances but also, unexpectedly, fundamental changes to sleep homeostasis. This is discussed in detail later.

Subsequent sleep microarray studies generally confirmed gene functional groups (particularly genes involved in metabolic homeostasis and synaptic functions) that are associated with sleep and wake status. These more recent studies have also discovered additional groups of sleep-wake–dependent genes. The coordinated changes in particular categories of genes associated with sleep or wake provided indications or support for various hypothesized sleep functions. For example, one study found genes that exhibited decreased expression in mouse hippocampus after 5-hour sleep were overrepresented by those involved in translation, including *Mtor* (mechanistic target of rapamycin), a key regulator of protein synthesis.[33] This finding is consistent with the hypothesis that sleep allows protein synthesis, which is also required for long-term memory formation. Another microarray study examined sleeping versus sleep-deprived mice at multiple time points across the entire day, a study design allowing identification of a large number of differentially expressed genes between sleep and wake. In particular, many mRNAs that were higher in the sleeping state are involved in macromolecule biosynthesis and transport.[29] This was most apparent for genes involved with cholesterol synthesis and lipid transport. In general, this supports the hypothesis that one function of sleep may be the restoration of certain molecular components that are perhaps depleted during wake. Furthermore, because microarrays have been used to investigate gene expression changes during sleep and wake in multiple studies and organisms, it is now possible

to characterize consistent patterns of sleep-wake–dependent gene expression across species and experimental conditions. As one of these attempts, a computational study performed a meta-analysis using microarray data from multiple sleep deprivation studies and found that IEG transcription factors, such as the *Egr* and *Nr4a* gene families, are sleep-wake–regulated genes conserved in mouse, rat, fruit fly, and white-crowned sparrow.[34] In addition, gene regulatory network analysis revealed that cyclic adenosine monophosphate–responsive element (CRE) is likely to be one of the key *cis*-regulatory elements responsible for sleep deprivation–induced transcriptional changes. Because glutamate receptors regulate the phosphorylation and activation of CRE-binding protein (CREB), this observation may highlight the role of glutamate neurotransmission during wakefulness, although it is also possible that it merely reflects the fact that CRE is one of the most well characterized transcriptional regulatory elements. Nonetheless, this study demonstrated the utility of bioinformatic tools in the efforts to eventually convert this kind of data to our increased understanding of sleep regulation, sleep functions, and sleep disorders.

In addition to protein-coding RNAs, studies have also reported changes in the expression of noncoding transcripts, such as microRNAs (miRNAs), during sleep and wake.[35-37] The miRNAs play a role in the post-transcriptional regulation of gene expression, and increasing evidence reveals their importance in central nervous system functioning. By silencing and destabilization of mRNAs, miRNAs thus add an additional level of gene regulation through which sleep and wake could alter the transcriptome. Interestingly, intracerebroventricular injection of a specific inhibitor to one of the identified miRNAs, *miR-138*, reduced total sleep time and EEG delta power during NREM sleep,[36] suggesting that some miRNAs can alter sleep regulation.

Gene expression changes during sleep and wake are likely to be influenced by the genetic background of the animals tested. One study addressed this issue by comparing sleep-deprived and control mice of three different inbred strains at four different time points over the 24-hour day.[35] Of more than 2000 brain transcripts found to vary as a function of time of day under control conditions, only 391 remained rhythmic when mice were sleep deprived, suggesting that most diurnal changes in gene expression are, in fact, sleep-wake dependent instead of being under direct circadian control. This study also demonstrated that many of the changes in gene expression were strain specific, and only a relatively small number of transcripts changed consistently in all three strains. Of these, *Homer1a* showed the most consistent and dramatic changes. *Homer1a* is a truncated form of *Homer1* that is involved in glutamate neurotransmission and probably in intercellular calcium homeostasis. Thus, it may be important for neuronal recovery or optimization after periods of wakefulness. The *Homer1* gene is also in the middle of a chromosome region shown to influence recovery from sleep deprivation[36] (see later), a finding that may lead to more definitive evidence of a role for this gene in sleep.

Another issue for studying gene expression changes after sleep deprivation is that sleep deprivation is generally stressful, leading to an increase in glucocorticoids and other stress-related changes. To address this issue, Mongrain et al[38] examined changes in gene expression with sleep deprivation in adrenalectomized versus control mice from three different strains that differ in their homeostatic response to sleep deprivation. Many genes involved in the pathways that were previously linked to sleep and wake were no longer affected by sleep deprivation after adrenalectomy, whereas others, such as *Homer1a*, remained affected by sleep and wake. *Per2*, the most consistent clock gene responding to changes in sleep and wake, continued to show a significant increased expression after sleep deprivation in adrenalectomized mice. Finally, similar to protein-coding mRNAs, miRNAs were also affected by both sleep deprivation and adrenalectomy.

In summary, gene expression studies have suggested that at least 5% of mRNAs vary across sleep and wake, but many of these changes may not be consistent across strains and species and may be dependent on the specific conditions of each experiment, including the level and type of stress. It seems likely that an even higher percentage of transcripts vary slightly with arousal state, but the present methods are generally not sensitive enough to pick up small changes in steady-state mRNA levels. Recent studies have demonstrated that genes showing time-dependent changes across the day in various tissues added to a total of 43% of all protein-coding genes.[39] Many of these genes may be driven by sleep-wake, the timing of which is in synchrony of the circadian clock under undisturbed conditions. Nevertheless, the mRNAs with measurable sleep-wake–dependent changes code for many different proteins that are likely to reflect specific functions of sleep and wake, but more data from different levels of organization are needed to document these specific functions. One concern raised by this kind of approach is the time course issue. This is perhaps most relevant with the changes in transcription factor mRNAs, which are among the most consistent and reliable changes documented thus far. Presumably, to produce a functional change in the brain, the mRNAs must first be made into proteins, return to the nucleus, and activate or inactivate other genes that alter their mRNA levels, and then these mRNAs must be made into proteins and perform some function that ultimately alters a neuronal property (such as resting membrane potential) before there is any fundamental change in sleepiness or other sleep-related variables. In most cases, this will take several hours. Of course, other molecular changes, such as phosphorylation of proteins, can take place in seconds and alter many neuronal properties; however, this does not elucidate how changes in mRNA levels ultimately affect sleep and wake. As discussed before, homeostatic need for sleep can build up during many hours and days, and certainly these long-term processes could be both monitored and regulated by these relatively slow transcriptional or translational changes. However, it has been shown in mice that sleepiness begins to accumulate after as little as 1 hour of wake,[31,36] raising the question of whether these slow mechanisms are fast enough to underlie the physiology of sleepiness. It is of course possible that there are both slower and faster homeostatic responses to different arousal states, as has been suggested for REM sleep,[31] and changes in gene expression and mRNA levels may underlie only the longer ones. It is also important to consider that most changes in steady-state mRNA levels are probably driven by sleep-wake changes and not the other way around.

Finally, an intriguing and rather surprising finding is that sleep deprivation results in a greater number of transcripts being significantly affected in the liver than in the brain.[35] Such a finding adds to the cautions of extrapolating from

changes in gene expression across arousal state to a functional role of these genes in sleep-wake regulation. If sleep is "of the brain, by the brain, and for the brain,"[40] how does one account for this observation? Perhaps the brain is protected from changes in transcription during sleep deprivation, or perhaps the increased number of significantly changed transcripts in the liver simply reflects its greater homogeneity compared with the brain with its numerous cell types, layers, nuclei, and structures that are functionally diverse and that can respond with equal diversity to sleep deprivation; or perhaps the liver in fact needs these greater changes to respond to increased wake. Is it even possible that the liver or other tissues are in fact sleeping or awake in any meaningful way? For example, sleep might define a neuroendocrine state, allowing peripheral organs to engage in activities that are not possible during wake. Until we understand the functions of sleep with more certainty, it is difficult to define what sleep may mean for peripheral tissues. In any case, a number of studies have reported sleep-wake–dependent gene expression in peripheral tissues. For example, one study in mice has demonstrated that the expression of 3% of the transcripts in the lung and 6% of the transcripts in the heart is influenced by sleep and wake state, highlighting tissue-specific metabolic processes.[37] Interestingly, results from this study also suggest that sleep modulates the circadian program of gene expression in the lung. Similar observations have also been made in the circadian transcriptome and metabolome in human peripheral blood.[41-43] Future studies are needed to further characterize the relationship between sleep-wake–dependent modulation of the transcriptome and the activities of peripheral organs, which may provide indications for the functional significance of sleep and wake to peripheral tissues. Nevertheless, accumulating evidence now links sleep deprivation to profound changes in metabolism[44] and the expression of genes in many peripheral tissues, indicating that sleep is more than "just for the brain" and that sleep-wake states and durations have pronounced effects on gene expressions throughout the entire body.[45]

IDENTIFICATION OF NATURALLY OCCURRING ALLELES THAT INFLUENCE SLEEP OR SLEEP-RELATED TRAITS

Although gene expression studies are likely to lead to a better understanding of certain aspects of sleep, there are many limitations to this approach. Therefore, it is important to use other complementary genetic approaches. There is abundant evidence to indicate that allelic differences in sleep-related genes exist, and the identification of these alleles and the genes themselves is likely to lead to important sleep-related functions. Many aspects of "normal" sleep as well as several sleep disorders have strong genetic components (reviewed by[46-49]). Results from twin studies make this especially clear (Figure 29-1). First, brain architecture and regional activity are much more similar in monozygotic versus dizygotic twins[50] (Figure 29-1, *A*). Second, EEG patterns of monozygotic twins have a much higher concordance than those of dizygotic twins, with the patterns in monozygotic twins being nearly as similar as the same individual recorded on two different occasions[51-53] (Figure 29-1, *B* and *C*). These results support the hypothesis that complex EEG traits are largely controlled by genes and that environmental factors play a lesser role. In fact, for many EEG traits, well above 80% of the variance appears to be accounted for by genetic factors, whereas for other sleep traits, such as the amount or timing of sleep, the relative importance of genes and environment is probably closer to 50% (again, see reviews cited before). Like twin studies in humans, genetic studies of sleep in the mouse, pioneered by Valatx, yielded substantial support for the genetic control of sleep. In the early 1970s, Valatx's group initiated a series of crossing experiments and recorded sleep in hundreds of inbred, recombinant inbred, and hybrid mice mainly to follow the segregation of REM sleep.[54-56] However, until very recently, none of the genes underlying these or any other sleep traits had been identified. The first significant breakthrough in the field occurred in 1999, with the discovery that a mutation of the hypocretin-2 receptor gene underlies canine narcolepsy[11] (see Chapter 89). This gene was certainly not one that would have been predicted to have a role in narcolepsy, highlighting the strength of the genetic approach.

In a genome-wide search for genes affecting a particular phenotype, no a priori assumptions are made on the genes involved. Although this approach may lead to already known physiologic mechanisms, its strength lies in the capability of uncovering previously unknown systems or pathways involved in sleep. Going from variability in a reliable sleep-related phenotype to the underlying genotypic variability of differing alleles (sometimes called forward genetics or traditional genetics) often involves the following approach.[57-60] In the first step, the mode of inheritance for a trait of interest is determined in segregating offspring, although for most complex traits this will not appear as simple mendelian inheritance patterns. Next, the localization of the underlying genes is mapped by examining the entire genome at regular intervals using polymorphic markers (e.g., restriction fragment length polymorphisms, simple sequence length polymorphisms, single nucleotide polymorphisms). Traits generally cosegregate with the markers most closely linked to the underlying genes. For simple mendelian traits, initial mapping in a few hundred offspring can yield sub-centimorgan resolution (typically on the order of 1 million base pairs, with perhaps 10 genes in the defined genetically linked region). However, for nonmendelian complex traits, in which several genes and environment contribute to a single trait, this initial step will usually narrow down the region to only about 10 to 30 cM. Subsequent fine mapping, if feasible, may further reduce these regions. Positional cloning techniques can then be applied to find and to characterize candidate gene sequences, with potential follow-up studies using gain- or loss-of-function knockout and transgenic mouse models (see later). This approach has been most successful with mendelian monogenic traits, such as for canine narcolepsy as discussed before, and for studies involving mutagenesis as discussed later, in which a single mutated gene usually accounts for the phenotype. However, positional cloning is becoming increasingly successful in even the more common and difficult cases in which multiple genes and environmental influences interact to produce a wide phenotypic range of a quantitative trait, such as differences in the spectral composition of the EEG signals among inbred strains of mice.

The standard approach to mapping of chromosomal regions that underlie quantitative traits is referred to as QTL analysis. QTL analysis is a good method to genetically dissect complex traits, like sleep, because naturally occurring allelic variations

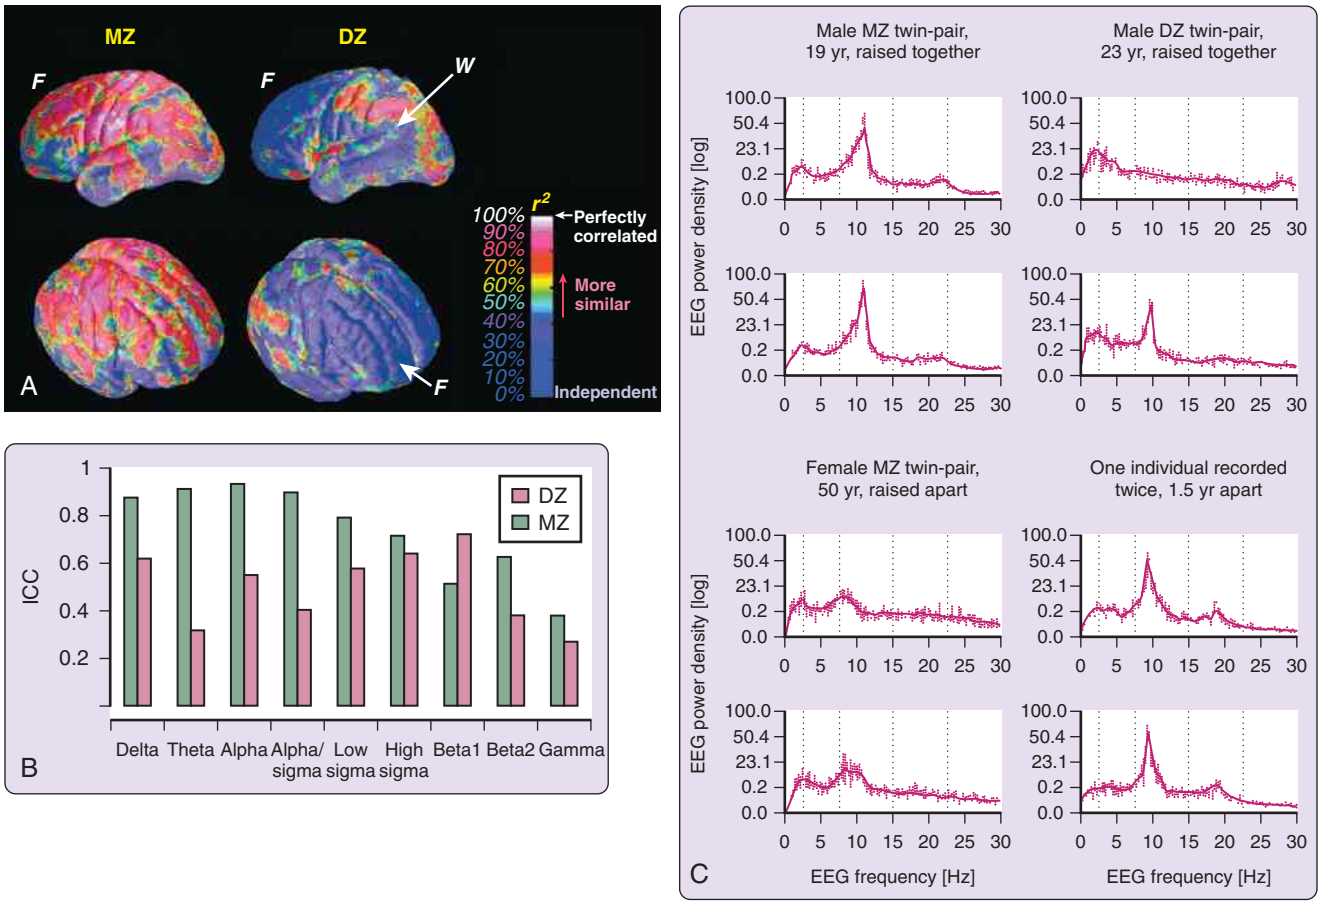

Figure 29-1 Basic brain structure and electroencephalogram (EEG) patterns are among the most highly heritable complex traits. **A,** Brain architecture is highly genetically determined. Genetically identical (monozygotic; MZ) twins are almost perfectly correlated in their gray matter distribution. Fraternal (dizygotic; DZ) twins are significantly less alike in frontal (F) cortices but are 90% to 100% correlated for gray matter in the perisylvian language-related cortex, including supramarginal and angular territories and Wernicke's language area (W). The significance of these increased similarities, visualized in color, is related to the local intraclass correlation coefficients (*r*). **B,** The spectral composition of the EEG during non–rapid eye movement (NREM) sleep is highly genetically determined. Intraclass correlation coefficients (ICCs) of EEG power in various frequency bands indicate a much higher concordance in MZ compared with DZ twin pairs, especially for lower frequencies (delta, theta, and alpha). **C,** The spectral composition of the waking EEG is equally under strong genetic control, and twin studies identified heritabilities of up to 90%, indicating that 90% in the variance of the phenotype can be accounted for by additive genetic factors. Note the higher similarity in MZ versus DZ twins even when raised apart. MZ twins are nearly as similar as the same subject recorded on two different occasions. or gene mutations with smaller effects can be mapped.[57-60] QTL analysis can be performed in segregating mouse populations that involve intercrosses, backcrosses, recombinant inbred (RI) strains, or heterogeneous stocks (outbred mice derived from breeding multiple inbred strains together). Often, two inbred mouse strains differing in a trait of interest are crossed, and their F1 offspring are then intercrossed to generate F2 offspring. To generate RI sets, F2 mice are inbred by brother-sister matings for more than 20 generations until essentially full homozygosity is achieved, thereby "fixing" a unique set of recombinations of the parental genomes in each RI strain.

Many aspects of sleep and the EEG parameters measured during sleep differ dramatically among different inbred strains of mice.[36,55,61-65] Such differences are likely due to genetic factors. As mentioned before, QTL analysis can be simplified in sets of RI strains that are derived from two parental inbred strains. In its most simple form, this mapping entails point-correlations between the strain-distribution pattern of the phenotype and the strain-distribution pattern of the genotype at each marker (see Figure 29-2 as an example of this approach). Polymorphic markers at a specific chromosomal locus that correlate significantly with the quantitative trait are presumably linked and cosegregate with the actual gene (or genes) whose differing alleles, derived from the two parental strains, contribute to the phenotypic variance. QTL analysis of traditional crosses, such as intercross and backcross panels, also follows these same principles, but with two primary

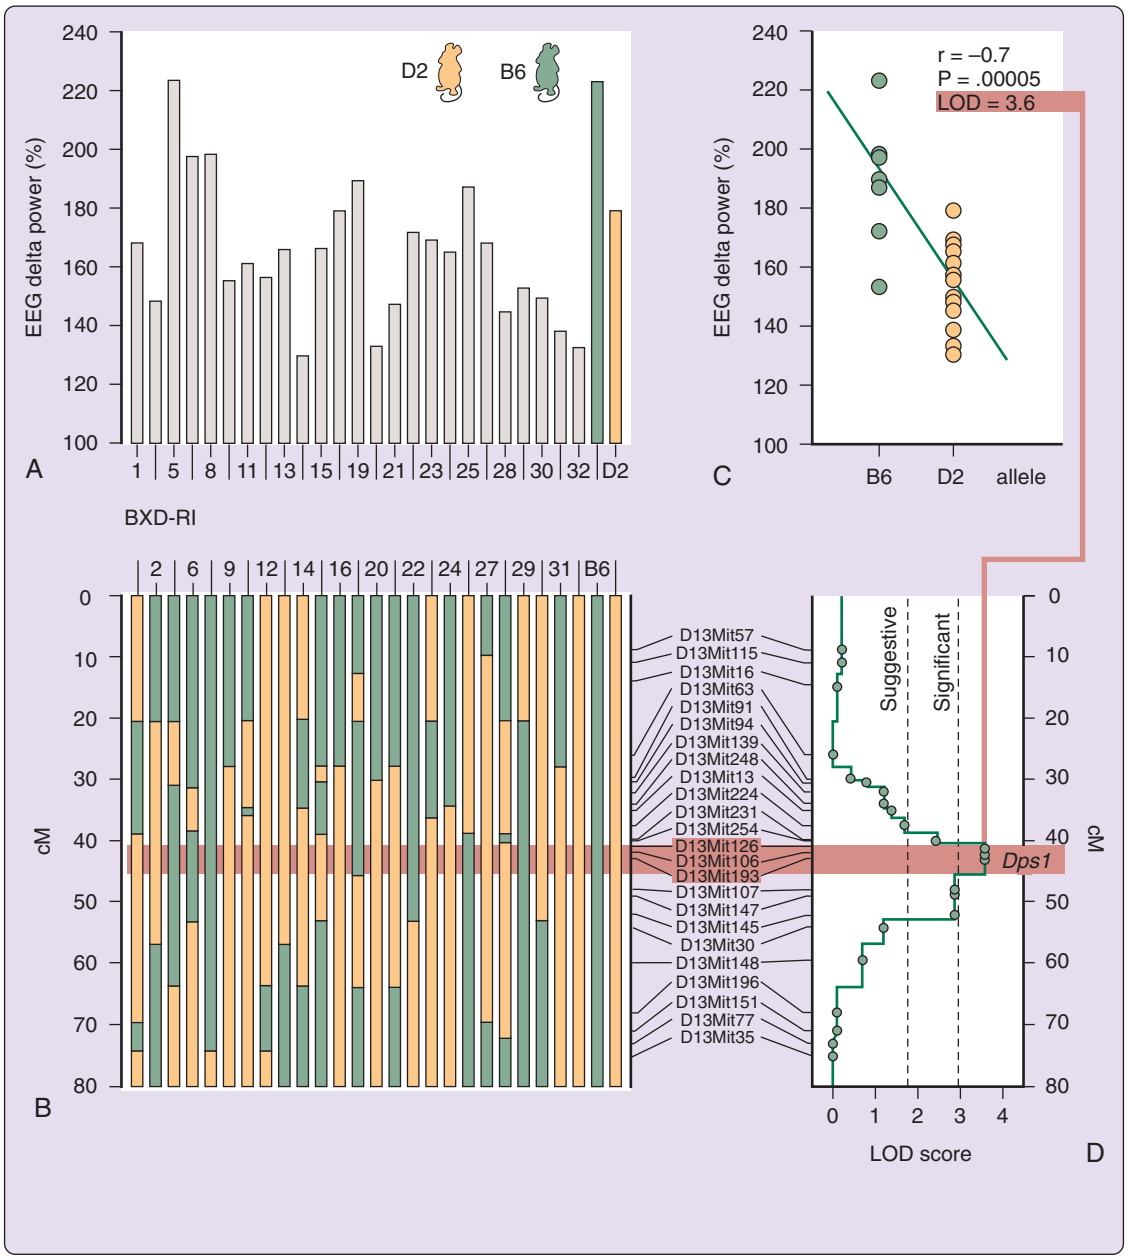

Figure 29-2 Quantitative trait locus (QTL) analysis for a sleep recovery trait in BXD recombinant inbred (RI) mice. QTL analysis is illustrated for the chromosome 13 *Dps1* QTL (see text and reference 35 for additional details). **A,** The strain-distribution pattern (SDP) of the sleep phenotype. In 25 BXD RI strains (BXD-1 to BXD-32) and their parentals C57Bl/6J (B6; *green*) and DBA/2J (D2; *orange*), the rebound in electroencephalogram (EEG) delta power was measured after 6 hours of sleep deprivation (*bars* indicate mean strain values; $n = 128$; 4-7/strain). **B,** BXD RI recombination pattern for chromosome 13 (B6 alleles in *green*; D2 alleles in *orange*). This pattern is based on the 24 Mit markers polymorphic between B6 and D2 that were genotyped in the BXD RIs. Relative map positions in centimorgans from the centromere. For QTL mapping for each marker, the genotype SDP is correlated with the SDP of the phenotype. **C,** The SDP for markers D13Mit126, 106, and 193 (along the *red horizontal bar* in **B**) yielded the best correlation coefficient (r), which was highly significant (P) and translated into a LOD score of 3.6. **D,** Among all 788 Mit markers used, only for these three markers was a genome-wide significant level ($P < .05$) obtained. This QTL was named *Dps1* (*delta power in sleep 1*). The underlying assumption of the QTL approach is that a gene (or genes) within the *Dsp1* region segregated with the three D13Mit markers in this BXD RI panel and that the B6 and D2 alleles for this gene are functionally different and modify the rebound in delta power after sleep deprivation. *Dsp1* has been confirmed for EEG delta power at sleep onset under baseline conditions, and refined mapping is in progress.

disadvantages. First, each offspring from these crosses is genetically unique and must be genetically mapped to determine the pattern of recombination of the parental genomes, unlike RI strains, in which the recombination pattern is fixed by inbreeding and has already been mapped. Also, because each individual offspring is unique in traditional crosses (and cannot be made again), it is not possible to average over multiple mice. By contrast, in RI strains, multiple identical mice can be averaged, thereby reducing the phenotypic variability. Moreover, using RI strains, one can study various phenotypes over development and aging, sex differences, and effects of environmental challenges in individual mice of the same genotype. A major advantage of traditional crosses is that a large number can be generated, unlike the limited number of RI strains. The limitation in numbers of RI strains is partially compensated by the increased number of recombinations in each strain during the inbreeding process, which produces improved mapping power per animal by approximately fourfold. The limitation in the number of RI strains is being addressed by expanding existing genetic reference populations, such as the BXD derived from the two inbred lines C57BL/6J (B6) and DBA2/J (D2),[66,67] and by creating new ones, such as the Collaborative Cross (CC), a very large effort that could revolutionize complex genetics in mice for the study of almost any trait of interest including sleep.[68] The CC line includes eight parental strains chosen for both their high genetic diversity and high diversity in almost every tested phenotype from cancer susceptibility to behavior. With plans for more than 1000 strains, and each strain having a very large number of historical recombination events fixed by inbreeding, it should be possible to map many QTL at subcentimorgan resolution, sometimes down to individual genes.[69] Because genetic reference populations have to be mapped only once, in theory, one can look at any trait in these mice, analyze the correlations with allelic distributions, and obtain a very good idea of the gene alleles contributing to this trait. In a few years, when the CC mice are available, combined with improved sequences for all eight founder strains, it may even be possible to immediately predict which nucleotide difference among strains is responsible for a given QTL (this is sometimes referred to as a QTN for quantitative trait nucleotide).

Until recently, although only small sets of RI strains were available, these strains nonetheless contributed significant advances to the understanding of genetic influences on sleep homeostasis. For example, the original BXD RI strains were examined for sleep-related traits by EEG analysis to identify QTL for the homeostatic regulation of NREM sleep.[36,47] The trait of interest was defined as the level of EEG delta power in NREM sleep reached after a 6-hour sleep deprivation (see Figure 29-2 for variance in this trait among the two parental strains D and B and the 25 BXD RI strains). Large interstrain differences were observed in this trait, and approximately 37% of the total variance could be attributed to additive genetic factors (i.e., heritability). The contribution of the chromosome 13 QTL to the total genetic variance amounted to 49%, suggesting the presence of a "major" gene. Confirmation of the chromosome 13 QTL was obtained in baseline recordings of the same animals. This QTL was designated *Dps1* for delta power in sleep 1. The basic assumption underlying the QTL analysis is that the identified chromosomal regions contain genes with functionally different alleles that somehow alter the sleep homeostatic process. As discussed in the previous section, *Homer1*, particularly its short splicing variant, *Homer1a*, is a favorable candidate gene for *Dps1* by subsequent molecular and bioinformatic studies.[35,70] *Homer1* encodes postsynaptic density scaffolding proteins for group 1 metabotropic glutamate receptors and is thought to be important for sleep control through regulating downstream effects of glutamate neurotransmission and intracellular calcium homeostasis. HOMER1A protein functions as a dominant negative regulator of the longer HOMER1 isoform. The expression of *Homer1a* is elevated after sleep deprivation and reduced to baseline after recovery sleep, consistent with its proposed role in the regulation of sleep homeostasis. However, a recent study challenges this view by showing that the specific knock out of *Homer1a* (with no disruption of the full-length transcript) has no effect on homeostatic EEG responses after sleep deprivation.[71] It is possible that the allelic difference between B6 and D2 in *Homer1a* indeed influences homeostatic EEG activity after sleep deprivation, whereas its role is somehow compensated by other functionally related genes in the *Homer1a* knockout mice. It is also possible that genetic variations of other genes in the *Dps1* region are responsible for the observed QTL effect. Ongoing efforts are under way to elucidate how the *Dps1* locus influences homeostatic EEG activity after sleep deprivation.

