The densest output from the SCN is to the SPZ, which is located immediately dorsal to the SCN and extends dorsocaudally ventral to the PVH.[60] Tracing studies have shown that the SCN core projects more strongly to the lateral SPZ, whereas the SCN shell projects more densely to the medial SPZ.[61] Consistent with these results, AVP-immunoreactive axonal terminals are found medially in the SPZ, whereas VIP-containing terminals are found more laterally. The SPZ innervates similar targets to the SCN but in much greater density, suggesting that the SPZ amplifies circadian output from the SCN. Cell-specific lesions of the SPZ eliminate circadian rhythms of sleep, locomotor activity, and core body temperature, suggesting that the SPZ is part of the primary neuronal pathway mediating the output of SCN-generated circadian rhythms.[62] Lesions in the ventral part of the SPZ abolish circadian rhythms of sleep and locomotor activity while having lesser effects on the body temperature rhythm, whereas lesions in the dorsal SPZ reduce the body temperature rhythm while having minimal effects on rhythms of wake-sleep or locomotor activity. The ventral SPZ, in turn, sends a strong projection caudally to the DMH. Cell-specific lesions of the DMH eliminate circadian rhythms of sleep—wake, locomotor activity, feeding, and plasma corticosteroids but not body temperature or plasma melatonin.[63] Hence, the major neuronal pathway mediating the SCN-generated circadian rhythm of sleep is through a first-order projection to the SPZ, followed by a second-order projection to the DMH.

As might be expected, the DMH projects heavily to brain areas involved in regulating sleep and wakefulness. For example, the DMH sends a primarily GABAergic projection to the VLPO. The VLPO contains the neurotransmitters GABA and galanin and is thought to promote sleep through its inhibitory projections to the ascending arousal systems.[64,65] Although the SCN and SPZ also send minor projections directly to the VLPO, the projection originating from the DMH is one of the largest inputs to this area.[66] The DMH also sends a primarily glutamatergic projection to the lateral hypothalamus, which contains wake-promoting neurons, including orexin-expressing neurons.[63] In summary, the DMH receives circadian input from the SCN and the SPZ and projects to the VLPO and LHA, defining a putative pathway for the circadian regulation of sleep and wakefulness (Figure 33-4). The relay of SCN circadian signals in the SPZ and then the DMH might allow for modification of circadian rhythms by other inputs such as food availability, external temperature, or social cues.

Consistent with this hypothesis, cell-specific lesions of the DMH impair the ability of rats to synchronize their sleep-wake, locomotor activity, and body temperature rhythms with restricted daytime feeding.[67] Also, restoring clock gene expression in the DMH of *Bmal1* null mice has been shown to rescue circadian adaptation to restricted feeding.[68] Two later

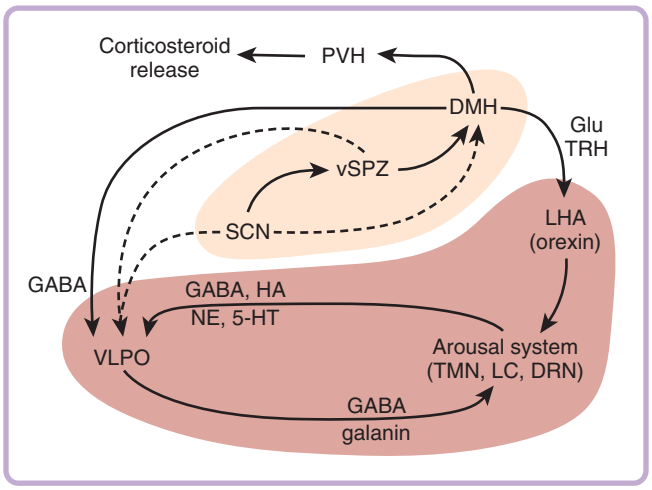

Figure 33-4 Circadian regulation of sleep-wake. The neuronal pathway that regulates circadian sleep-wake cycles (SCN to vSPZ to DMH, indicated in *beige*) directly interacts with arousal- and sleep-promoting brain regions (indicated in *light red*), providing a putative pathway for the circadian regulation of sleep-wake. *Solid arrows* indicate prominent neuronal projections, and *dashed arrows* indicate relatively small projections. Neurotransmitters contained in these projections are shown next to the *arrows*. DMH, dorsomedial hypothalamic nucleus; DRN, dorsal raphe nucleus; GABA, gamma-aminobutyric acid; Glu, glutamate; HA, histamine; 5-HT, 5-hydroxytryptamine (serotonin); LC, locus coeruleus; LHA, lateral hypothalamic area; NE, norepinephrine; PVH, paraventricular hypothalamic nucleus; SCN, suprachiasmatic nucleus; TMN, tuberomammillary nucleus; TRH, thyrotropin-releasing hormone; VLPO, ventrolateral preoptic nucleus; vSPZ, ventral subparaventricular zone.

studies questioned the necessity of clock genes for food entrainment by showing that wheel-running in *Bmal1* or *Per1/2* null mice anticipated meal times when the duration of daily food availability was decreased gradually over the course of days.[69,70] However, food anticipatory activity was not clearly demonstrated at the end of the experiments during continual food deprivation in the absence of light-dark cues,[69] so it could not be concluded that the activity pattern under those conditions was due to a self-sustained circadian clock mechanism. Notably, mice with genetic ablation of orexin neurons show blunted behavioral adaptation to restricted feeding cycles,[71] similar to DMH-lesioned rats, suggesting that the outflow pathway from the DMH to orexin neurons might be important for integrating photic and nonphotic information in order to establish a pattern of sleep-wake behavior that is most adaptive for survival.

Circadian Regulation of Melatonin and Cortisol

Under normally entrained conditions, synthesis of melatonin usually begins a few hours before a person's bedtime. Plasma melatonin levels are highest in the middle of the night and then decrease before usual wake time. The SCN is required for the circadian synthesis and release of melatonin in the pineal gland, which is regulated through a circuitous pathway.[72] A subset of SCN neurons projects directly to dorsal parvocellular neurons in the autonomic subdivision of the PVH. These PVH neurons send an excitatory projection to the sympathetic preganglionic neurons in the intermediolateral cell column in the upper thoracic spinal cord. The intermediolateral cell column sends a cholinergic projection to the superior cervical ganglion, and the superior cervical ganglion postganglionic sympathetic neurons send a noradrenergic projection to the pineal gland. The release of noradrenalin activates α- and β-adrenergic receptors in the pineal gland that stimulate the production of melatonin by controlling the enzyme serotonin *N*-acetyltransferase.

The SCN is most active during the biologic daytime and inhibits tonic activity of PVH neurons. This results in a lower firing rate in the remainder of the pathway, effectively inhibiting melatonin synthesis. Therefore melatonin is produced during the biologic night, when SCN activity is low, and this is a common feature of both diurnal and nocturnal animals. Exposure to light during the biologic night activates SCN neurons through the RHT, resulting in the inhibition of melatonin synthesis through the aforementioned pathway. Similar to circadian light resetting of the melatonin rhythm, light-induced suppression of melatonin synthesis is mediated by OPN4-containing RGCs.[29]

Melatonin can also provide direct feedback to the circadian system via melatonin receptors (MT1 and MT2) located in the SCN. Melatonin acutely inhibits SCN electrical activity, and this response is mediated by the MT1 receptor.[73] The locomotor activity rhythm of rats can be entrained by periodic administration of melatonin as long as the SCN remains intact,[74] suggesting that melatonin receptor signaling in the SCN is required for melatonin-induced entrainment. Melatonin-induced phase shifts persist in MT1 or MT2 receptor knockout mice, suggesting that melatonin receptor subtypes play an overlapping role in this response.[73,75] In humans, daily administration of melatonin can entrain the circadian system of blind persons,[76,77] indicating that melatonin elicits phase shifts of the human circadian clock and can be used to treat circadian rhythm sleep disorders even in the absence of photoreception.

Early lesion studies of the SCN showed loss of the circadian rhythm of adrenal corticosterone, the major glucocorticoid in rodents. In humans, the circadian rhythm of cortisol rises sharply before the waking period, presumably to promote a general state of readiness in anticipation of the myriad stressors and metabolic demands associated with the active phase. SCN neurons project directly and indirectly to the DMH, which sends efferents to the PVH and is critical for expression of the corticosteroid rhythm.[63] Corticotropin-releasing hormone–containing neurons in the PVH project to the median eminence, where corticotropin-releasing hormone is released into the portal circulation and activates the release of adrenocorticotropic hormone from the anterior pituitary gland. The SCN-driven release of adrenocorticotropic hormone into the blood results in rhythmic induction of corticosteroid secretion from the adrenal gland.

Diffusible Suprachiasmatic Nucleus Output Signals

In SCN-lesioned hosts, transplantation of fetal SCN grafts into the third ventricle restores a low-amplitude circadian rest-activity rhythm with the period of the donor animal.[78] In contrast, photic entrainment, reproductive responses to photoperiod, estrous cycles, and corticosteroid and melatonin rhythms are not restored by SCN transplants. Polymer-encapsulated SCN transplants that prevent neuronal communication between host and donor tissue reinstate low levels

of locomotor activity rhythms in SCN-lesioned hosts, suggesting that a diffusible factor can partially reconstitute the rest-activity cycle.[79] The distance of SCN transplants from the normal site of the SCN is an important factor for the recovery of the locomotor rhythm, indicating that a diffusible factor acts locally in a paracrine fashion.

Candidate diffusible mediators have been identified in the SCN that might regulate the output of circadian behavioral rhythms, including transforming growth factor-α, cardiotrophin-like cytokine, and prokineticin 2 (PK2). PK2 is a clock-controlled gene that is rhythmically expressed in the SCN, with higher expression levels observed during the biologic daytime. Intracerebroventricular injection of PK2 inhibits locomotor activity during the biologic night in rats (the active phase),[80] and PK2 null mice show attenuated circadian rhythms of sleep-wake, body temperature, and glucocorticoids.[81] Consistent with a role for PK2 as an SCN output factor, PK2 receptor has been described in many SCN output regions, including the PVH, DMH, PVT, paratenial nucleus, lateral septum, and the SCN itself.[80] Additionally, PK2 receptor knockout mice show reduced circadian expression of rest-activity and body temperature rhythms.[82]

SYNCHRONIZATION OF CENTRAL AND PERIPHERAL OSCILLATORS

The circadian system is thought to be hierarchically organized. The SCN contains a master clock for regulating behavioral rhythms, but circadian clocks are also found in tissues throughout the body. The molecular clock mechanism is preserved across different cell types, and circadian expression of clock genes has been demonstrated in nearly all tissues studied, as well as in many sites in the brain.[83] Notably, damage to SCN neurons causes peripheral clocks to fall out of synchrony, even though individual cells in peripheral tissues can continue to generate circadian rhythms of gene transcription.[84] Under most conditions, the SCN entrains peripheral clocks to ensure coordinated changes in physiology that are appropriately timed to the rest-activity cycle. The pathways by which the SCN entrains clocks in peripheral tissues is not fully understood, but there is evidence that shifts in temperature can reset peripheral, but not SCN, clocks.[85] Thus by controlling the daily cycle of body temperature, the SCN would reset clocks throughout the body and keep them in synchrony. Other aspects of physiology that are directly regulated by the SCN may also contribute to tissue circadian phase. For example, glucocorticoid signaling activates clock gene expression and influences the rate of entrainment of peripheral clocks to feeding cycles.[86,87] The phase of peripheral clocks can become uncoupled from the SCN pacemaker in animals that are given daily restricted access to food, as shown for circadian gene expression in tissues such as the liver, kidney, and heart.[88,89] Entrainment of peripheral clocks by feeding cycles can potentially occur through nutrient-sensing pathways because proteins involved in metabolism and energy balance (e.g., sirtuin 1 and AMP-activated protein kinase) interact with core clock proteins and affect their function.[90] Although it is well established that the circadian system plays an important role in regulating metabolism, recent work suggests that the dietary composition and timing of meals can also affect the molecular clock and clock-controlled metabolic function.[91] This has potential clinical implications for shift workers and other persons who regularly consume meals during the biologic night.

CLINICAL PEARL

The suprachiasmatic nucleus is an internal body clock that allows daily scheduling of wake-sleep, feeding, corticosteroid secretion, and other bodily functions during a normal light-dark cycle. This cycle can be modified by light exposure or by administration of melatonin, which resets the body clock, but feeding schedules can also reset the daily activity cycle by acting on circuits that are downstream of the clock. Thus in patients with difficulty adjusting to shift work, jet lag, or other disruptions of their schedules, in addition to adjusting light exposure and taking melatonin, it is usually possible to adjust to a new schedule more quickly if the meal times, social interactions, and sleep-activity schedule of the new environment are adopted as soon as possible.

SUMMARY

The circadian system plays an integral role in coordinating behavioral and physiologic rhythms. Under normally entrained conditions, exposure to light activates OPN4-containing RGCs, which transmit light information to the core region of the SCN by releasing glutamate and PACAP. The effects of light on SCN neuronal activity are modulated by input from NPY- and GABA-containing neurons in the IGL and serotoninergic input from the MRN. The solar cycle entrains the master clock in the SCN, which is responsible for generating circadian patterns of behavior. The SCN regulates the circadian sleep-wake rhythm through a primary projection to the SPZ, followed by a secondary projection to the DMH. The DMH, in turn, projects to brain areas critical for promoting sleep or wakefulness. A direct projection from the SCN to the PVH mediates rhythmic control of melatonin secretion from the pineal gland, and an indirect projection from the SCN to the PVH through the DMH is critical for the circadian release of corticosteroids. Although SCN neuronal projections are required for photic entrainment and circadian control of endocrine rhythms, SCN-diffusible factors are sufficient to support a weak circadian rest-activity rhythm. The SCN also coordinates the timing of peripheral clocks, which respond to SCN-directed circadian changes in temperature, glucocorticoids, and nutrient-sensing pathways. Through the aforementioned pathways, the circadian system ensures that sleep and other biologic rhythms are timed appropriately with respect to daily changes in the environment.

Chapter 34

Chapter Highlights

- The bilaterally paired suprachiasmatic nuclei (SCNs) of the anterior hypothalamus were first identified in the early 1970s as critical for the normal expression of circadian rhythms, and subsequent research employing a wide variety of approaches has firmly established a role for the SCN as the master circadian pacemaker in mammals. Substantial effort has been exerted to elucidate the intrinsic anatomic organization of the SCN and to map its major afferent and efferent pathways.
- The circadian pacemaker is synchronized ("entrained") by environmental light-dark cycles and other periodic events. Light entrainment depends on a subset of intrinsically photosensitive retinal ganglion cells that express the novel photopigment, melanopsin, and that give rise to the retinal-hypothalamic tract, terminating in the SCN and certain other "nonvisual" brain areas.
- The molecular basis of circadian rhythm generation has been revealed to involve transcription-translation feedback loops comprising a number of circadian "clock genes" and their protein products. Although rhythmic clock gene expression was first identified in SCN tissue, subsequent work has revealed similar molecular clocks in numerous cells and tissues throughout the body.
- The mammalian circadian system is now seen as hierarchically organized and widely distributed, such that the master pacemaker in the SCN synchronizes multiple "downstream" circadian clocks distributed throughout the brain and body, thereby maintaining system-wide temporal synchrony. Failure of internal synchrony appears to be both a cause and an effect of disease-related pathophysiology. Thus the balance between health and disease is strongly dependent on the proper synchrony within and between central and peripheral oscillating systems.

A great deal is now known about the mammalian circadian timing system at the molecular, cellular, neural systems, and behavioral levels. The basic neuroanatomy, neurochemistry, and molecular neurobiology of the circadian pacemaker, its synchronization (entrainment) to the external environment, and its role within the multioscillatory circadian timing system have now been elucidated. Despite the fact that the subtle details of these processes continue to be elucidated, much of the current work on the physiology of the circadian system concerns how the master circadian pacemaker in the hypothalamus receives inputs from the internal and external environments, how the pacemaker interacts with a multitude of peripheral clocks to regulate the diverse spectrum of rhythmic processes, and how these functions contribute to health and disease.

THE SUPRACHIASMATIC NUCLEUS: MASTER CIRCADIAN PACEMAKER

Pacemaker Function of the Suprachiasmatic Nucleus

The realization that molecular circadian clocks exist in cells and tissues throughout the brain and body has revolutionized our understanding of the overall organization of the mammalian circadian timing system. Nevertheless, it remains clear that the hypothalamic suprachiasmatic nucleus (SCN) is the site of a "master" circadian pacemaker, responsible for regulating—directly or indirectly—most, if not all, circadian rhythms.[1-3] Over the years, a variety of studies involving SCN lesions, in vivo and in vitro recordings of SCN neural activity, functional metabolic mapping, fetal tissue transplantation, and molecular rhythm analysis have revealed that the SCN not only is capable of sustained rhythmic activity, both in vitro and in vivo, but also is responsible for maintaining coherent circadian rhythmicity in central and peripheral tissues, as well as in a wide range of physiologic and behavioral processes.[4,5]

Although early mathematical models raised the possibility that the circadian pacemaker could be constructed from an ensemble of coupled, high-frequency (i.e., noncircadian) oscillatory units, it is now clear that the generation of circadian signals by the SCN is fundamentally a cellular process. Studies using a variety of in vitro models, including long-term SCN cell culture,[6] simultaneous recording of multiple single units using multielectrode plates,[7,8] and optical monitoring of calcium flux[9] or gene expression[10] in individual SCN neurons, have now provided compelling evidence that circadian oscillation is indeed a cell-autonomous process expressed in many, but probably not all, individual SCN neurons. Nevertheless, this multitude of cellular circadian oscillators normally

interact to produce coherent circadian patterns of behavior.[11] Although the mechanisms underlying intra-SCN oscillator coupling have not been identified completely, early studies using tetrodotoxin suggested that individual neuronal oscillators in the SCN apparently remain synchronized even in the absence of sodium-dependent action potentials, both in vivo and in SCN slice culture.[12,13] These findings led to the suggestion that gap junctions, glial coupling, calcium-dependent signaling, or local diffusible signals might be responsible for maintaining intercellular oscillator synchrony in the SCN.[14,15] On the other hand, more recent studies using tetrodotoxin have found that blocking of action potentials in SCN slices or in dispersed cell cultures can disrupt intercellular phase synchrony,[16,17] reviving interest in the possible role of synaptic signaling in oscillator coupling. In support of this hypothesis, in vitro and in vivo evidence has accumulated to indicate that both gamma-aminobutyric acid (GABA) and vasoactive intestinal peptide (VIP) release may contribute to coupling among cellular oscillators within the SCN.[18-23] Further, several sources of evidence now indicate that, despite the capacity of individual SCN neurons for autonomous rhythmicity, multicellular network interactions increase the amplitude and number of rhythmic cells detected in culture and contribute to the overall robustness of SCN pacemaker function.[24-27]

Molecular Basis of the Suprachiasmatic Nucleus Pacemaker

A critical role for protein synthesis in the mammalian circadian pacemaker was established in the late 1980s,[28,29] and elucidation of the fundamental molecular-genetic circadian oscillatory mechanism began about 10 years later. Thus the first mammalian circadian clock gene, *Clock*, was identified using a forward-genetics mutagenesis screen,[30,31] and this discovery was followed quickly by the identification of a number of other "core" clock genes, some of which showed clear homology to previously discovered circadian clock genes in the fruit fly (e.g., the *Per* genes).[32] Reciprocally, homologues to several clock genes first identified in mice were later shown to be expressed in flies, and this extreme evolutionary conservation facilitated the analysis of both mammalian and nonmammalian systems. The most well-studied mammalian clock genes include the three *Per* genes (*Per1, Per2, Per3*), two plant cryptochrome gene homologues (*Cry1* and *Cry2*), *Clock, Bmal1* (also known as *Arntl1* and *Mop3*), *CK1ε*, and more recently, *Rev-erba* and *Fxbl3*, all of which are expressed in SCN neurons.[33] As described more fully later, several of these genes code for proteins that interact directly to form interlocking negative and positive transcription-translation feedback loops that define the molecular core of the circadian oscillator, whereas others exert critical posttranslational processing that regulates the period and precision of the molecular clock.[32-34]

The primary negative feedback loop of the molecular clock involves negative regulation of the transcriptional activity of CLOCK/BMAL1 heterodimers by PER and CRY through direct protein-protein interactions (Figure 34-1). In turn, inhibition of CLOCK/BMAL1 activity results in reduced *Per* and *Cry* gene transcription, leading eventually to disinhibition of CLOCK/BMAL1 activity. PER protein is posttranslationally modified by CK1ε (and probably other CK1 isoforms) through phosphorylation, which regulates PER stability and also appears to control its nuclear translocation, thus influencing the period of the clock. More recently, it has been

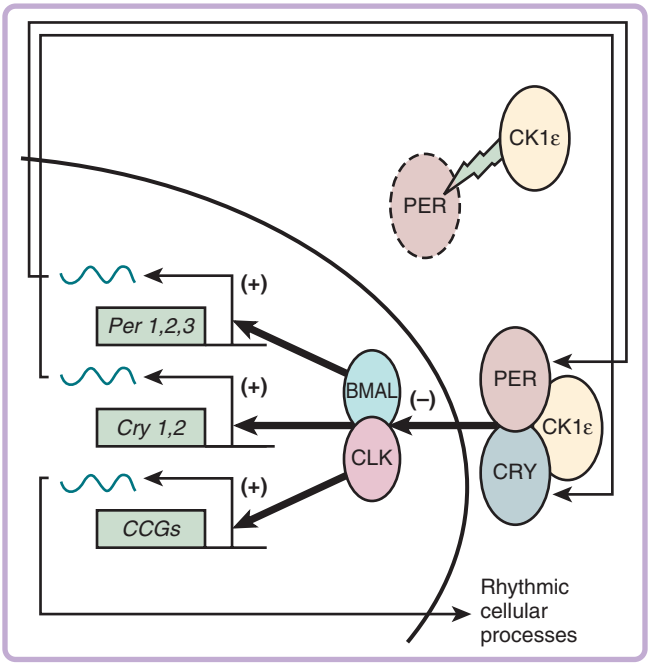

Figure 34-1 Essential elements of the core molecular loop underlying circadian timing at the cellular level in mammals. The transcription factors CLOCK (Clk) and BMAL1 (B) form a protein heterodimer that promotes the transcription of several rhythmically transcribed clock genes, including the *Per* ("period") genes *Per1*, *Per2*, and *Per3*, and the *Cry* (cryptochrome) genes *Cry1* and *Cry2*. CLOCK and BMAL1 also drive transcription of a large number of "clock-controlled genes" (CCGs) that convey the circadian timing signal to a wide variety of cellular processes. The protein products of the *Per* and *Cry* genes dimerize in several different combinations, including both PER-CRY (as shown here) and PER-PER pairings. After nuclear translocation, PER and CRY inhibit the transcriptional effects of CLOCK-BMAL1 through direct protein-protein interactions and thus exert negative autoregulation of their own transcription. This negative feedback results in circadian expression of Per and Cry transcripts. This basic transcription-translation negative feedback loop is modulated by several posttranslational processes. For example, casein kinase 1 epsilon (CK1ε) acts to regulate the nuclear translocation of the PER-CRY dimer and also functions to phosphorylate the Per protein, thereby tagging it for subsequent degradation by ubiquitin. Through these actions, CK1ε plays a critical role in regulating the period of the molecular clock. At the behavioral level, this model predicts (1) the shortening of free-running period seen in *tau*-mutant hamsters carrying a mutation of the *CK1ε* gene, (2) the lengthening of free-running period seen in *Clock*-mutant mice, and (3) the loss of coherent free-running rhythms seen in *Clock* mice and in *Per-* and *Cry*-knockout mice. Note that the molecular clockwork also includes a positive feedback loop, omitted from this diagram, that regulates the availability of BMAL1 and that appears to increase the overall stability of the clock.

discovered that FBXL3 is responsible for degrading the CRY proteins and that multiple *Fxbl3* mutations alter clock period.[35-37] In addition to this primary negative feedback loop, a secondary positive feedback loop regulates *Bmal* transcription through the clock gene *Rev-erba*, which is itself transcriptionally regulated by the CLOCK/BMAL1 complex. These interlocked loops result in rhythmic transcription of specific clock genes in the in vivo[38,39] and in vitro SCN,[10,40,41] and, as discussed later, in many non-SCN tissues as well. Finally, molecular elements of the core oscillator drive rhythmic expression of a large number of clock-controlled genes (i.e., genes that are controlled by, but not part of, the core circadian oscillator loop), which in turn serve as the basis for rhythmic outputs to myriad other cellular processes.[32,33] Ultimately, these cellular-molecular processes are reflected at the

behavioral level, as amply documented by analysis of altered circadian behavioral phenotype in animals bearing specific clock gene mutations.

As described earlier, BMAL1 provides positive transcriptional drive on the *Per* and *Cry* genes, so it is perhaps not surprising that *Bmal1* knockout mice express immediate arhythmicity under free-running conditions.[33] In contrast, the classic *Clock* mutation, which codes for a dominant-negative CLOCK protein, initially lengthens free-running period and results in a gradual loss of rhythmicity under long-term free-running conditions.[41] Surprisingly, however, *Clock* null mice express robust and persisting circadian rhythms, with a modest shortening of circadian period.[42] This is because the CLOCK paralogue, NPAS2, can substitute for CLOCK as a dimerization partner for BMAL1 within the SCN, thus maintaining circadian pacemaker function.[43,44] Regarding the *Per* genes, several different mutation and deletion models have been studied by different laboratories, but in general, *Per1* and *Per2* disruption shortens circadian period and reduces the robustness of free-running rhythms.[33,45] Similarly, *Cry* mutant mice also exhibit alterations in free-running period, whereas *Cry1/Cry2* double-mutants are rendered arrhythmic.[46,47] In contrast to other clock genes, the circadian clock function of *Ck1ε* was discovered by genetic analysis of so-called *tau*-mutant hamsters expressing a spontaneous single-gene mutation that dramatically shortens free-running period.[48] Cloning of the *tau* gene revealed its identity as *Ck1ε*, and subsequent transgenic insertion of this allele into mice recapitulated the hamster short-period phenotype, while deletion of *Ck1ε* in mice lengthened circadian period.[49] Finally, multiple mutations of the *Fxbl3* gene have been shown to lengthen free-running period.[35,36,37] For the molecular clock to drive circadian rhythmicity in physiology and behavior, rhythmic clock gene expression must be linked to intracellular signaling pathways regulating neuronal membrane potential and, ultimately, firing rate.[50] In turn, electrophysiologic rhythmicity in SCN neurons underlies the transmission of efferent signals to the "downstream" extra-SCN targets that more directly regulate neurobehavioral processes. (In addition, as discussed previously, similar mechanisms apparently contribute to intra-SCN oscillator coupling as well.) Remarkably, recent research demonstrates that ionic events at the cell membrane influence the molecular clock through some of the same intracellular signals that convey clock signals to the membrane, and in some cases, these ionic currents may be necessary for self-sustainment of the molecular clock.[50] Such results at a minimum serve to blur the distinction between the clock mechanisms and the so-called hands of the clock.

Finally, in addition to their effects on circadian behavior, circadian clock gene mutations affect sleep-wake homeostasis, as well as several forms of affective behavior, suggesting possible molecular links between the circadian, sleep-regulatory, and motivational systems of the brain.[51-53] Such effects could be due to alterations in SCN efferent signaling to affective systems in the brain as well as to altered clock gene expression within these downstream brain regions. We will return to the health implications of clock gene mutations later.

Functional Architecture of the Suprachiasmatic Nucleus

Traditionally, the SCN has been characterized as comprising distinct ventrolateral and dorsomedial subdivisions.[54] More recently, however, this scheme has been reconceptualized to include SCN "core" and "shell" subnuclei, a concept that may better accommodate species differences in the anatomic distribution of neuropeptides, afferent terminal fields, and gene expression patterns in the SCN[55,56] (Figure 34-2). Although SCN neurons express a large number of neuropeptides, core and shell subnuclei have been most commonly identified by the concentration of arginine vasopressin–positive neurons in the SCN shell and by VIP-positive and gastrin-releasing peptide (GRP)–positive neurons in the SCN core. Beyond this basic organization, however, clear species differences have been noted, even among nocturnal rodents. For example, the hamster SCN core contains a very distinct and compact cluster of photoresponsive calbindin-positive cells, which is

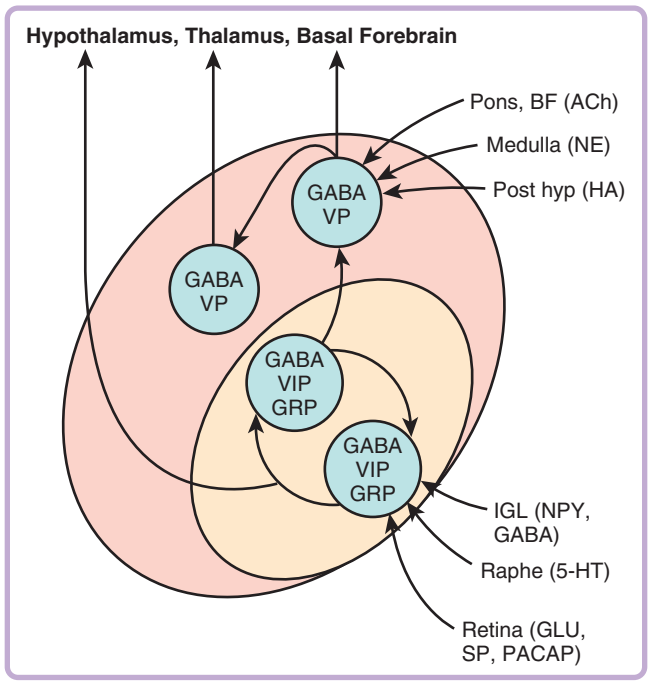

Figure 34-2 Core and shell organization of the suprachiasmatic nucleus (SCN). Most SCN neurons release the inhibitory amino acid transmitter gamma-aminobutyric acid (GABA). In the SCN core (*yellow*), GABA is commonly colocalized with one or more neuropeptides, including vasoactive intestinal polypeptide (VIP) and gastrin-releasing peptide (GRP), whereas neurons of the SCN shell (*orange*) frequently contain GABA colocalized with arginine vasopressin (VP). SCN core neurons project to other core neurons, to SCN shell neurons, and to extra-SCN targets, most prominently in the diencephalon and basal forebrain; SCN shell neurons project to other shell neurons and to extra-SCN targets, but not to SCN core neurons. This anatomic organization implies that the flow of information within the SCN is generally from core to shell. Consistent with this suggestion, the three best-characterized SCN afferent systems, originating in the retina, the intergeniculate leaflet of the thalamus (IGL), and the mesencephalic raphe nuclei, converge in the SCN core. Retinal afferents contain the excitatory amino acid transmitter glutamate (GLU) as well as the neuropeptides substance P (SP) and pituitary adenyl cyclase–activating peptide (PACAP); raphe afferents contain 5-hydroxytryptamine (5-HT; serotonin); and IGL afferents contain neuropeptide Y (NPY) and GABA. Beyond these core afferents, several less well-characterized afferent systems converge in the SCN shell, including acetylcholine (ACh)-containing projections from the basal forebrain (BF) and pons, medullary norepinephrine (NE)-containing projections, and histamine (HA)-containing projections from the posterior hypothalamus (Post hyp). A number of other anatomically identified but functionally uncharacterized SCN afferent systems have been omitted from this figure and are not discussed in the chapter.

absent in the rat.[55] In light of this and other species differences as well as other complexities in SCN organization, it has been argued that the popular distinction between SCN core and shell may be such an extreme oversimplification as to impede understanding of the functional organization of this critical structure.[2,57,58]

Although the specific functions of chemically defined SCN cell populations are not fully known, a reasonable heuristic is that VIP and GRP neurons of the SCN core serve to collate afferent information relevant to pacemaker entrainment, whereas the vasopressinergic (or other) neurons of the SCN shell are primarily responsible for the self-sustaining generation of the circadian timing signal. A preeminent role for the SCN core in pacemaker entrainment is supported by findings that major SCN afferent systems converge in the core subnucleus[54,55]; administration of SCN core peptides such as VIP and GRP can mimic both light-induced phase shifting and *Per* gene expression in the SCN in vivo and in vitro[59-61]; and light-evoked changes in SCN physiology and gene expression spread over time from core to shell.[18,62] Conversely, evidence for a preeminent role of the SCN shell in pacemaking includes findings that the core projects robustly to the shell but not vice versa[55]; spontaneous circadian rhythmicity in neuronal activity, neuropeptide release, and *cfos* and *Per* gene expression are seen more robustly and reliably in the shell than in the core[63-65]; and spontaneous rhythmicity in SCN gene expression appears to flow from the most dorsomedial toward more central-lateral regions over the course of the circadian cycle.[66,67] On the other hand, the view that SCN core and shell underlie completely discrete entrainment and pacemaking functions, respectively, is probably too simplistic because (1) several arousal-related afferents of limbic and brainstem origin target the SCN shell[54-56]; (2) in vitro studies have revealed independent free-running rhythmicity in secretion of core and shell peptides from the same tissue explant[68]; and (3) SCN core and shell can exhibit stable dissociation of rhythmic gene expression in vivo under certain conditions.[69] Together, these findings implicate separate core and shell oscillators. Further, studies using microlesions indicate that the integrity of the SCN core is essential for the maintenance of high-amplitude behavioral and molecular-level rhythmicity, suggesting that rhythmic signals from the core serve a permissive gatelike role in sustaining oscillatory function in the shell.[62,66]

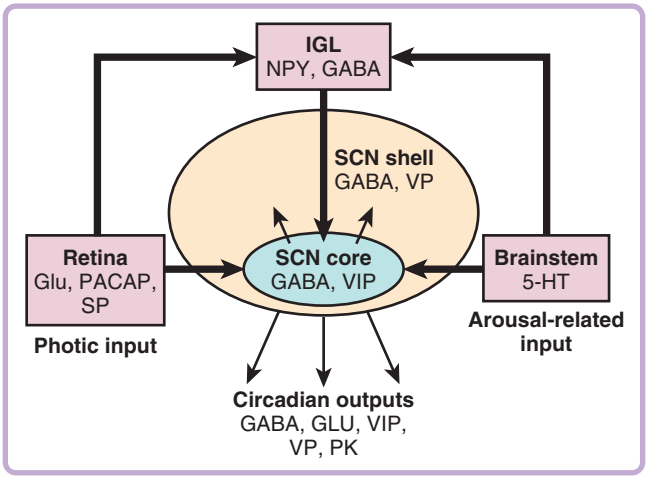

Figure 34-3 Overview of functional neuroanatomic pathways in the mammalian circadian system. Major suprachiasmatic nucleus (SCN) afferent systems originating in the retina and raphe nuclei also target the intergeniculate leaflet of the thalamus (IGL), which in turn projects to the SCN. Retinal projections to the SCN and IGL mediate photic input to the circadian system; raphe projections to the SCN and IGL mediate the effects of certain nonphotic, behavioral state–related signals; and IGL-SCN projections are involved in mediation of both photic and nonphotic signaling to the SCN pacemaker. As described in the text, photic and nonphotic pathways generally interact via both presynaptic and postsynaptic mechanisms to produce mutually antagonistic effects on the circadian pacemaker. Thus photic signals evoke circadian phase shifting during subjective night and antagonize nonphotic phase shifting during subjective day, whereas signals related to arousal and wakefulness evoke phase shifting during subjective day and antagonize photic phase shifting during subjective night. These antagonistic interactions are mediated in part at the level of the SCN, but the scheme presented here suggests that the IGL is also a probable locus for interaction between photic and nonphotic signals—a hypothesis that is largely unexplored. SCN outputs appear to include both neural efferents and secreted paracrine signals. GABA, Gamma-aminobutyric acid; GLU, glutamate; 5-HT, 5-hydroxytryptamine (serotonin); PACAP, pituitary adenyl cyclase–activating peptide; PK, prokineticin; SP, substance P; VIP, vasoactive intestinal polypeptide; NPY, neuropeptide Y.

Light Input to the Suprachiasmatic Nucleus: The Retinohypothalamic Tract

Although stimuli such as temperature, sound, food, and social cues appear to contribute to phase control, environmental light and darkness are the primary cues for circadian entrainment. A specialized retinal projection system, referred to as the *retinohypothalamic tract* (RHT), is both necessary and sufficient for photic entrainment of the circadian pacemaker.[2,70,71] Unlike the classic "image-forming" visual system, the RHT system functions more like a light meter than a camera lens, and it is thus not surprising to find a separate afferent pathway dedicated to circadian entrainment (and other light-dependent functions requiring irradiance coding, such as light-evoked pupillary responses, melatonin suppression, and affective responses).[71] The RHT originates from a distinct subset of retinal ganglion cells, separate from those giving rise to the primary visual pathways,[72] and terminates mainly in the SCN, as well as more sparsely in the anterolateral hypothalamus, subparaventricular zone, and supraoptic region.[73,74] RHT axon collaterals also project to the thalamic intergeniculate leaflet (IGL; Figure 34-3), which, as discussed later, is an important component of the circadian system.

Although nonretinal photoreception plays a major role in circadian entrainment in nonmammalian vertebrates,[75] mammalian photoreception appears to be based entirely on retinal mechanisms. Remarkably, retinally degenerate strains of mice, in which nearly all classic photoreceptors (i.e., rods and cones) are lost by early adulthood, exhibit normal circadian responses to light.[76] More recently, similar findings have been reported in genetically engineered mice with a total developmental absence of both rods and cones, demonstrating conclusively that circadian light entrainment can be mediated by a novel, nonrod, noncone photoreceptor system.[77] Recent studies indicate that the protein, melanopsin, found specifically within the small subset of retinal ganglion cells giving rise to the RHT, serves as a circadian photoreceptor molecule in a novel population of intrinsically photosensitive retinal ganglion cells (ipRGC).[78,79] Surprisingly, however, although melanopsin-containing ganglion cells are sufficient for circadian entrainment, studies with melanopsin knockout mice reveal that, despite parametric changes in photoresponsiveness, this photopigment is not necessary for entrainment.[80,81]

Indeed, entrainment is only fully abolished when both classic and melanopsin-based photoreception is eliminated,[82] revealing a potential degree of functional redundancy in how the SCN receives entrainment information from the photic environment. Although signals derived from both classic and nonclassic (ganglion cell) photoreceptors reach the SCN, rod- and cone-derived entrainment signals appear to be relayed to the SCN through synapses on ipRGCs.[83-86]

RHT terminals release the excitatory amino acid neurotransmitter, glutamate (or aspartate), in response to photic stimulation. Extensive evidence from in vivo and in vitro studies indicates that glutamate acts through both *N*-methyl-d-aspartate (NMDA) and non-NMDA receptors and a variety of intracellular signaling molecules (e.g., Ca^{2+}, nitric oxide, calmodulin/calmodulin kinase, protein kinase C, protein kinase G, cyclic adenosine monophosphate–responsive element-binding protein [CREB], and others),[71,87] and immediate early-response genes including *c-fos*,[88] leading to increased expression of *Per1* and, after a delay, *Per2*.[89,90] The protein products of these genes represent state variables of the molecular oscillator, such that alterations in their transcription levels, when superimposed on the ongoing circadian transcription cycle, correspond functionally to phase shifts of the oscillator (Figure 34-4).

In addition to glutamate, RHT terminals release two identified peptide cotransmitters, substance P (SP) and pituitary adenyl cyclase–activating peptide (PACAP). SP appears to play an important role in RHT transmission because selective SP antagonists block light-induced phase shifting and early-response gene expression in vivo,[91-93] as well as glutamate receptor–mediated phase shifting in vitro.[94] By itself, SP can mimic at least one component of the photic phase-response curve (phase delays during early subjective night) both in vivo and in vitro.[95] Supporting its putative role of a modulatory cotransmitter, the phase-shifting effects of SP appear to depend on SP-evoked glutamate release, and they can be blocked by the NMDA antagonist, MK-801.[94] In contrast, PACAP administration has been reported to either antagonize or mimic the effects of glutamate on circadian phase shifting and *Per* gene expression in vitro, depending on dose and on circadian phase of administration.[96-98] Specifically, when administered at relatively high doses, PACAP blocks the effects of glutamate during subjective night and evokes phase advances during subjective day, but when administered at much lower doses, PACAP actually mimics or potentiates the effects of glutamate on the SCN pacemaker.

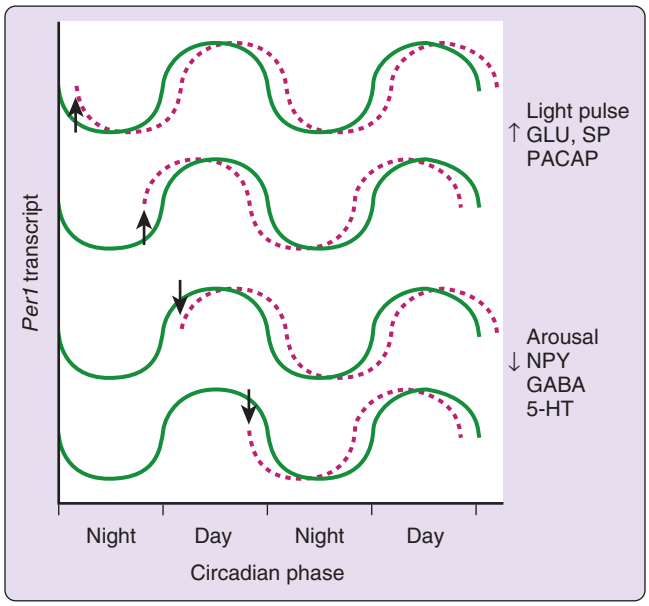

Figure 34-4 A simple qualitative-molecular model for circadian phase shifting by photic and nonphotic signals, and for their mutually antagonistic interaction. In this "phase-only" model, amplitude is fixed and the underlying state variable (here, *Per1* transcript level) can oscillate only within predetermined upper and lower bounds, such that the *Per1* level represents the phase of the molecular oscillator. During the subjective night, *Per1* levels are relatively low (*solid line*), and light pulses (or corresponding neurotransmitters or intracellular messengers) induce an abrupt increase in transcript level (*arrow*). Early in the night, when *Per1* levels are normally decreasing, this increase in transcription essentially forces the oscillator to repeat part of its normal trajectory and is thus equivalent to resetting the oscillator to an earlier phase, resulting in a permanent phase delay (*dashed line*). In contrast, late in the night, *Per1* levels are normally increasing, such that a light-induced increase in transcription forces the oscillator to omit part of its normal trajectory, equivalent to resetting the oscillator to a later phase and resulting in a permanent phase advance. Opposite to light pulses, arousal-related signals (or corresponding neurotransmitters or intracellular messengers) induce abrupt decreases in *Per1* transcription, resulting in phase delays during early subjective day and phase advances during late subjective day. Thus the model predicts that photic and nonphotic phase-response curves (PRCs) should have essentially identical shapes but should be phase-displaced by 180 degrees (12 circadian hours) along the horizontal axis; these predictions are at least roughly consistent with experimental observations.[98] Further, this model accounts for the general insensitivity of the circadian pacemaker to photic phase shifting during midsubjective day and to nonphotic phase shifting during midsubjective night: Because the underlying state variable can vary only within a predetermined range, stimuli that increase *Per1* transcription are ineffective when transcript levels are already maximal, and stimuli that decrease *Per1* transcription are ineffective when transcript levels are already minimal. Nevertheless, despite these periods of insensitivity, nonphotic signals would remain capable of counteracting light-evoked increases in transcription, and photic signals would remain capable of counteracting arousal-evoked decreases in transcription. Finally, the exact waveform and phasing of the photic and nonphotic PRCs would obviously depend on the exact waveform and phasing of the underlying spontaneous transcription cycle, here presented arbitrarily as two interlocking circular arcs centered over midsubjective day and midsubjective night. GABA, Gamma-aminobutyric acid; GLU, glutamate; 5-HT, 5-hydroxytryptamine (serotonin); PACAP, pituitary adenyl cyclase–activating peptide; SP, substance P; NPY, neuropeptide Y.

Other Functional Inputs to the Circadian Clock

An additional major SCN afferent system arises from the IGL, a distinct retinorecipient region of the lateral geniculate complex, intercalated between the dorsal and ventral lateral geniculate nucleus.[99-101] The projection from the IGL to the SCN is referred to as the *geniculohypothalamic tract* (GHT), and GHT neurons release both neuropeptide Y and GABA (see Figure 34-3). Retinal signals are conveyed to the IGL in part by axon collaterals of RHT neurons,[102] and GHT and RHT terminal fields are largely coextensive within the SCN core. It is therefore not surprising that early functional studies emphasized the possible role of the IGL/GHT system in providing a secondary, indirect pathway for photic entrainment of the circadian pacemaker.[100,101] Although lesion studies establish that the IGL is clearly not necessary for photic entrainment, lesions of the IGL/GHT system result in subtle modifications in the ability of light signals to effect phase and period control of the circadian clock.[101] Further, the IGL may have a significant role in entrainment under more naturalistic lighting conditions (e.g., regimens including twilight transitions, seasonally changing photoperiod, or

simulated moonlight), relative to the square-wave light-dark cycles commonly employed in the laboratory.[103,104] In addition to providing a secondary, indirect source of photic signaling to the circadian clock, the IGL also plays a preeminent role in the nonphotic regulation of the circadian system by arousal-related stimuli. Thus IGL lesions abolish the phase-shifting effects of novelty-induced wheel running[105,106] and benzodiazepine administration in hamsters,[107-109] as well as the period-shortening effect of running-wheel access in rats[110] and the entrainment effect of scheduled daily treadmill activity in mice.[111] More recently, evidence has been presented that IGL neurons may be sensitive to metabolic signals and that the GHT may mediate the effects of such signals on the SCN pacemaker.[112,113] This suggestion is of particular interest given the well-known role of neuropeptide Y (NPY) in integrating metabolic and appetite-related signals within other hypothalamic circuits.

Another major SCN afferent system converging mainly on the SCN core originates from the serotonergic midbrain raphe, especially the median raphe nucleus.[114,115] In addition, ascending serotonergic projections originating in the dorsal raphe nucleus innervate the IGL, providing a second potential route for serotonergic regulation of the SCN circadian pacemaker (see Figure 34-3). Extensive evidence has implicated serotonergic projections to the SCN (and IGL) in two distinct functions: (1) modulation of photic effects on the circadian pacemaker during the subjective night,[116] and (2) mediation of nonphotic effects on the pacemaker during subjective day.[117] Thus serotonin depletion potentiates photic phase shifting and impairs the response to nonphotic phase-shifting stimuli.[118,119] Conversely, electrical stimulation of the serotonergic raphe and systemic or intra-SCN administration of serotonergic agonists inhibits photic phase shifting during subjective night and evokes nonphotic phase shifting during subjective day.[120-123] These effects appear to be mediated in part through 5-hydroxytryptamine 1A (5-HT_{1A}) and $5HT_7$ receptors, and studies employing direct intracerebral administration of the serotonin 5-$HT_{1A/7}$ receptor agonist 8-OH-DPAT [8-hydroxy-2-(di-*N*-propylamino)tetralin] have identified several potential loci within the circadian system for these effects, including the SCN, the IGL, and the median and dorsal raphe nuclei.[122,123] Nevertheless, the ability of direct serotonin application to the in vitro SCN to evoke circadian phase shifts indicates that stimulation of intra-SCN serotonin receptors is sufficient to phase-shift the pacemaker.[124] In addition, serotonin inhibits light-induced phase-shifting through $5HT_{1B}$ receptors located presynaptically on RHT terminals.[125,126] Whereas light itself has little or no phase-shifting effect during midsubjective day, light at this phase can block the phase-shifting effects of a serotonin agonist,[127] indicating that serotonergic (nonphotic) and photic (glutamatergic) inputs to the SCN are mutually inhibitory.

Because the phase-shifting effects evoked by serotonergic stimulation closely resemble those seen with other nonphotic phase-shifting stimuli, including novelty-induced activity, sleep deprivation, and benzodiazepine and NPY administration, several studies have directly examined the potential role of serotonergic afferents to the SCN and IGL in mediating the effects of behavioral state on the circadian pacemaker. Thus arousal, wakefulness, and motor activity are all associated with increased forebrain serotonin release,[128-130] and serotonin content in the rat SCN is correlated positively with spontaneous activity level and negatively with free-running period.[131] Indeed, state-dependent variations in serotonin release appear to mediate (1) phase-shifting by activity or sleep deprivation,[129] (2) the effects of activity level on free-running period,[130] (3) entrainment by scheduled daily treadmill activity[111] and restricted daily running wheel access,[132] and (4) activity-dependent inhibition of photic phase shifting.[133]

Several other chemically identified pathways provide afferent inputs to the circadian system, including noradrenergic projections from the locus coeruleus, cholinergic projections from the basal forebrain and pontine tegmentum, and histaminergic projections from the posterior hypothalamus.[1] In addition, noradrenergic and cholinergic projections both innervate the IGL, providing an alternate pathway by which these transmitter systems could alter SCN circadian pacemaker function. Unlike the retinal, geniculate, and raphe projections described previously, which generally form overlapping terminal fields in the SCN core, these afferents target preferentially the SCN shell (see Figure 34-2).[55,56] Although SCN shell afferents are less studied than the SCN core afferents, sufficient data exist to suggest that these SCN shell afferents also contribute to circadian pacemaker regulation.[1] Finally, a recent review concludes that the "extended circadian rhythm system" includes direct monosynaptic projections to the SCN from at least 35 distinct brain areas,[58] revealing enormous potential for pacemaker modulation by a wide range of effective stimuli.

Suprachiasmatic Nucleus Output Pathways

Given the physiologic and behavioral ubiquity of circadian rhythmicity, it may be somewhat surprising that first-order SCN efferents innervate a relatively small number of target areas. On the other hand, these targets, concentrated mainly in the diencephalon and basal forebrain, include well-established relays to the autonomic and neuroendocrine systems, as well as to structures regulating affective, sensory, and motor processes.[134,135] SCN efferents emerge from both the core and shell subnuclei and release a number of neurotransmitters and peptides, including GABA, glutamate, and vasopressin. Remarkably, anatomically distinct populations of SCN neurons appear to innervate specific efferent targets, providing multiple waves of neuronal signals that regulate circadian phase in a target-specific manner.[136]

In addition to neuronal efferents, the SCN appears to regulate at least certain rhythmic processes through diffusible paracrine signals. The presence of a diffusible SCN output signal was first suggested by the finding that complete surgical isolation of the SCN within a "hypothalamic island" abolished SCN-dependent neuroendocrine responses but allowed for persisting locomotor activity rhythms in the same animals.[136] Although this surprising finding stood in conflict with prior studies suggesting that the ability of SCN transplants to restore rhythmicity in SCN-lesioned hosts depends on anatomic integration with the host brain,[137-139] evidence that transplantation of SCN tissue encapsulated within semipermeable capsules could restore locomotor rhythms provided strong confirmation of the paracrine hypothesis.[140] Several diffusible candidate molecules have now been implicated as circadian output signals, including prokineticin-2, tumor necrosis factor-α, and vasopressin.[136]

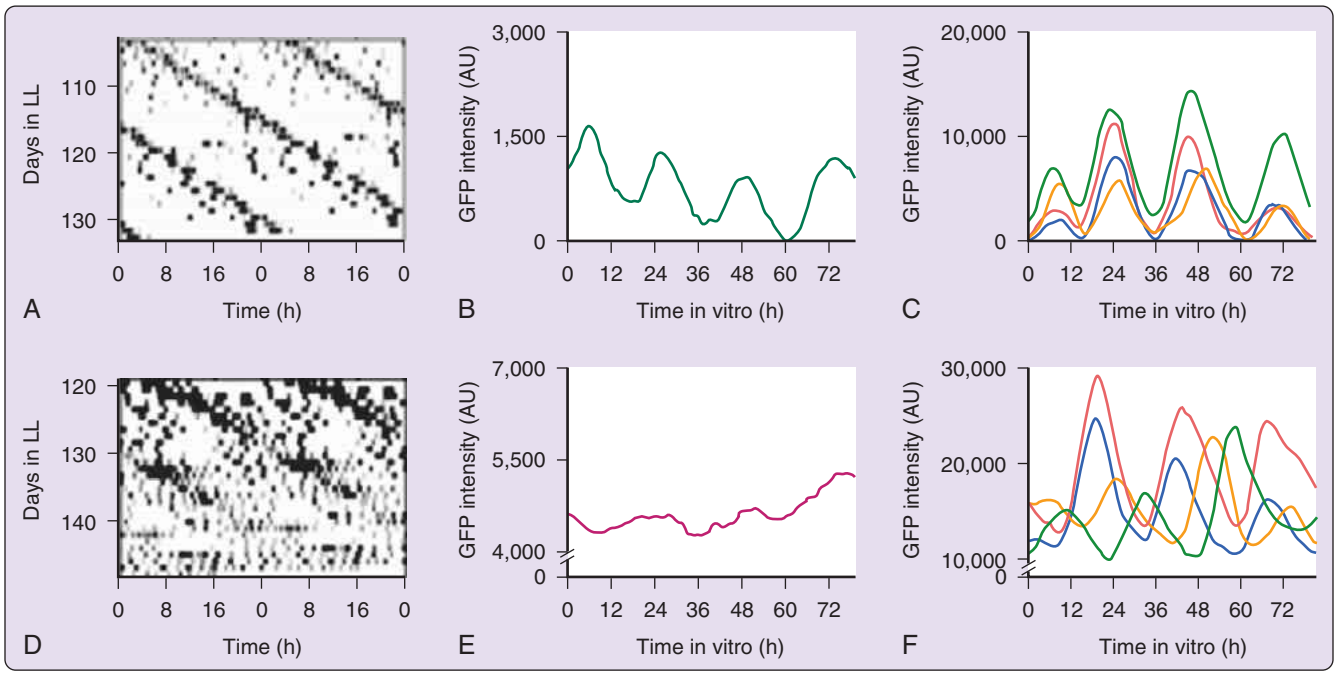

Figure 34-5 Relationship between rhythmicity at the behavioral (**A, D**), tissue (**B, E**), and cellular (**C, F**) levels. These experiments used *Per1:GFP* transgenic mice in which green fluorescent protein (GFP) serves as a real-time optical reporter of *Per1* gene expression, measured by fluorescent emissions and expressed in arbitrary units (AU) of intensity. When maintained in long-term constant light (LL), some animals sustain persisting, coherent rhythmicity at the behavioral level (e.g., **A**). When SCN tissue is cultured from such animals, robust gene expression rhythms are seen at both the whole-SCN (**B**) and individual neuronal (**C**) levels. In contrast, animals that become arrhythmic at the behavioral level (e.g., **D**) also fail to express coherent rhythmicity at the tissue level (**E**). Nevertheless, individual SCN neurons in such cultures continue to show robust gene expression rhythms but fail to show the normal intercellular synchrony as seen in rhythmic animals (**F**). Thus maintenance of normal coupling relationships among potentially autonomous cellular oscillators is essential for the display of coherent rhythmicity at the behavioral and physiological levels. (From Ohta H, Yamazaki S, McMahon DG. Constant light desynchronizes mammalian clock neurons. *Nat Neurosci* 2005;8:267–9.)

MULTIPLE-OSCILLATOR NATURE OF THE CIRCADIAN SYSTEM

The evidence reviewed previously (and in other chapters in this volume) amply demonstrates the critical role of the SCN in circadian regulation and justifies the use of the term *pacemaker* to describe its function. Nevertheless, the circadian system is now known to comprise a multiplicity of circadian oscillators that are distributed throughout the brain and body. As reviewed previously,[141,142] many behavioral and physiologic studies conducted in the premolecular era revealed that circadian systems exhibit several varieties of complex dissociations among multiple rhythmic subcomponents. For example, two or more discrete daily activity epochs may emerge from the single, normally consolidated activity period, a phenomenon known as *splitting*.[143,144] Such phenomena at the behavioral and endocrine level strongly imply the existence of an underlying multioscillatory neurobiologic circadian system. Nevertheless, interest in these complex phenomena was deprioritized for several years, coincident with the ongoing maturation of molecular analyses of the pacemaker mechanism, which focused largely on the SCN (or similar pacemaker-like structures in nonmammalian animals). It is probably fitting, then, that these same molecular approaches, and especially the finding that mammalian clock genes are expressed not only in the SCN but also in other brain regions[145,146] and in many peripheral tissues,[147-149] have spurred renewed interest in the identification and functions of multiple circadian oscillators and how they are organized into an anatomically distributed circadian timing system.

Within the SCN pacemaker, the observation that individual SCN neurons can express cell-autonomous rhythmicity in both molecular and physiologic processes[6-10] demonstrates that the pacemaker is itself composed of numerous, potentially autonomous but normally coupled, cellular circadian oscillators.[26] Further, the appearance of circadian desynchrony at the behavioral level may reflect robustly persisting but uncoupled rhythmicity at the neuronal level[150] (Figure 34-5). SCN cellular oscillators may also form functionally specific multicellular assemblies. For example, spontaneous or forced splitting of circadian activity rhythms into two distinct daily bouts is associated with splitting of SCN neurons into distinct neuronal populations with firing rhythms peaking in antiphase.[151,152] These two functionally distinct neuronal populations are likely to be associated with Pittendrigh's "morning" and "evening" oscillators. In addition, the clock genes *Per1* and *Per2* exhibit a significant degree of functional specialization within the SCN,[153,154] and according to one hypothesis *Per1* and *Per2*

represent state variables of morning and evening oscillators, respectively.[155,156] An important ongoing challenge for circadian biologists is to continue the integration of modern insights into the cellular and molecular nature of the circadian clock with the earlier and equally important era of the field when many of the formal properties and basic principles underlying circadian organization were initially defined.[157,158]

Outside the SCN, recent evidence suggests that several non-SCN neural and neuroendocrine tissues are capable of expressing autonomous (although generally highly damped) circadian oscillations.[146] The first demonstration of autonomous, self-sustained circadian rhythmicity in non-SCN mammalian neural tissue was the finding that cultured hamster retinae display persisting circadian rhythmicity in melatonin secretion.[159] More recently, real-time optical monitoring of *Per* gene (or protein) expression has been employed to demonstrate autonomous tissue-level and cellular-level rhythmicity in non-SCN neural tissue, including the retina,[160] as well as in a wide variety of nonneural tissues collected from *Per-luciferase* or *Per-GFP* transgenic reporter mice.[145-149] Within the central nervous system, such studies have revealed self-sustaining gene expression rhythms in the SCN, neuroendocrine tissues (pineal, pituitary), diencephalic nuclei (e.g., hypothalamic arcuate and paraventricular nuclei, thalamic paraventricular nucleus), and olfactory bulbs. Indeed, an impressive series of experiments have revealed that the olfactory bulb contains a self-sustained circadian clock that is normally entrained by the SCN and that regulates circadian rhythmicity in the functional sensitivity of the olfactory system.[161] Although the relationships between these extra-SCN neural oscillators and the SCN pacemaker have not been fully elucidated, it appears that at least certain types of behavioral rhythm splitting may involve dissociations between intra-SCN and extra-SCN central clocks.[162]

Similar techniques have also been used to reveal rhythmic *Per* expression in a wide variety of peripheral cells and tissues, including liver, lung, kidney, skin, skeletal muscle, heart, and fibroblasts.[147-149,163] The initial studies generally found these peripheral oscillators to be highly damped and dependent on periodic input from the SCN for their continuous expression. In contrast, however, use of a real-time reporter of PER2 protein levels[149] reveals that circadian oscillations in cultured peripheral tissues can in fact persist for many cycles (Figure 34-6). Nevertheless, these tissue-level rhythms depend on

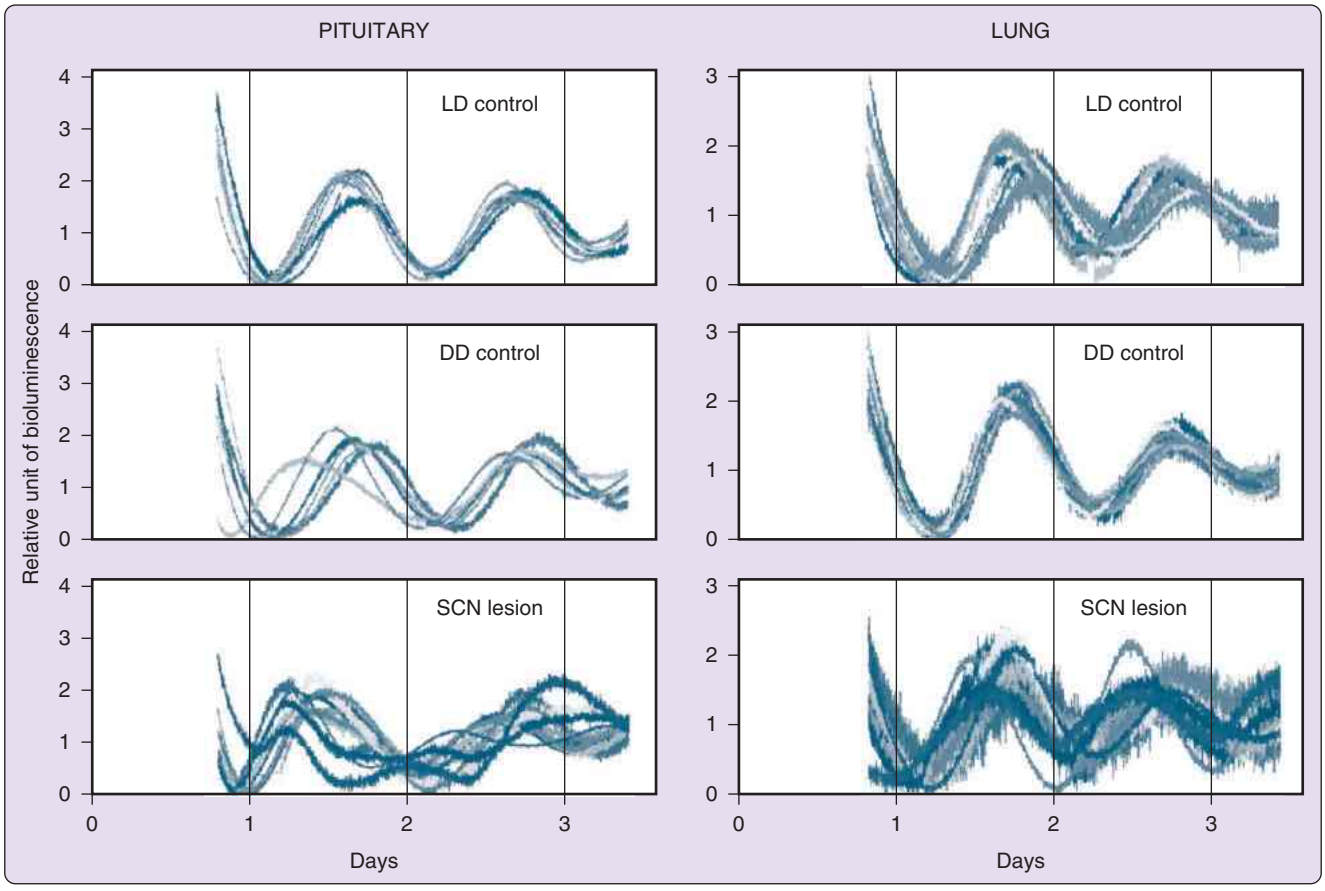

Figure 34-6 Superimposed plots of bioluminescent data from pituitary and lung tissues from individual animals that were intact and maintained on a light-dark cycle (LD controls) or in constant darkness (DD controls), as well as from suprachiasmatic nucleus (SCN)-lesioned animals. The tissue was maintained in vitro and made use of a Period2:Luciferase fusion protein as a real-time reporter of circadian dynamics. The first three cycles in culture are represented; each animal's record is a different shade. Although tissues collected from individual animals on an LD cycle, and relative to activity onset in DD control animals, were in phase with one another, phase desynchronization is evident in individual records of the SCN-lesioned animals for both tissues. (From Yoo SH, Yamazaki S, Lowrey PL, et al. PERIOD2:LUCIFERASE real-time reporting of circadian dynamics reveals persistent circadian oscillations in mouse peripheral tissues. *Proc Natl Acad Sci U S A* 2004;101:5339–46. Copyright [2004] National Academy of Sciences, U.S.A.)

SCN signals for maintaining proper phase relationships among tissue-level clocks[149] Further, as is also true for SCN neurons (see Figure 34-5), apparent damping at the tissue level may obscure robust, persisting rhythmicity at the cellular level.[163] Thus, even if not dependent on the SCN for their sustainability, SCN signals may serve to maintain temporal synchrony among multiple tissues or multiple cells from a given tissue.[150,164,165] Self-sustaining peripheral oscillators may also dissociate from the SCN pacemaker even in intact animals when exposed to certain environmental conditions, such as after light-dark cycle phase shifts (i.e., simulated jet lag)[166] or during restricted feeding schedules, which entrain peripheral but not SCN *Per* gene oscillations.[167] These observations indicate that the SCN pacemaker normally serves to entrain both central and peripheral secondary oscillations generated by a broadly distributed population of autonomous cellular oscillators, but that under certain conditions, these downstream oscillators are capable of adaptive (and possible maladaptive) disengagement from SCN control (Figure 34-7).

With the provocative title, "Circadian lessons from peripheral clocks: Is the time of the mammalian pacemaker up?" Brandstaetter suggested that the elucidation of peripheral circadian clocks might require "the hypothalamic SCN of a rodent . . . to resign from its major function."[168] Nevertheless, to paraphrase the American humorist, Mark Twain, we maintain that it is premature to announce the passing of the SCN pacemaker. For years before the identification of peripheral molecular clocks, the circadian research community speculated that the circadian pacemaker might regulate downstream "slave oscillators." Although it is now clear that many cells, tissues, and organs can produce autonomous circadian rhythms using similar molecular clock machinery as expressed in SCN cells in the absence of the SCN, this does not mean these downstream oscillators are normally *independent* of the SCN. Indeed, what is emerging in the field is the hypothesis that the SCN is still—as we write in late 2014—the "master oscillator" or pacemaker, regulating all (or nearly all) circadian rhythms, whether directly or indirectly. Rhythms are regulated directly when circadian information in the form of neural or neuroendocrine signals from the SCN directly imposes circadian timing on the neural and physiologic systems regulating a particular functional output. However, "indirect" control is also important, as, for example, when the SCN's direct control of behavioral rhythms (e.g., feeding, sleep-wake state, body temperature) alters an organism's metabolic, endocrine, or physiologic processes, which in turn control (entrain) other rhythms. In animals, a broad network of direct and indirect controls ensures that the SCN and other central and peripheral oscillators maintain specific phase relationships, resulting in the overall temporal coordination of the system.