The same BXD RI lines also led to another QTL on chromosome 14 that contributes to the delta oscillations (1 to 4 Hz) that mark NREM slow wave sleep.[72] Although the study began as a QTL analysis, the data suggested that a single locus accounted for the majority of the variance in this trait. Assisted by additional polymorphic markers in this region, haplotype analysis of additional mouse inbred strains that are phenotypically alike to either B6 or D2 defined a 350-kilobase region as the smallest genomic region associated with this trait. Within this region was retinoic acid receptor beta (*Rarb*) that contained a restriction fragment length polymorphism that cosegregated 100% with the trait. *Rarb* has two different promoters that produce four different transcripts. Targeted deletion of these different transcripts, coupled with gene sequencing and real-time reverse transcription polymerase chain reaction, clearly documented that alleles of *Rarb* did in fact underlie this EEG phenotype. Retinoic acid receptors and retinoid X receptors are nuclear receptors that form heterodimers, are highly expressed in the brain, and are implicated in neuronal functions such as brain development, control of locomotion, long-term potentiation, and effects on dopaminergic and cholinergic neurotransmission.[73] These last effects may underlie the role of *Rarb* in regulating the cortical synchrony that determines this EEG phenotype. This same research group was able to use similar methods to identify another major gene, acyl-coenzyme A dehydrogenase (*Acads*), that, when mutated, dramatically alters the frequency of the theta oscillations characterizing the REM sleep EEG.[74] Microarray analysis of gene expression in mice with mutations in *Acads* also implicated *Glo1* (glyoxylase 1) as a key factor. This work suggested the surprising involvement of a metabolic pathway involving fatty acid beta-oxidation in regulating theta oscillations during REM sleep. Because this work began as a QTL analysis, it would be fair to say that it represented the first successful identification of a gene that underlies a sleep-related QTL and one of the first for any brain or behavior phenotype.

Another recent example of successful QTL dissection of sleep traits is the case of "early running" mice that show activity traits similar to humans with advanced sleep phase syndrome (ASPS).[75] Virtually all "normal" mice begin their peak activity very close to dark onset. In contrast, a wild-derived inbred strain of mice, CAST/EiJ (CAST), and a significant portion of the B6 × (B6 × CAST) backcross progeny begin their activity 2 to 6 hours before dark onset (i.e., early runner), similar to ASPS humans who wake up several hours earlier than "normal." Early runner mice also have shorter free-running periods than B6 mice, but this does not fully account for the several-hour phase advance in activity onset observed in these mice. Some cases of human ASPS are highly familial and are called familial ASPS (see Chapter 31); they can be virtually mendelian with mutations in specific genes, such as *Per2*[76] or *CKI-delta*.[77] Alternatively, more subtle allelic effects, such as those occurring in human *Per3*, may influence "morningness" and "eveningness"[78,79] along with environmental factors. At some point, extreme morning or evening preference can become ASPS or delayed sleep phase syndrome. The dramatic cases with known mutations are rare (and therefore are referred to as mutations rather than alleles). In contrast, the *Per3* alleles mentioned before are common. Early runner mice are more like this example in humans in that the primary QTL on chromosome 18 accounts for only about 10% of the total variance in this trait,[75] although it contributes a higher percentage of the genetic variance and the total variance in general daytime activity. Congenic mice with CAST alleles at the QTL region with a more than 99% B6 background in the rest of the genome do not start their activity until lights-off because of direct inhibition of activities by light.[80] However, their circadian phase angle of entrainment (defined as the time of activity onset during constant darkness extrapolated to the last day of the prior light-dark cycle) was approximately 20 to 30 minutes earlier than that of the B6 control mice, indicating the CAST allele at the QTL region indeed contributes to an earlier timing of the activity-rest cycle. Interestingly, such a change is not accompanied by a shortening of circadian period, as is common in *Per2* or *CKI* mutant models of familial ASPS. Detailed study in the parental CAST mice suggests that the earlier activity might result from the output rather than from the central components of the circadian clock.[80,81] Such mice may be useful in testing new pharmaceuticals or nonpharmaceutical approaches to the treatment of ASPS.[82]

Apart from these studies, surprisingly few other QTL studies have investigated "natural" sleep and EEG traits, especially sleep architecture, duration of vigilance states, sleep fragmentation, and many other sleep phenotypes in large segregating populations. However, a study of natural sleep and EEG and electromyogram activity in a large B6 × (BALB/c × B6) backcross mouse population (n = 269) identified 52 significant QTL, representing at least 20 genomic loci, as being involved in the regulation of 20 diverse sleep-wake traits during the 12-hour light period, the 12-hour dark period, or the entire 24-hr day.[83] Because multiple sleep traits were investigated at the same time, it was possible to demonstrate the linkage relationships of their underlying QTL (the genetic landscape of sleep phenotypes). Sleep traits were first grouped into five distinct categories, including sleep fragmentation, state length, latency, REM sleep, and EEG power bands, based on exploratory factor analysis. Not surprisingly, QTL for the same category of traits tend to map to the same genomic location. However, QTL underlying different groups of traits can also colocalize with each other. For example, the number of brief arousals (a fragmentation trait), latency of REM sleep (a latency trait), and theta power during REM sleep (an EEG power band trait) all mapped to chromosome 1 at approximately 64 cM, suggesting perhaps shared genetic regulatory mechanisms for these seemingly different traits. Conversely, a number of QTL underlying traits thought to be closely related, such as the average duration and number of REM sleep bouts, were mapped to distinct loci, indicating diverse genetic control of related aspects of sleep. Interestingly, complex interactions between time of day and QTL were also observed: as many as 24 QTL influence sleep traits at a specific time of day (i.e., light versus dark period); some even exert the opposite effects during the light period compared with the dark period. These findings speak further to the complexity of the genetic landscape of the sleep.

Controversy exists concerning the efficacy of the QTL approach in identifying genes, and in the past, forward genetics by genome-wide mutagenesis has been favored because of greater ease of identifying the underlying gene once a genomic region of interest has been identified.[84] Nonetheless, 2000 or so QTL have now been mapped in mice with a high level of confidence for a variety of phenotypes, and although only about 100 of these have been identified at the gene level, improved methods are making positional cloning of QTL tractable, even for genes that only mildly affect the quantitative phenotype. QTL approaches may find sets of genes different from those uncovered in mutagenesis experiments and are thus complementary.[85] In addition, although it has been difficult to directly localize the actual gene (either coding or regulatory region) underlying a QTL because of the large candidate regions identified from the initial QTL analysis, recent developments combining QTL analysis for specific sleep traits with transcriptome profiling have provided an alternative method to identify candidate genes whose expressions are correlated with the QTL. For example, in the B6 × (B6 × BALB/c) study that revealed 52 QTL, one QTL located on chromosome 17 was found to influence the amount of REM sleep, number of REM sleep bouts, and wake amount.[83] Incorporating the expression of 28,053 transcripts by microarrays in three brain regions (frontal cortex, hypothalamus, and thalamus/midbrain) subsequently found that this QTL is tightly linked to an expression QTL that regulates the expression of *Ntsr1*, which encodes a receptor for neurotensin, a neuropeptide implicated in several psychiatric disorders.[86] Knock out of *Ntsr1* in mice confirmed its role in regulating REM sleep, particularly during the night.

Furthermore, with more sophisticated statistical methods, such as conditional independence models and Bayesian approaches, it is possible to mathematically disentangle the correlations and to establish causal relationships among phenotypic, genotypic, and gene expression data. This approach was also applied to the B6 × (B6 × BALB/c) sleep data set described before to identify "causal" candidates underlying two QTL regulating REM sleep and another QTL regulating amount of wake. By use of a causal inference test based on conditional independence models,[87] 65 genes in three brain regions were identified as causal candidates, mediating the effect of QTL and causal to observed variations in the amount

of REM sleep or wake.[88] Highlighted by gene network analysis, two candidate genes for REM sleep, *Acad10* and *Ncor2*, are particularly interesting. *Acad10* encodes acyl-coenzyme A dehydrogenase 10. As mentioned before, another acyl-coenzyme A dehydrogenase, encoded by *Acads*, influences theta oscillations during REM sleep.[74] *Ncor2* encodes a nuclear receptor corepressor that interacts with peroxisome proliferator-activated receptors, and the ligands of peroxisome proliferator-activated receptors have been implicated in the homeostatic regulation of sleep.[89] Both *Ncor2* and *Acad10* are involved in lipid and fatty acid metabolism, and they interact with each other in a large transcriptional regulatory network in the thalamus, suggesting a role of basic cellular metabolism in the thalamus in regulating REM sleep.[87]

The application of causal inference tests was further extended to identify candidate genes underlying all 52 QTL identified in the B6 × (B6 × BALB/c) sleep data set. To test the validity of the identified candidate genes, six of the candidates for which selective pharmacologic tools were readily available were tested for their sleep regulatory role in rats.[90] Remarkably, significant sleep regulatory effects that were consistent with the prediction of the causal inference test were observed for all six genes on perturbation by selective pharmacologic agents. Interestingly, this study also incorporated gene expression in the liver, an organ not traditionally thought to be involved in sleep regulation. *Glp1r* (glucagon-like peptide 1 receptor), whose expression in the liver was tested causal to amount of total and NREM sleep as well as the latency to NREM sleep, is among the six pharmacologically tested candidates. Administration of GLP1R agonists, exendin-4 and liraglutide, reduced wake in rats during the dark phase of the day and increased light sleep at the expense of deep slow wave sleep during the light period of the day.[90] Although current data do not indicate whether the site of sleep-regulating actions of GLP1R agonists is indeed in the liver, they raise an intriguing possibility that peripheral pathways could potentially affect sleep, which traditionally was thought to be under exclusive control of the central nervous system. As discussed before, sleep and wake states are associated with profound differences in gene expression in the brain as well as in peripheral tissues. Whereas sleep (or wake) might be associated with specific neuroendocrine environments that are permissive for certain cellular metabolic functions in peripheral organs, it may also be possible that the activities of peripheral tissues could set a global metabolic environment permissive for sleep (or wake), providing a feedback signal. Hence, as already stated earlier, sleep may not be just "of the brain, by the brain, and for the brain" as traditionally thought.[40] Future studies may further challenge this view by studying sleep and wake in animals with tissue-specific manipulations of target sleep genes.

Finally, the integration of multiscale data (phenotypic, genomic, transcriptomic, and other *-omic* data) allows modeling of multilevel interactive networks that link multiple sleep-wake phenotypes.[83,88,91] In addition, as comorbidities are frequently observed between sleep disruptions and neuropsychiatric and neurodegenerative disorders, ongoing work is using this "systems" approach to characterize interactive gene networks underlying the interaction between sleep and affective-like behaviors, stress responses, and neurodegeneration in large genetically segregating populations (Figure 29-3). In the future, such work can benefit from more advanced genetic reference panels, such as the CC lines mentioned before, which capture as much as 89% of genetic variance seen in mice and have the capacity of detecting small-effect QTL and mapping QTL to very refined regions.[92,93] Indeed, even before the CC lines have reached fully inbred, they have already demonstrated great potential in QTL analysis. A study screened incomplete-inbred CC mice using a high-throughput piezoelectric sleep recording system and has identified two sleep-wake QTL to small genomic regions.[69] One QTL influencing the time of peak activity after sleep deprivation even achieved sub-megabase resolution; it was mapped to a 530-kilobase region (29.70 to 30.03 Mb on chromosome 9), containing only three genes, including *Ntm* (neurotrimin), *Snx19* (sorting nexin 19), and a miRNA gene. The advantages of large RI panels are not limited to fine QTL mapping resolution. More importantly, they allow community efforts that accumulate multilayer *-omic* data (transcriptomic, metabolomic, proteomic, microbiome data) as well as a large collection of phenotypes (i.e., the "phenome").[94] Mining such databases will enable the identification of the interaction between sleep and other biologic functions, which will ultimately translate to what sleep means to the organism and what the functions of sleep are. In addition, incorporation of multilayer *-omic* data will allow establishment of models that describe how the functions of sleep are achieved or regulated by genetic information propagating through complex and interactive molecular networks.

MUTAGENESIS AND KNOCKOUT APPROACHES

The QTL analysis aims to identify "naturally" occurring allelic variants or gene mutations that modify sleep; in mutagenesis studies, however, gene function is assessed by randomly inducing mutations. Because mutagenesis studies involve a progression from phenotype to genotype (finding the mutation that alters the screened phenotype), it is also considered a forward genetic approach, similar to attempts to identify QTL associated with a particular phenotype or trait. In contrast, beginning with a gene of interest and using targeted deletion in mouse embryonic stem cells to knock it out is a reverse genetic approach because the progression is from gene to phenotype (see later). As with other approaches, these distinctions can blur. For instance, if a study is initiated on a large collection of knockout mice, without identified genotypic effects, one might begin with phenotypic assessment, an approach that would have similarities to mutagenesis and forward genetic approaches. This is now becoming feasible with the increasing number of knockout and other transgenic lines of mice and with high-throughput sleep analysis systems (see later). Whether it is forward or reverse genetics depends on whether one is screening more or less randomly or selecting only genes with suspected roles in the traits under study.

Mutagenesis has been a successful technique for the identification of genes that regulate circadian rhythms (as discussed in Chapters 27 and 28). A mutagen like *N*-ethyl-*N*-nitrosurea mutates spermatogonia at an average rate of 0.001 mutation/locus/gamete.[60] With high-throughput screening of several hundreds or thousands of offspring for dominant, semidominant, or recessive mutations, a major effect on a given trait can be expected to be identified.[95,96] The individual mouse, fruit fly, or other organism for which an

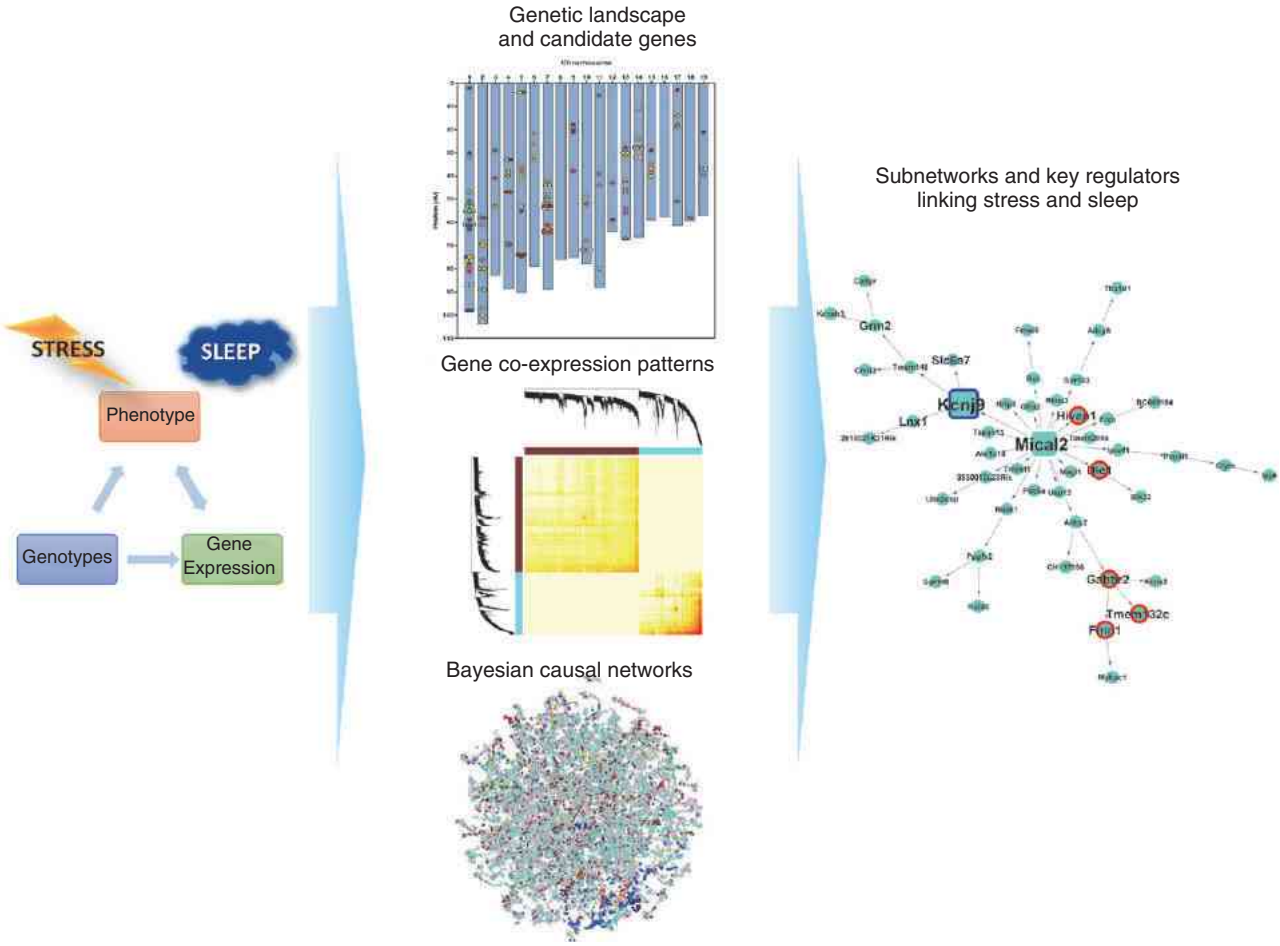

Figure 29-3 Systems approaches integrating genotypic and phenotypic data with gene expression can be used to identify gene regulatory networks underlying the interactions between sleep and other complex physiologic processes. In a chronically stressed (B6 × A/J) F2 population, Jiang and Scapa et al[162] characterized a total of 328 behavioral, physiologic, and electroencephalographic sleep phenotypes and identified more than 100 quantitative trait loci (QTL). By incorporating gene expression data in the striatum, it is possible to identify genes whose expression is underlying these QTL and causal to phenotypic variations. In addition, groups (or modules) of genes whose expressions are coregulated can be identified and associated with sleep and stress-related phenotypes. Furthermore, assisted by genotypic data, it is possible to decipher gene regulatory relationships from correlated gene expression and graphically represent these regulatory relationships in a Bayesian network. Combining all this information, one can identify subnetworks that are highly relevant to stress and sleep, such as a subnetwork driven by *Mical2*. Expression of genes in this network is highly correlated with a number of sleep and stress phenotypes. Genes downstream of *Mical2* include *Kcnj9*, whose expression was causal to stress-related behavioral phenotypes (*highlighted by blue rim*), as well as genes that were identified in genome-wide association studies as candidate genes for neuropsychiatric disorders (*highlighted by red rims*), suggesting potential molecular underpinnings linking sleep, stress, and neuropsychiatric disorders.

aberrant phenotype has been recorded then has to be crossed (usually with wild-type animals) to establish the mode of inheritance of this trait. The feasibility of this approach in the mouse was demonstrated by the isolation of the canonical circadian gene *Clock*.[97] Although some mutations may produce dramatic phenotypic changes, as was the case for the mutant *Clock* gene, others may produce only subtle effects that in addition can be confounded by epistatic interactions and genetic background (i.e., modifier genes).[98] In general, mutagenesis will probably be more successful for fully penetrant dominant or recessive mutations, whereas the QTL approach is more powerful in detecting natural allelic variations controlling complex traits.

The sleep field has been fortunate that gene alleles with very large effects on sleep-wake traits are present in the common inbred strains of mice. Whether QTL analysis or mutagenesis is used, both techniques require large numbers of mice to be screened to cover a majority of the genome (that is, to produce functional alterations in a majority of the estimated 30,000 or so genes).[95] Although screening a thousand mice is currently cumbersome with traditional EEG techniques, high-throughput methods to monitor sleep and wake in mice and other rodents may alleviate this problem.[99,100] One high-throughput, noninvasive technology uses piezoelectric films across the cage floor that act as an extremely sensitive motion detector. During sleep, the primary movement is

breathing, and thus the system records a consistent periodicity of about 3 Hz, a rate representative of the respiratory rate in mice. During wake, a variety of movements produce a more erratic signal because even during "quiet" wake mice are grooming or making many more postural adjustments than during sleep. It may eventually be possible to distinguish REM versus NREM sleep because respiratory variability increases during REM sleep, but this has not yet been achieved.[100,101] Not only could this make mutagenesis screening for sleep traits more feasible and take advantage of the large CC panel,[68] it could also be used as an initial screen for sleep- or wake-promoting drugs or to screen the increasing number of available transgenic mice (see later). Video methods for scoring sleep-wake traits are also showing increasing promise as a high-throughput method,[102,103] either in isolation or in combination with the piezo method.

The use of targeted gene deletion and other transgenic approaches has been an exciting area for sleep research. As discussed before, the use of these mouse models generally begins with a gene of interest that may influence some sleep phenotype and so is generally considered a reverse genetic approach (from gene to phenotype) as opposed to forward genetic approaches that assay the phenotype first. Reverse genetic approaches in mice have been made possible by the development of a range of techniques over the past several decades.[104,105] The field of sleep and circadian biology has benefited from knockout technology in which the insertion of a DNA construct into an exon results in a nonfunctional protein in mice that is then bred to homozygosity. Advances have also come from transgenic methodology or nonhomologous (illegitimate) recombination, in which one or more DNA construct copies are inserted into the genome at undefined locations, typically after injection of naked DNA into one of the two pronuclei at the one-cell stage.[104] These models generally produce loss- or gain-of-function mutations, respectively. The recently developed RNA-guided CRISPR-Cas9 nuclease system has dramatically transformed our ability to edit the genome in many species and is likely to replace the now classical transgenic techniques mentioned earlier. Cas9-mediated genome editing through nonhomologous end joining or homology-directed repair can be used to excise or to introduce DNA fragments, including single nucleotide polymorphisms of interest.[106,107]

These models are also useful in confirming the role of genes that were identified by forward genetic approaches. Advantages and problems of these techniques have been addressed in other reviews.[108] One important concern with respect to sleep regulation is developmental compensation, whereby other molecules, perhaps from the same gene family, could compensate for the lacking protein.[109] Other concerns involve nonspecificity (the relevant protein is absent in all the cells of the organism instead of the tissue of interest) and genetic background (genes that cosegregate with the introduced gene might differ between the background strain, often C57BL/6, and the strain in which the altered embryonic stem cells were introduced, usually a 129 strain) that might affect the phenotype.[110] Some of these issues have been addressed by developing (tissue-specific) conditional or inducible knockout models in which the acute effects of loss of function can be studied in structures of interest,[111] which has recently been successfully applied to the study of sleep-associated genes.

Despite these limitations, considerable knowledge has been gained from the study of knockout and other genetically altered mice, implicating genes in sleep and sleep-related traits in often unexpected ways. The first sleep studies using transgenic mice appeared in 1996.[112,113] Early as well as recent studies have focused on pathways with previously described roles in sleep regulation, such as monoamine neurotransmitters,[114] their receptors, and their transporters (reviewed in[47,115]). Additional studies have supported a role for cytokine pathways in the regulation of sleep, including interleukin-1, interleukin-10, tumor necrosis factor, and their receptors.[116] Finally, considerable information on sleep effects has been discovered about genes that are regarded as canonical circadian genes, such as *Clock*, *Bmal1*, *Per1*, *Per2*, *Cry1*, *Cry2*, and *Npas2* (a homologue of *Clock* expressed in the forebrain but not in the SCN), and genes known to alter circadian rhythms, such as *Dbp* and *Rab3a*.

The identification of genes involved in the homeostatic regulation of sleep has been advanced by the comparisons between baseline sleep and the responses to sleep deprivation. For instance, mice overexpressing growth hormone spend more time in REM sleep under baseline conditions but show normal recovery patterns after sleep deprivation.[117] Disruption of c-*fos* increases wakefulness, whereas *FosB* deletion reduces REM sleep. In addition, c-*fos* knockout mice respond to sleep deprivation primarily with an increased latency to sleep onset.[118] In mice lacking the transcription factor albumin D-binding protein, the circadian distribution of sleep was flatter and sleep was more fragmented. The NREM sleep response and the delta power response to sleep deprivation, however, did not differ from wild type.[119] Also, in *Clock* mutant mice, the relative increase in NREM sleep after sleep deprivation was the same as in wild-type mice, although NREM sleep amount in baseline conditions was significantly reduced.[120] Whereas a change in baseline sleep may reflect a change in sleep homeostasis, the lack of change after sleep deprivation raises the fundamental issue of what qualifies as a true change in the homeostatic response. For instance, mice lacking functional genes for the serotonin 2C receptor[121] or *Rab3a*[122] were reported to have an altered NREM sleep rebound after sleep deprivation. In these cases, however, the difference was attributable largely to NREM sleep differences under baseline conditions because no differences in recovery sleep were observed. Ideally, claims regarding an altered homeostatic regulation should be substantiated by quantifying the relationship between wake duration and the subsequent response of the regulated variable. This can be achieved either by establishing a "dose-response" relationship, in which the duration of the sleep deprivation is varied, or by mathematical means, whereby the effects of spontaneous and enforced periods of wakefulness on a regulated variable are quantified (see[36] for both approaches, and see[123] for general review). Furthermore, especially where the regulation of NREM sleep is concerned, one cannot rely on only one aspect because changes in the duration and intensity or consolidation of sleep have to be taken into account.

Changes in REM sleep homeostasis have also been observed in several knockout models. In mice lacking serotonin 1A or 1B receptors,[124,125] *Dbp*,[119] or *Cry1* and *Cry2*[31] and in *Clock* mutant mice,[120] sleep deprivation–induced loss of REM sleep was followed by a compensatory increase in REM sleep that was smaller than in wild-type animals or lacking

altogether. Apart from the serotonin 1A and 1B receptor knockout mice that displayed increased REM sleep during baseline conditions,[124,125] these changes in the REM sleep response after sleep deprivation could not be attributed to genotype differences in REM sleep during baseline. Differences in REM sleep under baseline conditions were also recently observed between *CKI-epsilon* mutant and wild-type mice as well as between congenic mice that carry naturally occurring polymorphisms at the *CKI-epsilon* locus.[126] The *CKI-epsilon* mutant (*tau* mutant allele) has long been known to shorten the circadian period.[127] Thus, this recent finding adds another example of canonical clock genes influencing sleep architecture and homeostasis in addition to controlling the timing of sleep and wake.

One rationale for studying sleep in mice with modified or deleted genes critical for circadian rhythm generation, such as *Clock*, *Per1*, *Per2*, *Cry1*, or *Cry2*,[128] is that they provide a model in which sleep homeostasis can be studied in the presence of an altered or absent circadian modulation of sleep-wake time. Previously, the interactions between circadian and homeostatic influences on sleep were studied after circadian rhythms were eliminated by lesions of the SCN[129-132] or in studies in which subjects followed a forced desynchrony protocol.[133,134] SCN lesion studies in rats revealed that direct circadian effects on the sleep homeostatic process were small if present at all (also see[135]). However, SCN lesion studies in mice[136] and in squirrel monkeys have found that SCN lesions can influence not only the timing of sleep but also the amount of sleep. Deletion or mutation in circadian genes also influences sleep-wake traits beyond just the timing of sleep, including alterations in the homeostatic regulation of sleep. A clear demonstration of this was observed in *Cry1*/*Cry2* double knockout mice that under baseline conditions showed all the hallmarks of high NREM sleep pressure, including a higher amount of NREM sleep, increased NREM sleep consolidation, and higher NREM sleep delta power, compared with wild-type controls.[31] After 6-hour sleep deprivation, there was no further increase in NREM sleep time or consolidation or in the reduced rebound in EEG delta power. This suggests that apart from their role in regulating circadian rhythms, cryptochromes or genes regulated by cryptochromes (such as *Per1* and *Per2*) play a role in sleep homeostasis. As *Per1* and *Per2* mRNA levels are responsive to sleep deprivation,[28,31] knockouts of these genes might be expected to have effects on sleep homeostasis. In two independent sets of experiments examining mice with nonfunctional *Per1*, *Per2*, or *Per3* and double knockouts of *Per1* and *Per2*, the authors suggested that there were no substantial alterations in sleep homeostasis.[137,138] However, in our view, these data may actually support an important role for *Per* genes in sleep homeostasis as a number of sleep-related changes were found in these mice. Results from these studies showed that *Per* mutations affected the total sleep time, the timing of sleep, and the effects of light and dark on sleep patterns, REM sleep, delta power during sleep recovery after sleep deprivation, and certain other parameters. The authors noted that the most clear-cut differences from wild-type controls were in sleep distribution, consistent with circadian alterations, with *Per1* knockouts sleeping more at the dark/light transition and *Per2* knockouts sleeping more at the light/dark transition. However, other sleep perturbations were also observed that do not appear to be primarily circadian in nature. *Per1* knockouts and *Per1*$^{-}$/*2*$^{-}$ double knockouts spent a much longer time in elevated delta power after sleep deprivation, from 5 to 12 hours compared with 3 hours in the wild-type mice. This contrasts with results found in *Cry1*$^{-}$/*2*$^{-}$ double knockouts, which have a greater overall sleep drive under baseline conditions, including a higher delta power, but have elevated delta power for only 1 hour after sleep deprivation. One possibility for the limited increase in delta power in sleep-deprived *Cry* knockouts is that delta power is already so high it cannot be increased any further. Taken together, these results are consistent with the possibility that the *Per* genes are involved in the process that ultimately produces delta power. The absence of a more dramatic change in sleep in response to deletion of the *Per* genes is perhaps not surprising because there are three *Per* genes, and each may be able to compensate for a loss in one or two of these genes.

Other genes in the molecular circadian clock network may also compensate for the loss of sleep. This compensation may be even greater in regions of the brain outside the SCN. Further evidence that clock genes play a role in sleep homeostasis comes from work on *Npas2*-deficient mice. *Npas2* is a clock gene that like *Clock* can bind with *Bmal1* and, although it is difficult to detect in the SCN, can substitute for a lack of *Clock*.[139] *Npas2*-deficient mice have normal circadian rhythms but altered sleep patterns that are most likely not the result of a disruption in circadian rhythmicity. *Npas2* knockout mice lack the typical nap found in the latter half of the dark period that is invariably present in wild-type mice of this strain background.[32] After sleep deprivation, however, these mice were also incapable of initiating the appropriate compensatory sleep response during the circadian phase when mice are usually awake. These mice are unable to survive when food availability is restricted to the light portion of the diurnal cycle.[140] These results suggest that the "clock" genes in the forebrain integrate behaviors such as sleep, wake, and feeding with physiologic cues, and when disrupted, the SCN-dependent circadian drive may dominate, limiting the expression of adaptive behaviors that may differ from the normal circadian peak for that behavior. These *Npas2* knockout results may be of particular interest because NPAS2/BMAL1 and CLOCK/BMAL1 heterodimers are redox sensitive, which may tie this gene network to basic energy metabolism.[141,142] Because restoration of an optimal neural energy state has long been considered a possible function of sleep as discussed before,[143] this gene network might underlie a fundamental energy restorative aspect of sleep homeostasis.

The suggestion that clock genes are fundamental to sleep homeostasis (in addition to their role in the circadian pacemaker) is strengthened by observations in the fruit fly *Drosophila*; mutants carrying loss-of-function mutations for the canonical circadian genes *Per*, *Timeless*, *Clock*, or *Cycle* (the *Bmal1* orthologue) show a more pronounced sleep rebound after sleep deprivation than wild-type flies[144] (as discussed in Chapter 28). *Cycle* mutant flies were exceptional in this respect because they clearly overcompensated for the amount of sleep lost, and this increase in sleep seemed permanent. In addition, *Cycle* mutant fruit flies died after sleep deprivations of 10 hours or more, whereas wild-type flies typically survive for about 70 hours. It has become increasingly accepted that rest and activity in flies share many features with sleep-wake states in mammals.[145-152] Recently, mice homozygous for the *Bmal1* deletion showed an attenuated rhythm of sleep and wakefulness distribution across the

24-hour period. In addition, these mice showed increases in total sleep time, sleep fragmentation, and EEG delta power under baseline conditions and an attenuated compensatory response to acute sleep deprivation.[153] Therefore, lack of circadian genes does not only affect circadian rhythms. In humans, as discussed in Chapter 30, a simple repeat polymorphism in *Per3* has been shown to significantly affect performance and EEG delta power after sleep deprivation[78,154] in addition to the morningness-eveningness trait mentioned earlier. Mice expressing these human PER3 isoforms also exhibited differences in EEG features in response to 12-hour sleep deprivation, which is accompanied by differences in the expression of sleep homeostasis-related genes but not circadian clock genes.[155] In retrospect, this might not be too surprising because circadian genes are expressed throughout the brain and the body, not only in the SCN. In addition, many of the circadian clock genes are pleiotropic and affect a number of physiologic processes, not just their timing. Nevertheless, the involvement of circadian genes in sleep homeostasis remains an intriguing molecular pathway for continued research.[156]

One other area in which knockouts, knockins, and other transgenic mice have been valuable in addressing questions about sleep is with animal models of human disorders that have serious sleep alterations or in which sleep may be part of the pathogenesis of the disease. Even in diseases for which mice are not an ideal model of the human condition, such as Alzheimer disease (AD), genetic models in mice have shed light on the role of sleep. For example, there is increasing consensus that not only is sleep disrupted in AD but poor sleep may contribute to and exacerbate the condition (see[157] for review). Different mouse models of AD have advantages and disadvantages,[158] but several have been shown to have altered sleep and circadian rhythms, and normal mice also experience daily fluctuations of the A-beta peptides that form AD plaques.[159,160] Further support for the connection between sleep and AD is the exciting finding that a major function of sleep may be to flush the brain, through the hypothesized "glymphatic system," including the flushing of toxic A-beta peptides.[161]

CLINICAL PEARL

An understanding of the genes and gene alleles that influence sleep and wake quality and the susceptibility to sleep loss may suggest novel targets or approaches to improve sleep and wake as well as for the treatment of sleep disorders. As in other areas of medicine, allelic differences in these genes may suggest different treatments for different individuals with the same disorder because the pathophysiology may be distinct. Rodent studies using molecular, forward, and reverse genetic approaches, in combination with human studies, are likely to lead to novel insights into the regulation and function of sleep, which can then be translated into improved treatments for sleep-wake disorders as well as for other mental and physical disorders associated with disrupted sleep.

SUMMARY

This chapter explores the progress in and various approaches to identification of genes important for an understanding of sleep and sleep-related traits in rodents and, by extension, in all mammals. Genetic and genomic methods have also led to or solidified an understanding of the neuroanatomy and neural pathways involved in sleep and wake regulation. Similar to other areas of medicine, an understanding of the underlying genetics will become increasingly important in sleep medicine as well. At this time, mice represent the best animal models for such studies, especially the many genetically modified mouse lines that have been created and the increasing use of various mouse strains that form important genetic reference populations for a wide range of biomedical research. Given the similarities in physiology and genetics across eutherian mammals, it is likely that genes influencing sleep traits in mice will also influence sleep traits in humans or at least help us identify the most critical molecular pathways and networks.

Genetics and Genomic Basis of Sleep in Healthy Humans

Hans-Peter Landolt; Derk-Jan Dijk

Chapter Highlights

- Distinct characteristics of human sleep are regulated by different molecular and genetic mechanisms with different degrees of heritability.
- The genetics of sleep and sleep-wake regulation are still relatively unknown compared with the genetics of other complex traits.
- The sleep electroencephalogram is one of the most heritable traits in humans. Elucidating the underlying genes may reveal novel sleep functions.
- Independent replication and confirmation of most of the currently proposed genetic associations with distinct characteristics of sleep and sleep regulatory processes in high-quality protocols and data sets are required.

EVIDENCE FOR TRAITLIKE AND GENOTYPE-DEPENDENT DIFFERENCES IN DIURNAL PREFERENCE, SLEEP TIMING, SLEEP ELECTROENCEPHALOGRAPHY, SLEEP ARCHITECTURE, AND SLEEP DURATION

Many aspects of sleep and sleep-wake regulation are highly variable among individuals, yet highly stable within individuals. Uncovering genetic factors contributing to these traitlike individual differences in healthy humans constitutes one of the most promising avenues to foster our understanding of the neurobiology of sleep in health and disease. This chapter summarizes the current evidence for genotype-dependent differences in timing, duration, and structure of sleep, as well as the sleep electroencephalogram (EEG) in healthy individuals. Table 30-1 summarizes known variations in genes and their functional significance that were investigated to date and whether they contribute to genotype-dependent differences in diurnal preference or sleep timing, sleep EEG, sleep structure, and sleep duration. The chapter also reviews how these differences may relate to the homeostatic and circadian regulation of sleep. Several sleep characteristics differ between the sexes and ethnic groups, but these differences are not discussed here.

The manifestation and regulation of sleep and the sleep EEG reflect different aspects of complex behaviors. Each of these aspects is likely to be under the control of multiple genes, which may interact, and are also influenced by the environment and other factors such as age. In humans, little is currently known about the genes that contribute to the traitlike, individual "sleep phenotypes." Similarly, little is known about the genes that contribute to individual "circadian phenotypes," although a considerable number of genes that contribute to circadian rhythmicity have been discovered in animals.

Two main techniques for the genetic dissection of normal human sleep are currently available. The first is to examine the effect of candidate genes, for which evidence exists that they are implicated in sleep and sleep-wake regulation. With this method, individuals with distinct genotypes of known genetic polymorphisms are prospectively studied in the sleep laboratory. This approach precludes discovery of novel "sleep genes" but may help to explain the consequences of these polymorphisms for sleep physiology. By contrast, genome-wide association (GWA) studies may lead to the identification of novel "sleep genes," which may lead to the discovery of novel sleep regulatory pathways. These studies, however, require very large sample sizes and multiple replications. The weaknesses and strengths of these strategies have been discussed in detail.[1]

Large interindividual differences are observed in preferred time of day for completion of distinct cognitive tasks, sleep timing, sleep EEG, sleep structure, and sleep duration. Genes contribute to each of these phenotypes, and a high degree of heritability (i.e., the percentage of variance explained by overall genetic effects) has been demonstrated for these variables. For some of these variables the magnitude of interindividual differences exceeds by far the size of the effects of manipulations of sleep regulatory processes, such as sleep deprivation.[2]

GENES CONTRIBUTING TO HUMAN MORNINGNESS-EVENINGNESS AND TIMING OF SLEEP

Candidate Genes

The timing of the peaks and troughs of daytime alertness and the timing of nocturnal sleep (i.e., diurnal preference) are highly variable among healthy individuals.[3] Some of us go to sleep when others wake up. Self-rating scales such as the Horne-Östberg Morningness-Eveningness Questionnaire and the Diurnal Type Scale show normal distribution along an eveningness-morningness axis,[4,5] indicating the contribution of additive, small effects of multiple genes in combination with the environment. Recent studies in large numbers of monozygotic (MZ) and dizygotic (DZ) twin pairs and population- and family-based cohorts revealed roughly 50% heritability for diurnal preference[6] and 22% to 25% for habitual bedtime.[7,8]

Morningness-eveningness and timing of sleep are thought to be determined in part by characteristics of the central circadian oscillator, and associations between the intrinsic period or phase marker of this oscillator and diurnal preference have been reported.[9-12] These oscillators consist at the molecular level of a network of interlocked transcriptional and translational feedback loops, which involve several clock-related genes, including the transcription regulators *CLOCK*, *BMAL1*, *PER1-3, CRY1-2,* and other genes. This knowledge has provided an obvious rational basis for the search for associations between these genes and morningness-eveningness and altered sleep timing.

The effect of a single nucleotide polymorphism (SNP) in the 3′-untranslated region (UTR) of the human circadian locomotor output cycles kaput gene (*CLOCK*) located on chromosome 4 on diurnal preference was first studied in middle-aged adults. This SNP may affect stability and half-life of messenger RNA (mRNA)[13] and thus alter the protein level that is finally translated. Katzenberg and colleagues[14] reported that homozygous carriers of the 3111C allele have increased evening preference for mental activities and sleep, with delays ranging from 10 to 44 minutes when compared with individuals carrying the 3111T allele. A similar association with diurnal preference was found in a Japanese population, and Morningness-Eveningness Questionnaire scores were significantly correlated with sleep-onset time and wake time.[5] By contrast, studies in healthy European and Brazilian samples failed to confirm an association between genetic variation in *CLOCK* and diurnal preference.[15,16] Interestingly, an almost complete linkage disequilibrium was shown between the 3111T>C and the 257T>G polymorphisms located in the other extremity of this gene.[16] Full-length analysis of secondary mRNA structure revealed no interaction between the two polymorphisms.

Mouse *Per1* and *Per2* are importantly involved in maintaining circadian rhythmicity,[17] and possible associations between variation in these genes and diurnal preference were thus also investigated in humans. Screening for missense mutations and functional or synonymous polymorphisms in promoter, 5′- and 3′-UTR and coding regions of the period-1 gene (*PER1*) in volunteers with extreme diurnal preference and patients with delayed sleep phase syndrome remained initially unsuccessful.[18,19] By contrast, the distribution of the C and T alleles of a silent polymorphism in exon 18 was found to differ between extreme morning and evening types.[19] Thus the frequency of the 2434C allele was roughly double in subjects with extreme morning preference (24%) compared with subjects with extreme evening preference (12%). This polymorphism may be linked to another functional polymorphism or directly affect *PER1* expression at the translational level.[19] In a candidate gene association study with replication, a polymorphism in *PER1* (single-nucleotide polymorphism identification number: rs7221412) was found to be associated with sleep timing based on actigraphy.[20]

A missense mutation in the human period-2 gene (*PER2*) currently provides the most striking example of a direct link between genetic variation in a clock gene and changed circadian rhythms. Linkage analyses in families afflicted with familial advanced sleep phase syndrome (FASPS) revealed associations with functional polymorphisms of *PER2* that cause altered amino acid sequences in regions important for phosphorylation of this protein[21] and a mutation in caseine kinase delta (CKδ), which plays an important role in phosphorylation.[22] The subsequent finding in a transgenic mouse model expressing the human FASPS mutation that casein kinase I delta (CKIδ) can regulate circadian period through *PER2* provided further important evidence that this gene is importantly involved in the mechanisms of circadian rhythm regulation in humans.[23] In accordance with this notion, a C111G polymorphism located in the 5′-UTR of *PER2* modulates diurnal preference in healthy volunteers.[24] Thus the 111G allele is significantly more prevalent in subjects with extreme morning preference (14%) than in individuals with extreme evening preference (3%). Computer simulation predicted that the 111G allele has different secondary RNA structure than the 111C allele and that the two transcripts may be differently translated.[24]

Findings in mice suggest that *Per3* has primary functions outside the central circadian clock.[17,25] Nevertheless, a variable-number tandem-repeat (VNTR) polymorphism in the human period-3 gene (*PER3*) also appears to modulate morning and evening preference. A 54-nucleotide sequence located in a coding region of this gene on human chromosome 1 is repeated in either four or five units. This difference may alter the dynamics in PER3 protein phosphorylation. The longer five-repeat allele was associated in European and Brazilian populations with morning preference and the shorter four-repeat allele with evening preference, respectively.[26-28] More recently in a sample of 925 healthy Japanese controls, the *PER3* SNP rs228697, which is associated with a proline-to-alanine amino acid substitution, was shown to be associated with diurnal preference such that the major C allele was more prevalent in morning types and the minor G allele more common in evening types.[29] In addition, in a sample of 966 young adults in Britain, a significant association between SNP rs10462020 of *PER3* and diurnal preference was reported such that G/G individuals had an increased morning preference compared with T/G and T/T individuals.[30] In this study an association between a polymorphism (rs922270) in *BMAL* (*ARNTL2*) and diurnal preference was also reported.

The gene encoding arylalkylamine *N*-acetyltransferase (*AANAT*) is located on human chromosome 17q25. This enzyme plays a key role in melatonin synthesis and may, thus, be important for diurnal preference and circadian rhythm disturbances. Comparison in a Japanese population between 50 outpatients diagnosed with delayed sleep phase syndrome and 161 unrelated healthy controls suggested that the frequency of a seldom-occurring threonine allele at codon 129 is significantly higher in patients than in controls.[31] This association was not confirmed in a Brazilian population, in which virtually no allelic variation at this position was found.[32] In a small study conducted in Singapore, it was suggested that a commonly occurring, silent −263G>C polymorphism of *AANAT* modulates sleep timing and sleep duration (also see later) among healthy students.[33]

Genome-wide Association Studies

Only three GWA studies of sleep-related phenotypes are currently available in humans.[7,34,35] In the Framingham Heart Study 100K Project,[7] phenotypic and genetic analyses were conducted in 749 subjects and revealed a heritability estimate for habitual bedtime of 22%. This small study suggests that a nonsynonymous polymorphism in a coding region of the gene encoding neuropeptide S receptor 1 (*NPSR1*) is a possible

modulator of usual bedtime as obtained from a self-completion questionnaire. This polymorphism leads to a gain-of-function mutation in the receptor protein by increasing the sensitivity for neuropeptide S receptor 10-fold.[36] Although a possible association of *NPSR1* to weekday bedtime is interesting, it has to be kept in mind that the statistical power of this pilot study is limited and necessary replication of this finding in independent samples is lacking. A recent analysis of a larger sample of the Framingham Offspring Cohort did not parallel the prior result.[8]

THE SLEEP ELECTROENCEPHALOGRAM IS AMONG THE MOST HERITABLE TRAITS IN HUMANS

Visual sleep state scoring relies on arbitrarily defined criteria and can reveal only limited information about sleep physiology. To obtain more detailed insights, quantitative analyses of the EEG signal recorded during sleep have to be performed. A powerful approach to quantify amplitude and prevalence of EEG oscillations with distinct frequencies is power spectral analysis based on fast Fourier transforms.[37-39] Recent studies strongly suggest that especially the sleep EEG, but also the waking EEG, are highly heritable traits in humans. All-night sleep EEG spectra derived from multiple recordings in healthy individuals show large interindividual variation and high intraindividual stability.[39,40] Buckelmüller and colleagues[40] recorded in eight young men two pairs of baseline nights separated by 4 weeks. Although the spectra in non–rapid eye movement (NREM) sleep differed largely among the individuals, the absolute power values and the shape of each subject's spectra were impressively constant across all nights (Figure 30-1). The largest differences among the subjects were present in the theta, alpha, and sigma (approximately 5 to 15 Hz) range. Hierarchical cluster analysis of Euclidean distances based on spectral values as feature vectors demonstrated that all four nights of each individual segregated into the same single cluster.[40] Similar results were obtained in rapid eye movement (REM) sleep and, by other researchers, in men and women of older age.[39] These data strongly suggest that the sleep EEG contains systematic and stable interindividual differences, which are at least in part genetically determined.

This notion is further supported by two recent twin studies investigating the heritability of the sleep EEG. Ambrosius and colleagues[41] quantified the sleep EEG profiles in 35 pairs of MZ twins (17 male pairs, 18 female pairs; age range: 17 to 43 years) and 14 pairs of DZ twins (7 male pairs, 7 female pairs; age range: 18 to 26 years). Stable and robust interindividual differences in a broad range of the NREM sleep EEGs were observed. Furthermore, intraclass correlation coefficients (ICC) of spectral power were significantly higher in MZ twins than in DZ twins.[41] The ICC reflect within-pair similarity of twin pairs. In frequencies between 0.75 and 13.75 Hz, the ICC equaled roughly 0.8 in MZ twins and roughly 0.6 in DZ twins. The differences between MC and DC twin pairs appeared most pronounced in theta and alpha (4.75 to 11.75 Hz) frequencies (see also Landolt[42]).

De Gennaro and colleagues[43] also conducted a twin study to test the hypothesis that the EEG in NREM sleep reflects a genetically determined, individual "fingerprint." They recorded baseline and recovery sleep after sleep deprivation in 10 MZ and 10 DZ twin pairs (mean age, 24.6 ± 2.4 years; five male and five female pairs in each group) and observed highest variability in the 8- to 16-Hz range. In this frequency band, group similarity quantified by an ICC procedure was more than double in MZ pairs (ICC = 0.934; 95% confidence interval [CI] = 0.911 to 0.965) than in DZ pairs (ICC = 0.459; 95% CI = 0.371 to 0.546) (Figure 30-2). This difference

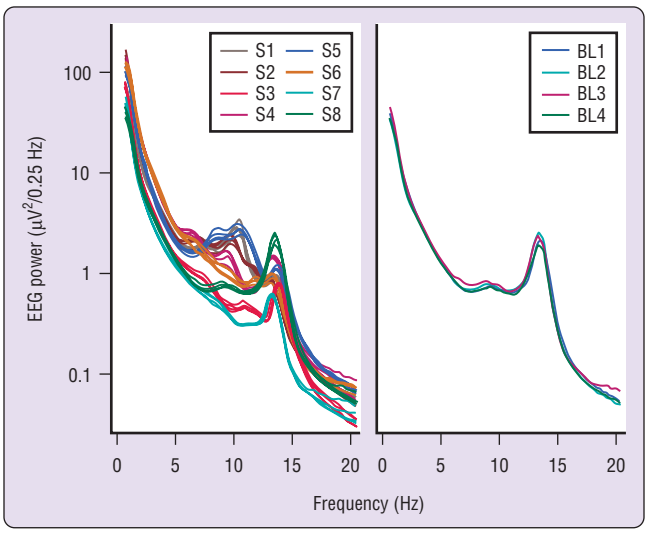

Figure 30-1 High *inter*individual variation (*left*) and high *intra*individual stability (*right*) in all-night electroencephalogram (EEG) power spectra in NREM sleep in 32 baseline nights of eight young men (S1 to S8). The largest interindividual variation is observed in theta, alpha, and sigma frequencies (~5 to 15 Hz). The spectra of all four baseline nights (BL1 to BL4) of one individual (S8) are virtually superimposable. (Modified from Buckelmüller J, Landolt HP, Stassen HH, Achermann P. suggested 95.9% heritability independently of sleep pressure.[43] As such, the sleep EEG qualifies as one of the most heritable traits known so far, only matched by heritability estimates for distinct brain characteristics like cortical gray matter distribution.[1] Thus it may be likely that trait characteristics of rhythmic brain oscillations during sleep and distinct neuroanatomic features are interrelated.

In conclusion, accumulating evidence suggests that the sleep EEG is a highly heritable trait, yet the underlying genetic determinants are largely unknown. Nevertheless, more and more studies investigate the effects of known allelic variants of candidate genes on the human sleep EEG (see Table 30-1). The findings demonstrate that genetic variation of various cells, molecules, and signaling pathways can profoundly modulate sleep EEG and other sleep phenotypes. Selected genes and pathways will be briefly discussed in the following paragraphs.

GENES CONTRIBUTING TO THE SLEEP ELECTROENCEPHALOGRAM

Circadian Clock Genes

A wealth of studies in genetically modified mice and flies demonstrates that circadian clock genes are strong determinants of major characteristics of the sleep EEG.[1,44] The only, yet intensively, studied "clock gene" variant in healthy humans is the previously mentioned VNTR polymorphism of *PER3* (rs57875989).[45] Apart from its impact on diurnal preference, this polymorphism also modulates the sleep EEG in NREM as well as in REM sleep. Compared with individuals with the $PER3^{4/4}$ genotype, young adult homozygous carriers of the long-repeat allele ($PER3^{5/5}$ genotype) exhibited higher EEG activity in the delta range (1 to 2 Hz) in NREM sleep and in the theta and alpha range (7 to 10 Hz) in REM sleep.[46] Partly similar observations were made in healthy older adults between 55 and 75 years of age.[47]

Adenosinergic Neuromodulation

The neuromodulator adenosine is released in an activity-dependent manner, and genes encoding adenosine-metabolizing enzymes and adenosine receptors are thought to play a major role in regulating the quality of sleep and wakefulness in animals and humans.[1,48] Adenosine kinase and adenosine deaminase (ADA) importantly contribute to the regulation of extracellular adenosine levels.[49] Genetic studies in mice suggest that both enzymes are involved in sleep-wake homeostasis.[50,51] In humans, the *ADA* gene is located on chromosome 20q13.11 and encodes two electrophoretic variants of ADA, referred to as ADA*1 and ADA*2 (rs73598374). The ADA*2 variant results from a guanine-to-adenine transition at nucleotide 22, which is translated into an asparagine-to-aspartic acid amino acid substitution at codon 8. The heterozygous ADA*1-2 (G/A) genotype shows reduced catalytic activity of ADA compared with homozygous individuals carrying the ADA*1 (G/G genotype) variant.[52] Rétey and colleagues[53] observed that this polymorphism affects the spectral composition of the sleep EEG. More specifically, EEG delta activity in NREM sleep (0.25 to 5.5 Hz) and REM sleep (2.0 to 2.25 Hz and 3.5 to 4.75 Hz) was higher in the G/A genotype than in the G/G genotype.[53] Inspired by studies in inbred mice showing that the genomic region encoding *Ada* modifies the rate at which sleep need accumulates during wakefulness,[51] it was then examined whether individuals with G/A and G/G genotypes respond differently to sleep deprivation. In accordance with the original study, delta (0.75 to 1.5 Hz) activity in NREM sleep was elevated in the G/A genotype compared with the G/G genotype in both baseline and recovery nights.[54] The *ADA* genotype-dependent EEG alterations, however, were not restricted to the low-delta range in NREM sleep but also included a pronounced increase in theta and alpha frequencies (~6 to 12 Hz) in NREM sleep, REM sleep, and wakefulness. Importantly, an independent study in a large epidemiologic sample confirmed that A-allele carriers have higher delta power in NREM sleep and increased theta power in NREM and REM sleep compared with homozygous G/G genotype carriers.[55]

The effects of adenosine on target cells are mediated through four different subtypes of G-protein-coupled adenosine receptors: A_1, A_{2A}, A_{2B}, and A_3 receptors. It is thought that adenosine modulates sleep primarily by binding to high-affinity A_1 and A_{2A} receptors.[48,56] No study yet investigated the possible effects of variants of the A_1 receptor gene on the human sleep EEG. By contrast, it was shown that the common variation rs5751876 of the adenosine A_{2A} receptor gene (*ADORA2A*) located on chromosome 22q11.2 affects the EEG in NREM and REM sleep.[53] This polymorphism is linked to a 2592C>T_{ins} polymorphism in the 3′–UTR of *ADORA2A* and may modulate receptor protein expression.[57] In a case–control study, Rétey and coworkers observed that EEG activity in the approximately 7 to 10 Hz range was invariably higher in all vigilance states in subjects with the C/C genotype of rs5751876 than in subjects with the T/T genotype.[53] Because the C allele is thought to facilitate A_{2A} receptor function compared with the T allele, these data may suggest that genetically increased A_{2A} receptor–mediated signal transduction enhances EEG theta and alpha activity independently of sleep state.

Neurotransmitters

Accumulating evidence suggests a contribution of dopamine to sleep-wake regulation in humans.[58,59] The enzyme catechol-*O*-methyltransferase (COMT) plays a major role in the metabolic degradation of brain catecholamines, including dopamine. The gene encoding COMT is located on human chromosome 22q11.2, in proximity to *ADORA2A*. Human *COMT* contains a common functional 544G>A variation that alters the amino acid sequence of COMT protein at codon 158 from valine (Val) to methionine (Met).[60] Individuals homozygous for the Val allele show higher COMT activity and lower dopaminergic signaling in prefrontal cortex than Met/Met homozygotes.[61,62] Sleep variables and the sleep EEG response did not differ between male carriers of Val/Val and Met/Met genotypes.[63] By contrast, the Val158Met polymorphism of *COMT* was associated with consistently lower EEG activity in the upper-alpha (11 to 13 Hz) range in NREM sleep, REM sleep, and wakefulness in Val/Val compared with Met/Met homozygotes.[64] The difference in NREM sleep was present before and after sleep deprivation and persisted after administration of the wake-promoting compound modafinil during prolonged wakefulness (Figure 30-3). These data demonstrate that a functional variation of the *COMT* gene predicts robust interindividual differences in the sleep EEG. In addition, this polymorphism profoundly affected the efficacy of modafinil to improve impaired well-being and

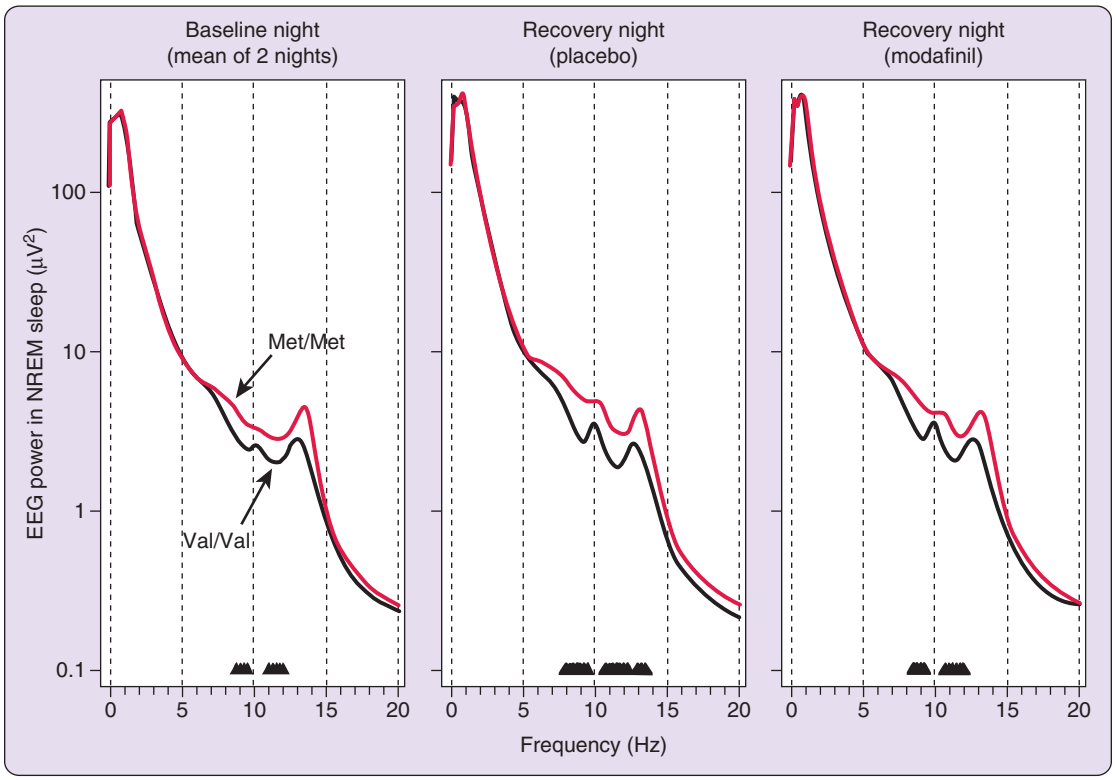

Figure 30-3 The Val158Met polymorphism (rs4680) of the gene encoding catechol-*O*-methyltransferase (COMT) modulates electroencephalogram (EEG) alpha activity in NREM sleep (all-night power spectra of stages 2 to 4). *Black triangles* at the bottom of the panels indicate frequency bins, which differ significantly between Val/Val ($n = 10$, *black lines*) and Met/Met ($n = 12$, *red lines*) genotypes ($P < .05$, unpaired, two-tailed t-tests). The frequency-specific effect of the genetic variation is robust against the effects of prolonged wakefulness and the stimulant modafinil. (Data from Bodenmann S, et al. cognitive functions after sleep deprivation.[65] Thus two-time 100 mg modafinil potently improved vigor and well-being and maintained baseline performance of executive functioning and vigilant attention throughout 40 hours of prolonged wakefulness in 10 Val/Val homozygotes, yet the same dose was virtually ineffective in 12 Met/Met homozygotes. Interestingly, an opposite relationship between Val158Met genotype of *COMT* and measures of daytime sleepiness may be present in patients suffering from narcolepsy (see Clinical Pearl).