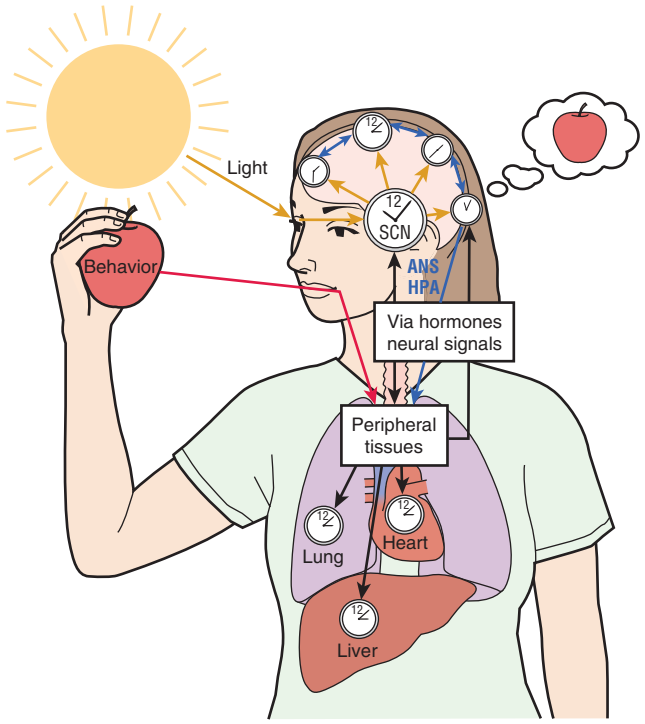

Figure 34-7 The multioscillatory circadian timing system includes a large number of autonomously rhythmic circadian clock cells distributed within both central and peripheral tissues. Molecular feedback loops drive circadian rhythms in gene expression and other cellular processes within individual clock cells (see Figure 34-1); these molecular loops are based on similar, but not necessarily identical, genes and proteins in different tissues. The circadian pacemaker resides in the SCN and is entrained by light-dark cycles and other environmental stimuli. Cellular oscillators within SCN neurons are characterized by relatively strong intercellular coupling, which maintains phase synchrony among individual cells and underlies robustly self-sustaining rhythmicity at the tissue level. Nevertheless, under certain conditions (e.g., constant light), these coupling relationships may be sufficiently weakened such that coherent rhythmicity is lost at the tissue (and behavioral) levels (see Figure 34-5). Cellular oscillators also underlie tissue-level rhythmicity in genomic and physiologic processes in other neural tissues as well as in many peripheral tissues and organs. In general, cellular oscillators outside the SCN appear to be less strongly coupled relative to those within the SCN and thus depend on rhythmic inputs from the SCN to maintain phase synchrony. In the absence of such input from the central SCN pacemaker, a loss of phase synchrony at the cellular level may be reflected in dampening of rhythmicity at the tissue level (see Figure 34-6). Together, SCN and non-SCN central neural oscillators result in rhythmic behavior (such as food intake and motor activity), autonomic nervous system (ANS) function, and hypothalamic-pituitary-adrenal (HPA) axis hormone secretion. These behavioral and physiologic rhythms in turn can give rise to other rhythmic signals (e.g., glucose availability, corticosterone levels, and body temperature) that serve to maintain phase synchrony among peripheral oscillators, probably in a tissue-specific manner. In turn, the activity of peripheral oscillators may give rise to rhythmic signals (e.g., peripheral hormones, autonomic afferents, and metabolic signals) that contribute to the synchronization of the SCN pacemaker and other central oscillators.

THE CIRCADIAN TIMING SYSTEM IN HEALTH AND DISEASE

This new picture of the circadian timing system has raised important questions about the potential adverse health effects that may be associated with a loss of normal synchronization between and among central and peripheral oscillations.[5,169-171] Thus circadian disruption at the molecular and systemic levels has been linked to sleep disorders, obesity and diabetes, heart disease, cancer, and psychiatric disorders. (See Chapters 39 and 40 for more complete discussion of the adverse health effects of disrupting the overall circadian temporal organization.) Indeed, the *Per2* gene appears to play an important role in suppression of mammalian tumorigenesis and may partially mediate the increased cancer risk seen in humans doing shift work and in mice subjected to experimental circadian disruption.[172,173] Given that approximately 5% to 10% of the entire genome is expressed rhythmically in any given tissue or organ,[174,175] many other mechanisms linking circadian synchrony and desynchrony to health and disease will undoubtedly emerge in the next few years.[176]

Although circadian dysregulation may be uncommon in natural animal populations, it certainly occurs quite often in humans, who can override their circadian clock and exert substantial volitional control over their sleep-wake cycles. Under such circumstances, abnormal phase relationships are expressed between sleep-wake behaviors (and other rhythmic processes tightly linked to sleep or wake states) and the circadian clock (and rhythmic processes tightly linked to it). Although the internal desynchronies that occur with jet lag and shift work may be the most dramatic, they are not the only examples of such desynchrony. Indeed, social constraints, work schedules, and the use of artificial lighting may result in the widespread occurrence of "social jet lag" even in people living under relatively stable entrained conditions.[177] Regardless of work or travel schedules, humans in our modern, around-the-clock society are certainly becoming less strictly diurnal, opposing millions of years of evolutionary selection.

CONCLUSIONS

The primary pacemaker for the mammalian circadian system is contained in the SCN, and the mechanisms underlying the pacemaker function of this structure are being elucidated rapidly at the molecular, cellular, and physiologic levels. The SCN contains a large number of normally coupled but potentially autonomous cellular oscillators that generate a circadian time base through the expression of a complex molecular feedback loop. The activity of the core molecular loop results in the circadian expression of a large number of clock-controlled genes, which in turn regulate coordinated circadian rhythms in the metabolism, electrical activity, and neurotransmitter and neuropeptide release of SCN neurons. These processes result in the transmission of circadian timing signals to both passive targets and inherently rhythmic downstream oscillators throughout the brain and periphery.

The core molecular loop is entrained by a number of convergent SCN afferent pathways. Photic signals are transmitted from a specialized set of photoreceptive retinal ganglion cells by a dedicated neural pathway (the RHT) to the SCN, and activity in this pathway results in the release of glutamate as well as multiple peptidergic cotransmitters. Other major SCN afferents arise from the IGL and raphe nuclei, which form terminal fields that largely overlap the RHT terminal field in the SCN core. These afferents serve to regulate photic signaling in the SCN during the subjective night and to mediate the phase-shifting effects of nonphotic stimuli, including behavioral activity and arousal, during the subjective day.

Two revolutionary developments in the circadian clock field—(1) the elucidation of the core molecular clock machinery and (2) the demonstration that most, if not all, tissues and organs can themselves generate the 24-hour molecular clock—have greatly stimulated biomedical research on the importance of internal circadian timing for health and disease. Thus it can be argued that we are at the beginning of a new era in understanding human health and disease. With hundreds and even thousands of genes oscillating in most, if not all, tissues and organs, under the control of both central and local self-sustained circadian oscillations, normal health and well-being undoubtedly depend on the maintenance of proper internal synchronization. Furthermore, internal synchronization (or desynchronization) can occur on two levels, between separate oscillating systems (i.e., among tissue-level clocks within the organism) and within each self-sustained system (i.e., among cellular clocks within individual tissues), and the balance between health and disease is likely to be highly dependent on proper synchrony at both levels.

CLINICAL PEARL

Most, if not all, mammalian organs, tissues, and cells contain the core molecular circadian clock machinery and can produce circadian rhythms in vitro. This greatly heightens the theoretical importance of internal synchronization for normal physiologic function. Abnormal circadian timing between and within tissue and organ systems could be just as important as the overproduction or underproduction of key cellular mediators to overall health. Internal temporal dysfunction may thus be at the root of many physical and mental diseases. Although jet lag and shift work have been the primary ways in which circadian desynchrony were thought to occur, it is probable that circadian desynchrony at the cellular, tissue, and behavioral levels may play much more widespread roles in human medical and psychiatric pathologies.

SUMMARY

The master pacemaker for the mammalian circadian system is contained within the SCN, and the mechanisms underlying the pacemaker function of this structure have been elucidated at the molecular, cellular, and physiologic levels. The SCN contains a large number of coupled cellular oscillators that generate rhythmicity through the expression of a complex molecular feedback loop. The activity of the core molecular loop ultimately regulates SCN electrical activity and neurotransmitter and neuropeptide release, resulting in the transmission of circadian timing signals to downstream oscillators throughout the brain and body. These peripheral oscillator cells also express the core molecular clock mechanism, and hundreds or even thousands of genes exhibit circadian expression patterns under the joint control of central and local circadian oscillations in any given tissue. Thus normal health and well-being depend on the maintenance of proper internal synchronization both within and between tissues throughout brain and body.

Chapter 35

Human Circadian Timing System and Sleep-Wake Regulation

Charles A. Czeisler; Orfeu M. Buxton

Chapter Highlights

- The circadian pacemaker (or biologic clock) confers endogenous rhythmicity with a period just slightly greater than 24 hours, persists in the absence of periodic changes in the external environment, and has timing or phase relative to the time of day that is genetically determined and influenced by environmental synchronizers.
- Under appropriate conditions, melatonin, body temperature, and many other physiologic processes can be used to assess circadian phase or biologic clock time.
- Although environmental light-dark schedules are the primary circadian synchronizer, other nonphotic stimuli such as exercise can shift circadian phase.
- The circadian pacemaker interacts with sleep-wake regulatory processes to influence many physiologic variables: hormone levels, autonomic nervous system activity, neurobehavioral performance, and the propensity for and timing and internal structure of sleep. Environmental, social, behavioral, and genetic factors, pharmacologic agents, and age influence most elements of this system.
- This chapter emphasizes for the benefit of the student and the practitioner the complexity of interactions of the circadian pacemaker and the sleep homeostat in regulating physiology, with important implications for health, performance, and clinical practice.

Circadian oscillations (or biologic clocks) are phylogenetically ubiquitous, found in species from prokaryotes to humans. Circadian clocks have several defining characteristics: endogenous rhythmicity that persists independent of periodic changes in the external environment, a near-24-hour period (*circadian* from Latin *circa* meaning "about" and *dies* meaning "day"), and the capacity for environmental input to modify or reset the timing or phase of the rhythm.[1,2] We provide an overview of the human circadian timing system and describe how this system interacts with sleep-wake regulatory processes to influence physiologic variables, including hormone levels, autonomic nervous system activity, neurobehavioral performance, and the propensity for, timing, and internal structure of sleep. We consider the influence of episodic and daily recurring behaviors, including sleep itself, on these physiologic variables relative to that of the endogenous circadian pacemaker.

IDENTIFYING THE MAMMALIAN CIRCADIAN PACEMAKER

In mammals, the suprachiasmatic nucleus (SCN) in the anterior hypothalamus is the central neural pacemaker of the circadian timing system. On the basis of careful patient histories characterized by disruptions of sleep-wake timing (e.g., insomnia, reversal of the sleep-wake schedule), Fulton and Bailey[3] postulated in 1929 that a region in the anterior hypothalamus appeared to regulate not the occurrence of sleep but its timing within the 24-hour day. In 1972, the SCN was identified as the site of the mammalian circadian pacemaker.[4,5] Physiologic studies show that multiple distributed circadian oscillators drive daily rhythms in peripheral systems.[6] Molecular research confirms the presence of peripheral clocks that use the same molecular machinery as the central circadian pacemaker in the SCN. Pacemakers like the SCN convey internal synchrony to these distributed oscillators.

INFLUENCE OF SLEEP AND CIRCADIAN RHYTHMS ON HUMAN PHYSIOLOGY

The discovery of the SCN's role as a central circadian pacemaker set the stage for understanding how it drives prominent circadian rhythms in a wide array of physiologic functions in humans synchronized to the 24-hour day and on a normal sleep-wake schedule (Figure 35-1, left column of panels).[7] Core body temperature is lowest and melatonin levels (not shown) are highest[8] during night sleep. Cortisol is low at habitual sleep onset but high at habitual morning wake time. When these endogenous circadian rhythms are entrained or synchronized to the 24-hour day, the temporal profile of each of these parameters exhibits a characteristic fingerprint that results from a combination of drives from the timing of the sleep-wake state to the endogenous circadian pacemaker and responses evoked by other factors such as posture, mood, exercise, and environmental lighting.[8]

To characterize the circadian pacemaker–driven component of a diurnal temporal profile from the effects of sleep-wake state, behavior, posture, and periodic environmental

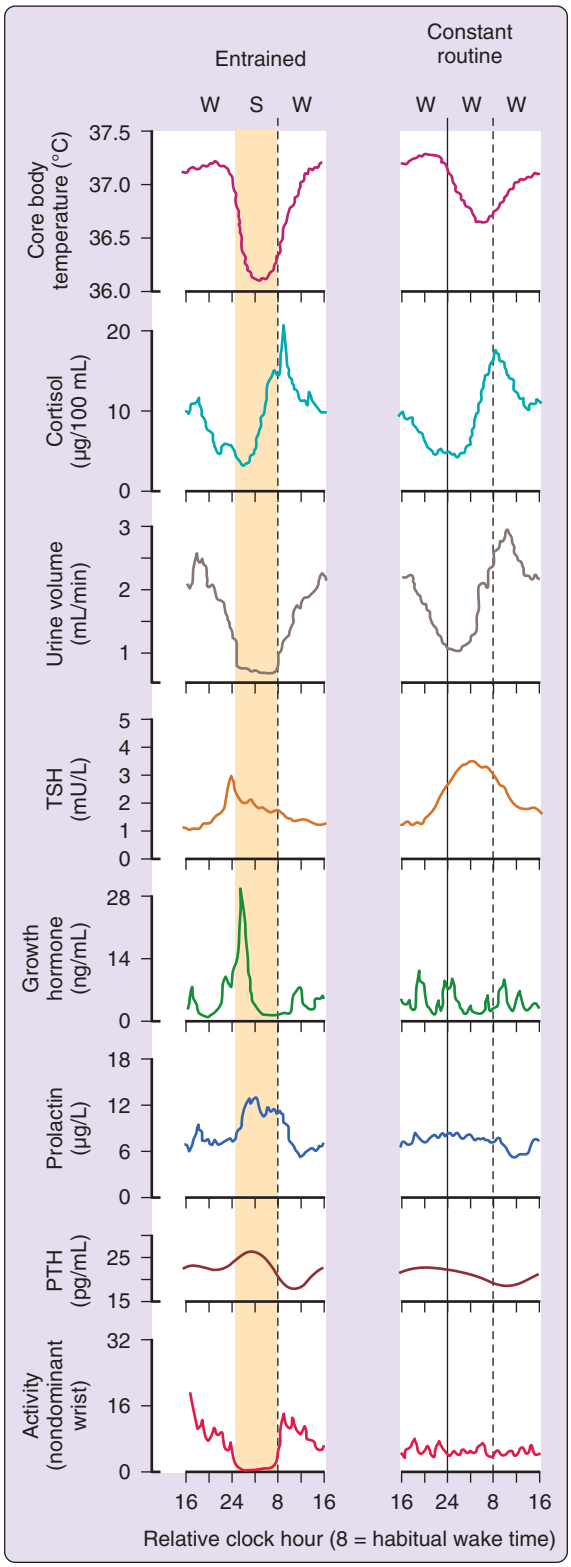

Figure 35-1 Comparison of temporal profiles of an array of physiologic and behavioral variables from participants studied under baseline conditions while maintaining a regular schedule of nocturnal sleep (S) (*yellow shaded area*) and daytime wake (W) at their habitual times (*left column of panels*) compared with profiles from participants under constant-routine conditions while maintaining a schedule of continuous wake in a semirecumbent posture (*right column of panels*). The *vertical dashed line* indicates habitual wake-up time during the week before the study, when participants were required to maintain a regular sleep-wake schedule. All data are from normal young men, 18 to 30 years old, studied under similar conditions. For a given variable, data in the *left panel* are from the same participants as data in the *right panel*; however, not all variables were monitored in the same participants. stimuli, the constant-routine protocol originally proposed by Mills and colleagues has been extended[9]; participants typically undergo continuous enforced wakefulness throughout day and night in a constant posture at a constant level of minimal physical activity and in constant, relatively dim, ambient illumination.[10] Under such conditions, the temporal profiles of many physiologic variables are significantly altered, and the components of these rhythms that are driven by the endogenous circadian pacemaker can be separated from those that reflect changes in the sleep-wake state, posture, or periodic external environment. Given the influence of posture[11] and the minimal influence of sleep[12] on the endogenous circadian melatonin rhythm, we have sometimes used a constant posture protocol in which participants are maintained in a constant semirecumbent posture in constant dim light but are allowed to sleep at night, so that endogenous circadian melatonin phase can be assessed.

Body temperature declines during sleep,[13-15] as illustrated by the profile of core body temperature recorded during a normal sleep-wake schedule and on a constant routine (see Figure 35-1, right column of panels). Sleep and changes in posture, light intensity, and activity level generate a drop in body temperature relative to wake.[6,15-19] This sleep episode–induced drop in body temperature combines with the circadian-driven decline in body temperature during the biologic night to yield a larger apparent amplitude than that of the endogenous circadian component alone (as measured on constant routine). Urine volume exhibits a robust oscillation under constant-routine conditions that is also influenced by sleep-wake state.[20]

Rhythmicity in some variables appears nearly independent of sleep-wake state. The temporal pattern of the hormone melatonin is relatively unchanged whether a participant is asleep or awake all night on a constant routine, although significant age-dependent effects of sleep and sleep deprivation on melatonin amplitude have been quantified.[12] Posture is reported to influence circulating melatonin concentrations somewhat.[11] Because the endogenous circadian cortisol rhythm is usually at its nadir at the time of habitual sleep onset, the overall profile of cortisol is relatively unchanged whether a person sleeps on a habitual schedule or remains awake all night, although cortisol levels will be elevated if the

person continues to remain awake throughout the following afternoon and evening.[21] However, suppression of plasma cortisol concentrations by deep slow wave sleep is evident whenever sleep onset occurs at the crest of the cortisol rhythm rather than at the nadir.[22]

Several other hormones are sensitive to sleep-wake state. Sleep opposes the circadian rhythm regulating thyroid-stimulating hormone (TSH), inhibiting TSH release during the peak of the endogenous circadian TSH rhythm, which would otherwise occur in the middle of the night.[23-25] Under entrained conditions, nocturnal TSH secretion is blunted by the timing of sleep, such that TSH levels are highest just before sleep onset and continue to be suppressed during the remainder of the sleep episode. This inhibitory effect of sleep on TSH secretion has been closely associated with slow wave sleep[26] and with relative delta power in the sleep electroencephalogram (EEG).[27] Growth hormone, prolactin, and parathyroid hormone levels all show a prominent sleep-dependent increase.[25] For growth hormone, a major sleep-related secretory episode is associated with slow wave sleep[28] and with relative delta power of the sleep EEG,[29] although such associations for prolactin, which remains elevated throughout the sleep episode, are controversial.[30] Interestingly, growth hormone levels blunted by acute sleep deprivation at night are increased during wakefulness the following day in sleep-deprived participants, compensating for the blunting of the major sleep-related pulse, such that average 24-hour levels are similar.[31] After sleep restricted to 4 hours per night from 1:00 to 5:00 AM for 1 week, growth hormone levels were maintained by the combination of a presleep, circadian-related secretory episode, together with a somewhat diminished sleep-related response.[32]

Leptin levels exhibit circadian rhythmicity, although the typical day-night pattern is reflected in the interaction of circadian rhythmicity with energy intake and expenditure[33] and sleep duration.[34] Ghrelin levels exhibit a day-night variation related to energy intake related to the presence of sleep[35] and to sleep duration.[36]

Ultradian variations in the release of renin from the kidney—a key factor in blood pressure control—are closely linked to the timing of the rapid eye movement (REM) and non–REM (NREM) sleep cycle,[37] an association evident even among patients with disturbed sleep, whose plasma renin profiles reflect pathologic changes in sleep structure. Increased relative delta power in the sleep EEG is associated with increased levels of plasma renin activity, whereas decreased slow wave activity is associated with a decrease.[38]

Even in the absence of sleep, prolactin and parathyroid hormone also have an endogenous circadian component that is lowest a few hours after habitual wake-up time,[25] and GH responses to exogenous growth hormone–releasing hormone exhibit a circadian rhythm.[39]

Effects of the interaction between sleep-dependent and circadian factors on these hormones can be important when the sleep-wake schedule is not synchronized with the circadian pacemaker. Shift workers who remain awake throughout the first night shift, for example, will secrete more TSH compared with that released at night under normal sleep-wake conditions during entrainment, owing to the absence of sleep-related suppression of TSH during the nocturnal peak of endogenous TSH secretory drive (see Figure 35-1); such increased secretion is not reversed during subsequent daytime sleep because the endogenous circadian rhythm of TSH secretion is already very low at that time. On the other hand, these workers would be deprived of their normally higher levels of growth hormone, prolactin, and parathyroid hormone during the waking night, although the sleep-related release of these hormones will recur during subsequent daytime sleep. Such alterations of the profiles of a variety of hormones have been documented in laboratory studies of night-shift workers.[40] In a laboratory simulation of circadian misalignment, participants exhibited increased leptin and increased glucose (despite increased insulin) and misalignment of the endogenous circadian rhythm of cortisol secretion with respect to the inverted sleep-wake schedule, along with the expected reduction in sleep efficiency.[41]

The circadian pacemaker significantly influences a variety of neurobehavioral and cognitive functions.[42-45] Under the conditions of the constant routine, participants display a circadian variation in short-term memory, cognitive performance, and alertness that is tightly coupled to the timing of the body temperature rhythm (Figure 35-2).[46] During a constant routine, these cognitive functions tend to be at their nadir shortly after habitual wake-up time due to an interaction between sleep loss and the circadian rhythms of performance.

EFFECTS OF LIGHT ON HUMAN CIRCADIAN RHYTHMS

The light-dark cycle is the primary environmental signal that synchronizes circadian systems in a wide array of species, including humans.[7,47] Nonvisual or non–image-forming retinal photoreception provides input to the circadian system, the pupillary light reflex, and other systems. Direct retinal input travels through the retinohypothalamic tract, a monosynaptic pathway by which information about the environmental light-dark cycle reaches the SCN. Postmortem studies reveal that the human brain contains the same key structural elements—the SCN and retinohypothalamic tract—as that of other mammals.[48] Neuropathologic studies associate damage to these structures with abnormalities in the timing of the sleep-wake cycle and other circadian rhythms.[49-51]

Studies in rodents and humans have shown that the three-cone system and rods, the visual photoreceptors, are not required for transmitting light signals to the circadian system.[7] A distinct set of ganglion cells in the inner retinal layer that project to the SCN are intrinsically photosensitive. Only the ganglion cells that project from retina to SCN selectively contain the vitamin A–based photopigment melanopsin.[52] Blue and short-wavelength green light (about 450 to 500 nm), which matches the sensitivity peak of melanopsin, is the most potent in shifting circadian phase in animals[53,54] and for melatonin suppression and phase-shifting responses in humans.[55] Both daytime and nighttime retinal exposure to such monochromatic blue (460 nm) light significantly improves reaction time, reduces attentional failures, and improves EEG correlates of alertness.[56] The magnitude and duration of the alerting effect of light at night depends on illuminance history and appears to be subject to sensitization and adaptation. The alerting response to light is greater and lasts longer when the light exposure occurred following prior exposure to dim light (1 lux) compared with ordinary indoor light (90 lux).[57] Within this specific set of intrinsically photosensitive retinal

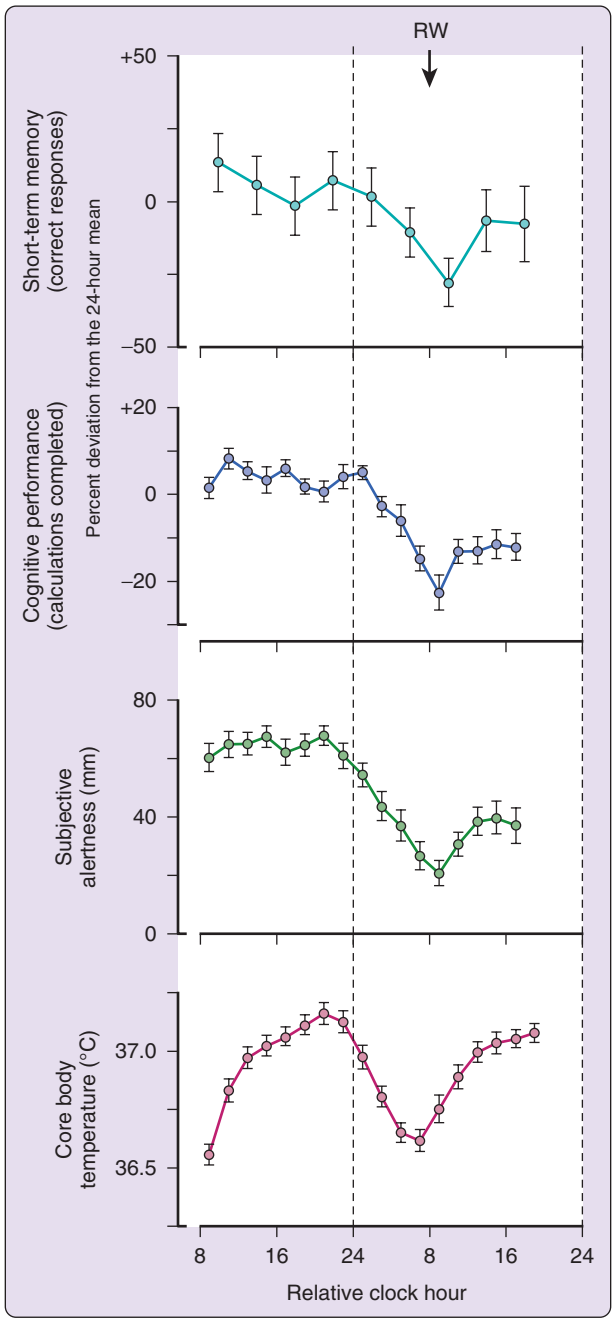

Figure 35-2 Daily patterns of short-term memory, cognitive performance, subjective alertness (mm), and core body temperature (°C) averaged across 18 participants during a 36-hour constant routine. Data collection times are normalized with respect to each participant's regular wakeup time (RW) (assigned a reference value of 8:00 AM and indicated by the *downward arrow*). The extent to which memory and performance scores deviated from the participant's 24-hour mean is averaged across participants. Data are expressed as percentages by which these absolute deviations differed from the participants' overall 24-hour mean score (assigned a reference value of zero). Each point is the centered mean (SEM) of all determinations made across a 2-hour interval for performance, alertness, and temperature and across a 4-hour interval for short-term memory. (Reproduced with permission from Johnson MP, Duffy JF, Dijk D-J, et al. Short-term memory, alertness and performance: a reappraisal of their relationship to body temperature. *J Sleep Res* 1992;1:24–9.)

ganglion cells, melanopsin is the active photopigment. Rods and cones that synapse onto melanopsin-containing ganglion cells also participate, creating redundancy in circadian photoreception.[58]

A neural output pathway of the SCN passes through the intermediolateral cell column of the upper thoracic spinal cord, to the superior cervical ganglion that provides sympathetic input into the pineal gland. The absence of melatonin in patients who have cervical spinal cord injury is due to disruptions of this neural pathway to the pineal gland[59] and is associated with decreased sleep efficiency.[60]

Photic Suppression of Melatonin Secretion

The neural pathway from the SCN to the pineal provides for the regulation of the pineal output of melatonin by the SCN, including inhibition of melatonin release by retinal light exposure through a retinohypothalamic pathway[61] that can be used as an assay for the functional input of light into the circadian system.[62,63]

Preservation of light-induced melatonin suppression in otherwise totally blind people suffering from severe damage to the outer retina[63,64] led to the discovery that a distinct visual system mediates photic entrainment.[65,66] The nocturnal increase in melatonin is illustrated in Figure 35-3 (upper panel) for a normally sighted participant on a constant routine.[63] During a second peak of melatonin on the next night, a bright light stimulus induced an acute suppression of melatonin levels, which returned to elevated nighttime levels after light exposure was terminated. In the lower panel, bright light still suppresses melatonin even in a totally blind participant with no conscious light perception and a negative electroretinogram. The loss of conscious light perception does not necessarily indicate the loss of photic input to the circadian timing system,[63] although that is the case in most blind individuals without light perception. Two distinct visual systems exist: one for visual perception and a separate non–image-forming visual system for synchronization of the circadian pacemaker in the SCN, alerting input to the sleep switch in the ventrolateral preoptic area, suppression of melatonin secretion, and mediation of the pupillary light reflex.[52,67] Even in visually blind individuals, non–image-forming photoreception through intrinsically photosensitive retinal ganglion cells can trigger some awareness for light, which stimulates higher cognitive brain activity, independent of vision and in the absence of functional impact from the rods and cones, and can engage supplemental brain areas to perform an ongoing cognitive process.[51,68]

In natural-light-only conditions, the internal circadian clock is synchronized to solar time with melatonin onset near sunset and melatonin offset before wake time and after sunrise, at a significantly earlier circadian phase.[69] In contrast, evening reading from an electronic tablet that emits short-wavelength–enriched visible light delays endogenous circadian melatonin phase and the timing of REM sleep and increases evening alertness, sleep latency, and morning sleepiness compared with reading a printed book.[70] Taken together, these findings suggest that artificial light between dusk and dawn alters physiology through the non–image-forming visual system by shifting circadian phase, inhibiting sleep-promoting neurons, activating arousal-promoting orexin neurons in the hypothalamus, and suppressing melatonin. These effects of nocturnal artificial light in turn mask sleepiness, transiently increase

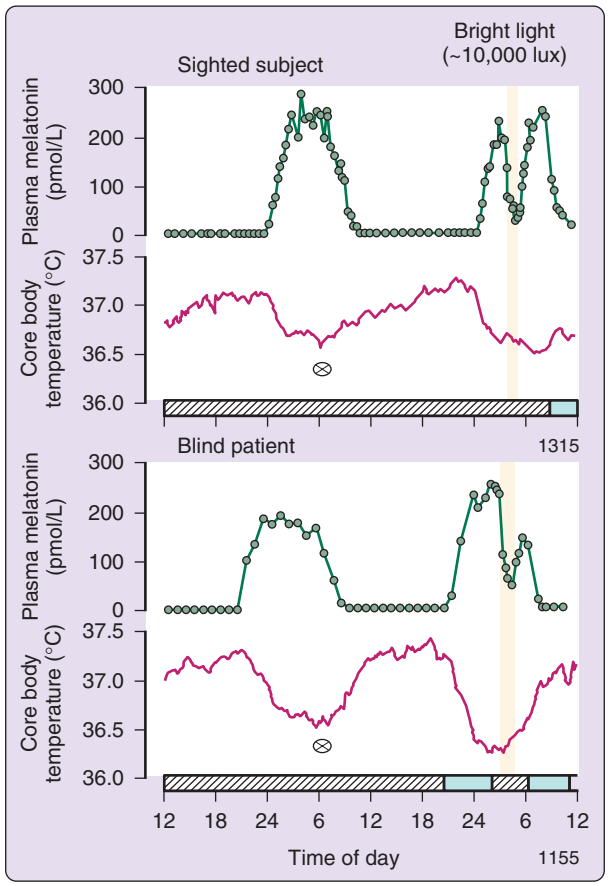

Figure 35-3 Melatonin-suppression test in a healthy sighted participant (*upper panel*) and a blind participant (*lower panel*). In each, plasma melatonin (*upper green traces*) and temperature (*lower red traces*) were measured repeatedly during a constant routine (*hatched bar*) and subsequent episode(s) of sleep (*solid blue bars*). The light intensity was ~10 to 15 lux during the constant routines, less than ~0.02 lux during the sleep episodes, and ~10,000 lux during 90 to 100 minutes of exposure to bright light (*open columns*) 22 to 23 hours after the initial fitted temperature minimum (*encircled Xs*). In both participants plasma melatonin concentrations decreased markedly in response to bright light and increased after the return to dim light. (Reproduced with permission from Czeisler CA, Shanahan TL, Klerman EB, et al. Suppression of melatonin secretion in some blind patients by exposure to bright light. *N Engl J Med* 1995;332:6–11.)

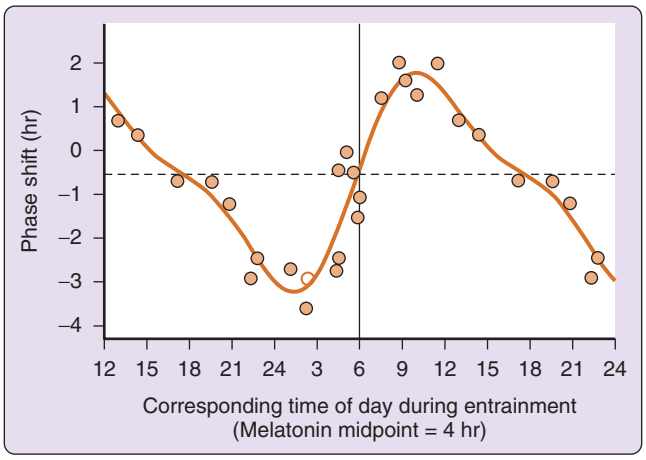

Figure 35-4 Phase-response curve to 6.7-hour light pulses in human participants. Phase shift in hours is plotted for a light pulse centered at different times relative to the initial endogenous circadian phase of the timing of melatonin secretion. By convention, phase advances to an earlier time are depicted as positive numbers, and phase delays as negative numbers. (Reproduced with permission from Khalsa SB, Jewett ME, Cajochen C, Czeisler CA. A phase response curve to single bright light pulses in human subjects. *J Physiol* 2003;549:945–52.)

alertness, and directly interfere with sleep, leading to chronic sleep deficiency.[71]

Human Phase-Response Curves to Light

In circadian biology, the phase-response curve (PRC) is used to characterize the synchronizing effects of light on a circadian pacemaker.[1,10,72,73] To construct a photic PRC, discrete light stimuli are applied systematically over the entire circadian cycle, and the magnitudes of light-induced phase shifts are plotted as a function of circadian phase at which the organism is exposed to the stimuli. In humans, measurement of the phase of endogenous circadian rhythms on a constant routine has been used to estimate both the initial circadian phase of the pacemaker before a stimulus and the final circadian phase after a stimulus, with the difference representing the phase shift.

All circadian systems exhibit a characteristic photic PRC, in which the largest light-induced phase shifts are generated in the biologic night. Phase delays are generated in response to light stimuli late in the biologic day and early in the biologic night, and phase advances are generated from stimuli in the late biologic night and early biologic day.[1] Figure 35-4 illustrates the PRC to a single pulse of light in humans. In humans, phase delays were observed in response to single, 1-hour and 6.7-hour bright light pulses applied before the minimum of the core body temperature cycle, which occurs on average about 2.3 hours before habitual wake-up time. Phase advances were observed when such light pulses were applied after the core body temperature nadir. The resultant human PRCs to single light pulses[74,75] exhibit the classic patterns of light PRCs in many organisms,[1,73] including phase advances and delays, and suggest that appropriate light intensities can shift the phase of the human pacemaker in morning and late afternoon or evening as well as at night. This has important clinical implications, such as use of phototherapy to reset circadian phase in delayed or advanced sleep phase disorder.

Photic Resetting of the Pineal Melatonin Rhythm

Because circadian rhythms are expressed in many physiologic and neurobehavioral variables, the phase of the pacemaker may be estimated by using any of these variables as a marker. In humans, the core body temperature rhythm is often a preferred marker of circadian phase, because it can accurately represent the underlying pacemaker's characteristics under certain conditions. However, melatonin can be an even more precise circadian marker,[76] which is less heavily influenced by sleep and posture.[77] In humans studied during a constant routine, melatonin reflects the phase of the underlying pacemaker following light-induced phase shifts better (less variability) than the endogenous component of the core body temperature rhythm.[77] Both rhythms shift equivalently whether to an earlier or a later hour.[76] Such studies demonstrate that the endogenous circadian melatonin rhythm can be reset to any desired phase within 2 to 3 days by light exposure.[76] Furthermore, photic stimuli designed to suppress the

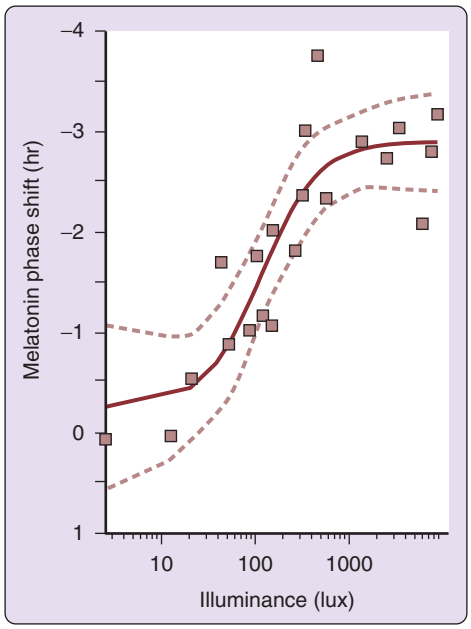

Figure 35-5 Illuminance-response curve of the phase-shifting effect of light on the human circadian pacemaker. Shifts in phase of the melatonin rhythm following the 6.5-hour light pulses, as assessed 1 day after the photic stimulus, are fit with a four-parameter logistic model, using a nonlinear least-squares analysis, that predicts an inflection point of the curve (i.e., sensitivity of the system) at ~120 lux; phase shifts saturate at ~550 lux. Data from individual participants represented by *closed boxes*, model by *solid line*, and 95% confidence intervals by *dashed lines*. (Modified with permission from Zeitzer JM, Dijk D-J, Kronauer RE, et al. Sensitivity of the human circadian pacemaker to nocturnal light: melatonin phase resetting and suppression. *J Physiol [Lond]* 2000;526:695–702.)

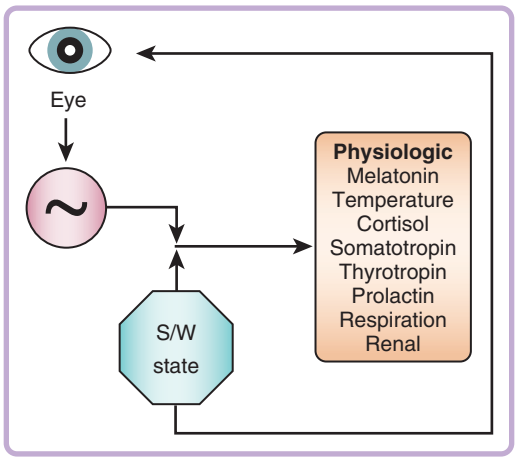

Figure 35-6 Schema illustrating influence of the circadian pacemaker (*circle with oscillator symbol*) and sleep-wake state (*octagon*) on several physiologic variables. Under normal conditions, the circadian pacemaker and sleep-wake state each influence these variables; relative contribution and nature of interaction (i.e., synergistic or oppositional) of each depends on the variable observed. Also illustrated are the influences of environmental illumination on the human circadian clock through the eye and of the sleep-wake state in determining timing of this illumination through behavioral action (i.e., switching off artificial indoor room lights, drawing bedroom window shades at bedtime, eyelid closure during sleep, and eyelid opening during waking).

amplitude of the endogenous circadian temperature cycle also suppress the amplitude of the endogenous circadian melatonin rhythm.[76]

The use of the melatonin rhythm as a circadian marker has additional practical advantages: melatonin in human saliva correlates well with that in plasma, and it allows the evaluation of circadian phase in patients with suspected circadian rhythm disorders or research participants relatively noninvasively.[78]

Human Dose-Response Curve to Circadian Phase-Resetting Effects of Light

In addition to dependence on wavelength and circadian phase, the degree of light-induced phase shift also depends on light stimulus intensity and consecutive days of exposure. Three consecutive daily pulses of light can generate a larger phase shift than a single light pulse. This intensity relationship also applies to brightness or illuminance level of light to which the retina is exposed. Following a 6.5-hour, single bright light stimulus of different intensities at a circadian phase known to generate a phase delay, an increase in resetting response is seen at 50 lux, with maximal slope at 100 lux and maximal shifts by about 550 lux (Figure 35-5).

The observation that ordinary room lighting of about 100 lux with only 1% of the intensity induces 50% of the resetting response to a 10,000 lux stimulus has important implications. We are exposed to bright light for a relatively short time each day,[79,80] but in modern industrialized societies we are exposed to ordinary indoor room light for many hours, a predominance of exposure that may have a greater impact on our circadian system than a few minutes of exposure to bright light. Phase-resetting and melatonin suppression responses to the resetting effects of evening light exposure are dose dependent and nonlinear; shorter light exposures (only 12 minutes long) more efficiently phase-shift the clock, suppress melatonin, and induce alertness than longer durations of retinal light exposure.[81]

Figure 35-6 illustrates the influence of the circadian pacemaker and the sleep-wake state on physiologic variables and the influence of light input through the eye to the circadian pacemaker. The feedback loop from the sleep-wake state to the eye represents the effects of exposure to the environmental light cycle because the sleeping state in humans is usually associated with eyelid closure and self-selected exposure to darkness, achieved by drawing window shades and switching off artificial light sources, whereas the waking state in humans is usually associated with opening of the eyelids and exposing the retina to light through self-selected use of artificial light or exposure to outdoor light during waking hours. Under a strict sleep-wake and light exposure schedule, the pacemaker's timing is consistent from day to day. However, whenever sleep is initiated late or terminated early, or a waking episode occurs within a sleep episode, the associated light exposure can reset the pacemaker. This association between waking and light exposure and the fact that low light intensity has a significant resetting effect on the pacemaker has practical relevance for routine sleep-wake scheduling and for understanding the influence of sleep disruption, which is often associated with light exposure, on circadian phase.

NONPHOTIC CIRCADIAN PHASE RESETTING AND REENTRAINMENT

Nonphotic input to the human circadian system is less well characterized than photic input. Results of early studies, which focused on social cues such as gong sounds or regularly

scheduled performance tests, meals, and bedtimes,[82] were confounded by limitations of phase measures used and self-selected lighting conditions. Exposure of healthy young men to nocturnal exercise of 1 to 3 hours' duration resulted in phase delays in nocturnal melatonin the following day.[83,84] Early evening 1-hour high-intensity exercise (at approximately 6:30 PM) elicited *phase advances* significantly different from the phase delays in response to morning, afternoon, and nocturnal exercise and in no-exercise participants (Figure 35-7). In a study of the facilitation of reentrainment to a delay-shifted sleep-wake episode in extremely dim light (to control for ambient light during exercise), exercise during the biologic night produced phase delays compared with no exercise.[84] Thus appropriately timed nonphotic stimuli such as exercise or other forms of arousal can facilitate adaptation to acute changes in light-dark cycle.

That appropriately timed exposure to exercise also results in phase advances is demonstrated by partial entrainment to a 23.5-hour light-dark and sleep-wake schedule in healthy volunteers exercising at moderate intensity twice daily (midday and late afternoon) over 2 weeks.[85] Participants exercising daily in late afternoon exhibited partial entrainment, advancing on average 10 minutes per day more than nonexercising controls, consistent with phase-advancing effects of late afternoon exercise on the human circadian clock. Given the slightly greater than 24-hour endogenous circadian period of humans and the net daily phase advance required for stable entrainment, evening exercise, particularly repeated daily

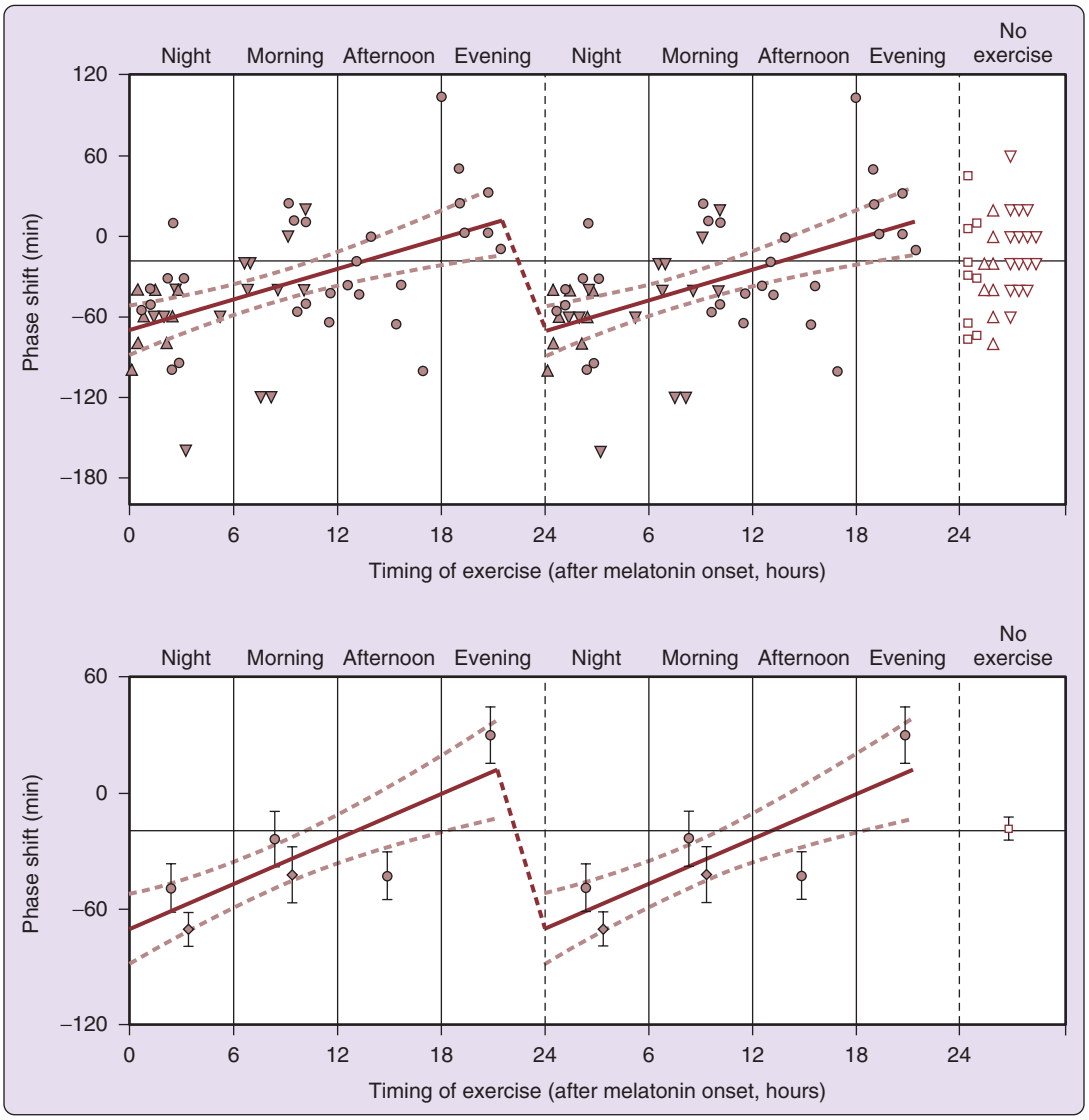

Figure 35-7 Phase-response curves in response to exercise at different circadian times of day. Phase delays were observed in response to nocturnal exercise; phase advances were observed in response to exercise during late afternoon or early evening. *Closed circles* indicate phase shifts in response to high-intensity, 1-hour nocturnal exercise and daytime exercise. *Upward* and *downward triangles* (*top panel*) and *diamonds* (*bottom panel*) indicate phase shifts in response to low-intensity, 3-hour exercise sessions. The *line* indicates a significant relationship between phase shifts and circadian time of exercise ($r^2 = 0.28$, $P = .0003$; slope significantly different from zero). *Dashed curves* indicate 95% confidence intervals of slope of line. Exercise elicits phase shifts and acute alterations of melatonin levels that vary with circadian phase. *Am J Physiol* 2003;284:R714–24. Copyright 2003 American Physiological Society.)

Figure 35-8 Professor Nathaniel Kleitman (*left*) attends to experimental equipment while fellow research participant Bruce Richardson lies in bed deep within Mammoth Cave in Kentucky where, for the first time, human participants were studied while shielded from periodic environmental changes on Earth's surface. The two pioneers lived on an imposed 28-hour sleep-wake schedule in these quarters from June 4 to July 6, 1938, in an effort to approximate uniform environmental and behavioral conditions, free from the influence of Earth's 24-hour day. In a 60-foot wide chamber free from any external environmental sounds, the temperature remained at 54°F (±1°), humidity approached complete vapor saturation, and darkness was absolute when the artificial light used during waking hours was shut off. The Mammoth Cave Hotel provided daily meals, which were consumed on awakening and after the 7th and 13th hour of each 19-hour waking day. (Photo courtesy of National Park Service, Mammoth Cave National Park, Mammoth, Kentucky; description adapted from Kleitman N. *Sleep and wakefulness*. Chicago: University of Chicago Press; 1963. p. 178–9.)

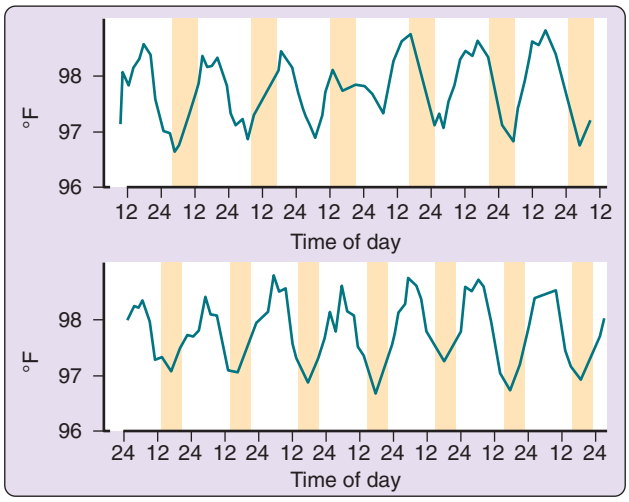

Figure 35-9 Weekly body temperature rhythms of a participant under two different routines of sleep and wake. *Top*, Data from participant K on a 28-hour daily routine of 19 hours' wake and 9 hours' sleep during Professor Kleitman's historic forced-desynchrony protocol (see Figure 35-8). Data based on last 3 weeks in Mammoth Cave. *Bottom*, Laboratory data recorded at the University of Chicago from participant K on his customary daily 24-hour routine of 17 hours' wake and 7 hours' sleep. *Shaded areas* indicate time in bed attempting to sleep. Data are from the 5 weeks after the 24-hour routine of living. Each weekly record shows seven body temperature waves, within minima in *shaded areas* on the customary 24-hour routine but not on the artificial 28-hour sleep-wake schedule. This participant's endogenous circadian temperature cycle maintained a near-24-hour oscillation, despite the scheduled 28-hour length of his sleep-wake cycle. Temperature data from participant R (not shown) appeared to adapt to the non-24-hour routine, something not observed in more recent forced-desynchrony studies. Interindividual differences in the strength of endogenous versus evoked components of the body temperature rhythm might account for what appeared to be circadian adaptation during forced desynchrony in participant R of Kleitman's pioneering experiment. (Figure and parts of legend adapted with permission from Kleitman N. *Sleep and wakefulness*. Chicago: University of Chicago Press; 1963. Copyright 1963 by the University of Chicago.)

exposure, could result in daily phase advances leading to nonphotic entrainment of the human circadian system if the timing and intensity of the exercise were optimized.

INVESTIGATING CIRCADIAN AND SLEEP-WAKE DEPENDENT MODULATION

The Kleitman Protocol

Separation from 24-Hour Environmental and Behavioral Cues

Nathaniel Kleitman was the first investigator to study human circadian rhythms in the absence of periodic 24-hour cues in the external environment (Figure 35-8).[42] Core body temperature records from one of his two participants in Mammoth Cave, Kentucky in 1938, who underwent a 28-hour imposed sleep-wake schedule, were compared with laboratory data collected at the University of Chicago from the same participant living on a 24-hour routine[42] (shown in Figure 35-9). On a 24-hour schedule, there were seven cycles of the body temperature rhythm, as one would expect over the course of a 1-week recording. The week with an imposed 28-hour schedule also has 7 cycles of body temperature rhythm, but only six sleep-wake cycles (see Figure 35-9, upper panel). Despite the confounding effect of sleep on core body temperature, this experimental protocol still separated the influence of timing of the sleep-wake schedule from that of the circadian pacemaker—at least in this participant.

This imposed desynchrony between sleep-wake schedule and output of the circadian pacemaker driving the temperature rhythm occurs when the non–24-hour sleep-wake schedule is outside the range of entrainment or range of capture of the circadian system. This protocol, termed the *forced-desynchrony* protocol, is useful in evaluating the influence of the circadian pacemaker on many physiologic variables because it allows separation of the confounding effect of the sleep-wake schedule from the output of the endogenous circadian pacemaker.[19,42,86] Figure 35-10 illustrates a raster plot of a forced-desynchrony experiment incorporating core body temperature and wake data for a participant living on a 28-hour day in a laboratory shielded from external time cues.[87] The waking episodes in this protocol are 18 hours, 40 minutes, followed by sleep episodes of 9 hours, 20 minutes. Core body temperature exhibited a period of 24.3 hours in this participant and was therefore desynchronized from both the 24-hour day and the timing of the imposed 28-hour sleep-wake schedule.

Separating Circadian Modulation and Sleep-Wake Modulation

The constant-routine protocol does not permit complete and unconfounded separation of the circadian and homeostatic influences on neurobehavioral and physiologic variables.

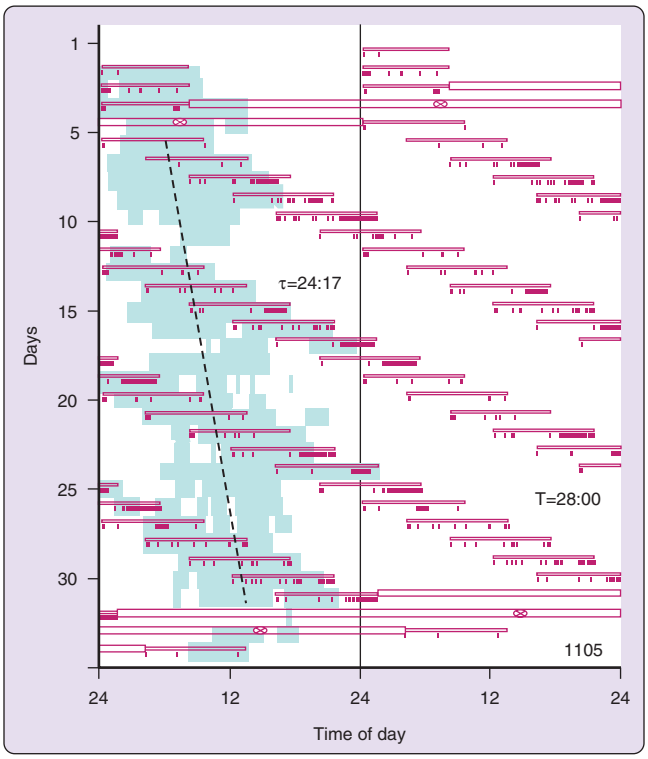

Figure 35-10 Double plot of a 28-hour forced-desynchrony protocol. Successive days are plotted next to and beneath each other. Scheduled sleep episodes are indicated by *narrow open bars*, polysomnographically determined wake within each sleep episode is indicated by *red tick marks* below the *narrow open bars*, and intervals during which core body temperature was below mean are indicated by the *blue area*. Intrinsic temperature cycle of 24.3 hours from this participant's data was estimated by nonparametric spectral analysis of core body temperature data during the forced-desynchrony part of the protocol. The *broken line* indicates the phase of circadian temperature rhythm minimum. The *encircled X* indicates the minimum of endogenous circadian rhythm of core body temperature unmasked by the 40-hour constant-routine protocol (*narrow open bars*). (Reproduced with permission from Dijk D-J, Czeisler CA. Paradoxical timing of the circadian rhythm of sleep propensity serves to consolidate sleep and wakefulness in humans. *Neurosci Lett* 1994;166:63–8.)

However, in the Kleitman forced-desynchrony protocol, sleep and wake are distributed much more evenly over the entire circadian cycle during the course of the experiment. It is thus possible to average data over either successive circadian cycles or successive sleep-wake episodes to separate these components. Averaging isolates the circadian profile of the variable of interest by removing the contribution of the confounding sleep-wake contribution in the averaging process. Conversely, the temporal contribution of the sleep-wake profile can be isolated from the confounding circadian influence. This averaging process is similar to that of cortical evoked potential recordings that effectively subtract background noise not temporally related to the evoked response.

Neurobehavioral Functions

To understand and predict the time course of neurobehavioral function, we must recognize the influence of the sleep-wake state on what is termed a *sleep homeostat*[19] driving neurobehavioral functions, as is apparent when we examine these variables during a longer course of sleep deprivation when more than one circadian cycle has elapsed.[46] The cyclic influence of the circadian pacemaker on alertness and performance is superimposed on an overall decline in function during the experiment, as described in models incorporating both homeostatic and circadian influences in the regulation of sleep and wake.[88,89] The rate of this performance decline increases sharply under conditions of chronic sleep restriction.

In a 20-hour forced-desynchrony protocol, the temporal profiles of cognitive performance and subjective sleepiness as a function of both circadian phase and time into the scheduled waking day[90] (Figure 35-11) suggest that the overall magnitudes of circadian and wake-dependent drives are similar during a typical waking day. From the timing of circadian and sleep-dependent profiles, we can qualitatively reconstruct their separate contributions to maintenance of alertness and performance over a normal waking day (see Figure 35-11). In the first half of the day following wake time, there is little homeostatic sleep drive because it was discharged by the prior sleep episode, so both alertness and cognitive performance are high. In the latter half of the waking episode, when homeostatic sleep drive would otherwise cause alertness and cognitive performance to decline, the circadian drive rises and opposes that decline, thereby sustaining a high, stable level of alertness throughout the normal waking day. Performance in the 3 hours before the onset of melatonin secretion (i.e., the wake maintenance zone) is significantly improved compared with performance during a 3-hour block earlier in the biologic day, despite a longer time awake. This effect is greater after extended wakefulness (i.e., on day 2 of a circadian rhythm), when homeostatic sleep pressure is high. The wake maintenance zone may therefore contribute to sleep-onset insomnia complaints when sleep timing is highly variable.[91] Remarkably, neurobehavioral performance, as measured by reaction time, can be preserved during this circadian wake maintenance zone even under conditions of chronic sleep restriction.[92]

Sleep and Wake

Similar dynamics apply for reconstructing the respective circadian and homeostatic contributions to sleep and wakefulness. The raster plot of the forced-desynchrony experiment (see Figure 35-10) shows that almost all wakefulness within a scheduled sleep episode occurs when the participant's sleep episode is not in phase with the body temperature nadir,[87] an observation first quantified by Kleitman from his Mammoth Cave data.[42] Averaging polysomnographically recorded sleep data from free-running participants on a self-selected cycle and in an environment free of time cues yields the data in Figure 35-12, showing the temporal profiles of sleep parameters as a function of circadian phase.[93] The circadian contribution to REM sleep timing is robust and exhibits a maximum centered just after the core body temperature nadir.

Figure 35-13 depicts sleep-dependent changes in the propensity for wake as a function of the circadian phase at which a sleep episode is initiated.[19] Under entrained conditions, a consolidated bout of sleep is maintained with minimal wake during the scheduled sleep episode by initiating the sleep episode at the end of the wake maintenance zone. However, when sleep is initiated in the early morning hours (as in a shift worker after the first night shift), a high percentage of time is spent in wake during the latter half of this intended sleep episode. During entrained conditions, homeostatic drive for

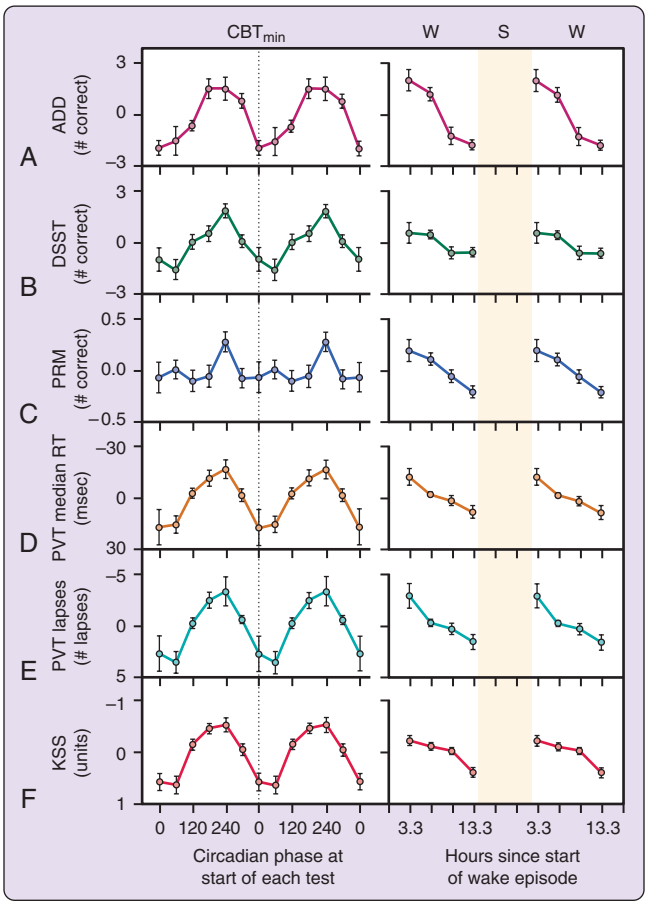

Figure 35-11 Double plots of the main effects of the circadian phase relative to the minimum of core body temperature CBT_{min} (*left panels*) and duration of scheduled wake (*right panels*: w = wake; s = sleep) on neurobehavioral measures. Plotted points show deviation from mean values during forced desynchrony and standard errors of the mean (SEMs). For all panels, values plotted lower in the panel represent impairment of that measure. Addition Task (ADD) **(A)**, Digit Symbol Substitution Task (DSST) **(B)**, and Probed Recall Memory (PRM) **(C)** scores were derived from total correct responses. Psychomotor Vigilance Task (PVT) results represent median reaction time **(D)** and total lapses (**E,** reaction times >500 msec). Karolinska Sleepiness Scale (KSS) scores **(F)** represent responses on this 1-9 Likert-type scale; higher scores represent greater sleepiness. (Reproduced with permission from Wyatt JK, Ritz-De Cecco A, Czeisler CA, Dijk DJ. Circadian temperature and melatonin rhythms, sleep, and neurobehavioral function in humans living on a 20-h day. *Am J Physiol* 1999;277:R1152–63.)

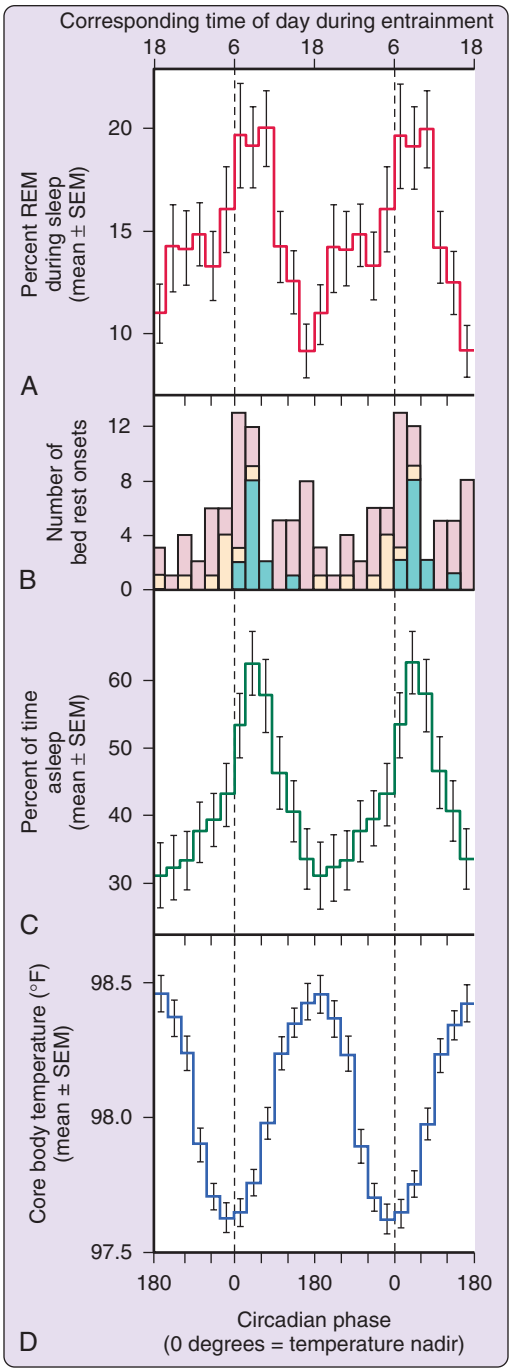

Figure 35-12 Variations in occurrence and internal organization of sleep with circadian temperature cycle phase (94 days of data from four participants). **A,** Percent of REM during sleep; **C,** Percent of time asleep; **D,** Core body temperature. In panel **B,** REM sleep episodes that occurred within 10 minutes after bed rest onset are indicated by *green* areas; those in which REM sleep episodes occurred within 30 minutes after bed rest onset are indicated by *peach* areas. (Reproduced with permission from Czeisler CA, Zimmerman JC, Ronda JM, Moore-Ede MC, et al. Timing of REM sleep is coupled to the circadian rhythm of body temperature in man. *Sleep* 1980;2:329–46.)

sleep is greatest after an extended bout of wake at sleep onset and facilitates sleep in the first half of the night. In the latter half of the sleep episode, as the homeostatic drive declines, the circadian drive for sleep becomes greater, thus maintaining elevated sleep drive through the end of the sleep episode. These two components interact to facilitate consolidated sleep throughout the night.[19,87]

The three-dimensional representation in Figure 35-14 combines the temporal profiles of circadian and sleep-dependent drives to illustrate their respective contributions in maintaining wake.[19,87] A maximum in sleepiness quantified by slow rolling eye movements occurs at the endogenous circadian temperature nadir, which corresponds to occurring just before the habitual wake time. The sleep-dependent contribution exhibits an increasing profile over the wake episode, with the greatest propensity to slow eye movements after 14 hours of wakefulness. The magnitude of the circadian rhythms of sleepiness and performance increases with increasing homeostatic sleep drive. Thus, when increasing homeostatic sleep pressure combines with an adverse circadian phase, the drive for sleep is so great that slow eye movements and lapses of attention often intrude involuntarily during wake. The performance

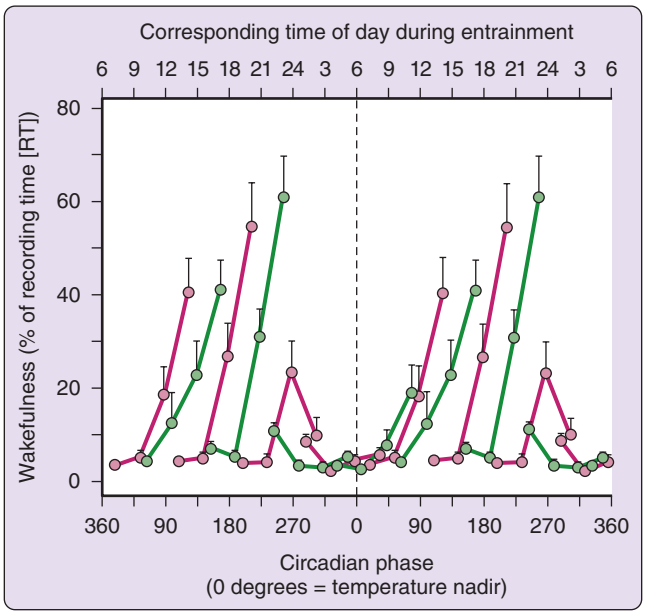

Figure 35-13 Wakefulness during scheduled sleep episodes (expressed as percentage of recording time) as a function of circadian temperature phase. Sleep episodes were assigned to twelve 30-degree bins based on circadian phase at lights out. (Modified with permission from Dijk D-J, Czeisler CA. Contribution of the circadian pacemaker and the sleep homeostat to sleep propensity, sleep structure, electroencephalographic slow waves, and sleep spindle activity in humans. *J Neurosci* 1995;15:3526–38.)