Signaling Pathways

Another functional polymorphism affecting the sleep EEG in theta and alpha frequencies is a guanine-to-adenine transition at nucleotide 196 of the gene encoding brain-derived neurotrophic factor (BDNF) (rs6265).[66,67] This polymorphism is located on human chromosome 11p13 and causes a valine-to-methionine amino acid substitution at codon 66 of the pro-BDNF sequence. In vitro studies suggest that the presence of a Met allele reduces intracellular trafficking and activity-dependent secretion of mature BDNF protein.[68] This polymorphism is typically associated with reduced performance on cognitive tasks that are also affected by sleep deprivation. Sleep and the sleep EEG were first investigated in case–control fashion in 11 carriers of the Val/Met genotype and 11 prospectively matched Val/Val homozygotes. It was found that the Val66Met polymorphism of *BDNF* not only reduced response accuracy on a verbal two-back working memory task but also modulated the spectral composition of the EEG in a frequency and vigilance state–specific manner.[66] More specifically, in baseline and recovery nights after sleep deprivation, delta, theta, and low-alpha activity in NREM sleep EEG was lower in Met allele carriers than in Val/Val homozygotes. Importantly, the genotype-dependent differences in the theta and low-alpha band (approximately 4 to 9 Hz) were recently confirmed in a large and ethnically diverse population-based epidemiologic sample.[67]

A point mutation at codon 178 (in rare cases also a mutation at codon 200) of the prion protein gene (*PRNP*) has been identified as the cause underlying the devastating disease, fatal familial insomnia.[69,70] Interestingly, although healthy relatives of fatal familial insomnia patients appear to have normal sleep EEG,[71] the polymorphic codon 129 of the *PRNP* gene may influence EEG activity during sleep.[72] Subjects with the Met/Val genotype showed lower slow-wave activity and higher spindle frequency activity than individuals with the Val/Val genotype, independent of codon 178.

GENES CONTRIBUTING TO SLEEP ARCHITECTURE

Not only the sleep EEG but also many variables characterizing sleep architecture demonstrate large variation among

individuals and high stability within individuals.[2,39,40,73] For example, the intraclass correlation coefficients, which estimate the intraindividual stability of a given variable across different conditions (i.e., baseline versus sleep deprivation), was reported to be 0.73 for slow wave sleep (SWS) and 0.48 for REM sleep.[2] This observation suggests the presence of traitlike, interindividual differences in sleep physiology, which have a genetic basis. Indeed, twin studies show striking similarity and concordance in visually defined sleep variables in MZ twins, yet not in DZ twins. The first polysomnographic sleep studies in MZ twins revealed almost complete concordance in the temporal sequence of sleep stages.[74] Subsequent work showed that in particular those variables, which most reliably reflect sleep need, are under tight genetic control. Apart from total sleep time, they include duration of NREM sleep stages, especially SWS, and density of rapid eye movements in REM sleep.[75-77] Linkowski[77] estimated that heritability of markers of sleep homeostasis is up to 90% (REM density).

Slow Wave Sleep

A few studies have conducted polysomnographic assessment in defined genotypes. The *CLOCK* genotypes that were associated with diurnal preference[14] did not significantly affect sleep variables derived from nocturnal polysomnography. By contrast, it was found that young homozygous carriers of the long-repeat genotype of *PER3* (*PER3*$^{5/5}$) fell asleep more rapidly and showed more SWS, particularly stage 4 sleep, compared with homozygous 4-repeat individuals.[46,78] A difference in SWS, yet on a lower level, was also observed in older people.[47]

Similarly, with respect to polymorphism rs73598374 of *ADA*, healthy carriers of the ADA*2 allele (G/A genotype) showed significantly more SWS than subjects with the G/G genotype.[53,54] All other sleep variables were similar in both *ADA* genotypes.

The impact of the Val66Met polymorphism of *BDNF* was also reflected in sleep architecture. In baseline and recovery nights, Val/Val allele carriers spent roughly 20 minutes more in deep stage 4 sleep than Val/Met allele carriers. By contrast, superficial stage 2 sleep was reduced.[66] Taken together, functional variation in the genes encoding *PER3*, *ADA,* and *BDNF* modulate not only the spectral characteristics of the sleep EEG but also sleep architecture.

GENES CONTRIBUTING TO HABITUAL SLEEP DURATION

Habitual sleep duration shows large variation among healthy individuals, and the physiologic sleep and circadian correlates of habitual short and long sleepers have been identified in small groups of subjects.[79-81] The temporal profiles of nocturnal melatonin and cortisol levels, body temperature, and sleepiness under constant environmental conditions and in the absence of sleep suggest that the circadian pacemaker programs a longer biologic night in long sleepers than in short sleepers.[81] Individual differences in this circadian program may contribute to the large variation in habitual sleep duration, which shows a perfect normal distribution in the general population.[82,83] Such a distribution is consistent with the influence of multiple, low-penetrance polymorphisms. Twin and GWA studies reported for sleep duration heritability estimates of 9% to 40%.[7,35,84-86]

Circadian Clock Genes

A candidate gene study of 194 SNPs in clock genes and self-reported sleep duration on the Munich Chronotype Questionnaire was recently conducted in a European population ($n = 283$).[87] The top two associations were both located in the gene *CLOCK* on chromosome 4. With one of these variants, rs12649507, sleep duration was significantly associated in the original discovery sample, in a replication sample ($n = 1011$), and in the meta-analysis of the two populations ($P < .009$).[87] Two recent studies aimed at replicating this initial finding; however, they revealed inconsistent results. Although Evans and colleagues[88] reported successful replication of the previously described association in 2527 male elderly participants, Lane and coworkers[89] found no evidence of an association. These authors collected objective polysomnographic data in three large independent cohorts of European ancestry. This analysis with more than 99% power to detect an effect of similar magnitude as previously reported did not support a significant association of *CLOCK* variants with sleep duration.

Evidence for a role of clock genes in modulating sleep duration also came from work in a small family who apparently needed just 6 hours of sleep per night.[90] This family-based candidate gene study revealed a point mutation in exon 5 of the gene encoding class E basic helix-loop-helix protein 41 (*BHLHE41*), also known as the transcriptional repressor gene *DEC2*. By this missense mutation (c.1151C>G), proline is replaced by arginine at amino acid position 384 (p.Pro384Arg) of BHLHE41 protein. This protein is part of the transcription factor family that is regulated by the mammalian circadian clock and influences the expression of *CLOCK/BMAL1*.[91,92] Interestingly, knocking-in the human mutation into mice and *Drosophila* species was reported to result in reduced sleep duration in transgenic animals.[90] Based on this study, other variants of the *BHLHE41* gene were searched for by DNA sequencing in two larger cohorts ($n = 417$) of healthy volunteers, and two other rare variants in the same exon of *BHLHE41* were found.[92] The phenotypic data reported in three carriers of the nonsynonomous variant c.1151C>A (p.Pro384Gln) and in one DZ twin pair discordant for the functional c.1086C>T (p.Tyr362His) polymorphism may suggest that variants that alter the suppression of *CLOCK/BMAL1* activation lead to short sleep, whereas a polymorphism that does not affect this suppression has no effect on sleep duration.[92]

Neurotransmitters

It is well established that the regulation of sleep and mood are closely related. A regression analysis of 23 risk variants of major depressive disorder covering 12 different genes with self-reported sleep duration was conducted in 3147 healthy individuals of two population-based Finnish cohorts. Polymorphism rs687577 (g.123445253A>C) of the gene *GRIA3* (ionotropic glutamate receptor, AMPA subunit 3) located on chromosome X was found to be significantly associated with sleep duration in healthy women.[93] More specifically, the frequency of the C/C genotype was highest in all age groups younger than 70 years in women reporting to sleep 8 hours or less. The frequency of this genotype decreased with longer sleep duration, and individuals with 9 to 10 hours of sleep showed higher frequencies of C/A and A/A

genotypes than midrange sleepers (7 to 8 hours). It was concluded that mood disorders and short sleep may share a common genetic and biologic background involving glutamatergic neurotransmission.[93]

Transporters

It has long been suggested that serotonin (5-hydroxytryptamine [5-HT]) is critically involved in sleep-wake mechanisms,[94] yet the specific roles for this neurotransmitter in sleep-wake regulation remain uncertain.[95] Current evidence supports the view that 5-HT contributes to the buildup of sleep need during wakefulness. Apart from its intracellular metabolism by monoamine oxidase, 5-HT is removed from the synapse by high-affinity serotonin transporters (5-HTT). In the brain, the 5-HTT is among the most important sites of action for many currently used antidepressant treatments.[96] A functional 44-base pair insertion and deletion polymorphism in the promoter region of the *5-HTT* gene (*5-HTTLPR*) located on chromosome 17q11.2 has been associated with neuropsychiatric diagnoses and individual responses to antidepressant treatments. Although this polymorphism can be subdivided further,[97] researchers commonly report it with two variations in humans: a long (L) or a short (S) variant allele. In vitro studies showed that basal transcriptional activity of the L allele is more than doubled when compared to the S variant allele.[98] Human individuals homozygous for the L/L variant show higher 5-HTT mRNA levels in postmortem brain tissue than subjects carrying the S allele (L/S + S/S).[99] Moreover, reduced transcription associated with the S allele may affect serotonergic tone and 5-HT receptor–mediated neurotransmission.[100] An association study in 157 patients suffering from primary insomnia suggested that the S variant is overrepresented in insomnia patients compared with healthy controls (n = 827).[101] Furthermore, this polymorphism may also mediate individual differences in the effects of chronic stress or stressful life events on impaired sleep quality and self-reported short sleep duration.[102,103] Nevertheless, other research indicated poorer sleep in L/L homozygotes than in carriers of at least one S allele, suggesting that the effects of this gene may be heterogeneous in different populations.[104]

Genome-wide Association Studies

The Framingham Heart Study 100K Project revealed a linkage peak to usual sleep duration on chromosome 3, including the gene encoding prokineticin 2 (*PROK2*).[7] This neuropeptide may be an important output molecule from the SCN, in particular in defining the onset and maintenance of the circadian night.[105,106] Because the danger of false-positive inferences from small GWA studies is high, the methodologic limitations of this work discussed previously also apply to this potential association. It was not corroborated in a larger sample of the Framingham Cohort.[8]

To identify novel genes associated with sleep duration, Allebrandt and colleagues performed GWA studies for self-reported average weekly sleep duration in seven discovery cohorts of a European consortium (n = 4251).[34] Meta-analysis revealed a genome-wide significant signal in the *ABCC9* (adenosine triphosphate [ATP]-binding cassette, subfamily C member 9) gene locus (rs11046205) that encodes one subunit of the ATP-sensitive potassium (K_{ATP}) channel.[34] The finding from the discovery cohorts was replicated when an *in silico* (GWA data) sample as well as a subgroup population of a large de novo (single genotyping) sample were additionally included in the meta-analysis. To confirm the role of *ABCC9* in modulating sleep duration, the homologue of this gene was knocked down in *Drosophila* species, which shortened nighttime sleep duration. Approximately 5% of the variance in sleep duration may be explained by this genetic variation in *ABCC9*.[34] In a candidate gene approach of another group attempting to replicate the proposed association, a significant association of the *ABCC9* gene with sleep duration was seen for a different polymorphism (rs11046209) and only in a rare homozygous genotype (n = 2).[107] By contrast, the previously suggested polymorphism of *ABCC9* (rs11046205) was associated with depressive symptoms.

A very recent study combining 18 community-based cohorts including more than 47,000 individuals of European ancestry revealed a genome-wide significant association with polymorphisms in a gene located on chromosome 2 encoding the thyroid-specific transcription factor *PAX8* (paired box gene 8).[108] The finding was replicated in an African American sample of about 4800 individuals. Although the finding is interesting, each copy of the minor allele only causes an estimated increase in usual sleep duration of approximately 3 minutes per copy and explains as little as 0.07% of variance in sleep duration.

In conclusion, no GWA studies of habitual sleep duration in humans have yet been convincingly reproduced or have explained a major portion of the variance in sleep length. Large sample sizes are needed for detecting genome-wide significant variants of genetically complex traits such as sleep duration. Thus the phenotypic data in the available studies typically rely on questionnaire-derived, self-reported sleep duration or time in bed. These measures differ when assessed with different questionnaires, as well as when compared with objectively verified sleep duration, which may challenge the reliability and reproducibility of the currently available studies.

GENETIC BASIS OF SLEEP-WAKE REGULATION: INTERACTION BETWEEN CIRCADIAN AND HOMEOSTATIC SYSTEMS

Many of the traits and genes described earlier concern sleep-wake characteristics as assessed under baseline conditions. How these alterations in sleep characteristics relate to sleep-wake regulation and how they may lead to functional consequences remain largely unexplored. The available data, however, already indicate that the effects cross boundaries between sleep and wakefulness and homeostatic and circadian aspects of sleep-wake regulation. For example, the polymorphisms in *PER3, ADORA2A,* and *COMT* affect the EEG in NREM sleep, REM sleep, and wakefulness. To investigate whether these changes reflect changes in EEG generating mechanisms with or without a relation to sleep regulatory processes requires these processes to be challenged by, for example, sleep deprivation.

Circadian Clock Genes

Comparing the effects of sleep deprivation with $PER3^{4/4}$ individuals revealed that the increase in theta activity in the EEG during wakefulness was more rapid in carriers of the $PER3^{5/5}$ genotype.[46] In addition, in recovery sleep following total sleep deprivation, REM sleep was reduced in $PER3^{5/5}$ individuals.

Finally, some data suggested that the increase in slow wave energy after sleep restriction was slightly higher in adults carrying the *PER3*$^{5/5}$ genotype than in *PER3*$^{4/5}$ and *PER3*$^{4/4}$ allele carriers[109] and also that the decline of cognitive performance during prolonged wakefulness and after sleep restriction differed as a function of the *PER3* genotype.[110-112] The differential susceptibility to the negative effects of sleep loss on waking performance was particularly pronounced in the second half of the circadian night and on tasks of executive functioning.[110] One interpretation of these data is that the VNTR polymorphism in *PER3* affects the dynamics of the homeostatic process, which then through its interaction with the circadian regulation of performance leads to differential sleep ability and vulnerability to the negative effects of sleep loss.[110,112] Indeed, it has previously been shown that individuals differ not only with respect to baseline characteristics of sleep but also in their response to sleep loss and that this vulnerability is a traitlike characteristic. The data suggest a contribution of *PER3* to individual tolerance to shift work and jetlag, which are highly prevalent in society.

A 6-hour sleep deprivation in mice carrying the Pro384Arg mutation of *BHLHE41* resulted in a smaller rebound in both NREM sleep and REM sleep and in a smaller relative increase in EEG delta power compared with control mice.[90] Furthermore, a functional variant (c.1086C>T) at another location in the same exon was studied in a DZ twin pair. The carrier of the variant was reported to have less recovery sleep following sleep deprivation and to produce fewer performance lapses during prolonged waking than the no-variant carrier. The variant reduced the ability of *BHLHE41* to suppress CLOCK/BMAL1 and NPAS2/BMAL1 transactivation in vitro, suggesting that genetic variants modifying the normal function of BHLHE41 may affect the homeostatic response to sleep deprivation.[92]

Adenosinergic Neuromodulation

Quantitative trait-locus analyses in inbred mouse strains revealed that a genomic region including *Ada* modifies the rate at which NREM sleep need accumulates during wakefulness.[51] Based on this observation, it was investigated whether human carriers of G/A and G/G genotypes of *ADA* respond differently to sleep deprivation.[54,113] Bachmann and colleagues first systematically studied attention, learning, memory, executive functioning, and self-reported sleep duration in 245 healthy adults.[54] They found that heterozygous carriers of the variant allele (G/A genotype, $n = 29$) performed significantly worse on the d2 attention task than G/G homozygotes ($n = 191$). To test whether this difference reflected elevated sleep pressure, sleep and sleep EEG before and after sleep deprivation were recorded in two prospectively matched groups of 11 G/A and 11 G/G genotypes. Corroborating two independent studies,[53,55] EEG delta activity and SWS were higher in the G/A than the G/G genotype. In addition, sustained attention (d2 and psychomotor vigilance tasks) and vigor were reduced, whereas EEG alpha oscillations in waking, as well as sleepiness, fatigue, and α-amylase activity in saliva (a proposed biomarker of sleep drive), were increased throughout prolonged wakefulness.[54] These convergent behavioral, neurophysiologic, subjective, and biochemical data demonstrated that genetically reduced ADA activity is associated with elevated sleep pressure. By contrast, the dynamics of the homeostatic response to sleep deprivation were not affected by *ADA* genotype.[54,113] Thus the data suggest an elevated level in overt NREM sleep propensity in the G/A genotype compared with G/G homozygotes, which may be due to elevated adenosinergic tone at the synapse because of genetically reduced ADA activity.

Convergent observations in candidate gene and GWA studies strongly suggest that genetic variation of *ADORA2A* is a determinant of individual sensitivity to subjective and objective effects of caffeine on sleep.[114,115] Interestingly, caffeine-sensitive and caffeine-insensitive individuals appeared to be differently affected by sleep loss.[116] These observations suggest that genetic variants of *ADORA2A* may alter the accumulation of homeostatically regulated sleep propensity during prolonged wakefulness. Convergent findings in mice[117] and humans[118] are consistent with this notion. They indicate that the sleep-deprivation–induced rebound of EEG delta activity in NREM sleep, the most reliable marker of sleep homeostasis, depends on the functional state of A_{2A} receptors.[119]

Neurotransmitters

Valomon and coworkers[120] recently investigated whether the Val158Met polymorphism of *COMT* (rs4680) affects actigraphy-derived rest-activity cycles and sleep estimates in 110 healthy adults. No genotype-dependent differences in actigraphy-derived circadian rest-activity patterns were found. Nevertheless, *COMT* genotype modulated the magnitude of sleep rebound on rest days compared with workdays. This difference is thought to reflect the compensation for a sleep debt accumulated during workdays ("social jetlag"). The Val/Val and Met/Met homozygotes significantly prolonged habitual sleep on rest days, whereas the Val/Met heterozygotes did not.[120] Similarly, neurophysiologic markers of sleep homeostasis did not differ between homozygous Val/Val and Met/Met allele carriers.[63,65] By contrast, one study suggested that the Val158Met polymorphism of *COMT* may be related to interindividual differences in sleep homeostasis and physiologic sleep responses to partial sleep deprivation.[121] To further tackle the question of whether COMT plays a role in sleep homeostasis, the effects of pharmacologic interference with COMT enzymatic activity on the consequences of sleep deprivation in different *COMT* genotypes may be studied.

Transporters

Genetically modified animals with reduced dopamine clearance exhibit an increased homeostatic response to prolonged wakefulness compared with wild-type animals. For example, mutant flies (*Dat*^{fo}) with reduced dopamine acetyltransferase activity show a greater sleep rebound after prolonged waking than wild-type controls.[122] Furthermore, *Drosophila* species and mouse mutants lacking functional dopamine transporter (DAT) exhibit prolonged wakefulness and shortened sleep.[123-125] In mammals, the DAT is highly expressed in basal ganglia where it is responsible for reuptake of dopamine and constitutes a rate-limiting mechanism of dopaminergic neurotransmission.[126] An important role for the basal ganglia in sleep-wake regulation has been recently suggested.[127,128] The response to sleep deprivation was studied in 57 adult volunteers genotyped for the 3′-UTR VNTR polymorphism (rs28363170) of the gene (*DAT1*, *SLC6A3*) encoding DAT. Ten (10R) or nine repeats (9R) of a 40-base pair sequence of this gene on chromosome 5p15.3 are most common, whereas the 10R-allele homozygotes have 15% to 20% reduced DAT

availability in the striatum compared with heterozygous and homozygous 9R-allele carriers.[129,130] Consistent with the evidence from transgenic animals, it was found that the sleep deprivation–induced increase in SWS, EEG delta activity, and number, amplitude, and slope of low-frequency (0.5 to 2.0 Hz) oscillations in NREM sleep was significantly larger in the 10R/10R genotype than in the 9R carrier genotype.[59] The data indicated an increased homeostatic response to sleep deprivation in 10R/10R allele carriers of *DAT1* compared with 9R allele carriers.

Signaling Pathways

Recent findings in rats suggested a causal relationship between BDNF and the regulation of EEG delta activity in NREM sleep.[131,132] Inspired by these studies, the possible effect of the Val66Met polymorphism on the regulation of neurophysiologic markers of sleep homeostasis was examined in humans.[66] Delta power in the first NREM sleep episode of a baseline, as well as of a recovery night after prolonged wakefulness, was specifically higher in Val/Val compared with Val/Met genotype subjects. By contrast, activity in high-alpha/low-sigma frequencies (approximately 10 to 13.5 Hz) was reduced. Thus *BDNF* genotype modulated established EEG markers of NREM sleep intensity, whereas the rebound in delta activity after sleep deprivation and its dissipation throughout the nights were only subtly affected. These findings suggest that Val/Val genotypes exhibit overall higher NREM sleep pressure than Val/Met genotypes, which may obscure subtle genotype-dependent differences in the dynamics of sleep homeostasis.

Immune Response

The human leukocyte antigen (HLA) *DQB1*0602* allele is the best HLA marker for narcolepsy, a neurologic disorder characterized by excessive daytime sleepiness, fragmented sleep, and shortened REM sleep latency. Although more than 90% of patients with narcolepsy-cataplexy carry HLA-*DQB1*0602*, 12% to 38% of allele-positive carriers are healthy sleepers.[133,134] A study in 129 healthy subjects suggested that *DQB1*0602*-positive individuals showed decreased sleep homeostatic pressure with steeper declines and greater sleepiness and fatigue in baseline.[135] During partial sleep deprivation, slow wave energy increased in positive and negative subjects, whereas *DQB1*0602*-positive individuals showed more fragmented sleep and altered REM and stage 2 sleep in baseline and during partial sleep loss. Although these preliminary findings are interesting, independent replication is critically required for their validation.

HUMAN SLEEP PHARMACOGENETICS

Individual responses to treatments with pharmacologic agents vary widely in healthy individuals and diseased patients. The differences may relate to weight, body composition, age, gender, and ethnic descent. Furthermore, genetic factors modifying pharmacokinetic or pharmacodynamic properties of molecules and constitutive pathways are becoming increasingly recognized as key determinants of individual responses to pharmacologic treatments. Apart from potentially important implications for the neurobiology of sleep-wake disorders and their pharmacologic management, sleep pharmacogenetics also offers a powerful novel approach to identifying molecular mechanisms contributing to sleep-wake regulation in humans. For example, pharmacogenetic studies of caffeine not only revealed insights into a distinct molecular contribution to individual caffeine sensitivity but also indicated that adenosine A_{2A} receptors and DAT are part of a biologic pathway that regulates sleep.

Adenosinergic Neuromodulation

Since people drink coffee, it is well known that some people are sensitive to its stimulant effects whereas some others are not. With respect to sleep disturbances, already the first scientific study 100 years ago showed that "a few individuals show complete resistance to the effects of small doses of caffeine."[136] Because subsequent work revealed no consistent pharmacokinetic differences between caffeine-sensitive and caffeine-insensitive subjects, endogenous diversity at its site of action was proposed to influence caffeine's effects on sleep.[137] Recent work in mice provided strong evidence that the stimulant promotes wakefulness primarily by blocking the A_{2A} subtype of adenosine receptors.[138] In humans, the variant rs5751876 in the coding region of the *ADORA2A* gene contributes to individual sensitivity to caffeine effects on sleep.[114] In 4329 responders to a brief Internet questionnaire, caffeine consumption was associated with subjectively reduced sleep quality in caffeine-sensitive respondents, but not in caffeine insensitive respondents, and the distribution of carriers of C/C and T/T alleles of *ADORA2A* differed between caffeine-sensitive and caffeine-insensitive individuals. Double-blind study of the effects of the stimulant on the sleep EEG confirmed the self-rated caffeine sensitivity, suggesting that genetic variation of *ADORA2A* is a determinant of individual sensitivity to the effects of caffeine on sleep.[114]

Indeed, Byrne and colleagues[115] provided a recent confirmation of a role for *ADORA2A* in caffeine-related sleep disturbances. They conducted a GWA study in 2402 twins and their families of the Australian Twin Registry. More than 2 million common polymorphisms were examined. Caffeine-associated sleep disturbance was based on the participants' report of whether or not they have ever experienced caffeine-induced insomnia, statistically corrected by a "general insomnia factor score" derived from a questionnaire. Importantly, the previously suggested association between genetic variation of *ADORA2A* and disturbed sleep after caffeine was successfully replicated. This finding is remarkable in the genetics of complex traits because only a small minority of candidate genes has typically been confirmed.[139] The original variant (rs5751876) was not typed in the GWA sample. Nevertheless, this variant forms a perfect linkage-disequilibrium with several other variants of *ADORA2A* that significantly affect caffeine-induced sleep disturbance.[115]

Rétey and associates[114] combined self-reports and polysomnography after double-blind caffeine administration to document individual differences in the effects of caffeine on sleep. By contrast, the replication study was restricted to self-classification of caffeine sensitivity. The successful replication with this less accurate and less reliable (i.e., subjective) phenotype indicates that questionnaires are useful in large-scale epidemiologic studies. Subsequent follow-up with objective measurements in animals and humans can provide novel insights into the molecular bases of healthy and disturbed sleep. Thus sleep pharmacogenetics of caffeine may have important implications for the pathophysiology and the

rational treatment of insomnia, as well as for recommendations for the critical use of caffeine, which is consumed on a daily basis by up to 90% of adults in Western societies.

Dopaminergic Neurotransmission

Apart from being an adenosine receptor antagonist, the stimulant actions of caffeine also depend on the dopaminergic system. Data in *Dat* knockout animals and human homozygous carriers of the 10R allele of *DAT1* (*SLC6A3*) suggest that reduced DAT expression is associated with elevated sensitivity to the stimulant.[59,125] Furthermore, Holst and colleagues[59] found that caffeine reduced distinct neurophysiologic markers of sleep homeostasis, such as number, amplitude, and slope of individual slow waves, in a *DAT1* genotype-dependent manner. This finding suggested that the interference of caffeine with neurophysiologic markers of sleep homeostasis not only relies on adenosinergic mechanisms but also involves dopaminergic processes.

Like caffeine, the potency of the wake-promoting compound modafinil shows pronounced interindividual variation. The neurochemical mechanisms and cerebral regions through which modafinil produces wakefulness are incompletely understood. However, modafinil reduces DAT-mediated reuptake of dopamine in animals[140] and humans.[141] Consistent with a dopaminergic mode of action of modafinil, the compound was ineffective in promoting wakefulness in *Dat* knockout mice[125] and attenuated elevated sleepiness after sleep deprivation reflected in EEG theta (5.5 to 7 Hz) power in sleep-deprived volunteers in a *DAT1* genotype-dependent manner.[59]

Functional variants in the gene encoding COMT also alter dopaminergic neurotransmission in the brain. They may, thus, also contribute to individual differences in the wake-promoting effects of modafinil. Support for this hypothesis was obtained in both sleepy patients (see Clinical Pearl) and healthy volunteers subjected to sleep deprivation.[142] In healthy young men, placebo-controlled, double-blind, randomized administration of modafinil (2 × 100 mg) during prolonged wakefulness similarly reduced subjective sleepiness and EEG 5- to 8-Hz activity in Val/Val and Met/Met allele carriers of *COMT*.[63] By contrast, modafinil differently affected the NREM sleep EEG in recovery sleep. Furthermore, it maintained sustained vigilant attention and executive functioning at baseline level throughout prolonged waking in Val/Val allele carriers, whereas the compound was virtually ineffective in the Met/Met genotype.[65] These data highlight a role for dopamine in impaired waking functions after sleep loss. The functional significance of the modafinil-induced, genotype-dependent effects on the NREM sleep EEG during recovery from sleep loss remains to be determined.

CONCLUDING REMARKS

Sleep is a complex behavior, and any functional genetic variation associated with changes in one of the many neurotransmitter and neuromodulator systems can be expected to affect sleep and the sleep EEG. Polymorphic variations in a number of genes have now been shown to affect several characteristics of sleep, and some of these genes may indeed be involved in sleep regulatory processes. However, many associations need to be replicated, and failure of replication is common. Nevertheless, after robust associations have been established, elucidating the signaling pathways that are affected will aid our understanding of individual differences in sleep-wake behavior.

CLINICAL PEARL

Distinct alleles and genotypes in the genes of monoamine oxidase type A (MAO-A)[143] (but see Dauvilliers and colleagues[144]) and COMT[144] are thought to be associated with the clinical manifestation of narcolepsy. The Val158Met polymorphism of COMT exerts a sexual dimorphism and a strong effect of genotype on disease severity.[144] More specifically, women narcoleptics with high COMT activity fall asleep twice as fast during the Multiple Sleep Latency Test than those with low COMT activity. An opposite relationship, although less pronounced, is observed in men. Also, the response to treatment with modafinil to control excessive daytime sleepiness differs between COMT genotypes. Patients (female and male) with the Val/Val genotype need an almost 100 mg higher daily dose than patients with the Met/Met genotype.[145] Intriguingly, in male healthy volunteers, the effect of the Val158Met polymorphism of COMT on the efficacy of modafinil to improve excessive sleepiness after sleep deprivation is opposite that in narcolepsy patients.[65]

SUMMARY

Sleep is a very rich phenotype, and many aspects of sleep differ considerably in the population of healthy individuals (even when only a very narrow age range is considered). Interindividual variation in sleep timing (diurnal preference), sleep duration, sleep structure, and the EEG in NREM sleep, REM sleep, and wakefulness have all been shown to have a genetic basis. The response to challenges of sleep regulatory processes such as sleep deprivation and circadian misalignment has also been shown to vary between individuals. Some of the polymorphic variations in genes contributing to variation in sleep characteristics have now been identified. They include variations in genes associated with the circadian system (e.g., *CLOCK, PER1, PER2, PER3, BHLHE41*), the adenosine system (*ADA, ADORA2A*), and the catecholaminergic system (e.g., *COMT, SLC6A3, SLC6A4*), as well as other signaling pathways (e.g., *ABCC9*, *BDNF*, *PRNP*). For some of these genes, so far only associations with one aspect of sleep have been reported (e.g., *PER2* and sleep timing). Variations in other genes have been shown to affect multiple aspects of sleep and wakefulness, as well as the response to sleep loss or pharmacologic interventions. For example, *PER3* and *ADA* affect the EEG and performance during prolonged waking, whereas *ADORA2A*, *COMT,* and *SLC6A3* modulate EEG and response to the stimulants caffeine and modafinil. All currently known polymorphic variations explain only a small part of the variation in healthy human sleep phenotypes, and many more genetic contributions remain to be discovered.

Genetics and Genomic Basis of Sleep Disorders in Humans

Allan I. Pack; Brendan T. Keenan; Enda M. Byrne; Philip R. Gehrman

Chapter Highlights

- This chapter provides an overview of the approach to genetic studies in humans.
- Known genetic risk factors for sleep disorders are described.
- Genetic determinants of normal variants of sleep duration, chronotype, and response to sleep deprivation are identified.
- Genetic studies in narcolepsy show that HLA variants confer increased risk for and protection from narcolepsy.
- Genetic studies in narcolepsy show not just HLA variants but also variants in T-cell alpha receptor, supporting the autoimmune basis of the disorder.
- Genetic studies of restless legs syndrome identify novel pathways whose role needs to be identified.
- Variations in clock-associated genes affect not only timing of sleep but also sleep duration and response to sleep deprivation.

APPROACH TO IDENTIFYING GENETIC VARIANTS IN HUMANS

Overview

The overwhelming majority of biologic traits and disorders in humans have a genetic component as part of their etiology. Sleep and disorders of sleep are no exception. The total proportion of variation in risk to a disease in the population that can be attributed to genetic variation is known as the heritability. There are now a large number of studies showing that sleep disorders are heritable, that is, genetics play a substantial role in their etiology. These are also reviewed in chapters that cover specific disorders (e.g., movement disorders, Section 13; sleep breathing disorders, Section 14; and narcolepsy, Chapter 89).

The role of genetic and genomic factors in human disease has been studied for decades, progressing from classical heritability and linkage studies to more focused candidate gene analyses, then to genome-wide analyses made possible by the sequencing of the human genome and more recently including whole exome and genome sequencing analyses as well as evaluation of epigenetic modifications. Since the sequencing of the human genome, biomedical research has made great progress in understanding the genetic architecture and molecular pathways underlying human disease.[1,2] Whereas a greater understanding of genetic factors underlying complex disease has been achieved, the large amount of so-called missing heritability, that is, the unexplained genetically inherited disease risk, suggests that there is still opportunity and need for important discoveries.[1,2] This is particularly true for sleep disorders, despite the established genetic heritability; to date, only a small number of validated genetic risk variants have been discovered for sleep-related traits. There are a number of reasons for this lack of discovery, including inadequate sample sizes, variable phenotypes that add noise, and numerous pathways to disease.

Heritability analyses are the first step in understanding the genetic underpinnings of disease. They establish whether there is a relationship between genetic risk factors and a disease phenotype by estimating the amount of disease variability that is explained by genetic variants. In the past, after it was established that a disorder is heritable, *linkage studies* were a likely next step to try to further our understanding of the existence of genetic etiology by trying to pinpoint specific chromosomal regions that harbor genetic variants influencing disease risk. *Candidate gene studies* can then be used to examine these identified regions in finer detail or, more recently, to replicate genes identified through genome-wide analyses. The Human Genome Project,[1,3-6] the International HapMap Project,[7,8] and The 1000 Genomes Project[9] have firmly established and characterized interindividual variability throughout the human genome.

The primary focus of current studies examining the association between genetic variants and disease has been on *single-nucleotide polymorphisms* (SNPs). This is because SNPs, which are a difference in the DNA sequence at one nucleotide among individuals, are the most frequent form of genetic variation. Owing to the block-like structure of the genome, where regions of the genome that are close together tend to be transmitted together, genotyping of one SNP can provide information on genetic variation at many nearby SNPs. Initial publications suggested that approximately 500,000 common polymorphisms provided power to capture 90% of the variability in the genome.[2,10] Analysis approaches distinguish between common polymorphisms (occurring with >5% frequency in the population), which are likely to confer small effect sizes for complex disease, and rare polymorphisms (<5% frequency), which may lead to larger effects but are more difficult to discover because of their less frequent occurrence (Figure 31-1). Whereas for the latter individuals variants may be rare, there may exist multiple different rare variants

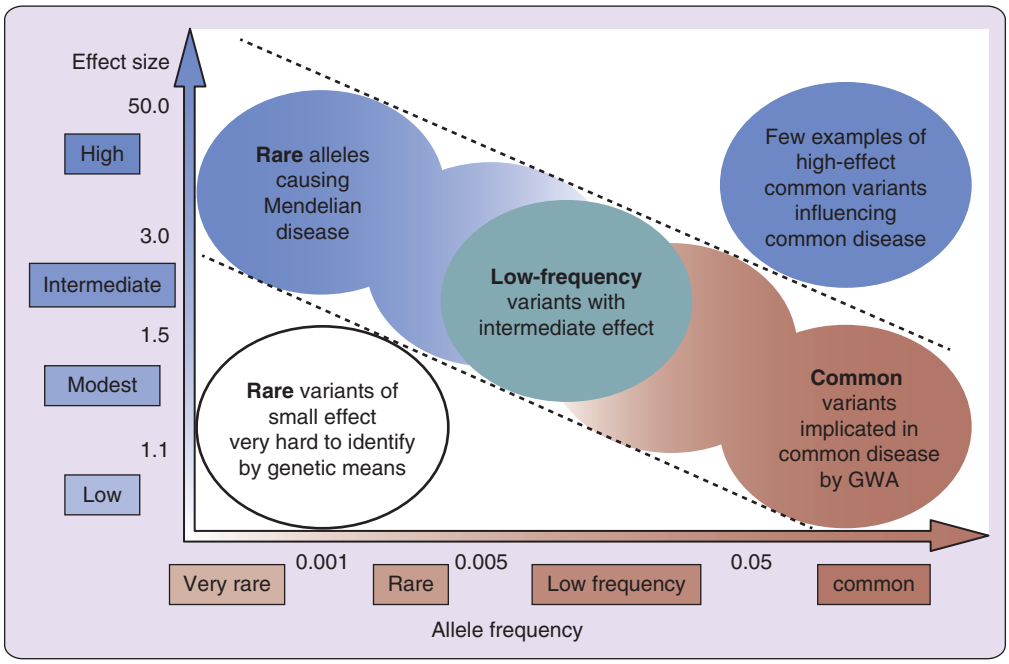

Figure 31-1 Relationship between allele frequency of variant (x-axis) and effect size of variant. Common variants at bottom right of figure have frequency in population of more than 5% but have smaller effect in controls. Variants to the left are rare but have large effects. in the same gene, and so one can evaluate the evidence for a role for rare genetic variants as a set rather than just individually.

In addition to SNPs, *copy number variation*,[11,12] including insertions and deletions, provides additional mechanisms for genetic underpinnings of disease.[11,13] Finally, there is an increasing focus on the role of epigenetics,[14,15] including DNA methylation, in elucidating the biological pathways to disease. The level of methylation in certain regions of genes or functional elements outside of genes affects the level of gene expression. Unlike the DNA sequence itself, methylation patterns are not fixed and can be influenced by a variety of environmental factors. It can occur in multiple sites in the genome. Because it can be permanent, it can be passed through the germline to offspring. Thus, environmental influences that individuals experience before they have children can influence which genes are expressed in particular cell types in their offspring. The following gives a brief overview of the potential approaches to genetic studies of sleep disorders. Later in the chapter, we explain what is known about the genetics of sleep and some common sleep disorders.

Heritability Estimation

Heritability can be broadly defined as the proportion of phenotypic variability that is attributable to genetic factors; higher estimates suggest that genetic variability has a large influence on the variability of a given trait in the population. Heritability analysis has been used for decades to estimate whether a given phenotype is influenced by genetic factors and how strong that influence is relative to nongenetic risk factors. Numerous techniques exist for estimating heritability; these range from use of phenotype information from twins[16] or family pedigree data[17,18] to more recently developed statistical techniques for estimating heritability based on genome-wide genotyped data on unrelated individuals.[19]

Estimating the heritability of a given trait with use of twin or family data does not require specific measurement of genetic variants. Rather, these methods take advantage of the known shared genetic variance among related individuals. The general principle behind heritability analysis is that people who are more genetically related to each other should be more similar to each other for the phenotype of interest. For binary traits like sleep disorders, one can measure the recurrence risk to relatives. That is, given that a family member has been diagnosed with a disorder, what is the risk in the family members of having the same disorder? This recurrence risk in families can be compared with the risk of disease in the general population to give an estimate of heritability. For heritable traits, the relative recurrence risk ratio should decrease as the family relationships examined become less similar genetically; for example, the recurrence risk in siblings of affected individuals should be greater than for first cousins of the affected.

Results from family studies are complicated by the fact that family members often share a similar environment. It can be difficult to parse out whether the higher risk in certain families compared with the general population is due to shared genetic risk factors, shared environmental risk factors, or a combination of the two. Twin studies help to separate out shared genetic variance from other sources of variance because twin pairs are assumed to share many common environmental factors—they are born at the same time, shared the same intrauterine environment, and often attend the same school. With this source of variance controlled for, the similarities and differences between twins can be separated into genetic and environmental sources. Estimates of heritability are derived by

comparisons between monozygotic and dizygotic twin pairs. Increased similarity in phenotype between monozygotic pairs (who are genetically identical) compared with dizygotic twin pairs (who share half of their genetic variants with each other) provides evidence for heritability. As presented in a recent publication establishing the heritability of performance deficit accumulation during sleep deprivation,[20] there are several complementary methods that may be used for evaluating heritability in twin samples. We briefly describe these methods.

As discussed with respect to performance deficits during sleep deprivation,[20] three methods for estimating heritability in twins are (1) classical heritability estimation, (2) analysis of variance (ANOVA) approach, and (3) likelihood-based estimation of variance components. Each of these methods can be useful in comparing the heritability to existing literature as well as in evaluating different assumptions. Classical heritability is derived using the differences in the intraclass correlation coefficient (ICC) statistics between monozygotic (ICC_{MZ}) and dizygotic (ICC_{DZ}) twin pairs.[21] Using these values, heritability (denoted h^2) is estimated as $h^2 = 2 \bullet (ICC_{MZ} - ICC_{DZ})$. In addition to estimating heritability, the classical approach can also provide an estimate of the shared common environmental variance, which is estimated as $2 \bullet ICC_{DZ} - ICC_{MZ}$. Next, the ANOVA approach uses combinations of the monozygotic and dizygotic within-twin and among-twin pair mean squares estimates in combination with specific assumptions about the variability (e.g., that total variability is equal in monozygotic and dizygotic twins).[22,23] Finally, the maximum likelihood variance components approach uses model-specific covariance matrices[23-25] and, importantly, allows the examination of specific patterns of genetic transmission and calculations of standard errors and *P* values associated with heritability estimates. These models of genetic transmission include components related to additive genetic effects (A), dominant genetic effects (D), common environmental effects (C), and unique individual effects (E).[25] For example, the ACE model assumes additive genetic effects, shared environments, and unique individual components of variability. By comparison of different models, specific questions about the mode of genetic inheritance can be assessed. Overall, we see that each method of heritability estimation has unique advantages. Whereas the classical method provides a more simplistic approach to the computation, the advantage of the ANOVA model is the ability to assess specific assumptions about the validity of the twin model. Although it is potentially more complex, the maximum likelihood variance components approach can provide information on specific genetic transmission models.

As discussed later in the chapter, more recently established techniques allow estimation of heritability in unrelated individuals by simultaneously examining the association between a given trait and all genotyped genetic polymorphisms.[19,26-28] These techniques have recently been used and extended to more accurately capture the amount of variability we can expect to explain through genome-wide association analyses.

Establishing that a given trait is heritable strongly implies that underlying genetic factors play a role in determining the phenotype. Many sleep-related disorders and intermediate phenotypes have been shown to be heritable in the last few decades, including sleep duration,[29-31] chronotype,[32-35] response to sleep loss,[20] restless legs syndrome (RLS),[36-38] insomnia,[29,39-41] parasomnia,[42] obstructive sleep apnea (OSA),[43-49] and key intermediate traits for OSA (such as craniofacial structures,[50] upper airway soft tissue volumes,[51] and ventilatory responses to hypoxia and hypercapnia[52]). Among behavioral traits, one of the most heritable is the spectral characteristics of the electroencephalogram (EEG) during sleep.[53]

Heritability is only an estimate for the specific population included in a study. There is not one true heritability for a given disorder or trait. Instead, the heritability can vary over time as environments change, and it can be different in specific ethnic groups or in particular age groups (see Visscher et al[19] for a review of heritability concepts). For instance, the heritability of sleep duration in adolescents is likely to be different from that in older adults. The relative importance of genes and environment in population variation may vary over the life span. Hence, estimates of heritability can vary substantially across studies.

Despite observing heritability estimates of more than 50% for some of these traits, the genetic variants discovered to date typically explain on the order of less than 5% of the known overall variability in any given phenotype. Finding the causes of this "missing heritability" is an ongoing area of research, and methods for determining heritability of a given phenotype continue to develop (for reviews, see[1,2,54-56]). Explanations for missing heritability are numerous, including a large number of common variants with small effects, multiple rare variants with large effects, insufficient tagging of causal variants in current genotyping platforms, gene-gene and gene-environment interactive effects, and other types of genetic variations (such as copy number variants and epigenetic modification). Ultimately, explaining the missing heritability is likely to require very large sample sizes and both rigorous and novel analytic techniques.

Linkage Analysis

Once a trait has been shown to be heritable, the next obvious question is, Which genes or regions are associated with the phenotype? One strategy for answering this question is to perform a genetic linkage analysis, which relies on the inheritance structure associated with family pedigrees. That is, genetic linkage analysis uses the observation that genes close to one another are more likely to be passed down to offspring than are genes that are farther away.[57-63] At their most basic level, linkage studies involve comparing chromosomal regions between affected and unaffected individuals to identify those DNA segments that are more commonly shared between affected relatives and not between affected and unaffected.[58,59] Genetic regions that are more likely to be shared among affected individuals in a family than between affected and unaffected individuals are expected to contain disease-related genetic factors. The approach does not involve initial assessment of genes but rather use of multiple polymorphic microsatellite markers that are equally spaced across the genome (typically 400 to 1000 markers). These markers in intergenic regions have high sequence variation between different individuals. The approach involves calculating the maximum likelihood log-odds (LOD scores) as a function of marker location. Because there are multiple such computations, false associations may occur by chance, and criteria to control for this have been developed (see later). Once a marker location with a high LOD score is identified, the genomic region can be narrowed and the linkage validated by determining LOD scores for an additional set of markers that are specific to this region—fine

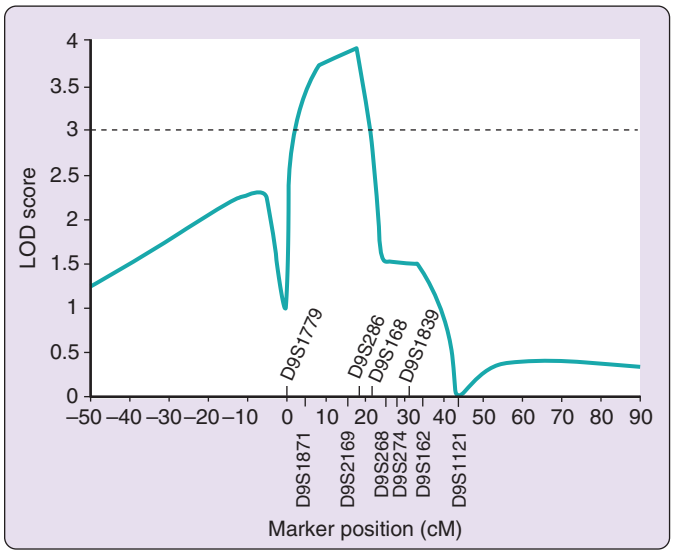

Figure 31-2 Example of identifying a region by linkage analysis. Marker location is on x-axis and LOD score on y-axis. When a significant linkage is found with equally spaced polymorphic markers across the genome (*dashed line* represents threshold for genome-wide significance linkage), LOD scores for additional markers in region (see annotations on x-axis) are calculated. As shown, this results in narrowing of the genomic region and leads to increased LOD scores. In this example, there is little doubt that there is a variant conferring risk for restless legs syndrome in this region. (From Chen S, Ondo WG, Rao S, et al. Genomewide linkage scan identifies a novel susceptibility locus for restless legs syndrome on chromosome 9p. *Am J Hum Genet* 2004;74:876-85.)

mapping (see example, Figure 31-2). Linkage analyses should not be reported without this step. With the advent of extensive SNP data across the genome, an alternative strategy is to do case-control association analyses with all known SNPs in the linkage region. This limits the number of comparisons compared with that in genome-wide association analysis. This strategy has been successfully employed in studying the genetic risk factors for RLS[64] (see further later). Linkage analysis can also be extended to examine quantitative traits, rather than binary. Moreover, analyses can examine the linkage between single genetic loci or multiple loci.[60,63]

Multiple methods may be used for performing genetic linkage analyses, depending on the hypothesized model of inheritance, including parametric (or model based) and nonparametric (or model free).[57-63] Briefly, parametric linkage analysis involves testing whether the inheritance pattern follows a prespecified model, including disease and allele frequencies, and calculating the LOD score (equal to the log of the likelihood ratio) for each polymorphic genetic marker through statistical modeling.[57,58,63] Nonparametric linkage analysis, on the other hand, relies on a sib-pair design to test whether affected individuals are more likely to share genetic regions than would be expected under the assumptions of independence between trait and inheritance.[61-63] Nonparametric linkage is an important tool for complex traits, as parametric linkage has been shown to be quite sensitive to misspecification of the mode of inheritance.[58,63] Research has extended these methods to use linkage maps and a unified multipoint approach that includes all relevant pedigree information, rather than restricting to specific models or subsets of pedigree information.[60,63,65-67]

Importantly, previous research from Lander and Kruglyak[58] has provided LOD score thresholds for statistical significance in complex traits, depending on the mapping method and model of inheritance. These thresholds include a LOD = 3.3 for genome-wide significant linkage (corresponding to a $P = 4.9 \times 10^{-5}$) and a LOD = 1.9 for suggestive linkage ($P = 1.7 \times 10^{-3}$) for analysis in humans and slightly higher thresholds of LOD = 3.6 and LOD = 2.2 in sib-pair studies. Although suggestive signals are of interest, they should be interpreted with caution as they could be false positives, and many will likely not be replicated in independent samples. Subsequent to the identification of a genomic region with significant linkage, fine-mapping analysis, examining specific genetic markers within the identified region, is an important next step to narrow genomic regions and to identify specific variants associated with the phenotype of interest. Modern sequencing and genotyping technologies have facilitated these more detailed examinations.

Linkage studies have been around for several decades, and one of the most successful examples in sleep-related diseases is the identification of five linkage regions, that is, *RLS-1* through *RLS-5*, for RLS (Table 31-1).[68-72] This was based on studies of a number of large family pedigrees with RLS in different parts of the world. Subsequent fine-mapping analyses identified specific variants of interest in these genes,[64] leading to new insights into RLS genetics. In contrast to these positive findings in RLS, early linkage analyses for OSA in Europeans and African Americans have led to results that have not been replicated.[73-75] These studies reported linkage with most LOD scores not even in the suggestive range and did not do any fine mapping.[73-75] Thus, these early studies were underpowered for robust effects. It seems unlikely that linkage approaches will lead to identification of genomic regions linked to OSA.

Linkage analysis proved to be an important tool for mapping the variants underlying many single-gene disorders, such as Huntington disease and cystic fibrosis. Furthermore, linkage analysis aided in the identification of genes underlying polygenic disorders such as RLS, in which one variant or a very small number of variants explain a large proportion of the heritability in the population. However, linkage analysis has not proved a successful strategy for complex disorders for which hundreds of variants likely contribute to risk at the population level. This is primarily because linkage analysis requires family-based data. It is cumbersome to collect enough families to have enough power to detect variants that do not have a large effect on disease risk. Allied to this, linkage analysis primarily used microsatellite markers found throughout the genome, often at large distances from each other, and therefore a signal from a linkage analysis could implicate very large regions of the genome containing many genes. For these reasons among others, linkage analysis has now largely been replaced by association-based analysis using SNPs.

Candidate Gene Studies

A more directed approach to discovering important genes and genetic variants is by association studies using a candidate gene approach. Rather than having to focus on related individuals and family pedigree data, candidate gene studies can use unrelated individuals (e.g., cases and controls) as well as families and targeted genotyping to examine the association between variants within or near a priori hypothesized genes of interest and a given phenotype.[59,76] Hypothesized candidate

The linkage regions for restless legs syndrome are given with their chromosomal position by chromosome band, the proposed inheritance mode, and the logarithm of the odds (LOD) scores from parametric linkage analysis. Both 2-point and multipoint scores are reported. Numbering of loci has been indicated as listed in Online Mendelian Inheritance in Man (OMIM).

genes may arise from several areas, including linkage analyses and genome-wide association results or from existing knowledge about the biological mechanisms involved in pathogenesis, and should be chosen by considering information relative to biologic pathways associated with the disease phenotype of interest. Using strong functional hypotheses is an important aspect for candidate gene studies as false-positive associations may arise because of linkage disequilibrium between candidate regions and true causal variants as well as because of population stratification (see further later).[59,76,77] This potential for confounding, coupled with the large number of gene associations that are not replicated in independent data sets, has led to considerable debate about the utility and interpretation of results based on these approaches.[59,76,78-81]

At their most basic level, association studies using candidate genes are no different from typical epidemiologic studies examining the relationship between nongenetic risk factors and a phenotype of interest. Candidate gene studies involve making a priori assumptions about which genetic regions are most likely to be associated with a phenotype and thus may be limited by the amount of information currently known about the functional effects of a given gene. Once candidate genes have been established, standard statistical modeling can be used to assess the correlation between the candidate alleles in these genes and the phenotype of interest. Compared with linkage analysis, candidate gene studies have been shown to have stronger statistical power for complex disease traits as they can identify genes or gene variants with smaller effects.[76,82] Like many types of association analyses, initial candidate gene studies are prone to overestimates of the true association (also referred to as winner's curse).[79-81] This initial overestimation, as well as the fact that many early studies use relatively small sample sizes, is a major reason that many novel genetic associations fail to replicate in later studies. A previous study by Ioannidis et al,[79] examining 36 genetic associations through a meta-analysis of 370 studies, showed that both a small sample size in initial publications and a large number of studies for a particular trait were independent predictors of discrepant results. With regard to sample size, they found statistically significant discrepancies in 5 of 7 cases in which the first publication had fewer than 150 subjects compared with only 3 of 29 when the initial sample size was more than 150.[79] This further emphasizes the importance of considering the size of the study population in interpreting genetic associations (for review, see[77]).

Detailed reevaluation of evidence for association for candidate genes in other fields with a larger genetics literature than for sleep disorders has indicated that very few if any associations with SNPs in candidate genes replicate in larger samples.[83,84] These findings mean that caution should be exercised in interpreting results from candidate gene studies for sleep disorders.

Another important consideration in interpreting the results of genetic association studies is population stratification,

which occurs when differences in disease prevalence and genotype frequency between populations of different ethnicities result in apparent associations between genotype and phenotype.[85-91] Because of evolution and genetic drift, SNP allele frequencies differ between populations. Moreover, different diseases are more or less prevalent in different parts of the world. The combination of a higher disease prevalence and higher or lower genotype frequency will result in inflated *P* values and significant associations in analyses that combine data from multiple ethnic populations, even if the two factors are unrelated. Approaches to correct for population stratification have been discussed in detail[85,88-91] and include correction by principal components estimated through ancestry informative genetic markers. Whenever possible, genetic analyses of individual variants should be performed separately within populations of differing ethnicity, in the case of both candidate gene studies and genome-wide associations. However, specific programs and genotyping platforms for capturing differences in associations between admixed populations have been developed.[92]

Candidate gene studies have been conducted for many sleep-related disorders, including chronotype[93-97] and OSA.[98-100] Candidate gene studies for chronotype have focused on the associations with clock genes (e.g., *CLOCK*, *PER1*, *PER2*, and *PER3*). Although not all studies have found significant associations, most likely because of small samples, the general pattern suggests significant roles of these functional genes on chronotype (see later). As extensively reviewed by Varvarigou et al,[100] candidate studies in OSA have focused on a wider variety of genes, including those related to obesity and craniofacial phenotypes, as well as specific genes with previously suggested associations (e.g., *APOE* ε2 and ε4); whereas some significant associations have been seen, only an SNP in the regulatory region of *TNFα* was found to be significant in the meta-analysis plan. This may not be related to risk for OSA but rather to the subjects with this SNP being more likely to be excessively sleepy and hence seeking evaluation.[101] As is the case with many candidate gene studies, those currently performed in OSA have had relatively small sample sizes and therefore have been greatly underpowered to find the type of effect sizes (e.g., odds ratio = 1.2) expected for common variants associated with complex diseases[100] (Figure 31-3). Much larger studies are needed.

By design, candidate gene studies focus primarily on variants in the coding regions of genes. However, it is becoming increasingly apparent that common genetic variation found

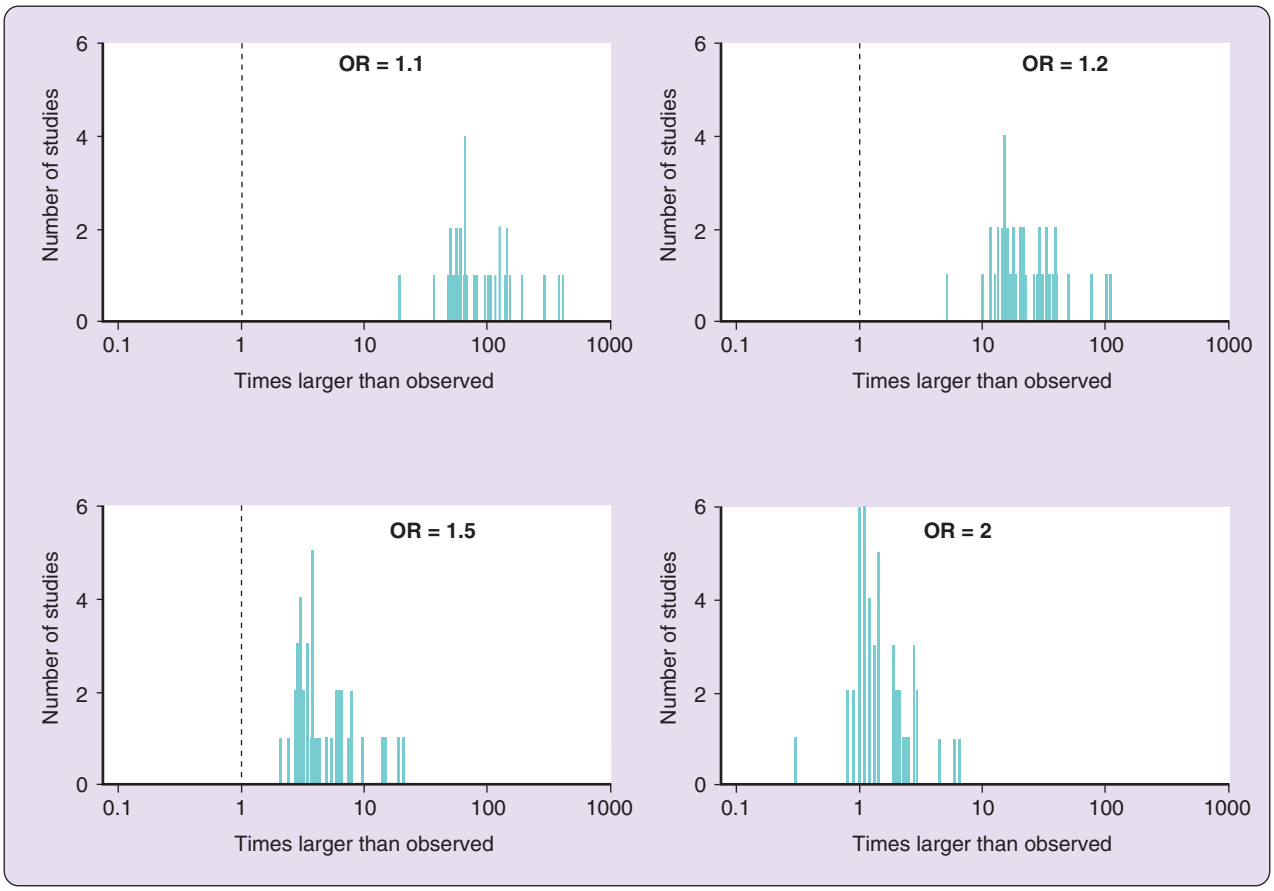

Figure 31-3 Calculation of how much larger candidate gene studies for obstructive sleep apnea would be needed to identify odds ratios (OR) of 1.1 (*top left panel*), 1.2 (*top right panel*), 1.5 (*bottom left panel*), and 2.0 (*bottom right panel*). Common variants typically result in low OR, such as 1.2. As can be seen for this OR, studies would need to be between 10 and 100 times larger than was used in the original studies. The majority of studies are underpowered to even detect an OR of 2.0, an effect typically not found with common variants. (From Varvarigou V, Dahabreh IJ, Malhotra A, et al. outside of protein-coding genes contributes to the etiology of disease. Our understanding of noncoding functional areas of the genome has improved dramatically in the past few years, and it is no longer sufficient to focus solely on variants in the exome.