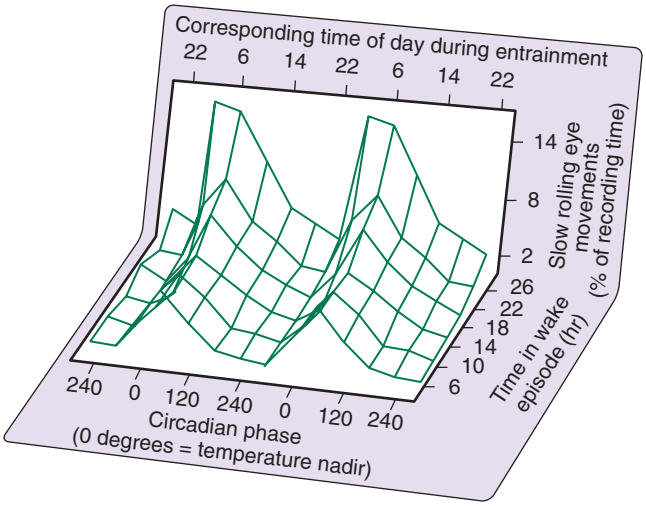

Figure 35-14 Quasi three-dimensional plot of slow rolling eye movements (SREMs) within scheduled wake episodes relative to circadian phase and time elapsed since start of wake episode. Data were assigned to twelve 30-degree circadian-phase bins and six 112-minute time-since-start-of-wake-episode bins. Each point represents SREMs expressed as percentage of recording time in a bin. (Modified with permission from Cajochen C, Wyatt JK, Bonikowska M, et al. Non-linear interaction between circadian and homeostatic modulation of slow eye movements during wakefulness in humans. *J Sleep Res* 2000;9:58.)

impairment is an order of magnitude more severe when extended wakefulness coincides with an adverse circadian phase under conditions of chronic sleep restriction.[92]

The circadian and sleep-wake modulation of sleep-wake propensity and neurobehavioral function are illustrated schematically in Figure 35-15. Experimental evidence indicates that a simple additive model cannot account for variations in alertness and cognitive performance data.[44,46,94] In fact, when

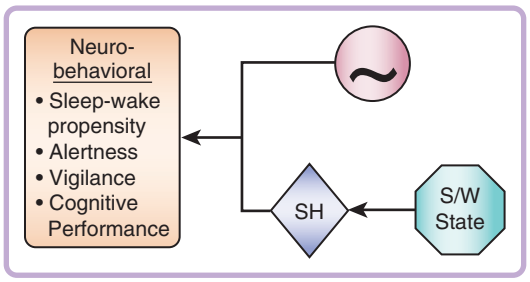

Figure 35-15 Schema illustrating combined influence of circadian clock and sleep-wake state on neurobehavioral variables (sleep-wake propensity, alertness, vigilance, and cognitive performance). Sleep-wake state (S/W State) influence is illustrated by an intermediary of the sleep homeostat (*SH in blue diamond*).

averaged across all circadian phases, there is relatively little circadian variation in various waking neurobehavioral measures in the first few hours of wakefulness, when homeostatic sleep drive is low, and the circadian contribution increases as a function of number of hours awake, suggesting that homeostatic and circadian drives are not independent and further suggesting a nonadditive interaction between homeostatic and circadian systems that drive alertness and cognitive performance.[95] Furthermore, the buildup of the homeostatic drive in response to acute sleep deprivation is distinct from the response to chronic sleep loss.[92]

Internal Sleep Structure

REM sleep propensity varies with circadian phase.[19,93,96] Studies with nap opportunities evenly distributed throughout day and night every 1.5 to 3 hours first established the REM sleep propensity rhythm in a protocol that did not involve concomitant variations in prior wake length.[93,97,98] REM sleep latency, the rate of REM sleep accumulation, REM sleep episode duration, and REM sleep propensity were then shown to vary with phase of the endogenous circadian temperature cycle in free-running participants whose self-selected rest-activity cycle spontaneously desynchronized from the timing of the endogenous circadian temperature cycle (see Figure 35-12).[93,99] The peak of the endogenous circadian rhythm in REM sleep propensity in these participants was just after the nadir of the endogenous component of the circadian temperature cycle, coincident with the circadian peak of sleepiness and sleep propensity (see Figures 35-11 to 35-14).[93,99] During such spontaneous desynchrony, free-running participants who chose to go to bed near the peak of the REM sleep propensity rhythm usually exhibited sleep-onset REM sleep episodes,[93,99] an otherwise rare phenomenon normally diagnostic of narcolepsy. Under these conditions, the density of REMs per minute of REM sleep exhibits a sleep-dependent variation apparently dissociated from the REM sleep propensity rhythm itself.[100]

These findings on the timing of the circadian REM sleep propensity rhythm have since been confirmed and extended with polysomnography data from participants studied in the forced-desynchrony protocol.[19,87] Because sleep episodes in the forced-desynchrony protocol always begin after a fixed duration of enforced wakefulness, the results were less subject to the confounding effects of systematic variations in prior wake durations characteristic of spontaneous desynchrony. Furthermore, because participants were scheduled to remain in bed for a fixed interval on the forced-desynchrony protocol,

results were not confounded by self-selected termination of the sleep episode, although circadian variations in sleep efficiency prevent complete elimination of this confounding factor. Nonetheless, under such conditions, the twofold circadian variation in REM sleep propensity again peaked just after the nadir in the endogenous circadian component of body temperature rhythm, within each one fifth of the scheduled sleep episode, notwithstanding the average sleep-dependent increase in REM sleep propensity. A sleep-dependent increase in REM sleep propensity independent of circadian phase was also quantified. A significant nonadditive interaction between circadian phase and time since the start of the sleep episode was found from the REM sleep data collected during forced desynchrony.[19]

With the forced-desynchrony protocol, significant and substantial circadian and sleep-dependent variations in NREM sleep propensity were also observed, whereas the robust sleep-dependent decline in slow wave activity was associated with only a small but statistically significant variation of slow wave activity as a function of circadian phase.[19] Similar circadian variations in internal sleep structure are documented in a blind patient whose circadian pacemaker was not synchronized to the 24-hour day, despite his decades-long maintenance of a regular sleep-wake schedule.[101] Such blind patients, in essence, live in society on the biologic equivalent of a forced-desynchrony protocol because the 24-hour day is outside the range of entrainment of the circadian pacemaker in such patients.

Quantitative analysis of the sleep EEG reveals circadian variations in EEG activity during NREM and REM sleep,[102] with low-frequency sleep spindle activity in NREM sleep paralleling the endogenous circadian melatonin rhythm. Overall, these data indicate that the timing and internal structure of sleep are profoundly dependent on an interaction between robust circadian and homeostatic regulatory factors, with circadian factors predominant in the regulation of REM sleep and with sleep-dependent factors predominant in the regulation of slow wave sleep.

Potential Feedback Pathways

As is typical of physiologic regulatory systems, feedback pathways play a significant role in this system. The neurobehavioral variables influenced by the circadian pacemaker and the sleep homeostat can influence the sleep-wake state through the influence of wake and sleep propensity on determination of sleep and wake times. For example, a sleep episode is more likely to be initiated following a rise in sleep propensity to a high level during an extended waking episode, and a sleep episode is more likely to be terminated following a decline in sleep propensity to a low level over the course of a sleep episode. This influence on behavior, in turn, influences the level of the sleep homeostat and, because of associated changes in light exposure and activity, it can affect the phase or amplitude (or both) of the circadian pacemaker.

There may be another important feedback pathway in this system. Studies demonstrating that melatonin receptors can be found on cells within the human SCN draw attention to a potential feedback pathway from the pineal gland to the SCN through circulating melatonin. Several physiologic studies suggest that exogenous melatonin has a phase-resetting effect on the human circadian pacemaker, and both a melatonin PRC and dose-dependent phase shifting have been reported. The first such study that has thoroughly controlled for retinal light exposure has revealed that the resetting responses to melatonin are even greater than previously reported.[103] There is also great interest in the potential efficacy of melatonin as a hypnotic because the sleep-promoting effects of exogenous melatonin depend on circadian phase, as established in young adults on a forced-desynchrony protocol.[104]

Examination of the temporal profile of endogenous melatonin secretion during the forced-desynchrony protocol shows a daily circadian increase in melatonin levels coincident with a decrease in wake (Figure 35-16).[102] This melatonin rise might open a gate that allows sleep to occur.[105] These data suggest feedback from the pineal gland to both the circadian pacemaker and neurobehavioral variables involved in regulating the sleep-wake state. Other physiologic systems might also affect sleep-regulating mechanisms, such as an effect of growth hormone on sleep.[106,107]

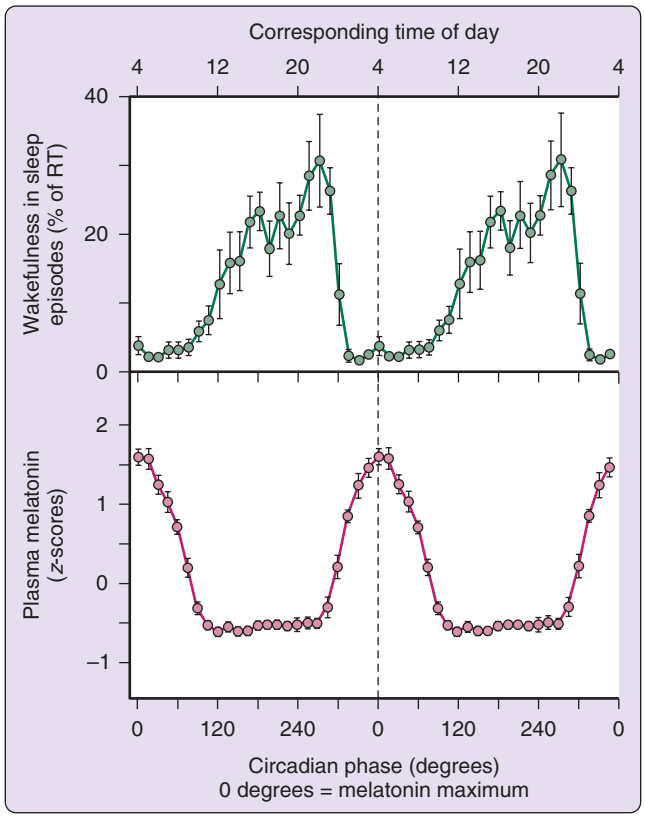

Figure 35-16 Phase relationships between endogenous circadian rhythms of wakefulness and plasma melatonin were assessed during a forced-desynchrony protocol. Data were plotted against the circadian phase of the plasma melatonin rhythm (0 degrees on the lower abscissa scale corresponds to fitted melatonin maximum). To compare with entrained conditions, the upper abscissa scale indicates the approximate clock time corresponding to circadian melatonin rhythm during the first day of the forced-desynchrony protocol (i.e., immediately on release from entrainment). Plasma melatonin data are expressed as *z*-scores to correct for interindividual differences in mean values. Wakefulness is expressed as a percentage of recording time (RT). Data are double plotted (i.e., all data plotted left of the *dashed vertical line* are repeated to the right of the *vertical line*). (Modified from Dijk D-J, Shanahan TL, Duffy JF, et al. Variation of electroencephalographic activity during non–rapid eye movement and rapid eye movement sleep with phase of circadian melatonin rhythm in humans. *J Physiol [Lond]* 1997;505[3]:851–8.)

Intrinsic Period of the Human Circadian Pacemaker

Early human studies were performed in the absence of environmental synchronizers but were confounded by self-selected exposure to ordinary room light, which led to the erroneous conclusion that the average period of the human circadian pacemaker was 25 hours.[47,86] Participants were permitted to illuminate their living quarters while awake and switch off lighting while asleep because these experiments were predicated on the incorrect belief that ordinary room light had no resetting effect on the human circadian system.[108,109] Thus results of these studies were systematically compromised by this retinal light exposure.[47,86] Recognition of this confounding effect led to the use of Kleitman's forced-desynchrony protocol to assess the intrinsic period of the human circadian pacemaker.[47,86,110]

Subsequent studies using the Kleitman forced-desynchrony protocol have controlled the intensity of background illumination and timing of exposure to the light-dark cycle.[47,86] With this forced-desynchrony protocol in participants living in dim light (about 10 to 15 lux) on either a 28-hour or a 20-hour schedule, the average intrinsic period of the circadian pacemaker is estimated to be much closer to 24 hours, with an average period of about 24.15 hours[110,111] rather than 25 hours (Figure 35-17). This holds true for all of the circadian markers tested—core body temperature, melatonin, and cortisol—and is consistent with results of other studies under a variety of protocols.[112-115] The average intrinsic period of the human circadian pacemaker is significantly shorter in women [24.09 ± 0.2 hour (24 hours, 5 minutes ± 12 minutes)] than in men [24.19 ± 0.2 hours (24 hours, 11 minutes ± 12 minutes)].[111] Entrainment studies have functionally confirmed the intrinsic circadian period in humans to be near 24 hours because a weak stimulus (candlelight during the scheduled day and sleep in darkness during the scheduled night) can entrain most people to a light-dark cycle with an imposed period of 24.0 hours but not an imposed period of 23.5 or 24.6 hours.[116]

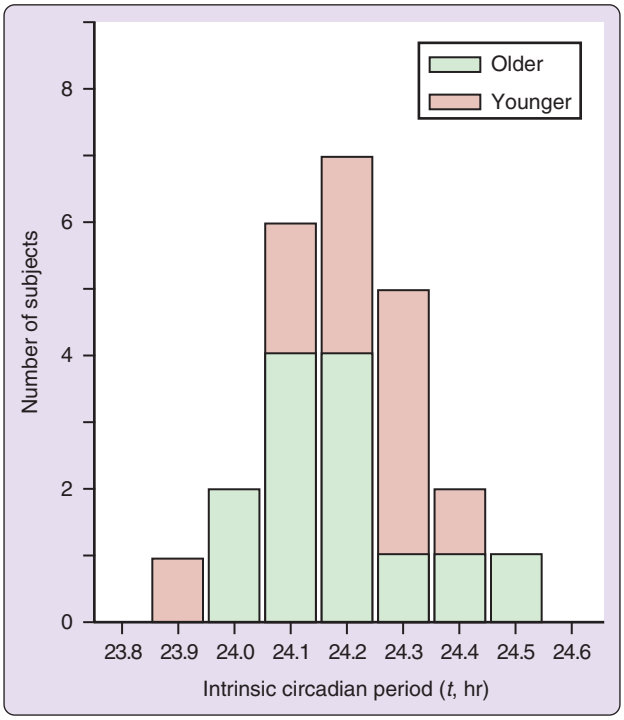

Figure 35-17 Histogram of intrinsic circadian period estimates derived from young and older participants. *Green bars* indicate intrinsic circadian period (*t*) estimates of older participants; *pink bars* indicate young participants. Each participant's estimated intrinsic circadian period is reported as the average of estimated periods from his or her core body temperature, melatonin, and cortisol rhythms. (Reproduced with permission from Czeisler CA, Duffy JF, Shanahan TL, et al. Stability, precision, and near–24-hour period of the human circadian pacemaker. *Science* 1999;284:2177–81.)

AGING AND CIRCADIAN SLEEP-WAKE REGULATION

Aging also has a pervasive influence on many aspects of the circadian and sleep-wake regulating system.[117-123] The prevalence of disrupted sleep complaints is much greater in older than in young people. In fact, 57% of people in the United States older than 65 years complain of at least one chronic sleep problem, 43% complain of difficulty initiating or maintaining sleep, and 19% complain of awakening too early in the morning.[124] Key to examining this question is the extent to which the circadian pacemaker or the sleep homeostat is involved in these age-related changes.

On average, the circadian clock is set to an earlier hour, and the amplitude of some endogenous circadian rhythms is lower in older people than it is in young adults (Figure 35-18).[119,125] However, intrinsic circadian period does not shorten with age in healthy humans.[110,111,126] Importantly, young participants can sleep over a much wider range of circadian phases than older people, who awaken spontaneously at an earlier internal circadian phase.[125,127] Because older people usually awaken at an earlier circadian phase, they are typically exposed to light at an earlier hour; this earlier light exposure, which will reset the circadian pacemaker to an earlier hour, likely accounts for the earlier average entrained circadian phase observed in older people.[125] Remarkably, older participants are much less vulnerable to the adverse effect of sleep loss and misalignment of circadian phase on neurobehavioral performance.[128] At the same time, a common clock gene polymorphism is associated with the timing of activity rhythms and with the time of death, such that rs7221412GG individuals have a mean time of death nearly 7 hours later than rs7221412AA/AG individuals.[129]

INFLUENCE OF SOCIAL AND WORK-RELATED FACTORS

The self-selection of sleep and wake times in humans is another important factor in the sleep-wake regulatory system. Although circadian and homeostatic drives for sleep influence the choice of sleep and wake times through a feedback pathway, social factors (e.g., child care, school and work responsibilities, entertainment, social interaction) and environmental factors (e.g., noise, artificial light, alarm clocks) often override those biologic determinants. In contrast, animal behavior exhibits activity and sleep predictable enough to be used as markers of the biologic time of day. Humans, especially since the advent of alarm clocks and artificial lighting, can and do override the signals from the circadian and sleep-wake regulating system and freely decide to stay awake later than they otherwise would or wake up earlier than they would

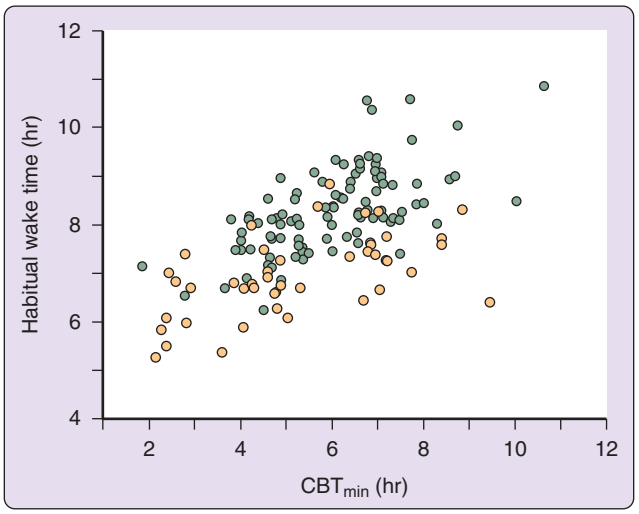

Figure 35-18 Habitual wake time versus endogenous circadian phase of young and older adults. Symbols represent average self-reported wake time from the pre-study week versus the phase of core body temperature minimum (CBT_{min}) for each participant. *Pink circles* indicate older participants ($n = 44$); *green circles* indicate young participants ($n = 101$). Between-groups relationship is significant (slope of older participants, 0.266 ± 0.06; slope of young participants, 0.471 ±0.05). (Reproduced with permission from Duffy JF, Dijk D-J, Klerman EB, Czeisler CA. Later endogenous circadian temperature nadir relative to an earlier wake time in older people. *Am J Physiol* 1998;275:R1478–87.)

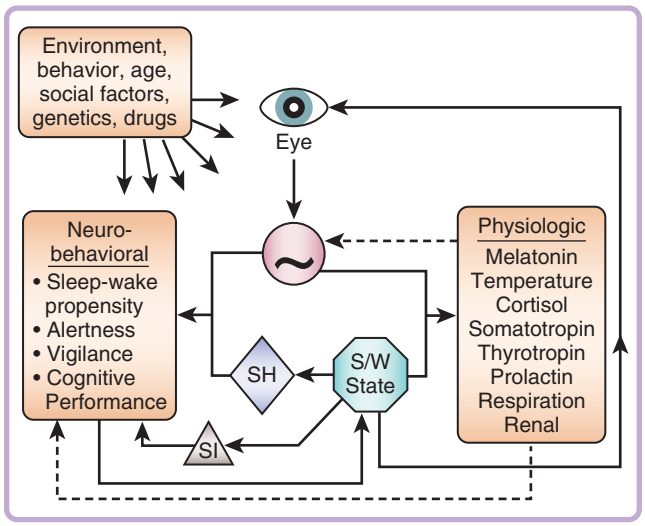

Figure 35-19 Overall schema illustrating potential influence of the circadian clock on neurobehavioral and physiologic variables and of physiologic variables (e.g., melatonin, body temperature) on neurobehavioral variables or circadian clock (*dashed arrows*), feedback influence of variables on sleep-wake state (S/W State) (*solid arrow*), influence of sleep-wake state on variables through sleep homeostat (SH) and sleep inertia (SI) (*solid arrows*). Global influence of environment, behavior, age, social factors, genetics, and drugs on virtually all elements contributing to sleep-wake regulation are also represented.

spontaneously because of job or school requirements or recreational and social events. Thus modern humans may be more sleep deprived than their ancestors.[130] The long-term consequences of this relatively recent trend in industrialized society are unknown. Yet the modern consolidated sleep episode is significantly different from that under more naturalistic conditions in which sleep episode duration was determined by longer length of darkness in the natural winter environment.[69,130,131] The most conspicuous example of this self-selection is rotating shift work, when people choose to work in direct opposition to the modulation of circadian and homeostatic regulatory systems, resulting in internal temporal dissociation, fragmented sleep, and impaired wake. This does have consequences. Resident physicians working extended-duration work shifts (24 to 30 hours) every third day showed progressive deterioration in performance across 3 successive weeks of work in an intensive care unit. Response times deteriorated with time on shift and cumulatively, demonstrating chronic sleep deficiency with each successive extended-duration work shift.[132] Prolonged exposure to prolonged sleep restriction with concurrent circadian disruption in controlled laboratory conditions decreases resting metabolic rate and increases plasma glucose concentrations after a meal, an effect resulting from inadequate pancreatic insulin secretion, suggesting that prolonged sleep restriction with concurrent circadian disruption alters metabolism and could increase the risk for obesity and diabetes.[133] Therefore, in any realistic model of the human circadian and sleep-wake regulatory system used to manage performance and prevent disease, such environmental and societal influences must be recognized.

We can assemble an overall system schema and incorporate the feedback pathway of neurobehavioral variables on sleep-wake state and the putative feedback pathways from melatonin and other physiologic variables onto the circadian pacemaker and neurobehavioral function (Figure 35-19). This schema incorporates the global influence of environmental, social, behavioral, genetic, pharmacologic, and age as factors influencing all elements of this system, together with the decrements in neurobehavioral performance and alertness that immediately follow the sleep-to-wake transition, a phenomenon called *sleep inertia*. The time course of sleep inertia has been shown to persist for up to 2 hours after a long sleep episode, and it is most profound within the first few minutes after awakening.[134,135] Although the final schema incorporates much of what is known about the roles of the circadian pacemaker and sleep homeostat in regulating sleep, it is not intended to completely represent all factors involved in the regulation of sleep, which is beyond the scope of this chapter. Nevertheless, its strength is its use in understanding the interplay between circadian and homeostatic drives and perhaps as a framework for initiating future scientific inquiry.

CLINICAL PEARL

Disruption of the circadian timing system by shift work, travel across time zones, and the activities of our round-the-clock society has an adverse effect on many physiologic variables including hormones, glucose, metabolism, autonomic nervous system activity, the immune system, inflammation, neurobehavioral performance, and the propensity for, timing, and internal structure of sleep. This disruption can result in patient complaints of insomnia or excessive daytime sleepiness and can impair overall health.

SUMMARY

The circadian pacemaker interacts with sleep-wake regulatory processes to influence many physiologic variables: hormone levels, autonomic nervous system activity, neurobehavioral performance, and the propensity for and timing and internal structure of sleep. Environmental, social, behavioral, and genetic factors, pharmacologic agents, and age influence most elements of this system. Under ordinary circumstances, when people sleep at night in darkness and are awake in daylight, it is difficult to distinguish the relative contributions of the sleep homeostat and that of the circadian pacemaker to a given recurrent daily characteristic, symptom, or disorder of sleep or wakefulness (e.g., narcolepsy, delayed sleep phase syndrome). A pathologic event, such as a nocturnal seizure, that occurs the same time each night may be driven by the circadian pacemaker, the sleep homeostat, a specific sleep stage, or some combination of these processes. It is currently possible, although difficult, to experimentally dissociate these factors for research purposes (e.g., using the forced-desynchrony protocol in humans or suprachiasmatic lesions in animals). Clinically feasible techniques, such as measurement of dim-light salivary melatonin onset, can provide useful information about circadian phase.[136] Continued basic and clinical research is needed to assess the impact of the complex interaction of sleep and circadian rhythmicity on sleep disorders, such as insomnia, and overall health and well-being.

Sleep Homeostasis and Models of Sleep Regulation

Peter Achermann; Alexander A. Borbély

Chapter 36

Chapter Highlights

- Sleep homeostasis refers to the aspect of sleep regulation dependent on sleep and waking, as homeostatic mechanisms counteract deviations from an average reference level of sleep. These mechanisms augment sleep propensity when sleep is curtailed or absent, and they reduce sleep propensity in response to excess sleep. In general, homeostasis can be defined as "the coordinated physiological processes, which maintain most of the steady states in the organism."[1,2]
- Non–rapid eye movement sleep is not a homogeneous substate of sleep but can be subdivided according to the predominance of slow waves in the electroencephalogram (EEG). One of the most important functional EEG parameters is referred to as slow wave activity; It is equivalent to delta activity and encompasses components of the EEG signal in the frequency range of approximately 0.5 to 4.5 Hz as obtained by spectral analysis. Under physiologic conditions, this EEG variable can be regarded as an indicator of sleep depth or sleep intensity.[7]
- The two-process model postulates that a homeostatic process rises during waking and declines during sleep and interacts with a circadian process that is not directly dependent of sleep and waking. The model served as a conceptual framework and inspired many experiments to test its predictions.[3,27,83]
- Models may address processes at different levels (from the microscopic [cellular] level to the macroscopic [systemic] level) and at different time scales (from the range of milliseconds or seconds up to hours or days).[74] Many mathematical models of sleep regulation represent extended versions of the two-process model incorporating neurophysiologic processes. Being aware of the power and limitations of models is important for selecting the most appropriate one for the question to be addressed.

Three distinct processes underlie sleep regulation. A homeostatic process, whose level is a function of prior sleep and waking, plays a major role in sleep regulation. Sleep is also modulated by a circadian process, a clocklike mechanism that is independent of prior sleep and waking. An ultradian process occurs within sleep and is represented by the alternation of the two basic sleep states: non–rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep.

One of the main topics of this chapter is sleep homeostasis. *Homeostasis* has been defined as "the coordinated physiological processes, which maintain most of the steady states in the organism."[1] The term *sleep homeostasis*[2] refers to the aspect of sleep regulation dependent on sleep and waking, as homeostatic mechanisms counteract deviations from an average reference level of sleep. These mechanisms augment sleep propensity when sleep is curtailed or absent, and they reduce sleep propensity in response to excess sleep.

The interest in the modeling approach to sleep regulation has increased over the past decades. Models help delineate the processes involved in the regulation of sleep and thereby offer a conceptual framework for the analysis of existing and new data.[3] For reviews of modeling circadian rhythms related to sleep, see Roenneberg and colleagues,[4] Beersma,[5] and Klerman and St Hilaire.[6]

HOMEOSTATIC REGULATION OF SLEEP

Electroencephalographic Slow Wave Activity: A Physiologic Indicator of NREM Sleep Homeostasis

Slow Wave Sleep and Slow Wave Activity

NREM sleep is not a homogeneous substate of sleep but can be subdivided according to the predominance of slow waves in the electroencephalogram (EEG). One of the most important functional EEG parameters is referred to as slow wave activity (SWA). It is equivalent to delta activity and encompasses components of the EEG signal in the frequency range of approximately 0.5 to 4.5 Hz as obtained by spectral analysis.[7]

In addition to delta waves, a low-frequency component with a mean peak value of 0.7 to 0.8 Hz is present in the EEG power spectrum of NREM sleep.[8-10] The typical decline in delta activity from the first to the second NREM sleep episode was not present at frequencies below 2 Hz.[8] This could indicate that the low-frequency component reflects a separate process that differs from the one represented by delta activity. Alternatively, the results could be due to a frequency shift in the course of sleep.[11] The changes of the low-frequency component in response to naps did not differ from those of SWA.[12] Increased sleep pressure resulted in a redistribution of waves

between 0.5 and 2 Hz: The number of waves per minute was reduced below 0.9 Hz but was increased above 1.2 Hz; EEG power was increased only above 1 Hz.[13] Periodicities at even lower frequencies include the recurrence of sleep spindles at 4-second intervals,[8,14] the tendency of slow waves to recur at 20- to 30-second intervals,[8] and a cortical infra slow oscillation (0.02 to 0.2 Hz).[15,16]

Slow Waves and Sleep Intensity

It was recognized as early as 1937 that sleep intensity is reflected by the predominance of slow waves in the sleep EEG.[17] Subsequent studies confirmed that the responsiveness to stimuli decreases as EEG slow waves become more predominant.[18] Under physiologic conditions, this EEG variable can be regarded therefore as an indicator of sleep depth or sleep intensity.

Global Time Course of Slow Wave Activity during Sleep

Slow wave sleep (SWS; the high-intensity part of NREM sleep) appeared to be a good candidate for a physiologic marker of sleep homeostasis. The predominance of SWS in the early part of the sleep episode was documented in several early studies.[18-20] All-night spectral analysis of the sleep EEG made it possible to quantify SWA and to delineate its time course during sleep.[7] Its mean value per cycle plotted for consecutive NREM-REM sleep cycles showed a monotonic decline over the first three cycles. Figure 36-1 (*left*) shows the changes of mean EEG power density over four cycles for the frequency range between 0.25 and 20 Hz. The values of each bin are expressed relative to the reference level of cycle 4 (100%). Note that although the largest changes occur in the low delta range, they encompass frequencies up to the theta band.

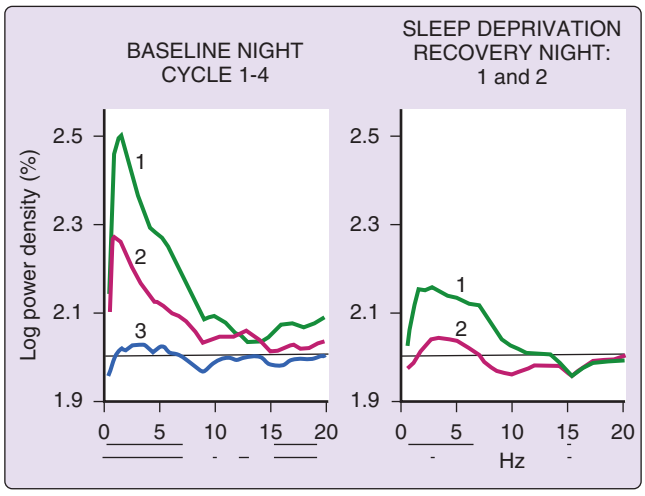

Figure 36-1 *Left,* Changes of relative spectral power density over the first four NREM-REM sleep cycles of a baseline night (N = 8). In each frequency bin the data are expressed relative to the value in the fourth cycle (100%; *horizontal line*). *Right,* Effect of sleep deprivation (40.5 hours waking) on spectra of the sleep electroencephalogram (EEG). In each bin, the values of the first two recovery nights are plotted relative to the baseline night (100%). The *upper* and *lower horizontal bars* below the abscissa indicate for the left part significant differences between cycles 1 and 2, and between cycles 2 and 3, respectively, and for the right part between recovery 1 and baseline, and between recovery 2 and baseline, respectively. (Modified from Borbély AA, Baumann F, Brandeis D, et al. Sleep deprivation: effect on sleep stages and EEG power density in man. *Electroencephalogr Clin Neurophysiol* 1981;51:483–93.)

Nap Studies

The analysis of daytime naps is useful for assessing the level of SWA after various durations of waking. Naps taken later in the day contained more SWS than naps taken earlier in the day. In a detailed study of daytime naps scheduled at 2-hour intervals throughout the day, direct evidence for a monotonic rise of SWA was obtained.[12,21-23] If naps reverse the rising trend of slow wave propensity, a reduction of SWA in the subsequent nighttime sleep can be expected. This prediction was borne out by the results of several experiments (see Werth et al.[24] for literature references). Furthermore, when the duration of nighttime sleep was shortened, SWA in a subsequent morning nap was enhanced.[25,26]

Effect of Sleep Deprivation

It has repeatedly been shown that partial or total sleep deprivation gives rise to increased SWS in the recovery night (see Borbély[27] for a review of the older literature). Webb and Agnew[20] presented compelling evidence that SWS increases as a function of prior wake duration. The quantitative assessment of SWA using all-night spectral analysis revealed that a night without sleep (i.e., 40.5 hours of wakefulness) resulted in an enhancement of this EEG variable during recovery sleep.[7] Figure 36-1 (*right*) illustrates the changes of power density in the two recovery nights relative to the baseline level (100%). In the first recovery night, the largest increase was present in the low delta range, the part of the spectrum undergoing the largest changes in the course of baseline sleep (see Figure 36-1, *left*).

Figure 36-2 depicts the global trend as well as the ultradian dynamics of SWA over successive NREM-REM sleep cycles. The prolongation of the waking period causes a prominent rise of SWA during recovery sleep. A declining trend over three to four cycles is evident in both records. Note that the peaks are at a steady low level during the last four cycles of recovery sleep.

The enhancement of SWA by sleep deprivation was confirmed in numerous studies[28,29] (for references before 1992, see Borbély and Achermann[30]). The extent of the increase was shown to be a function of the duration of prior waking.[23,31]

Selective Slow Wave Deprivation

The propensity of SWA does not necessarily dissipate during sleep but may persist at an elevated level if SWS is prevented. Thus suppression of slow waves by acoustic stimuli during the first 3 hours of sleep resulted in a prominent rise of SWA after the stimuli were discontinued.[32] In another study, daytime sleep episodes with and without SWS deprivation were compared.[33] The experimental suppression of SWS during an interval corresponding to 90% of the undisturbed episode resulted in an increased accumulation of SWS and an extension of sleep duration. Topographic studies revealed regional differences in the effectiveness of and response to selective SWS deprivation.[34] Taken together the results indicate that slow waves are not merely an epiphenomenon of sleep but instead reflect major sleep-regulating mechanisms. This is supported by the findings that selective slow wave deprivation impairs perceptual[35] and visuomotor learning.[36] In another study, two nights of SWS disruption increased sleepiness but had only minor effects on daytime functioning.[37]

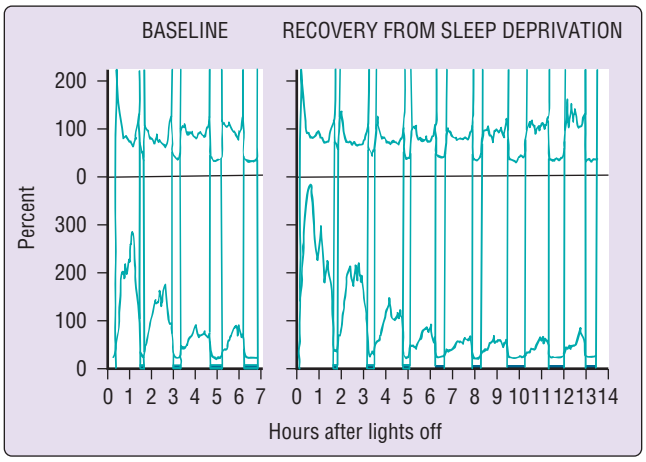

Figure 36-2 Time course of slow wave activity (power in the 0.75- to 4.5-Hz band; *lower curves*) and activity in the spindle frequency range (13.25- to 15.0-Hz; *upper curves*) recorded under baseline conditions and after sleep deprivation (36 hours of wakefulness). NREM sleep episodes were subdivided into 20 equal intervals, and REM sleep episodes were divided into 5 intervals. Mean values per interval were calculated before averaging across subjects (N = 8 except for cycle 8 of recovery sleep where N = 6) and were expressed relative to the mean level in baseline NREM sleep (100%). The mean timing of REM sleep episodes is delimited by *vertical lines* and *horizontal bars* above the abscissa. (Reanalysis of the data from Dijk DJ, Brunner DP, Borbély AA. Time course of EEG power density during long sleep in humans. *Am J Physiol* 1990;258:R650–1, by D. Aeschbach.)

Ultradian Dynamics of Slow Wave Activity and Spindle Frequency Activity

Buildup of Slow Wave Activity within NREM Sleep Episodes

The mean level and the peak of SWA are determined not only by the duration of prior waking and sleep but also by the rise rate within single NREM sleep episodes.[38-40] It is evident from Figure 36-2 that the rise rate of SWA decreases over the first three episodes both under baseline conditions and during recovery from sleep deprivation. In addition, the effect of prolonged waking manifests itself in a steeper buildup (of SWA) within NREM sleep episodes.[28,29,40] A decrease in the slope of single slow waves was associated with a reduction of sleep pressure during sleep in humans and animals,[41,42] a change that could be simulated in a model by reducing synaptic strength.[43] However, amplitude and slope of slow waves were highly correlated in the 0.5- to 2-Hz range.[13]

Slow Wave Activity and Spindle Frequency Activity

The term *spindle frequency activity* (SFA) is used to denote the power in the frequency range of sleep spindles (12 to 15 Hz). There is a close correspondence between this measure and measures based on the occurrence of sleep spindles.[28]

The time courses of SWA and SFA differ in several respects. The global decline of SWA does not occur in the spindle frequency range. Within NREM sleep episodes, SFA shows a bimodal pattern with an initial and a terminal peak. This gives rise to a U-shaped curve within the episode and a partly inverse relationship to SWA[28,44-49] (see Figure 36-2).

Regulation of REM Sleep

The principles underlying REM sleep regulation seem to be more complex than those for NREM sleep regulation. This was evident in a selective REM sleep deprivation experiment,[50] in which two salient observations were made that were difficult to reconcile. On the one hand, REM sleep deprivation necessitated a dramatic rise in the frequency of interventions during the night to prevent this sleep state. On the other hand, there was a modest rise in the number of interventions across the three consecutive deprivation nights, and the 40% REM sleep rebound in the first recovery night by no means compensated for the amount of REM sleep lost. Two hypotheses were advanced. In the first, it is assumed that the homeostatic drive is strong, which is reflected by the dramatic rise in interventions during the deprivation nights. Waking may in part substitute for REM sleep, thereby accounting for the moderate night-to-night increase in interventions and the small REM sleep rebound. According to the second hypothesis, the homeostatic drive for REM sleep is weak, and the rising trend in the number of interventions is attributed to circadian factors as well as to a sleep-dependent disinhibition of REM sleep propensity. This hypothesis could explain the limited savings from one night to the other as well as the modest rebound. For a recent review on possible functions of REM sleep, see Vyazovskiy and Delogu.[51]

NREM versus REM Sleep Homeostasis

Effect of NREM Sleep Pressure on REM Sleep Homeostasis

During recovery from total sleep deprivation, SWS and EEG SWA exhibit an immediate rebound, whereas the increase in REM sleep is delayed to subsequent nights or is not present at all. Selective REM sleep deprivation augments REM sleep pressure, which is manifested by the increasing number of interventions required to prevent REM sleep episodes (for the older literature, see Borbély[27]). However, the occurrence of REM sleep rebound during recovery sleep is smaller than expected on the basis of the deficit.[50,52] This suggests that REM sleep is not as finely regulated as NREM sleep. However, this notion is contradicted by partial sleep deprivation studies. A REM sleep deprivation in the first 5 hours of sleep induced a REM sleep rebound in the subsequent 2.25 hours.[53] A curtailment of sleep duration during two or four nights, which induced a substantial REM sleep deficit, was followed by REM sleep rebound in the two recovery nights.[54,55] In these experiments, the REM sleep rebound occurred at a time when slow wave pressure was either low at the end of sleep[53] or was much less increased than REM sleep pressure.[54,55] These results also suggest that REM sleep is indeed regulated but that the manifestation of REM sleep homeostasis is hampered by an elevated slow wave pressure.

Effect of REM Sleep Pressure on the NREM Sleep Electroencephalogram

In accordance with the notion of a mutual inhibitory interaction of the factors controlling SWA and REM sleep,[27] not only is REM sleep inhibited by slow wave pressure, but SWA is also inhibited by REM sleep pressure. Thus selective REM sleep deprivation led to a significant reduction in the low-frequency activity of the NREM sleep EEG,[53] an observation that was also made in an animal experiment.[56] The rise in REM sleep pressure induced by repeated partial sleep deprivation suppressed the typical low-delta peak in the NREM sleep spectrum.[54,55] However, this effect was not seen after selective REM sleep deprivation.[50]

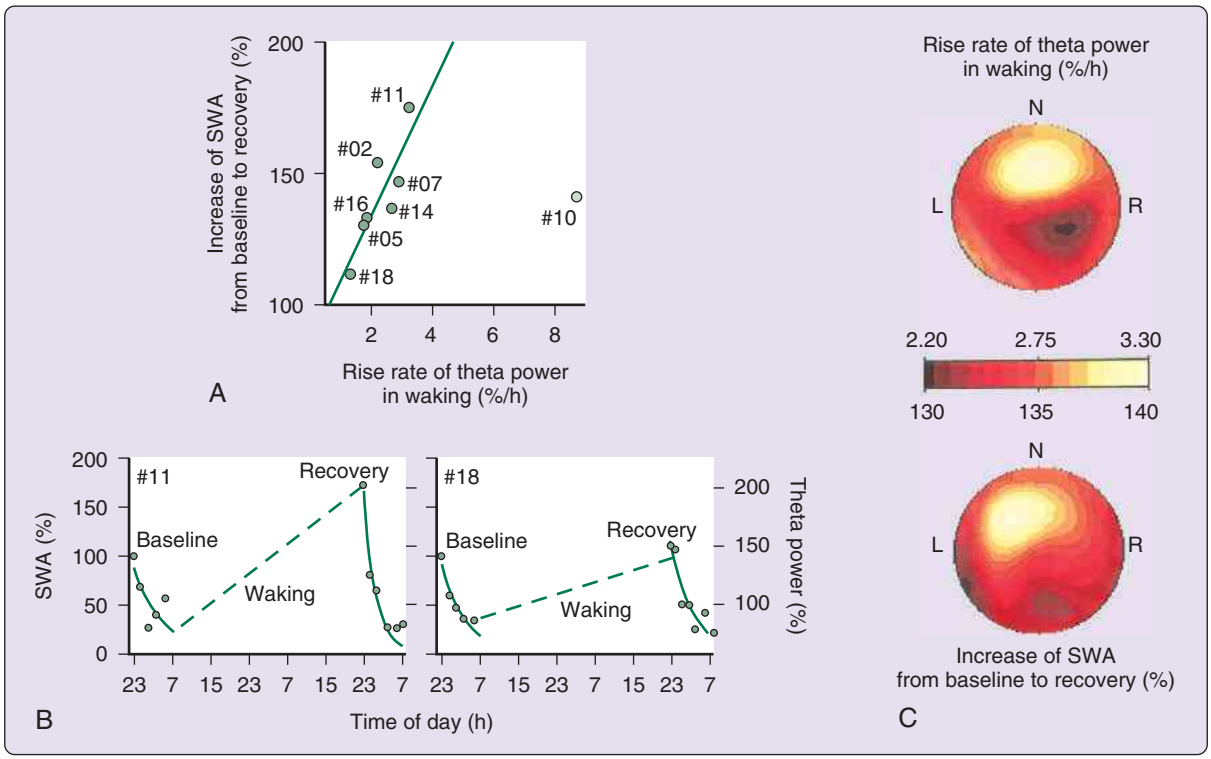

Figure 36-3 **A,** Relationship between homeostatic markers of the sleep electroencephalogram (EEG) and waking EEG. Increase (%) of slow wave activity (SWA; 0.75–4.5 Hz) in the first NREM sleep episode from baseline to recovery sleep is plotted as a function of the rise rate (%/h) of theta power (5.0–8.0 Hz) in waking. The linear regression line fitted through 7 data points is indicated ($r = 0.851$, $r^2 = 0.724$, $P = .015$). Subject no. 10 was excluded from the regression. **B,** Association between rise of SWA in sleep and theta activity in waking illustrated for two subjects. Mean SWA per NREM sleep episode is plotted at the beginning of each episode and expressed relative to the baseline value of the first NREM sleep episode (100%). Exponential functions were fitted through the data points (*solid curves*). The regression line represents theta power in waking (*interrupted line*). **C,** Topographic distribution of the rise rate of theta power (*top*) during waking and of the increase of SWA (*bottom*) in the first NREM sleep episode from baseline to recovery sleep. Maps are based on 27 EEG derivations (average reference; extended 10-20 system). Values are plotted on a color scale at the corresponding position on the planar projection of the hemispheric scalp model. Values between electrodes were linearly interpolated. (Modified from Finelli LA, Baumann H, Borbély AA, Achermann P. Dual electroencephalogram markers of human sleep homeostasis: correlation between theta activity in waking and slow-wave activity in sleep. *Neuroscience* 2000;101:523–9.)

Homeostatic Marker in the Waking Electroencephalogram

It had been shown in early studies that power in the theta band (theta activity) and alpha activity of the waking EEG is associated with sleepiness[57,58] and that total[58] or partial sleep deprivation[55] enhanced the power in these frequency bands. A saturating exponential function with a time constant of 18.18 hours was reported to fit the rise of theta activity in the waking EEG.[59] Spectral analysis showed that the largest changes occurred in the theta band (see Borbély and Achermann[60] for review). These undergo a circadian modulation in addition to the changes related to wake time.[61-66] During prolonged wakefulness, subjective sleepiness correlated positively with theta activity with a focus in frontal derivations and negatively with alpha activity at all derivations.[67] A forced desynchrony study with a scheduled waking episode of 28 hours showed a monotonic rise of delta and beta activity in the frontocentral derivation.[65] An analysis of persons subjected to sleep deprivation revealed that the rise rate of theta activity in the waking EEG is correlated with the increase of SWA in the first NREM sleep episode of recovery sleep (Figure 36-3, *A* and *B*).[61] Moreover, both effects were largest in frontal areas (Figure 36-3, *C*). In summary, theta activity in waking and SWA in sleep may be markers of a common homeostatic sleep process.

Independence and Interactions of Homeostatic and Circadian Processes

There is evidence that homeostatic and circadian facets of sleep regulation can be independently manipulated and therefore may be controlled by separate mechanisms. Thus throughout a 72-hour sleep deprivation period, the subjective alertness ratings continued to show a prominent circadian rhythm.[68] Conversely, in a study in which the phase of the circadian process (as indexed by body temperature and plasma melatonin) was shifted by bright light in the morning, the time course of SWA remained unaffected.[69]

A powerful experimental paradigm is the forced desynchrony schedule in which the homeostatic and circadian facet of sleep can be separately analyzed.[70,71] In this long-term protocol, the imposed sleep-wake cycle (e.g., 20 hours or 28 hours) lies outside the range of entrainment of the circadian pacemaker. When this schedule is maintained for 3 weeks,

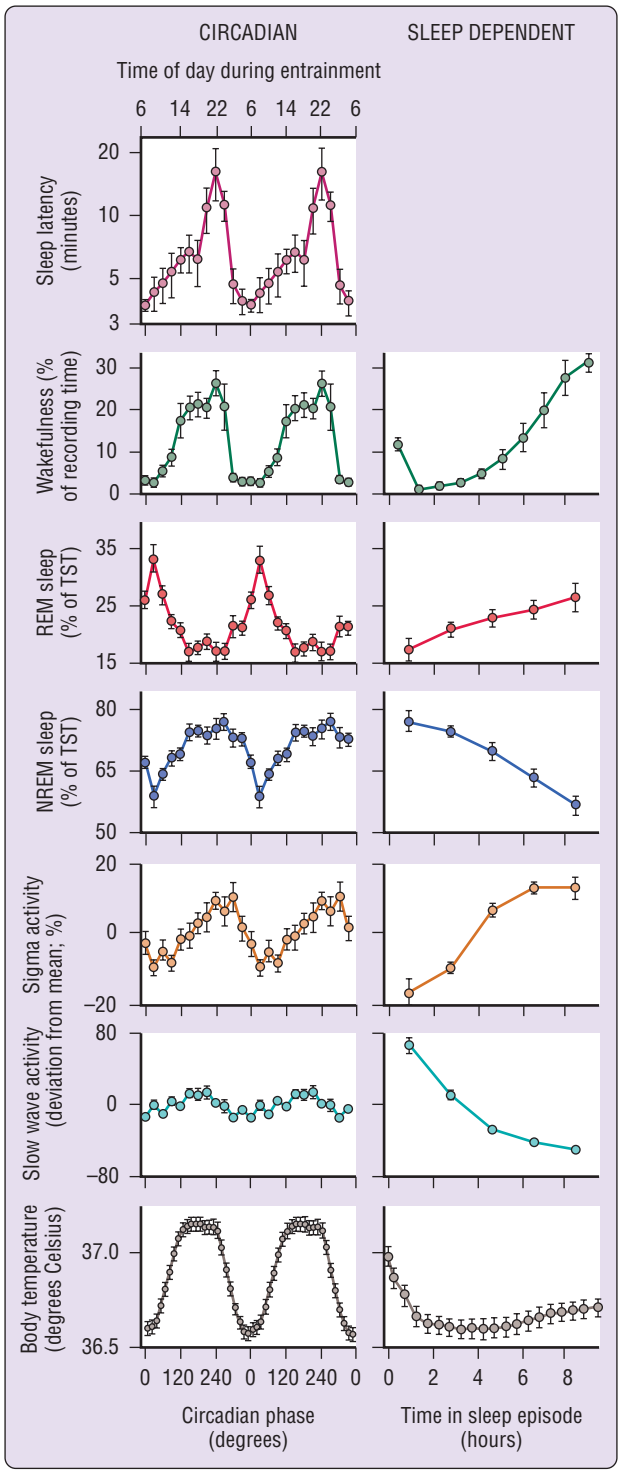

Figure 36-4 Circadian and sleep-dependent or homeostatic factors in sleep regulation. The main effects of circadian phase and sleep homeostasis on sleep were analyzed by aligning the data relative to the circadian component of the body temperature cycle (*left panels*) or the beginning of the sleep opportunity (*right panels*). Slow wave activity shows weak circadian and strong sleep-dependent modulation; sigma (sleep spindle) activity shows strong circadian and sleep-dependent modulation. NREM sleep percentage shows equal circadian and sleep-dependent components. REM sleep percentage shows marked circadian maximum just after the temperature nadir and sleep-dependent increase (disinhibition). Wakefulness in scheduled sleep episodes shows that the circadian drive for wakefulness is maximum 7 to 9 hours before temperature nadir, which is 1 to 3 hours before habitual bedtime; there is a strong wake-dependent increase. Sleep latency shows strong circadian modulation; the longest sleep latencies occur 7 to 9 hours before the body temperature nadir, and the shortest sleep latencies occur at the body temperature nadir. TST, Total sleep time. (Modified from Dijk DJ, Czeisler CA. Contribution of the circadian pacemaker and the sleep homeostat to sleep propensity, sleep structure, electroencephalographic slow waves and sleep spindle activity in humans. *J Neurosci* 1995;15:3526–38; and Dijk DJ, Czeisler CA. Paradoxical timing of the circadian rhythm of sleep propensity serves to consolidate sleep and wakefulness in humans. *Neurosci Lett* 1994;166:63–8. Corresponds to Figure 34-4 of Dijk DJ, Franken P. Interaction of sleep homeostasis and circadian rhythmicity: dependent or independent systems? In: Kryger MH, Roth T, Dement WC, editors. *Principles and practice of sleep medicine.* 4th ed. Philadelphia: Saunders; 2005. p. 418–34.)

sleep occurs at different circadian phases. The contributions of the homeostatic and circadian components can be estimated by folding the data of the variable investigated either at the period of the imposed sleep-wake cycle or at the period of circadian rhythm. Various claims of the two-process model were supported by the results obtained in this paradigm.[70] As shown in Figure 36-4, the variation of SWA is accounted for mainly by homeostatic (i.e., sleep-wake dependent) factors, whereas the percentage of REM sleep, NREM sleep, SFA (sigma activity), and sleep consolidation are determined by both homeostatic and circadian factors. Furthermore, a previously postulated sleep-related disinhibition of REM sleep[27] was confirmed. Severe sleep restriction attenuates the circadian modulation of sleep.[71,72] The role of the metrics used and whether homeostatic and circadian processes exhibit a linear or a nonlinear interaction are still under discussion.[73]

MODELS OF SLEEP REGULATION

Models help delineate the processes involved in the regulation of sleep and thereby offer a conceptual framework for the analysis of existing and new data. In addition, they inspire new experiments to test predictions of the models.

Models may address processes at different levels (from the microscopic [cellular] level to the macroscopic [systemic] level) and at different time scales (from the range of milliseconds or seconds up to hours or days[74]). Being aware of the power and limitations of models is important for selecting the most appropriate one for the question to be addressed.

The term *model* has been loosely applied to hypothetical descriptions of events, features, and processes related to sleep. The following synopsis is restricted to major models that include a mathematical description and address sleep regulation. Their main features are summarized in Tables 36-1 and 36-2. We describe only selectively models addressing the generation of specific features of the sleep EEG and do not include molecular state variables of sleep regulation.[75]

Table 36-1 Two-Process Model and Related Models

Designation	Assumption	Description and Comment
Two-process model[27,78,82,83]	Sleep propensity is determined by a homeostatic process S and circadian process C. The interaction of S and C determines the timing of sleep and waking.	Time course of S derived from EEG slow wave activity; phase position and shape (skewed sine wave) of C derived from sleep duration data obtained at various times of the 24-hr cycle.
Model of ultradian variation of slow wave activity[84-86]	Derived from the two-process model. The level of S determines the buildup rate and the saturation level of slow wave activity within NREM sleep episodes.	In contrast to the original two-process model, the change of S, not the level of S, corresponds to slow wave activity; that is, the decline of S is proportional to the amount of slow wave activity. A REM sleep oscillator triggers the decline of slow wave activity before REM sleep.
Three-process model of sleepiness-alertness regulation[97-99,167]	Sleepiness and alertness are simulated by the combined action of a homeostatic process, a circadian process, and sleep inertia (process W). Extension to include performance, sleep latency, and sleep length. Adaptation of homeostatic process to account for performance prediction in sleep-restriction protocols.	Parameters derived from rated sleepiness during sleep-wake manipulations. Alertness nomogram for sleep-related safety risks.
Interactive mathematical models of alertness and cognitive throughput[100]	Alertness and cognitive throughput are determined by a nonlinear interaction of a homeostatic (H) and a circadian (C) process. Sleep inertia is also included. H shows a sigmoidal decline during waking and a saturating exponential increase during sleep at a rate determined by the circadian phase.	Parameters derived from sleep inertia studies, sleep deprivation studies initiated across all circadian phases, and 28-hr forced desynchrony studies.

Two-Process Model and Related Models

The two-process model and related models are summarized in Table 36-1. Further models inspired by the two-process model addressing performance simulations were discussed in a special issue of *Aviation, Space and Environmental Medicine*[76] and elsewhere.[3,30,60,77-79]

The relationship between SWS and the duration of prior waking has been documented by Webb and Agnew[20] and placed into a theoretical framework by Feinberg.[80] The two-process model, originally proposed to account for sleep regulation in the rat,[2,81] postulates that a homeostatic process (process S) rises during waking and declines during sleep and interacts with a circadian process (process C) that is not directly dependent on sleep and waking. The time course of the homeostatic variable S was derived from EEG SWA (Figure 36-5, *A*). Various aspects of human sleep regulation were addressed in a qualitative version of the two-process model.[27] An elaborated, quantitative version of the model was established in which process S varied between an upper and a lower threshold that are both modulated by a single circadian process.[82,83] This model was able to account for such diverse phenomena as recovery from sleep deprivation, circadian phase dependence of sleep duration, sleep during shift work, sleep fragmentation during continuous bed rest, and internal desynchronization in the absence of time cues.[83]

In a later version of the model (proposed by Beersma et al.[21] and Dijk et al.[32] and formalized by Achermann and Borbély[84,85]), it is the change of S, and not its level, that is proportional to the momentary amount of SWA. The elaborated model addressed not only the global changes of SWA as represented by process S but also the changes within NREM sleep episodes. In general, a close fit was obtained between the simulated and empirical SWA data and their time course (Figure 36-5, *D*). In particular, the occurrence of late SWA peaks during extended sleep could be simulated (Figure 36-5, *C*). The simulations demonstrated that the model accounts in quantitative terms for empirical data and predicts the changes induced by the prolongation of waking or sleep. This version of the model was used to simulate the dynamics of SWA in an experimental protocol with an early evening nap[24] and the effect of changes in REM sleep latency on the time course of SWA.[86] Zavada and colleagues[87] used this model's approach to investigate regional aspects of sleep homeostasis.

The homeostatic process S is modeled by two exponential functions, one describing the rising limb during waking, the other the declining limb during sleep (see Figure 36-5, *A*). The buildup of sleep pressure is approximated by a saturating exponential function (time constant of increase; upper asymptote), its dissipation by a declining exponential function (time constant of decrease; lower asymptote). Thus, process S oscillates between an upper and lower asymptote (relaxation oscillator), its dynamics being determined by the distance between the asymptotes and by the time constants. The time constants show significant interindividual variability[88] and vary also across brain regions.[89] Importantly, homeostasis is mainly reflected in the time constants, and it was hypothesized that a slower buildup may be associated with an increased tolerance to sleep deprivation.[88] A slowing of the buildup of sleep pressure was observed in preschool children in the course of development[90] and during early adolescence.[91] It is important to recognize that the absolute values of SWA are highly variable

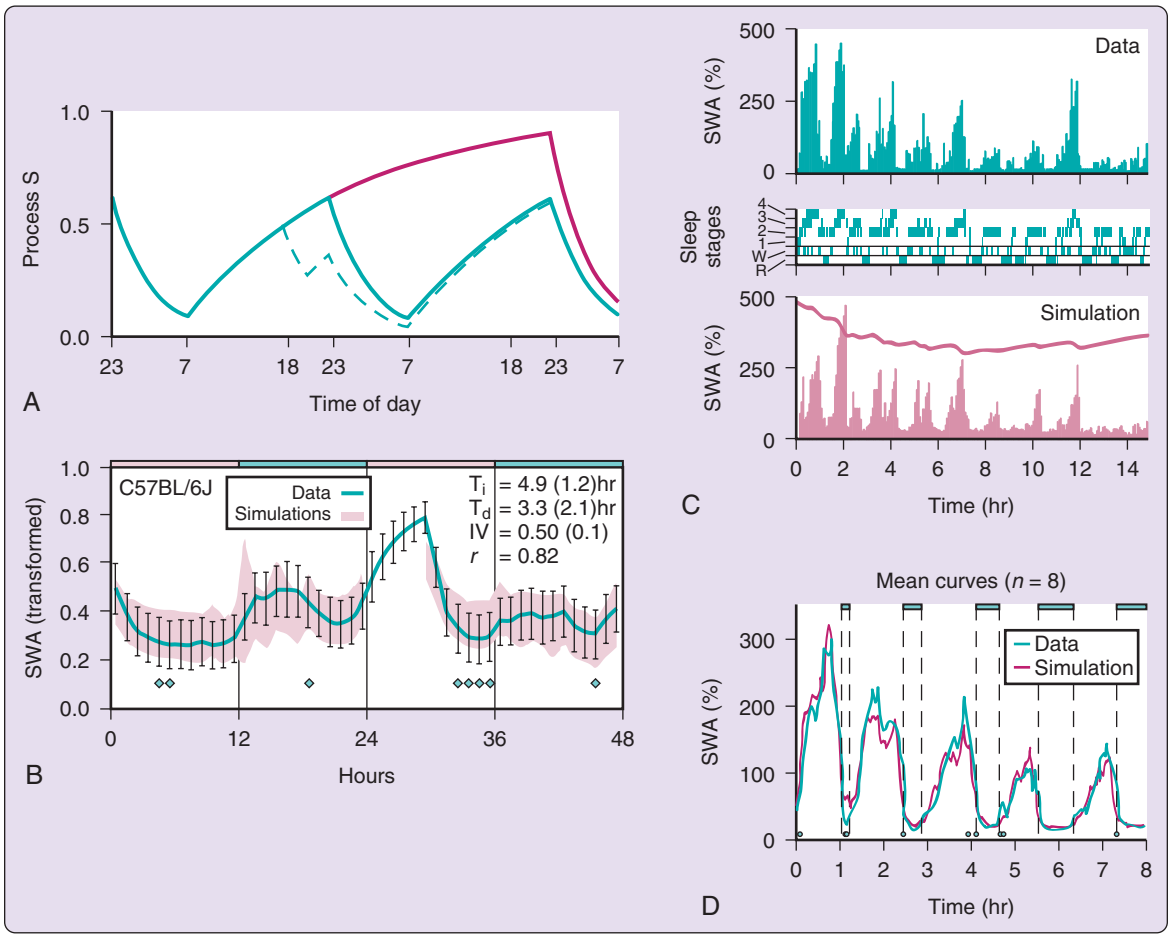

Figure 36-5 Two-process model of sleep regulation. **A,** Simulations of the homeostatic process S according to different experimental conditions. The *green line* indicates baseline condition with an 8-hour sleep episode; the *red line* indicates sleep deprivation (40 hours of wakefulness) and recovery sleep; the *dashed line* indicates effect of a 2-hour daytime nap at 18:00 hours. **B,** Sleep regulation in the mouse. Time course of slow wave activity (SWA) and simulation with the optimized time constants for the increase (Ti) and decrease (Td) and initial value (iV) of process S for C57BL/6J mice (N = 8). *Curves* and *shaded areas* connect 1-hour mean values (±SEM) for 24-hour baseline, 6-hour sleep deprivation, and 18-hour recovery. The close fit between the simulation of process S (*pink areas*) and time course of empirical SWA (*solid line*) indicates that the model can predict SWA from the temporal organization of sleep. *Diamonds* indicate differences between simulation and data ($P < .05$; two-tailed paired t-test). For the comparison between SWA and S, SWA was transformed according to a linear regression. *Inset:* Mean values of Ti, Td, and iV (SEM) and the mean *r* value of the fit between SWA and S. **C,** Empiric SWA (*top*), sleep stages (*center*), and simulation of SWA and process S (*bottom*) of an individual extended baseline sleep episode starting at 00:00 hours (prior waking: 17:00 hr). Empiric and simulated SWA were standardized with respect to the mean value of the first 7 hours of sleep. Values are plotted for 1-minute intervals. **D,** Mean empirical (*green line*) and simulated SWA (*pink line*) (N = 8) of an extended baseline experiment (analysis of first 8 hours). Significant differences are indicated by *open circles* (paired t-test; $P < .05$). *Bars on top* and the *interrupted vertical lines* indicate REM sleep episodes (mean values). (**B** modified from Huber R, Deboer T, Tobler I. Effects of sleep deprivation on sleep and sleep EEG in three mouse strains: empirical data and simulations. *Brain Res* 2000;857:8–19. **C** and **D** modified from Achermann P, Dijk DJ, Brunner DP, Borbély AA. A model of human sleep homeostasis based on EEG slow-wave activity: quantitative comparison of data and simulations. *Brain Res Bull* 1993;31:97–113.)

between individuals and are in a large part dependent on age.[92] Thus absolute levels of SWA are not a measure of sleep pressure or homeostasis per se, but it is the relative change in SWA in response to a challenge that is informative (e.g., for total or partial sleep deprivation, sleep restriction, naps). Furthermore, the distance between the asymptotes may be interpreted as the capacity of the brain to generate slow waves.[88,90,91]

Finally, the data analysis showed that not only the timing of sleep but also the changes in daytime vigilance are governed by the interaction of processes S and C, as simulated by Daan and colleagues.[83] The rising homeostatic sleep pressure during waking seems to be compensated by the declining circadian sleep propensity.[83,93-95] Conversely, during sleep the rising circadian sleep propensity might serve to counteract the declining homeostatic sleep pressure, thereby ensuring the maintenance of sleep.[96]

Based on a similar concept, the changes of subjective sleepiness/alertness ratings were simulated by a combined action of a homeostatic process (S), a circadian process (C), and a process representing sleep inertia (W) (three-process

Table 36-2 Neurophysiologic Network Models of Sleep-Wake Regulation (Brainstem and Hypothalamic Control of Sleep-Wake States)

Designation/Model	Assumption*	Description/Comment
Quantitative model of sleep-wake dynamics based on physiology of the brainstem ascending arousal system Phillips and Robinson[125,132-137,168-171]	Model includes VLPO (where circadian and homeostatic drives enter the system), monoaminergic and cholinergic nuclei of the ascending arousal system, and corresponding interconnections Mutual inhibition between wake-promoting monoaminergic group and sleep-promoting VLPO causes flip-flop behavior REM sleep not incorporated	Human sleep: simulation of basic sleep behavior; effects of sleep deprivation, effect of caffeine, fatigue, impulsive stimuli, internal desynchronization, and shift work Animal sleep: simulation of interspecies differences and unihemispheric sleep
Biologically based mathematical model of the sleep-wake cycle Rempe et al.[126]	Model is based on flip-flop conceptual models for sleep-wake and REM-NREM sleep alterations Includes the sleep-promoting neurons in the VLPO, the wake-promoting monoaminergic cell groups, and orexin neurons Mutual inhibition of REM-on and REM-off populations	Human sleep: simulation of basic sleep patterns; sleep deprivation; role of orexin; and sleep-onset REM sleep
Mathematical model of neuronal regulation of waking, NREM sleep, and REM sleep Kumar et al.[172]	Two distinct flip-flop circuits, one governing wake-NREM sleep transitions (POAH, MRF, CRF, and orexinergic groups) and the other NREM sleep–REM sleep transitions (LDT/PPT and LC) REM sleep generation by presynaptic inhibition of substantia nigra onto REM-off terminals projecting on REM-on neurons. Putative REM sleep homeostasis. Mutual inhibition of REM-on and REM-off populations	Human sleep: simulation of basic sleep patterns; sleep deprivation; and role of orexin (orexinergic neurons stabilize the wake-sleep cycle)
Quartet neural system model of sleep and wakefulness mechanisms Tamakawa et al.[127,173]	Neural system consisting of sleep-active preoptic or anterior hypothalamic neurons (N-R group); wake-active hypothalamic and brainstem neurons (WA group); brainstem neurons (REM group); and basal forebrain, hypothalamic, and brainstem neurons (W-R group) WA neurons have mutual inhibitory couplings with REM and N-R neurons. W-R neurons have mutual excitatory couplings with WA and REM neurons. REM neurons receive unidirectional inhibition from N-R neurons. N-R neurons are activated by sleep-promoting substances Reciprocal interaction between REM-on and REM-off populations	Human sleep: simulation of basic sleep-wakefulness rhythms Rodent sleep: model reproduced sleep and wakefulness patterns of rats; microinjection experiments; circadian modulation
Mathematical model of network dynamics governing mouse sleep-wake behavior Diniz Behn et al.[124,174]	Sleep-wake network composed of coupled relaxation oscillators Network includes wake-, sleep-, and REM sleep–promoting populations Incorporation of orexin signaling Reciprocal interaction between REM-on and REM-off populations	Rodent sleep: simulation of dynamics underlying state transitions
Modeling framework of the sleep-wake regulatory network in the brainstem and hypothalamus Diniz Behn & Booth[128,175-179]	Neurotransmitter-mediated interactions among brainstem and hypothalamic neuronal populations that participate in the transitions between wake, REM sleep, and NREM sleep Reciprocal interaction between REM-on and REM-off populations	Human sleep: simulation of basic sleep behavior and internal desynchronization Rodent sleep: simulation of basic sleep behavior; microinjection experiments; circadian modulation; temporal architecture of sleep patterns

CRF, Caudal reticular formation; LC, locus coeruleus; LDT/PPT, laterodorsal tegmentum/pedunculopontine tegmentum; MRF, midbrain reticular formation; POAH, pre-optic anterior hypothalamus; VLPO, ventrolateral preoptic area.