Genome-Wide Association Studies

The completion of the Human Genome Project and the subsequent mapping and sequencing projects that characterized genetic variation among individuals dramatically increased our ability to perform genetic association studies.[1,3-9] Rather than relying on the identification of broad regions through linkage or restricting our focus to hypothesized candidate genes, genome-wide genotyping allowed an unbiased examination of the relationship between a given trait and individual genetic variants throughout the genome. This type of "hypothesis-free" analysis is referred to as a genome-wide association study (GWAS). The first GWAS results were published with respect to age-related macular degeneration,[102,103] with the initial large-scale GWAS led by the Wellcome Trust Case Control Consortium, examining seven common diseases in 14,000 cases and 3000 controls.[104] Since these initial GWAS results, thousands of genetic loci have been associated with complex traits, as detailed by the National Human Genome Research Institute GWAS Catalog (available at http://www.genome.gov/gwastudies/).[105,106] These analyses are typically restricted to common genetic variants (i.e., with minor alleles occurring in more than 5% of the population), many of which have small but significant effects on complex diseases such as sleep-related disorders. GWAS analyses are proving to require very large samples of well-phenotyped individuals to obtain robust and reproducible results. Important considerations, discussed briefly, include interpretation of results, appropriate genome-wide significance thresholds, and the need for well-designed studies with replication samples and analyses.

GWAS rely on the haplotype or correlation structure among SNPs across the human genome, based on initial publications suggesting that approximately 500,000 common SNPs captured a substantial proportion of the variability in the genome.[2,10] Given this structure, rather than examine every SNP in the genome, designed genotyping platforms capture a majority of the information by genotyping several hundred thousand SNPs across the genome. Moreover, current statistical genetics approaches combine this individual-level genotype data with correlation structures inferred from established reference panels of fully sequenced individuals, such as the International HapMap Project[7,8] and The 1000 Genomes Project,[9] to impute nongenotyped SNPs for inclusion in GWAS analyses (for review, see[107]).

After genetic data have been collected, performing a GWAS involves conducting individual regression models assessing the relationship between each common variant and the phenotype of interest (e.g., a linear regression model for quantitative phenotypes or a logistic regression model for disease phenotypes). In these models, SNPs may be coded additively with respect to the number of copies of the allele of interest or assuming a dominant or recessive genotype effect. Because of the large number of tests resulting from all SNPs being examined individually, a multiple comparisons correction is necessary to determine statistical significance and to protect against false-positive associations. Whereas there are different methods for performing this correction, a P value less than 5×10^{-8} is typically required to claim genome-wide significance, reflecting a Bonferroni correction for 1 million independent tests of the hypothesis that SNPs are associated with a phenotype.[2,77,108,109] As the number of genetic variants included in analyses continues to increase, stricter criteria will be necessary to ensure robustness of associations.

As with candidate gene association studies (discussed earlier), although reaching statistical significance is important, determining a robust genetic association requires a critical review of initial studies and replication analyses. The National Cancer Institute–National Human Genome Research Institute (NCI-NHGRI) Working Group on Replication in Association Studies has published an excellent review on the interpretation, validity, replication, and publication of genotype-phenotype associations.[77] Criteria for establishing the validity of initial association reports include sufficient sample size and power to detect reasonable effects, appropriate correction for multiple comparisons across all tests, consistent results for any similar phenotypes and population subsets, standard and well-described quality control methods applied to genotypes, assessment of potential confounding by population stratification (as in candidate gene studies), similar associations between the most highly associated SNP and those in linkage disequilibrium, and reported results from replication studies (even if these are null).[77] Replication analyses are critical for genetic studies, given the likelihood of false positives; this is true for all approaches, not just GWAS. Replication analyses require reproducing observed SNP associations from initial discovery analyses within an independent population. As discussed in the NCI-NHGRI review,[77] many of the same criteria for establishing the soundness of initial results apply to replication studies, including adequate sample size, similarity in phenotypes, population and effect sizes, strong rationale for SNP selection, and, when possible, joint analysis combining discovery and replication analyses that results in lower P values. Meta-analyses and joint analyses combining observed results across multiple studies are typically a good way to ensure validity of genetic associations.[79] Ultimately, it is important to consider all of these issues in examining the robustness of genetic associations in complex diseases, including sleep-related disorders.

Despite the established heritability, GWAS for sleep-related traits have led to mixed results. These are discussed in detail in the sections that follow. Whereas there has been notable success in GWAS studies in RLS and narcolepsy, no GWAS has been reported for OSA. Some have argued that this is the next logical step in studying genetics of OSA.[110] Compared with other fields, understanding of the genetic architecture of sleep-related phenotypes through GWAS is in a relatively nascent stage. Because other fields have moved beyond GWAS, it is increasingly difficult to obtain funding for GWAS studies, making it even more challenging for studies of sleep and its disorders.

Rare Variant Analysis

Whereas GWAS analyses have increased our understanding of the genetic architecture underlying disease, analyses of genetic variants obtained through genotyping chips are typically restricted to common SNPs with minor allele frequencies of more than 5%. SNPs that occur with a frequency of less than 5% are typically referred to as rare variants and

require different analytical approaches. Rare variants may be analyzed in family or twin studies as well as in identified extreme phenotypes by examining the shared occurrence of rare variants in a particular region within individuals with the same phenotype.[111,112] As discussed in more detail later, rare variants may also be examined in unrelated individuals with more recently established techniques.[111,113-120] Information about SNPs of this frequency is typically obtained by deep-sequencing analyses, which can be performed either in a targeted fashion (capturing specific genes or regions) or, more recently, by whole exome or whole genome genotyping methodologies.[121] Exome sequencing looks for variants only in protein-coding regions of the genome. Whereas common variants tend to confer small effects for complex disease, rare variants are more likely to result in large effect sizes within subjects carrying the risk allele. The existence of rare variants with large effects is one explanation for the missing heritability in complex disease. Although early studies evaluating rare variants proposed that the large effects, combined with extreme phenotyping designs, would allow identification of important variants in even small samples, recent publications have indicated that sample sizes similar to those in common variant analyses are required to detect associations.[122]

As discussed with respect to GWAS analyses, common variant analyses in unrelated individuals involve examining the relationships between individual SNPs and a given phenotype. However, individual variant tests examining the associations between outcomes of interest and SNPs with a minor allele frequency of less than 5%, as is done with common variants, are typically underpowered. Instead, rare variants can be analyzed with a variety of established techniques, depending on certain assumptions, typically by collapsing all relevant variants across genes or regions of interest, including burden tests and kernel-based association methods.[113-120] The burden test is most powerful when the rare variants have effects going in the same direction (i.e., all harmful or all protective), whereas kernel-based association methods (e.g., SKAT) are more powerful when a region contains rare variants that are both harmful and protective. One recently established method, the SKAT-O test, has the burden and SKAT tests as special cases and is optimal across multiple scenarios in which rare variants are associated with complex disease; it can also be modified to increase power in small case-control samples.[114,115] In addition to basing these tests on specific chromosomal regions, tests can consider only functional rare variants, that is, those predicted to have a significant impact on the function of protein by altering the amino acid composition. Restricting only to these functional variants can lead to increased power for detecting rare variant association through elimination of neutral nonfunctional variants. Functional prediction scores can be incorporated into rare variant tests.[113] In addition to providing an optimal tool for analyzing rare variant associations within a given locus or gene, these methodologies can be extended to perform meta-analyses of the rare variant effects across regions[123] and to assess the combined effect of rare and common variants.[114,115]

Although rare variant analysis is an emerging field, developing along with the improvements in sequencing technology, rare variants in the *BHLHE41* gene (class E basic helix-loop-helix protein 41; also known as *DEC2*) have been shown to affect sleep duration in humans.[124,125] Using targeted sequencing of clock genes in one study[124] and focused sequencing of *DEC2* in another,[125] studies were able to identify specific mutations within a small number of subjects with short sleep duration (<6 hours) that showed no evidence of daytime impairment. Importantly, once rare variants with large effects were found, functional studies were performed to identify specific biological effects. Of three variants in *DEC2* found, this method of discovery followed by functional analysis showed that the variants with clear effects on sleep duration resulted in a reduction in the ability of *DEC2* to suppress CLOCK/BMAL1 transactivation.[125] Another variant with no obvious effect on sleep duration had no effect on this process.[125] Final proof of the functional significance of one of the variants was obtained by knocking the variants into both mice and *Drosophila* and replicating the phenotype.[124] This is one of the clear advantages of studies of rare variants with large effects, that is, using model systems to prove beyond any doubt their functional significance. Thus, we see the potential of rare variant analysis to inform about important biological disease pathways related to sleep and its disorders.

Current and Future Directions: Sequencing, Copy Number Variation, and Epigenetics

Whereas current sleep-related literature has focused on heritability, linkage, and candidate gene or genome-wide association analyses, emerging areas of focus in genetic research include whole exome and whole genome sequencing, study of copy number variation (CNV), and epigenetic effects.

As mentioned in the context of rare variant analysis, emerging sequencing technologies have resulted in the ability of researchers and clinicians to sequence large regions of the genome at lower cost. Thus, rather than relying on imputation or targeted sequencing of candidate genes for fine-mapping and rare variant analyses, more studies are performing whole exome (i.e., the protein-coding regions) or whole genome sequencing. Coupled with emerging bioinformatics techniques for variant calling, whole exome and whole genome sequencing provide accurate identification of all genetic variation within protein-coding genes or the entire genome, respectively.[121,126,127] Accurate variant identification through sequencing allows identification of important variants, including de novo mutations.[121,127]

Research has focused on relationships between single-nucleotide variation and phenotypic variability. However, two additional types of genetic variation may account for some of the missing heritability in current research. The first, CNV, is defined as structural variations in DNA that are greater than 1 kilobase in size, including deletions, insertions, and duplications.[11-13] CNVs have been shown to associate with complex disease, at times being tagged by genotyped SNPs, including body mass index.[128] In contrast to SNPs, where only a single base is changed in the DNA sequence, CNVs lead to the removal or duplication of large numbers of bases, including in some instances whole genes or groups of genes, and hence there is reason to believe that CNVs can have large effects on phenotypes. CNVs have been shown to confer risk to a wide range of disorders,[129] but particular focus has been on the role of CNVs in neuropsychiatric disorders, in which it has been established that although rare, they confer a large risk to disease in carriers.[130,131] Because they can have large effects on development and functioning, individual CNVs are often very rare, and hence association with individual CNVs can be difficult to detect. For this reason, many studies have

focused on evaluating whether there is an overall increase in the number of CNVs in cases compared with controls. To our knowledge, there has been only one study conducted on CNVs and sleep disorders. Yamasaki et al[132] found an enrichment of rare, large (<1% frequency and >100 kilobases long) CNVs in Japanese narcoleptic patients compared with controls. Their analysis also implicated the region near *PARK2* as harboring CNVs associated with narcolepsy. Given their impact on behavioral traits, analysis of the role of CNVs in sleep disorders is likely to prove fruitful in the future. In addition to CNVs, state-of-the-art genetic research has begun examining the impact of epigenetic modifications, including histone modifications and DNA methylation, on complex disease.[14,133,134] Epigenetic modification is expected to play an important role in disease, given its ability to regulate and to modify gene expression within specific cell types.[14] As the field continues to advance, recent progress includes the use of genome-wide characterizations of DNA methylation, resulting in the first epigenome-wide association studies, which have recently been published for a number of traits, including body mass index.[135,136]

As methodologies for analyzing these data continue to develop and prices for sequencing continue to decrease, research in these emerging genetic areas will further our current understanding of the genetic architecture that underlies complex diseases. Given the known heritability of many traits of sleep and circadian rhythm in humans and of sleep disorders, this will be a major opportunity for sleep research.

GENETICS OF SLEEP DURATION

The duration of sleep in different individuals varies substantially in the general population. In the Finnish population, 14.5% of the population has a sleep duration less than the average 7 to 8 hours, whereas 13.5% have more.[137] In the United States, there is a much larger percentage of the population with short sleep, with 35% sleeping less than 6 hours/night on average. Whereas much of this short sleep is behaviorally induced, being secondary to commitments of modern life, there is a genetic component. Classic twin studies analyzing the differences in sleep duration in monozygotic and dizygotic twins give estimates of heritability on the order of 0.31 to 0.44 for sleep duration.[29-31]

Both common variants associated with sleep duration and rare variants have been described. A number of GWAS have been reported. An initial GWAS, based on the Framingham cohort, used a relatively small sample ($n = 738$) and evaluated 70,987 SNPs. No genome-wide significant associations with sleep duration were identified. The most significant association was with sleepiness assessed by the Epworth Sleepiness Scale and an SNP in the intron of *PDE4D*, which encodes a cyclic adenosine monophosphate–specific phosphodiesterase, a plausible biological candidate.[138]

Another GWAS with a larger number of subjects ($n = 42,517$; all of European ancestry) found a genome-wide significant association in the discovery phase.[139] This was an intronic variant in *ABCC9*. This gene encodes one of the 17 transmembrane domains of the pore-forming subunit of an adenosine triphosphate–sensitive potassium channel. However, the association with this variant and sleep duration was not significant in the replication phase. Moreover, subsequent GWAS have failed to demonstrate this association.[140,141] A study specifically designed to confirm the association described by Allebrandt et al[139] failed to replicate this finding.[142] There was, however, a significant association with another variant in *ABCC9* and depression symptoms.[142]

Although it seems highly unlikely that this variant of *ABCC9* explains variation in sleep duration in human populations, Allebrandt et al[139] did examine further the role of this gene in sleep-wake control. Using a *Drosophila* model and expressing an RNA interference in neurons to knock down the expression of a *Drosophila* homologue of the gene, they found that it reduced sleep amounts at night, particularly in the early part of the night, but not during the day. Thus, this channel likely does play a role in sleep-wake control, and further investigation of this is warranted.

Ollila et al[140] also performed a GWAS based on a Finnish sample ($n = 1941$). They found no genome-wide significant associations. They proceeded, however, to test in a follow-up sample ($n = 6834$) the most suggestive associations. These showed some degree of association that was not significant after correcting for multiple comparisons. The most interesting was KLF6. This is a transcription factor expressed in the mouse cerebral cortex.[143] It can activate the promoter for inducible nitric oxide.[144] Interestingly, higher expression of KLF6 in circulating mononuclear lymphocytes was related to shorter sleep duration, and its expression in these cells was increased with experimental sleep restriction.[140]

The largest study reported to date comes from the CHARGE consortium.[141] The study used data from 18 community-based cohorts that had data on self-reported sleep duration and had genotyped their subjects. The sample size was 47,180. This large sample size led to the finding of not only genome-wide significant associations but also, for the first time, associations that were replicated in independent samples.

The most strongly associated locus that was found was located on chromosome 2 between two genes: PAX8 and cobalamin synthase W domain–containing strand (CBWD). PAX8 is a transcription factor involved in thyroid development but potentially more broadly. CBWD has unknown function but is widely expressed in brain. The initial association was found in individuals of European ancestry but replicated in an independent sample of African Americans ($n = 4771$). The causative variant remains to be identified.

That this large study involving cohorts from across the globe found genome-wide significant associations that were replicated, whereas other studies did not reach this threshold, is telling. Sleep duration, particularly by self-report, is a noisy quantitative phenotype. There are major behavioral influences that override the genetic contribution. Given this variance, it will take large sample sizes such as those used by Gottlieb et al[141] to reach definitive conclusions. Smaller studies in this area for common variants seem pointless. International consortia are needed. Moreover, it would be beneficial if phenotyping was by quantitative methods, such as actigraphy, rather than by self-report. The study by Gottlieb et al requires follow-up to identify likely causative mutations and to assess the role of the relevant genes in model systems and whether they affect sleep duration.

Rare variants affecting sleep duration have also been described.[124,125] Unlike the challenge with GWAS, which is about sample size, the challenge for identifying rare variants is selecting individuals with a clear extreme phenotype. The

seminal study of He et al[124] is based on only two subjects who slept from around 10:00 PM to 4:00 AM (i.e., 6 hours) without evidence of daytime impairment. Given that, in a sense, this is a timing difference, He et al sequenced all clock and clock-associated genes in these subjects. They found a mutation in exon 5 of *BHLHE41*. This mutation is in exon 5 of the gene at the amino acid position 384. The mutation results in a proline at this location being replaced by an arginine. What makes rare mutations easier to work with is that they lead to large effects. Thus, their role can be assessed functionally in both in vitro systems and model organisms such as *Drosophila* and mice. When He et al knocked this mutation into *Drosophila* or mice, it resulted in less sleep (i.e., shortened sleep duration). Moreover, in mice with this mutation, there was a marked reduction in recovery sleep after sleep deprivation compared with wild-type controls.

Given that genes that exhibit rare mutations with large effects may show multiple such mutations (i.e., they are "hot spots"), it is not unreasonable to suspect that other mutations of this gene may be found. Pellegrino et al[125] addressed this question and sequenced *DEC2* in two human samples, one from a previous twin study[20] and one from a study of chronic partial sleep deprivation.[145] Two new mutations in *DEC2* were identified. One was at a different location in the same exon. It also resulted in an amino acid change in the protein. This occurred in one member of a dizygotic twin pair. The twin with the mutation slept 2 hours less per day than the twin partner and had substantially less performance lapses during prolonged sleep deprivation. The other mutation was at the same site as that described by He et al[124] and was found in three unrelated individuals in the cohort who had chronic partial sleep duration. There was, however, no obvious effect of this variant on sleep duration.

To further investigate why some variants of *DEC2* had effects on sleep duration whereas others did not, Pellegrino et al knocked these different mutations into a cell-based system that used a PER2:luciferase reporter to assess rhythmic changes in expression of PER2. Both the variant described by He et al[124] and that in the twin (see before) resulted in reduced ability of *DEC2* to suppress CLOCK/BMAL1 transactivation (i.e., they had clear functional consequences). In contrast, the mutation found in the three unrelated individuals had no such functional effect. This is likely the reason that there is no effect on sleep duration in these individuals. Random mutagenesis of exon 5 in *DEC2* found a number of other mutations that reduced the ability of *DEC2* to suppress CLOCK/BMAL1 transactivation. Whether these mutations also occur in human populations remains to be determined. It seems likely, however, that other variants of *DEC2* will be identified that result in short sleep.

PER3 VARIABLE NUMBER OF TANDEM REPEATS

Perhaps the most studied gene variant with respect to its role in normal sleep-wake behavior is the polymorphism with variable number of tandem repeats in *PER3* component of a 54–base pair motif in exon 18 that is repeated either four or five times (for review, see[146]). This polymorphism is found only in primates and not in other species (e.g., mice and rats).[147,148] The number of repeats varies in different primate species, with a range of 2 to 11.[148] Humans can be homozygous 4/4, homozygous for the 5/5 repeats, or heterozygous 4/5. In populations of European ancestry, about 10% are $PER3^{5/5}$, with 50% homozygous for 4/4 and 40% heterozygous.[149] In New Guinea, the prevalences of the different genotypes are reversed.[149] Thus, it is a common polymorphism with likely a small effect. As such, as described previously, large samples with replications are needed to be sure of a real association. Studies in this area have, however, had very small sample sizes, on the order of 20. Power has been increased by selectively recruiting individuals on the basis of genotype, thereby enriching the sample studied for the less common $PER3^{5/5}$ genotype. Even with this, the studies remain underpowered. This issue of power likely contributes to the varying results in the literature. Moreover, this polymorphism has been associated with a large number of different phenotypes (Table 31-2), therefore further inflating the likelihood of finding spurious associations.

The initial claim for this polymorphism was related to diurnal preference. The $PER3^{5/5}$ genotype was found to be of higher prevalence in morning types and very low in individuals with delayed sleep phase syndrome.[94] The strength of the association with diurnal preferences attenuates with age.[150] The association with diurnal preferences was replicated in Brazil but not with delayed sleep phase.[151] Association with diurnal preference has also been found in South Africa[152] but not in Colombia[153] or in Norway.[154] The latter negative study cannot be attributed to age because it was conducted in Norwegian university students.

Following these initial observations, a more in-depth phenotyping study was done in a small sample of $PER3^{5/5}$ homozygotes ($n = 10$) and $PER3^{4/4}$ homozygotes ($n = 14$).[155] No difference was found in circadian behavior, including the timing of the onset of melatonin secretion. Instead, the major difference between genotypes was in sleep and wake behavior, particularly during sleep deprivation. Individuals with the $PER3^{5/5}$ genotype showed the following compared with the 4/4: (1) larger rise in theta power during constant wakefulness; (2) worse performance on a battery of tests during extended wakefulness; the $PER3^{5/5}$ homozygotes performed particularly poorly during the biologic night; and (3) stronger inhibition of rapid eye movement sleep during recovery sleep after sleep deprivation. A subsequent report highlighted that the *PER3* polymorphism affects the impact of sleep deprivation on performance in the early morning hours.[156] There are, however, again negative studies (see[20,157,158]). The best direct evidence that this polymorphism tandem repeat in *PER3* directly affects sleep homeostasis comes from recent elegant studies in mice.[159] Hasan et al created mice on a C57BL/6 background into which they knocked in the humanized 4/4 or 5/5 *PER3* tandem repeat. The phenotypes of these mice were assessed and compared with wild-type mice. There was no difference in baseline sleep-wake or circadian behavior. There was, however, a difference in the response to sleep deprivation. The increase in EEG delta power, a measure of sleep homeostasis, with sleep loss was greater in the $PER^{5/5}$ mice than in the other genotypes, and these mice more fully compensated for the effects of sleep deprivation. Changes in gene expression with sleep loss in cortex and hypothalamus were also different between genotypes.

These results in mice are compatible with the positive human studies. Ultimately, translation of these findings to humans will require study in a much larger sample of humans, a replication sample, and careful phenotyping. Currently, the

CHRONOTYPE AND CIRCADIAN RHYTHM SLEEP DISORDERS

Chronotype and circadian rhythm sleep disorders (CRSDs) would be logical candidates for genetic studies, given the tremendous success in identifying the components of the molecular circadian clock intrinsic to all cells. The molecular circadian clock consists of an autoregulatory negative feedback loop involving the *Period* (*PER1*, *PER2*, and *PER3*) and *Cryptochrome* (*CRY1* and *CRY2*) genes.[160] Other genes involved in the molecular generation of circadian rhythms include *casein kinase I-delta* and *I-epsilon* (*CK1δ* and *CK1ε*), *CLOCK*, *NPAS1*, *NPAS2*, *DEC2*, and *BMAL1* and *BMAL2*.

With respect to chronotype, several twin and family studies have estimated the heritability of the broader trait of morningness and eveningness, rather than examining CRSD. Most of these studies assessed chronotype with the Horne-Östberg Morningness-Eveningness Questionnaire.[161] With use of twin data, the heritability of chronotype was estimated to be 54% in the United States[33] and 44% in the Netherlands.[34] Family-based studies of Hutterites[35] and in the Amazon[32] estimated lower heritability, with h^2 estimates of 14% and 23%, respectively. Taken together, results suggest that chronotype is a moderately heritable trait, with genetic factors potentially explaining as high as 50% of the variability within populations. The heritability of CRSD is currently unknown.

There have been a few reports of extended families with high rates of CRSDs, primarily advanced sleep phase syndrome (ASPS). In the first such report, three family members with very strong advanced sleep phase based on clinical history and objective markers were found to have a shorter intrinsic period of their endogenous rhythm.[162] In other families, it has been possible to identify specific genetic variants that segregate with ASPS. A serine to glycine mutation in the casein kinase I-epsilon binding region of *PER2* was reported in one study,[163] although there was no evidence of this mutation in two ASPS pedigrees in Japan.[164] In another pedigree, a missense mutation in the *CKI-delta* gene was identified as the causal variant.[164] Of note in this study, the gene was studied in transgenic *Drosophila* and mice, with the model systems showing opposing phenotypes of longer and shorter circadian period, respectively. This demonstrates the power of using model systems in combination with human studies to better isolate causal variants and their mechanisms of action.

Several studies have used a candidate gene approach and examined the association between circadian genes and either chronotype or CRSD. One study found an association between

the 3111C allele of the *CLOCK* gene and *PER3* and eveningness, with some[93,165] but not all[95,166,167] studies finding a significant association. Morningness has been found to be associated with polymorphisms in the clock genes *PER1* and *PER2* in other studies.[96,168] Associations have been found between delayed sleep phase syndrome and the *PER3* variable number of tandem repeats polymorphism[94,97,151] (for further discussion, see earlier) and 3111C allele of the *CLOCK* gene.[93] Polymorphisms in the *PER3* and *ARNTL2* genes were associated with chronotype in a sample of 966 British adults.[169] The results of these studies are therefore mixed, which is likely due to the relatively small sample sizes ($n < 450$), but the overall patterns suggest that not surprisingly, circadian genes play an important role in the determination of chronotype. Too few studies have been conducted in CRSD for any conclusions to be drawn.

GENETICS OF INSOMNIA

There are very few studies on the genetics of insomnia. In part, this may reflect uncertainty as to the appropriate phenotype. Insomnia as a clinical diagnosis is defined as difficulty in initiating or maintaining sleep that is associated with significant distress or daytime consequences. As such, a phenotype for genetic studies could rely on self-reported insomnia symptoms on a questionnaire such as the Insomnia Severity Index.[170] Alternatively, phenotypes could be based on quantitative parameters of questionnaires or sleep diaries, such as sleep latency or wakefulness after sleep onset. The former approach has the advantage of allowing case-control comparisons, which is the approach typically taken in genetic studies, although treating the parameters as quantitative traits is associated with greater statistical power. Another approach would be to use objective assessment of sleep by actigraphy or polysomnography to generate quantitative parameters. There is intuitive appeal to this approach, given that it avoids the cognitive biases associated with self-reports and considering that EEG-based parameters are some of the most heritable traits that have been measured.[53] A limitation of the objective assessment of insomnia is that there is often a discrepancy between these measures and self-reports of sleep in patients with insomnia.

A number of family and twin studies using self-reported measures of insomnia traits have demonstrated moderate heritability. In one of the only studies of childhood-onset insomnia, Hauri and Olmstead[39] found that patients whose insomnia began in childhood reported a positive family history of sleep complaints at a higher rate (55%) than did those with adult-onset insomnia (39%). In a larger cohort study,[40] there was no significant difference in positive family history of insomnia in those categorized as good sleepers, having symptoms of insomnia, and meeting criteria for a full insomnia syndrome (32.7%, 36.7%, and 38.1%, respectively). Significant differences were found only when the good sleepers were separated into those with and without a personal history of insomnia, and those without a personal history had a significantly lower rate of family history (29.0%) than those with a past history (48.9%). Several twin studies have examined the heritability of insomnia-related traits, such as sleep latency and sleep quality. A study conducted by the Australian Twin Registry of 1792 monozygotic and 2101 dizygotic twin pairs included several questions related to sleep quality, disturbance, and overall patterns.[29] Additive genetic influences were found for sleep quality ($h^2 = 0.32$), initial insomnia ($h^2 = 0.32$), sleep latency ($h^2 = 0.44$ for men and 0.32 for women), "anxious insomnia" ($h^2 = 0.36$), and "depressed insomnia" ($h^2 = 0.33$). In a study of twin pairs from the Vietnam Era Twin Registry,[41] heritability estimates were for trouble falling asleep ($h^2 = 0.28$), trouble staying asleep ($h^2 = 0.42$), waking up several times per night ($h^2 = 0.26$), waking up feeling tired and worn out ($h^2 = 0.21$), and a composite sleep score ($h^2 = 0.28$). Overall, self-reported insomnia traits are moderately heritable, with 30% to 40% of the variance attributable to additive genetic factors.