*Basic assumption in all models is that transitions between sleep or NREM sleep and wake are mediated by mutual inhibition between sleep or NREM sleep–promoting and wake-promoting neuronal populations. Inclusion of homeostatic and circadian components.

model; Table 36-1[97,98]). The model has been expanded[99] to account for discrepancies observed in chronic sleep restriction experiments.

Jewett and Kronauer (Table 36-1[100]) proposed interactive mathematical models of subjective alertness and cognitive throughput in humans. A homeostatic component (H) falls in a sigmoidal manner during waking and rises according to a saturating exponential function during sleep. The rise of H during sleep is determined by the circadian phase. H interacts with a circadian component (C[101]), accounting for the effect of light on the circadian pacemaker. The amplitude of C depends on the level of H. In addition, a sleep inertia component (W) is included. In contrast to the two- and three-process models, a nonlinear interaction is assumed. Whether the interaction is linear or nonlinear is still unresolved.[102,103] A statistical approach to test for nonlinear interactions was proposed[73] and is based on a comparison of model predictions and empiric data.

Experiments with chronic sleep restriction demonstrated that the homeostatic sleep drive is not associated with neurobehavioral performance.[104] The latter showed a cumulative impairment with a considerable degree of individual variability. To account for the slow recovery of neurobehavioral functions after sleep deprivation, the possibility of a second homeostatic process with a very long time constant was considered.[105] McCauley and colleagues[72,106] expanded the two-process model to a broader class of models that have a dynamic repertoire capturing waking neurobehavioral functions across a wide range of wake-sleep schedules. Models of sleep, fatigue, and performance based in large part on the two-process model are reported in a special issue of *Aviation, Space and Environmental Medicine*.[76] For a recent review, see Dawson et al.[107]

Because most of these models are based on average data, predictions of individual performance are limited.[108] A difficulty in addressing individual differences is due to the fact that individual parameters need first to be determined. Two approaches to predict individual performance in sleep deprivation experiments have been proposed.[109,110] Both approaches are based on the two-process model and allow a continuous parameter adaptation in an iterative process as new empiric data become available.

Although the qualitative version of the two-process model had originated from animal data,[2,81] the quantitative version was elaborated on the basis of findings from human studies. In the meantime, quantitative simulations of NREM sleep homeostasis were also performed in rats[111-114] and mice[115,116] (Figure 36-5, *B*). SWA of consecutive 4-second epochs in a 24-hour baseline, a 6-hour sleep deprivation, and 18-hour recovery period[115] served as the database for the simulation in mice. Like in the original human version of the model, process S was assumed to decrease exponentially in NREM and REM sleep and to increase according to a saturating exponential function in waking. Unlike in the human model, S increased also in REM sleep. After optimizing the initial value of S (IV) as well as its time constants (increase Ti; decrease Td), a close fit was obtained between the hourly mean values of SWA in NREM sleep and the prediction of process S (see Figure 36-5, *B*).

Modeling REM Sleep

Whereas many models have focused on NREM sleep homeostasis, on the interaction of NREM and REM sleep, and on the circadian oscillator, REM sleep regulation per se has been largely ignored. This is because of the complex and not yet clearly understood principles underlying REM sleep regulation (see earlier). The NREM-REM sleep cycle has been accounted for by the limit cycle reciprocal interaction model on the basis of interacting neuronal systems (for a elaborated version and for the activation-synthesis model, see Pace-Schott and Hobson[117]). Attempts were made to integrate various concepts into a combined model.[118,119] Saper and coworkers proposed in their flip-flop model a mode of interaction between different neurotransmitter systems that accounts for the sharp state transitions between waking and sleep[120] as well as between NREM and REM sleep.[121,122] Mathematical models incorporating these neurophysiologic aspects are summarized in Table 36-2.

Neurophysiologic Models

Neuronal models may be subdivided into neurophysiologic models based on detailed neuronal architecture (e.g., neurons, synapses) addressing thalamocortical interactions[123] and models that capture essential features based on the dynamics of neuronal populations (approximation of activity of a large ensemble of neurons; see Table 36-2).

Extended versions of the two-process model were derived from neurophysiologic data[124-129] (see Table 36-2). For a recent review and mathematical analysis of the models, see Booth and Diniz Behn.[130] Interactions of neuronal populations in the brainstem and hypothalamus were used to simulate transitions between sleep and waking or between NREM and REM sleep. In addition, a homeostatic and a circadian component was included. To a large degree, the slow dynamics (hours to days) of these models resemble the dynamics of the two-process model.[130,131] The degree of similarity between the two-process model and the Phillips-Robinson model[125] was recently explored.[131] The authors demonstrated that the slow dynamics of the Phillips-Robinson model could be explicitly related to the two-process model providing a neurophysiologic interpretation of the thresholds. This model[125] (see Table 36-2) was applied to simulate sleep fragmentation experiments,[132] differences in mammalian sleep patterns,[133] and subjective fatigue during sleep deprivation.[134] It was refined to simulate effects of caffeine[135] and spontaneous internal desynchronization through feedback of the sleep-wake cycle on the circadian component.[136,137]

For a better understanding of sleep-wake regulation, the development and analysis of models based on neurophysiologic mechanisms are essential. However, these models become more and more complex and comprise a large parameter space with only few parameters that can be determined empirically. Additionally, large numbers of simulations have to be performed to establish the system behavior. Therefore it is difficult to compare the performance of the different models. A further challenge is model validation. What are the relevant end points to investigate? The replication of qualitative patterns of behavioral state transitions is insufficient for parameter estimation of such highly complex models. Thus the application of sophisticated statistical approaches to determine model parameters is needed for further progress.[130]

A large-scale network[123] based on detailed neuronal architecture (65,400 neurons; 4,860,450 connections) has been proposed. It encompasses portions of two visual areas and associated thalamic and reticular thalamic nuclei addressing

the generation of slow oscillations (slower than 1 Hz). The areas are characterized by slow membrane potential fluctuations of cortical neurons, with depolarizing (up-state) and hyperpolarizing (down-state) components alternating with a frequency slower than 1 Hz. The model was used to simulate effects of neuromodulators or changes in synaptic strength[43] in slow waves. Furthermore, in a modified model encompassing three-layered motor cortex, effects of transcranial magnetic stimulation were investigated.[138]

CONCLUSIONS AND PERSPECTIVES

Ever since the first EEG recording by Hans Berger with a Siemens galvanometer, technical advances were instrumental for progress in sleep research. This has been evident in regard to the issues addressed in this chapter. The increasing ease of recording the sleep EEG from multiple derivations, combined with access to computer programs to analyze and visualize the data, has made it possible to explore the sleep process on a regional level. Differences became readily apparent between frontal and occipital derivations.[139,140] Frontal derivations have been shown to exhibit the largest response to changes in sleep pressure in terms of both SWA during sleep and theta activity during waking.[141-144] The topographic analysis of the EEG revealed that the frontal predominance of low-frequency activity is a common feature of NREM sleep, REM sleep, and waking and therefore represents a state-independent trait.[142,145] Thus basic features of the homeostatic process are present throughout the sleep-wake cycle, suggesting that sleep and waking could be seen as part of a continuum.[144]

Regional differences pose a challenge to modeling because differences in the characteristics of the homeostatic process (e.g., time constants, level of asymptote) may reflect different regulatory features of specific neuronal ensembles.[87,89]

The report of unihemispheric deep sleep in the dolphin[146,147] not only constituted evidence for a regional segregation of the sleep process but also raised the question of its functional significance. Hypotheses have been advanced implying that regional increases in neuronal activity and metabolic demand during wakefulness might result in selective changes in EEG synchronization of these neuronal populations during NREM sleep.[148-153]

The theory of a local, use-dependent increase of sleep intensity was tested by investigating whether a local activation of a particular brain region during wakefulness affects the EEG recorded from the same site during sleep. The first positive result consisted of the increase in low-frequency activity over the contralateral somatosensory cortex in the first hour of sleep following a vibratory stimulus to the contralateral hand.[154] This regional use-dependent effect was subsequently confirmed and extended.[155,156] Analogous findings were obtained in the rat and human, in which unilateral sensory or optic stimuli, respectively, during waking caused an interhemispheric shift in low-frequency power in the NREM sleep EEG.[157,158] Conversely, in a human study the selective understimulation of the cortical arm projection area during waking achieved by unilateral arm immobilization induced a reduction of power over the corresponding cortical region during subsequent sleep.[159]

The notion of sleep homeostasis, originally derived from the sleep-wake-dependent changes of the EEG slow waves, was recently expanded to the synaptic level. Tononi and Cirelli[151,152] proposed a synaptic homeostasis hypothesis postulating that synaptic strength is maintained over time by alternating phases of predominant potentiation during waking with phases of predominant depression during sleep. NREM sleep and the typical slow waves would subserve synaptic downscaling and thereby safeguard energy, space, and cellular supplies. The synaptic homeostasis hypothesis has the merit of relating the changes at the level of the EEG to well-known mechanisms at the synaptic level and thereby allowing specific predictions that can be not only simulated,[43] but also tested by electrophysiologic and neurochemical techniques in both humans and animals.[160-163] Vyazovskiy and Harris[153] proposed that periods of reduced synaptic input (so-called off periods or down states) serve prophylactic cellular maintenance. Krueger and collaborators[164-166] also underline the local aspect of sleep. Starting from an early theoretical paper,[149] they view sleep as an emergent property of cortical columns and propose a nonlinear mathematical model to account for the interactions between columns.[150]

In conclusion, models have proved useful for delineating regulating processes underlying such a complex and little-understood phenomenon as sleep and thereby offer a conceptual framework for analyzing existing and new data. The major models have already inspired a considerable number of experiments.

CLINICAL PEARL

The common experience that a good night's sleep dissipates fatigue and tiredness and regenerates energy points to a specific restorative function of sleep that cannot be achieved by merely resting. Sleep homeostasis denotes a basic principle of sleep regulation that can lead to a better understanding of sleep pathologies. Deficient sleep homeostasis might account for the altered sleep architecture in depression, and the transient normalization of sleep propensity can explain the antidepressant effect of sleep deprivation. The elucidation of sleep homeostasis at the cellular and molecular levels could open new avenues for the pharmacologic therapy of sleep disorders.

SUMMARY

Sleep homeostasis denotes a basic principle of sleep regulation. A sleep deficit elicits a compensatory increase in the intensity and duration of sleep, whereas excessive sleep reduces sleep propensity. It is as though sleep pressure is maintained within a range delimited by an upper and lower threshold. Sleep homeostasis is represented in the two-process model of sleep regulation by process S, which increases during waking and declines during sleep. The timing and propensity of sleep are modulated also by a circadian process. EEG SWA serves as an indicator of sleep homeostasis in NREM sleep. The level of SWA, a correlate of sleep intensity, is determined by the duration of prior sleep and waking. In the waking EEG, theta activity shows a rising trend with the progression of wakefulness and represents a marker of process S. However, in contrast to SWA, theta activity undergoes a marked circadian modulation. Advanced versions of the two-process model were applied to simulate the SWA pattern in a variety of experimental schedules. Other models addressing sleep regulation are derived from neurophysiologic data.

Circadian Rhythms in Sleepiness, Alertness, and Performance

Rylie J. Gabehart; Hans P.A. Van Dongen

Chapter Highlights

- Alertness and performance vary across the day, driven by the circadian rhythm of the biologic clock. We tend to be less alert in the early morning and late at night, but the changes in alertness and performance over time also depend on the circumstances.
- A variety of other factors (e.g., activity, posture, caffeine intake) influence the pattern of circadian rhythmicity as observed in alertness and performance measures. Investigating the effect of the biologic clock requires careful control over these so-called masking effects.
- Temporal patterns of alertness and performance also reflect the interaction of the circadian process with a homeostatic process regulating sleep. Accounting for this homeostatic process is critical for understanding and predicting the occurrence of performance deficits across the 24 hours of the day.

Both wakefulness and sleep are modulated by an endogenous, circadian regulating system, the biologic clock, located in the suprachiasmatic nuclei of the anterior hypothalamus. The impact of the biologic clock goes beyond compelling the body to fall asleep and to wake up again. The biologic clock also modulates hour-to-hour waking behavior, as reflected in alertness and performance, generating circadian rhythmicity in almost all neurobehavioral variables investigated.

Before focusing on circadian rhythmicity in waking neurobehavioral functions, it is important to give a brief description of some variables capturing aspects of waking functioning because different definitions can be found in the literature.[1-3] Here, we use the term *sleepiness* for subjective reports of sleepiness or the desire to sleep. In operational settings the term *fatigue* is often used in lieu of sleepiness[4] (but in this chapter, the term is not used). By *alertness* we mean the antonym of sleepiness (although these terms have been differentiated[5]) and the ability to sustain attention. *Performance* refers to cognitive functioning on tasks ranging from psychomotor vigilance and working memory tests to logical reasoning and decision-making tasks. These concepts may be discussed collectively as *neurobehavioral functioning*.

The term *sleepiness* captures the link between alertness and performance during wakefulness on the one hand and sleep on the other hand. The interaction of the circadian and sleep-wake systems in regulating sleepiness, alertness, and performance is described in the second part of this chapter. Sleep propensity[6,7] is not covered in this chapter; the focus here is on effortful cognitive performance and the associated subjective states.

CIRCADIAN RHYTHMS

Self-Report Measures of Sleepiness and Alertness

Many different techniques are available for the detection of circadian rhythmicity in neurobehavioral variables, including a wide array of subjective measures of sleepiness and alertness. These include an array of visual analogue scales (VAS)[8]; Likert-type rating scales such as the Stanford Sleepiness Scale[9] and the Karolinska Sleepiness Scale[10]; and adjective checklists such as the Profile of Mood States.[11] Despite structural differences among these scales, self-report measures of sleepiness and alertness tend to be highly correlated over time. They have been used to index circadian rhythmicity by applying them repeatedly across the day.[12-14]

Subjective measures of sleepiness and alertness are subject to numerous confounding influences, which can "mask" their circadian rhythmicity. *Masking* refers to the evoked effects of noncircadian factors on measurements of circadian rhythmicity. The context in which such measurements are taken (i.e., the environmental and experimental conditions) is a major source of masking effects.[15] Masking can alter or obscure a circadian rhythm or create the appearance of a circadian rhythm where there is none. Masking factors affecting sleepiness and alertness may include the following: demand characteristics of the experiment,[16] distractions by environmental stimuli and noise,[17] boredom and motivational factors,[18-20] stimulation,[21] stress,[22] food intake,[23,24] posture and activity,[25,26] ambient temperature,[19] lighting conditions,[27,28] and drug intake (e.g., caffeine).[29]

Physical, mental, and social activities can be masking factors for circadian rhythms in subjective sleepiness and alertness as well. For example, subjects report feeling less alert after performing a challenging cognitive task than before performing said task.[30] In general, prior activity can influence subjective estimates, and it can interact with circadian effects if not properly controlled when measuring rhythmicity in subjective states. Sleep and wakefulness can also be considered masking factors when measuring circadian rhythmicity in neurobehavioral variables. Sleep and sleep loss have significant effects on alertness and performance, as discussed in the second half of this chapter.

A variety of factors also affect the biologic clock itself, changing its timing by causing phase advances or delays. Such

factors are called *zeitgebers* (time givers or time cues) and include exercise, social cues, food intake, sleep, and especially light exposure.[31-34] Their effects typically vary depending on the timing of exposure relative to the circadian cycle of the biologic clock, making it difficult to account for them. As such, it is important to control zeitgeber exposure in studies designed to measure circadian rhythms in neurobehavioral variables. Zeitgebers are discussed further in other chapters in this volume.

Cognitive Performance

Rather than relying on subjective measures, many studies of circadian rhythms have used objective performance measures. For example, studies have employed search-and-detection tasks[35] and simple and choice reaction time tasks[36] to obtain objective measures of circadian variation in cognitive performance. In many tasks, the speed or accuracy of responses to a series of stimuli are analyzed. The sensitivity of the performance metrics in such tasks depends on speed and accuracy tradeoffs (which in turn depend on the demand characteristics of the experiment); on task duration; on the stimulus density (i.e., the number of stimuli presented per unit time); and on whether the task is subject paced or rather experimenter or computer paced.[37-39]

Many performance outputs have been considered, including signal detection,[40] simple sorting,[41] logical reasoning,[42] memory access,[43] meter reading accuracy,[44] and school performance.[45] Furthermore, a number of subcomponents of cognition and cognitive processes involved in task performance can be distinguished, such as sensory input, stimulus encoding, working memory updating, and motor response.[46,47] A variety of tasks have been used to study circadian variation in these different aspects of performance. Some studies concluded that different tasks[48,49] and different task outcomes[50,51] may yield different peak phases of circadian rhythmicity. This has led to speculation that there are many different circadian rhythms and multiple different clock mechanisms controlling them.[52,53]

Under strictly controlled laboratory conditions, however, most of the intertask differences disappear.[54,55] As illustrated in Figure 37-1, it can generally be stated that under such conditions, the circadian rhythms of neurobehavioral performance variables covary with subjective sleepiness. Furthermore, these rhythms reflect the circadian rhythm of core body temperature (CBT), a conventional marker of the biologic clock. High and low CBT roughly correspond to good and poor performance, respectively.[55-57] However, there is a phase difference, such that neurobehavioral variables exhibit their average minimum approximately between 3.0 and 4.5 hours after the time of the body temperature minimum.

This phase delay contradicts the common belief that alertness and performance are worst at the body temperature minimum. Although body temperature predominantly reflects the endogenous biologic clock, neurobehavioral functions are also affected by homeostatic pressure for sleep, which builds up over time awake (as discussed in the second half of this chapter) and contributes to the phase delay. Thus neurobehavioral functions generally show a circadian decline at night, as is observed in CBT, but they continue their decline after CBT begins to rise, making the subsequent 2- to 6-hour period (i.e., clock time approximately 6 AM to 10 AM) a zone of maximum vulnerability to degraded alertness and performance failure.

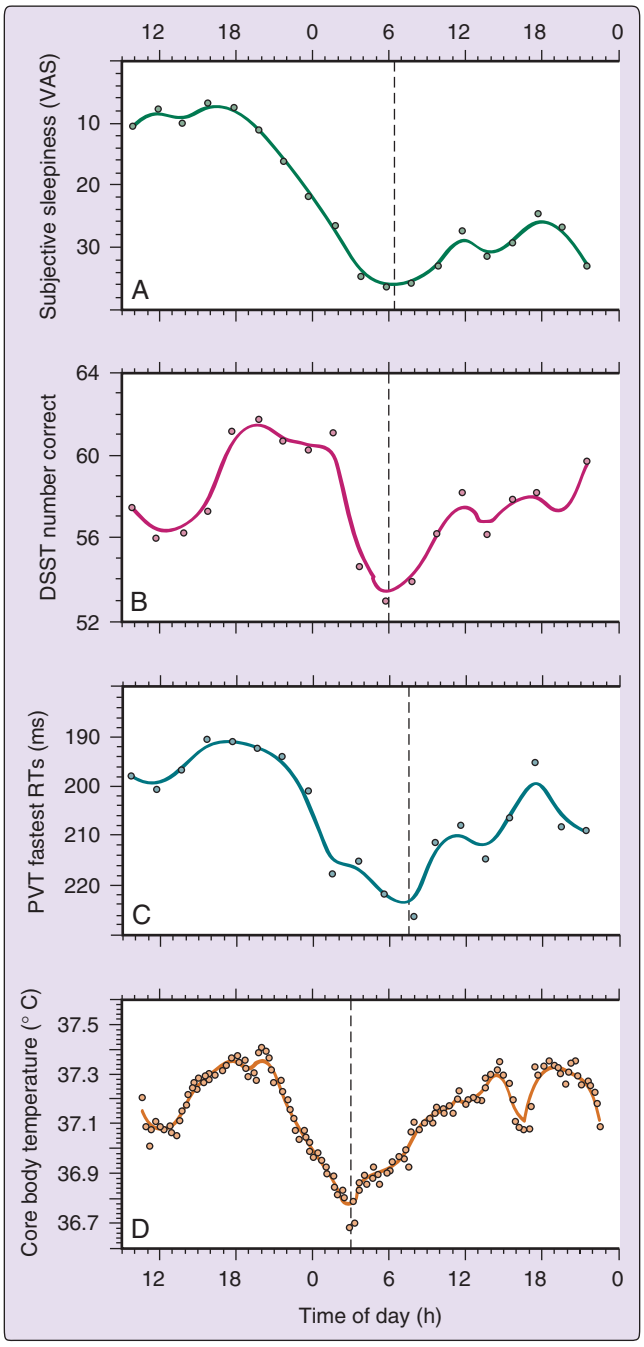

Figure 37-1 Covariation of circadian changes in neurobehavioral variables and core body temperature. **A,** Subjective sleepiness (scale reversed) as assessed by visual analogue scale (VAS).[8] **B,** Cognitive performance as assessed by the digit symbol substitution task (DSST).[129,155] **C,** The 10% fastest reaction times (RTs; scale reversed) as assessed by the psychomotor vigilance test (PVT).[119] **D,** Core body temperature as assessed using a rectal probe. Data shown are the mean values from five subjects who remained awake in dim light, in bed, in a constant routine protocol, for 36 consecutive hours (a distance-weighted least-squares function was fitted to each variable). The circadian trough in each variable is marked by a *vertical broken line.*

In comparison with subjective sleepiness and alertness, assessment of circadian rhythmicity in cognitive performance tends to be complicated.[58] On some tasks, subjects may change their performance strategy on a task over time, for example, by invoking subvocalization in a rhythmic, circadian pattern.[59]

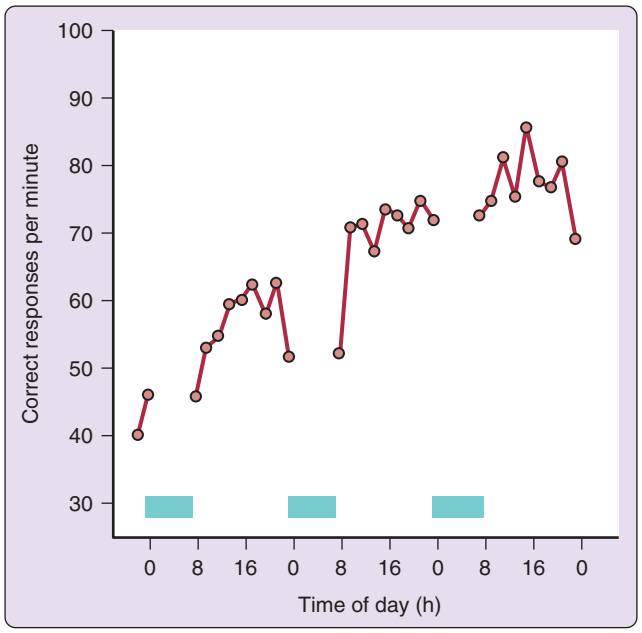

Figure 37-2 Practice effect on the serial addition-subtraction test. Data shown are mean cognitive throughput (correct responses per minute) of 29 subjects tested every 2 hours from 7:30 AM until 11:30 PM each day over a 3-day period. In the serial addition-subtraction test, subjects are presented with a rapid sequence of two single digits (0–9) followed by an operator (+ or –). They are instructed to enter only the least-significant single digit of the algebraic sum, unless the result is negative, in which case 10 is to be added to the answer first.[156] The *solid bars* indicate 8-hour sleep periods (from 11:30 PM until 7:30 AM).

Thus it can be difficult to distinguish the circadian rhythm in task performance per se from that of simultaneous changes in performance strategy. The same issue applies to compensatory effort (i.e., increased effort to keep up performance). The effect of compensatory effort may be especially notable if subjects are informed about their results during a performance task (i.e., performance feedback).[60] Differences among people in aptitude for a task may also confound the assessment of circadian rhythmicity in cognitive performance. This issue can be avoided by means of within-subject study designs and analyses.

Another complicating factor for the assessment of circadian rhythmicity in cognitive performance is the practice effect (or learning curve). This is illustrated in Figure 37-2, which shows performance on a serial addition-subtraction task improving substantially across 3 consecutive days (note the doubling of mean correct responses within 30 test bouts). This practice effect dominates the performance profile, obscuring circadian changes within days. The practice effect contaminates most cognitive performance tasks, and it is difficult to dissociate from the circadian rhythm in performance. This problem may be circumvented, however, by training subjects to asymptotic performance levels before attempting to assess circadian rhythmicity in cognitive performance.

Many of the variables that mask circadian rhythmicity in subjective estimates of sleepiness and alertness (e.g., demand characteristics, distractions, motivation, posture, ambient temperature, lighting conditions; see earlier) may also mask circadian variation in performance. The effects of masking include distortion of the magnitude of circadian variation, shifting of the timing of observed circadian rhythmicity, and changes in the shape of the circadian profile; even total concealment of the circadian rhythm is possible (see Figure 37-2, where sleep prevents measurement of nocturnal performance and the practice effect obscures circadian variation in diurnal performance). Thus it is difficult to extract meaningful information about the amplitude (magnitude) and phase (timing) of the circadian rhythm in performance measures without understanding the masking effects that influence these variables.

Physiologic Measures

The circadian rhythm in cognitive performance reflects functional changes in the brain over time of day. Evoked or event-related potentials (ERPs)—waves (peaks and troughs) in the electroencephalogram (EEG) produced by the brain in response to a stimulus—have been used to measure alertness and cognitive performance. Typically, many ERP measurements are needed (i.e., many stimuli must be presented) to average out the background EEG. Therefore ERPs are usually recorded during repetitive search-and-detect and reaction time tasks. Diurnal changes in the amplitude and the location of ERP waves have been interpreted as reflecting circadian variations in alertness.[61,62] Hemispheric differences have been detected,[63] suggesting separate circadian rhythms for the left and right hemispheres. However, masking from a variety of sources presents a problem in the interpretation of ERP data.[64]

Changes in the background EEG during wakefulness have also been associated with circadian variation in alertness. Despite difficulties in the recording and analysis of the waking EEG,[65,66] the amounts of theta and alpha activity (i.e., EEG activity in the frequency bands from 4 to 8 Hz and from 8 to 12 Hz, respectively) in the resting EEG with eyes held either open or closed (to avoid artifacts from blinking) have been related to alertness level.[67-69] However, significant effects in the EEG occur primarily when alertness is much lower than what is normally encountered at the trough of circadian variation—such as when subjects are sleep deprived.[70]

The EEG has also been used to measure the latency to fall asleep—a measure of sleep propensity—at various times of day. These sleep latency tests include the Multiple Sleep Latency Test[6] and the Maintenance of Wakefulness Test[71] and variations of these paradigms. Sleep latency tests are covered in other chapters in this volume.

Slow eyelid closures have been found to be systematically related to sleepiness.[72,73] Similar findings have been reported for slow-rolling eye movements and other ocular variables.[10,74-79] Pupil diameter is related to autonomic tone (i.e., pupils dilate with greater sympathetic dominance), which covaries with sleep pressure.[80] Pupillometry may therefore also yield estimates of sleepiness,[81] but only if environmental light and other sources of error variance are strictly controlled. The various ocular measures of sleepiness have been investigated primarily under conditions of considerable sleep loss, when the observed effects are more substantial than across the circadian cycle. The same applies for cardiovascular measures that have been found to correlate with sleepiness, such as heart rate variability.[82] Whether ocular and cardiovascular measures can be employed reliably for detecting circadian fluctuations in sleepiness remains to be determined.

Interindividual Differences

Interindividual differences in circadian phase[83] and amplitude[84] are reported throughout the literature. Interindividual

differences in the free-running circadian period have been reported as well,[85] although it should be emphasized that under normal, entrained circumstances the circadian period equals 24 hour.[86] Interindividual differences in circadian variables have been linked to development[87,88] and aging[89-91] and to genetic factors,[92] which are discussed in other chapters in this volume.

Morningness-eveningness (i.e., the tendency to be an early "lark" or a late "owl") is a well-known, phenotypic aspect of interindividual variation in circadian rhythmicity.[93] Morningness-eveningness is commonly measured with questionnaires that ask about a person's preferred timing of sleep and daily activities.[94,95] Laboratory studies have shown that morning- and evening-type individuals differ in the phase (timing) of the endogenous circadian rhythms in CBT[83] and circulating levels of melatonin.[96] This difference is echoed in the diurnal course of their neurobehavioral functioning[97,98]—some people are more alert and perform better in the morning hours, whereas others are at their best later in the day.

In some individuals, there appears to be an afternoon dip in the circadian profiles of CBT and neurobehavioral variables,[99] which is referred to as the midafternoon, siesta, postprandial, or postlunch dip. This phenomenon has been observed in field studies[44] and in controlled laboratory experiments[100] and is thought to be endogenous and independent of food intake. Epidemiologic analyses of human performance (e.g., road accident rates across the 24 hours of the day[101]) seem to support the existence of a midafternoon dip (Figure 37-3). However, proper interpretation of such data requires accounting for temporal variation in exposure, that is, differential amounts of activity contributed by varying numbers of people over time,[102] which is complicated. More direct evidence for the existence of a midafternoon dip in some individuals comes from studies on sleep propensity[103,104] and on the natural timing of daytime naps.[105] This suggests that interindividual differences in sleep-wake parameters may play a role.

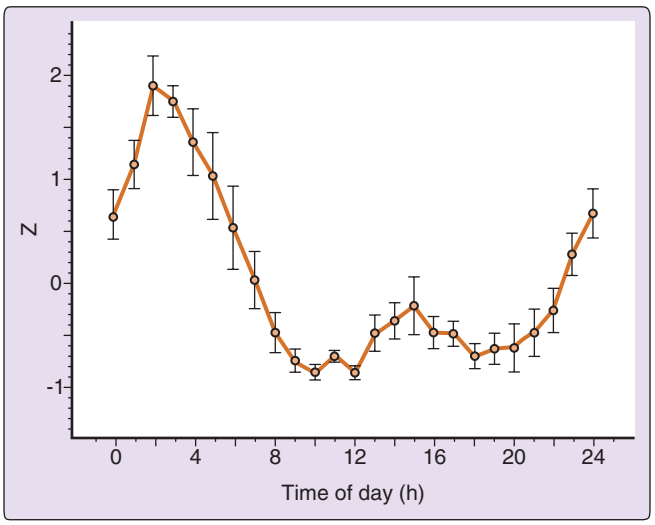

Figure 37-3 Circadian rhythm in road traffic accident risk. Data shown are mean (with standard error) over six published studies after Z transformation. (From Folkard S. Black times: temporal determinants of transport safety. *Accid Anal Prev* 1997;29:417–30, with permission.)

CIRCADIAN RHYTHMICITY VERSUS SLEEP-WAKE CYCLES

Sleep Deprivation

Considerable research effort has been devoted to unmasking circadian rhythms, that is, eliminating sources of extraneous variance to expose the endogenous circadian rhythms in variables of interest, including alertness and cognitive performance. The constant routine procedure[106,107] is generally regarded as the gold standard for measuring unmasked circadian rhythms. By keeping subjects awake with a fixed posture in a constant laboratory environment for at least 24 hours, circadian rhythms in a variety of physiologic and neurobehavioral variables can be recorded without confounds. Indeed, for CBT and melatonin, the circadian rhythm is believed to be free of masking effects when measured under constant routine.

The elimination of sleep (i.e., sleep deprivation) and the stimulation required to sustain wakefulness constitute masking factors for neurobehavioral variables. In constant routine experiments, these masking effects are evident in subjective and objective measures of alertness.[83,108] Figure 37-1 shows the somewhat increased sleepiness and reduced cognitive performance after 30 hours awake under constant routine compared with the values of these variables 24 hours earlier (i.e., at the same circadian time but without sleep deprivation).

Typically, superimposed on the circadian rhythm in a neurobehavioral variable, there is a progressive change across time spent awake.[109,110] When total sleep deprivation is continued for several days (whether in a constant routine procedure or an experimental design involving ambulation), the detrimental effects on alertness and performance increase. Although the circadian rhythm can thus be exposed,[111] it is overlaid by a continuing change reflecting a buildup of pressure for sleep.[112]

This is illustrated in Figure 37-4, which shows lapses of attention on a psychomotor vigilance test (PVT)[113] during a 16-hour baseline day and a 64-hour period of sleep deprivation. As seen in the figure, lapses on the PVT are relatively rare during the baseline day and during the first 16 hours of the sleep deprivation period, both of which fall on the diurnal portion of the circadian cycle and have little pressure for sleep. However, after the first 16 hours of the sleep deprivation period, lapses are clearly evident, indicating a substantial increase in neurobehavioral dysfunction. There is a steady rise in lapses across days, modulated by a pronounced circadian rhythm—the combined effect roughly takes the form of a staircase function.

Neurobehavioral functions that show circadian variation also appear to respond to sleep loss, and vice versa. The interaction of the circadian rhythm with the effect of sleep deprivation, which is nonlinear,[114,115] makes it difficult to dissociate the two effects in constant routine and sleep deprivation experiments (although it is possible by focusing on interindividual differences[116]). However, a reasonable separation of the two effects can be achieved with other experimental designs, as discussed later.

It is noteworthy that performance impairment during the circadian trough and while sleep deprived is associated with increased moment-to-moment variability in brain functioning,[117,118] of which lapses of attention on the PVT are a sensitive measure.[119] The state instability hypothesis posits that the moment-to-moment variability is caused by sleep-initiating

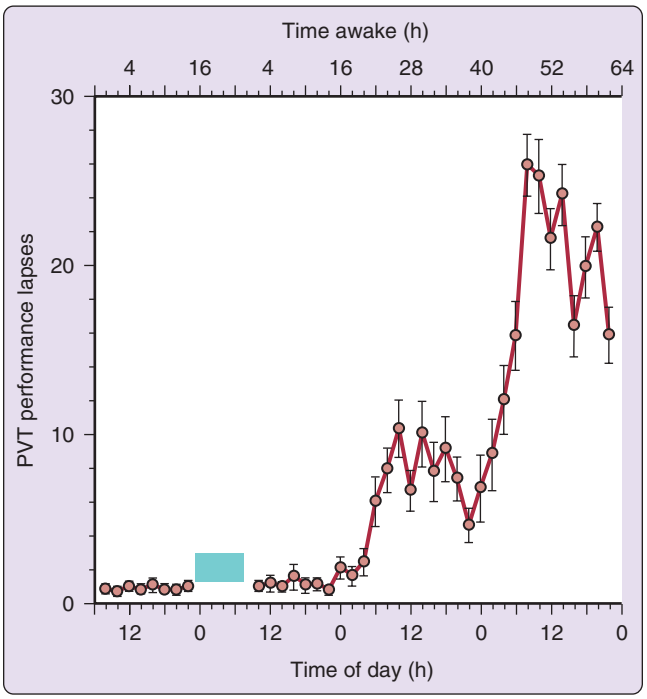

Figure 37-4 Performance lapses on the psychomotor vigilance test (PVT) during a 16-hour baseline day and a 64-hour period of sleep deprivation. Data shown are mean (with standard error) number of lapses (reaction times longer than 500 ms) for 24 subjects tested every 2 hours on the 10-minute PVT. This simple reaction time task requires subjects to respond as quickly as possible to a stimulus that appears on a display at random intervals of 2 to 10 seconds.[119] The *solid bar* indicates an 8-hour sleep period (from 11:30 PM until 7:30 AM) between the baseline day and the sleep deprivation period.

mechanisms interfering with sustained wakefulness, making cognitive performance unstable and dependent on compensatory mechanisms such as increased effort to perform.[120] According to local sleep theory,[121] the state instability may occur specifically in brain networks involved in performance of the cognitive task at hand.[122]

Sleep-Wake Regulation

The observed superposition of circadian modulation of alertness and performance on monotonic change during sleep deprivation (see Figure 37-4) has prompted efforts to mathematically model the regulatory processes involved. The two-process model of sleep regulation has been applied to describe the temporal profiles of sleep[123,124] as well as waking alertness and performance.[124,125] The model consists of a homeostatic process (process S) and a circadian process (process C), which combine to determine the onset and offset of sleep. The two processes together also drive waking neurobehavioral functioning.

The homeostatic process represents a drive for sleep that increases during wakefulness and decreases during sleep. When the "homeostat" increases above a certain threshold, sleep is triggered; when it decreases below another threshold, wakefulness is invoked. The circadian process represents daily oscillatory modulation of the two thresholds.[123] An alternative (but equivalent) view is that the circadian process promotes wakefulness to counteract the homeostatic drive for sleep.[126,127] The two-process model is discussed more extensively in another chapter in this volume.

The circadian and homeostatic processes interact to determine waking neurobehavioral functions as expressed in alertness and performance.[110,114,128] This is clearly seen in prolonged sleep deprivation experiments (see Figure 37-4). For alertness and performance, sleep and sleep loss are not only masking factors but also dynamic biologic forces that interact with the circadian system.

Under conditions of chronic sleep restriction—that is, daily curtailment of sleep (rather than total sleep deprivation)—there is a progressive buildup of pressure for sleep across days that is not predicted by the two-process model.[129] It has been hypothesized that this reflects allostatic adjustment of the set point of the homeostatic process.[130] The buildup of sleep pressure across days notwithstanding, the circadian process partially protects the afternoon and early evening from neurobehavioral impairment,[131] as illustrated in Figure 37-5 (see also Figure 37-1). The period when this is most noticeable, a window of several hours preceding habitual bedtime, is known as the "forbidden zone for sleep"[132] or "wake maintenance zone."[133]

Forced Desynchrony and Ultradian Days

The forced desynchrony protocol[127,134,135] is an experimental procedure designed to dissociate the effects of the circadian and homeostatic processes. In this protocol, a subject stays in an environmentally and temporally isolated laboratory in which the sleep-wake cycle is scheduled to deviate substantially from the normal 24-hour day (e.g., 20-hour and 28-hour sleep-wake cycles have been used). The biologic clock is unable to synchronize to such a schedule. The subject therefore experiences two distinct influences simultaneously: the schedule of predetermined sleep and wake times controlling the homeostatic process, and the rhythm of the subject's unsynchronized (i.e., free-running) circadian process.

Neurobehavioral variables can be recorded during the subject's waking periods of this experimental design. By folding the data over either the free-running circadian cycle or the imposed sleep-wake cycle, the influence of the other cycle can be averaged out. In this manner, the effects of the circadian and homeostatic processes on the recorded variables are separated. As expected, forced desynchrony studies have found that both the circadian and homeostatic processes influence alertness and performance. The interaction of the two processes appears to be oppositional during natural diurnal wake periods (from about 7 AM until 11 PM) such that a relatively stable level of alertness and performance can be maintained throughout the day.[127] This explains why studies of alertness and performance tend to find little temporal variation during the waking portion of a normal day (see Figure 37-4).

Another way to dissociate the circadian and homeostatic processes is through study designs with very short (i.e., ultradian) sleep-wake cycles. Such paradigms seek to redistribute the opportunities for sleep and wakefulness across the natural 24-hour day to sample waking behavior across the circadian cycle without significantly curtailing the total amount of sleep. Studies have been done with a 7-/13-minute sleep-wake schedule,[7] which alternately allows subjects to sleep for 7 minutes and forces them to stay awake for 13 minute; with a 90-minute day schedule,[136] which alternately permits subjects to sleep for 30 minutes and forces them to stay awake for 60 minutes; and with a 3-hour ultra-short sleep-wake schedule,[137] which alternates 1 hour of sleep and 2 hours of wake periods.

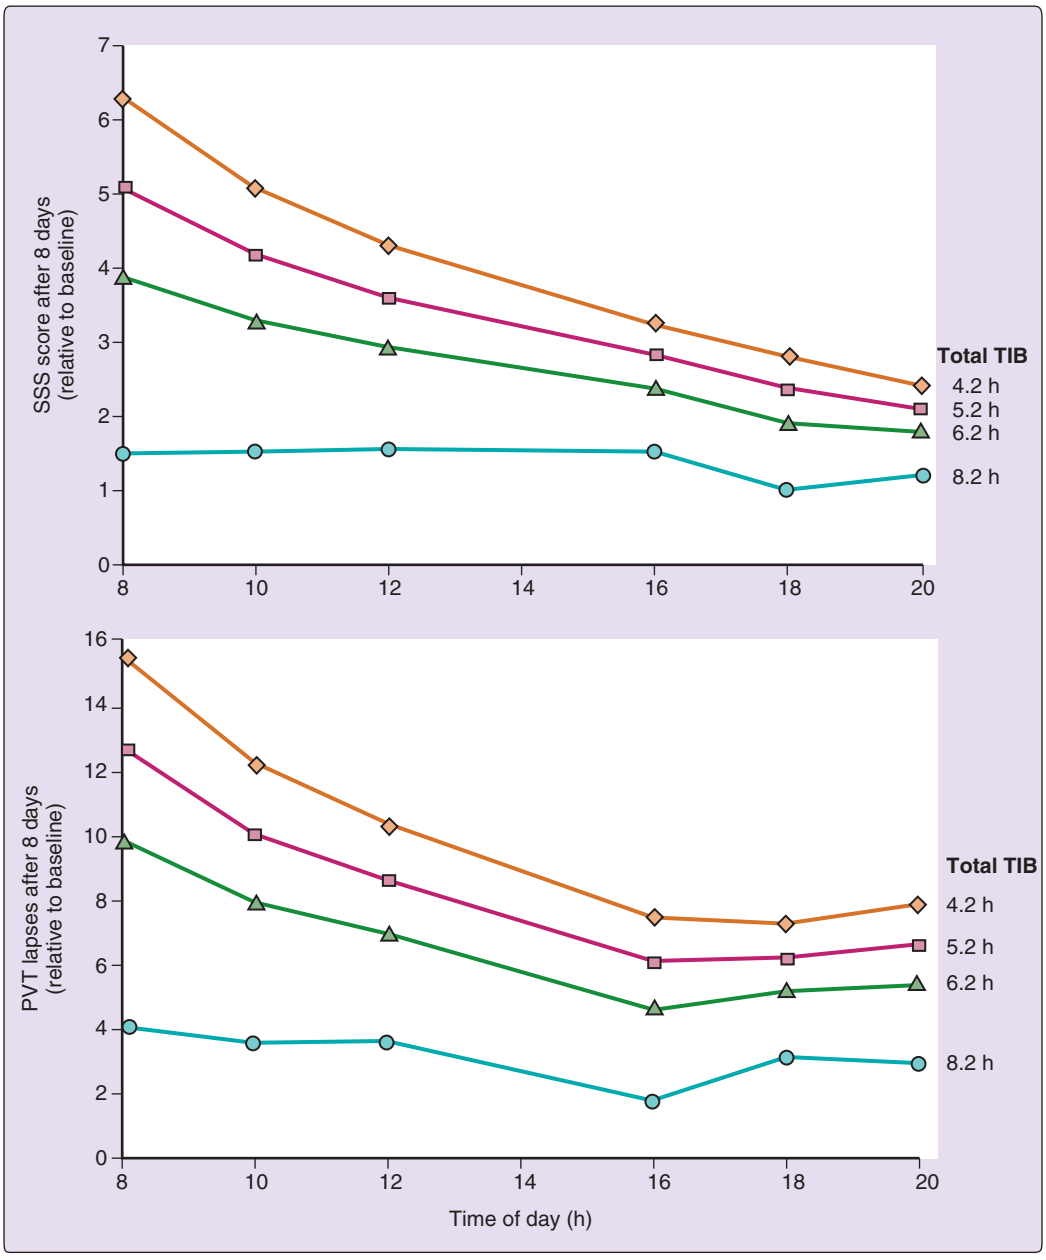

Figure 37-5 Sleepiness and performance under conditions of chronic sleep restriction as a function of time of day. Data shown are mean subjective sleepiness score on the Stanford Sleepiness Scale[9] (SSS; *top panel*) and mean number of lapses (reaction times longer than 500 ms) on the 10-minute PVT[119] (*bottom panel*) after 8 days of nocturnal sleep restriction with or without a daytime nap. Total time in bed (TIB) per day was 4.2 hours, 5.2 hours, 6.2 hours (sleep restriction conditions), or 8.2 hours (control condition); 90 subjects were each randomized to one of these conditions. (From Mollicone DJ, Van Dongen HPA, Rogers NL, et al. Time of day effects on neurobehavioral performance during chronic sleep restriction. *Aviat Space Environ Med* 2010;81:735–44, with permission.)

With respect to objective measures, studies with very short sleep-wake cycles have focused primarily on sleep propensity. However, cognitive performance was assessed in an experiment using the 7-/13-minute sleep-wake schedule and in an experiment employing the 3-hour ultrashort sleep-wake schedule. Robust circadian rhythms emerged for response times on a choice reaction time task[138] and on an abbreviated (5 minutes) version of the PVT.[137]

Subjective sleepiness scores were recorded in the 7-/13-minute sleep-wake schedule,[139] the 90-minute day schedule,[136] and the 3-hour ultrashort sleep-wake schedule,[137] and also showed clear circadian rhythms. However, after a 24-hour period of 7-/13-minute sleep-wake cycles (but not after 24 hours on the schedules with 90-minute or 3-hour cycles), the level of subjective sleepiness was elevated with respect to the initial level 24 hours earlier. This suggests that across 24 hours of the 7-/13-minute sleep-wake schedule, the recovery potential of the sleep obtained—which itself is modulated by the circadian process—may have been insufficient.

All things considered, the separation of circadian and homeostatic influences on neurobehavioral variables presents a conceptual, experimental, and mathematical problem. The

interaction of the two processes has been found to be nonlinear.[114,115] It is therefore difficult, if not impossible, to quantify the relative importance of the two influences on neurobehavioral functions, even in forced desynchrony and ultradian day experiments. Moreover, the relative contributions of the two processes may vary across different experimental conditions[54,114] and among subjects.[116,140]

Sleep inertia is yet another problem that may interfere with the assessment of alertness and performance in circadian studies and with the dissociation of the circadian and homeostatic processes. Sleep inertia refers to the cognitive performance impairment, feeling of disorientation, grogginess, and tendency to return to sleep experienced immediately after awakening.[141] Sleep inertia may affect alertness and performance on every artificial day of a forced desynchrony study or ultradian sleep-wake cycle study. The circadian and homeostatic processes appear to interact with sleep inertia,[142-145] varying the impact of sleep inertia across the artificial days in these study designs and making it difficult to account for its effects.

Circadian Regulation of Alertness and Performance in Context

Figure 37-6 shows a conceptual schematic of how the circadian drive for wakefulness, the homeostatic drive for sleep, the sleep inertia effect, and various internal states and external circumstances simultaneously affect neurobehavioral functioning.

As illustrated in the upper part of the figure, wakefulness typically begins with rapidly dissipating sleep inertia, which suppresses neurobehavioral functioning for a brief period after awakening. The homeostatic drive for sleep accumulates throughout wakefulness and progressively downregulates neurobehavioral performance and alertness. Unlike the circadian process, which is limited in amplitude, the homeostatic drive for sleep may accumulate far beyond the levels typically encountered in a 24-hour day (indicated in Figure 37-6 by the increasing density of downward arrows).

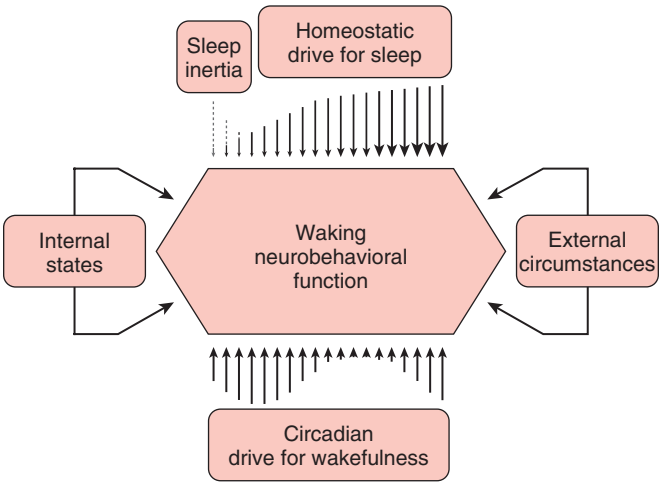

Figure 37-6 Schematic representation of the conceptual interplay of circadian and homeostatic processes and other factors in the regulation of neurobehavioral functioning. Sleep inertia and the homeostatic process degrade performance. Sleep inertia dissipates rapidly after awakening, whereas the homeostatic drive for sleep builds up progressively over time awake. The circadian process provides an oscillatory countereffect by promoting wakefulness during the day and withdrawing the effect at night. A wide range of internal states and external circumstances modulate waking neurobehavioral functions. Their effects are typically transient and may improve or degrade neurobehavioral functioning in interaction with the homeostatic and circadian processes.

In opposition to these suppressing influences on performance and alertness is the endogenous circadian rhythm of the biologic clock, as illustrated in the bottom part of the figure. The circadian process modulates performance and alertness by promoting wakefulness. The improvement in waking neurobehavioral functions by the circadian drive for wakefulness is an oscillatory process, which periodically involves robust opposition to the homeostatic process alternated with withdrawal of the circadian drive.

Modulators of neurobehavioral functions other than the sleep and circadian drives are subsumed in Figure 37-6 under the broad categories of internal states and external circumstances. They may include wake-promoting factors—endogenous (e.g., anxiety) or exogenous (e.g., caffeine intake)—that counteract the homeostatic drive for sleep. They may also include sleep-promoting factors—endogenous (e.g., immune response-induced) or exogenous (e.g., rhythmic motion)—that oppose the circadian drive for wakefulness, either directly or indirectly by exposing the homeostatic drive for sleep.

The neurobiologic substrates of these exogenous and endogenous factors are diverse. Although common in the real world, they are considered masking factors in most laboratory experiments. However, with regard to the regulation of alertness and performance, they cannot be regarded as mere confounds that should be eliminated or controlled. Although the effects of internal states and external circumstances tend to be transient, they are an integral part of the regulation of neurobehavioral functions and the interaction of individuals with their environment.[93]

Understanding the complexity of circadian rhythmicity in neurobehavioral functions is important when the sleep-wake rhythm is misaligned, as is the case during night-shift work,[146] or when the circadian rhythm is misaligned, as is the case after transmeridian flights.[147] In such situations, the circadian and homeostatic processes are not properly synchronized, and their interaction degrades alertness and performance. This problem is compounded when sleep is lost chronically,[129,148-150] putting individuals at increased risk for accidents.[151-154]

CLINICAL PEARL

Clinicians should recognize that 24-hour profiles of alertness and performance combine the effects of endogenous circadian rhythmicity, homeostatic regulation of sleep, sleep inertia, and a variety of endogenous and exogenous "masking" influences. Distinguishing these factors and accounting for interindividual differences is important for diagnosis and treatment of sleep disorders involving excessive daytime sleepiness or circadian dysregulation.[3]

SUMMARY

The biologic clock drives circadian rhythms and regulates changes in behavior over the 24 hours of the day. There are circadian rhythms in almost all variables describing alertness and performance. People tend to be less alert in the early morning and late at night, but it also depends on the

circumstances. A variety of factors (e.g., activity, posture, light exposure) can mask circadian rhythms. Even with masking influences experimentally controlled, measurements of the endogenous circadian rhythmicity in alertness and performance still reflect the interaction of the biologic clock with the homeostatic regulation of sleep. It has been argued that certain masking factors (e.g., sensory stimulation, body movement) are an integral part of the mechanisms regulating waking neurobehavioral functions. Accounting for their interactions with the biologic clock helps to explain or predict the occurrence of cognitive performance deficits across the circadian cycle.

Chapter
38

Central and Peripheral Circadian Clocks

Edith Grosbellet; Etienne Challet

Chapter Highlights

- The master clock in the suprachiasmatic nucleus (SCN) controls the sleep-wake cycle and hormonal rhythms as well as a multitude of other circadian rhythms.
- The suprachiasmatic clock conducts the multitude of brain and peripheral clocks to ensure circadian temporal organization and its adjustment to the daily variations of the environment.
- Rhythmic signals from the SCN couple the master clock to secondary brain and peripheral clocks through behavioral, nervous, and neurohumoral pathways. Endocrine rhythms (e.g., pineal melatonin and adrenal glucocorticoids) distribute internal temporal messages within the body.
- Light perceived by the retina is the most potent synchronizer of the master clock in the SCN, whereas most brain and peripheral clocks can be shifted as a function of meal time as well as the timing of sleep.
- Circadian clocks and intracellular metabolism are tightly and reciprocally connected.

THE CENTRAL CIRCADIAN CLOCK

Self-Sustained Oscillations

In mammals, the central clock is located in the suprachiasmatic nucleus (SCN) of the hypothalamus (Figure 38-1). See Chapter 27 for the genetics and genomics of circadian clocks. The SCN controls most circadian rhythms in behavior (e.g., sleep-wake cycle) and physiology (e.g., hormonal rhythms). The SCN consists of a heterogeneous population of neuronal and glial cells distributed in two anatomic subdivisions: a ventral "core" region, receiving retinal input, and a dorsal "shell" region, receiving dense input from the core. A majority of core neurons express vasoactive intestinal polypeptide (VIP), and fewer express gastrin-releasing peptide. In contrast, most shell neurons express vasopressin. Most neuropeptides colocalize with gamma-aminobutyric acid (GABA), and most synapses between SCN neurons are GABAergic.[1]

When physically isolated, either in vitro or in vivo, the SCN generates pronounced circadian rhythms of electrical activity.[2,3] Furthermore, recordings of firing rate in a dissociated culture of SCN neurons revealed the presence of single-cell circadian pacemakers, expressing circadian oscillations with different phases and periods.[4] SCN neurons are intrinsic but unstable oscillators, which need network interactions to stabilize their otherwise noisy cycling.[5] As a multicellular structure, the SCN provides a more precise and robust output than single SCN neurons.[6,7] Neuronal firing, chemical, and electrical (gap junctions) synapses are required for circadian coupling within the SCN in vivo.[1] The molecular clock machinery involves 24-hour oscillations of core clock components called *clock genes* (i.e., genes whose protein products are necessary for generating circadian rhythmicity within individual cells).[8] Within the molecular clockwork, two transcription factors, CLOCK and BMAL1, dimerize and bind to E-box sequences in the promoters of other clock genes, *Period 1 to 3 (Per1, Per2, Per3)* and *Cryptochrome 1* and *2 (Cry1, Cry2)* to activate their transcription. After reaching a given concentration in the cytoplasm, PERs and CRYs dimerize and translocate into the nucleus to inhibit their own transcription mediated by CLOCK/BMAL1 dimers. Auxiliary loops are composed of the circadian nuclear receptors REV-ERBα-β and RORα-β-γ, which modulate negatively and positively the circadian oscillations of *Bmal1* expression, respectively.[8,9] The SCN clock machinery also modulates the expression of numerous clock-controlled genes (e.g., vasopressin), which constitute circadian outputs that provide either local or distributed timing signals.[10] Many levels of regulation are involved in the proper functioning of the circadian clock, including transcriptional, posttranscriptional, and posttranslational mechanisms. Transcription rates can be affected by the recruitment of different transcription factors or by modifications within the chromatin structure. Of note, CLOCK possesses a histone-acetylase activity, essential for rescuing circadian rhythmicity in *Clock* mutant cells, revealing a crucial role of chromatin remodeling in clock mechanisms (Figure 38-1).[11] Moreover, posttranscriptional mechanisms regulate the stability and translation levels of messenger RNA (mRNA),[12] whereas posttranslational mechanisms, such as phosphorylations, control the targeting of clock proteins for proteosomal degradation.[13] All together, these regulations provide robust oscillations, resilient to large fluctuations in temperature and overall transcriptions.[14]

Photic Entrainment of the Master Clock

The daily synchronization of a self-sustained oscillator by an external signal (zeitgeber) is called *entrainment.* The most potent synchronizer of the central clock in mammals is light perceived by the retina. In the absence of environmental inputs, the clock free-runs with a period close to, but not exactly, 24 hours. The synchronizing effects of light depend on when the clock receives light cues, defining a so-called phase-response curve. In a nocturnal rodent, light exposure in

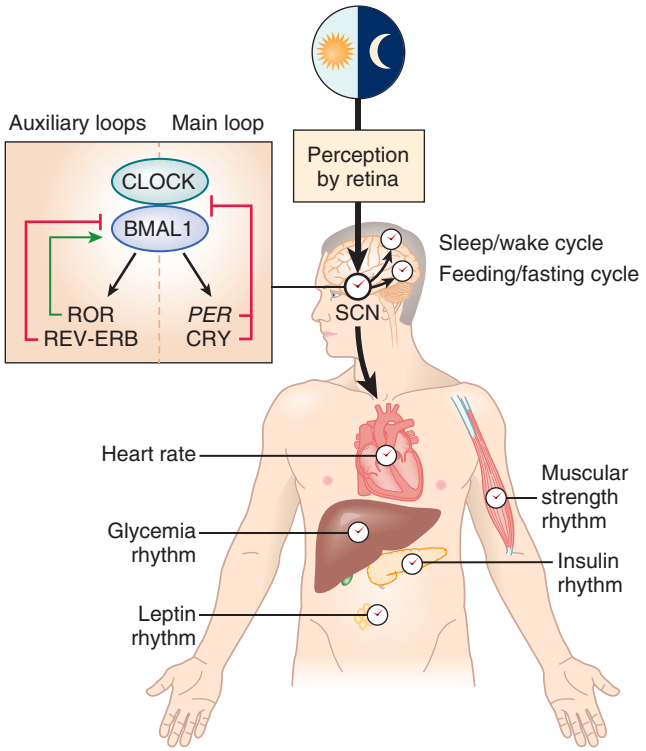

Figure 38-1 Hierarchic organization of the circadian system. The master clock located in the suprachiasmatic nucleus (SCN) synchronizes a network of brain and peripheral clocks, leading to circadian rhythms of physiologic, metabolic, and hormonal parameters. The molecular clockwork relies on transcriptional-translational feedback loops. The main loop involves CLOCK-BMAL1 stimulating the transcription of *Per* and *Cry* genes, which in turn inhibit the transcriptional activity of CLOCK-BMAL1. In the auxiliary loops, after stimulation of their transcription by CLOCK-BMAL1, ROR and REV-ERB stimulate and inhibit the transcription of *Bmal1*, respectively. The auxiliary loops help stabilize the 24-hour oscillations of clock proteins. early and late subjective night produces phase delays and advances, respectively, whereas light during the middle of the subjective day has no shifting effect on the central clock.[15] Interestingly, the same phase-response curve is obtained in diurnal rodents, whose clock gene expression and temporal patterns of SCN activity are in phase (in astronomical or circadian times) with nocturnal rodents, despite opposite sleep-wake cycles.[16,17] This strongly suggests that the distinction between nocturnal and diurnal animals relies on mechanisms that operate downstream of the SCN clock.

Light intensity is detected in the retina by classic photoreceptors, namely rods and cones, and by intrinsically photosensitive ganglion cells containing the photopigment melanopsin, highly responsive to blue light.[18] The axons of these ganglion cells constitute the retinohypothalamic tract and project monosynaptically to the SCN core, where they release mainly glutamate and pituitary adenylate cyclase–activating protein (PACAP).[19] Importantly, the retinohypothalamic tract projects not only to the SCN but also to the intergeniculate leaflet (IGL) of the thalamus. From the IGL, the geniculohypothalamic tract projects to the SCN and can thus indirectly convey light information by releasing neuropeptide Y, GABA, and enkephalin.[20] A few other structures could also convey indirect light information to the SCN, such as the basal forebrain nuclei that send cholinergic projections to the SCN.[21]

In response to light, glutamate and PACAP are released from retinohypothalamic terminals and bind to their receptors expressed in ventral SCN neurons.[15] This downstream signaling induces acute expression of clock genes *Per1* and *Per2*, in addition to several immediate early response genes such as *c-fos*,[22-24] which are induced by light only at night (i.e., during the photosensitive phase of the SCN). Antisense oligonucleotides against *Per1* or *Per2* inhibit light-induced phase shifts, highlighting the importance of these clock genes in the photic resetting processes.[25-27] Stimulation of glutamate and PACAP receptors induce Ca^{2+} influx, activating several kinase pathways.[28] The most extensively studied pathway involves ERK (extracellular signal–regulated kinase), which phosphorylates cycle adenosine monophosphate (cAMP) response element–binding (CREB) protein. CREB stimulates *Per1* and *Per2* transcription by binding to a CRE element in their promoter regions. Because only the SCN core receives photic inputs, synchronization of the shell to light is mediated through core-to-shell projections involving GABA, nitric oxide, and VIP signaling.[15,29,30]

In addition to its phase-shifting effects, light also modulates daily rhythmicity by direct, clock-independent responses to light. For example, bright light at night has an immediate inhibitory effect on physical activity and promotes sleep in nocturnal rodents, whereas it enhances alertness and sustained attention in (diurnal) humans.[31,32] Furthermore, light at night inhibits melatonin secretion.[33] Light also influences other peripheral functions, such as heart rate, blood glucose, and glucocorticoids.[34-37] These direct effects of light could be conveyed successively by the SCN clock, the subparaventricular hypothalamic region, and the sympathetic nervous system.[34,36] Because melanopsin-containing ganglion cells project to several brain targets beyond the SCN, such as the previously mentioned subparaventricular hypothalamic zone,[19] light cues can also bypass the SCN and reach directly this hypothalamic region that could, in turn, relay photic signals to peripheral organs through the sympathetic pathways. This alternative mechanism is supported by the properties of light-induced release of glucocorticoids.[37]

Nonphotic Phase Shifting of the Master Clock

Even if the light is the most important zeitgeber, the environment provides numerous other temporal cycling cues (e.g., temperature, food availability, social interactions) called *nonphotic* (i.e., different from light) *synchronizers*. One of the best studied nonphotic factors is exercise, voluntary or forced. Transient hyperactivity in nocturnal rodents typically causes phase advances of their locomotor activity rhythm if it occurs during the subjective day, corresponding to their normal resting period.[38-40] In humans, exercise in evening and late night leads to phase advances and delays, respectively.[41] Metabolic cues serve as other nonphotic signals that could affect or entrain the SCN clock. They are discussed at the end of the chapter. At least two major input pathways are considered to transmit nonphotic messages to the SCN: the geniculohypothalamic fibers from the IGL and the serotonergic input from the midbrain raphe nuclei, also projecting to the IGL.[20,42] Stimulation of neuropeptide Y or serotonin receptors in the SCN activates kinase-mediated phosphorylation events,[43,44]

leading to a reduction in *Per1* and *Per2* mRNA levels.[45,46] Injections of antisense oligonucleotides against *Per1* in the SCN region produce nonphotic-like phase advances of the rest-activity rhythm.[47] Most nonphotic and photic stimuli interact with one another, usually in opposite directions: one stimulus inhibiting the phase-shifting effect of the other one.[48] The IGL, which receives both photic and nonphotic cues, may be involved in integrating these conflicting signals before they reach the SCN.[20]

Outputs from the Master Clock

Because the SCN clock does not generate peripheral rhythms, but controls their timing, it is considered as a conductor within the multioscillatory circadian network. Rhythmic signals from the SCN are distributed to the brain and the entire body by two main pathways: (1) release of neurotransmitters and neuropeptides from terminals of SCN efferents, a pathway critical for controlling hormonal rhythms[49]; and (2) a neurohumoral pathway involving secretion of diffusible output signals regulating preferentially the rest-activity rhythm.[50] The SCNs project most densely to the medial hypothalamus, in particular to the subparaventricular zone. These SCN efferents are mainly GABAergic, although also glutamatergic and neuropeptidergic.[51] For instance, preautonomic neurons in the paraventricular hypothalamic nucleus (PVN) and arousal-promoting orexin (hypocretin) neurons in the lateral hypothalamus are controlled by glutamatergic and GABAergic inputs from the SCN. Neurosecretory corticotropin-releasing factor neurons in PVN, involved in the hypothalamic-pituitary-adrenal axis, are inhibited by vasopressinergic inputs from SCN.[51] Furthermore, GABAergic and vasopressinergic SCN neurons project to dorsomedial hypothalamic nucleus, a key site for the integration of circadian timing into numerous physiologic processes.[51] Moreover, dopaminergic neurons of the oscillator in the tuberoinfundibular nucleus that express rhythmic mRNA of *Per1* and *Per2* are directly regulated by VIPergic projections from the SCN.[52,53] The second possible mode of transmission for circadian cues from the SCN is the secretion of molecules into the extracellular space and cerebrospinal fluid. The existence of such a neurohumoral pathway was first supported by the fact that SCN grafts, encapsulated to prevent axonal growth and sprouting, are still capable of restoring behavioral rhythmicity in otherwise arrhythmic SCN-lesioned rodents.[50] Thus the rest-activity rhythm is thought to be regulated preferentially by diffusible output signals. Three candidate diffusible factors synthesized in the SCN have been proposed to modulate the timing of locomotor behavior: transforming growth factor-α, prokineticin 2, and cardiotropin-like cytokine.[54-56] These three molecules contribute to the suppression of locomotor activity, although possible stimulatory factors have not yet been identified.

BRAIN AND PERIPHERAL CIRCADIAN CLOCKS

Extra–Suprachiasmatic Nucleus Brain Clocks

The development of transgenic animals containing luciferase reporter driven by promoters of clock genes was particularly instrumental to reveal that the core clock mechanism described in the SCN is present in almost all brain regions and peripheral (i.e., outside the brain) tissues studied so far.[57,58] Many brain areas exhibit daily oscillations of clock genes.[59,60] Retina and olfactory bulbs are the only extra-SCN brain clocks with very strong oscillatory capacities that have been identified so far.[61,62] Other brain areas, such as arcuate nucleus and dorsomedial hypothalamic nucleus, two structures of the mediobasal hypothalamus involved in feeding and energy metabolism, are capable of self-sustained oscillations for several cycles when isolated in vitro. Cells of these oscillators exhibit independent circadian rhythms, but are weakly coupled, and their synchronization requires daily inputs.[63,64] Strikingly, the timing of clock gene oscillations and the rhythm of electrical activity in the secondary brain clocks of nocturnal rodents differ from the SCN in most cases. In the SCN, electrical activity and *Per1* expression peak during (subjective) daytime, while the corresponding peaks occur at night (i.e., during the active period) in extra-SCN oscillators.[63,65] In sharp contrast, the bed nucleus of stria terminalis, a basal forebrain structure modulating a wide range of physiologic and motivational processes, displays electrical activity in phase with the SCN, suggesting a strong coupling between the two structures.[65] Furthermore, several brain structures, such as the ventromedial hypothalamic nucleus, display a daily rhythmicity dependent on timed inputs because these structures become arrhythmic as soon as they are isolated in vitro.[64] Of note, the core clock mechanisms in brain oscillators seem very close to those identified in the SCN. In the forebrain, however, NPAS2 replaces CLOCK as a partner of BMAL1 in the positive loop.[66]

Clocks in Peripheral Tissues

Circadian transcriptome profiling studies in the master and peripheral clocks reveal that about 10% of a tissue's transcriptome has a circadian pattern of expression.[67,68] Most peripheral cells contain the molecular clock machinery.[69,70] Bioluminescent constructs (e.g., luciferase under the control of *Per* promoter) have allowed for real-time visualization of oscillations in clock genes, both in vitro and in vivo.[57,58,71] Peripheral clocks, such as liver explants, can generate a number of circadian cycles of *Per2*-luciferase expression.[58] With in vivo conditions, the SCN participate in the phase coherence between hepatocytes.[72] How peripheral oscillators are entrained by neuronal, endocrine, and behavioral signals coming from the SCN is described in a later section.

Cultured fibroblasts have been an in vitro model of choice to study the molecular regulation of the circadian clocks.[69,70] Similar to the master clock, cultured fibroblasts are resilient to large changes in temperature and overall transcription rates.[14] Activation of a multitude of intracellular pathways affects their clockwork.[73] Cultured fibroblasts do not generate metabolic rhythmicity as assessed by 2-deoxyglucose uptake, despite synchronized oscillations of clock genes. Sustained oscillations of 2-deoxyglucose uptake, however, can be produced in fibroblasts if they are cocultured (without physical contact) with immortalized SCN cells.[74]

In the liver, clock-controlled genes encode key enzymes involved in hepatic metabolism of fatty acids, cholesterol, bile acids, amino acids, and xenobiotics.[75-77] Specific inactivation of *Bmal1* in the liver of mice (L-*Bmal1*$^{-/-}$) disrupts rhythmic expression of glucose regulatory genes and glucose metabolism, including circulating glucose levels. L-*Bmal1*$^{-/-}$ mice are mildly hypoglycemic during the resting phase, suggesting that the hepatic clock drives a daily rhythm of hepatic glucose export counterbalancing the brain-driven fasting-feeding cycle.[78]

The adipose tissue also exhibits robust oscillations of core clock components, controlling the circadian expression of many transcription factors.[79,80] The lipoprotein lipase (i.e., an extracellular lipase synthesized in adipocytes and hydrolyzing triacylglycerols from circulating lipoproteins) displays a rhythmic activity in adipose tissue, suggesting that the adipose clock is somehow involved in lipid metabolism.[81] Moreover, the adipose tissue secretes several hormones termed *adipokines*, including leptin and adiponectin, involved in the regulation of energy balance. Several adipokine genes show a rhythmic expression in mouse adipose tissue.[79] Circulating levels of leptin display clear diurnal variations in both rodents and humans.[82-84] Moreover, leptin secretion was shown to be rhythmic in cultured adipocytes, suggesting that rhythmic synthesis or secretion of this adipokine may be under the control of the adipose clock.[85]

All together, the results show that peripheral cells, such as fibroblasts, hepatocytes, or adipocytes, fulfill the usual criteria to consider them as peripheral cellular clocks. In most peripheral tissues, however, neighboring cellular clocks fail to maintain phase coherence, in contrast to the strong intercellular coupling in the SCN. Another functional difference with the SCN is the fact that CLOCK is indispensable for circadian gene expression in peripheral tissues, at least the liver and lung.[86] Moreover, there can be specific differences in the characteristics of the clockwork according to the cell type in a given tissue, as exemplified in the skin.[87]

Molecular Links between Core Clock Components and Metabolism

Several transcriptional networks connect the core clock mechanisms with intracellular metabolic pathways. These interactions involve, among others, a number of nuclear receptors, including REV-ERBs and RORs (i.e., circadian components defining auxiliary loops in the clock mechanism) and peroxisome proliferator-activated receptors (PPARs), which are transcription factors activated by fatty acids. In the skeletal muscle, RORα directly regulates genes involved in fatty acid metabolism.[88] Moreover, REV-ERBα plays a pivotal role at the interface between the liver clock and lipid metabolism. Genetic loss and gain of function experiments showed that REV-ERBα participates in the circadian modulation of sterol regulatory element-binding protein activity and its target genes, which are involved in cholesterol and lipid metabolism.[89] REV-ERBα also plays a pivotal role in the daily variations of fuel utilization.[90] *Pparα* is rhythmically expressed in tissues with high rates of fatty acid oxidation, such as the muscles, heart, or liver, and is strongly involved in lipoprotein and lipid metabolism.[91] *Pparα* is a clock-controlled gene whose activation involves CLOCK and BMAL1, which in turn can activate *Bmal1* transcription.[92,93] Thus PPARα provides a close link between circadian clocks and lipid metabolism in peripheral tissues, in particular in the liver. PPARα can also directly activate *Rev-erbα* expression, and PER2 is able to recruit PPARα and REV-ERBα to modulate *Bmal1* expression, highlighting further reciprocal interactions between clock components and metabolism.[94,95] Additionally, a critical role has been demonstrated for PGC-1α, a coactivator of PPAR (PPAR coactivator-1α), which stimulates *Bmal1* expression through coactivation of RORs. Because PGC-1α is a metabolic regulator sensitive to various signals, including nutritional status and temperature, it could be a key component in the coupling of metabolism to clocks.[96] Furthermore, lipidomic profiling in adipose tissue indicates that PER2 is implicated in normal lipid metabolism. This effect is mediated by PPARγ, a major regulator of adipogenesis and lipid metabolism in adipose tissue, whose transcriptional activity is directly repressed by PER2.[97]

Interactions between the circadian clocks and cellular metabolism also involve cellular energy sensors such as sirtuin1 (SIRT1) and AMP-activated protein kinase (AMPK). SIRT1 catalyzes NAD^+-dependent deacetylation of various substrates. By deacetylating histones, SIRT1 participates in chromatin condensation and thus epigenetic silencing. SIRT1 also contributes to multiple metabolic pathways, such as gluconeogenesis, lipid metabolism, insulin secretion, and mitochondrial activity. SIRT1 plays a crucial role in the life-span extension associated with calorie restriction, in part through the SCN clock.[98] SIRT1 influences the transcription of several clock genes and promotes deacetylation and degradation of PER2, thus modulating the timing of the core clock loops.[99,100] Inhibition of SIRT1 leads to circadian disturbances and to the acetylation of BMAL1 and histone H3, both substrates of the acetylase function of CLOCK.[100]

Besides SIRT1, AMPK is another important metabolic fuel gauge, sensing changes in the intracellular AMP/ATP ratio. AMPK integrates nutritional and hormonal signals in peripheral tissues and the hypothalamus, where it mediates cellular effects of adipokines (e.g., leptin) in regulating glucose and lipid homeostasis. Like SIRT1, AMPK responds to low energy levels.[101] In mouse skeletal muscle, AMPK enhances SIRT1 activity by increasing cellular NAD^+ levels, resulting in the deacetylation and modulation of the activity of SIRT1 targets, such as PGC-1α,[102] which in turn affects the circadian clock. AMPK also has direct actions on the clock machinery. AMPK phosphorylates not only the clock protein CRY, but also casein kinase 1ε, leading to subsequent degradation of PER2 and phase shifts of peripheral oscillations.[103,104]

The connections between the cellular metabolism and the clockwork have been intensively investigated in peripheral tissues. Although much less is known, close mechanisms may be found in central extra-SCN oscillators. In particular, AMPK is a potent regulator of energy balance within the hypothalamus. For example, leptin inhibits specifically AMPK in arcuate nucleus and PVN, and this inhibition is required to mediate anorexigenic and weight loss effects of leptin.[101] AMPK signaling is thus a likely route through which circadian and feeding signals are integrated in the hypothalamus.[105]

COUPLING BETWEEN CENTRAL AND PERIPHERAL CLOCKS

Entrainment of Peripheral Clocks by Nervous Outputs of the Suprachiasmatic Nucleus

It is now well established that the SCN clock controls timing in peripheral organs through the sympathetic pathways.[51,106] To illustrate this, the liver and the white adipose tissue have been chosen as two representative examples in this section. The next section will consider two other peripheral organs, namely the pineal and adrenal glands, whose timing is also controlled by the SCN and that share the feature of delivering hormonal timing signals.

The liver plays a pivotal role in glycemic regulation as a site of glucose uptake and a major source of glucose production.[107] The daily rhythmicity of plasma glucose, peaking before activity onset in rats, is not a passive response to food intake.[108] A functional liver clock is important for glucose metabolism, as was previously mentioned,[78] but is not sufficient because SCN-lesioned rats lose their daily rhythmicity of blood glucose.[108] Retrograde tracing studies from the liver revealed projections through both sympathetic and parasympathetic components of the autonomous nervous system to third-order neurons in the SCN. Moreover, the glucose rhythm can be abolished by inactivation of either the sympathetic or parasympathetic inputs, underlying the importance of balanced inputs from the autonomous nervous system. Rhythmic GABAergic input from the SCN is considered to inhibit the sympathetic and parasympathetic preautonomic neurons of the PVN, predominantly during the day. By contrast, glutamatergic projections from the SCN stimulate sympathetic preautonomic neurons of the PVN. Thus the entrainment of circadian glucose rhythm is performed by the SCN, fine-tuning the balance between both branches of the autonomous nervous system that innervate the liver clock.[107] Moreover, hypothalamic expression of orexin exhibits a diurnal rhythm entrained by GABAergic inputs from the SCN. Besides its role in behavioral activation, orexin is also a key regulator of plasma glucose in rats, modulating in particular the daily peak at dusk through the sympathetic nervous system.[109]

The rich innervation of adipose tissue by sympathetic fibers is well known, and their activation enhances lipolysis. Parasympathetic innervation of white adipose tissue has been shown more recently.[110] As for the liver, the SCN controls both branches of the autonomous nervous system that innervate adipose tissues, thus modulating circadian rhythmicity of metabolic and endocrine outputs of the adipose clock. For instance, activity of the hormone-sensitive lipase exhibits a daily rhythmicity that is modified by adipose denervation.[110] Moreover, the leptin rhythm is under the control of both the local adipose and SCN clocks because lesions of the SCN abolish the daily rhythm of plasma leptin in rats.[82,85] Through modulation of the autonomic innervations of liver and adipose clocks, the SCN therefore controls circadian rhythmicity of metabolites (carbohydrates and lipids) and metabolic hormones (e.g., leptin). Some peripheral clocks, however, do not respond directly to neural cues, and rhythmic hormones (glucocorticoids and melatonin) may additionally transmit timing signals from the SCN to a variety of peripheral organs that express glucocorticoid or melatonin receptors.

Entrainment of Peripheral Clocks by Suprachiasmatic Nucleus–Controlled Hormonal Outputs

Melatonin and glucocorticoids are two hormones with time-giving properties because their rhythmic release is tightly controlled by the SCN through nervous pathways, and when released, these endocrine messages can in turn affect or even entrain peripheral clocks (Figure 38-2).

Melatonin synthesized in the pineal gland is best known as a transducer of the photoperiodic information into neuroendocrine changes, through the duration of its nocturnal peak.[111,112] The daily high-amplitude rhythm of melatonin also has a circadian role. Melatonin synthesized from tryptophan is always secreted during the dark phase in both nocturnal and diurnal mammals.[113] The release of melatonin is driven by the SCN clock through a multisynaptic pathway, including the PVN, the intermediolateral cell column of the spinal cord, and the superior cervical ganglions that send sympathetic fibers which release noradrenalin in the vicinity of the pinealocytes. This noradrenergic release triggers the nocturnal synthesis of melatonin.[114] The daily rhythm of nocturnal melatonin provides temporal signals to a multitude of tissues expressing melatonin receptors, including peripheral organs and the SCN (see later). In isolated adipocytes, rhythmic melatonin mimicking a biologic night triggers expression of clock genes, such as *Per1* and *Clock*, and stimulates a lipogenic response.[115] Melatonin modulates clock gene expression in adrenal explants.[116] Furthermore, in the pars tuberalis of the adenohypophysis, rhythmic oscillations of clock genes (i.e., *Cry1* and *Per1*) are driven by the daily rhythm of melatonin.[117] The nocturnal rhythm of endogenous melatonin is a reliable phase marker of the SCN clock because it is relatively impervious to most internal and external disturbances, except bright light exposure at night, which immediately inhibits its synthesis, therefore blunting its temporal message.[33]

Glucocorticoids (corticosterone in rats and mice; cortisol in humans) show a strong daily rhythm, peaking systematically at about wake-up time (dawn and dusk in nocturnal rodents and humans, respectively). This daily peak results from the adrenal clock, which is controlled by SCN cues through the hypothalamic-pituitary-adrenal axis and sympathetic fibers, the latter modulating the sensitivity of the adrenal

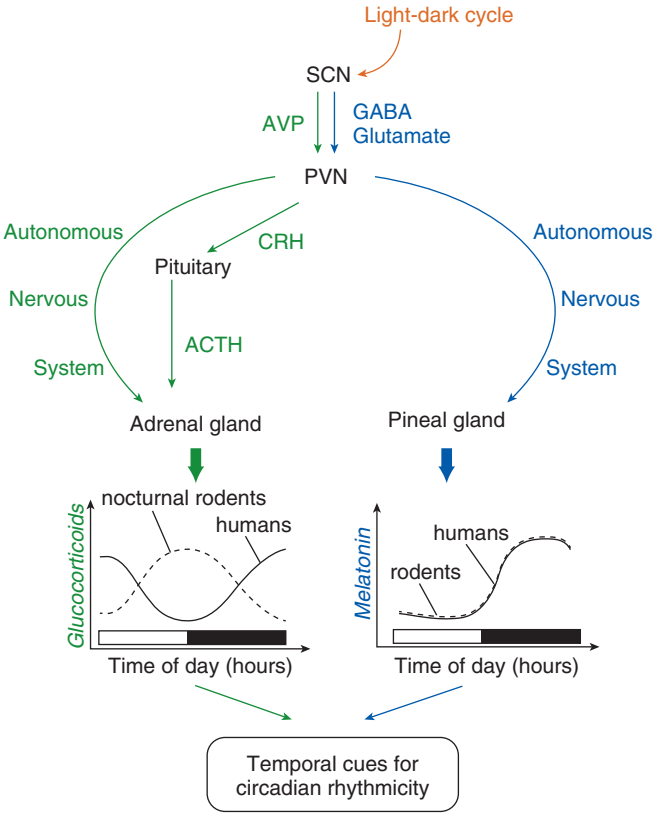

Figure 38-2 Rhythmic secretion of glucocorticoids and melatonin is driven by the suprachiasmatic nuclei (SCN) and acts in turn as temporal cues for circadian rhythmicity. AVP, Arginine-vasopressin; ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; GABA, gamma-aminobutyric acid; PVN, paraventricular nucleus.

glands to ACTH.[118-120] The glucocorticoid nuclear receptors are expressed in most cell types in periphery and the brain, with the notable exception of adult SCN cells.[121] Dexamethasone, a glucocorticoid receptor agonist, activates *Per1* expression and synchronizes rat fibroblasts in vitro. Moreover, dexamethasone produces in vivo phase shifts of peripheral clocks (liver, kidney, and heart), but not of the SCN clock.[122] Activity of glucocorticoid receptors is directly modulated by the clockwork because their transcription can be repressed by CRYs and they can be acetylated by CLOCK.[123,124] In extra-SCN brain structures, such as the bed nucleus of stria terminalis and central amygdala, oscillations of the clock protein PER2 disappear after adrenalectomy and are restored by rhythmic supply of corticosterone through drinking water.[125] In midbrain raphe nuclei that do not express clock genes, rhythmic corticosterone also drives the daily rhythm of tryptophan hydroxylase mRNA, a limiting enzyme for synthesis of serotonin.[126] Thus daily variations of circadian glucocorticoids possess resetting and time-giving properties for central and peripheral structures. It should be emphasized, however, that the circadian rhythm of glucocorticoids can be blunted or markedly modified by environmental conditions, including stressful events, light, and feeding. Acute stress leads to ACTH-induced release of glucocorticoids that is not necessarily in phase with the circadian pattern.[119] Also, light exposure at night induces *Per1* gene expression in the adrenal gland and corticosterone release by activation of sympathetic fibers independently of the hypothalamic-pituitary-adrenal axis.[36] In addition, restricted feeding triggers an anticipatory rise in circulating glucocorticoids before food access. This anticipatory peak is ACTH independent and distinct from the circadian rhythm of glucocorticoids controlled by the SCN clock.[127] It should be noted therefore that circulating glucocorticoids can influence circadian clocks by conveying various temporal signals, only some of them being strictly dependent on the SCN.

Feedback of Peripheral Hormonal Signals to the Suprachiasmatic Nucleus

As detailed previously, in undisturbed conditions, the circadian rhythms of plasma melatonin and glucocorticoids are tightly controlled by the SCN clock. The presence of both MT1 and MT2 receptors in the SCN suggests that melatonin may have feedback effects on the master clock.[128] Daily injections or perfusions of supraphysiologic doses of melatonin entrain the free-running activity of rats in constant darkness, when injections occur at the subjective dusk.[129,130] In vitro application of melatonin on cultured SCN explants induces two distinct effects. First, melatonin acutely inhibits neuronal firing.[131] Second, melatonin shifts the circadian rhythm of electrical activity of SCN neurons in a time-dependent manner.[132] The acute inhibitory effect seems to be mediated by MT1 receptors, whereas the phase-resetting effect may rely on MT2 receptor signaling.[133-135]

Glucocorticoids are not expected to feed back directly to the SCN because their receptors are not expressed in sizeable amount within adult SCN cells.[121] Furthermore, as previously mentioned, the glucocorticoid agonist dexamethasone can induce phase shifts of clock gene expression in peripheral clocks, but not in SCN neurons.[122] However, glucocorticoids modulate the daily synchronization of the SCN to light, as evidenced by faster reentrainment to a new light-dark cycle in adrenalectomized rodents.[136,137] The indirect feedback of glucocorticoids to the SCN is thought to be mediated through serotonergic projections from midbrain raphe.[136] Such a feedback would prevent uncoordinated resetting of the circadian system (e.g., in response to sporadic light exposure), and thus serves as a protection from zeitgeber noise.[137] Together, melatonin and glucocorticoid rhythms appear to stabilize the functioning of the circadian system.

ADJUSTING CLOCKS WITH FEEDING

Extra–Suprachiasmatic Nucleus Clocks Are Entrained by Feeding Time

Among the different ways used by the SCN to synchronize peripheral clocks, the feeding rhythm is a strong zeitgeber for many tissues. In normal conditions, food intake takes place during the active period. Restricted feeding in nocturnal rodents (i.e., when food access is limited to few hours during daytime, a time when nocturnal rodents usually rest) inverts the phase of gene expression in peripheral organs within about a week, thereby uncoupling peripheral clocks from the SCN that remain phase-locked to the light-dark cycle.[138,139] The synchronization velocity is tissue specific. Indeed, food-induced phase resetting proceeds faster in liver than in kidney, heart, or pancreas, with large phase shifts within 2 days of altered feeding schedule. Furthermore, there are peripheral clocks, such as the submaxillary salivary glands, that fail to entrain to restricted feeding (Figure 38-3).[106]

In the brain, food restriction entrains the activity of a number of, but not all, oscillating structures outside the SCN. For example, the multineuronal activity in the lateral hypothalamus of rats under restricted feeding shows a peak entrained to the time of feeding.[140] Moreover, daily patterns of *Per1* and *Per2* mRNA in the cerebral cortex, striatum, and PVN from mice entrained to restricted feeding also show a phase shift with peaks around mealtime, as opposed to the nocturnal peaks of expression in animals fed ad libitum.[59,60] Other structures, such as the hippocampus, display small or no phase change in patterns of clock gene expression in response to feeding time.[59] Nevertheless, in total the data suggest that most secondary clocks within and outside the brain are affected by restricted feeding schedules.

Under restriction feeding, several behavioral and physiologic functions become entrained to the availability of food. More specifically, body temperature and plasma corticosterone rise before food access in phase with behavioral activation, called *food-anticipatory activity,* thought to be the laboratory equivalent of food-seeking behavior in the wild. This rhythmic bout of activity is still expressed in SCN-lesioned animals and is considered a behavioral output of a food-entrainable clock.[141] The precise location of the food-entrainable clock (outside the SCN) and its mechanisms have been the subject of much debate and controversy. Most experimental arguments support the current view that the food-entrainable clock is a network of coupled neural structures, likely involving mediobasal hypothalamic nuclei, which interact together to provide timing and behavioral entrainment of feeding.[142]

Possible Mechanisms of Entrainment of Extra–Suprachiasmatic Nucleus Clocks by Food

The nature of signals that arise from feeding and that entrain peripheral clocks has been an area of intense investigation.

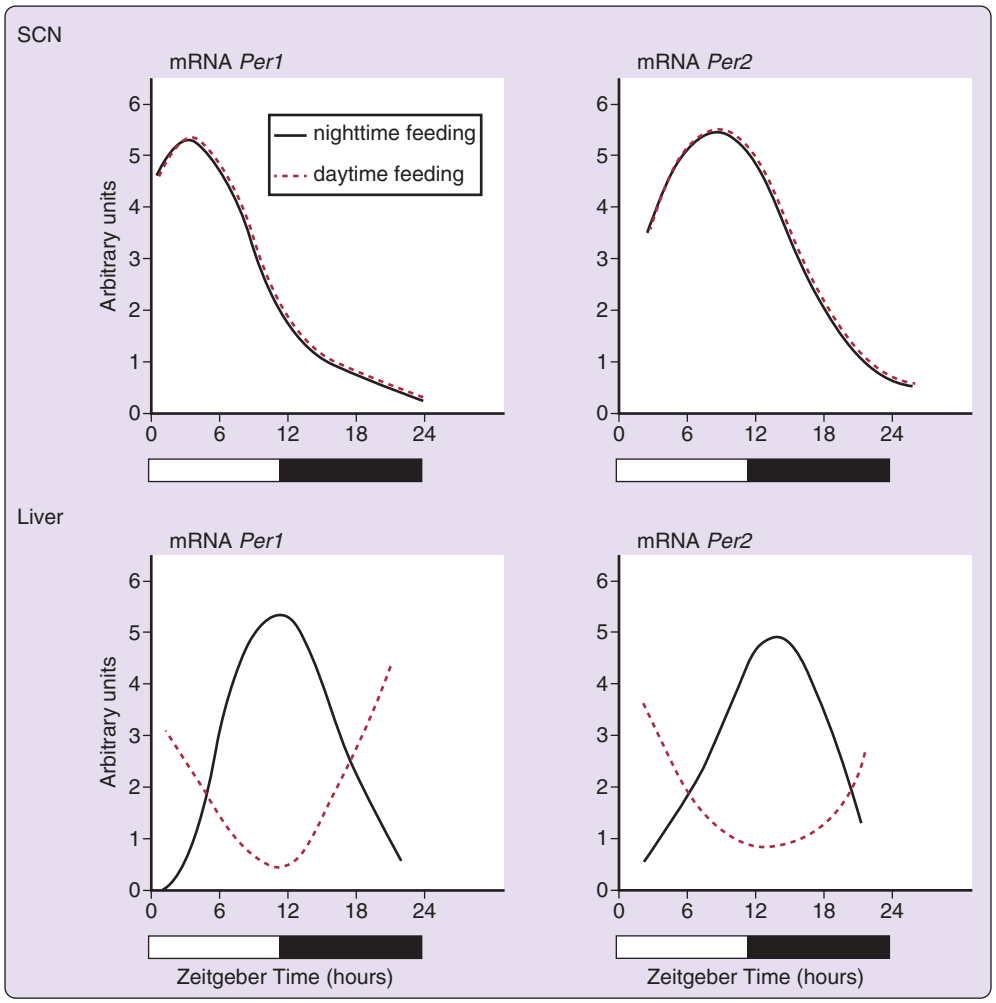

Figure 38-3 Daily expression of *Per1* and *Per2* in the liver and in the suprachiasmatic nucleus (SCN) of mice fed at nighttime (*solid lines*) or at daytime (*dotted lines*). Zeitgeber time 0 is defined as time of lights on. Feeding time affects daily rhythmicity of clock gene expression in peripheral clocks, but not in the SCN. Timed changes in metabolism can thus lead to an uncoupling of peripheral oscillators from the central pacemaker. (Data from Damiola F, Le Minh N, Preitner N, et al. Restricted feeding uncouples circadian oscillators in peripheral tissues from the central pacemaker in the suprachiasmatic nucleus. *Genes Dev* 2000;14:2950–61.)

Feeding cues include a number of parameters, including food absorption, postprandial increase in temperature, secretion of metabolic hormones, food-derived metabolites, and changes in the energetic status of cells.

Variations in temperature are known to entrain behavioral rhythms of heterotherms, such as *Drosophila*.[143] Moreover, temperature fluctuations mimicking body temperature rhythms sustain previously induced oscillations in cultured rat fibroblasts. Inverted environmental temperature cycles in vivo reverse circadian rhythms of clock genes (*Per2* and *Cry1*) in the mouse liver without affecting the SCN.[144] Thus diet-induced thermogenesis during the postprandial period could be an entraining pathway from the feeding-fasting cycle in homeothermic organisms. The mechanisms of entrainment by temperature involve heat-shock factor 1 (HSF1), as revealed in vitro by genetic loss of function experiments and pharmacologic antagonists of heat-shock signaling pathway.[145,146] Hepatic HSF1 exhibits a highly rhythmic activity, which drives the expression of heat-shock proteins in liver.[147] Therefore HSF1 could be a key component linking temperature fluctuations and the phase of molecular clocks.

Anorexigenic (insulin) and orexigenic hormones (ghrelin) may participate in the entrainment of peripheral clocks by feeding. On one hand, insulin that rises in the plasma during the postprandial period causes an acute induction of *Per1* mRNA levels in cultured rat fibroblasts.[73] Moreover, insulin triggers upregulation of *Per2* mRNA and downregulation of *Rev-erbα* mRNA in the liver, thus mimicking the effects of refeeding after fasting.[148] The insulin-dependent phase shifts of peripheral clocks involve PI3K- and MAPK-mediated signaling pathways.[149] Feeding-induced insulin secretion may thus be a critical step in feeding-induced entrainment of the liver clock. On the other hand, released ghrelin from the stomach during fasting is thought to signal hunger state to the brain. Cerebral activation of ghrelin signaling has been implicated in the bout of activity, so-called food-anticipatory activity, that the animals express before timed food access.[150,151]

Another hormone linked to meal entrainment is corticosterone. An anticipatory rise of plasma corticosterone is induced by restricted feeding schedules,[152] and corticosterone is known to entrain peripheral clocks (see earlier).[122] However, corticosterone injections fail to mimic the phase-shifting effects of

feeding in rats.[139] Gene expression rhythms in the liver of adrenalectomized or glucocorticoid receptor–deficient mice are still entrained by restricted feeding. Glucocorticoid signaling may actually provide resetting cues conflicting with feeding synchronizers because food-induced phase shifts of the liver are actually faster in the absence of glucocorticoids.[153] The net effect of these synchronizing interactions depends on the tissue because the liver clock appears to be more sensitive to feeding cues, whereas the lung and kidney clocks are more easily reset by glucocorticoids.[154]

Fascinatingly, the application of glucose in the culture medium of rat fibroblasts causes a downregulation of *Per1* and *Per2* mRNA levels and induces rhythmic expression patterns of numerous genes, including transcription factors. The decrease of *Per1* and *Per2* mRNA levels by glucose seems indirect and mediated by glucose metabolism (i.e., involving transcriptional regulators) rather than by glucose.[155] Many nuclear receptors, such as PPARs, contribute to the daily variations of lipid and glucose metabolism. As a reminder, PPARs are ligand-dependent transcription factors activated by fatty acids (released, for instance, during the fasting state). In addition to their role as mediators of metabolism, PPARs interact with clock components (see earlier).[93] Thus both plasma fatty acids and glucose, two major circulating metabolites, are potential mediators by which food-related cues entrain peripheral clocks.

Another possibility for feeding entrainment is that clock proteins, such as CLOCK (or its paralogue NPAS2), BMAL1, or PERs, sense directly food-related signals. These proteins all contain a PAS domain, which detects redox state (i.e., the reduced or oxidized environment within the cell), reflecting the energy status. Redox signals are transduced by PAS domains, which modulate the functional state of the protein.[156] For example, DNA-binding activity of the dimers CLOCK/BMAL1 and NPAS2/BMAL1 is altered by cellular redox status. The reduced forms of the nicotinamide adenine dinucleotide, NADH and NADPH, activate DNA binding of CLOCK (or NPAS2)/BMAL1, whereas the oxidized forms, NAD^+ and $NADP^+$, inhibit DNA binding. The NAD(P)H/$NAD(P)^+$ ratio is closely tied to mitochondrial activity, and the switch between activation and inhibition of DNA binding is very sensitive, providing a rapid mechanism that could convey changes in fuel availability to the cellular clocks.[66] Therefore, even if feeding can be viewed as a dominant entraining factor for peripheral clocks, the underlying mechanisms are complex because multiple signals seem to be involved at different levels of the circadian system.

Effect of Nutritional Cues on the Central Clock

Although most peripheral clocks are highly sensitive to the synchronizing effects of feeding time and food-related cues, the SCN clock seems impervious to them, provided that animals are exposed to a light-dark cycle and ingest enough daily energy.[138,139] However, the SCN can respond to nutritional cues under specific caloric conditions. Indeed, rats under a light-dark cycle and entrained to timed hypocaloric feeding display phase advances of daily rhythms of locomotor activity, body temperature, and pineal melatonin.[157] Entrainment to a light-dark cycle is also altered in mice submitted to a timed calorie restriction. In addition to the phase-advanced rest-activity rhythm (i.e., nocturnal mice becoming partially diurnal), expression of clock proteins and the clock-controlled factor *Vasopressin* is phase-advanced in the SCN, and the circadian responses of the SCN to light are altered.[158,159] In addition, circadian phase-shift responses to light are reduced in animals under low glucose availability.[160] All together, these results challenge the idea that the SCN is impervious to any nutritional cues. Notably, the reward aspect of food also seems important because in mice housed in constant dark conditions, the SCN entrains to rhythmic access to palatable food (chocolate) given in addition to regular food pellets available ad libitum.[161]

Little is known about the pathways conveying metabolic signals to the SCN. One could first imagine a direct effect of timed calorie restriction, changing the redox status of SCN cells, as in peripheral clocks (see previous paragraph), and affecting subsequently the SCN molecular clockwork. Self-sustained redox cycles have been identified in the SCN cells, where they regulate neuronal activity.[162]

In addition, receptors of feeding-related hormones such as insulin, ghrelin, and leptin are present in the SCN and metabolic hypothalamus (i.e., nuclei of hypothalamus involved in the regulation of energy balance).[163-165] When isolated in vitro, the SCN clock can be phase-advanced by leptin or ghrelin.[166,167] Moreover, leptin modulates firing rates of SCN neurons in hypothalamic slices.[168] However, insulin applied in vitro inhibits the firing rate of the SCN neurons during the subjective day.[169] These hormones are thus possible candidates for conveying metabolic information to the SCN, either directly or indirectly. Indeed, besides a direct modulation on the SCN clock, another possibility would involve relays from brain structures sensitive to nutrients. As previously discussed, nonphotic cues can be conveyed to the SCN by projections from raphe nuclei and IGL. Experiments of lesions suggest an involvement of the IGL in the transmission of metabolic information to the SCN.[170,171] Moreover, orexigenic and anorexigenic neurons in the hypothalamus that control feeding behavior respond to fluctuations in circulating nutrient (e.g., glucose, fatty acids, amino acids) levels that reflect the nutritional status.[172] Because the SCN receives numerous projections from various hypothalamic nuclei, the metabolic region of the hypothalamus could integrate and transmits information from circulating nutrients to the SCN. For example, the mediobasal hypothalamus may be involved in mediating the behavioral phase advance produced by timed calorie restriction.[173,174]

CONCLUSIONS

This overview of the central and peripheral clocks shows the hierarchic organization of the mammalian circadian system at the top of which is the SCN. Because light is the most potent synchronizer of this central clock, a proper temporal organization is normally achieved under a light-dark cycle. When synchronized to light, the SCN controls behavioral (i.e., sleep-wake and feeding-fasting cycles) and physiologic rhythms (e.g., body temperature and plasma melatonin and glucocorticoids) that will, in turn, reinforce the robustness of daily rhythmicity by sending internal timing cues. Forced or voluntary feeding limited to the usual rest period is a potent timer of peripheral oscillations that disturbs internal coupling between the various clocks, depending on their sensitivities to meal resetting. As a consequence of the close connections between cellular clocks and intracellular metabolism, genetic

clock disruptions affect metabolism in rodents. Moreover, chronic alterations in the main zeitgebers of the circadian system, such as bright light exposure during the subjective night (chronic jet lag, shift work) and meal times, lead to circadian desynchronization, with detrimental consequences on metabolic health.

CLINICAL PEARL

As a consequence of the reciprocal connections between circadian clocks and intracellular metabolism, situations of circadian misalignment such as night-eating syndrome, shift work, and chronic jet lag, disrupt sleep homeostasis and increase metabolic risk factors, including obesity, impaired glucose tolerance, and hypertension.

SUMMARY

The master clock, located in the SCN of the hypothalamus, synchronizes a multitude of brain and peripheral clocks. These clocks allow organisms, tissues, and cells to anticipate ongoing changes and optimize the efficiency of a given function at the expected time of daily occurrence. Brain and peripheral clocks also segregate incompatible behaviors (e.g., sleep and feeding) and chemically incompatible reactions (e.g., hepatic gluconeogenesis and glycolysis), respectively. Rhythmic signals from the SCN couple the master clock to secondary brain and peripheral clocks through behavioral, nervous, and neurohumoral pathways. Endocrine rhythms (i.e., pineal melatonin and adrenal glucocorticoids) distribute internal temporal messages within the body.

Light perceived by the retina is the most potent synchronizer of the central clock in the SCN. A few other stimuli, different from light, called nonphotic cues (e.g., exercise, arousal) can phase-shift the SCN, especially when the photic synchronizer is weak or absent. Clocks in peripheral tissues share many molecular properties with the SCN. Besides the stronger intercellular coupling in the SCN, another functional difference is the high sensitivity of most brain and peripheral clocks to the synchronizing effects of feeding as opposed to the relative resistance of the SCN. Cellular clocks and intracellular metabolism are tightly and reciprocally connected. Even if the SCN is not shifted by meal time, metabolic cues can affect SCN clockwork and modulate its synchronization to light.

Circadian Dysregulation in Mental and Physical Health

Chapter 39

Sabra M. Abbott; Roneil G. Malkani; Phyllis C. Zee

Chapter Highlights

- Circadian rhythms are a key component of human health, and dysregulation has been shown to contribute to the pathogenesis, expression, and severity of medical and psychiatric disorders.
- Evidence indicates that dysregulation of circadian clock function at the molecular, cellular, and systems levels in central or peripheral tissues or misalignment because of environmental and behavioral disruptions due to shift work and social jet lag increases the risk for adverse health outcomes.
- Approaches to enhance circadian function and achieve proper alignment between endogenous central and peripheral rhythms with the external environment have the potential for significant positive effects on human health.

Circadian rhythms are a fundamental property of all biologic processes and are essential for the coordination of physiologic and behavioral functions with the 24-hour environment. Therefore disruption to the circadian system can result in a broad range of adverse mental and physical health consequences. The primary mammalian circadian pacemaker is located within the suprachiasmatic nucleus (SCN) in the hypothalamus. The inherent circadian rhythmicity is genetically regulated and is maintained through a transcription-translation feedback loop of core circadian clock genes. These include positive elements: *CLOCK* and *BMAL1* (*ARNTL*); negative elements: Period *(PER)* and Cryptochrome (*CRY*); and regulatory elements including casein kinase (*CK*) Iδ and Iε, glycogen synthase kinase (*GSK*), retinoic acid receptor–related orphan receptor-α (*RORA*), and nuclear receptor subfamily 1, group D, member 1 (*NR1D1) (Rev-Erbα)* (further details available in Chapter 27). These core clock genes are also present in peripheral tissues, from liver to heart to the immune system. The SCN is thought to serve as the master pacemaker, coordinating the timing of these peripheral tissue clocks. Polymorphisms in these core clock genes have been associated with a wide variety of disorders, although data are often limited by small sample sizes or population-specific effects.

Melatonin is a key marker of circadian function. Melatonin is secreted by the pineal gland, and levels peak in the middle of the night. Light suppresses the normally observed nocturnal rise in melatonin. Melatonin can be measured in the blood, saliva, and urine, and both the timing and amplitude of secretion can be evaluated as measures of circadian alignment.[1]

Classically it was thought that circadian disturbances were simply a consequence of underlying disease, but it is increasingly appreciated that dysregulation at a number of different levels, from a mismatch between environmental and internal time, to direct dysfunction at the level of the SCN, to dysregulation in the coordination between peripheral clocks, may play a role in the expression and development of disease (Figure 39-1).

Although the full extent of the effect of circadian dysregulation on human diseases is beyond the scope of this chapter, we will focus on several examples of disorders that highlight how circadian dysregulation can occur at the environmental, physiologic, and molecular levels. One of the most common causes of circadian dysregulation comes from environmental disruption, easily recognized in shift work and jet lag. In addition, circadian rhythm changes can also serve as one of the early indicators of cardiometabolic and neurologic disorders, as is illustrated in diabetes, Alzheimer disease (AD), and Parkinson disease (PD). Finally, at the molecular level direct changes in the core clock genes have been associated with an increased risk for mental and physical disorders, with the largest number of studies to date in mood disorders, although the strength of many of these studies is limited. Overall, however, understanding the influence of circadian clock function in disease expression and treatment represents a novel approach for clinical medicine.

CIRCADIAN MISALIGNMENT

Shift Work and Social Jet Lag

Shift work is a major source of circadian dysregulation because workers are required to be awake during times when they would normally sleep. Although workers can adapt to the change in timing, many live in a chronic state of varying degrees of circadian misalignment, being awake at night on workdays and during the daytime on days off because of social and family responsibilities. In addition to typical shift work, a large number of individuals are required to wake up much earlier on workdays than they would prefer to, then sleeping in on nonworkdays. The mismatch between work and nonwork sleep times is referred to as *social jet lag*. There is growing evidence that the circadian misalignment associated with shift work or social jet lag contributes to the development of disease, with the strongest evidence for an increased risk for cancer and cardiometabolic disorders.

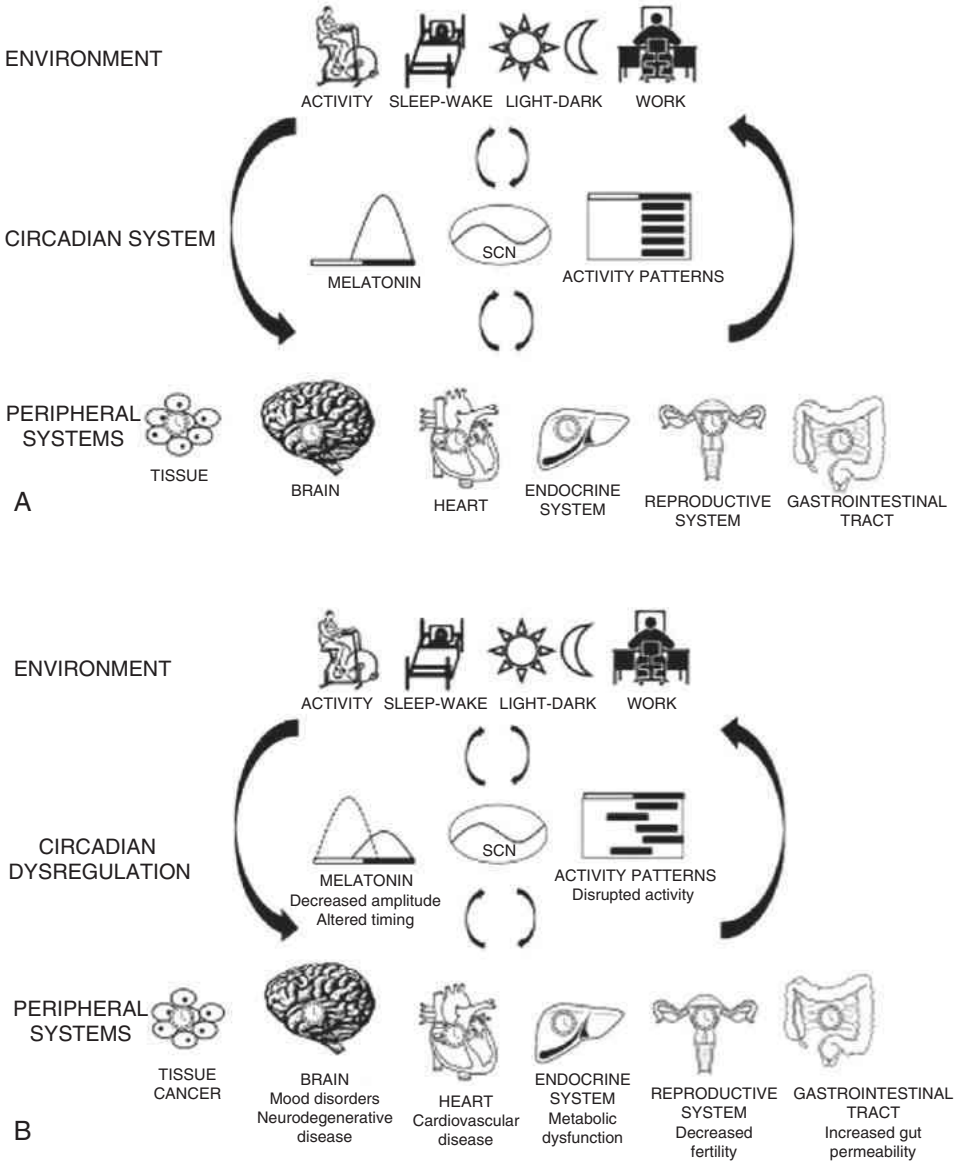

Figure 39-1 Normal circadian regulation **(A)** and dysregulation **(B)**. Circadian dysregulation can occur at multiple levels. The primary circadian pacemaker is located in the hypothalamus in the suprachiasmatic nucleus (SCN). The SCN maintains rhythmicity through a transcription-translation feedback loop of core clock genes, of which various mutations can contribute to human disease. Environmental time cues from the light-dark cycle help to regulate the circadian clock and can be disrupted in shift work. Finally, peripheral organ systems have circadian activity that must be appropriately aligned with the SCN and other peripheral tissues for proper function.

Shift Work and Cancer

The initial evidence for an increased cancer risk among shift workers came from several case–control studies of women with breast cancer. A study of Norwegian telegraph operators found an increased odds ratio for breast cancer among women older than 50 years and those who were exposed to night shift work for more than 2.7 years.[2] A case–control study in Seattle found the risk for breast cancer was significantly increased in woman who worked the "graveyard" shift,[3] whereas a case–control study in France evaluated women with newly diagnosed breast cancer for occupational history, and the odds ratio for developing breast cancer was 1.35 for women who had ever worked overnight shifts. This risk was highest among women who had worked night shifts for more than 4 years before their first full-term pregnancy.[4] A Danish study looking at female military employees showed an odds ratio for developing breast cancer of 1.4 among women who had ever worked night shifts, with the effect being most pronounced among woman with a combination of a strong morning chronotype preference and high exposure to night shift work.[5] Similar results have also been shown in a case–control study of Norwegian nurses.[6] The Nurses' Health Study found that a cohort of women who worked on the night shift for 30 or more years had a relative risk of 1.36 for developing breast cancer,[7] whereas a cohort of 4036 Swedish women found a hazard ratio of 2.02 for developing breast cancer if working shifts that included night work.[8] A recent meta-analysis of 28 studies evaluating circadian disruption and breast cancer risk

found that the relative risk for breast cancer was 1.19 for shift work.[9] Shift work has also been associated with an increased risk for prostate cancer,[10] ovarian cancer,[11,12] lung cancer,[13] and non-Hodgkin lymphoma.[14] Overall these results prompted the International Agency for the Research on Cancer in 2007 to conclude that shift work involving circadian disruption is probably carcinogenic (group 2A).[15] However, several studies have not found an association between shift work and breast cancer, including a cohort of 73,029 Chinese women surveyed regarding lifetime shift work exposure and breast cancer.[16] Interestingly the Electromagnetic Fields and Breast Cancer on Long Island Study did not show a direct association with shift work, but did find an increased incidence of breast cancer in women with greater exposure to light at night.[17]

Mechanisms by which light at night may contribute to cancer include an increased degree of circadian disruption or suppression of the normal nocturnal pineal melatonin secretion. Because melatonin can have tumor suppressant properties in animals,[18] low nocturnal melatonin levels have been proposed to increase the risk for cancer. In support of this hypothesis, studies have found significantly lower levels of 6-sulfatoxymelatonin, the urinary metabolite of melatonin, in both female[19] and male[20] night shift workers and lower amplitude of melatonin secretion over a 24-hour period in shift workers compared with nonshift workers.[21] However, a direct causal relationship between melatonin levels and cancer has not been established.

In human breast cancer cells, melatonin has been demonstrated to bind to MT-1 receptors, suppressing cyclic adenosine monophosphate and blocking linoleic acid uptake and conversion to 13-hydroxyoctadecadienoic acid (13-HODE). 13-HODE normally activates growth factor pathways, so downregulation by melatonin can decrease cell proliferation.[22] In addition, recent in vitro work has shown that melatonin induces expression of PER2.[23] These results suggest that shift workers with increased evening light exposure, resulting in increased melatonin suppression, would have decreased expression of PER2. Mice deficient in mPER2 show an increased incidence of cancer,[24] whereas overexpression of mPER2 induces cancer cell apoptosis.[25] PER2 downregulates the protein β-catenin, which regulates cyclin D. In the absence of PER2, cyclin D increases, resulting in increased cell proliferation.[26] Melatonin has also been demonstrated to activate glycogen synthase kinase 3b (GSK3b), which normally inhibits the epithelial to mesenchymal transition that can promote cancer progression; however, in the absence of melatonin, this process is upregulated, resulting in increased cancer progression.[27]

In support of the circadian disruption hypothesis, there have been multiple studies showing that impaired circadian rhythmicity, seen either in flattening of the diurnal cortisol rhythm or decreased amplitude of the daily rest activity pattern, corresponds with a worse prognosis in lung and colorectal cancer, respectively[28,29]; however, these studies describe correlations, so it is not known whether circadian disruption is the cause of or a result of worsening prognosis. To further evaluate the role of circadian disruption in malignancy, several studies have evaluated the possible role of circadian clock genes. Recent studies have looked specifically at the *hPER2* mutation found in familial advanced sleep-wake phase disorder (ASWPD) and have shown that this mutation results in accelerated tumorigenesis in mice[30]; however, there are currently no reports of an increased incidence of cancer in humans with ASWPD.

Several small studies have evaluated other circadian clock genes for their possible role in carcinogenesis. Recent analysis has shown a decreased expression of hPER3 in individuals with more advanced head and neck cancer,[31] and low hPER3 has also been found in patients with recurrent breast cancer.[32] Specific polymorphisms in *CRY2* have been significantly associated with increased breast cancer risk in women with estrogen and progesterone receptor–negative breast tumors.[33] In chronic lymphocytic leukemia, elevated expression of CRY1 is associated with higher risk disease.[34] Polymorphisms in the *CLOCK* gene have been associated with improved survival in colorectal cancer, as well as reduced risk for breast cancer.[35,36] Evaluating subjects from the Nurses' Health Study cohort demonstrated that polymorphisms in *NPAS2* were associated with increased breast cancer risk, particularly among shift workers,[37] whereas a study of Norwegian nurses demonstrated that polymorphisms in *ARNTL*, *AANAT,* and *RORB* increased the risk for breast cancer in shift workers.[38] In addition, polymorphisms in the *TIMELESS* gene have also been associated with a reduced risk for breast cancer.[24] Although these findings simply reflect association, it is intriguing and quite plausible that circadian clock dysregulation at least in part confers an increased risk for cancer.

Finally, along with the potential increased risk for cancer, there is growing evidence that the presence of circadian dysregulation may also negatively affect treatment response. In one study evaluating sleep-log data and chronotype, those reporting "going to bed at preferred bedtime" had a significantly longer disease-free interval (81.9 vs. 46.9 months) compared with those who were going to bed later or earlier than the preferred bedtime.[39] Evidence for one potential mechanism for the difference in disease progression comes from rat studies, which demonstrated that light exposure at night, promoting circadian disruption, resulted in both increased tumor growth and resistance to tamoxifen, a common medication used in the treatment of breast cancer.[40]

Shift Work and Metabolic Syndrome

There is substantial evidence that exposure to night shift work, rotating shift work, and even social jet lag is associated with an increased risk for metabolic syndrome and its varying components. Metabolic syndrome describes a group of risk factors, including central obesity, elevated blood pressure, elevated triglycerides, elevated fasting glucose, and low high-density lipoprotein (HDL) cholesterol, which increase the risk for cardiovascular disease and diabetes.

One of the first studies to evaluate this relationship included 27,485 workers in Sweden and found an increase in obesity, elevated triglycerides, decreased HDL, and impaired glucose tolerance among shift workers.[41] It has also been found that shift work is associated with an increase in systolic[42] and diastolic blood pressure[43] and with a loss of the normal nocturnal dip in blood pressure.[44] In addition, prospective trials have found that both men and women working rotating shifts have an accelerated development of metabolic syndrome compared with day workers.[45,46] One question that arises is whether these risks are primarily due to social and behavioral differences between shift workers and day workers. However, in a Finnish study, even after controlling for education, smoking, physical activity, alcohol, and insomnia, the

increased prevalence of metabolic syndrome among shift workers persisted.[47]

There are several potential causes of this increased risk. Certainly one component is sleep restriction. Studies have shown that night and rotating shift workers have a decrease in total sleep time ranging from 1 to 4 hours compared with controls,[48,49] and short sleep duration has been associated with many of these risk factors. Under laboratory conditions looking at healthy control individuals, the combination of 3 weeks of sleep restriction and circadian disruption resulted in decreased resting metabolic rate and increased postprandial plasma glucose due to decreased insulin secretion.[50]

In addition to sleep deprivation, shift workers get increased light exposure at night. In animal studies light at night results in increased weight and reduced glucose tolerance.[51] These effects may in part be due to the light-induced suppression of nocturnal melatonin, although of note, not all mouse strains secrete melatonin,[52] and the pattern of melatonin release in the mouse strain used in this study is unknown. However, in support of this concept in humans, decreased morning urinary melatonin levels have been associated with an increased risk for hypertension[53] and diabetes.[54]

CIRCADIAN DYSREGULATION AND PHYSICAL HEALTH

Outside of environmental and genetic disruption, circadian dysregulation has also been demonstrated to play an important role in a variety of other physical disorders from cardiovascular to respiratory disease to reproductive health.

Cardiometabolic Dysfunction

Although the greatest evidence for the role of circadian dysregulation in cardiovascular disease comes from shift work studies, there are many other ways in which the circadian system has been demonstrated to play a role. Major cardiovascular events, including myocardial infarction, sudden cardiac death, and stroke, all have a peak occurrence in the morning,[55-57] which appears to be regulated by circadian factors. Recent research indicates that this may be due to circadian alterations in clotting, affecting both platelet activation[58] and prothrombotic factors.[59] Alteration in the timing of these factors in relation to underlying activity could presumably result in further increased cardiovascular disease risk.

Recent data have demonstrated that even among day shift workers, greater degrees of social jet leg have been associated with an increase in body mass index.[60] In addition, having a later chronotype as determined by midsleep point is associated with poorer glycemic control in type 2 diabetes.[61] Those with later chronotypes are more likely to suffer from social jet lag, again suggesting that it is this mismatch between the internal circadian system and the external environment that is contributing to the increased metabolic risk.

Low nocturnal melatonin levels, either due to light at night, circadian dysregulation, or overall low secretion, also seem to play a role in cardiometabolic disease risk. It is known that loss of normal melatonin secretion in rats through pinealectomy can induce hypertension.[62] In humans, studying a small group of elderly patients with hypertension comparing those who lack the usual nocturnal dip in blood pressure (nondippers) with those who do exhibit a normal dip (dippers), it was found that the total 24-hour urinary melatonin level was the same between groups. However, the nondippers were noted to lack the usually observed nocturnal surge in melatonin,[63] suggesting that the timing may be more important than the absolute level of melatonin. Exogenous melatonin has been demonstrated to act directly on the vascular system as a vasodilator.[64] In addition, it has been postulated that through its antioxidant properties, melatonin decreases oxidative injury and endothelial dysfunction,[65] which regulate vascular resistance and blood pressure.

At a genetic level polymorphisms in the gene coding for the MT2 melatonin receptor have been associated with increased fasting plasma glucose and risk for type 2 diabetes.[66,67] The MT2 receptor is found on pancreatic islet cells and may mediate the inhibition of insulin secretion by melatonin.[68] This association persists in a meta-analysis of 23 studies, although of note the data seem to be stronger in white people than East or South Asians.[69] In mice, mutations in the *CLOCK* gene, resulting in circadian disruption, have been associated with symptoms of metabolic syndrome.[70] Smaller human studies have shown that polymorphisms in the *CLOCK* gene are associated with both the development of metabolic syndrome[71] and the response to dietary interventions to treat metabolic syndrome,[72] whereas polymorphisms in *ARNTL* are associated with hypertension and diabetes.[73] In addition, *NR1D1,* another core clock gene, seems to be involved in lipid and glucose metabolism,[74] although further research in this area is needed.

Pulmonary Disease

From a respiratory standpoint it has long been recognized that asthma attacks tend to worsen overnight.[75] Forced desynchrony protocols in healthy individuals have demonstrated a circadian pattern in pulmonary function, specifically forced expiratory volume in 1 section (FEV_1) and the ratio of FEV_1 to forced vital capacity, independent of sleep state.[76] More recently it has been found that evening types are more likely to have nocturnal asthma than intermediate types,[77] again suggesting a circadian component to the illness, as well as a potential role for circadian dysregulation as a contributing factor, although more research in this area is needed.

Other Disorders

Although there is still only a limited amount of human data in this area, there is growing evidence from animal studies that circadian dysregulation can also contribute to multiple other disease pathologies. In rodent studies, circadian dysregulation has been demonstrated to be associated with increased risk for steatohepatitis, gut leakiness, and fetal loss.[78,79] However, this is clearly an area in which additional human research is needed.

CIRCADIAN REGULATION AND NEUROLOGIC DISORDERS

Many common neurologic disorders exhibit circadian patterns in their occurrence and severity, although it can sometimes be difficult to separate the circadian pattern of symptoms from the underlying sleep-wake cycle. Both seizure and headache onset often peak at specific times of day, as detailed later. In addition, melatonin can be an effective intervention for many neurodevelopmental disorders, again suggesting a circadian component to these illnesses. Autism has been associated with a decreased amplitude of melatonin secretion,[80] and sleep

duration and sleep latency as well as daytime behavior significantly improve following administration of nocturnal melatonin (0.75 to 15 mg).[81] Other less common neurodevelopmental disorders also are associated with abnormal melatonin profiles and can improve with supplemental melatonin. Smith-Magenis syndrome is a neurodevelopmental disorder associated with an inverted melatonin rhythm, resulting in daytime sleepiness and nighttime insomnia,[82] whereas Angelman syndrome is associated with low melatonin levels, and sleep initiation and maintenance improve with supplemental melatonin (2.5 to 5 mg).[83]

Different seizure types have varying patterns of expression, and these also can vary between children and adults. In children being monitored on an inpatient epilepsy unit, tonic and tonic-clonic seizure occurred more frequently during sleep, whereas absence, atonic, and myoclonic seizures occurred primarily during wakefulness, and clonic seizures and epileptic spasms had two peaks, during the early morning and afternoon.[84] In adults monitored outside of the hospital, frontal lobe seizures occurred more frequently during the early morning, whereas temporal lobe seizures occurred more frequently during the afternoon.[85] To try to separate the degree to which these difference are dependent on sleep state versus circadian time, five subjects with epilepsy underwent a forced desynchrony protocol. Overall, interictal epileptiform discharges were most common coming out of non–rapid eye movement sleep; however, in addition there did seem to be a circadian pattern to interictal epileptiform discharge frequency, although the specific pattern varied between subjects.[86] However, this was a very small study looking primarily at subjects with idiopathic generalized epilepsy, so it is hard to generalize these findings at this point.

Headaches also have both strong circadian and sleep-wake components. Cluster headaches often reoccur at the same time of day, and there is functional magnetic resonance imaging evidence for hypothalamic activation during cluster headache onset, suggesting involvement of the SCN.[87] In addition, individuals with cluster headaches have both an advance and a decrease in amplitude of melatonin secretion.[88] Interestingly, hypothalamic deep brain stimulation has been an effective treatment for some individuals with refractory cluster headaches.[89] Migraine headaches tend to more frequently begin during the morning,[90] and more recently it was demonstrated that the mutation responsible for ASWPD is also associated with familial hemiplegic migraine, again suggesting a circadian component.[91]

Circadian Dysregulation in Neurodegenerative Disease

Neurodegenerative disorders are frequently associated with disruptions in circadian timing. This is most commonly seen in the alterations in the sleep-wake cycle, with "sundowning" representing a frequent problem for both patients and caregivers. However, as we will illustrate in more detail with AD and PD, circadian dysregulation may also be one of the earliest indications of the presence of a neurodegenerative disease, and circadian-based interventions may improve the overall disease course.

Alzheimer Disease

AD is the most common form of dementia in adults. The primary clinical manifestation is progressive cognitive deterioration. The pathologic hallmarks include deposition of β-amyloid plaques and hyperphosphorylated tau protein neurofibrillary tangles.[92]

Circadian dysfunction in the sleep-wake rhythm has long been recognized in AD. Several cross-sectional studies, although small, have shown alterations in the sleep-wake rhythm in demented patients. Using wrist actigraphy monitoring, patients with AD appear to have less overall activity, dampened amplitude, and increased fragmentation of the rest-activity rhythm, leading to more nocturnal wake time and daytime napping.[93-95] The degree of reduction in amplitude of the rest-activity rhythm correlates with the severity of AD.[95] The degree of daytime sleepiness based on the Multiple Sleep Latency Test is apparent even in mild to moderate AD and correlates with the degree of cognitive dysfunction.[93] Greater interdaily instability of the rest-activity cycle is associated with cognitive impairment and depression,[96] whereas decreased daytime activity predicts worsening cognition, functional and social impairment, and greater apathy.[94,96] Furthermore, the rest-activity rhythm may be predictive of the risk for dementia. In one large study of 1282 women, those in the lowest quartile for amplitude and robustness and those with a later timing of the rest-activity rhythm had higher risk for developing mild cognitive impairment or dementia over 4.9 years of follow-up.[97]

There are several potential mechanisms for the circadian disruption in AD. Age-associated reduction in exposure to synchronizing agents, such as light and structured social and physical activities, have been shown to contribute to circadian dysfunction. Actigraphy data have demonstrated that patients with severe dementia spend less time exposed to bright light and also have a blunted amplitude of daily activity compared with nondemented nursing home patients.[98] Increased physical activity has been associated with a decrease in dementia-related mortality, independent of age, gender, and cardiovascular risk factors.[99] However, regardless of the total amount of daily activity, greater fragmentation of rest-activity patterns has been associated with decreased cognitive performance.[100] Interventions that increase the amplitude of social and physical activity rhythms as well as daytime light exposure have been shown to decrease daytime sleep and in some cases also improve nocturnal sleep quality.[101] For example, structured social activity for 1 to 2 hours daily for 21 days in 147 nursing home residents with dementia improved consolidation of nighttime sleep and reduced daytime sleepiness.[102] Several small studies (n = 14 to 133) incorporating physical and social activity as part of a multicomponent program have shown some benefits in sleep or circadian rhythms for nursing home residents.[103-105] A larger clinical trial (n = 173) across several nursing homes did show decreases in daytime sleep with these interventions, but no improvement in nighttime sleep measures, thought to result in part from an inability to fully decrease nocturnal noise.[106]

Alzheimer tangles have been seen in the SCN,[107-110] and the degree of pathology is associated with reduced amplitudes in activity, core body temperature rhythms,[111] and melatonin secretion.[112-114] However, the sleep fragmentation seen with AD appears to be more strongly correlated with loss of galanin-containing neurons in the intermediate nucleus, rather than the loss of vasoactive intestinal peptide– or arginine vasopressin–immunoreactive cells in the SCN.[115]

Decreased melatonin secretion can be found even in early pathologic stages of AD and correlates with severity of

pathology.[116] This low melatonin secretion may play a role in the expression of AD. In vitro, melatonin inhibits formation of pathologic β-amyloid fibrils, tau protein phosphorylation, and neurotoxicity.[117,118] In transgenic animal models of AD, melatonin administration inhibits the development of Alzheimer pathology[119-122] and may reduce deterioration of learning and memory in most studies performed.[119,121] One study failed to show changes in cortical levels of β-amyloid plaques following melatonin administration, but melatonin was given when the mice were older, after amyloid plaques typically appear, so the intervention may have been too late.[123]

Another potential mechanism of cognitive dysfunction in AD may be circadian desynchrony of rhythms in brain networks.[124] The hippocampus and other brain regions involved in AD have semiautonomous clocks,[124] and their circadian oscillations differ in their dependence on the SCN.[125] Finally, recent data from transgenic mouse model of AD show that β-amyloid has a diurnal rhythm, increasing during wakefulness and decreasing during sleep.[126] During sleep, toxic products such as β-amyloid are cleared from the brain,[127] whereas β-amyloid continues to increase during sleep deprivation.[126] It remains unclear whether the accumulation and clearance of β-amyloid are directly influenced by the circadian system.