Only two GWAS analyses have been conducted in insomnia. One study, conducted in Korea, included 10,038 individuals who were classified as insomnia cases or controls on the basis of responses to a series of questions about their sleep patterns.[171] An association was found between case-control status and the *ROR1* gene, which modulates synapse formation, although this association did not reach genome-wide significance. In the Australian twin cohort mentioned before, a GWAS was conducted on 2323 individuals with more than 2,000,000 SNPs either tagged or imputed.[172] No SNPs reached genome-wide significance, but the strongest associations were between sleep latency and a group of SNPs in the third intron of the *CACNA1C* gene ($P = 1.3 \times 10^{-6}$), a gene repeatedly associated with bipolar disorder and schizophrenia in multiple studies. This finding did not replicate in a second cohort but was then subsequently replicated in a separate report.[142]

Clearly, the study of the genetics of insomnia is in its infancy. As has been the case in the psychiatric genetics field, significant genetic associations will likely require sample sizes, an order of magnitude higher than those currently reported.

NARCOLEPSY

It has been known since 1984, following a study in Japan, that narcolepsy is associated with specific HLA antigens.[173] HLA antigens are expressed in immune cells and are involved in presenting foreign peptides to receptors on T cells. In Japanese and those of European descent, the risk allele for narcolepsy is DQB1*0602, which occurs together with DQA1*0102 on a haplotype.[174] There are differences in African Americans.[175] In African Americans, the DQB1 alleles are found with distinct DRBI haplotypes—DRB1*1503, DRB1*1501, DRB1*1101, and DRB1*0806.[176,177] The association between DQB1*0602 and narcolepsy is particularly strong in cases of narcolepsy with cataplexy compared with cases without cataplexy.[178] Recent data from the European narcolepsy study showed a very high association in multiple European countries between narcolepsy with cataplexy and DQB1*0602, with a strong aggregate odds ratio of 251 (Table 31-3).[179] This may be the result of a clearer definition of cases.

There are also protective HLA class II haplotypes for narcolepsy.[180] These were demonstrated in a GWAS in European individuals with a case-control design with an independent replication sample. After identification of a protective variant near HLA-DQA2, analysis revealed that cases almost never carried a *trans* DRB1*1301-DQB1*0603 haplotype (odds ratio, 0.02; $P < 6 \times 10^{-14}$). The magnitude of these effects is such that studying HLA antigen profiles in suspected cases

of narcolepsy could have clinical utility. This remains to be assessed.

Although there is a very strong association between narcolepsy with cataplexy and DQB1*0602, this is a common variant in many individuals without narcolepsy. The frequency of this varies by ethnic group, with 12% in Japanese and 38% in African Americans.[174] Thus, having this variant, even if one is homozygous, is not sufficient to develop narcolepsy. There are two possible explanations for its role. First, narcolepsy could be a complex disorder with multiple gene variants other than DQB1*0602 being involved. Second, the presence of DQB1*0602 could make individuals susceptible to as yet largely unidentified environmental insults. These are not mutually exclusive possibilities.

To address the former, Hallmayer et al[181] did an innovative GWAS (Figure 31-4). They assembled multiple cohorts of cases with narcolepsy and cataplexy of different ethnicities. All individuals were positive for DQB1*0602. This ensured that this signal was removed so that other potential gene variants could be identified. Without this, a GWAS would have identified DQB1*0602 and overwhelmed other signals. With this strategy, they identified three SNPs within the T-cell receptor alpha locus that were significantly associated. The highest association had an odds ratio of 1.87 ($P = 1.9 \times 10^{-12}$). These associations were replicated in independent samples of Caucasian patients and Asians from Japan and Korea. There was a similar trend in the African American sample, but this was not significant. This may be an issue of sample size because this was the smallest sample studied. This association has already been replicated in other studies—in the European narcolepsy study[179] and in China.[182]

This association with the T-cell receptor alpha locus was also replicated in a study using an "immune chip" to evaluate variants relevant to the immune system.[183] This study also identified two other associations, one in cathepsin H and one in tumor necrosis factor (ligand) superfamily member 4 (TNFSF4). This led the authors to propose that antigen presentation to T-cell receptor is a key part of the pathogenesis of narcolepsy (Figure 31-5).

Another GWAS study in narcolepsy with cataplexy has identified an SNP in the 3′ untranslated region of the purinergic receptor subtype $P2Y_{11}$ gene (*P2RY11*).[184] The variant has an odds ratio of 1.28 (95% confidence interval, 1.19–1.39; $P = 6.1 \times 10^{-10}$). It seems that this variant may also play a role in the immune system. The variant is associated with substantial reduced expression of P2RY11 in $CD4^+$ T lymphocytes and natural killer cells. Thus, narcolepsy is a complex disorder, but all variants recognized to date are likely to affect the immune system. Thus, there is a strengthening basis to consider narcolepsy a specific autoimmune disorder.

All cases and controls in the study were positive for HLA DQB1*0602. There was an initial discovery phase followed by three replication samples in different ethnic groups. The variants found replicated in Caucasians and Asians but not in African Americans. There was, however, a much smaller sample of African Americans that might be the explanation for this failure to replicate. SNPs, Single-nucleotide polymorphisms; TCRA, T-cell receptor alpha. (From Hallmayer J, Faraco J, Lin L, et al. Narcolepsy is strongly associated with the T-cell receptor alpha locus. *Nat Genet* 2009;41:708-11.)

As in other areas, there are also rare variants with large effects that can lead to narcolepsy. These are typically part of syndromes in which narcolepsy is part of the syndrome. One syndrome is autosomal dominant cerebellar ataxia, deafness, and narcolepsy. Symptoms typically develop at 30 to 40 years of age. Narcolepsy and deafness typically appear before ataxia. Exome sequencing in three individuals identified rare

mutations in DNA methyltransferase (*DNMT1*).[185] This enzyme is responsible for maintaining methylation patterns in development. It is known to be expressed in immune cells and is required for the differentiation of $CD4^+$ cells into T regulatory cells. Another variant of this gene was described in a single Brazilian patient.[186]

Another rare variant in myelin oligodendrocyte glycoprotein in a family with narcolepsy and cataplexy has been described.[187] This discovery was based on a linkage study of a single large family with 12 affected individuals. Exome sequencing identified a rare mutation in the second exon of the gene. This mutation was present in all affected individuals but absent in all unaffected family members and in 775 unrelated control subjects.

There are likely other rare variants conferring risk of narcolepsy, and studies with exome sequencing and whole genome sequencing are in progress.

Although it is clear that the presence of specific HLA-DQB1* alleles confers substantial risk or protection for narcolepsy with cataplexy,[179,180] a recent article from Ollila et al[188] presents the idea that HLA typing of HLA-DQA1*, in addition to HLA-DQB1*, to better characterize the specific haplotypes and possible heterodimers, may be an important next step in understanding this relationship. They propose an allele competition model, under which the risk conferred by specific DQB1* alleles is modified on the basis of the specific DQA1* alleles present because of the differences in binding affinity between specific DQA1* and DQB1* alleles. For example, whereas patients homozygous for the DQA1*01:02~DQB1*06:02 haplotype have the highest risk of narcolepsy, patients with only one DQA1*01:02~DQB1*06:02 haplotype may either have moderately increased risk (odds ratio, 1.0–1.5) if they have DQA1*01:02 and a DQB1*05/06 allele that is not DQB1*06:02 at the other chromosome or be protected from narcolepsy (odds ratio, 0.5) if they carry a DQA1*01 allele that is not DQA1*01:02 on the other chromosome. Although preliminary data support these assertions, the validity of the allele competition model hypothesis has been questioned.[189] Regardless, it remains clear that HLA-DQ alleles are strongly associated with narcolepsy.

RESTLESS LEGS SYNDROME

The discoveries related to RLS are one of the major accomplishments in the modern genetic era of elucidating gene variants for a sleep disorder. That this occurred where the primary phenotype is based on a questionnaire is particularly notable. That the key gene variants have now been replicated in multiple studies should put to rest the debate by critics as to whether this is a real disorder. This accomplishment was based on a solid base of defining diagnostic criteria.[190]

Genetic research in this area was initially stimulated by the findings of a large proportion of patients with RLS who had positive family histories.[191-193] Twin studies confirmed heritability.[36-38] Complex segregation analyses studied the mode of inheritance in German families with RLS.[194] For early age at onset of RLS (i.e., before 30 years of age), the pattern of inheritance was best described by an autosomal

dominant model with a single major gene. A similar study in the United States[195] came to the same conclusion.

Because family aggregation was so high in RLS, this led to use of linkage analyses within large family pedigrees. This was done in different parts of the world, including Canada in a French Canadian pedigree, northern Italy, North America, and southern Tyrol. These studies resulted in strong evidence of linkage that was genome-wide significant (see Table 31-1). A number of different linkage regions were found. However, until case-control association analyses of SNPs in these linkage regions were performed, linkage studies on their own did not identify specific gene variants.

The first linkage region to be investigated in this way was RLS-1 on chromosome 12.[64] Case-control association was conducted with 1536 SNPs in this region in the discovery phase, with 24 of the most significantly associated SNPs being investigated in an independent case-control replication sample. A significant association with an SNP in neuronal nitric oxide synthase was identified that was protective (odds ratio, 0.76; 95% confidence interval, 0.64–0.91).[64]

A similar strategy was used to evaluate the RLS-3 region on chromosome 9 with 3270 SNPs in the discovery phase and 8 in the independent replication sample.[196] Two different SNPs in introns of the protein tyrosine phosphatase receptor type delta (PTPRD) were shown to significantly associate with RLS. There are two independent association signals. The function of this gene has been studied in mouse knockout models.[197,198] PTPRD knockout mice show impairment in long-term potentiation in memory formation and abnormal axon targeting to motoneurons during development.[197,198] It is conceivable that this developmental role could underlie the role of this gene in RLS. An independent replication of this association has been reported.[199]

Whereas linkage studies have led to new insights with this combined approach, the seminal event in RLS genetics was the direct, simultaneous publication in 2007 of two independent successful GWAS.[200,201] The first study, conducted in Germany and in French Canadians,[200] used questionnaire-based case definition. The study employed a discovery phase with two independent case-control samples for replication. It identified three different loci: two intronic SNPs in *MEIS1* on chromosome 2 (odds ratio, 1.74); five intronic SNPs in *BTBD9* on chromosome 6p; and seven intronic or intergenic SNPs in chromosome 15q in the *MAP2K5* gene and the adjacent *SKOR1* gene. *MEIS1*[202] and *SKOR1*[203] play a role in development (for design of study, see Figure 31-6).

The other study, conducted primarily in Iceland,[201] used a discovery sample in Iceland and two independent replication case-control samples—one in Iceland, one in the United States. These investigators used a different phenotyping strategy as they measured, using actigraphy of the legs, the frequency of periodic limb movements over several nights of recording. They found an association with the same SNP for *BTBD9* (odds ratio, 1.7). This association was found only in cases with periodic limb movements and not in cases with only sensory symptoms. Thus, this specific gene variant likely contributes to the motor manifestations of RLS. Interestingly, this SNP was associated with ferritin levels in this study. It has long been known that alterations in iron metabolism can play a role in the pathogenesis of RLS (for review, see[204]). *BTBD9* has, however, not been found as a genetic variant determining iron metabolism in other studies.[205] Moreover,

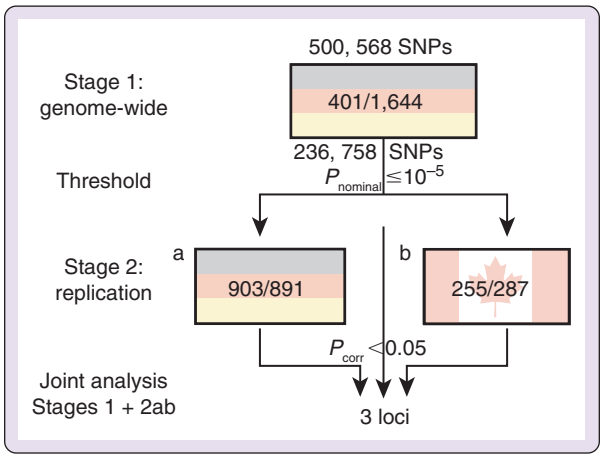

Figure 31-6 Design of the seminal genome-wide association study (GWAS) on restless legs syndrome. The stage 1 discovery phase involved assessing a large number of single-nucleotide polymorphisms (SNPs) in 401 cases and 1644 controls. The few SNPs that were nominally significant at $P < 10^{-5}$ (they were not genome-wide significant) were assessed in two replication samples: one had 903 cases and 891 controls, whereas the other had 255 cases and 287 controls. The SNPs that were significant in the replication samples were then assessed in a joint analysis across all three samples. (From Winkelmann J, Schormair B, Lichtner P, et al. Genome-wide association study of restless legs syndrome identifies common variants in three genomic regions. *Nat Genet* 2007;39:1000-6.)

studies looking for association of RLS with genes known to affect iron metabolism have been negative.[206]

The association of *MEIS1* and *BTBD9* has been confirmed in one study,[207] and all three loci were identified in other studies.[208-210] Interestingly, in a secondary form of RLS that occurs in patients with end-stage renal disease, the variant of *BTBD9* is again associated with RLS.[211]

Although these findings are exciting, the variants so far identified account for only around 3% of the heritability of RLS.[212] This, unfortunately, is not unusual for complex traits.[54] The reasons for missing heritability were described earlier, including the role of rare variants. Rare variants can be identified by deep resequencing of relevant genes and exome sequencing or whole genome sequencing. Efforts to use these approaches to investigate the genetics of RLS have begun but are in their infancy. Individuals with RLS have an excess of rare variants of *MEIS1* compared with controls.[213] In particular, there is an excess of loss-of-function alleles in cases with RLS.[213]

Exome sequencing has also started to be applied.[214] A variant of *PCDHA3* in a family with RLS that was absent in 500 controls suggests a functional role. This gene encodes protocadherin alpha 3 that is a member of the protocadherin gene family. It is expressed in neurons and is present at synaptic junctions, where it plays a role in neural cell-cell interaction.[215]

There is little doubt that a search for rare variants with new sequencing technology will continue in RLS, as will studies of CNV and altered methylation patterns. Given the large number of carefully assembled case-control and family-based cohorts, we can look forward to further exciting developments in this area.

GENETICS OF OBSTRUCTIVE SLEEP APNEA

OSA is a common condition.[218] The major risk factor in middle-aged adults is obesity.[218] With increasing obesity rates in the United Sates, the prevalence of this condition is increasing.[219] It has long been known that OSA aggregates in families. The initial finding that OSA has a major genetic component came from a study of a single family with a high prevalence of OSA.[49] Subsequently, it was shown that symptoms of OSA, such as habitual snoring, excessive sleepiness, snorting, gasping, and witnessed apneas, also aggregate in families.[48]

These observations led to studies including measurement of apneas and hypopneas during sleep. Such studies were conducted in the United States,[44,47] Israel,[46] Scotland,[45] and Iceland.[43] Because obesity, a major risk factor for OSA, is itself heritable,[220-223] whether family aggregation of OSA is simply due to obesity needs to be addressed. The important Cleveland Family Study addressed this issue and assessed increased relative risk of OSA in first-degree family members. This increased risk was not affected after controlling for body mass index.[47] Thus, family aggregation is unlikely to be simply explained by obesity.

Obesity as an explanation for family aggregation of OSA was more definitively addressed by Mathur and Douglas.[45] They examined the prevalence of OSA in first-degree relatives of less obese individuals with OSA (body mass index < 30 kg/m^2) and compared this with that in controls chosen at random from a list of patients in a primary care practice. Controls were matched for age, gender, height, and weight. The prevalence of OSA was significantly higher in first-degree relatives of OSA patients than in controls. First-degree relatives also had more retroposed mandibles and maxillae than controls did.[45] Thus, in these less obese cases, subtle differences in craniofacial structure likely played the key role, and hence genes for craniofacial structure could be involved. (For review of these early studies on genetics of OSA, see review by Redline and Tischler.[224])

Although family aggregation has been known for 2 decades, there has been little progress in identifying relevant gene variants. Studies in this area have been particularly problematic. Early family-based linkage studies were underpowered, did not find genome-wide significant linkages, and did not employ fine mapping to confirm the peak and to narrow the linkage region.[73-75] Candidate gene studies examining multiple candidates did not employ any replication samples.[98] Candidate gene studies have been massively underpowered, given that one is looking for small effects (typically, odds ratios of around 1.2) for common variants[100] (see Figure 31-2). Meta-analyses reveal that most claimed candidate gene variants, including *APOE* ε4, show no association.[100,225] The one exception is −308 tumor necrosis factor-alpha promoter polymorphism. This affects transcription of this gene.[226] Association with this SNP and OSA has been identified in European populations[227] and in Indians.[228] However, it seems unlikely that this gene variant actually contributes to the risk of OSA. In the pediatric population with OSA, excessive sleepiness is more pronounced in patients with OSA with this SNP than in those patients without the SNP.[101] Thus, this SNP may contribute to one of the key consequences of OSA that patients may recognize and have (e.g., it is more likely that they seek evaluation). This concept adds additional difficulty to determining the gene variants conferring risk for OSA.

The most convincing evidence of a relevant gene variant comes in a recent study that used subjects who were part of the Cleveland Family Study and the Sleep Heart Health Study.[99] They used a custom candidate gene array with 45,237 SNPs for more than 2000 candidate genes chosen because of their potential relevance to heart, lung, blood, and sleep disorders.[229] Replication samples came from the Western Australia Sleep Health Study for subjects of European ancestry and from the Cleveland Sleep Apnea Study and Case Transdisciplinary Research on Energetics and Cancer Colon Polyp Study for African Americans.

In African Americans, one SNP in the intronic region of the *LPAR1* gene showed genome-wide association with log apnea-hypopnea index (AHI). Using AHI as a quantitative phenotype is challenging, given the known night-to-night variability in the measure.[230] This association was greater in the nonobese than in the obese subjects. This association with OSA status was confirmed in African Americans in the replication sample. In European samples, this SNP also showed evidence of association to an apnea phenotype ($P = .01$) and a trend for association with log AHI ($P = .06$). This gene is lysophosphatidic acid receptor 1 (*LPAR1*). The gene is thought to play a proinflammatory role.[231,232] It is also expressed in developing cerebral cortex.[233] A mouse knockout of the gene results in changes in behavior as well as in craniofacial abnormalities.[234] Thus, the connection with OSA might be due to either neural differences in airway control or craniofacial alterations.

From the studies of cohorts of European ancestry, no SNP met criteria for a statistically significant association with log AHI. One SNP in the intronic region of the prostaglandin receptor 2 was significantly associated with OSA. There was some evidence of association in the replication sample.

That genetic studies of OSA have had such limited success is not only related to the poor study designs; it is also an extremely challenging area. There are multiple pathways contributing to OSA risk or protection (Figure 31-7), each with many likely variants.

As discussed, a major risk factor is obesity. We now know from multiple GWAS of body mass index that there are 97 loci that contribute to variations in body mass index.[235] The

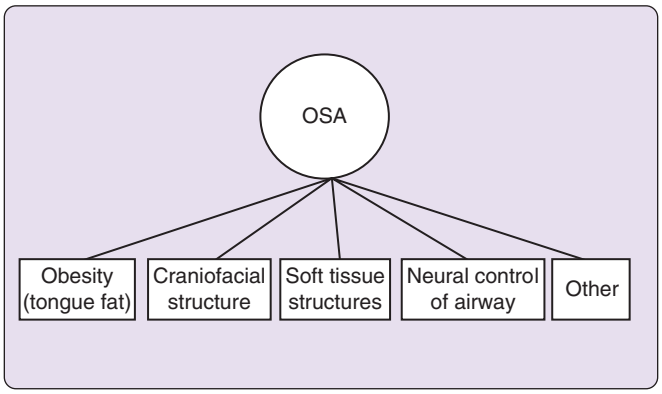

Figure 31-7 Multiple pathways to obstructive sleep apnea (OSA). Each is likely to have many genetic variants involved. These multiple pathways make finding gene variants conferring risk or protection for OSA challenging.

role of these in OSA has not been determined. It may, however, not simply be obesity but rather a particular distribution of fat. Novel imaging studies reveal that there is a difference in volume of fat in the tongue between cases with OSA and controls even after controlling for differences in overall body mass index.[236] There are gene variants associated with other specific distributions of fat (e.g., pericardial fat).[237] Determining whether tongue fat is a unique fat distribution is an area of opportunity.

The volume of soft tissue structures also likely contributes to the genetics of OSA. The volume of key upper airway soft tissues that confer risk for OSA is heritable.[51] The heritability of the volume of the lateral pharyngeal walls is 25.6%; for tongue volume, 37.8%; and for total volume of upper airway soft tissue structures, 41.3%. This is not simply related to obesity because after controlling for total neck fat volume, heritability estimates either stay the same or increase.

Soft tissue structures are not the only relevant structural risk factor; so too is craniofacial structure. Although several differences in craniofacial structures have been demonstrated between OSA cases and controls, the most robust finding is reduced mandibular length in OSA cases as revealed by meta-analyses.[238] Heritability of craniofacial dimensions by cephalometric analysis has been shown.[239,240] This heritability has been confirmed by three-dimensional analysis with magnetic resonance imaging.[50] Mandibular length and mandibular width are both heritable.

These different structural risk factors play a different role in different ethnic groups. An elegant study comparing whites with the same degree of OSA in Sydney, Australia, with Chinese OSA subjects in Hong Kong found that the Caucasians were more obese and had a larger tongue volume.[241] Craniofacial dimensions played a larger role in Chinese with more restriction of the craniofacial base.[241] Thus, the relative role of different genetically determined pathways to OSA varies by ethnic group.

There are, however, not only structural risk factors for OSA but also physiologic ones.[242] The key physiologic variables are overall loop gain, arousal threshold, and airway muscle responsiveness. Among these, overall loop gain is the most important.[242,243] There are individuals with OSA who do not have particularly collapsible airways but do have high loop gain.[242] The main determinant of loop gain is ventilatory response to hypoxia and hypercapnia. The hypoxic response is also a highly heritable trait as revealed by studies in twins.[52] Gene variants determining the hypoxic response have, however, not been identified to date. Thus, this is another potential genetic contribution to OSA.

These advances in understanding of the different phenotypic pathways to OSA underscore the inherent difficulty in determining genetic variants conferring risk for or protection from OSA. They also suggest that a productive approach, given the inherent complexity, is to address gene variants not for OSA itself but rather for each of the relevant intermediate traits.

GENETICS OF CONGENITAL HYPOVENTILATION

Congenital hypoventilation syndrome (also called Ondine's curse) is a rare disorder, but considerable progress has been made in understanding the genetic basis. It typically is manifested in early life. Individuals with this disorder ventilate normally during wakefulness. They can increase ventilation when asked to do so. The problem arises during sleep. When they fall asleep and loose the wakefulness drive to breathe, they hypoventilate. The problem is in their CO_2-dependent ventilatory system. They have very low or absent ventilatory responses to hypercapnia. This hypoventilation can be major with marked elevations in Pco_2. Hence, they require assisted ventilation during sleep. This is typically done by creating a tracheostomy early in life with positive pressure ventilation through the tracheostomy during sleep (for review, see[244]).

The relevant gene is *PHOX2B*. This is a transcription factor involved in the development of the autonomic nervous system. The role of this gene in this condition was identified by Amiel et al in 2003.[245] Mice that bear a frequent mutation of the disease in humans do not respond to hypercapnia and die in the early postnatal period.[246]

In humans, the most common mutation is expression of polyalanine repeats in exon 3 of the gene.[245] The upper limit of normal for the number of repeats is 20.[245] Most mutations occur de novo (i.e., there is no family history).[247] There are rare cases that are autosomal dominant, and up to 25% of cases show somatic mosaicism, that is, the mutation is found in some cells in the parents of cases[248] but not in all; 92% of cases with this condition have expansion of the polyalanine repeats (25 to 33 repeats).[249] There are case reports of individuals with 25 repeats who presented as adults.[250]

Patients with this disorder who do not have increased polyalanine repeats in exon 3 most commonly have other mutations in *PHOX2B*.[247,251] Patients with congenital hypoventilation syndrome have an increased rate of Hirschsprung disease and tumors of neural crest origin.[251] These associated conditions are more common in patients who have different mutations in *PHOX1B* compared with those with increased polyalanine repeats.[251]

CLINICAL PEARLS

- Clinicians should be aware of the relevance of sample size (power) and of the importance of independent replication in assessing literature on gene variants for sleep and its disorders.
- There are both many common gene variants with small effects and rare variants with large effects that contribute to risk for and protection from sleep disorders.
- There have been successful genetic studies in narcolepsy, RLS, and congenital hypoventilation syndrome.
- Variants of the clock-associated gene *DEC2* affect duration of sleep and response to sleep deprivation. Their functional role is confirmed by studies in model systems.

SUMMARY

In this chapter, we have provided an overview of the rapidly developing methodology being used to identify gene variants conferring risk for or protection from sleep disorders. We have explained the importance of study design, sample size, and replication. Unfortunately, much of the published literature on genetics of sleep disorders does not meet the criteria required for firm conclusions to be reached.

There have been important discoveries in narcolepsy, RLS, and congenital hypoventilation syndrome. For congenital hypoventilation syndrome, genotyping to identify the

causative mutation is now part of routine clinical care. For narcolepsy and RLS, the genetic variants identified have not at present altered current clinical practice. The findings in narcolepsy, in particular with respect to the role of different HLA antigens, do suggest that studying these variants in individual patients could have a clinical role. This remains to be determined. This is not the case for RLS because the variants identified to date explain so little of the heritability. The current key value of the results in this area is identification of novel genes and hence pathways. The question now is, What do these genes do? This opens up entirely new opportunities to understand the fundamental pathogenesis of sleep disorders and to develop novel targets for therapeutic intervention. One example of this is the gene *BTBD9*, which has been found to be associated with RLS in multiple studies, as described earlier. The approach to begin to identify its function is to study animal models in which expression of the gene is altered. For *BTBD9*, this has been done in both *Drosophila* and mice. A knockout of *BTBD9* in mice led to phenotypic differences.[252] Knockout mice had enhanced long-term potentiation in hippocampus and enhanced cued and contextual fear conditioning. Thus, *BTBD9* is involved in synaptic plasticity. Sleep was not studied to date in these mice. Studies in *Drosophila* tie *BTBD9* more directly to the function of dopamine neurons and to iron metabolism.[253] Flies with loss of function of *BTBD9* have fragmented sleep. Knockdown of *BTBD9* only in dopaminergic neurons using RNA interference leads to the same phenotype. Flies with loss of *BTBD9* had lower dopamine levels in brain, and agonists of dopamine that are used to treat RLS in humans reverse the sleep fragmentation phenotype in *Drosophila*. The connection to iron comes from studies in cell culture. Specifically, overexpression of *BTBD9* leads to reduction in iron-responsive element-binding protein with a resultant increase in ferritin levels. The connection between dopamine neuronal function and iron metabolism has not been investigated.

These functional studies are a start and in the future may lead to personalized approaches to managing patients.[254] Ultimately, we need to understand the role of these newly identified gene variants and whether they represent potential targets for future treatment development. Thus, we are at the early stages of this exciting journey, and much remains to be discovered.

Introduction: Master Circadian Clock and Master Circadian Rhythm

Fred W. Turek; Phyllis C. Zee

One of the distinguishing characteristics of sleep in animals as diverse as insects, fish, and mammals is that the timing of sleep and wake for the majority of species is rigidly confined to certain times of the day or night. As detailed in a number of chapters in this section, the master biologic clock regulating the timing of sleep and wake in mammals also regulates most if not all 24-hour (i.e., circadian) behavioral, physiologic, and biochemical rhythms. This master circadian clock is located in the bilaterally paired suprachiasmatic nucleus (SCN) in the anterior hypothalamus (Chapters 33 and 34). Although it has recently been discovered that many tissues and organs can generate circadian rhythms in vitro, and therefore independent of the SCN (Chapter 33), the SCN remains at the top of the hierarchy of the mammalian circadian clock system.

Similarly, one could argue that the sleep-wake cycle represents the "master circadian rhythm"; the SCN control of this rhythm in turn controls the timing and expression of a multitude of downstream rhythms. Although the expression of many 24-hour rhythms may be primarily under the control of the circadian clock in the SCN, many rhythms are largely dependent on whether the organism is asleep or awake, regardless of the circadian clock time.[1] Undoubtedly, the expression of most rhythms at the behavioral, physiologic, and biochemical levels is regulated by the integration of inputs from the circadian clock and the sleep-wake state of the animal. Indeed, it can be argued that the entire temporal organization of an organism represents some combined effect of circadian clock inputs and the sleep-wake state of the organism. Thus, the circadian and sleep control centers have evolved together to ensure that the timing of internal events relative to one another and to the external environment is coordinated in such a fashion to maximize the survival of the species.