Because of the findings of circadian disruption in AD, many treatment strategies have focused on strengthening circadian signals, primarily focusing on using either melatonin, light, or a combination of the two. Treatment with melatonin has had mixed effects. On the one hand several small or uncontrolled studies using melatonin in older adults have been reported to improve sundowning,[128] agitation,[129] nocturnal activity,[113,130] and the amplitude of the rest-activity rhythm.[131] However, only two of these studies specifically examined AD. One large study of 157 people with AD did not confirm an objective benefit from melatonin administration by actigraphy, although improvements in caregiver ratings of the participants' sleep quality were noted.[132] Bright light therapy appears to more consistently improve sleep and circadian dysfunction in AD. Morning bright light therapy (usually 2500 lux or more) increases nighttime sleep and daytime wakefulness and also improves evening agitation.[133] Evening light exposure improves consolidation of the rest-activity rhythm[133]; even 30 lux of blue light improves sleep efficiency.[134] Light exposure given continuously throughout the day increases total sleep time, improves interdaily stability of the rest-activity rhythm, improves mood, and even slightly attenuates cognitive deterioration when given long term.[133,135] A 24-hour lighting scheme may be helpful to improve the sleep-wake rhythm, decrease agitation, and reduce falls at night.[136] This plan consists of high amount of light exposure during the day and low amount at night, with the exception of nightlights to reduce falls if awake at night. Finally, a combination of light and melatonin (5 mg) demonstrated a significant improvement in daytime activity and an overall strengthening of the rest-activity pattern compared with light alone.[137]

Parkinson Disease

PD is a neurodegenerative disorder with clinical manifestations of bradykinesia, rigidity, and tremor. The pathologic hallmark in PD is the accumulation of Lewy bodies, which are intraneuronal α-synuclein inclusions, in the dopamine-containing nigrostriatal neurons. Sleep and wake disturbances, particularly sleep fragmentation and hypersomnia, are reported in about 60% to 90% of patients with PD.[138,139] Recent evidence from a transgenic mouse model for PD demonstrated increased fragmentation of the rest-activity pattern and decreased firing of the SCN neurons early in the disease course, suggesting that circadian dysregulation may underlie these sleep disturbances and may even contribute to the pathophysiology of PD.[140]

In human studies, circadian patterns of activity and hormone release also appear to be altered in PD. The few studies of the rest-activity rhythm in PD using wrist actigraphy show reduction in overall activity, increased nocturnal activity, and increased daytime sleep, resulting in an overall decreased amplitude.[141-143] In addition, patients with hallucinations had decreased day-to-day stability of the rest-activity rhythm and lower relative activity amplitude than those without hallucinations.[142]

Melatonin rhythms are also affected in PD. Earlier studies suggested that people with PD on dopaminergic treatment have a phase advance in melatonin rhythms compared with untreated patients.[144,145] More recent studies have not been able to confirm this but did demonstrate that individuals with PD on dopaminergic therapy had a larger phase angle between salivary DLMO and habitual sleep-onset time compared with untreated patients and controls.[146] In addition, patients with PD had a lower amplitude of daily melatonin secretion compared with controls, with the lowest amplitudes seen in those with complaints of daytime sleepiness (Figure 39-2).[147] Smaller studies have also shown disturbances in the circadian rhythms of blood pressure,[148] core body temperature,[149] and cortisol rhythm.[150]

Potential mechanisms underlying these circadian disturbances may include alteration of exposure to zeitgebers or degeneration of afferents to the SCN (e.g., retina), the SCN itself, or downstream efferents. People with PD may get less light exposure during the day,[151] although this has not been clearly demonstrated. In addition, age-related meiosis and cataracts may lead to decreased retinal illumination.[152] Dopamine, the primary neurotransmitters affected in PD, enhances melanopsin expression in retinal ganglion cells that project to the SCN[153] and may influence the ability of light to reset retinal PER2 rhythms.[154] Alterations in dopamine function, from either neurodegeneration or dopaminergic therapy, may therefore influence the light response. The SCN itself may also be affected in PD. In a mouse model of PD, decreased firing of SCN neurons has been observed, and this may impair the ability of the SCN to drive peripheral rhythms.[155] There is also some evidence that areas downstream of the SCN that play an important role in regulating circadian rhythms may also be disrupted, such as striatal neurons in which dopamine influences expression of circadian genes *PER1* and *PER2*.[156]

Because of the apparent circadian disruption noted in this disease, there have been some efforts to look at circadian-based interventions, but data examining therapies such as exogenous melatonin or bright light therapy to improve circadian rhythms are limited. Melatonin (3 to 5 mg) at bedtime can improve subjective sleep quality,[157] subjective sleep quantity, and daytime sleepiness.[157,158] However, high doses (50 mg) result in only a small objective improvement in sleep duration.[158] Light therapy for about 1 hour before bedtime

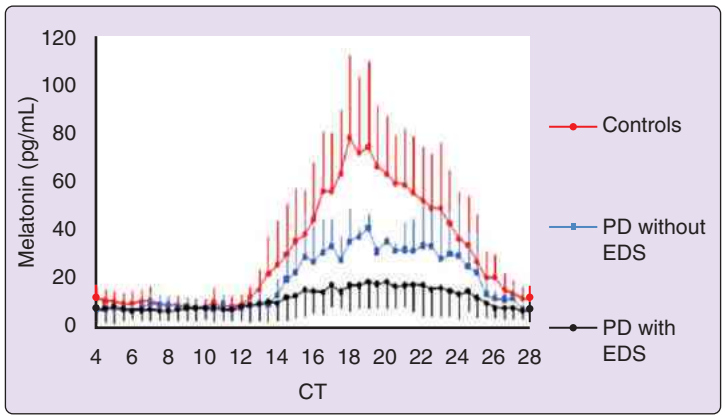

Figure 39-2 The amplitude of daily melatonin release is decreased in Parkinson disease (PD) compared with controls, and a greater decrease is seen in PD individuals with excessive daytime sleepiness (EDS) compared with those without EDS. CT, Circadian time.

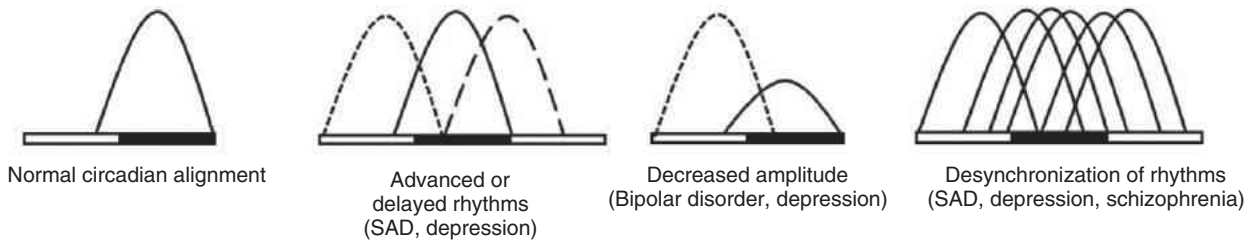

Figure 39-3 Circadian dysregulation can be associated with mood disorders in multiple ways. The phase of the rhythm can be shifted earlier (depression) or later (seasonal affective disorder [SAD]). The overall amplitude of the rhythm can be decreased, which can be seen in symptomatic bipolar patients, or there can be internal desynchrony, in which rhythms are no longer appropriately aligned.

can improve not only sleep onset latency and sleep efficiency but also motor symptoms and mood.[159,160] A controlled prospective study of morning bright light therapy (7500 lux for 30 minutes) in PD also improved subjective motor symptoms and mood, but it did not improve objective motor symptoms.[161]

CIRCADIAN DYSREGULATION AND PSYCHIATRIC DISORDERS

Circadian Dysregulation in the Pathophysiology of Psychiatric Disorders

Many psychiatric disorders have been noted to have a component of circadian dysregulation associated with them, with the strongest evidence for mood disorders, such as seasonal affective disorder (SAD), depression, and bipolar disorder. However, there is also evidence for disruption in the circadian activity pattern in schizophrenia[162] and a greater prevalence of delayed sleep phase disorder in patients with obsessive-compulsive disorder.[163,164] The observed circadian changes generally present as either a shift in the circadian phase, a decrease in circadian amplitude, or a misalignment between rhythms, most frequently seen in the relationship between sleep and the 24-hour patterns of hormone release (Figure 39-3).

SAD consists of depressive symptoms that are primarily present in the late fall and winter, during a period of shorter days when there is decreased exposure to natural bright light as well as a decrease in the intensity of light that is available. It was theorized that the decrease in exposure to an advancing light signal in the morning facilitated delay in the timing of circadian rhythms. Based on this theory, a small trial was performed using morning bright-light exposure as a treatment for SAD, demonstrating a positive response in seven of eight subjects.[165] Interestingly, symptoms appeared to correlate with the initial degree of misalignment between the timing of the dim-light melatonin onset and the midsleep point, and normalization of this difference improved treatment response.[166] These findings suggest that a shift in overall timing of melatonin release, resulting in misalignment between the melatonin and sleep-wake rhythms, contributes to the pathophysiology of this disorder. More recent data suggest that in addition to these factors, impaired light input to the circadian clock may also play a role. Light normally reaches the circadian system through melanopsin-containing retinal ganglion cells. Using a measure of pupillary light constriction as a surrogate marker for melanopsin cell function, it has been demonstrated that individuals with SAD have a decreased sensitivity to light compared with controls,[167] suggesting that it is not only a lack of exposure to light but also a decreased ability to respond to light that contributes to the underlying pathology.

Depression, on the other hand, is often associated with early morning awakenings and decreased rapid eye movement

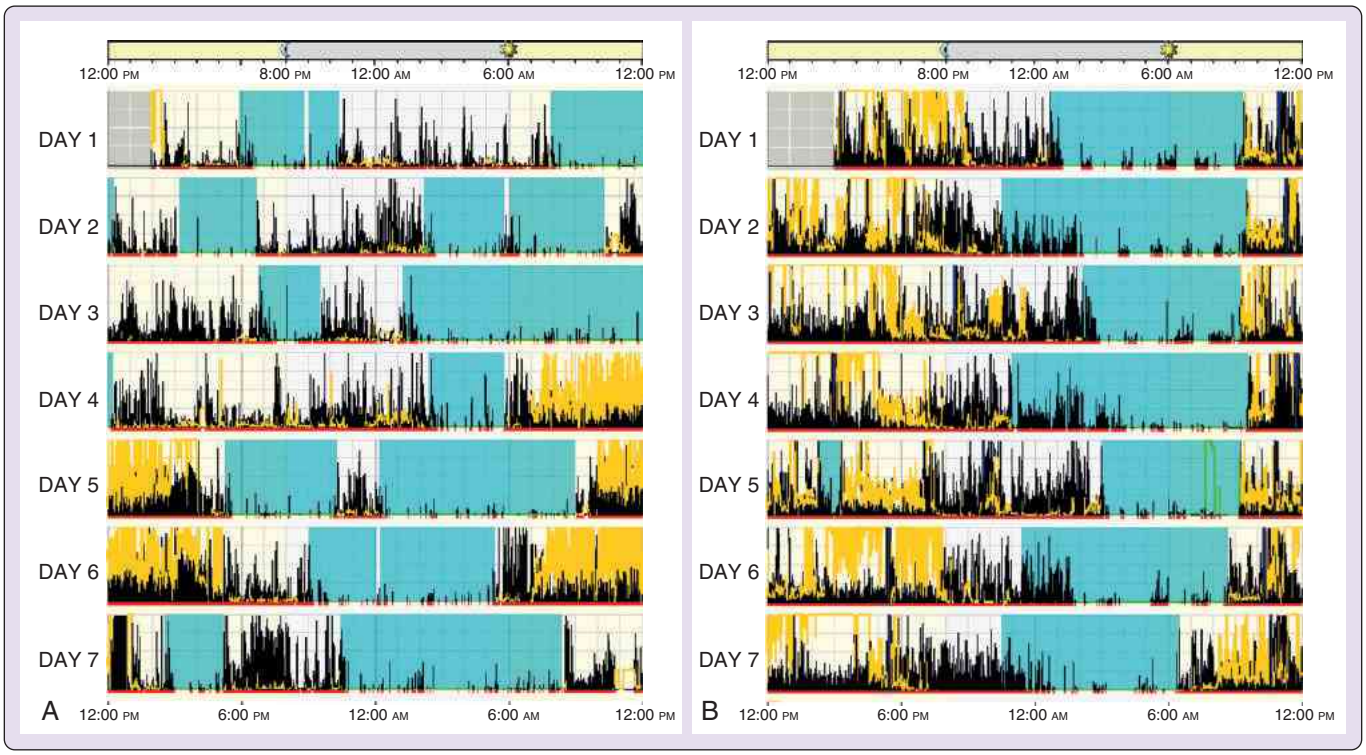

Figure 39-4 Sample actigraphy data from a subject with bipolar disorder during a period of depression **(A)** and during a period of stable mood **(B)**. The total activity and overall amplitude of the daily activity rhythm are decreased during the symptomatic period.

sleep latency, leading to early suggestions of the phase advance hypothesis[168] for the pathophysiology of depression. Supporting this is evidence that 24-hour patterns of cortisol and norepinephrine release are advanced in individuals with depression, and the amplitude of cortisol release is also decreased.[169] However, these effects seem to be age dependent, with younger individuals exhibiting greater phase delays in sleep-wake patterns and older individuals showing primarily a decrease in amplitude of the daily pattern of activity.[170] Things are further complicated by the high comorbidity of mood disorders in individuals with delayed sleep-wake phase disorder, suggesting that symptoms are not always due to a phase advance in circadian rhythms.[171,172] Overall these results suggest that the problem may be more complicated than simply an advance or delay in the circadian rhythm, leading to more recent research focused not just on the phase of circadian rhythms with respect to the environment but also on the alignment between rhythms, examining the relationship between hormone release, core body temperature, and the sleep-wake cycle, as well as the overall amplitude. Data are limited, but it appears that a shorter phase angle between either DLMO[173] or core body temperature[174] and the sleep midpoint may be associated with greater depression. Further research is needed in this area.

Patients with bipolar disorder exhibit recurring cycles of depression and mania or hypomania suggesting an underlying disorder of timing, and there is evidence of greater eveningness preference[175] among individuals with bipolar disorder. In addition, studies have demonstrated decreased stability of the sleep-wake pattern and decreased amplitude of activity rhythms, particularly among symptomatic individuals (Figure 39-4).[176] Data regarding abnormalities in circadian phase or alignment in these individuals are extremely limited to date, and this is an area in need of further research.

Given the findings of circadian dysregulation in psychiatric disorders, there has been extensive work performed looking for associations between polymorphisms in known clock genes or alterations in clock gene expression in psychiatric disorders. However, any potential associations to date have been limited by small sample sizes or poor replication across different ethnic groups. There is some evidence that *CRY1* polymorphisms are associated with major depression in both European[177] and Chinese[178] cohorts, whereas *CRY2* variants are associated with dysthymia.[179] The T3111 polymorphism of the *CLOCK* gene has previously been demonstrated to be associated with morningness-eveningness preference,[180] and a small study demonstrated an association between *CLOCK* polymorphisms and bipolar disorder.[177] However, replicable results have not been found in studies looking at depression,[181] SAD,[182] or schizophrenia.[183-185] A polymorphic repeat domain of *hPER3* has previously been associated with diurnal preference[186] but has not shown consistent associations with psychiatric disorders across different ethnic backgrounds.[184,187-189] Furthermore, associations have not been found between other circadian clock genes, such as *TIMELESS*, *CKIε*, and *δ* polymorphisms with depression, schizophrenia, or bipolar disorders.[190,191]

To try to address the limitations of small samples sizes and geographically limited populations, two large genome-wide association studies have been performed, but again results are not consistent. One study found several associations with bipolar disorder, depression, and schizophrenia,[192] but these

findings were not replicable in a second study, thought to be related to analyzing the data as a pooled data set rather than as individual genome-wide association studies.[193] Alternatively, rather than looking for associations with individual polymorphisms, another group evaluated whether the overall circadian pattern of gene expression differs between affected and control individuals. By performing time-of-death analysis of postmortem brains in individuals with depression and controls, Li and colleagues demonstrated that individuals with depression had alterations in peak timing of core clock gene expression, as well as disrupted phase relationships between gene expression patterns, resulting in weaker overall amplitudes of cyclical patterns.[194] However, this does not distinguish whether the altered expression patterns are a cause or an effect of the underlying disorder. Although circadian rhythms are often disrupted in psychiatric disorders, the exact biologic mechanisms underlying this relationship are unclear.

Chronobiology as Treatment for Psychiatric Disorders

There is growing evidence that treatments based on addressing circadian dysregulation can be effective adjunctive treatment for treating several psychiatric disorders. The best studied and most widely accepted of these treatments is bright-light therapy for the treatment of SAD. SAD symptoms are greater in individuals with a larger degree of circadian misalignment, and response to treatment corresponds with the degree of realignment.[166] In depression light therapy is generally not considered first-line treatment, but it can be successfully used as an adjunctive therapy for patients with drug-resistant depression or for individuals for whom medications may be undesirable (e.g., depression).[195] Finally, for patients with bipolar disorder, interpersonal and social rhythm therapy is a successful treatment strategy that, along with standard medication therapy, focuses on behavioral strategies to address patients' sleep and circadian vulnerabilities.[196] Overall the evidence indicates that circadian dysregulation plays an important role in disorders of mental health, and circadian-based approaches can be used to enhance treatment effectiveness.

CLINICAL PEARLS

- Circadian dysregulation is increasingly being recognized as an important component of disease risk.
- Assessing circadian timing and alignment in all patients, particularly those with cardiometabolic, neurologic, and psychiatric disorders, should be an important element of the clinical history.
- Circadian-based interventions have the potential to decrease disease risk and improve treatment outcomes.

SUMMARY

Disrupted circadian rhythms, either intrinsically due to genetic mutations or alterations in the SCN and its afferent and efferent pathways or extrinsically due to social and work demands, can affect the expression and development of many of the most common and challenging disorders in our modern society, including heart disease, diabetes, neuropsychiatric disorders, and neurodegenerative disorders. Exciting recent evidence points to circadian dysregulation as an early biomarker of neurodegeneration, as is seen in AD and PD. Together these findings suggest increasing importance of biologic timing in sleep medicine and in medicine as a whole.

Circadian Disorders of the Sleep-Wake Cycle

Sabra M. Abbott; Kathryn J. Reid; Phyllis C. Zee

Chapter Highlights

- Circadian rhythms are regulated by the suprachiasmatic nucleus in the hypothalamus.
- Circadian rhythm sleep-wake disorders can result from (1) changes in the light-dark cycle in relation to the internal clock, (2) changes in the internal clock in relation to the light dark cycle, and (3) dysfunction in the clock mechanism.
- Circadian rhythm sleep-wake disorders can be treated with a combination of behavioral interventions and carefully timed light and melatonin.

The sleep-wake cycle is generated by a complex interaction of endogenous circadian and sleep homeostatic (need for sleep increases as a function of prior wakefulness) processes, as well as social and environmental factors. Physiologic sleepiness and alertness not only vary with prior waking duration but also exhibit circadian variation. In humans, daily variation in physiologic sleep tendency reveals a biphasic circadian rhythm of wake and sleep propensity,[1,2] with a midday increase in sleep tendency occurring at about 2 to 4 PM, followed by a robust decrease in sleep tendency and increase in alertness that lasts through the early to middle evening hours. A primary role of the circadian clock is to promote wakefulness during the day and thus also to facilitate the consolidation of sleep during the nighttime hours.[1,3-5] In humans, this interaction between circadian and homeostatic processes results in approximately 16 hours of wakefulness and 8 hours of nocturnal sleep.

The timing and duration of the sleep-wake cycle depends on the synchronization of the endogenous circadian clock with the external physical light-dark (LD) cycle, as well as social or professional demands. Circadian rhythm sleep-wake disorders (CRSWDs) arise when there is either disruption of this internal timing mechanism or a misalignment between the timing of the circadian clock and the 24-hour social and physical environments. In this chapter, the nomenclature and diagnostic criteria for CRSWD and its subtypes are based on the criteria published in the *International Classification of Sleep Disorders,* third edition. These dyssynchronous states fall into three categories: (1) the terrestrial LD cycle may change relative to circadian timekeeping (shift work and jet lag), (2) circadian timekeeping may change relative to the terrestrial LD cycle (delayed sleep-wake phase disorder [DSWPD], advanced sleep-wake phase disorder [ASWPD], or non-24-hour sleep-wake rhythm disorder [N24SWD]), or (3) dysfunction in clock mechanisms (irregular sleep-wake rhythm [ISWRD]). The first circumstance occurs in the presence of a normal circadian timekeeping system and is generally self-limited or resolves with environmental change. The second circumstance is believed to occur because of chronic alteration in the circadian system, resulting in the inability of the circadian pacemaker to achieve a conventional phase relation with the external world, and the third is primarily due to dysfunction of the central clock or its afferent-efferent pathways. This chapter focuses on the second and third group of disorders. Because circadian variation in wakefulness and sleep propensity is the most apparent of the many behavioral and physiologic outputs of the circadian pacemaker, it is not surprising that the most apparent circadian rhythm disorders to be recognized involve the sleep-wake cycle.[6]

Disruptions in the timing of sleep and wakefulness are often associated with symptoms of difficulty falling or staying asleep or excessive sleepiness that cause patients to seek medical attention. Thus, in clinical practice, CRSWD is often underrecognized, yet should be considered in the differential diagnosis of any patient presenting with symptoms of insomnia or hypersomnia. A multimodal treatment approach of behavioral or pharmacologic strategies aimed to improve circadian function and alignment of circadian rhythms to the 24-hour environment is often necessary to consolidate sleep and improve daytime function in patients with CRSWD. Growing knowledge about how the circadian system responds to photic as well as to nonphotic entraining agents is increasing the number of practical therapies that can be used in "real life" clinical settings.

REGULATION AND ENTRAINMENT OF CIRCADIAN RHYTHMS

The suprachiasmatic nucleus (SCN), in the anterior hypothalamus, is the central pacemaker responsible for the generation of circadian rhythmicity in mammals.[7] Animals and humans removed from the external LD cycle and other time cues (zeitgebers) exhibit a self-sustaining cycle of sleep and wakefulness as well as many other physiologic and hormonal rhythms.

The endogenous frequency of this cycle of oscillation or free-running period is largely genetically determined.[8] The basic molecular mechanism by which SCN neurons generate and maintain a self-sustaining rhythm is through an autoregulatory feedback loop in which oscillating circadian gene products regulate their own expression through a complex system of transcription, translation, and posttranslational processes.[9] In the mouse[10] and hamster,[11] genes have been identified that lengthen[10] and shorten[11,12] the free-running period. The mammalian circadian period is generally slightly longer than 24 hours in diurnal animals and slightly shorter than 24 hours in nocturnal animals. In humans, the average circadian period has been estimated to be approximately 24.18 hours[13] and must therefore be synchronized or entrained on a regular basis to the 24-hour terrestrial day by external influences.

Entrainment by Light

Light is the major external time cue in mammals. Light reaches the SCN by afferent projections from the retina through the retinohypothalamic tract.[7] Recent evidence indicates that the primary circadian photoreceptors are the melanopsin-containing retinal ganglion cells, which in turn send photic information through projections to the SCN.[14,15]

Although circadian rhythms can be entrained to LD cycles that are not exactly 24 hours in duration, entrainment is restricted to cycles with periods that are "close" to 24 hours in duration.[16] The range of entrainment can vary from species to species and is dependent on the experimental conditions (e.g., intensity of LD cycle, whether period of LD cycle is changed gradually or rapidly), but in general, animals do not entrain readily to LD cycles that are more than a few hours shorter or longer than the period of the endogenous circadian rhythm. If the period of the LD cycle is too short or long for entrainment to occur, the circadian rhythm will free-run with a period of the endogenous pacemaker.

One of the most widely used methods to examine how the LD cycle influences the circadian system has been to expose animals and humans maintained in constant conditions to pulses of light. The effects of the light pulse on a phase reference point of a circadian rhythm (e.g., onset of melatonin, minimum of body temperature) in subsequent cycles is then determined. The direction and magnitude of the phase shifts are strongly dependent on the circadian time at which the light pulse occurs. A phase-response curve (PRC) is a plot of the magnitude and direction of the time shift induced by an environmental perturbation as a function of the circadian time at which the perturbation is given. Light pulses presented near the onset of the subjective night (part of the circadian cycle that occurs during the dark or nighttime) delay circadian rhythms, whereas light pulses presented in the late subjective night or early subjective day (part of the circadian cycle that occurs during the light or daytime) phase-advance circadian rhythms. Extensive studies have demonstrated that the LD cycle can entrain circadian rhythms and that bright light can be used to manipulate human rhythms under a variety of experimental conditions.[17,18] Although bright light (intensities approximating sunlight) is a very strong and reliable entraining agent for the circadian system,[18] there is evidence that lower intensities, such as those encountered in ordinary room lighting, can also affect the timing of human circadian rhythms.[19] The recent discovery that, in humans, both light-induced phase shifts and melatonin suppression are most sensitive to short wavelength light of approximately 460 nm[20,21] provides an exciting new avenue for the development of light therapies to treat circadian rhythm sleep disorders.

Entrainment by Nonphotic Signals

The role of activity and social cues as synchronizing agents for the human circadian system has been recognized since the early 1970s. Studies by Aschoff and colleagues showed that scheduled bedtimes, mealtimes, and various timed social cues were able to entrain circadian rhythms.[22] More recent studies indicate that sleep and social schedules may also phase-shift the circadian clock.[23] In addition, physical exercise during the night can produce a phase delay in human circadian rhythms,[24,25] whereas exercise during the morning can accelerate entrainment following a phase advance in the sleep-wake cycle.[26] These findings indicate that scheduled social and physical activity programs may also be useful strategies for the treatment of circadian rhythms sleep disorders.

Melatonin

Melatonin is an important modulator of circadian rhythms[27] and alters the timing of circadian rhythms in animals[28] and humans.[29] The circadian rhythm of melatonin production and release is controlled by the SCN through an indirect pathway, a noradrenergic synapse from the superior cervical ganglion to the pineal gland.[30] The PRC for melatonin in humans indicates that administration of exogenous melatonin to humans in the early evening advances the phase of circadian rhythms, whereas administration in the early morning delays the phase, with the strongest phase-shifting effects of exogenous melatonin occurring during the evening, just preceding the increase in endogenous melatonin levels.[31-33] In addition to its phase resetting properties, evidence supports a role for melatonin in sleep modulation by increasing evening sleep propensity and reducing core body temperature.[27] Melatonin has been shown to decrease the firing rate of SCN neurons,[34] and it has been proposed that by its inhibition of SCN firing, the increase of melatonin in the evening creates a sleep-permissive state.

The potential importance of melatonin for regulating the sleep-wake cycle has led to interest in its use for treatment of insomnia and circadian rhythm sleep disorders. Indeed, there is good evidence that melatonin may be effective for entraining circadian rhythms in blind people with free-running sleep-wake cycles[35] and phase-advancing circadian rhythms in people with delayed sleep phase disorder.[36] Another potential use for melatonin has been to maintain consolidation of sleep during the early morning hours in elderly people.[37]

DELAYED SLEEP-WAKE PHASE DISORDER, DELAYED SLEEP PHASE TYPE, DELAYED SLEEP PHASE SYNDROME

Clinical Features

DSWPD is characterized by sleep onset and wake times that are usually delayed more than 2 hours and often up to 3 to 6 hours relative to conventional sleep-wake times (Figure 40-1). The typical patient finds it difficult to initiate sleep before 2 to 6 AM and, when free of societal constraints, prefers wake times of 10 AM to 1 PM. Sleep itself is reported to be normal

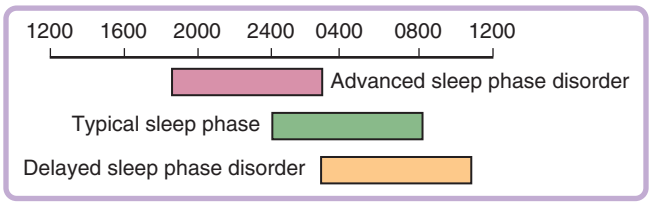

Figure 40-1 Schematic representation of the temporal distribution of sleep and wake in patients with circadian rhythm sleep disorders. Patients with advanced sleep phase disorder typically complain of evening sleepiness and either early-morning awakening or sleep disruption. Patients with delayed sleep phase disorder complain of difficulty initiating sleep, usually before 2 AM, and have difficulty awakening in the morning.

for age.[38,39] These symptoms are chronic, usually of at least 3 months—and quite often of many years duration. The clinical picture may be similar to sleep-onset insomnia. Patients are unable to advance their sleep times despite repeated attempts and may report a history of prolonged sedative-hypnotic drug use, bedtime use of alcohol, behavioral interventions, or psychotherapy.[40] Patients often report feeling most alert in the late evening and score highly as evening types on a morningness-eveningness scale.[41] Enforced "conventional" wake times may result in chronically insufficient sleep and excessive daytime sleepiness. Sleepiness is greatest in the morning and lessens as the circadian drive for wakefulness peaks in the late afternoon. In adolescents the syndrome may be associated with daytime irritability and poor school performance,[42] whereas in adulthood, the syndrome may be associated with impaired job performance and associated financial difficulty, as well as marital problems.[43] DSWPD may be mistaken for depression, in which the sleep-wake cycle may also be delayed (or advanced). Several studies, generally from psychiatric clinics, have emphasized an association of DSWPD with mood, obsessive-compulsive symptoms, and personality disorders.[43-46]

Epidemiology

DSWPD has been reported as young as preadolescence and beyond 60 years of age.[43] Although the actual prevalence of DSWPD in the general population is not well characterized, evidence from one population-based study indicates a prevalence of 0.17%.[47] DSWPD is reported to be more common in adolescents and young adults, with a reported prevalence of 3.3% to 7%,[48,49] whereas in middle-aged adults, the prevalence may be one tenth of that, or 0.7%.[50] In a group of New Zealand adults the prevalence was found to be 1.51% to 8.90%, depending on the definition used.[51] In a sleep disorders clinic, 6.7%[39] to 16%[44] of patients seen for a primary complaint of insomnia were determined to have DSWPD. There are no known gender differences in prevalence.

Pathogenesis

It has been pointed out that the tendency for late sleeping is not simply a function of the circadian drive for wakefulness interacting with the sleep homeostat but is analogous to eating or other behaviors that are mandated by physiology but overlaid by varying individual emotional, social, and medical states.[44] Although the exact cause of DSWPD is not known, there have been several mechanisms proposed, including both behavioral and physiologic factors. Behavioral preference may play a major role in some cases of DSWPD, particularly when bed times and rise times are not enforced.

In adolescence, for example, the biologic delay in the timing of circadian rhythms[52] is likely exacerbated by late evening activities, such as doing homework, watching TV, and using the Internet.[53] Other factors may include use of caffeine to combat sleepiness during normal waking hours. Staying up late and waking up late in the morning or afternoon may result in an abnormal relationship between the endogenous circadian rhythm and the sleep homeostatic process that regulates sleep and wakefulness. Evidence also shows that under certain conditions (a background of dim light), ambient artificial light (as low as 100 lux) at night may be of sufficient intensity to affect circadian timing.[19] Therefore light exposure later in the evening may also perpetuate and exacerbate the phase delay. Furthermore, late wake times will delay exposure to light in the morning and may prevent active advancement of the circadian clock, allowing it to drift to a new phase relation with external clock time. Studies in adolescents with subclinical DSWPD have found that simply following a fixed advanced sleep-wake schedule can result in significant advances in salivary melatonin rhythms,[54] suggesting a strong behavioral component.

For many individuals with DSWPD, however, symptoms often persist despite attempts to structure sleep and wake times, resulting in severe social or professional consequences[40,55,56] and suggesting that behavioral factors alone do not fully explain this disorder. There is considerable evidence that DSWPD is the result of alterations in the endogenous circadian system. For example, many physiologic markers of circadian phase persist in a delayed pattern despite enforced sleep-wake times.[40] There is also evidence that some individuals with DSWPD have a hypersensitivity to nighttime suppression of melatonin by bright light.[57] Reduced sensitivity of the oscillator to photic entrainment (i.e., a reduction in the amplitude of the advance portion of the PRC to light) has also been hypothesized, as has a prolonged free-running period length of the circadian cycle.[40,58,59] Furthermore, the duration and timing of environmental light and dark exposure may play a role in the expression of the DSWPD phenotype. For instance, the prevalence of DSWPD may be increased at extreme latitudes.[60] DSWPD has also been reported following minor traumatic brain injury.[61] There is also evidence for a genetic basis to DSWPD. In some cases the syndrome may be familial, presenting with an autosomal dominant mode of inheritance.[43,62] Further support for a genetic basis for DSWPD derives from reports of polymorphisms in circadian genes such as, *hPer3*, arylalkylamine *N*-acetyltransferase, human leukocyte antigen, and *Clock* that are associated with diurnal preference and DSWPD.[63-67]

Although it is commonly accepted that DSWPD is predominantly a result of alterations of circadian timing, there is recent evidence that alterations in the homeostatic regulation of sleep may play an important role as well.[68,69] Polysomnography (PSG) recordings of sleep in both adults and adolescents with DSWPD have shown that sleep architecture is not disrupted after the initiation of sleep when subjects are allowed to sleep until their desired wake times,[42,43,70,71] although individuals with DSWPD have been shown to have increased difficulty awakening from rapid eye movement (REM) sleep compared with controls.[72] Following 24 hours of sleep deprivation, subjects with

DSWPD, compared with controls, show a decreased ability to compensate for sleep loss during the subjective day and the first hours of subjective night.[68,73] Therefore it is likely that both alterations in circadian timing and impaired sleep recovery contribute to symptoms of insomnia and excessive sleepiness in DSWPD.

Diagnosis

The diagnosis of DSWPD is usually made on the basis of the patient's history of chronic or recurrent complaint of symptoms of insomnia due to a stable delay in the timing of the major sleep and wake period.[74] The sleep disturbance is associated with impairment of social, occupational, or other areas of functioning. In addition, sleep log or actigraphy monitoring should be performed for at least 7 days, but preferably 14 days, to demonstrate a stable delay in the timing of the habitual sleep period. Actigraphy is a practical tool for assessing sleep-wake cycles relative to clock time and has become more widely available clinically[75] (Figure 40-2). A morningness-eveningness questionnaire, such as the Horne-Ostberg[41] or the Munich chronotype[76] questionnaire, may be useful in confirming the patient's circadian preference but is not required to make the diagnosis.[77,78]

To make the diagnosis, medical, mental, or sleep disorders that may cause alterations in the sleep-wake cycle, insomnia, or excessive sleepiness should be excluded or be adequately treated. In adolescents, social maladjustment, family dysfunction, school avoidance, and affective disorders should be considered in the differential diagnosis. Nocturnal PSG is not necessary to establish the diagnosis but should be performed when another primary sleep disorder such as sleep apnea or parasomnia is suspected. When performed during conventional sleep laboratory hours, PSG often shows a prolonged sleep-onset latency as well as prolonged REM latency and may sometimes, in conjunction with an antecedent sleep log, be a clue to the diagnosis.

The use of other physiologic markers of circadian timing, such as continuous recording of body temperature[79] or dim light plasma melatonin onset (DLMO),[80] may also aid in determining the phase relation of circadian and terrestrial time, although routine clinical availability remains limited. DLMO is probably the most useful marker for circadian pacemaker output.[81,82] Individuals with DSWPD usually have DLMO times that occur after 10 PM.[80,83,84] (Figure 40-3). Determination of DLMO can be made by measurements of melatonin from plasma or saliva. Commercially available salivary determination of DLMO for clinical use may be feasible in the near future.

Treatment

The goal of therapy is to align the timing of the circadian clock with the desired 24-hour LD cycle. Richardson[6] has noted that treatment of DSWPD is the same whether it is the result of a primary behavioral or a primary physiologic process. Adherence to good sleep hygiene principles and identification and treatment of comorbid medical and psychiatric disorders are essential components in the management of DSWPD. In addition, chronotherapy, light therapy, and pharmacologic agents, such as melatonin, have been shown to be useful treatments for patients with DSWPD.

Figure 40-2 Representative rest-activity cycles recorded with wrist-activity monitoring of patients with circadian rhythm sleep disorders. The *black bars* indicate activity levels recorded at the nondominant wrist. Delayed sleep-wake phase disorder with sleep-onset times of approximately 3 to 4 AM and wake time of noon (*top panel*). Advanced sleep-wake phase disorder with sleep onset between 8 and 10 PM and wake time of 4 to 5 AM (*bottom panel*).

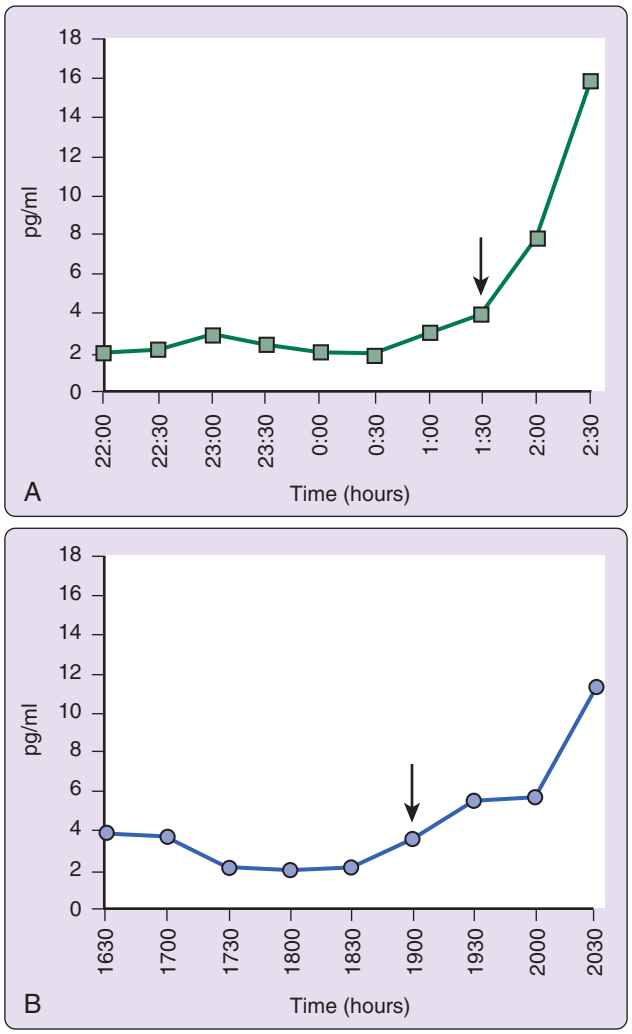

Figure 40-3 Dim light melatonin profiles of an individual with delayed sleep-wake phase disorder with a dim light melatonin onset (DLMO) at 1:30 AM (**A**) and an individual with advanced sleep-wake phase disorder with at DLMO at 7 PM (**B**). The *arrow* indicates the DLMO calculated as 2 standard deviations above the mean of baseline.

Chronotherapy

The use of chronotherapy has been successful in a small group of patients in a laboratory setting.[40] Chronotherapy requires a successive delay of sleep times by 3 hours daily over a 5- to 6-day period until the desired sleep time is achieved. This shift is followed by rigid adherence to a set sleep-wake schedule and good sleep hygiene practices. However, outside the laboratory setting, the potential confounding effects of light exposure at the wrong circadian time may limit the effectiveness and practicality of this approach.[6] In addition, caution must be maintained because there are case reports of individuals with severe DSWPD developing a non-24-hour sleep-wake pattern following chronotherapy.[85,86]

Light

As described earlier, light plays a major role in resetting the human circadian pacemaker.[17,18,87] Therapy with bright light in the morning (the advance portion of the human PRC) should advance the phase of circadian rhythms in DSWPD and may be more practical than chronotherapy.[88,89] Although a number of reports of successful application of bright light therapy in DSWPD exist,[90-93] large, randomized, placebo-controlled studies to determine the intensity, duration, and overall effectiveness are still needed. Rosenthal and colleagues found that 2 hours of bright light exposure (2500 lux) in the morning, together with light restriction in the evening, successfully phase-advanced (by 1.4 hours) circadian rhythms of core body temperature and multiple sleep latencies in 20 patients chosen prospectively after meeting clinical criteria for DSWPD.[93] In contrast, a retrospective report from a referral sleep clinic found that only 7 of 20 patients with DSWPD treated with bright light alone were able to entrain reliably to a desired sleep schedule.

The human PRC to a single 3-hour bright light pulse suggests that a light pulse given slightly before the time of body temperature minimum will result in a maximal phase delay, whereas a pulse given slightly after the minimum will cause a maximal phase advance (each about 2 hours).[87] When light pulses over three successive cycles are used, larger shifts (4 to 7 hours) can be produced. Because body temperature minimum is not routinely measured clinically, light therapy is usually timed using sleep logs to estimate the patient's endogenous circadian phase. A light pulse of 1 to 2 hours' duration and between 2500 and 10,000 lux is usually administered toward the end of the sleep-wake cycle. Because the portion of the PRC at which the greatest phase advance can be achieved occurs during sleeping hours, light is usually given immediately on awakening in the morning, which results in a smaller phase advance. It should be noted, however, that in severely delayed individuals the sleep-wake cycle may not necessarily correlate with circadian phase; therefore early morning light could in theory be inadvertently given on the delay portion of the PRC, worsening the problem. Regenstein and Pavlova reported a patient who slept later after receiving light exposure at 6 AM.[44] Another factor that may limit the practicality of bright light treatment is that many individuals with DSWPD may find it difficult to wake in time for administration of bright light therapy.[44]

Although the timing, intensity, and duration of light exposure have not been fully established in clinical practice, there is sufficient evidence to support the efficacy of bright light therapy for the treatment of DSWPD. The practice parameters established by the American Academy of Sleep Medicine considered light therapy as a treatment guideline for DSWPD.[77]

Melatonin

Administration of exogenous melatonin also shifts the phase of the endogenous circadian clock. It should be noted that the PRC for melatonin is nearly opposite the PRC for light exposure: melatonin delays circadian rhythms when administered in the morning and advances them when administered in the afternoon or early evening.[31,33] In a randomized, double-blind, placebo-controlled crossover study of eight patients with DSWPD, 5 mg of melatonin administered at 10 PM resulted in a phase advance in all subjects, with a mean advance of sleep onset time of 82 minutes and of wake time of 117 minutes.[94] On stopping melatonin, all patients reverted to their previous sleep-wake cycle within 2 to 3 days. A study to determine the optimal timing and dose of melatonin to treat DSWPD indicates that melatonin given about 6 hours before

the DLMO resulted in the largest phase advance and that there was no significant difference in the effect of either a 0.3-mg or 3-mg dose.[95] A more recent PRC specifically examining the effects of lower doses of melatonin (0.5 mg) demonstrated maximal phase advances when administered 2 to 4 hours before DLMO.[96] The physiologic (phase-shifting) dose of melatonin is approximately 0.1 to 0.5 mg or one tenth to one fiftieth of commercially available preparations.[97] Side effects of melatonin at these dose ranges are minimal, although sedative effects occur at higher (80 mg) doses. Melatonin has also been used successfully in several recent studies in children or adolescents with a combination of delayed sleep phase and other comorbid conditions such as attention deficit disorder and neurodevelopmental disabilities.[98-100]

Although several studies have demonstrated the potential effectiveness of melatonin administered in the evening,[36,94,95,99,101,102] the relatively small number of clinical studies, together with the variability in dose and time of administration, have been limiting factors in the development of a standardized approach for treatment with melatonin. The most recent practice parameters established by the American Academy of Sleep Medicine considered melatonin as a treatment guideline for DSWPD.[77]

More recently, several studies have evaluated the use of a combination of bright light and melatonin. A combination of bright light on awakening and melatonin 3 mg taken 8 hours before bedtime resulted in significantly larger advances (1.04 hours) than either melatonin (0.72 hours) or light (0.31 hours) alone.[103] Using a combination of bright light (10,000 lux) for 30 to 45 minutes on awakening in conjunction with 3 mg of melatonin taken 8 hours before sleep midpoint resulted in significant improvement in daytime sleepiness, fatigue, and cognitive functioning.[104]

In summary, the clinical approach to a patient with DSWPD should initially include assessment of circadian sleep phase by sleep diary or actigraphy measures for a period of at least 7 days but ideally 14 days.[75,77] Behavioral interventions such as a structured sleep-wake schedule, good sleep hygiene practices, and avoidance of exposure to bright light in the evening should be prescribed for all patients.[77] In addition, exposure to bright light in the morning (1 to 2 hours shortly after awakening) or administration of melatonin in the evening (5 to 6 hours before habitual sleep time) can advance the timing of the sleep-wake cycle. It is important to note that melatonin has not been approved by the U.S. Food and Drug Administration for this indication.

ADVANCED SLEEP-WAKE PHASE DISORDER, ADVANCED SLEEP PHASE TYPE, ADVANCED SLEEP PHASE SYNDROME

Clinical Features

ASWPD is characterized by habitual and involuntary sleep and wake times that are usually more than 2 hours earlier than societal averages (see Figure 40-1). Sleep itself is normal for age. Individuals frequently complain of persistent and often irresistible sleepiness in the late afternoon or early evening, often preventing their participation in desired evening activities. Because their circadian drive for wakefulness begins to rise prematurely, they may complain of involuntary early morning awakening (2 to 5 AM), which occurs even if sleep onset is voluntarily delayed. Because of professional or social obligations, later bedtimes can lead to chronically insufficient sleep and excessive daytime sleepiness. In general, individuals with ASWPD have less difficulty adjusting to the earlier schedule than those with DSWPD because societal constraints on sleep time are less rigid than on wake time. Individuals with ASWPD may gravitate to professions that are in phase with their endogenous circadian clock. Because of the symptoms of early morning awakening, a diagnosis of depression may be erroneously made.

Epidemiology

ASWPD is less frequently reported than DSWPD, possibly because affected individuals may not perceive it to be pathologic. The actual prevalence of ASWPD in the general population is unknown but is thought to be rare.[47,105] The prevalence in middle-aged adults has been estimated to be about 1%,[50] and it increases with age. Both genders appear to be equally affected.

Pathogenesis

As with DSWPD, the etiology of ASWPD is not well understood, although several hypotheses have been proposed. An abnormal PRC to light exhibiting an increased area under the advance portion of the curve could in theory result in a persistent phase advance. ASWPD may also be the result of a shortened endogenous period. Evidence of a shortened free-running period of less than 24 hours has been demonstrated in a 66-year-old woman with advanced sleep and wake times, with intact or even enhanced responsiveness to photic entrainment,[17] and in a single member of a familial case of ASWPD.[106]

Several familial cases of ASWPD have been reported in the literature.[106-109] These families show a clear autosomal dominant mode of inheritance of ASWPD. Genetic analysis of these familial cases indicates that there is heterogeneity of this disorder between and even within large families. Gene polymorphisms have been identified in the circadian clock gene *hPer2* in a large family with advanced sleep phase,[110] and in another family a missense mutation in CKI-δ has been reported.[111] More recently, several studies of adults born prematurely have demonstrated significant advances in the sleep-wake cycle in preterm infants with low birth weight.[112,113]

Diagnosis

A diagnosis of ASWPD is made primarily on the basis of the clinical history. Individuals have a chronic or recurrent complaint of difficulty staying awake until the desired time in the evening and inability to remain asleep until the desired and socially acceptable time for awakening. The sleep disturbance is associated with impairment of social, occupational, or other areas of functioning.[74] When allowed to choose their preferred schedule, patients will exhibit normal sleep quality and duration for age and maintain an advanced but stable phase of entrainment to the 24-hour day. Sleep log or actigraphy monitoring for at least 7 days and preferably 14 days should be performed to confirm a stable advance in the timing of the habitual sleep period.[74] The use of actigraphy, if available, is frequently helpful (see Figure 40-2).

Other medical, mental, or sleep disorders that may cause alterations in the sleep-wake cycle, insomnia, or excessive

sleepiness should be excluded or adequately treated. Major affective disorders should be carefully excluded. PSG is not required for the diagnosis, but in some patients, it may be necessary to evaluate for sleep-disordered breathing, periodic limb movements, or other causes of sleep disruption. PSG should ideally be performed during the patient's normal sleep period. If it is carried out at conventional laboratory hours, a shortened or normal sleep-onset latency, early REM, and early wake time may be seen. Therefore it is important to consider depression, narcolepsy, or other disorders in the differential diagnosis.[105,114]

When the diagnosis is in question, additional physiologic measures of circadian timing, such as continuous ambulatory monitoring of body temperature or collection of salivary melatonin samples to determine DLMO (see Figure 40-3), may be clinically useful to confirm the advance in circadian phase. Patients with ASWPD have been reported to have a DLMO[107,108] and core body temperature minimum[106] that are advanced several hours compared with controls. A morningness-eveningness scale, such as the Horne Ostberg or Munich chronotype questionnaire to gauge the patient's best time of performance, is also useful.[41,115]

Treatment

There are several therapeutic approaches used to treat ASWPD, each with practical limitations. A chronotherapeutic approach—advancing bedtime by 3 hours every 2 days until the desired bedtime was reached—has been reported,[105] although relapse occurred quickly.[114] Bright light therapy during the delay portion of the PRC (early evening) is usually tried, although data on its efficacy in ASWPD are limited. Bright light from 7 to 9 PM in elderly subjects with sleep maintenance complaints resulted in a phase delay and reduced awakenings.[116] The recent practice parameters established by the American Academy of Sleep Medicine considered bright light as a treatment option for ASWPD.[77]

Melatonin given in the early morning, usually on awakening, could in theory result in a phase delay according to data from the PRC to melatonin.[31,97] However, evidence for its effectiveness or safety in the treatment of patients with ASWPD is generally lacking.[78,117] It should be noted that the sedating effects of melatonin, which can be variable in patients, may limit its usefulness in this regard.

NON–24-HOUR SLEEP-WAKE DISORDER, FREE-RUNNING DISORDER, NONENTRAINED TYPE, HYPERNYCHTHERMAL SYNDROME

Clinical Features

N24SWD is thought to be the result of a circadian pacemaker that has no stable phase relation to the 24-hour LD cycle. Because most individuals must maintain a regular sleep-wake schedule, the clinical picture is that of periodically recurring problems with sleep initiation, sleep maintenance, and rising as the circadian cycle of wakefulness and sleep propensity moves in and out of synchrony with a fixed sleep period time.[118] Without social constraints, sleep onset and wake times are often successively delayed each day (Figure 40-4). This is analogous to the free-running state created when all zeitgebers are removed.[85,119] Because the duration and quality of sleep depend on when it occurs in relation to the circadian cycle,[3] phase "jumps" between two physiologically permissive periods for sustained sleep can be observed.[120-122]

Epidemiology

N24SWD is rare in sighted people, occurring most often in totally blind individuals.[118,119,123-126] In one series, 50% of totally blind persons had free-running plasma melatonin rhythms[125]; in another, 73% were not entrained to a 24-hour sleep-wake rhythm.[127] In a large study of 1073 blind individuals, N24SWD was estimated to occur in 18% of those who were totally blind and 13% of those who were almost blind.[128] The circadian pattern of melatonin production was analyzed in a large cohort of blind women, and in those without light perception only 37% were normally entrained, whereas among those with light perception 69% were normally entrained.[129] A few cases of free-running disorder have also been reported in sighted individuals.[85,130,131]

Pathogenesis

The etiology in blind people is most likely either reduced or absence of the entraining effects of light, although nonphotic time cues, such as an externally imposed 24-hour sleep-wake cycle and social activity, also appear insufficient to entrain some individuals.[118] The melatonin rhythm may be damped[132] or nonexistent[133] or may be normal but delayed.[85,124] Coexistent mental disability, which could make it difficult to process

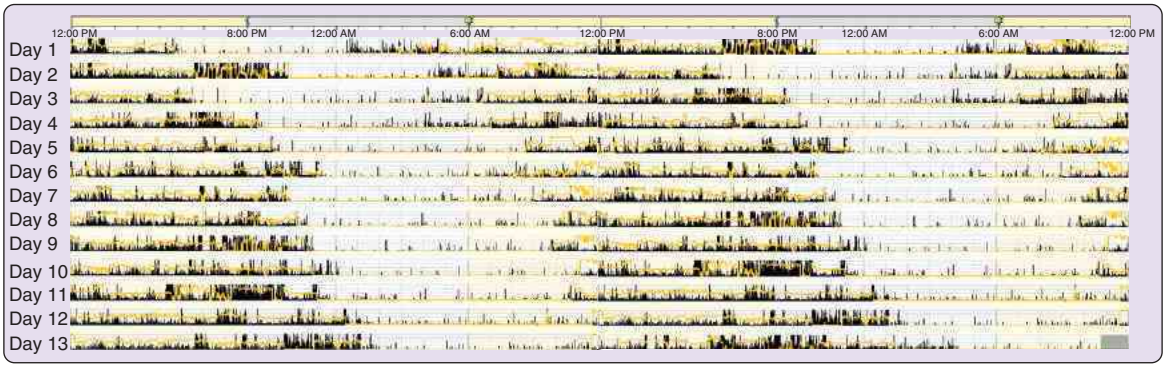

Figure 40-4 Rest-activity cycles recorded with wrist-activity monitoring of a sighted individual with non–24 hour sleep-wake disorder. The *black bars* indicate activity levels recorded at the nondominant wrist. Note that sleep onset is later on each consecutive day and that sleep is initiated from anytime between 5 PM and 1 AM for the 13 days represented in this actogram.

social time cues, may contribute to the symptoms in some individuals.[123] In some cases, totally blind persons without conscious perception of light nevertheless exhibit normal suppression of melatonin when exposed to very bright light and do not appear to have sleep difficulties.[127]

The etiology in sighted individuals is unknown. It has been postulated that sighted individuals may have a reduced sensitivity to the phase-resetting effects of light[85] and may have an increased incidence of psychiatric conditions[131] such as depression or certain personality disorders, which could precipitate the development of the syndrome by changing or removing social time cues.[85] In addition a recent study of six sighted individuals with N24SWD demonstrated that the intrinsic period was significantly longer than in controls.[134]

Nonentrained sleep-wake cycles have developed after chronotherapy for apparent delayed sleep phase type,[85,86] prompting the proposal that such therapy could prolong the free-running period to the point at which it becomes nonentrainable to a 24-hour LD cycle.[86] However, free-running periods, which are too short (<23 hours) or too long (>27 hours)[18] for stable entrainment to a 24-hour cycle, have never been demonstrated in humans. Because persons with DSWPD tend to receive more light exposure in the delay (evening) portion of their PRCs than during the advance portion (early morning), progressive phase delays may sometimes be observed and mistaken for a nonentrained pattern.[6,85]

Diagnosis

The diagnosis of N24SWD is made primarily by a clinical history of insomnia or excessive sleepiness related to abnormal synchronization between the 24-hour LD cycle and the endogenous circadian rhythm of sleep and wake propensity.[74] The pattern of sleep and wake times typically delay each day with a period longer than 24 hours. The pattern is present for at least 1 month and can be confirmed by sleep diary or actigraphy for at least 7 days (but preferably longer) to establish the progressive daily drift in the timing of sleep and wake times (see Figure 40-4). Close analysis of the sleep-wake cycle may reveal two distinct sleep-wake cycle periods, alternation between which can be manifested by phase jumps.[121,122] The sleep disturbance should be accompanied by impairment of social, occupational, or other areas of functioning.

It is important to exclude or adequately treat other medical, mental, or sleep disorders that may cause alterations in the sleep-wake cycle, insomnia, or excessive sleepiness. If the diagnosis is in question, PSG may be useful to evaluate for other types of sleep disorders. PSG, when performed at the appropriate circadian time, is usually normal.[85] Overriding behavioral factors predisposing to irregular sleep-wake cycles (substance abuse, dementia, personality, or affective disorders) should also be considered in the evaluation.

Treatment

Melatonin receptor agonists have been used as the initial treatment of choice in blind and sighted individuals with N24SWD.[29,85,119,123,124,126,135-138] For example, administration of melatonin is started when the patient's free-running period approaches the normal or desired phase (i.e., sleep onset times of 10 to 11 PM). Doses sufficient for phase shifting (0.1 to 0.5 mg) are then given at 8 to 9 PM, or near the expected time of DLMO.[85,126] Initiating evening dosing when the free-running period is not in the "normal" phase could result in an inappropriate delay or advance of circadian phase and prolong the time to entrainment. More recently the melatonin agonist tasimelteon (20 mg) has been approved for use in the treatment of N24SWD, given in a similar manner as melatonin at a fixed time every night.[139] Common side effects include sedation, headache, elevated liver enzymes, and nightmares. Bright light entrainment is an option in sighted individuals or in blind individuals who exhibit intact photic suppression of melatonin.[140] Vitamin B_{12} has been anecdotally reported to be effective in treating nonentrained type,[141,142] although the mechanism is unknown. Benzodiazepines have not been systematically studied, although several anecdotal reports of their possible effectiveness exist.[141,142] Entrainment by nonphotic stimuli (e.g., structured social cues) alone has not been successful. The recent practice parameters established by the American Academy of Sleep Medicine considered bright light and melatonin administration as options for the treatment of N24SWD and in blind individuals recommended melatonin administration as a treatment guideline.[77]

IRREGULAR SLEEP-WAKE RHYTHM DISORDER, IRREGULAR SLEEP-WAKE TYPE, IRREGULAR SLEEP-WAKE DISORDER

Clinical Features

ISWRD is characterized by the absence of a well-defined circadian sleep-wake cycle. There is typically no major sleep period. Rather, patients present with three or more sleep episodes of varying length during a 24-hour period. Diagnosis of this disorder requires a complaint of insomnia or excessive sleepiness associated with multiple irregular sleep bouts or naps during a 24-hour period.[74] Despite irregular and fragmented sleep periods, the total sleep time per 24-hour period is usually normal for age.

Epidemiology

The prevalence of ISWRD in the general population is unknown, but it is estimated to be rare.[143] There is no evidence of gender differences. ISWRD is most commonly seen in association with age related comorbid neurologic disorders such as dementia and Alzheimer disease.[78] It is also seen in patients with brain injury and in children with mental disability.

Pathogenesis

ISWRD is thought to result from dysfunction of the central processes responsible for the generation of circadian rhythms[144,145] or reduced exposure to bright light and regular social schedules. A recent case report demonstrated decreased amplitude of core body temperature rhythmicity in two individuals with ISWRD.[146] In institutionalized elderly patients and those with dementia, these factors are thought to contribute to the development and maintenance of irregular sleep-wake patterns.[147,148] Even when controlling for the level of dementia, lower daytime light levels have been associated with an increase in nighttime awakenings.[149] Evidence suggests that both dysfunction of circadian regulation and reduced exposure to environmental signals are likely involved in the etiology of irregular or arrhythmic sleep and wake patterns.

Diagnosis

In addition to a clinical history, continuous monitoring of sleep and wake activity with actigraphy or a sleep log for a

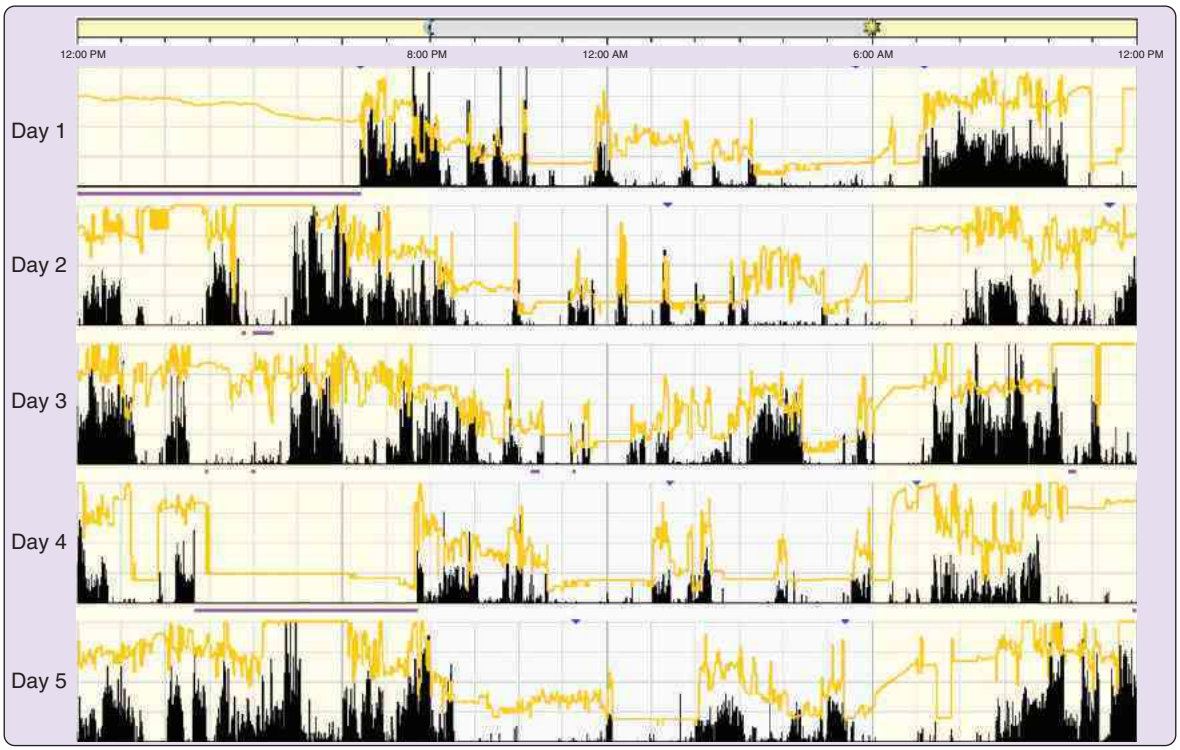

Figure 40-5 Rest-activity cycle recorded with wrist-activity monitoring of an older adult with irregular sleep-wake rhythm disorder. The *black bars* indicate activity levels, and the *yellow bars* indicate the level of ambient light exposure recorded at the nondominant wrist. Note the lack of a discernible circadian sleep and wake rhythm. Sleep is characterized by nocturnal fragmentation and multiple short periods of sleep and wake across the entire 24-hour day.

minimum of 2 weeks is useful diagnostically. Actigraphic recordings show disturbed or low-amplitude circadian rhythm and loss of the normal diurnal sleep-wake pattern with at least three distinct sleep periods per 24 hours (Figure 40-5). This disturbed sleep-wake pattern should be associated with a chronic complaint of insomnia (usually sleep maintenance) and excessive daytime sleepiness. ISWRD should be distinguished from poor sleep hygiene and voluntary maintenance of irregular sleep schedules as seen with shift work.[74]

Treatment

Clinical management aims to improve the amplitude of circadian rhythms and their alignment with the external environment. Increasing exposure to synchronizing agents, such as bright light,[150-153] and structured social and physical activities[154] have been used to consolidate sleep-wake cycles. Mixed-modality therapies combining bright light exposure, physical activity, and other behavioral elements are indicated in the treatment of ISWRD, as outlined in the recent parameters established by the American Academy of Sleep Medicine.[77] Recent randomized controlled studies using mixed-modality therapies have shown increases in the robustness of the rest-activity rhythm and reductions in nighttime awakening following treatments that include increasing light levels, increasing light in combination with evening melatonin administration, implementing measures to keep nursing home residents out of bed during the day, structuring physical activity, instituting a bedtime routine, and taking measures to reduce nighttime noise and light in residents' rooms.[155-158] Another study using a combination of bright light, chronotherapy, vitamin B_{12}, and hypnotics was successful in 45% of patients with irregular sleep cycles.[143]

Evening melatonin administration has been used successfully to improve disturbed sleep-wake patterns in children with mental disability.[159-161] In this population melatonin is recommended as a treatment option in the recent practice parameters established by the American Academy of Sleep Medicine.[77] Despite the potential utility of both behavioral and pharmacologic interventions, treatment may be difficult and outcomes variable.

CLINICAL PEARLS

Circadian rhythm sleep disorders should be considered in the differential diagnosis of patients presenting with symptoms of insomnia or excessive sleepiness. Furthermore, CRSWDs, such as DSWPD, may be comorbid with other types of sleep disorders, making the diagnosis and treatment even more challenging. For effective management of CRSWD, one must obtain as accurate a measure of circadian timing as possible. Sleep-onset time (determined by sleep diary or actigraphy) can be useful to determine circadian phase (DLMO occurs approximately 2 hours before sleep onset) in the clinical setting.

Behavioral interventions such as sleep hygiene, particularly enforcement of stable sleep and wake times, exposure to light at the correct time of the day, and avoidance of exposure at the wrong time of the day is the basic approach for all patients. For the treatment of DSWPD and N24SWD, the use of melatonin may be useful (see specific sections for details). However, the use of melatonin for the treatment of CRSWD has not been approved by the U.S. Food and Drug Administration, and vascular and endocrine adverse effects need to be taken into account, particularly in patients who are at increased risk.

SUMMARY

Disorders of the sleep-wake cycle attributed to the disruption of the circadian timing system are characterized by an abnormal temporal distribution of the major sleep period within the 24-hour day. Although there is evidence that many of these disorders are the result of alterations in the circadian clock, more studies are needed to confirm this theory. The effect of these disorders is probably larger than estimated in terms of numbers, misdiagnoses, and health consequences. Most sleep clinics do not yet provide specific diagnostic tools to assess circadian rhythm profiles. Furthermore, many of the proposed diagnostic tools and therapies, including light, are often considered experimental by the health insurance industry. Application of our expanding knowledge of basic human circadian and sleep physiology to clinical practice remains an important challenge.