Of particular note of the "downstream" rhythms regulated by the circadian clock is the feeding rhythm. In the last few years, a number of studies have demonstrated that the timing of food intake can regulate the expression of circadian clock genes in many peripheral tissues,[2] which in turn control the 24-hour rhythm in the expression of many clock-controlled genes (perhaps as many as 10% to 50% of all genes expressed in a given tissue).[3] The many interactions between the systems regulating circadian, sleep, and energy balance, from molecular to behavioral rhythms, have led to much interest in the importance of these linkages to obesity, diabetes, and cardiometabolic disorders.[2]

The need to "rest" and the need to adjust to the daily changes in the physical environment due to celestial mechanics certainly represented two darwinian pressures that guided the evolution of living organisms since life appeared on earth. (At an earlier time in the history of the earth, the solar day is thought to have been 18 hours; with the change to the current 24-hour day occurring over millions of years, there was plenty of time for clock genes to be altered so the molecular circadian cycle stayed in synchrony with the solar day.) As detailed in

the rest of this chapter, the early linkage for the need to rest, and to rest at a specific phase of the daily external environment, may have resulted in the circadian clock and sleep-wake cycle evolving together and being integrated with one another at many different levels of organization.

INTEGRATION OF THE CIRCADIAN CLOCK AND SLEEP-WAKE SYSTEMS

Two chapters in this section deal with the circadian clock system, with a focus on the anatomy of the neural clock system in mammals (Chapter 33) and the physiology of the mammalian circadian clock system (Chapter 34). Chapters that review the molecular and genetic bases for the actual circadian clock core machinery, which has been highly conserved at least from insects to mammals, are included in Section 3 of this volume. Chapters 35 and 37 involve discussions from different vantage points about how the circadian clock system is highly integrated with the sleep-wake regulatory system.

Chapter 37 focuses on how the circadian clock and sleep loss together and independently regulate neurobehavioral performances. Whereas the disruption of circadian rhythms in humans during rapid travel across time zones and in shift workers has been linked to a variety of mental and physical abnormalities for many years (see Section 10), only in the last few years have animal models begun to emerge that are elucidating the extent of the importance of internal circadian synchronization for the health and well-being of the organism as well as for the molecular events that are disrupted at the level of cells and tissues (Chapters 38 and 39). Indeed, there is now considerable evidence that disruption of the circadian clock can exacerbate and perhaps cause a variety of mental and physical disorders, as reviewed in Chapter 39. The final chapter in this section (Chapter 40) reviews how the clock system underlies disorders related to the timing of the sleep-wake cycle that can lead to a disruption of the timing of internal rhythms with one another as well as of the timing of the sleep-wake cycle and other rhythms with the external environment.

In the now classic two-process model of Borbely and colleagues, the timing of sleep and wake is a function of a homeostatic process that defines sleep need as being dependent on the previous amount of sleep and wake (process S) and the circadian clock (process C) that modulates the timing and propensity of sleep (Chapter 36). However, as noted by Buxton and Czeisler, the interactions between the circadian pacemaker and sleep homeostat should not be underestimated, and there is great difficulty in separating these two processes functionally. In addition, recent genetic and anatomic findings (see Section 3 and Chapter 33) also tend to "blur" the distinction between the homeostatic and circadian inputs in the regulation of the sleep-wake cycle. It is noteworthy that at the 2014 European Sleep Research Society meeting in Tallinn, Estonia, there was a symposium entitled "Farewell to the Two-Process Model." Whereas the two-process model has guided and will continue to guide our understanding of sleep regulation mechanisms, there are many new findings that need to be taken into consideration regarding how the circadian, homeostatic, and perhaps other processes underlie the complex regulation of the sleep-wake cycle.

In the two-process model, the electroencephalographic slow wave activity in non–rapid eye movement (NREM) sleep serves as an indicator of sleep homeostasis either under baseline or after sleep deprivation conditions. Whereas there is substantial evidence to indicate that "sleep homeostasis," as defined by the slow wave activity during NREM sleep, is independent mechanistically from the circadian clock, it is not known how the two processes actually contribute to the overall "sleep need" of the organism or what role the circadian clock may play in other homeostatically regulated sleep-wake events, such as total sleep time and NREM or rapid eye movement (REM) sleep time under baseline or sleep deprivation conditions. Indeed, the finding that different alleles in the *per* gene in humans are associated with differences in slow wave sleep emphasize how closely linked the circadian clock and the homeostatic process are in regulating sleep (see Section 3).

REGULATING SLEEP AMOUNT: A HOMEOSTATIC AND A CIRCADIAN INPUT

Many sleep and wake traits are under homeostatic control. That is, the longer one is awake or deprived of specific sleep stages (e.g., REM sleep deprivation), the greater will be the drive to recover the lost sleep or sleep stage. However, this may be true only after short periods of sleep deprivation because during continuous chronic partial sleep deprivations in rodents, there is a loss of the homeostatic recovery sleep increase, as the sleep-wake system appears to change from a homeostatic to an allostatic response system.[4] In addition, the different phases of normal sleep and wake are under circadian control; the clock is doing more than saying wake up or go to sleep at specific times of day. An unanswered question is, What actually regulates the amount of sleep? Or put another way, What are the relative contributions of the homeostatic and circadian process to the actual amount of time a given animal is awake and interacting with the external world or asleep and avoiding the external world?

Studies in laboratory, zoo and, wild animals reveal that sleep times are unrelated to taxonomic classification, and as noted by Siegel,[5] "the range of sleep times of different primates extensively overlaps that of rodents which overlaps that of carnivores, and so on across many orders of mammals." The total sleep time is correlated in a global sense to body size; for example, the opossum sleeps 18 hours, the ferret sleeps 14.4 hours, the cat sleeps 12.5 hours, the dog sleeps 10.1 hours, humans sleep 8 hours, and the elephant sleeps 3 hours.[6] Although on a global level body size (and associated metabolic rate) is inversely related to total sleep time, there appear to be other factors regulating sleep time as indicated by the fact that the smaller mouse sleeps about the same amount as the larger rat.[6,7] Indeed, there is considerable variability in sleep time among strains of mice; strains of mice that are of similar size and of the same species can show total sleep time differences up to as much as 2.5 hours.[7]

In the evolution of life on earth, there has been great pressure for organisms to adapt their lifestyle to the external world and to coordinate the internal temporal environment so as to maximize the chances of survival and to pass on their genetic material to the next generation. Total sleep time could be expected to be part of the survival strategy to ensure that animals are engaged as well as disengaged with the external environment at the appropriate times of day and night. Similarly, as noted at the beginning of this chapter, the sleep-wake

cycle can be considered the master circadian rhythm, as the expression of so many behavioral and physiologic rhythms is tied to the sleep-wake/activity-rest cycle. Thus, the total amount of sleep and wake may have evolved in individual species, in part, to create an internal temporal framework, in conjunction with the circadian clock, to maximize survival and reproduction fitness.

The fact that the circadian clock is a major determiner of the pressure to sleep or the ability to stay awake has mechanistic indications on various neural, genetic, and molecular levels as well as potentially important therapeutic implications for treating sleep-wake disorders. The recent findings in humans and rodents that the circadian clock is regulating not only the timing of sleep and wake but also the propensity to sleep and wake render the circadian clock system a potential target for interventions that could promote sleep and wakefulness that go beyond interventions in use today.

CLINICAL PEARL

Our 24/7 society has led humans to be the only animal species that routinely ignores its biological clock as we are often awake when the clock is telling us to be asleep. Both the chronic disruption of circadian organization and chronic insufficient sleep have been associated with a wide range of mental and physical disorders. Modern medicine is only beginning to recognize that the treatment of many disorders of human health may need to take into account circadian medicine to improve overall 24-hour temporal organization between and within the central nervous system and peripheral tissues.

Anatomy of the Mammalian Circadian System

Chapter 33

Chapter Highlights

- Circadian rhythms in mammals, including sleep-wake cycles, are endogenously driven by the suprachiasmatic nucleus (SCN) in the anterior hypothalamus. The SCN is a master clock that transmits circadian output signals to effector systems to temporally coordinate behavioral and physiologic rhythms with daily changes in the environment.
- The near-24-hour rhythm of neuronal activity in the SCN is normally entrained to the 24-hour light-dark cycle defined by Earth's rotation. Light information is transmitted to the SCN from specialized retinal ganglion cells that contain the photopigment melanopsin. On activation by light, retinal axons release glutamate and pituitary adenylate cyclase–activating polypeptide onto SCN neurons. Clock cells in the SCN also receive dense input from the intergeniculate leaflet in the thalamus and the median raphe nucleus, which play a modulatory role in regulating circadian rhythms.
- The primary neuronal pathway underlying the circadian regulation of sleep-wake cycles involves a dense SCN efferent projection to the adjacent subparaventricular zone, followed by a secondary projection to the dorsomedial hypothalamic nucleus, which projects to other brain regions critical for regulating sleep and wakefulness. The SCN also projects directly and indirectly to the paraventricular hypothalamic nucleus to regulate corticosteroid secretion and synthesis of the hormone melatonin. In addition to regulating circadian cycles of behavior and endocrine function, the SCN plays a hierarchical role in coordinating the timing and function of clocks located in peripheral tissues.
- Understanding the neuroanatomic basis of circadian rhythms is important for developing therapies to improve the quality of sleep-wake cycles, especially in persons with circadian rhythm sleep disorders. This chapter describes the intrinsic organization, inputs, and outputs of the circadian clock in the SCN, with emphasis on the neuronal circuitry and neurotransmitters underlying circadian control of sleep-wake and rest-activity cycles.

Most animals show a pronounced daily rhythm of rest-activity that is synchronized with the solar cycle. To a large degree, the timing of these rhythms is determined by the circadian ("about a day") system. Circadian rhythms persist even in the absence of periodic environmental cues but are normally entrained by the light-dark cycle and feeding schedules. The primary role of the circadian system is to ensure that behavioral and physiologic rhythms are temporally coordinated with daily changes in the environment. By providing an internal representation of day and night, the circadian system anticipates the rising and setting of the sun, hence allowing animals to time appropriately sleep and foraging behavior. The circadian system therefore facilitates adaptation to daily environmental cycles to maintain energy balance, which is thought to increase survival and reproductive fitness. This chapter reviews the organization of the circadian system and the anatomic basis for circadian regulation of sleep-wake cycles and endocrine function.

THE MASTER CIRCADIAN CLOCK IN THE SUPRACHIASMATIC NUCLEUS

The master circadian clock for behavioral rhythms, including the sleep-wake cycle, is located in the suprachiasmatic nucleus (SCN).[1] The SCN is situated in the anterior hypothalamus immediately dorsal to the optic chiasm and lateral to the third ventricle (Figure 33-1, *A*). The circadian rhythm of neural activity in the SCN is generated at the cellular level by a transcriptional-translational molecular feedback mechanism. If the molecular clock is rendered dysfunctional, patterns of rest-activity exhibit irregular and non–24-hour cycles. Similarly, lesions of the SCN or its efferent projections abolish behavioral and endocrine rhythms, demonstrating a critical role for the SCN clock in generating the circadian rhythm of sleep.

Based on neurotransmitter phenotype and afferent-efferent connections, the SCN can be divided into ventrolateral (SCNvl) and dorsomedial (SCNdm) components, commonly referred to as the *core* and *shell*, respectively.[2] The core contains many vasoactive intestinal polypeptide (VIP)-containing neurons (Figure 33-1, *B*), whereas the shell contains a large population of arginine vasopressin (AVP)-containing neurons (Figure 33-1, *C*). In studies of the SCN, the boundaries of the core and shell are often defined by the distribution of VIP and AVP immunoreactivity because these cell groups are conserved in the SCN of rodents, monkeys, and humans. By comparison, the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) is heavily expressed throughout

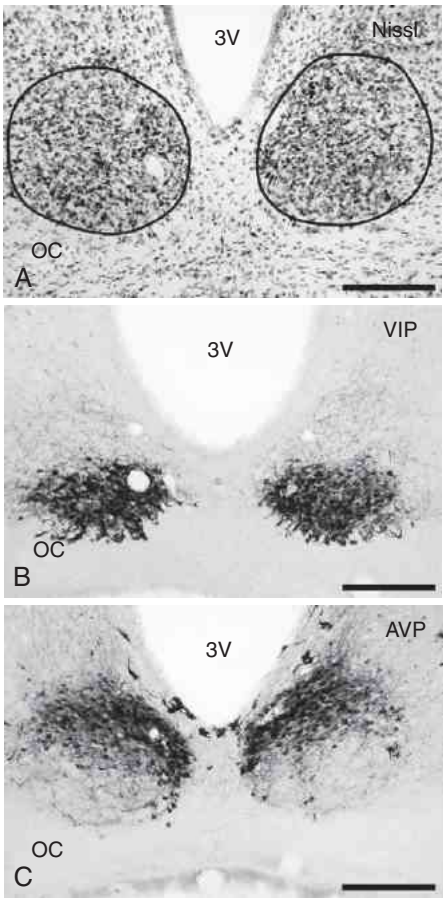

Figure 33-1 The suprachiasmatic nucleus (SCN) is composed of ventrolateral (SCNvl) and dorsomedial (SCNdm) subdivisions. **A,** In Nissl-stained coronal sections in rats, the SCN can be identified by its tightly compacted small-diameter neurons located immediately dorsal to the optic chiasm and lateral to the third ventricle. **B,** VIP-immunoreactive perikarya are found in the SCNvl. **C,** AVP-immunoreactive cell bodies are found in the SCNdm. 3V, Third ventricle; AVP, arginine vasopressin; OC, optic chiasm; VIP, vasoactive intestinal polypeptide. both SCN subdivisions, and it is contained in most, if not all, SCN neurons.[3] The core of the SCN in rodents also contains many neurons that express gastrin-releasing peptide (GRP) and smaller numbers expressing neurotensin (NT). In humans, an extensive population of NT-immunoreactive cells is found throughout the SCN,[4] and neuropeptide Y (NPY)-containing neurons are located predominantly in the central part of the nucleus, where they overlap with the distribution of VIP-immunoreactive cells. Smaller subpopulations of neurons containing angiotensin II, enkephalin (ENK), somatostatin, and substance P have also been described in the SCN, but there are species-specific differences in the abundance and distribution of these neurotransmitters.[4] Therefore, the human SCN is likely functionally homologous to the SCN of other mammals, but the relative contributions and combinations of SCN neurotransmitters that regulate circadian rhythms might vary across species.

SCN neurons are highly interconnected, which is presumably important for coupling individual cellular oscillators to produce a coherent neural activity rhythm. The SCN is functionally subdivided, however, such that the SCN core receives most of the retinal input (discussed in greater detail later). Retinal axons form synapses on SCN neurons containing VIP and GRP, and these cells are activated by light, as demonstrated by increased accumulation of the transcription factor c-Fos. VIP and GRP levels in the SCN show a diurnal rhythm in a light-dark cycle, but not in constant darkness, suggesting that the concentration of these neurotransmitters is regulated predominantly by light. VIP-immunoreactive neurons project heavily to both subdivisions within the SCN, consistent with the distribution of $VPAC_2$ receptor (also known as VIP receptor type 2), whereas GRP receptors are found primarily in the SCN shell. A functional role for VIP and GRP in transmitting photic information in the SCN is supported by studies demonstrating that microinjection of either VIP or GRP into the SCN region induces phase resetting of rest-activity rhythms similar to the effects of light.[5] VIP knockout mice exhibit normal diurnal locomotor rhythms in a light-dark cycle, but they show a reduction in the circadian amplitude of wheel-running activity in constant darkness.[6] As in VIP-deficient mice, $VPAC_2$-receptor knockout mice can synchronize their behavior to the light-dark cycle, probably owing to the masking effects of light on behavior, but they have profoundly weakened locomotor activity rhythms in constant darkness.[7] These findings suggest that VIP signaling in the SCN plays a role in coordinating the activity rhythm of SCN neurons.[8,9]

Despite the abundance of AVP and it receptors (V1a and V1b) in the SCN shell, AVP signaling is not required for generating the SCN rhythm or for output of rest-activity cycles. There is robust circadian gene expression of AVP in the SCN, but rats that are AVP deficient show normal behavioral circadian rhythms, and injection of AVP or V1 receptor antagonists into the SCN region does not alter the phase or period of locomotor activity.[10] Nonetheless, a role for AVP signaling in circadian behavior was recently demonstrated in double knockout mice for the V1a and V1b receptors. Mutant $V1a^{-/-}V1b^{-/-}$ mice are resistant to jet lag compared with wild-type mice and can rapidly adapt to a large shift in the timing of the light-dark cycle.[11] It is possible that AVP-mediated communication between SCN neurons limits responses of the clock to external perturbation, and hence large phase shifts are possible when AVP signaling is disrupted.

The output of SCN neurons is thought to be principally inhibitory, based on the observation that most clock cells contain GABA. Histologic and functional studies indicate that GABA acts on both ionotropic $GABA_A$ receptors and metabotropic $GABA_B$ receptors in the SCN. In hypothalamic brain slices, $GABA_A$ receptor agonists inhibit neuronal and metabolic activity of SCN neurons,[12,13] and the $GABA_B$ receptor agonist baclofen inhibits optic nerve–stimulated field potentials.[14] Consistent with these findings, light-induced phase shifts of locomotor activity are blocked by both $GABA_A$ and $GABA_B$ receptor agonists.[15] In dissociated cell culture, daily administration of GABA synchronizes SCN neuronal electrical rhythms,[16] suggesting that GABAergic signaling might also play a role in coordinating the circadian phase of individual SCN cellular oscillators.

SUPRACHIASMATIC NUCLEUS INPUTS

The endogenous circadian rhythm of neuronal activity in the SCN is close to, but not exactly, 24 hours. To entrain to the imposed solar day length, the SCN clock must therefore be reset daily by extrinsic time cues, most notably the light-dark cycle. The SCN rhythm can be further tuned by nonphotic

inputs to coordinate behavioral and physiologic patterns with diurnal changes in the environment. The SCN core receives dense input from the retina, intergeniculate leaflet, and midbrain raphe nuclei,[17] whereas the SCN shell primarily receives projections from other hypothalamic areas, basal forebrain, limbic cortex, septal area, and brainstem (Figure 33-2, *A*).[18] Below, we discuss some of the major pathways that regulate the timing of the SCN neural activity rhythm.

Retina

The retinohypothalamic tract (RHT) projects bilaterally to the SCN, with a slight to moderate contralateral predominance in most species (Figure 33-3, *A*). The RHT sends its densest projection to the SCN core where VIP-immunoreactive cells are located, but smaller numbers of RHT axons also reach the SCN shell, subparaventricular zone (SPZ), and other hypothalamic areas. Retinal ganglion cells (RGCs) at the origin of the RHT contain the photopigment melanopsin (OPN4),[19,20] which is preferentially sensitive to short-wavelength (blue) light. Although OPN4-containing RGCs are intrinsically photosensitive, they also receive indirect light information from rod and cone photoreceptors in the outer retina.[21,22] In the absence of rod and cone function, melanopsin-containing RGCs are sufficient to mediate circadian responses to light, as demonstrated in blind humans and sightless mice with intact function of the inner retina.[23,24] Also, in normally sighted individuals, phase shifting and melatonin suppression are most sensitive to short-wavelength light,[25,26] suggesting that melanopsin plays an important role in circadian photoreception. OPN4-deficient mice with intact rod-cone function show moderate deficits in circadian light resetting, but these animals can still entrain to light-dark cycles, suggesting that visual photoreceptors and melanopsin play overlapping roles in circadian photoreception. Consistent with these findings, spectral responses of the circadian system in humans suggest involvement of rod-cone photoreceptors and OPN4, although the relative contribution of these photoreceptor types appears to depend on the irradiance and duration of exposure to light.[27] Based on studies in mice, circadian responses to light are only eliminated when rod-cone and OPN4 signaling pathways are disrupted

simultaneously, or if OPN4-containing RGCs are genetically ablated.[28,29] Hence RGCs that express *Opn4* appear to function as a necessary conduit for light information to reach the circadian clock in the SCN. The OPN4-containing RGCs project not only to the SCN but also to other brain areas that are involved in nonvisual photoreception, including the ventrolateral preoptic nucleus (VLPO), which is a sleep-promoting area in the anterior hypothalamus; the SPZ, which is important for circadian regulation of sleep (discussed later); the olivary pretectal nucleus (OPT), which is part of the afferent pathway mediating the pupillary light reflex; and the intergeniculate leaflet (IGL), which plays a role in modulating circadian rhythms (see Figure 33-3, *B*).[30,31] Each of these retinorecipient brain areas is interconnected with the SCN, suggesting that photic input from OPN4-containing RGCs can modulate sleep and circadian rhythms via multiple routes.

Several lines of evidence suggest that photic information is conveyed to the SCN through the release of excitatory amino acids such as glutamate from RHT terminals. For example, optic nerve stimulation induces the release of glutamate and aspartate in the SCN in brain slice preparations,[32] and glutamate mimics the effects of optic nerve stimulation on the circadian rhythm of SCN neuronal activity in vitro.[33] Microinjection of *N*-methyl-d-aspartate (NMDA) into the SCN region in vivo also mimics the phase-shifting effects of light on rest-activity rhythms.[34] Additionally, receptor subunits from the NMDA-, α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionic acid (AMPA)–, and kainate-preferring classes of ionotropic glutamate receptors are found in the SCN, in addition to subunits from metabotropic glutamate receptors.[35]

OPN4-containing RGCs that give rise to the RHT also express pituitary adenylate cyclase–activating polypeptide (PACAP),[36] which colocalizes with glutamate at RHT terminals. PACAP binds the PACAP-type 1 (PAC_1) receptor and $VPAC_2$ receptor with equal affinity, both of which are expressed in the SCN. Mice deficient in PACAP or PAC_1 receptors show abnormal circadian resetting but can nonetheless entrain to light-dark cycles,[37] suggesting that PACAP signaling plays a partially redundant role with glutamate in photic circadian entrainment.

Light activation of SCN neurons triggers Ca^{2+} influx and activation of intracellular signaling cascades,[38] leading to increased expression of *Period* genes, which is thought to be the molecular mechanism by which light resets circadian rhythms in mammals.[39] Circadian resetting and expression of c-Fos protein are likely regulated in part by the Ca^{2+}-binding proteins calbindin-D28K (CB) and calretinin (CAL). In hamsters, RHT axons form synapses on CB-containing neurons in the SCN core, and light induces c-Fos in these cells.[40] Targeted disruption of the *Calb1* gene in mice reduces the amplitude of circadian behavior[41] and alters circadian resetting responses and clock gene expression.[42] CB- and CAL-immunoreactive neurons have also been described in the SCN of monkeys and humans,[43,44] suggesting involvement of Ca^{2+}-binding proteins in the regulation of circadian behavior in primates.

Intergeniculate Leaflet

In rodents, the IGL is a thin cellular layer sandwiched between the dorsal and ventral subdivisions of the lateral geniculate nucleus (LGN) of the thalamus. The IGL projects heavily to the SCN core through the geniculohypothalamic tract and also sends efferents to hypothalamic areas adjacent to the SCN, including the SPZ and retrochiasmatic area (RCA).[45] Additionally, the IGL sends axons to the dorsomedial hypothalamic nucleus, midline thalamus, pretectum, periaqueductal gray matter, superior colliculus, and lateral and dorsal terminal nuclei of the accessory optic system. The IGL receives dense bilateral projections from OPN4-containing RGCs, the IGL itself, and the RCA, as well as smaller projections from the SCN, locus coeruleus, midbrain raphe nuclei, and brainstem cholinergic nuclei. Unlike the dorsal LGN, which is thought to function primarily as a relay in image-formation visual processes, the IGL has a well-established role in contributing to circadian rhythm regulation.[46] Lesions of the IGL have been reported to result in a broad array of circadian phenotypes, including a slower rate of reentrainment following a shift in the photoperiod, a block in the lengthening of circadian period by constant light, and elimination of circadian resetting induced by introducing a running wheel into the animal's cage.[47] Based on these findings, the IGL is thought to transmit both photic and nonphotic information to the circadian clock. Animals with lesions placed in the region of the IGL are clearly able to entrain to light-dark cycles, however, indicating that the IGL is not necessary for photic circadian entrainment and rhythm generation, but instead plays a modulatory role.

Most IGL neurons contain the inhibitory neurotransmitter GABA, and the IGL is characterized by large populations of NPY- and ENK-containing neurons.[48] In rodents, NPY-containing neurons in the IGL project heavily to the SCN core region and form synapses on VIP-containing neurons. It is currently unclear whether there is an IGL homologue in the human brain, but a population of NPY-containing neurons has been identified in the pregeniculate nucleus bordering the LGN.[49] There is a dense NPY-immunoreactive terminal plexus in the human SCN, but it has yet to be determined whether this originates solely from NPY-containing cells within the boundaries of the nucleus or whether there is an additional source of input from neurons in the pregeniculate nucleus.

In rodents, the effects of NPY and photic stimuli on the circadian pacemaker appear to be mutually inhibitory. Consistent with the effects of NPY on SCN electrical activity in hypothalamic slices, microinjection of NPY into the SCN region induces a phase advance shift in locomotor activity when administered during the biologic daytime, and NPY-induced phase shifts are attenuated by glutamate or light.[47] Conversely, glutamate-induced phase shifts in SCN electrical activity or light-induced phase shifts in locomotor activity are inhibited by NPY. Pharmacologic studies suggest that NPY attenuates light-induced phase shifts through Y1 or Y5 receptors,[50] whereas the Y2 receptor mediates phase resetting of the locomotor activity rhythm.[51] In contrast to Y1/Y5 receptors, however, Y2 receptors have yet to be detected in the SCN using in situ hybridization or immunohistochemistry techniques. Hence additional studies are needed to determine the mechanisms by which NPY induces phase shifts of SCN neural activity.

Midbrain Raphe Nuclei

The SCN receives a dense serotoninergic input from neurons in the median raphe nucleus (MRN) and relatively sparse

input from neurons in the dorsal raphe nucleus (DRN).[52] Serotonin (5-HT)-immunoreactive axonal terminals in the SCN overlap extensively with the terminal fields of the RHT and geniculohypothalamic tract, forming synapses with VIP-containing neurons. In contrast to the MRN, the DRN projects to the IGL and to the SPZ immediately dorsal to the SCN, with few fibers to the SCN itself. The midbrain raphe nuclei are not required for photic circadian entrainment or for maintaining circadian rhythmicity, but 5-HT modulates photic and nonphotic input to the circadian clock. Lesions of the midbrain raphe nuclei have been reported to phase-advance the locomotor activity onset, lengthen the activity phase, induce deficits in rhythmicity in constant light, and reduce the amplitude or precision of circadian rhythms.[53]

Similar to NPY, the effects of 5-HT and photic stimuli on the circadian pacemaker appear to be mutually inhibitory. Phase shifts induced by light, optic nerve stimulation, or glutamate are attenuated by administration of 5-HT during the biologic night, whereas 5-HT-induced phase advance shifts are inhibited by glutamate agonists or optic chiasm stimulation.[54] The 5-HT_{1B} receptor mediates inhibitory effects of 5-HT on light-induced phase shifts,[55] and electron microscopic studies have shown that 5-HT_{1B} receptor immunoreactivity is predominantly found in presynaptic terminals in the SCN, including axonal terminals from the RHT.[56] Consistent with pharmacologic studies conducted in vitro, 5-HT_7 agonists induce phase advances in hamster behavioral circadian rhythms when administered during the biologic daytime,[57,58] and the 5-HT_7 receptor has been localized to dendrites of GABA-,VIP-, and AVP-containing SCN neurons and also to presynaptic axonal terminals.[56]

SUPRACHIASMATIC NUCLEUS OUTPUTS

Considering the important role that the SCN plays in regulating circadian behavior and physiology, the number and density of SCN efferent pathways are surprisingly limited (see Figure 33-2, *B*).[59,60] The SCN projects rostrally to limbic structures, including the lateral septum and bed nucleus of the stria terminalis (BSTL), and to the medial preoptic area (MPOA) and VLPO. The SCN sends projections dorsally to the midline thalamus, including the paraventricular thalamic nucleus (PVT) and paratenial thalamic nuclei, and dorsocaudally to the SPZ, paraventricular hypothalamic nucleus (PVH), and dorsomedial hypothalamic nucleus (DMH). A caudal projection from the SCN terminates in the RCA, and some fibers branch toward the supraoptic nucleus and the lateral hypothalamic area (LHA). The SCN also sends a minor projection laterally to the IGL and small posterior projections to the OPT and central gray matter. Based on retrograde tracing studies in rats, the SCN shell projects more strongly to the MPOA, DMH, and BSTL, whereas the SCN core projects more strongly to the lateral septum and tuberal hypothalamus.[59,61] Both SCN subdivisions project strongly to the SPZ and midline thalamus. In monkeys, VIP-immunoreactive axons from the SCN project rostrally into the MPOA and dorsally into the SPZ and anterior hypothalamic area ventral to the PVH, and small numbers of terminals are also observed in the PVH, LHA, and PVT. A dense VIP-containing projection extends caudally into the RCA, and some fibers continue into the capsule of the ventromedial hypothalamic nucleus, DMH, and dorsal hypothalamic area. In humans, VIP-containing SCN neurons project most heavily into the region just dorsal to the SCN and extending to the area just ventral to the PVH, corresponding to the SPZ in rodents.[4] Similar to that in monkeys, the SCN in humans sends a dense VIP-immunoreactive projection caudally into the RCA. Together, these studies demonstrate that the SCN projects extensively to other hypothalamic regions, and the pattern of projections is generally conserved across mammalian species.