Chapter 41

Hypnotic Medications: Mechanisms of Action and Pharmacologic Effects

Thomas S. Kilduff; Wallace B. Mendelson

Chapter Highlights

- Most currently available hypnotics induce sleep by acting at various moieties of the gamma-aminobutyric acid A ($GABA_A$)–benzodiazepine receptor complex. This receptor is a member of the ligand-gated receptor family and is composed of several subunits, each of which appears in multiple isoforms.
- Microinjection studies indicate that the neuroanatomic sites of action of hypnotics from a variety of pharmacologic classes include the preoptic area and specific hypothalamic nuclei. These brain areas express GABA receptors and also contain GABAergic neurons.
- Connections between the preoptic area and the forebrain and brainstem and the integrative nature of the anterior hypothalamus help explain the mechanism by which sleep—and drugs that affect sleep—interact with a variety of physiologic systems.
- Novel hypnotic agents directed toward the hypocretin-orexin receptors have recently become available for clinical use.

Approximately 10% to 15% of the U.S. population suffer from chronic insomnia.[1] The clinically used sedative-hypnotics in the United States currently include five benzodiazepines available in both proprietary and generic forms, three nonbenzodiazepine gamma-aminobutyric acid (GABA) agonists (zolpidem, zaleplon, and eszopiclone), and two melatonin receptor agonists (ramelteon) available as prescription agents (Table 41-1). This market resulted in more than 60 million prescriptions in 2011, a growth of 20% over the previous 5 years,[2] and approximately $3.7 billion in sales.[3] During the 15-year period from 1994 to 2007, prescriptions for nonbenzodiazepine hypnotics increased 30-fold.[4] The most widely prescribed medication for insomnia has typically been the antidepressant trazodone.[5-7]

Although these are large numbers, one could make a case that, in the population at large, prescription hypnotics are taken relatively infrequently by insomniacs. In a survey of more than 7000 enrollees in five large health maintenance organizations,[8] patients with insomnia were divided into those with only sleep complaints (Level 1) and those who believed that their sleep difficulties had an adverse effect on their daytime functioning (Level 2). The percentage of Level 1 insomniac patients taking prescription and nonprescription hypnotics was 5.5% and 11.2%; comparable values for Level 2 insomniac patients were 11.6% and 21.4%, respectively. Many patients, of course, receive other classes of prescription drugs given for purposes of helping sleep. One study of primary care patients in a health maintenance organization indicated that 13% of insomniacs who were not considered to have affective disorder were receiving antidepressant medications such as trazodone.[9] Many people self-medicate with alcohol; a telephone survey of approximately 1000 adults

Table 41-1 Pharmacokinetic Properties and Dosages of Some Hypnotic Drugs Used in the Treatment of Insomnia

	Half-Life (h)	T_{MAX} (h)*	Pharmacologically Active Metabolites	Dose (mg)
Benzodiazepine Hypnotics[†]				
Quazepam (Doral)	48–120	2–3	*N*-desalkyl (flurazepam)	7.5–15
Flurazepam (Dalmane)	48–120	1.5–4.5	*N*-desalkyl (flurazepam)	15–30
Triazolam (Halcion)	2–6	1–2	None	0.125–0.25
Estazolam (ProSom)	8–24	1.5–2	None	1–2
Temazepam[‡] (Restoril)	8–20	1–2	None	15–30
Loprazolam[§] (Dormonoct)	4.6–11.4		None	1–2
Flunitrazepam[§] (Rohypnol)	10.7–20.3		*N*-desmethyl (flunitrazepam)	0.5–1
Lormetazepam[§] (Loramet)	7.9–11.4		None	1–2 (Elderly: 0.5–1)
Nitrazepam[§] (Alodorm)	25–35		None	5–10
Nonbenzodiazepine Hypnotics				
Zolpidem: Oral tablet	2.5 (1.4–4.5)	1.6 (0.5–1.5)	None	5 (age >65 yrs) 5–10 (age <65 yr)
Zolpidem: Extended release (Ambien CR)	2.8 (1.6–4.5)	1.5 (1.5–2.0)	None	6.25–12.5
Zolpidem: Sublingual (Intermezzo)	2.5 (1.4–3.6)	0.6 (0.6–1.3)		women: 1.75; men: 3.5
Zolpidem: Sublingual (Edluar)	2.7 (1.5–6.7)	1.4 (0.5–3.0)		5–10
Zolpidem: Oral spray (Zolpimist)	2.8 (1.7–8.4)	0.9		10
Zopiclone[§] (Imovane)	5–6		None	3.75 (age >65 yr) 7.5 (age <65 yrs)
Zaleplon (Sonata)	1 (0.8–1.3)	1 (0.5–2)	None	5–10
Eszopiclone (Lunesta)	6 (5–8)	1.5 (0.5–2)	None	2–3 (age <65 yr); 1–2 (age >65 yr)
Ramelteon	1–2.6[¶]	0.75 (0.5–1.5)	M-II	8
Doxepin	15 (10–30)	3.5 (1.5–4)		3–6 (Silenor) 10–50[**] (generic)
Suvorexant	12	0.5–6.0	None	10–20
Nonhypnotics Sometimes Used to Aid Sleep[‖]				
Clonazepam (Klonopin)	20–40	1–2.5	4-Amino derivative	0.5–1[**]
Diazepam (Valium)	30–100		*N*-desmethyl	2–10[**]
Chlordiazepoxide (Librium)	24–28		*N*-desmethyl (chlordiazepoxide, demoxepam, oxazepam)	10–25[**]
Alprazolam	6–20	0.6–1.4		0.5–1[**]
Lorazepam	10–20	0.7–1		0.5–1[**]
Quetiapine (Seroquel)	6	1–2	Quetiapine sulfoxide	25–50[**]
Trazodone (Desyrel)	9 (7–15)	1–2	*m*-CPP	25–50[**]

**Because there is not an FDA indication for sleep, there is no FDA recommended dose for this purpose. Doses stated here are approximations of those often used in clinical practice.

m-CPP, m-Chlorophenylpiperazine.

from the general population found that 10% had done so in the past year.[10] A survey in the Detroit area reported that 13% had used alcohol to aid sleep during the past year, whereas 18% used medication (either prescription or over-the-counter), and 5% had used both.[11] Thus alcohol use to help sleep is common, even though it exposes the patient to the risk for ethanol dependence and is relatively ineffective. Although orally administered ethanol has some sleep-inducing properties, it often promotes sleep disturbance as the night progresses.

MECHANISM OF ACTION

$GABA_A$ Agonists: Benzodiazepines and Nonbenzodiazepines

GABA is the main inhibitory neurotransmitter and is produced by 15% to 20% of all neurons. GABA exerts its effects within the central nervous system (CNS) by acting at two types of receptors. The $GABA_A$ receptor, often referred to as the $GABA_A$-benzodiazepine receptor complex, is part of the ligand-gated ion channel family that also includes the glycine, $5HT_3$, neuronal nicotinic acetylcholine, and other receptors.[12] In contrast, the $GABA_B$ receptor is a member of the G protein-coupled receptor family. Although some hypnotic development activity has been directed toward the $GABA_B$ receptor (e.g., gamma-hydroxybutyrate, used in the treatment of narcolepsy, acts through the $GABA_B$ receptor), the $GABA_A$–benzodiazepine receptor complex may be the most intensely studied receptor for all of neurotherapeutic development.

Since the late 1970s, the pharmacologic effects of GABA and the benzodiazepines have been recognized to result from saturable, stereospecific binding to a specific recognition site.[13,14] The $GABA_A$-benzodiazepine receptor is a pentameric transmembrane structure that is composed of combinations of different subunits that, together, form a benzodiazepine recognition site, a $GABA_A$ recognition site, and a chloride ionophore (Figure 41-1). In humans, there are six alpha, three beta, three gamma, three rho, and one each of the delta, epsilon, theta, and pi subunits.[15,16] The binding site for benzodiazepines appears to be located at the junction of the alpha and gamma subunits, whereas the GABA binding site is at the junction of the alpha and beta subunits. The alpha-1 subunit appears to mediate both sedation and memory effects of agonists.[17]

The most common pentameric subunit combinations are the type I (alpha-1, beta-2, gamma-2) and type II (alpha-3, beta-2, gamma-2), but the total number of receptor isoforms is unclear.[15] Type I represents roughly 40% of $GABA_A$ receptors and is found in most areas of the brain, including on interneurons of the hippocampus and cortex. Type II is perhaps half as common and is found in spinal cord motoneurons and hippocampal pyramidal neurons. Most traditional benzodiazepine hypnotics bind to both types. Some of the nonbenzodiazepine agents, including zolpidem and zaleplon, bind with relatively greater specificity to the type I receptor. This selective binding is thought to underlie specific pharmacologic properties. Indeed, the hypnotic effects of zolpidem have been attributed to the alpha-1 subunit.[18]

Benzodiazepine agonist binding to its specific site results in a net flux of negatively charged chloride ions through the chloride ionophore and hyperpolarization of membrane potential so that the neuron is less likely to produce an action potential. This inhibitory mechanism is very potent because the $GABA_A$ receptor is the most widespread receptor at inhibitory synapses, comprising up to 30% of all synapses in the CNS.

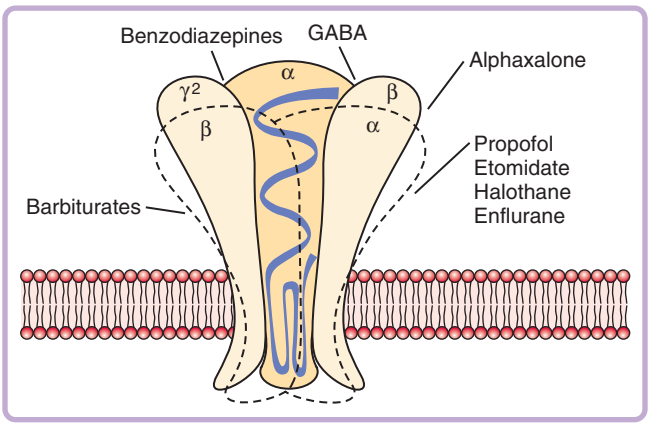

Figure 41-1 Schematic representation of the $GABA_A$-benzodiazepine receptor complex, and possible sites of action of sleep-inducing drugs. (From Rudolph U, Mohler H: Analysis of GABA-A receptor function and dissection of the pharmacology of benzodiazepines and general anesthetics through mouse genetics. *Annu Rev Pharmacol Toxicol* 2004;44:475–98.)

The original characterization of the BZ receptor complex indicated that it mediates the anxiolytic, muscle relaxant and anticonvulsant effects of benzodiazepines.[13,14] A series of studies also showed that this receptor complex mediates sleep-inducing effects. Some β-carboline compounds that act as BZ receptor inverse agonists increase wakefulness and, at low doses, block sleep induction by benzodiazepines.[19] The binding of benzodiazepines is stereospecific, such that an enantiomeric form (the B_{10} compounds) have opposite effects, in which one enantiomer induces sleep whereas the other promotes wakefulness.[19]

Studies of the $GABA_A$-benzodiazepine receptor complex have provided insight into a long-standing mystery—how medications of many different pharmacologic classes can produce sleep: nonbenzodiazepine agents such as zolpidem and zaleplon bind to a subclass of benzodiazepine recognition sites, ethanol has profound effects on chloride channel function, and barbiturates bind to yet another site on the receptor complex. Barbiturates can cause chloride channels to open for prolonged periods,[20] whereas benzodiazepines may increase the frequency of opening.[21] Similarly, the active metabolite of chloral hydrate[12] and the anesthetic propofol[22] modulate $GABA_A$ receptor function. Several lines of evidence have also suggested that the hypnotic effects of benzodiazepines may involve presynaptic effects mediated by voltage-dependent calcium channels. The calcium-channel blocker nifedipine, for instance, can block the sleep-inducing effects of microinjections of triazolam into the medial preoptic area,[23] suggesting that modulation of voltage-gated calcium channels may be another mechanism to induce sleep.

Neuroanatomic Substrates for the Effects of Hypnotic Medications

In contrast to our understanding of the interaction of benzodiazepine agonists at a molecular level, the anatomic sites at which they act to induce sleep are less well understood. The

most parsimonious hypothesis would posit that hypnotics act at loci thought to be important in sleep regulation. Accordingly, when the BZ triazolam was microinjected into many areas (e.g., the locus coeruleus, the gigantocellular tegmental fields, the basomedial nucleus of the amygdala, and the ventrolateral preoptic area), there was either no effect on sleep or increased wakefulness (the dorsal raphe nuclei).[24] In contrast, microinjections into the medial preoptic area (MPA) consistently enhanced sleep. These results were anatomically specific because injections into nearby structures (the lateral preoptic area, the horizontal limb of the diagonal band of Broca) had no effect.

The basal forebrain, MPA, and anterior hypothalamus have long been thought to have an important role in sleep regulation.[25-27] The MPA is a complex structure that receives afferents from many forebrain and brainstem regions. Among these are projections from various areas of the hypothalamus, as well as serotonergic fibers from the dorsal raphe nuclei and noradrenergic projections from the locus coeruleus.[28] GABA is ubiquitous throughout the hypothalamus, and its synthetic enzyme is found in high concentrations in the preoptic area.[29] $GABA_A$-benzodiazepine receptors occur in significant concentrations,[30] and the expression of different receptor subunits are under homeostatic as well as circadian regulation.[31] The preoptic area also contains cells that are responsive to temperature, osmolarity, glucose, and steroids,[32] and receives afferents from various sensory systems.[28] Neurons in both the median preoptic[33,34] and ventrolateral preoptic area[35,36] have elevated discharge rates and accumulate Fos during sleep; basal forebrain neurons also increase firing during non–rapid eye movement (NREM) sleep compared with waking ("sleep-active neurons").[37] Neurons in these regions are GABAergic and inhibit posterior hypothalamic wake-promoting areas.[38,39] The preoptic area and the MPA, in particular, appear to have a role in coordinating various systems involved in reproductive and homeostatic functions.[28] Given the interactions of sleep with cardiovascular, thermoregulatory, endocrine, and sensory systems, the preoptic area is likely involved in integrating sleep with other regulated physiologic functions. Microinjection of triazolam into the perifornical hypothalamus reduces sleep latency and increases total sleep time in rats, raising the possibility that BZ hypnotics reduce wakefulness either directly through the perifornical area or indirectly through modulation of GABAergic outputs from the preoptic area.[40] Thus the preoptic area is likely among the loci at which benzodiazepine agonists act to induce sleep. Microinjections of pentobarbital and other GABA receptor agonists into the mesopontine tegmental area induced an anesthesia-like state, raising the possibility that this area may be involved in drug-induced loss of consciousness.[41]

The Hypocretin-Orexin System

Since the link was made between the sleep disorder narcolepsy and the hypocretin-orexin system in the late 1990s,[42-45] there has been considerable interest in this neuropeptidergic system as a mechanism of arousal. Hypocretin cell bodies are found in a very discrete region of the perifornical and lateral hypothalamus,[46,47] but these cells send widespread projections throughout the CNS[48,49] to innervate brain regions that express the orexin receptor-1 (OX1R) or orexin receptor-2 (OX2R).[50] Among these projection sites are wake-promoting monoaminergic and cholinergic groups in the brainstem, hypothalamus, and basal forebrain.[48,49] This system has been the subject of intense research focus in the sleep field in the past 15 years, as reviewed elsewhere.[51-55] Whereas microinjection of the hypocretin-orexin peptides promotes wakefulness in virtually every region studied,[56-59] receptor antagonists promote sleep.[60-64] Whether the sleep-inducing effects are mediated through OX2R[61,62,65] or through both receptors[61,63,64] has been controversial. The effects of orexin-A on wakefulness and NREM sleep were significantly attenuated in receptor knockout mice, with substantially larger attenuation in *OX2R*$^{-/-}$ mice than in *OX1R*$^{-/-}$ mice.[66] In mid-2014, the U.S. Food and Drug Administration (FDA) approved the dual orexin receptor antagonist suvorexant for treatment of insomnia.

Other Neurotransmitters

Microinjections of pentobarbital,[67] ethanol,[68] adenosine,[69] and propofol[70] into the MPA also enhance sleep. Because adenosine is known to accumulate extracellularly in the basal forebrain with prolonged wakefulness,[71] adenosinergic modulation of cortically-projecting basal forebrain cholinergic neurons may be the mechanism by which the propensity to sleep is enhanced by prolonged wakefulness.[72] Similarly, some of the sleep-promoting effects of antihistamines and tricyclic antidepressants (many of which have significant anticholinergic properties) may be mediated by alteration of basal forebrain cholinergic neuron activity. The wakefulness-promoting histaminergic system, whose cell bodies reside in the tuberomammillary nucleus of the posterior hypothalamus, sends efferents to the preoptic area[73] as well as to the perifornical area[74,75] and the cortex. Thus the sedative effects of antihistamines and some tricyclic antidepressants may be mediated by altering the influence of the tuberomammillary nuclei on these brain regions. Microinjection of the GABA receptor antagonist gabazine into the tuberomammillary nuclei inhibits the effects of centrally administered GABAergic agents, suggesting that this area may be involved in their pharmacologic actions.[76] Attention has recently been focused on the melanin-concentrating hormone neurons of the lateral hypothalamus and midbrain, most of which are GABAergic. Optogenetic stimulation of these cells either induces sleep with short latency or facilitates the transition from NREM to rapid eye movement (REM) sleep.[77-79]

CLINICAL EFFECTS

At the clinical level, less is understood about the mechanisms by which hypnotics act. One possibility is that hypnotics may also alter the *perception* of sleep and wakefulness.[80] This notion stems from the classic observation by Rechtschaffen that poor sleepers, when experimentally awakened early in stage 2 sleep, tend to report that they had been awake, whereas good sleepers tend to report that they had been asleep. Later studies[81,82] replicated this observation and demonstrated that, after administration of triazolam, flurazepam, or zolpidem, insomniacs were more likely to report that they believed they had been asleep compared with when they were given placebo. In contrast, this effect was not evident when flurazepam or zolpidem were given to normal subjects.[83] One interpretation of these data is that hypnotics such as triazolam and zolpidem may correct a misperception of sleep in some insomniac patients, such that their experience of whether they are awake or asleep becomes more like that of good sleepers.

Other Sleep-Inducing Agents

Most over-the-counter hypnotics are first-generation antihistamines such as diphenhydramine and doxylamine. Although they possess to varying degrees other properties, including anticholinergic effects, their common underlying mechanism is inhibition of the histamine-1 (H_1) receptor. Later generations of antihistamines such as fexofenadine enter the CNS less readily and thus produce less sedation.[84] Tolerance to daytime sleepiness appears to develop rapidly, in about 4 days.[85] As discussed earlier, antihistamines may produce drowsiness by inhibiting the wake-promoting histaminergic pathways originating in the tuberomammillary nucleus of the posterior hypothalamus. Some tricyclic antidepressants, notably doxepin, have significant antihistaminergic (H_1 and H_2) properties as well as effects on other neurotransmitter systems, including antagonism at α_1-adrenoreceptors and muscarinic cholinergic receptors as well as binding to serotonin 2a and 2c receptor subtypes. However, these compounds were not developed for insomnia, have long half-lives, and consequently, result in daytime sedation

Although there is debate about the efficacy and range of side effects of melatonin as a hypnotic,[86] agonists of melatonin MT1 and MT2 receptor subtypes are on the market in the United States (ramelteon and tasimelteon), and agomelatine has been approved in Europe. Melatonin and melatonin agonists are thought to affect the circadian system through melatonin receptors in the suprachiasmatic nucleus, but the mechanism by which this would alter sleep is not well understood. It has been suggested that binding of agonists to the melatonin MT1 receptor decreases the waking signal from the suprachiasmatic nucleus. One possibility is that sleep-promoting effects of agonists at melatonin receptors are at least in part GABAergic. Melatonin administration is known to raise GABA concentrations in the rat hypothalamus as well as 3H-diazepam binding in the forebrain.[87] Similarly, decreases in motor activity produced by melatonin in the hamster are prevented by the benzodiazepine receptor blocker flumazenil.[88] Microinjections of melatonin into the MPA have been reported to enhance sleep in the rat, suggesting that its site of action may be similar to that of benzodiazepines, barbiturates, adenosine, and ethanol, as described previously.[89]

Although the topic of anesthetics is beyond the scope of this chapter, we will briefly mention the intravenous agent propofol, which has made it much more practicable to induce anesthesia for prolonged periods in intensive care unit settings. Although its neurochemical mechanism of action has not been fully elucidated, propofol is known to interact with the $GABA_A$-benzodiazepine receptor complex, with resultant decreases in acetylcholine release from the frontal cortex and hippocampus, and to also increase functional activity of dopamine and serotonin in the cortex. Interestingly, microinjection of propofol into the MPA of rats induces sleep, and this effect is blocked by the benzodiazepine receptor blocker flumazenil.[70]

PHARMACOKINETICS

Benzodiazepines

With the possible exception of temazepam, the benzodiazepines used as hypnotics are rapidly and completely absorbed, with most achieving peak plasma levels in 1 to 1.5 hours. Some, notably flurazepam, are detectable primarily in the form of their active metabolites, and many display kinetics that reflect enterohepatic circulation. Generally, oral administration is more reliable and complete than intramuscular injection. Although there is significant protein binding, there are few or no cases in which displacement of other protein-bound drugs is clinically relevant. Most are highly lipophilic and rapidly enter the CNS where concentrations reflect unbound drug in plasma. The older, longer acting agents are metabolized to active compounds, and the shorter-acting agents such as triazolam are broken down into inactive substances (see Table 41-1; Video 41-1). The elimination half-lives vary widely, from the relatively short-acting triazolam, to intermediate agents such as temazepam, to long-acting substances such as flurazepam (see Table 41-1). Accumulation of the longer elimination half-life agents when taken nightly has significant bearing on a major clinical issue—the appearance of daytime residual sedation (Figure 41-2). Because of the lipophilicity, many are rapidly redistributed, which may play an important role in the decline in CNS effects as they are metabolized. Another implication of the high lipophilicity is that the volume of distribution is often increased in older adults (who tend to have a higher ratio of lipid to muscle), resulting in an increased half-life. Most are broken down by hepatic microsomal systems and excreted as conjugated glucuronides. There is no stimulation of the hepatic microsomal systems and hence no enhancement of the rate of breakdown of other drugs that undergo the same metabolic processes. Metabolism of these compounds may be inhibited by use of other drugs such as cimetidine and some steroids and may be accelerated in people who smoke.

The Z Drugs

Zolpidem was the first of the "Z drugs" (zolpidem, zaleplon, zopiclone, eszopiclone), nonbenzodiazepines that bind to various subtypes of the $GABA_A$ receptor. In general, their clinical effects are similar to those of benzodiazepines; however, on the basis of animal studies, it has been argued that they have a wider separation in doses producing hypnotic

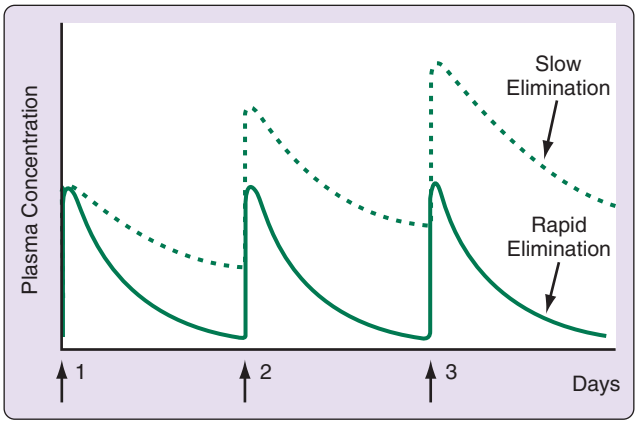

Figure 41-2 A hypnotic with a relatively long elimination half-life (e.g., >24 hours) will accumulate during nightly use, in contrast to an agent with relatively short elimination half-life (e.g., 6 hours). (From Nicholson AN: Hypnotics: clinical pharmacology and therapeutics. In: Kryger MH, Roth T, Dement WC, editors. *Principles and practice of sleep medicine*. 2nd ed. Philadelphia: Saunders; 1989. p. 355–63.)

to nonhypnotic effects.[90] Several studies have suggested that they have a lower risk for dependence and misuse than the benzodiazepines. A German prescription event study, for instance, described a rate of misuse about one third that of benzodiazepines.[91] It has been speculated that this may be due to lower affinity for the alpha-2 subtype, which may be related to abuse potential. In the United States, the Z drugs are considered Class IV Drug Enforcement Administration (DEA) restricted agents, the same classification as the benzodiazepines.

Insomniac patients have been shown in several studies to have higher general health care use and costs than noninsomniac patients. One study has suggested that, during the first 6 months after initiation of treatment of insomnia with the newer nonbenzodiazepine hypnotics, general health care costs show a relative decline compared with those of untreated insomniacs.[92] The broader issue of the interaction of insomnia and its treatment with other illnesses is addressed in a review.[93]

Zolpidem

Zolpidem, an imidazopyridine compound with relative selectivity for the type I $GABA_A$-benzodiazepine receptor, is rapidly absorbed; because of first-pass metabolism, it has a bioavailability of 67% after oral administration of doses up to 20 mg.[94] Peak concentrations are reached after 1.6 hours. Total protein binding is approximately 92%. Absorption is slightly decreased when taken on a full stomach. It has no pharmacologically active metabolites and is eliminated primarily by renal excretion. In the United States, it is also marketed as a coated two-layer tablet in which the inner layer has a more extended release time (Ambien CR).

Zopiclone and Eszopiclone

Zopiclone, which is on the market in Europe and Asia but not the United States, is a cyclopyrrolone that acts at the $GABA_A$-benzodiazepine receptor complex, but possibly at a different binding domain or by producing different conformational changes than the benzodiazepines.[95] It is rapidly absorbed, with peak plasma concentrations occurring in 0.5 to 2 hours. Bioavailability is about 80%, implying that the first-pass effect is relatively small. It is very lipophilic and enters rapidly into the CNS. Protein binding is approximately 45%. It has two major metabolites, the *N*-oxide, which has lower pharmacologic activity, and the inactive *N*-desmethyl derivative, which along with various minor metabolites is excreted primarily by the kidneys and lungs.

Eszopiclone, the S-isomer of racemic zopiclone, is marketed in the United States as Lunesta. Peak concentrations are achieved in 1 hour with an elimination half-life of approximately 6 hours. It is weakly bound to protein and metabolized through oxidation and demethylation; its biotransformation is attributed to CYP3A4 and CYP2E1.[96] Eszopiclone has been found to have effectiveness without tolerance for at least 6 months[97] and was the first hypnotic medication approved by the FDA without a limit on duration of administration.

Zaleplon

A pyrazolopyrimidine that binds selectively to the type I benzodiazepine receptor, zaleplon is rapidly absorbed after oral administration, with peak concentrations reached in 1 hour and an elimination half-life of approximately 1 hour. Protein binding is approximately 60%. It is rapidly metabolized to inactive forms, with approximately 71% of labeled compound recovered in the urine and 17% in feces. Recommendations for administration in the United States include taking it immediately before bedtime or after the patient has gone to bed and has experienced difficulty falling asleep. In the latter case, it should be taken at least 4 hours before time of arising to avoid any possible memory difficulties and residual sedation.

Ramelteon

Ramelteon is a potent agonist at the melatonin type I and II receptors with negligible affinity for the $GABA_A$, dopamine, serotonin, or muscarinic cholinergic receptors. It reaches peak plasma concentrations in 0.75 to 0.94 minutes and has an elimination half-life of 1 to 2.6 hours; an active hydroxylated metabolite (M-II) has a slightly longer half-life of 2 to 5 hours. It is metabolized in the liver, primarily with CYP1A2 and to a lesser degree CYP2C9 and CYP3A4. Its mechanism of action is not fully understood, but it has been hypothesized that binding at melatonin receptor subtypes in the suprachiasmatic nucleus attenuates the waking signal. Clinically, its efficacy is primarily in reducing sleep latency, with little effect on awakenings during the night. It has essentially no dependence-producing effects, and in the United States it is not a DEA-restricted drug.

PHARMACOLOGIC PROPERTIES

Although the hypnotic benzodiazepines are given for purposes of aiding sleep, they share a spectrum of pharmacologic properties with agents given as daytime sedatives or anxiolytics; indeed, some authors have suggested that the designation of some benzodiazepines as hypnotics is as much a marketing plan as a pharmacologic decision. Among their effects are anxiolytic, myorelaxant, and anticonvulsant properties. Many, particularly the longer-acting agents, have mild respiratory depressant properties,[98,99] which are much less evident in shorter-acting agents. There is some evidence that triazolam may improve sleep-disturbed respiration in central sleep apnea,[100] although whether this is related to direct respiratory effects or secondary to decreasing the number of arousals (and hence postarousal respiratory pauses) during sleep is not clear. Even for the longer-acting agents, however, respiratory depression is much milder than those of older hypnotics such as the barbiturates. In practical terms, there is no significant effect in patients with normal ventilation, although it may become evident when there is preexisting compromised respiration such as in patients with chronic obstructive pulmonary disease or persons with unrecognized sleep-disordered breathing. The newer nonbenzodiazepines appear to have very few respiratory effects. One study of clinically used doses of zaleplon, for instance, found few effects on measures of sleep-disturbed respiration in patients with mild to moderate obstructive sleep apnea on continuous positive air pressure.[101] In most cases, the preceding generalizations in this section apply to zolpidem as well. There is some evidence from animal studies that there is a greater separation of hypnotic and sedative doses for zolpidem. In humans, zolpidem has been reported to lack respiratory depressant properties up to doses of 10 mg in healthy normal individuals and to exhibit very mild inhibition of mean inspiratory drive at 20 mg.[102] Zopiclone in therapeutic doses appears to have no significant effect on sleep-disordered

breathing in patients with chronic obstructive pulmonary disease.[103]

In general, adverse reactions to hypnotics are relatively rare and mild; one review of 3 years' experience in a 1000-bed teaching hospital found the median rate of reported adverse events to be 0.01% (1 in 10,000) doses administered and ran as high as 0.05%.[41] The rate for triazolam was 0.02%.[104] Although effective, benzodiazepine compounds manifested other problems: rebound insomnia on cessation and occasionally a state of "confusional arousal" in which the patient may have been acting out unaware, half asleep but moving around, not unlike sleepwalking, which has led to legal cases. Consequently, triazolam was withdrawn from many markets or the dose decreased. Even nonbenzodiazepines that act at $GABA_A$ receptors sometimes result in impaired cognition, amnesia, and ataxia.[55] Based on preclinical studies,[105-107] such impairments would not be expected in patients treated with hypocretin-orexin receptor antagonists.

Unlike older hypnotics such as the barbiturates, the benzodiazepines are relatively benign in overdose when taken alone by a medically healthy individual. They may be very toxic, however, when taken in combination with other CNS depressants such as alcohol. Because a significant portion of overdoses involve a combination of drugs, it is wise to treat them as potentially toxic or even lethal agents. In practice, this translates into being very conscious of the possibility that a patient seeking help for sleep disturbance may be suffering from unrecognized depressive illness, and if it is present, initiation of antidepressant therapy may be more appropriate.

EFFECTS ON SLEEP

Polysomnographic studies of benzodiazepines indicate that, consistent with their clinical effects, sleep latency and wake time after sleep onset are generally reduced, and total sleep time is increased. As with barbiturates and ethanol, spindle activity may be increased. REM sleep time may be reduced mildly, in contrast to the very potent REM suppression induced by barbiturates. In the early years after the introduction of benzodiazepines into the U.S. market, much was made of this observation, which was interpreted to mean that they somehow produced a more natural sleep. In hindsight, many investigators recognize that the psychological effects of REM deprivation are much less clear than originally thought and that, in the case of depressed patients, REM deprivation may be therapeutic, so whether having only mild REM suppressant properties translates into a clinical advantage seems uncertain.

In contrast to the barbiturates, however, the benzodiazepines are potent suppressors of slow wave sleep. The same dilemma that arises in terms of REM sleep recurs: Because the function of slow wave sleep has not been clearly determined, the clinical significance of pharmacologically suppressing this stage remains uncertain. The nonbenzodiazepine zolpidem shares with the benzodiazepines the very mild effects on REM sleep but, in contrast, does not alter slow wave sleep, which may even increase toward more expected values in patients with insomnia and low baseline levels. The development of neuroimaging techniques is also beginning to give insights into how the newer nonbenzodiazepines may affect the brain. A positron emission tomography study indicates that following eszopiclone administration, there is a more rapid decline in metabolic activity in the midbrain and pontine reticular formation during the transition from waking to NREM sleep.[108] One interpretation would be that the drug is reducing the hyperarousal often seen in insomnia.

Clinical efficacy studies indicate that virtually all these agents improve polygraphic measures of sleep and result in better subjective ratings of sleep quality during short-term use. One of the few distinctions among the benzodiazepines is that the longer acting agents such as flurazepam may not have much effectiveness on sleep latency until the second night of administration. A concern that was initially raised regarding the short-acting agents such as triazolam was the possibility that the relatively rapid metabolism might lead to sleep disturbance after several hours; later studies analyzing awakenings in the latter part of the night have generally found no evidence that this is the case.[109,110]

Another pharmacologic property to consider is the potential for dependence. A review of this topic by a panel from academia, industry, and the government concluded that the dependence potential of currently available hypnotics in patients without a history of substance abuse is minimal.[111] Ramelteon has been found to have no dependence-producing properties in standard measures. Griffiths and Johnson[112] present an excellent review of abuse liability and toxicity of 19 hypnotics from the days of the barbiturates through ramelteon. A variety of other issues at a clinical level include determination of whether tolerance develops during long-term nightly administration, and the effectiveness of nonnightly use.

FUTURE HYPNOTICS

Since the previous edition of this volume zolpidem became generic in the United States, and the landscape for hypnotic development has changed markedly. The previous edition listed a number of compounds that were under development at the time, including antagonists to specific serotonin receptor subtypes, alpha-2-delta calcium-channel blockers, and orexin antagonists. The serotonin subtype 2 receptor has been of interest for some time in relation to the action of some antidepressants and most atypical antipsychotics. Serotonin subtype 2A antagonists, including eplivanserin, pimavanserin, and others, were previously under development as hypnotics, with studies emphasizing improvements in sleep continuity and minimal daytime sedation. Some compounds combine antagonism at serotonin 2C receptors with melatonin receptor agonism. Compounds that bind to alpha-2-delta subunits of voltage-gated calcium channels, such as the anticonvulsants pregabalin and gabapentin, increase calcium ion entry into neurons and alter GABA concentrations. Both appear to increase slow wave sleep and decrease awakenings, and were also under development as hypnotics. An antagonist to orexin receptors, GW649868, was under development as a hypnotic as well. To the best of our knowledge, the above programs have ceased. On the other hand, several new drugs have been approved. Low-dose administration of the tricyclic antidepressant doxepin, which has significant antihistaminergic properties as well as antagonism at $alpha_1$ adrenoceptors and other properties, was approved by the FDA in 2010. The first orexin antagonist, suvorexant, was approved in mid-2014, and others are still in development. Advances in medicinal chemistry have enabled the creation of hypnotics that may come in

multiple preparations varying in duration of action. There has been interest in novel modes of administration including inhalation, oral sprays, and oral dissolving tablets. A sublingual form of zolpidem was approved by the FDA in 2011. However, the existence of a safe and relatively effective hypnotic in generic form raises the bar for the development of new clinical entities for insomnia. Only compounds directed at novel mechanisms such as the orexin receptors are likely to be able to address shortcomings of current nonbenzodiazepine hypnotics to overcome this economic barrier.

CLINICAL PEARL

Most currently available hypnotics induce sleep by acting on various moieties of the $GABA_A$-benzodiazepine receptor complex; knock-in studies of the alpha-1 subunit suggest that it is unlikely that hypnotics that act by this mechanism can be developed that will be able to have sleep-inducing, but not amnestic, properties. Hypnotics with novel mechanisms of action such as the orexin receptor antagonisms have recently become available for clinical use.

SUMMARY

Most currently available hypnotics induce sleep by acting at various moieties of the $GABA_A$-benzodiazepine receptor complex. This receptor is a member of the ligand-gated receptor family and is composed of several subunits, each of which appears in multiple isoforms. Microinjection studies indicate that the neuroanatomic sites of action of hypnotics from a variety of pharmacologic classes include the preoptic area and hypothalamus. These brain areas express GABA receptors and also contain GABAergic neurons. Connections between the preoptic area and the forebrain and brainstem, and the integrative nature of the anterior hypothalamus, help explain the mechanism by which sleep—and drugs that affect sleep—interact with a variety of physiologic systems. Novel hypnotic agents directed toward the hypocretin-orexin receptors have recently become available for clinical use.

Chapter
42

Clinical Pharmacology of Other Drugs Used as Hypnotics

Daniel J. Buysse; Shachi Tyagi

Chapter Highlights

- Insomnia is the most prevalent sleep disorder and affects large proportions of the population on a situational, recurrent, or persistent basis. There is a growing awareness in the population regarding insomnia, which has led to an increase in diagnosis and treatment of insomnia in primary care.
- Pharmacologic treatment of insomnia is managed by hypnotic drugs from several classes. While benzodiazepine receptor agonists remain the most widely used hypnotics approved by the U.S. Food and Drug Administration (FDA), melatonin receptor agonists are also FDA approved for the treatment of insomnia. In addition, various other drugs originally developed as antidepressants, anticonvulsants, and antipsychotics, as well as hormones and other "natural" substances, have been used as hypnotics.
- Safe use of these drugs in clinical practice depends on the knowledge of pharmacokinetics, pharmacodynamics, sleep effects, and side effects of these medications. The purpose of this chapter is to provide a comprehensive review of the pharmacotherapeutic agents available for insomnia treatment to guide students and practitioners in treating the condition and to stimulate additional research to refine our understanding of this condition.

Benzodiazepine receptor agonists (BzRAs) are the most widely used drugs for the treatment of insomnia. Although BzRAs are popular among prescribers, they can be associated with rebound insomnia on discontinuation and a variety of well-described side effects such as tolerance, dependence, and abuse. Increasing concern has also been raised about their potential for more serious long-term adverse effects, including increased risk for dementia[1] and mortality.[2] Off-label use of sedating antidepressants is considered to be relatively safe and less likely to induce dependence; however, there are few clinical data establishing their efficacy and safety in insomnia, and side effects can be limiting.

Pharmacoepidemiology data indicate that prescribers often use non-BzRA drugs to treat insomnia. Data from National Health and Nutrition Examination Survey (NHANES) between 1999 and 2010 show that trazodone is one of the most commonly prescribed medications for insomnia, second only to zolpidem.[3] Data from a variety of other sources also demonstrate that trazodone and other antidepressants continue to be either the first- or second-choice hypnotic agents prescribed in the United States.[4-6] Use of drugs from other classes as hypnotics, although widely accepted clinically, raises several concerns. Most serious is the lack of evidence regarding safety and efficacy. Because most of these drugs have not been rigorously evaluated with regard to their sleep effects, vital information regarding appropriate dose, efficacy, and side effects is largely unknown.

Recent development of hypnotic drugs has arguably become more focused. Research is focused not only on novel targets (e.g., suvorexant targeting the orexin system) but also on developing new formulations of existing drugs specifically for insomnia treatment (e.g., low-dose doxepin).

A MODEL OF SLEEP-WAKE REGULATION RELEVANT TO SLEEP-PROMOTING DRUGS

Recent findings from the basic and clinical neuroscience of sleep-wake regulation permit specific models of sleep-wake regulation and insomnia to be advanced and tested (see also Chapters 7, 12, and 26). The model in Figure 42-1 describes non–rapid eye movement (NREM) sleep and wakefulness in humans as the products of dynamic interactions among several neural systems.[7-13] Wakefulness and arousal states are generated by the ascending activity of monoaminergic brainstem nuclei, histaminergic nuclei in the posterior hypothalamus, and cholinergic nuclei of the pontine tegmentum and basal forebrain (a to c in Fig. 42-1). Activity of these arousal systems is promoted by input from orexin (hypocretin) neurons in the perifornical lateral hypothalamus (LHA) during wakefulness and inhibited by gamma-aminobutyric acid (GABA) and galaninergic neurons in the ventrolateral preoptic area (VLPO) and median preoptic area (MnPO) of the hypothalamus at the onset of sleep (c). The LHA and VLPO/MnPO are in dynamic equilibrium with each other to ensure stable sleep-wake states (d). The timing and overall level of activity in the LHA and VLPO are tightly regulated by homeostatic sleep drive and the circadian timing system (e), which also indirectly affect output of brainstem arousal centers (f). Descending inputs from cortical-diencephalic cognitive and affective centers further modulate sleep-wake balance (g) and are in turn modulated by

ascending input from arousal centers, both directly and through thalamic pathways (a, b). Finally, corticothalamic oscillations underlie the characteristic electrophysiologic events of NREM sleep, sleep spindles, and delta oscillations.

Findings from human functional neuroimaging studies are consistent with this model. Compared with wakefulness, NREM sleep is associated with decreased global blood flow and glucose metabolism as well as large decreases in subcortical (brainstem, thalamus, basal ganglia, basal forebrain) and cortical (prefrontal and orbitofrontal cortex, anterior cingulate cortex, and precuneus) regions.[14-17] The influence of the circadian timing system is suggested by diurnal variation in regional metabolism during wakefulness in humans, with increased brainstem-hypothalamic activity in the morning compared with evening.[18] Finally, increasing homeostatic sleep drive with total sleep deprivation (TSD) leads to large reductions of metabolism in cortical, diencephalic, and brainstem structures during wakefulness and sleep.[19-21]

See text for explanation of letters and numbers.

Sleep-promoting medications may affect sleep-wake regulatory systems at several levels, as indicated in Figure 42-1. Benzodiazepine receptor agonists (1 in Fig. 42-1) may directly affect the sleep-wake state-switching system but also have direct cortical, thalamic, and brainstem effect due to the widespread distribution of GABA-A receptors. Sedating antidepressant and antipsychotic medications (2), through their activity on monoaminergic systems, affect corticolimbic systems and brainstem-hypothalamic arousal systems. Antihistamines (3) antagonize histamine-1 (H_1) receptors in the hypothalamus and cortex that receive projections from the tuberomamillary nucleus. Melatonin and melatonin receptor agonists (4), through their effects on melatonin-1 (MT_1) and MT_2 receptors, influence the "wake signal" from the suprachiasmatic nucleus and circadian timing system. Orexin antagonists[22] (5) inhibit the effect of orexin-hypocretin on brainstem and hypothalamic arousal centers, and 5-HT_2 antagonists (6) are most likely to have corticolimbic and brainstem sites of action. Thus different types of sleep-promoting drugs achieve their effects through very different actions on very different components of the sleep-wake regulatory system.

SEDATING ANTIDEPRESSANTS

Overview

More than two dozen drugs are approved by the U.S. Food and Drug Administration (FDA) as antidepressants, but several of these are used, mainly in low doses, for the treatment of insomnia. These include the tricyclic antidepressants (TCAs) doxepin, trimipramine, and amitriptyline, as well as the heterocyclic drugs trazodone, and mirtazapine. Of these, low-dose doxepin is the only FDA-approved antidepressant for insomnia treatment. Pharmacokinetic properties of these drugs are summarized in Table 42-1. The complex receptor effects of sedatives antidepressants are summarized in Table 42-2.

Most data regarding the effects of antidepressant drugs on human sleep come from studies in patients with depression,

Table 42-1 Pharmacokinetic Properties of Sedating Antidepressant Drugs*

Drug	Drug Class	Time to Maximal Concentration (h)	Metabolism (CYP Enzymes)	Elimination Half-Life (h) (Range)	Usual Dose (mg)	
					Antidepressant	Hypnotic†
Doxepin	Tricyclic	2–8	Major: 2D6, 2C19 Minor: 1A2, 3A4	20 (10–30)	100–300	3, 6
Amitriptyline	Tricyclic	2–8	Major: 2D6, 2C19 Minor: 1A2, 3A4	30 (5–45)	100–300	10–150
Trimipramine	Tricyclic	2–8	Major: 2D6, 2C19 Minor: 1A2, 3A4	25 (15–40)	100–300	25–150
Trazodone	Phenylpiperazine	1–2	3A4, 2D6	9 (3–14)	200–600	25–150
Nefazodone	Phenylpiperazine	1	3A4, 2D6, 2C19	2–4 (6–18 for active metabolites)	150–450	50–150
Mirtazapine	Noradrenergic and specific serotonergic antidepressant	1–3	3A4, 2D6, 1A2	25 (13–40)	15–45	7.5–30

CYP, Cytochrome P-450 (individual letters and numbers in table represent specific CYP enzymes).
*Data from references 23, 25, 53, 54, 74, 161, and 213.
†Except doxepin, hypnotic doses are based on published studies and common clinical practice without formal dose-ranging studies for this indication.

Table 42-2 Receptor Pharmacology of Sedating Antidepressant Drugs*

Drug	Receptor Effects†						
	NE Reuptake	5-HT Reuptake	5-HT_2 Receptor Antagonism	α_1 Antagonism	M_1 Antagonism (Anticholinergic)	H_1 Antagonism (Antihistamine)	Other Effects
Doxepin	+	0/+	+	+++	++	+++	
Amitriptyline	+	++	+	+++	+++	++	
Trimipramine	0	0	+	+++	++	+++	
Trazodone	0	+	++	++	0	0/+	5-HT_{1A}, 5-HT_{1C}, and α_2 antagonism
Nefazodone	0	++	++	++	0	+	
Mirtazapine	0/+	0	++	+	+	+++	α_2 and 5-HT_1 antagonism

5-HT, Serotonin; α, α-adrenergic receptor; H, histamine receptor; M, muscarinic cholinergic receptor; NE, norepinephrine. Numbers after receptor abbreviations indicate specific receptor subtype.
*Data from references 23, 26, 53, 161, and 214. Receptor actions are noted for usual antidepressant doses of each medication. Receptor actions at hypnotic doses may differ. Please refer to text.
†"+" Indicates strength of effect relative to other antidepressant drugs; "0" indicates no significant effect.

Table 42-3 Polysomnographic Effects of Sedating Antidepressant Drugs on Sleep*

Drug	Sleep Latency	Sleep Continuity†	Stage 3/4 NREM Sleep Amount (%)	REM Sleep	Other
Doxepin	↓	↑	↔	↓ amount, % of REM ↑ phasic eye movements (REM density)	↓ sleep apnea (minor effect); ↔ or ↑ periodic limb movements; ↑ restless legs symptoms; may induce eye movements during NREM sleep
Amitriptyline	↓	↑	↔	↓ amount, % of REM ↑ phasic eye movements (REM density)	
Trimipramine	↓	↑	↔	↔ amount, %	
Trazodone	↓	↔ to ↑	↑	↔ amount, % (↓ to ↑ in individual studies)	
Nefazodone	↔	↑	↔	↔	
Mirtazapine	↓	↑	↔	↔	

*Reported effects are based on a preponderance of evidence from published studies (see text for details). Many effects are inconsistent between individual studies. ↑ indicates increase from pretreatment baseline; ↓ indicates decrease from pretreatment baseline; ↔ indicates no change from pretreatment baseline. Effects noted are for antidepressant doses of each drug. Effects of hypnotic doses may differ.
†Sleep continuity refers to the proportion of sleep relative to wakefulness after sleep onset, as reflected by measures such as sleep efficiency. Other indicators of sleep continuity, such as wakefulness after sleep onset or number of awakenings, would have opposite signs. Thus ↑ indicates improvement in overall sleep continuity.

using doses higher than those typically used for insomnia. Formal dose ranging studies have not been conducted to determine optimal hypnotic doses, except for doxepin. Sleep effects of sedating antidepressant drugs have been discussed elsewhere[23,24] and are summarized in Table 42-3.

Tricyclic Antidepressant Drugs

TCAs share a core cyclic structure and differ from one another in their specific side chains (see Fig. 42-1). TCAs can be classified according to side chain structures as tertiary or secondary amines; tertiary amine TCAs undergo hepatic metabolism to form secondary amine TCAs. Tertiary TCAs are generally more sedating than secondary TCAs, and their metabolites have measurable blood levels and pharmacologic activity.

Pharmacokinetics

TCAs are absorbed moderately quickly from the gastrointestinal tract, with maximum concentrations occurring within 2 to 8 hours. They undergo extensive (30% to 90%) first-pass metabolism and are extensively protein bound (e.g., 90% or greater). Consequently, bioavailability is low following oral administration.[23,25,26] TCAs are very lipophilic, ensuring large volumes of distribution and high concentrations in the brain. TCAs have half-lives of approximately 15 to 30 hours.

TCAs undergo extensive hepatic metabolism, including oxidative demethylation of the side chains and hydroxylation of the ring structure[23-25] followed by conjugation and renal excretion. Hepatic metabolism of TCAs primarily

involves CYP2C19 and CYP2D6, as well as CYP1A2 and CYP3A4.[24-26] At usual doses, metabolism of TCAs follows linear kinetics, that is, drug blood levels (and metabolism) are proportional to dose, but at higher doses, metabolic enzymes can become saturated, leading to nonlinear pharmacokinetics, that is, higher blood levels than predicted by dose alone.[24] Wide interindividual variability in metabolism of TCAs is due to population variability in CYP2D6 polymorphisms and activity.[27] About 7% of patients in the population metabolize TCAs slowly due to a variant CYP2D6 isoenzyme, causing up to a 30-fold difference in plasma concentrations among different patients given the same TCA dose.[26] Age is associated with decreased metabolic clearance by CYP3A4 and decreased renal clearance.[23,25]

CYP3A4 can be induced by drugs such as barbiturates and tamoxifen, leading to reduced TCA levels, whereas CYP2D6 can be inhibited by drugs such as antipsychotic drugs, methylphenidate, fluoxetine, and paroxetine, leading to increased TCA levels.[24] Grapefruit juice is a common, if unsuspected, inhibitor of CYP3A4.

Pharmacodynamics and Receptor Pharmacology

TCAs interact with receptors of a variety of neurotransmitter receptors, including serotonin, norepinephrine, acetylcholine, and histamine. Effects on sleep likely represent the combined effects of many of these actions. Amitriptyline and doxepin inhibit both serotonin and norepinephrine reuptake transporters, whereas trimipramine has minimal reuptake effects. Tertiary TCAs, including amitriptyline and doxepin, have relatively more pronounced effects on serotonin than norepinephrine reuptake, whereas their secondary amine metabolites have more pronounced effects on norepinephrine reuptake.[24,28] After chronic dosing, additional effects on serotonergic and noradrenergic neurotransmission are also observed: desensitization of presynaptic 5-HT_{1A} autoreceptors; upregulation (sensitization) of postsynaptic 5-HT_{1A} receptors; and both downregulation and antagonism of postsynaptic 5-HT_2 receptors.[29] At 5-HT_2 receptors, antagonism of the 5-HT_{2C} subtype is more strongly associated with increasing slow wave sleep compared with 5-HT_{2A} receptors.[30] The net effect of TCA receptor effects is an enhancement of 5-HT effects in the central nervous system (CNS). Noradrenergic effects of TCAs include desensitization of presynaptic α_2 autoreceptors and a compensatory downregulation of postsynaptic β receptors,[23] with a net effect of increasing noradrenergic neurotransmission. TCAs also antagonize peripheral α_1 and α_2 adrenergic receptors, which accounts for their cardiovascular effects.

Sedating TCAs also antagonize M_1 muscarinic cholinergic and H_1 receptors. Amitriptyline is the most anticholinergic of all antidepressants, and doxepin is a more potent antihistamine than many drugs marketed as antihistamines, including diphenhydramine. Doxepin at low doses is also highly selective for this effect, with more than seven times greater affinity for the H_1 receptor relative to any other receptor.[31,32] As a result, low doses of doxepin (3 and 6 mg) can achieve selective H_1 blockade, with no serotonergic, adrenergic, and cholinergic effects.[33-36]

Effects on Human Sleep

Subjectively, tertiary tricyclic drugs are perceived as sedating, associated with reports of decreased sleep latency and wakefulness during the sleep period and improved sleep quality among depressed patients. Secondary TCAs such as desipramine are less sedating and may even be subjectively alerting. The polysomnography (PSG) effects of sedating TCAs in depression have been studied extensively. Reduced sleep latency, reduced wakefulness during sleep, and increased sleep efficiency have been reported in depressed patients treated with amitriptyline,[37-39] doxepin,[40] and trimipramine[41,42] and in primary insomnia patients treated with doxepin[43,44] and trimipramine.[45] By contrast, secondary TCAs such as desipramine and nortriptyline have little or no effect on sleep onset and continuity measures in depressed patients.[38,46]

Doxepin and amitriptyline have consistent effects on sleep stage architecture, including reductions in rapid eye movement (REM) sleep percentage and increases in phasic REM activity and REM sleep latency.[37,39,40,47,48] Trimipramine differs from most TCAs in its effects on REM sleep, which has been reported to increase, decrease, or remain unchanged during treatment.[39,41,42,45] Doxepin, amitriptyline, and trimipramine have inconsistent effects on stage 3/4 REM sleep, which has been reported to increase in some studies,[48] but not in most others.[39,41,42,44] The effects of a TCA on PSG sleep are illustrated in Figure 42-2.

In early studies of insomnia patients, moderate doses of doxepin (25 to 50 mg) and trimipramine (50 to 200 mg) have been associated with improved overall subjective sleep quality

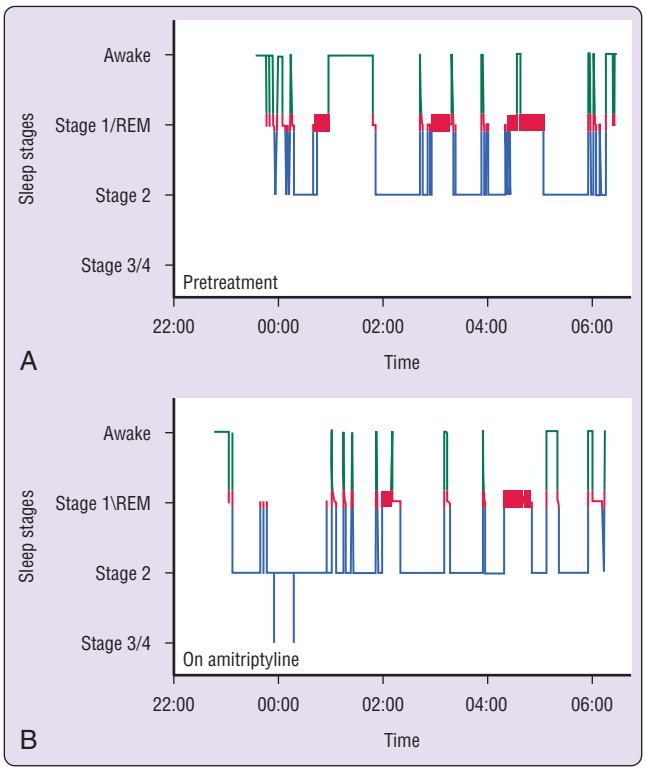

Figure 42-2 Effects of amitriptyline on electroencephalogram sleep in a 54-year-old depressed woman. **A,** Baseline sleep histogram during acute depressive episode showing prolonged sleep latency, reduced sleep efficiency, and reduced stage 3/4 sleep. **B,** Sleep histogram after treatment with amitriptyline for 24 days (final dose, 200 mg) and remission of symptoms. Compared with baseline, the histogram during treatment shows reduced sleep latency, improved sleep efficiency, reduced REM sleep, and prolonged REM latency.

and daytime well-being compared with placebo.[44,45] PSG effects of doxepin include reduced wakefulness and sleep latency and increased sleep time and sleep efficiency.[49] Studies using low doses of doxepin (1, 3, and 6 mg) demonstrated increased total sleep time, reduced wakefulness after sleep onset, and improved sleep efficiency.[33-36] Sleep efficiency was increased in the last quarter of the night, but with no demonstrable effect on next-day alertness or psychomotor performance. Trimipramine has been reported to reduce wakefulness and improved sleep efficiency without affecting sleep time or sleep latency.[50]

Other effects of TCAs on PSG sleep can include increases in periodic limb movements during sleep and the appearance of eye movements during NREM sleep; such effects are particularly noted with strongly serotonergic TCAs such as clomipramine. TCAs do not worsen sleep apnea and may have a small beneficial effect.[47] The acute effects of TCAs on sleep in depression are maintained over 1 to 3 years of maintenance treatment.[47,51] Rebound insomnia, indicated by decreased sleep time and sleep efficiency, may occur on discontinuation of sedating TCAs.[52]

Side Effects

Anticholinergic side effects of high- and moderate-dose doxepin and amitriptyline include dry mouth, increased perspiration, constipation, and urinary retention. More serious effects include precipitation of ocular crises in patients with narrow angle glaucoma, seizures, and anticholinergic delirium, which are dose related and typically occur at blood levels higher than 300 ng/mL.[23] Side effects related to antihistaminic properties include sedation and weight gain. Studies of very low-dose doxepin (1 to 6 mg) show a low incidence of side effects, with somnolence and headache being the most common.[33-36] Side effects related to α_1 antagonism include orthostatic hypotension with attendant risks for lightheadedness, syncope, and falls. TCAs typically increase heart rate. They also slow cardiac electrical conduction due to type I antiarrhythmic (quinidine-like) effects, which can lead to prolongation of the QRS duration and PR and QT intervals and heart block. The overdose lethality of TCAs is largely due to their cardiovascular toxicity, which can occur at doses as low as 10 times the therapeutic antidepressant daily dose. On the other hand, TCAs have no effect on cardiac contractility, and they can suppress atrial and ventricular ectopy.[23]

Trazodone

Trazodone is a tetracyclic antidepressant drug, and nefazodone is structurally similar. Nefazodone is not recommended for the treatment of insomnia because of potential hepatotoxicity and is not further discussed here.

Pharmacokinetics

Trazodone is rapidly absorbed, with peak plasma concentrations occurring 1 to 2 hours after oral doses. Like TCAs, it is highly (85% to 95%) protein bound. Trazodone has a relatively short half-life, approximately 5 to 9 hours.

The major metabolic pathway for trazodone is *N*-dealkylation to produce meta-chlorophenylpiperazine (m-CPP), an active metabolite that possesses serotonergic activity.[26,53] Trazodone also undergoes oxidation. Trazodone and m-CPP are substrates for CYP2D6, and trazodone is also metabolized to a lesser extent by CYP3A4. Drugs that inhibit CYP3A4, such as ketoconazole, inhibit trazodone metabolism and decrease m-CPP formation.[53]

Pharmacodynamics and Receptor Pharmacology

Trazodone is a relatively weak but specific inhibitor of the serotonin reuptake transporter with minimal affinity for norepinephrine or dopamine reuptake. Trazodone also inhibits serotonin 5-HT_{1A}, 5-HT_{1c}, and 5-HT_2 receptors. It has essentially no affinity for M_1 receptors, but it does have moderate H_1 receptor antagonism. Finally, trazodone is a relatively weak antagonist of α_2 adrenergic receptors and a somewhat more potent antagonist of α_1 receptors.[26,53]

The potent 5-HT agonist properties of the active metabolite m-CPP may play a role in the mechanism of action of trazodone. m-CPP inhibits serotonin reuptake and is a partial agonist at postsynaptic 5-HT_{2C} receptors. These actions can lead to increased side effects from trazodone among individuals who are "poor metabolizers" through CYP2D6 or who are taking inhibitors of CYP2D6, such as fluoxetine.[54]

Effects on Human Sleep

Studies of trazodone effects on human sleep have been limited by small sample sizes, particularly in PSG studies, and by study designs that have typically included sleep only as a secondary end point. In addition, many studies specifically addressing trazodone's sleep effects have not included double-blind, placebo-controlled, randomized study designs. Sedation is a commonly reported effect of trazodone in the treatment of depression, reported by more than 40% of patients. When specifically assessed, subjective sleep quality is improved by trazodone in healthy controls[55] and in patients with depression,[56-59] fibromyalgia,[60,61] and alcohol dependence.[62] However, some negative studies with respect to sleep quality in depressed subjects have also been reported.[63]

PSG studies have not consistently reported trazodone's effects on sleep continuity. The available evidence is inconsistent with regard to effects on sleep latency, total sleep time, and sleep efficiency; about half of the published studies show improvements in these measures.[64] Trazodone improved sleep efficiency, total sleep time, and wakefulness during sleep in older controls[55]; patients with depression,[57,65,66] including depressed patients concurrently treated with selective serotonin reuptake inhibitors[59]; and abstinent alcohol-dependent patients.[67] Some negative studies with regard to sleep continuity have also been reported in younger healthy controls,[68] in which ceiling effects may have been an issue, and in some studies of depressed patients with small numbers of subjects.[56,63]

Unlike most TCAs, trazodone has little effect on the amount of REM sleep, with most studies showing no significant change[57,65,66,68] or a small decrease.[55,63] Trazodone is also associated with increased stage 3/4 NREM sleep in most studies.[56,57,59,68] In one study, a small reduction in apnea-hypopnea index and no change in periodic limb movements were noted.[57] Although no information has been published regarding its long-term effects on sleep, rebound insomnia has been noted on discontinuation after several weeks of use.[55]

Only two studies have been published on the effects of trazodone in primary insomnia, compared with placebo[69] and both placebo and zolpidem.[70] Compared with placebo, trazodone 50 mg was associated with fewer night-time awakenings, minutes of stage 1 sleep,[69] reduced subjective sleep

latency, awakenings and wake time during sleep, and increased subjective sleep time, ease of falling asleep, and sleep quality.[70] The magnitude of effects with trazodone was similar to that for zolpidem 10 mg.[70]

Side Effects

Trazodone can produce side effects including orthostatic hypotension, lightheadedness, and weakness.[53] Unlike TCAs, trazodone does not have anticholinergic side effects, but it can have antihistaminic effects such as weight gain. Case reports suggest a potential for ventricular tachyarrhythmias.[71] A potentially serious effect of trazodone is priapism, sustained painful erections in men.[72] Although uncommon, priapism can be serious, requiring prompt surgical treatment. The risk appears to be greatest early in the course of treatment and can occur even at low doses. The incidence of abnormal erections during trazodone treatment is about 1 per 6000 male patients treated. Fatalities have been reported with overdoses of trazodone, although most of these occurred in conjunction with other drug ingestion. Unlike zolpidem and triazolam, trazodone is not associated with subjective effects associated with abuse potential.[73]

m-CPP, the metabolite of trazodone, can contribute to the development of the "serotonin syndrome" when this drug is used in combination with other serotonergic drugs such as selective serotonin reuptake inhibitors. The serotonin syndrome includes symptoms of confusion or delirium, restlessness similar to akathisia, muscular irritability, hyperreflexia, and autonomic instability, including hypotension.

Mirtazapine

Pharmacokinetics

Mirtazapine is rapidly absorbed, undergoes extensive first-pass metabolism, and is about 85% protein bound, yielding bioavailability of about 50%.[74,75] Mirtazapine has an elimination half-life of approximately 20 to 40 hours.

Mirtazapine undergoes *N*-demethylation (producing an active metabolite) and *N*-oxidation, followed by conjugation and excretion. CYP2D6 and, to a lesser extent, CYP3A4 and CYP1A2 are the major enzymes involved in mirtazapine metabolism. Mirtazapine follows linear pharmacokinetics, but its metabolism is affected by both age and sex; metabolic clearance is reduced in women and in older adults, as well as those with liver disease.[74] Although mirtazapine itself does not strongly inhibit or induce hepatic enzymes, mirtazapine blood levels are decreased by medications such as carbamazepine that induce CYP enzymes and increased by medications such as fluoxetine that inhibit CYP enzymes.

Pharmacodynamics and Receptor Pharmacology

Mirtazapine is a very weak inhibitor of noradrenergic reuptake and has no effect on serotonin reuptake.[76] However, similar to TCAs, it increases serotonergic and noradrenergic neurotransmission through blockade of α_2 autoreceptors and heteroreceptors.[54] It also has prominent antagonist activity at $5HT_2$, $5HT_3$, H_1, and α_1 adrenergic receptors,[76] which may contribute to its hypnotic effects.

Effects on Human Sleep

Mirtazapine is reported to be subjectively sedating in clinical studies of depression. In a PSG study in healthy adults, mirtazapine decreased sleep latency, awakenings, and stage 1 NREM sleep and increased stage 3/4 sleep.[77] In a study of 10 depressed patients, mirtazapine had similar effects, increased sleep continuity, with significant increases in slow wave and low delta sleep.[78] Thus, although potentially promising, mirtazapine has not yet been adequately evaluated as a hypnotic.

Side Effects

In addition to causing sedation, mirtazapine is associated with increased appetite, weight gain, and dry mouth, probably related to its antihistaminic properties. Clinical observations suggest that mirtazapine may be less sedating at doses greater than 30 mg per day than at lower doses. This is hypothesized to be related to greater noradrenergic effects relative to antihistaminic and serotonergic effects at lower doses.[79] Mirtazapine has not been associated with serious toxicity or death in overdose.

Serotonin Receptor ($5\text{-}HT_{2a/2c}$) Antagonists

As discussed previously, several antidepressants are antagonists of serotonin $5\text{-}HT_2$ receptors, which is thought to underlie some of their sedative effect. Other compounds that antagonize $5\text{-}HT_{2A}$ and $5\text{-}HT_{2C}$ receptors have been investigated more specifically for their sleep effects, in addition to possible antidepressant or antianxiety effects. $5\text{-}HT_{2A/2C}$ receptors are G-protein–coupled receptors that are widely distributed in the CNS, including the cortex, hippocampus, amygdala, thalamus, hypothalamus, and brainstem. They functionally interact with and affect the activity of GABAergic, dopaminergic, and cholinergic neurons.[80]

Early evidence in healthy humans showed that ritanserin, a $5\text{-}HT_{2A/2C}$ antagonist, increased slow wave sleep and delta electroencephalogram (EEG) activity in a dose-dependent fashion, with inconsistent and smaller magnitude effects on subjective sleep quality and PSG sleep latency and awakenings.[81,82] Ritanserin was found to have few effects on sleepiness or psychomotor function, even with daytime administration. Among poor sleepers, ritanserin had a small effect on the number of awakenings, in addition to the previously described SWS effect and improved subjective sleep quality.[83,84] Another $5\text{-}HT_2$ antagonist, SR 46349B, was observed to have very similar effects to ritanserin, increasing visually scored slow wave sleep and suppressing REM sleep.[85] Ultimately, ritanserin was not further developed as a hypnotic medication, and several newer $5\text{-}HT_2$ antagonists have also been taken out of development for lack of efficacy or adverse effects.

MELATONIN AND MELATONIN RECEPTOR AGONISTS

Biosynthesis, Physiologic Regulation, and Specific Compounds

Melatonin is a hormone endogenously synthesized from serotonin and produced in the pineal gland, retina, and intestinal tract. The noradrenergic sympathetic nervous system, acting through the superior sympathetic ganglion, stimulates pineal melatonin production. Specifically, β_1 stimulation with α_1 amplification leads to increased availability of *N*-acetyltransferase, the rate-limiting enzyme in melatonin biosynthesis.[86] Hence, β- and α-adrenergic antagonists may affect melatonin synthesis. Environmental light, acting through the hypothalamic tract and superior cervical ganglion,

suppresses endogenous pineal melatonin secretion. A number of synthetic melatonin receptor agonists have been developed and tested in clinical studies. These include two melatonin receptor agonists, ramelteon and tasimelteon, and agomelatine (S-20098), a serotonergic-melatonergic antidepressant.[87,88]

Pharmacokinetics

Exogenous melatonin is rapidly absorbed, with peak levels occurring in about 20 to 30 minutes. It has a 40- to 60-minute elimination half-life.[89] When formulated with absorption-retarding binders, systemic availability can be prolonged to mimic the normal period of nocturnal secretion.[90,91] About 85% of an oral dose is removed by hepatic first-pass metabolism. Metabolism includes oxidation by CYP1A2 and CYP2C19, followed by glucuronate and sulfate conjugation and renal excretion.[92] Melatonin is secreted in breast milk. Ramelteon is also rapidly absorbed, with time to maximal concentration of 0.75 to 1 hour and elimination half-life of 0.8 to 2.5 hours.[93] Tasimelteon's time to reach maximum plasma concentration ranges from 1.9 hours with low dose to 3 hours with higher doses.[94] Agomelatine is rapidly absorbed, irrespective of food intake, reaching peak plasma concentration in 1 to 2 hours.[95]

Pharmacodynamics and Receptor Effects

Three subtypes of melatonin receptors have been identified, with the MT_1 and MT_2 subtypes being most prevalent in the suprachiasmatic nucleus and retina and mediating the phase-shifting effects of melatonin. Melatonin receptors are also found in reproductive organs, immune cells, and vasculature, where they can mediate both vasoconstriction and vasodilation. Melatonin has effects in regulating retinal light sensitivity, seasonal breeding patterns, systemic immunity, and cancer cell growth. Tasimelteon, like ramelteon, has a high affinity for MT_1 (pKi = 9.45 ± 0.04 [0.35 nM]) and MT_2 (pKi = 9.8 ± 0.07 [0.17 nM]), which is similar to the affinity of melatonin for both receptors.[96] Agomelatine, on the other hand, is not only an MT_1 and MT_2 receptor agonist but is also a 5-HT_{2C} receptor antagonist that has chronobiotic, antidepressant, and anxiolytic effects.[97]

Effects on Human Sleep

In humans, melatonin has been studied both as a chronobiotic (where the intended effect is to phase-shift circadian rhythms) and as a hypnotic (where the intended effect is to induce or maintain sleep). Its use as a chronobiotic is discussed elsewhere in this volume. The potential hypnotic actions of melatonin have been studied in healthy adults,[98,99] adults and children with insomnia,[100,101] older adults with insomnia,[90] dementia patients,[91,102] medically ill adults,[103] and patients with affective disorders.[104] These studies have used a wide range of doses from less than 1 mg to greater than 80 mg and a variety of administration schedules.[105,106] A dose-response effect has not been demonstrated.

A number of studies have shown that melatonin is associated with reduced sleep latency and improved quality of sleep by self-report, with less consistent effects on sleep maintenance and duration.[107] Studies using actigraphy and PSG outcomes in pediatric, older adult, and nursing home populations also suggest modest effects on sleep latency, with less consistent increases in total sleep time.[108,109] Melatonin has been reported to decrease sleep latency and awakenings and increase sleep time in children with neurodevelopmental disabilities and sleep or circadian rhythms disturbances.[110,111] Paradoxically, melatonin may act preferentially as a hypnotic in situations of low homeostatic drive for sleep, such as during the daytime period of low endogenous secretion.[112-114] A meta-analysis of 17 studies, predominantly in healthy subjects, showed that melatonin was associated with a mean decrease of 4 minutes in sleep latency, mean increase of 2.2% in sleep efficiency, and mean increase in sleep duration of 12.8 minutes.[115] Heterogeneity in melatonin doses and subject characteristics may have affected these findings, as well as the fact that most studies were not conducted in subjects with insomnia.

Ramelteon is associated with reduced sleep latency and increased sleep time, but not with consistent changes in wake after sleep onset (WASO) or other sleep continuity measures. In several studies, changes on PSG measures were more robust than self-report measures. When administered to healthy adults in the novel sleep laboratory environment, ramelteon was associated with improved subjective sleep quality, reduced subjective and PSG sleep latency, and increased PSG sleep time, but not changes in sleep continuity.[116] In short-term (two nights) administration to adult chronic insomnia patients, ramelteon was associated with reduced subjective and PSG sleep latency, increased PSG sleep time, reduced slow wave sleep, and no effect on WASO[117]; a similar study in older adults yielded similar findings but with a significant effect on sleep efficiency and no effect on self-report measures. Five-week studies in adults with chronic insomnia show a similar pattern of reduced sleep latency and increased sleep time by self-report and PSG, but no change in sleep efficiency.[118,119] Effect on sleep latency was persistent after 6 months of treatment, without any change in total sleep time, sleep efficiency, or subjective sleep measures.[120] Ramelteon had no effect on sleep-disordered breathing or other measures of sleep in patients with sleep apnea.[121,122]

Agomelatine, an antidepressant with both melatonin MT_1/MT_2 agonist and serotonin 5-HT_{2C} antagonist properties, may also have effects on sleep and circadian rhythms. A study of agomelatine administration in the evening hours to healthy elderly men showed no effects on PSG measures of sleep, but phase advances were observed in circadian rhythms of body temperature and cortisol.[123] In 6-week studies of depressed patients, agomelatine was associated with improved subjective measures of sleep latency and sleep quality,[124] decreased PSG WASO, and increased sleep efficiency and slow wave sleep.[125]

Tasimelteon is a newer melatonin receptor agonist. It has recently been approved by the FDA for treatment of non–24-hour sleep-wake disorder,[126] but there have been no studies assessing its efficacy as a hypnotic. In a phase 2 study, tasimelteon showed a dose-dependent shift in plasma melatonin rhythm to an earlier hour.[94] Tasimelteon 100 mg advanced the melatonin rhythm by an average of 2 to 3 hours within hours of administration, which led to the postulation that this drug might improve sleep, at least partly, by shifting the circadian pacemaker.

Side Effects

Melatonin has a wide therapeutic index in humans. Despite widespread use of melatonin at low doses, no obvious public health risk has yet emerged. Nonetheless, the actual risks of protracted melatonin consumption remain unknown. The most common side effect reported from taking melatonin is

headache. Acutely, increased sleepiness and fatigue might contribute to the loss of vigilance in critical work situations. Melatonin is nonaddicting. Ramelteon is generally well tolerated, with the most common side effects including headache, dizziness, somnolence, fatigue, and nausea. Rebound insomnia has not been observed, and there is no evidence for abuse potential.

Headache was the most commonly reported side effect from tasimelteon (more than 10%). Fewer (1% to 10%) patients experienced increased alanine transaminase, nightmares or abnormal dreams, upper respiratory infections, and urinary tract infections. Tasimelteon is a pregnancy category C medication, so benefits must outweigh any potential risks.

ANTIHISTAMINES

Specific Agents

Antihistamine drugs used in the treatment of insomnia are reversible antagonists of H_1 receptors. Antihistamines are a diverse group of drugs broadly divided clinically into two groups based on their sedative potential.[127] First-generation agents include doxepin (discussed earlier under antidepressants), diphenhydramine, doxylamine, chlorpheniramine, hydroxyzine, meclizine, promethazine, and cyproheptadine. Essentially all of the over-the-counter antihistamine drugs marketed for insomnia treatment include diphenhydramine, the prototype of this class, or doxylamine. In addition, most analgesic-hypnotic combination medications ("p.m." preparations) contain diphenhydramine. Second-generation nonsedating antihistamine drugs are used primarily for treatment of seasonal, environmental, and other allergic reactions and are not used for the treatment of insomnia.

Pharmacokinetics

Antihistamines are well absorbed from the gastrointestinal tract and widely distributed throughout the body, including the CNS. Most first-generation antihistamines, including diphenhydramine, achieve peak plasma concentrations in 2 to 3 hours, and effects usually last 4 to 6 hours; however, specific agents such as chlorpheniramine, hydroxyzine, and meclizine may last up to 24 hours. Diphenhydramine is extensively metabolized by CYP enzymes and has an elimination half-life of 4 to 8 hours.[128]

Pharmacodynamics and Receptor Pharmacology

Histamine is widely present throughout the CNS and the body. Three types of histamine receptors have been described, labeled H_1, H_2, and H_3. Histamine is synthesized from histidine by the action of L-histidine decarboxylase and is metabolized by methylation and oxidative deamination.[127] In most tissues, histamine is stored in mast cells, which mediate allergic responses. In the CNS, histamine serves as a neurotransmitter localized to the tuberomamillary nucleus of the posterior hypothalamus. Histaminergic neurons project widely to the brainstem and cerebral cortex and promote wakefulness.[129] Histaminergic neurons fire actively during wakefulness, reinforced by excitatory input from hypocretin-containing neurons of the lateral hypothalamus, and are inhibited during sleep by the activity of GABAergic projections from the ventrolateral preoptic area.[130]

Histamine has a variety of effects in the periphery, including H_1 receptor–mediated vasodilation, increased capillary permeability, bronchoconstriction, contraction of the gut, and H_2-mediated gastric acid secretion. H_3 receptors serve as presynaptic autoreceptors that mediate feedback inhibition of histamine synthesis and release.

H_1 receptor antagonists have a variety of CNS and systemic effects. Well-described CNS effects include sedation, decreased alertness, decreased reaction times, and sleepiness.[131] Paradoxically, a minority of patients respond with CNS activation, including restlessness, anxiety, and increased alertness. Systemic effects of antihistamines include inhibition of immediate hypersensitivity reactions mediated by mast cell release of histamine. In addition, H_1 antagonists decrease capillary permeability, thus inhibiting edema, wheal reactions, and the itch response. H_1 antihistamines also have minor effects on antagonizing respiratory smooth muscle, relaxing bronchospasm, and promoting vasodilation.[132]

Many of the early sedating antihistamines, including diphenhydramine, have muscarinic anticholinergic effects similar to atropine. In addition, diphenhydramine increases serotonergic neurotransmission and antagonizes α-adrenergic receptors. The "nonsedating" H_1 antagonists have very little CNS effect because of their inability to penetrate the blood-brain barrier, thus limiting their actions to the periphery.

Effects on Human Sleep

Antihistamines such as diphenhydramine and doxylamine are associated with subjective drowsiness and sleepiness, leading to their widespread use as over-the-counter hypnotic agents. However, their efficacy has not been well studied. A study of 10 healthy adults showed increased motor activity with diphenhydramine compared with placebo and no significant effect on self-reported sleep outcomes.[133] Clinical trials using doses of 12.5 to 50 mg in hospitalized and outpatient samples of poor sleepers have shown subjective improvements in sleep latency, nocturnal awakenings, sleep duration, and sleep quality.[134-136] A comparative trial of temazepam 15 mg and diphenhydramine 50 mg in older adults with insomnia showed a reduction in awakenings, but not in sleep latency, total sleep time, or sleep quality with diphenhydramine.[137] Approximately 50% of subjects experienced rebound symptoms with temazepam and diphenhydramine, and the rate of other side effects was similar. The largest published trial compared diphenhydramine and valerian-hops combination to placebo in a total of 184 adults.[138] Diphenhydramine was associated with significantly greater change in self-reported sleep efficiency, but not in sleep latency or total sleep time, relative to placebo; a global measure of self-report outcome, the Insomnia Severity Index, showed significantly greater reductions in the diphenhydramine groups than placebo groups. PSG-measured sleep latency, sleep efficiency, and total sleep time also showed no significant group differences. Other PSG studies have examined daytime sleepiness with sedating and nonsedating antihistamines. These studies confirm the hypnotic effect of drugs such as diphenhydramine, while showing no significant sedation with nonsedating drugs such as astemizole, loratadine, or cetirizine,[139-141] and also show tolerance to the daytime sedative effect of diphenhydramine.[142]

Side Effects

Impairment of psychomotor performance with diphenhydramine has been well documented.[131] Epidemiologic studies have also suggested cognitive impairment associated with

diphenhydramine use in the older adults.[143] Other side effects related to CNS activity include dizziness, fatigue, and tinnitus. Peripheral side effects can include decreased appetite, nausea, vomiting, diarrhea, and constipation as well as weight gain. A number of case reports have also documented potentially serious side effects of doxylamine, including coma, rhabdomyolysis, and resultant kidney failure.[144]

VALERIAN

Pharmacokinetics

Valerian preparations include more than 400 extracts, mainly derived from the roots of the plant species *Valeriana officinalis*. These extracts contain a number of chemicals with CNS activity, including sesquiterpenes, valepotriates, valerinic acid, and various other alkaloids, in unknown proportions.[145] The constituents of a specific valerian preparation also depend on the actual valerian species used, the method of extraction (aqueous versus ethanolic), and the combination with other herbs or agents such as hops.[146] Because of the multiple constituents of valerian preparations, their pharmacokinetics have not been well described. Doses in clinical studies have typically ranged from 400 to 900 mg per day.

Pharmacodynamics and Receptor Pharmacology

The exact mechanism of action of valerian preparations is also unknown. The GABA-like activity of valerian extracts is suggested by their sedative, anxiolytic, myorelaxant, and possible anticonvulsant effects.[147] Valerian extracts contain a small amount of GABA, but GABA is not transported across the blood–brain barrier, and valerian extracts do not act on benzodiazepine receptors. Valerenic acid may actually inhibit brain GABA metabolism. Other potential mechanisms of action include serotonin receptor activity and adenosine receptor antagonism. Finally, some components of valerian, including valepotriates, may act as prodrugs transformed into homobaldrinal, a compound that inhibits motor activity in mice.[145]

Effects on Human Sleep

The effects of valerian extracts on sleep in humans have been investigated in healthy young adults and middle-aged and older adults with insomnia. Duration of treatment has ranged from 1 to 14 days, and outcome measures have included self-reports, actigraphy, and PSG. Subjective effects of valerian preparations include decreased sleep latency, improved sleep quality, and decreased awakenings.[148,149] Effects on PSG sleep include increased stage 3/4 and reduced stage 1 NREM sleep.[150,151] Although improved sleep latency and sleep efficiency have been observed in some PSG studies, sleep continuity effects of valerian are inconsistent.[150-152] A systematic review of valerian preparations found no significant effects of ethanolic extracts on subjective or objective sleep measures; inconsistent effects of aqueous valerian extracts; limited and variable evidence for valepotriate preparations; and mixed but predominantly negative evidence regarding valerian combinations.[146] Overall, this review concluded that research findings to date do not support the efficacy of valerian preparations for improving subjective sleep outcomes.

Side Effects

Side effects associated with valerian have been reported to be few and mild and include headache and weakness. Morning sleepiness is an infrequent side effect.[145]

GABAPENTIN AND PREGABALIN

Gabapentin and pregabalin were initially developed as anticonvulsant drugs, but they have subsequently found widespread use in treating neuropathic and fibromyalgia pain, periodic limb movement disorder, bipolar mood disorder, and insomnia. Some evidence suggests that GABA levels in the brain (occipital cortex, anterior cingulate gyrus, and thalamus) are lower in patients with primary insomnia compared with control participants.[153,154] Therefore medications that indirectly increase GABA might be therapeutic in patients with insomnia.

Typical daily doses of gabapentin range from 300 to 2100 mg, taken in divided doses with larger doses in the evening hours. Gabapentin absorption is moderately rapid (2 to 3 hours to maximal absorption), and it has a bioavailability of 35% to 60%, with lower availability at higher doses (nonlinear pharmacokinetics). It is distributed extensively and has an elimination half-life of 5 to 9 hours. Doses of pregabalin are typically 150 to 600 mg in divided doses. Absorption of pregabalin is rapid (1 hour to maximal absorption) and is not affected by dose (linear pharmacokinetics). It has a half-life of 4.5 to 7 hours. Gabapentin and pregabalin are not metabolized in humans, are not bound to plasma proteins, and are excreted unchanged, mainly in the urine.[155] Therefore doses of both drugs may need to be adjusted in patients with reduced renal clearance.[156,157]

Gabapentin and pregabalin may have several mechanisms of action for their analgesic and sedative effects. Both drugs are structural analogues of GABA but do not appear to interact with GABA-A or GABA-B receptors or influence GABA reuptake, although they may promote formation of GABA in the CNS.[155,158] The drugs selectively bind with high affinity to the alpha-2-delta subunit of N-type voltage-gated calcium channels, which both increases GABA concentration in synapses and decreases stimulus-evoked release of excitatory neurotransmitters such as glutamate and norepinephrine.[159,160] Other potential mechanisms of action include antagonism of NMDA receptors and interaction with the L-amino acid transporter receptor.[161] Side effects associated with gabapentin and pregabalin include sedation and fatigue, dizziness, headache, ataxia, and a less common risk for leukopenia. Gabapentin and pregabalin are consistently associated with improvement on self-reported sleep measures in patients with various pain conditions (e.g., fibromyalgia, neuropathic pain, postherpetic neuralgia, postsurgical pain).[157,159,162]

Although these drugs are sometimes used clinically for primary insomnia or other forms of comorbid insomnia, their sleep effects have not been systematically evaluated. A small study of gabapentin administered for 16 days to healthy adults showed no change in subjective sleep quality for most subjects, trends for reduced awakenings and periodic limb movement arousal index, and a significant increase in slow wave sleep.[163] Pregabalin administered to healthy adults was likewise associated with improved subjective sleep quality, reduced sleep latency and REM sleep, and increased sleep efficiency, total sleep time, and slow wave sleep.[164] Similar effects on self-report and PSG sleep continuity, but not slow wave sleep, were seen when pregabalin was added to monotherapy with other drugs in epilepsy patients.[165] In patients with restless legs syndrome, gabapentin has been associated with improved sleep continuity, increased stage 3/4 sleep, and reduced periodic limb movements.[166] An open pilot study of gabapentin

in alcohol-dependent patients with comorbid insomnia showed improvements in insomnia symptoms and feelings of tiredness in the morning.[62] Another international, multicenter, double-blind, placebo-controlled trial of pregabalin in patients with fibromyalgia demonstrated improved sleep as assessed by the Medical Outcomes Study Sleep Disturbance subscale and the Sleep Quality diary.[167] In patients with generalized anxiety presenting with concurrent insomnia, pregabalin was shown to improve anxiety symptoms while specifically improving insomnia.[168]

One small, uncontrolled study with 18 primary insomniacs receiving gabapentin treatment for at least 4 weeks showed improved Pittsburg Sleep Quality Index score, as well as increased PSG-measured sleep efficiency and slow wave sleep, decreased wake after sleep onset, and spontaneous arousal index.[169]

GABOXADOL

Gaboxadol, also known as THIP, is a direct GABA-A receptor agonist with effects distinct from those of BzRA.[170] BzRAs are active at a wide range of GABA receptor subtypes, but especially those with α_1 subunits, which are primarily synaptic in location. Synaptic GABA receptors are activated during fast synaptic transmission, transiently hyperpolarize and inhibit postsynaptic neurons, and desensitize rapidly. Gaboxadol is a potent agonist of GABA receptors that contain α_4, α_6, and δ, subunits, which have more restricted anatomic distribution in the thalamus, hippocampus, and cerebellum and are mainly extrasynaptic in location. Extrasynaptic GABA receptors are sensitive to low concentrations of GABA, they desensitize slowly, and their activation induces sustained neuronal effects.[171,172] Gaboxadol is rapidly absorbed, reaching peak concentration within 30 minutes, with a half-life of approximately 1.5 to 2 hours.[171]

In experimental models using healthy subjects, gaboxadol 5 to 15 mg reduced self-reported and PSG sleep latency and WASO and increased total sleep time and delta and theta EEG activity.[173-175] Short-term studies in patients with primary insomnia show similar findings, comparable to those seen with zolpidem as an active comparator.[176,177] Gaboxadol also increased slow wave sleep. Gaboxadol is not associated with typical indicators of abuse potential in animal or human studies.[171] Common side effects include headache, nausea and vomiting, somnolence, and fatigue. Gaboxadol has also been associated with dissociative reactions including hallucinations and disorientation, which have led to suspension of clinical studies in the United States.

OREXIN ANTAGONISTS

Orexin (hypocretin) is a peptide neurotransmitter localized to the perifornical neurons of the lateral hypothalamus. Orexinergic neurons have widespread excitatory projections to the brainstem and posterior hypothalamic arousal centers and are key neuropeptides responsible for generating and maintaining wakefulness.[178-180] Two receptors respond to orexin signaling: Orexin-1 receptor (OX1R) and orexin-2 receptor (OX2R) both have partially overlapping nervous system distributions. Suvorexant is a potent and selective antagonist of OX1R and OX2R and was the first drug in this class approved by FDA for the treatment of insomnia. It is orally bioavailable, has good brain penetration, and has high receptor occupancy.[181] Suvorexant's peak concentrations occur at a median of 2 hours (30 minutes to 6 hours) under fasted conditions. The mean absolute bioavailability of 10 mg is 82%. It is extensively bound (>99%) to plasma proteins and has a terminal half-life of 9 to 12 hours,[22] with some next morning residual effects.[182] CYP3A4 and, to a lesser extent, CYP2C19 are the major enzymes involved in suvorexant metabolism. In healthy subjects, suvorexant 50 mg and 100 mg decreased latency to onset of persistent sleep and wake after sleep onset and increased sleep efficiency and total sleep time, whereas suvorexant 10 mg decreased wake after sleep onset. In patients with primary insomnia, 4 weeks of suvorexant treatment improved sleep efficiency and wake after sleep onset. Total sleep time also improved with greater time spent in REM and stage 2 sleep.[183] During 1-year treatment with suvorexant, insomniac patients reported subjective improvements in total sleep time, time to sleep onset, WASO, and sleep quality.[184]

The most common adverse events reported with suvorexant are somnolence, fatigue, and dry mouth. The key safety concerns are residual sedation, rapid onset of somnolence if administered during the daytime, motor impairment, driving impairment, and hypnogogic hallucinations.[182,184,185] At higher dosages (50 and 100 mg), the medication significantly decreased reaction time and reduced subjective alertness tested the morning after drug administration.[182] Although effects resembling cataplexy are a theoretical concern, given the role of deficient orexin neurotransmission in narcolepsy-cataplexy,[186] these effects were not found in clinical trials. Adverse events appeared to be dose- and plasma-exposure-dependent. It is possible that these residual effects are related not only to half-life but also to a combination of pharmacokinetic (slow elimination or metabolism) and pharmacodynamic effects (slow equilibration and off rates).[22] Moreover, endogenous orexin production appears to follow a circadian pattern with a peak in the late waking period,[187] which could lead to more potent effects of orexin receptor antagonists during daytime than nighttime hours.

Given the stricter FDA policy for hypnotics to use the lowest effective dose to minimize safety risk, 10 and 20 mg strengths of suvorexant have been approved,[185] as opposed to 30 and 40 mg strengths, which were tested in a phase 3 trial.[184]

CHLORAL HYDRATE

Chloral hydrate has been used as a hypnotic and as a sedative in children undergoing clinical procedures. Chloral hydrate is a prodrug, rapidly converted by alcohol dehydrogenase in the liver to the active compound trichloroethanol, which acts at the barbiturate recognition site on GABA-A receptors. Metabolism of trichloroethanol occurs through hepatic conjugation, with a half-life of approximately 5 to 10 hours. Sleep effects include subjective and objective reduction in sleep latency and improvement in sleep continuity, with little effect on stage 3/4 or REM sleep.[131] Because chloral hydrate is a skin and mucous membrane irritant, it can have side effects of unpleasant taste, gastrointestinal distress, nausea, and vomiting. Other potential side effects include lightheadedness, nightmares, and ataxia. More serious potential side effects include hepatic injury. Fatal overdoses are possible, and chronic use can result in severe withdrawal. Chloral hydrate is not recommended for treatment of insomnia in adults or children,

given its low therapeutic index and the availability of safer alternative drugs.

SEDATIVE ANTIPSYCHOTIC DRUGS

Second-generation antipsychotic drugs have significantly higher rates of somnolence than placebo in clinical trials.[188] This effect may be clinically useful in the treatment of insomnia, particularly among patients with severe depression, bipolar disorder, and psychotic disorders. Although many different antipsychotic drugs have sedative effects (see Monti and Monti[189] for review), olanzapine and quetiapine are the drugs most commonly used in nonpsychotic and nonbipolar patients for this purpose. Typically olanzapine is administered in doses 2.5 to 20 mg and quetiapine in doses of 25 to 200 mg at bedtime.

Unlike older antipsychotic drugs that antagonize primarily dopamine receptors, olanzapine has a variety of receptor effects, including antagonism of serotonin 5-HT_{2A}, muscarinic cholinergic, H_1, and α_1-adrenergic receptors, as well as activity at serotonin 5-HT_{2C}, 5-HT_3, and 5-HT_6 receptors.[161,190,191] Olanzapine is structurally similar to benzodiazepines. Quetiapine, like olanzapine, is an antagonist of serotonin 5-HT_{2A}, H_1, and α_1 receptors. It has somewhat more potent dopamine D_2 receptor antagonism than olanzapine, but its dopamine binding is rapidly reversible.

Olanzapine is rapidly absorbed, but a significant portion of the drug is metabolized in first-pass circulation. Its peak concentration occurs at about 6 hours, and it has a terminal elimination half-life of 20 to 54 hours. It is metabolized through the activity of CYP1A2 and CYP2D6. Quetiapine is also rapidly absorbed but reaches peak concentration in about 1.5 hours and has a terminal elimination half-life of approximately 6 hours. Quetiapine is also metabolized in the liver, primarily through CYP3A4.

Both of these antipsychotic drugs have a lower incidence of extrapyramidal side effects than traditional antipsychotic drugs such as haloperidol. However, both can cause hypotension. In addition, olanzapine has been associated with weight gain and glucose intolerance, as well as neurocognitive impairment at higher doses. Quetiapine has been associated with prolongation of the QT_c interval on electrocardiogram.

Both olanzapine and quetiapine are subjectively sedating. Uncontrolled and placebo-controlled treatment studies using these medications as primary or adjunctive treatments demonstrate improved subjective sleep quality and reduced sleepiness in patients with schizophrenia,[192,193] unipolar depression,[194,195] and bipolar depression.[196] In PSG studies with small numbers of healthy control subjects, olanzapine is associated with decreased sleep latency, wakefulness, and stage 1 NREM sleep; increased sleep efficiency, stage 2, and stage 3/4 NREM sleep; no consistent effect on REM; and improved subjective sleep quality.[197-201] Similar self-report and PSG effects have been demonstrated in small clinical studies of patients with depression,[202] mania,[203] and schizophrenia.[198] Quetiapine administered acutely to healthy subjects has been reported to decrease sleep latency; increase sleep time, sleep efficiency, and subjective sleep quality; and reduce REM sleep.[204] One double-blind randomized controlled trial evaluating efficacy of quetiapine 25 mg in primary insomnia showed no significant improvement of self-reported total sleep time and sleep onset latency.[205]

Small uncontrolled and controlled studies have also examined the effects of other second-generation antipsychotics, including risperidone and clozapine, in patients with schizophrenia.[189] Both drugs are associated with improved sleep continuity, and risperidone is associated with increased slow wave sleep.

Given their potentially significant neurologic and metabolic side effects, antipsychotic drugs are best reserved for treatment of individuals who have insomnia comorbid with major psychiatric disorders, particularly psychotic and bipolar disorders.

SODIUM OXYBATE (GAMMA-HYDROXYBUTYRATE)

Sodium oxybate, the sodium salt of gamma-hydroxybutyrate (GHB), is FDA approved for the treatment of cataplexy in patients with narcolepsy and is also recommended for the treatment of excessive sleepiness.[206] GHB is an endogenous short-chain fatty acid that is synthesized from GABA. GHB acts as a neuromodulator and neurotransmitter, has two specific neuronal recognition sites, and is also a ligand for $GABA_B$ receptors. It is widely distributed in the brain, including the hippocampus, nucleus accumbens, basal ganglia, cortex, and brainstem. GHB acts primarily to inhibit the release of colocalized neurotransmitters, but its net effect may be to increase or decrease neuronal activity, depending on which other neurotransmitter (e.g., dopamine, GABA, serotonin, glutamate) is affected. Pharmacologic concentrations of GHB act primarily to decrease neuronal activity through $GABA_B$ modulation, but this brief period of inhibition may be followed by increased neuronal activity; this effect may explain the initial sedative effect of GHB when administered at night, followed by increased alertness the following day.[207] GHB effects on the CNS include sedation and, in higher doses, coma. GHB has few effects on cardiovascular or respiratory systems.

GHB is absorbed rapidly after oral administration, particularly because it is administered as a liquid, with peak concentrations approximately 30 to 60 minutes after administration. GHB is not bound to plasma protein. It is metabolized to a limited extent to GABA. GHB is also decomposed to water and carbon dioxide and exhaled. The mean half-life is quite short, ranging from 20 to 70 minutes (mean, 53 minutes).[208]

GHB is subjectively sedating. In healthy subjects, GHB increases stage 3/4 sleep, decreases stage 1 sleep, and reduces REM sleep latency.[209,210] When administered to patients with narcolepsy, its PSG effects include reduced REM latency and awakenings and increased stage 3/4 sleep, sleep efficiency, and sleep duration.[207,211] A study in fibromyalgia patients showed similar results, with reduced sleep latency and REM sleep, increased stage 3/4 sleep, and a reduction in alpha EEG activity intrusion during NREM sleep.[212] GHB has not been formally assessed for its hypnotic properties in patients with other types of insomnia.

The rapid sedative effects of GHB, particularly when combined with alcohol, have led to abuse. Other side effects of GHB include excess salivation, increased dreaming, sleepwalking, and gastrointestinal effects such as vomiting. It is also associated with amnesia, similar to other BzRA hypnotic agents. In overdoses, GHB can be associated with acute

delirium.[208] High-dose recreational users of GHB have been described to have a withdrawal symptom characterized by insomnia, tremor, and anxiety. Concerns regarding safety and abuse, as well as its strict regulation by the U.S. Drug Enforcement Agency, make sodium oxybate an impractical choice for the treatment of insomnia.

CLINICAL PEARL

Antidepressants, antihistamines, and other drugs (Tables 42-4 and 42-5) are often considered safer alternatives to BzRAs for treatment of insomnia. However, in most cases, their efficacy has not been well demonstrated, and they can have clinically important side effects. Understanding the clinical pharmacology and known sleep effects of these medications is critical to their rational use in clinical practice. These drugs may be useful when BzRAs are contraindicated or ineffective or when comorbidities such as severe psychiatric illness are present.

Table 42-4 Summary of Other Drugs Used to Treat Insomnia*

Drug	Drug Type	Time to Maximal Concentration	Metabolism	Elimination Half-Life	Mechanism of Action
Melatonin	Hormone	20–60 min	Conjugation; oxidation by CYP enzymes	40–60 min	Agonist at melatonin type 1 and type 2 receptors
Diphenhydramine	Ethanolamine antihistamine	2–2.5 h	Hepatic demethylation, oxidation	4–8 h	Antagonize H_1 receptors
Doxylamine	Ethanolamine antihistamine	2–3 h	Most excreted unchanged in urine; some hepatic metabolism	10	Antagonize H_1 receptors
Valerian	Plant extract	Uncertain because of multiple constituents	Uncertain because of multiple constituents	Uncertain because of multiple constituents	Uncertain; may increase GABA formation, interact with L-amino acid transporter receptor, or act as adenosine receptor agonist
Gabapentin	Anticonvulsant (structural analog of GABA)	3–3.5 h	Renal excretion (unchanged)	5–9 h	Uncertain; may affect GABA release or interact with L-amino acid transporter protein
Tiagabine	Anticonvulsant	1–1.5 h	CYP3A4	8 h	Inhibits GABA transporter GAT-1
Suvorexant	Orexin receptor antagonists	30 min to 6 h	CYP3A4, CYP2C19	9–12 h	Blocks the binding of wake-promoting neuropeptides orexin A and orexin B to receptors OX1R and OX2R
Choral hydrate	Two-carbon molecule	Short	Converted to trichloroethanol, which undergoes conjugation	5–10 h (for trichloroethanol)	Barbiturate-like effect at GABA-A receptors
Olanzapine	Thienobenzodiazepine antipsychotic	4–6 h	CYP1A2, CYP2D6	20–54 h	Antagonizes H_1, α_1, α_2, M_1, 5-HT_2, D_2 receptors
Quetiapine	Dibenzothiazepine antipsychotic	1–2 h	CYP3A4	6 h	Antagonizes H_1, α_1, M_1, 5-HT_2, D_2 receptors
Gamma–hydroxybutyrate (GHB)	Endogenous four-carbon molecule	30–45 min	Metabolized to GABA, succinic semialdehyde, H_2O and CO_2	20–70 min	May act directly as neurotransmitter, increase brain dopamine levels

5-HT, 5-Hydroxytryptamine (serotonin); α, α-adrenergic receptor; CYP, cytochrome P-450 system (individual letters and numbers represent CYP families); D_2, dopamine type 2 receptor; GABA, gamma-aminobutyric acid; H_1, histamine type 1 receptor; M_1, muscarinic cholinergic type 1 receptor.
*Data compiled from sources indicated in text.

Table 42-5 Polysomnographic Effects of Other Drugs Used to Treat Insomnia*

Drug	Sleep Latency	Sleep Continuity†	Stage 3/4 NREM Sleep Amount (%)	REM sleep	Other
Melatonin	↓	↔ to ↑	↔	↔	
Diphenhydramine	↓	↔ to ↑	↔ to ↑	↓	
Valerian	↓	↔ to ↑	↔ to ↑	↔ to ↑	Inconsistent effects on sleep continuity, stage 3/4 across studies
Gabapentin	↔	↔ to ↑	↑	↔	Reduced periodic limb movements
Tiagabine	↔	↑	↑	↔	Results based on single study
Suvorexant	↔	↑	↔	↑	
Chloral hydrate	↓	↑	↔	↔ to ↓	Rapid tolerance may develop
Olanzapine	↔ to ↓	↑	↑	↔ to ↓	Reports of increased periodic limb movements, sleep-eating
Gamma-hydroxybutyrate (GHB)	↔ to ↓	↑	↑	↔ to ↓	↓ Alpha NREM intrusions in fibromyalgia patients

*Reported effects are based on preponderance of evidence from published studies (see Buysse[131] and text for details). Many effects are inconsistent between individual studies. ↑ Indicates increase from pretreatment baseline; ↓ indicates decrease from pretreatment baseline; ↔ indicates no change from pretreatment baseline.

†Sleep continuity refers to the proportion of sleep relative to wakefulness after sleep onset, as reflected by measures such as sleep efficiency. Other indicators of sleep continuity, such as wakefulness after sleep onset or number of awakenings, would have opposite signs. Thus ↑ indicates improvement in overall sleep continuity.

SUMMARY

Pharmacologic treatment of insomnia is managed by hypnotic drugs from several classes. Although BzRAs remain the most widely used FDA-approved hypnotics, melatonin receptor agonists are also FDA approved for the treatment of insomnia. In addition, various other drugs originally developed as antidepressants, anticonvulsants, and antipsychotics, as well as hormones and other "natural" substances, have been used as hypnotics. Safe use of these drugs in clinical practice depends on the knowledge of pharmacokinetics, pharmacodynamics, sleep effects, and side effects. Sedating tricyclic and other antidepressant drugs primarily act through serotonin, norepinephrine, and histamine receptor effects but show considerable heterogeneity in terms of biologic half-lives, receptor pharmacology, and sleep effects. Efficacy data for most of these drugs on sleep continuity have been derived from studies of depressed patients. Some antidepressants increase slow wave sleep and reduce REM sleep. Low-dose doxepin, one of the tricyclic compounds, is FDA approved for treatment of insomnia. Melatonin and melatonin receptor agonists reduce sleep latency by acting on melatonin receptors in the suprachiasmatic nucleus and cortical regions. Two melatonin receptor agonists are FDA approved, one of which, ramelteon, is approved for insomnia. Antihistamines antagonize the effects of histamine, a wake-promoting neurotransmitter synthesized in posterior hypothalamus with widespread cortical projections. They are widely used because of their subjective sedation. A limited amount of evidence exists regarding their effects on nocturnal sleep, and like antidepressants, they can have clinically important side effects. Valerian extracts have uncertain pharmacokinetics and mechanisms of action. They appear to affect primarily sleep latency, although some studies also show increased slow wave sleep. Small numbers of studies suggest that sedating antipsychotic drugs, tiagabine, gabapentin, and sodium oxybate (GHB) may all increase slow wave sleep, with variable effects on sleep continuity. These drugs have a wide variety of receptor effects, and the mechanisms of their effects on human sleep are less well understood. Few clinical studies have been conducted with any of these agents in patients with insomnia. A newly approved dual orexin receptor antagonist, suvorexant, has been shown to improve sleep continuity in individuals with insomnia. Future studies will be needed to understand the appropriate role of these drugs in the treatment of sleep disorders and specifically how they will fit into emerging treatment algorithms for insomnia.

Chapter Highlights

- Central nervous system stimulants currently used in sleep medicine include amphetamine-like compounds (L- and D-amphetamine and methamphetamine, L- and D-methylphenidate, pemoline), mazindol, modafinil-armodafinil, some antidepressants with stimulant properties (e.g., bupropion), and caffeine.
- The effects of most of these drugs on wakefulness are primarily mediated by an inhibition of dopamine reuptake and transport and in some cases by increased dopamine release. Inhibition of adrenergic uptake also likely has some stimulant effects.
- Biogenic amine transporters (for dopamine, norepinephrine, and serotonin) are located at nerve terminals and are important in terminating transmitter action and maintaining transmitter homeostasis. The results of pharmacologic studies using animals suggest the importance of the dopamine transporter for the mode of action of amphetamines and amphetamine-like compounds on wakefulness.
- The mode of action of modafinil, a more recent compound that rapidly became a first-line treatment for excessive daytime sleepiness in narcolepsy, is controversial but is increasingly suggested to primarily involve dopamine reuptake inhibition.
- Other agents with mechanisms of action involved in wake promotion include adenosine receptor antagonists, such as those found in caffeine. More recently, novel classes of wake-promoting therapeutics are being developed, including glutamatergic and histaminergic modulators, and preclinical and clinical evaluations are in progress.

CENTRAL NERVOUS STIMULANTS: DEFINITIONS

Although widely used, the term central nervous system (CNS) stimulant is a loosely defined scientific term. In *Drugs and the Brain* by S. Snyder, stimulants are "drugs that have an alerting effect; they improve the mood and quicken the intellect." In *Handbook of Sleep Disorders* by J. D. Parkes, CNS stimulation implies "an increase in neuronal activity due to enhanced excitability, with a change in the normal balance between excitatory and inhibitory influences. This may result from blockage of inhibition, enhancement of excitation, or both." In *A Primer of Drug Action* by R. M. Julien, the term "psychomotor stimulants (psychostimulants)" is used, and "psychostimulants" are said to induce excitement, alertness, euphoria, a reduced sense of fatigue, and increased motor activity. Psychostimulants include dopamine (DA) uptake blockers, DA-releasing agents, adenosine receptor blockers, and acetylcholine receptor stimulants. In *The Pharmacological Basis of Therapeutics* by Goodman and Gilman, the term "indirect sympathomimetic amines" refers to amphetamines as the "most potent compounds with respect to stimulation of the CNS."

In this chapter, the generic term *CNS stimulants* will be used for all wake-promoting compounds of potential use in the treatment of excessive daytime sleepiness (EDS) (see Chapters 4 and 44 for the classification of EDS disorders and the indication of CNS stimulants for patients affected with sleep disorders). EDS is a common symptom in patients with sleep disorders and in the general population at large. CNS stimulants are generally effective in patients with EDS independently of its underlying cause; however, they sh ould be used cautiously because of their potential for misuse and abuse. This chapter reviews the neurochemical, neurophysiologic, and neuropharmacologic properties of the CNS stimulants most commonly used in sleep medicine. This will be followed by a perspective on future stimulant treatments.

AMPHETAMINES AND AMPHETAMINE-LIKE COMPOUNDS

Historical Perspective

Amphetamine was first synthesized by Alles in 1897, but its stimulant effects were not recognized until 1929. Alles wanted to find a synthetic substitute for the recently banned ephedrine, a compound isolated from the *Ephedra vulgaris* plant in 1925. Amphetamine increases energy, elevates mood, prevents fatigue, increases vigilance and prevents sleep, stimulates respiration, and causes electrical and behavioral arousal from natural or drug-induced sleep. It was rapidly shown to be a safer and cheaper alternative to ephedrine as a stimulant. In World War II, amphetamine was supplied to paratroopers

and commandos. British troops alone were issued 72 million tablets. In Japan, methamphetamine, initially used for munitions factory workers, flooded the civilian market at the end of the war; 5% of the Japanese population between the ages of 16 and 25 years became dependent on the drug. More than 50 "amphetamine" preparations containing amphetamine or derivatives, alone or in combination with other drugs (most notably barbiturates), were on the market after World War II.

Narcolepsy was probably the first condition for which amphetamine was used clinically. It revolutionized therapy for the condition, although it was not curative. The piperazine derivative of amphetamine, methylphenidate, was introduced in 1959 by Yoss and Daly.[1] The use of amphetamine in treating parkinsonism dates back to 1937, when it was first used to alleviate the muscular rigidity of postencephalitis parkinsonism. By 1968, its use in the treatment of this condition was largely suspended owing to the use of more effective dopaminergic agents. Until the dangers of amphetamine dependence and abuse became recognized, amphetamine was widely used in the treatment of obesity. It was also prescribed in the treatment of sedative abuse and alcoholism to offset sleepiness and lethargy.

Bradley and Bowen (1941) were the first to report on the use of amphetamine to modify antisocial behavior in children[2]: "When children are withdrawn or lethargic, the amphetamine tended to make them more alert, more accessible to persons and the environment." A paradoxical calming effect was also noted in some children and aggressive adults. Most notably, a selected group of children who were "hyperactive" tended to move less, to be calmer, and to be less quarrelsome after being treated with amphetamine. In 1958, methylphenidate was introduced to treat hyperactivity in children.[3] These observations preceded reports on the effects of amphetamine and methylphenidate in children who are hyperkinetic, a disorder now referred to as attention-deficit/hyperactivity disorder (ADHD).

Although no controlled trials have investigated the use of stimulants in depression, many case series suggest the effectiveness in some treatment-resistant cases. The use of stimulants with monoamine oxidase (MAO) inhibitors is generally not advised but has not been reported to induce significant hypertension or hyperthermia. Amphetamines are often prescribed in combination with low (anticataplectic) doses of tricyclic agent in narcolepsy-cataplexy without any problem, and combining these substances in depression has been shown to be effective, although not recommended because of the risk for dependence and abuse. Part of the beneficial effects of amphetamine on depression may be due a reduction of fatigue and apathy rather than a genuine antidepressant effect.

From a historical perspective, the number of indications for amphetamine stimulants has narrowed considerably over the years to primarily include narcolepsy, ADHD, and treatment-resistant depression. The rationale for this change has been the realization of the risk for abuse and dependence with these compounds. The introduction of other effective therapies for these conditions (e.g., modafinil for narcolepsy, atomoxetine for ADHD) has also led to narrower indications, although many new formulations and isomer-specific preparations have been recently developed and are increasingly used, mostly for the treatment of ADHD.

Structure-Activity Relationships and Major Chemical Entities

Distinguishing *potency* and *efficacy* is helpful to the understanding of the pharmacology of stimulant drugs; these terms are too often used incorrectly when using colloquial language. Efficacy refers to the therapeutic effects that can be achieved by a drug, whereas potency describes the amount of the drug needed to achieve therapeutics effects. In general, potency correlates with the affinity of the drug for its target, whereas efficacy reflects how much maximal effect can be achieved when the targets are fully occupied. These two characteristics are uncorrelated.

Phenylisopropylamine (amphetamine) has a simple chemical structure resembling endogenous catecholamines (Figure 43-1). This scaffold forms the template for a wide variety of pharmacologically active substances. Although amphetamine possesses strong central stimulant effects, minor modifications can result in a broad spectrum of effects, including nasal decongestion, anorexia, vasoconstriction, antidepressant effects (for the MAO inhibitor tranylcypromine), or hallucinogenic properties (methylenedioxymethamphetamine [MDMA] and methylenedioxyamphetamine [MDA]).

The phenylisopropylamine molecule can be divided into three structural components: an aromatic nucleus, a terminal amine, and an isopropyl side chain. Substitution on the aromatic nucleus generally produces less potent, if not entirely inactive, stimulants.[4] The substitution of two or more methoxy groups and the addition of ethyl, methyl, or bromine groups on the aromatic nucleus creates hallucinogens of various potencies. MDMA ("Ecstasy") is built on a methamphetamine backbone, with a dimethoxy ring extending from the aromatic group. If a similar compound is synthesized with a primary amine (without the methyl group), then it creates "Love" (MDA). Substitution at the amine group is the most common alteration. Methamphetamine, which is characterized by an additional methyl group attached to the amine (a secondary substituted amine), is more potent than amphetamine, probably because of increased CNS penetration. An intact isopropyl side chain appears to be needed to maintain stimulant efficacy. Changing the propyl to an ethyl side chain, for example, creates phenylethylamine and an endogenous neuroamine, which has mood- and energy-enhancing properties but is less potent and has a much shorter half-life than amphetamine.

The pharmacologic effects of most amphetamine derivatives are isomer specific. These differential effects occur both at the pharmacokinetic level (absorption, brain penetration, metabolism, distribution volume, elimination) and in terms of pharmacodynamic profile (actual pharmacologic effects). D-Amphetamine, for example, is a far more potent stimulant than L-amphetamine. In electroencephalographic (EEG) studies, D-amphetamine is four times more potent in inducing wakefulness than L-amphetamine.[5] The relative effects of the D- and L-isomers of amphetamine on norepinephrine (NE) and DA transmission explains some of these pharmacodynamic differences (for details, see the pharmacology discussion for each compound). Not all effects are stereospecific, however. For example, both enantiomers are equipotent in suppressing rapid eye movement (REM) sleep in humans and rats and in producing amphetamine psychosis.

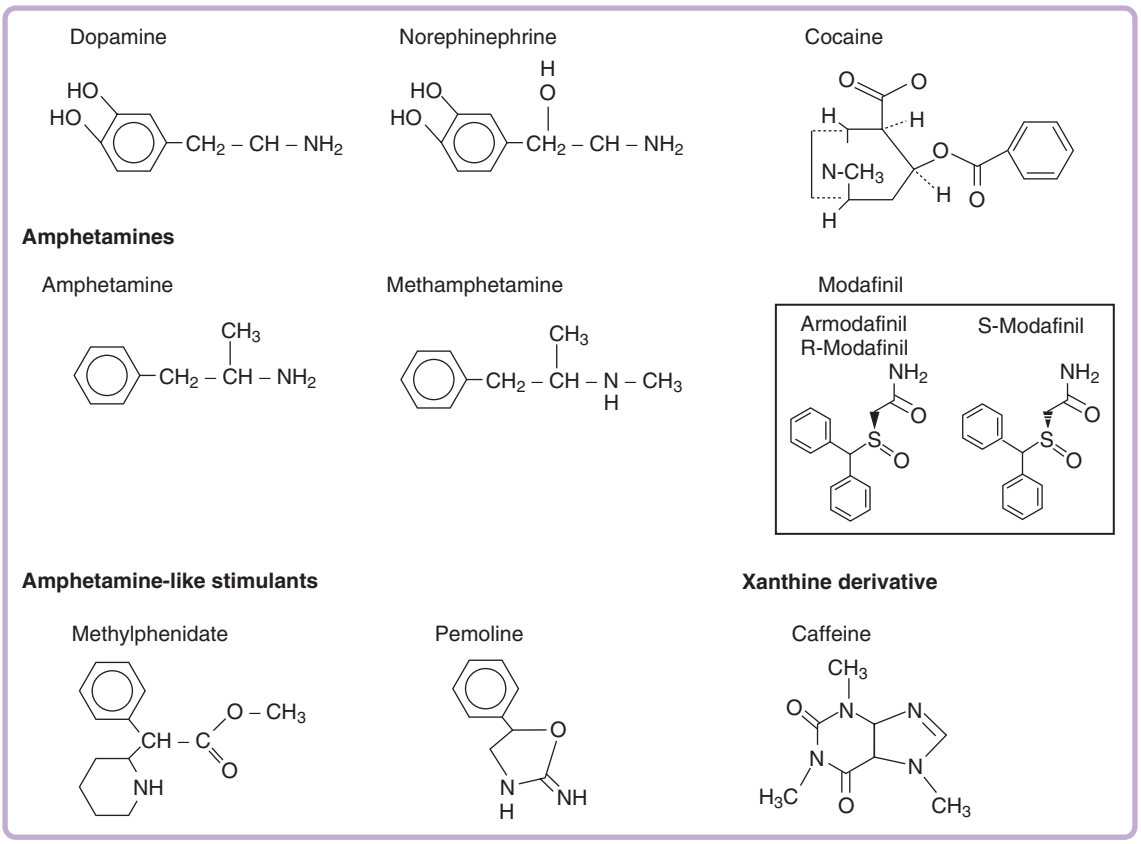

Figure 43-1 Chemical structures of amphetamine-like stimulants, modafinil, armodafinil, and xanthine derivatives compared with catecholamine.

Amphetamine-like compounds, such as methylphenidate, pemoline, and fencamfamin, are structurally similar to amphetamines; all compounds include a benzene core with an ethylamine group side chain (see Figure 43-1). Both methylphenidate and pemoline were commonly used for the treatment of EDS in narcolepsy, but pemoline has been withdrawn from the market in several countries because of liver toxicity (Table 43-1). The most commonly used commercially available form of methylphenidate is a racemic mixture of both a D- and L-enantiomer. In this preparation, the D-methylphenidate mainly contributes to its clinical effects, especially after oral administration. This is because L-methylphenidate, but not D-methylphenidate, undergoes a significant first-pass metabolism (by deesterification to L-ritalinic acid). A single isomer form of D-methylphenidate is also marketed under the brand name of Focalin.

Cocaine also mediates its psychostimulant effects by blocking catecholamine reuptake (mainly DA), but its structure is different from amphetamine-like compounds (see Figure 43-1). The fact that cocaine and some DAT inhibitors are drugs of abuse is responsible for schedule labeling of such drugs by the U.S. Food and Drug Administration (FDA).

Amphetamines are highly lipid soluble molecules that are well absorbed by the gastrointestinal tract. Peak levels are achieved approximately 2 hours after oral administration, with rapid tissue distribution and brain penetration. Protein binding is highly variable, with an average volume of distribution of 5 L/kg.

Both hepatic catabolism and renal excretion are involved in the inactivation of amphetamine. Amphetamine can be metabolized in the liver through either aromatic or aliphatic hydroxylation, yielding parahydroxyamphetamine or norephedrine, respectively, both of which are biologically active. The metabolism of amphetamine and amphetamine-like compounds is pH dependent. Amphetamine is metabolized into benzoic acid (23%), which is subsequently converted to hippuric acid or to parahydroxyamphetamine (2%). This in turn is converted to parahydroxynorephedrine (0.4%). Thirty-three percent of the oral dose is excreted unchanged in the urine. Urinary excretion of amphetamine and many amphetamine-like stimulants is greatly influenced by urinary pH. At urinary pH of 5 the elimination half-life of amphetamine is short, about 5 hours, but at pH of 7.3 it increases to 21 hours. Sodium bicarbonate will delay excretion of amphetamine and prolong its clinical effects, whereas ammonium chloride will shorten amphetamine action (and can possibly induce toxicity).

Methylphenidate is almost totally and rapidly absorbed after oral administration. Methylphenidate has low protein binding (15%) and is short acting; effects last approximately 4 hours, with a half-life of 3 hours. The primary means of clearance is through the urine, in which 90% is excreted.

Molecular Targets of Amphetamine Action

The molecular targets mediating amphetamine-like stimulant effects are complex and vary depending on the specific

Table 43-1 Commonly Used Pharmacologic Compounds for Excessive Daytime Sleepiness

Stimulant Compound	Usual Daily Doses*	Half-Life (hr)	Side Effects, Notes
Amphetamines and Amphetamine-like CNS Stimulants			
D-Amphetamine sulfate (schedule II)	5–60 mg (15, 100 mg)	16–30	Irritability, mood changes, headaches, palpitations, tremors, excessive sweating, insomnia
Methamphetamine HCl[†] (schedule II)	5–60 mg (15, 80 mg)	9–15	Same as D-amphetamine; may have a greater central over peripheral effects than D-amphetamine[‡]
Methylphenidate HCl (schedule II)	10–60 mg (30, 100 mg)	~3	Same as amphetamines; better therapeutic index than D-amphetamine with less reduction of appetite or increase in blood pressure; short duration of action
Pemoline (schedule IV)	20–115 mg (37.5, 150 mg)	11–13	Less sympathomimetic effect, milder stimulant, slower onset of action; occasionally produces liver toxicity; had been withdrawn from the U.S. market
Dopamine and Norepinephrine Uptake Inhibitor			
Mazindol (schedule IV)	2–6 mg (NA)	10–13	Weaker CNS stimulant effects; anorexia, dry mouth, irritability, headaches, gastrointestinal symptoms; reported to have less potential for abuse
Other Agents for Treatment of EDS			
Modafinil[§] (schedule IV)	100–400 mg (NA)	9–14	No peripheral sympathomimetic action; headaches, nausea; reported to have less potential for abuse
Armodafinil (schedule IV)	100–300 mg (NA)	10–15	Similar to those of modafinil
MAO Inhibitors with Alerting Effect			
Selegiline	5–40 mg (NA)	2	Low abuse potential; partial (10%-40%) interconversion to amphetamine
Xanthine Derivative			
Caffeine[¶]	100–200 mg (NA)	3–7	Weak stimulant effect; 100 mg of caffeine roughly equivalent to one cup of coffee; palpitations, hypertension

*Dosages recommended by the American Sleep Disorders Association are listed in parentheses (usual starting dose and maximal dose recommended).
[†]Methamphetamine is reported to have more central effects and may predispose more to amphetamine psychosis. The widespread misuse of methamphetamine has led to severe legal restriction on its manufacture, sale, and prescription in many countries.
[‡]L-Amphetamine (dose range, 20-60 mg) is not available in the United States but probably has no advantage over D-amphetamine in the treatment of narcolepsy (slightly weaker stimulant).
[§]The half-life of the s-enantiomer of modafinil is short (3-4 hr) and thus the half-life of racemic modafinil mostly reflects the half-life of armodafinil (r-enantiomer).
[¶]Caffeine can be brought without prescription in the form of tablets (No Doz, 100 mg; Vivarin, 200 mg caffeine) and is used by many patients with narcolepsy before diagnosis.
CNS, Central nervous system; EDS, excessive daytime sleepiness; MAO, monoamine oxidase; NA, not applicable.

analogue or isomer used and the dose administered. Amphetamine increases catecholamine (DA and NE) release and inhibits reuptake from presynaptic terminals. This results in an increase in catecholamine concentrations in the synaptic cleft and enhances postsynaptic stimulation. The presynaptic modulations by amphetamines are mediated by specific catecholamine transporters[6] (Figure 43-2). Axelrod and colleagues first demonstrated that epinephrine could be rapidly and selectively taken up by the heart, spleen, and glandular organs, each of which has significant sympathetic innervation. It was subsequently discovered that NE-containing neurons bind and take up NE against a concentration gradient, suggesting the existence of selective norepinephrine transporters (NETs). Further experiments also found that these transporters can not only carry catecholamine back into nerve terminals but can release catecholamines through reverse efflux.

The molecules responsible, the dopamine transporter (DAT) and the NET, have now been cloned and characterized. The DAT and NET proteins are about 620 amino acid proteins with 12 putative membrane-spanning regions. Amphetamine derivatives are known to inhibit the uptake and enhance the release of DA, NE, or both by interacting with the DAT and the NET. These transporters normally move DA and NE from the outside to the inside of the cell. This process is sodium dependent; sodium and chloride bind to the

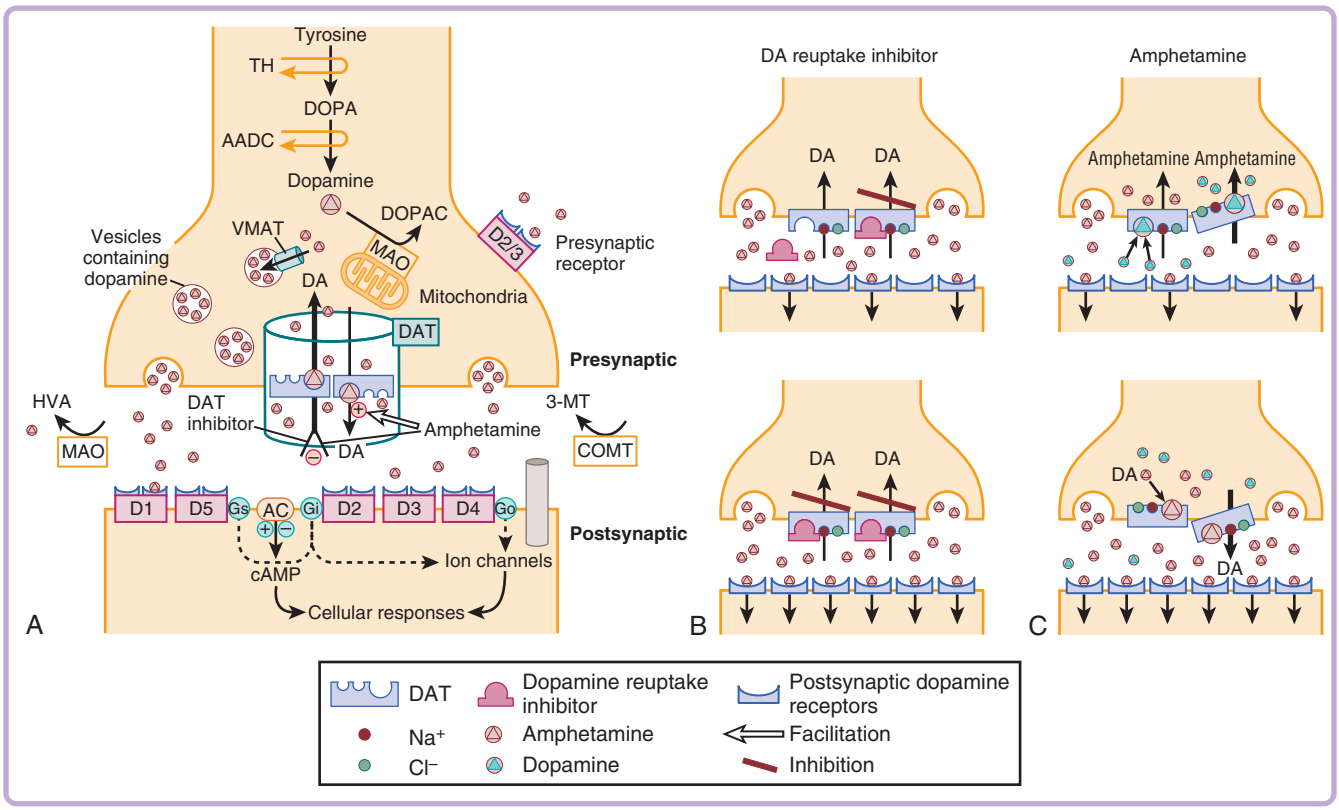

Figure 43-2 A, Schematic representations of dopaminergic terminal neurotransmission in relation to mode of action of dopamine (DA) reuptake inhibitors and amphetamine and effects of DA reuptake inhibitors and amphetamines at the dopaminergic nerve terminal. Dopamine transporter (DAT) is one of the most important molecules located at the dopaminergic nerve terminals and regulates dopaminergic neurotransmission. Amphetamine interacts with the DAT carrier to facilitate DA release from the cytoplasm through an exchange diffusion mechanism. At higher intracellular concentrations, amphetamine also disrupts vesicular storage of DA and inhibits monoamine oxidase (MAO). Both these actions increase cytoplasmic DA concentrations. Amphetamine also inhibits DA uptake by virtue of its binding to and transport by the DAT. These mechanisms all lead to an increase in DA synaptic concentrations, and these are independent of the phasic activity of the neurons. Increased synaptic concentration of DA stimulates postsynaptic DA receptors (D1 type [1, 5] and D2 type [2, 3, 5] receptors). **B,** Sodium and chloride bind to the DAT to immobilize it at the extracellular surface. This alters the conformation of the DA binding site on the DAT to facilitate substrate (i.e., DA) binding. DAT reuptake inhibitors bind to DAT competitively and inhibit DA-DAT bindings, resulting in increasing DA concentrations in the synaptic cleft. **C,** Amphetamine, in competition with extracellular DA, binds to the transporter. Substrate binding allows the movement of the carrier to the intracellular surface of the neuronal membrane, driven by the sodium and amphetamine concentration gradients, resulting in a reversal of the flow of DA uptake. Amphetamine dissociates from the transporter, making the binding site available to cytoplasmic DA. DA binding to the transporter enables the movement of the transporter to the extracellular surface of the neuronal membrane, as driven by the favorable DA concentration gradient. DA dissociates from the transporter, making the transporter available for amphetamine and thus another cycle. AADC, Aromatic acid decarboxylase; AC, adenylyl cyclase; cAMP, cyclic adenosine monophosphate; COMT, catechol-Omethyltransferase; D1 to D5, dopamine receptors 1 through 5; DOPA, 3,4-dihydroxyphenylalanine; DOPAC, dihydroxyphenylacetic acid; Gi, Go, and Gs, protein subunits; HVA, homovanillic acid; TH, tyrosine hydroxylase; VMAT, vesicular monoamine transporter.

DAT or NET to immobilize it at the extracellular surface and to alter the conformation of the DA or NE binding site so that it facilitates substrate binding. Substrate binding allows movement of the carrier to the intracellular surface of the neuronal membrane, driven by sodium concentration gradients. Interestingly, in the presence of some drugs such as amphetamine, the direction of transport appears to be reversed (see Figure 43-2). DA and NE are thus moved from the *inside* of the cell to the *outside* through a mechanism called exchange diffusion, which occurs at low doses (1 to 5 mg/kg) of amphetamine. This mechanism, rather than a simple inhibition of monoamine reuptake, is involved in the enhancement of extracellular catecholamine release by amphetamine. It explains why amphetamine in particular is more potent than expected based on its relatively low binding affinity for DAT and NET.[7,8] A recent in vitro experiment has shown that amphetamine transport causes an inward sodium current.[6] As intracellular sodium ions become more available, a DAT-mediated reverse transport of DA occurs, producing DA release through the DAT transporter.

At higher dose other effects are involved. Increased serotonin (5-HT) release is also observed. Moderate to high doses of amphetamine (>5 mg/kg) also interact with the vascular monoamine transporter 2 (VMAT2).[6] The vesicularization of the monoamines (DA, NE, 5-HT, and histamine) in the CNS is dependent on VMAT2; VMAT2 regulates the size of the vesicular and cytosolic DA pools. Amphetamine is highly lipophilic and easily enters nerve terminals by diffusing across plasma membranes. Once inside, amphetamine depletes vesicular monoamine stores by several mechanisms. First, it binds directly, albeit with low affinity, to VMAT2, thereby inhibiting vesicular uptake. Second, amphetamine, a weak base, diffuses across the vesicular membrane in its uncharged (lipophilic) form and accumulates in the granules in its charged form (because of the lower pH of the synaptic vesicle interior). As vesicular amphetamine concentration increases, the buffering capacity of the catecholamine-containing vesicle is lost. The vesicular pH gradient diminishes, a loss of the free energy necessary for monoamine sequestration occurs, and vesicular monoamine uptake decreases. In addition, the collapse of the gradient purportedly results in a competition for protons between the native monoamines and amphetamine, thereby increasing uncharged vesicular neurotransmitter concentrations. All these mechanisms lead to a diffusion of the native monoamines out of the vesicles into the cytoplasm along a concentration gradient. Amphetamine can therefore be viewed as a physiologic VMAT2 antagonist that releases the vascular DA and NE loaded by VMAT2 into the cytoplasm. The high doses of amphetamine also inhibit MAO activity. These mechanisms, as well as the reverse transport and the blocking of reuptake of DA and NE by amphetamine, all lead to an increase in NE and DA synaptic concentrations,[6] and these are independent on the phasic activity of the neurons.

Various amphetamine derivatives have slightly different effects on all these systems. For example, methylphenidate also binds to the NET and DAT and enhances catecholamine release. It has less effect, however, on the VMAT granular storage site than native amphetamine. Similarly, D-amphetamine has proportionally more releasing effect on the DA versus the NE system when compared with L-amphetamine. MDMA has more effect on 5-HT release than on catecholamine release. Of note, other medications acting on monoaminergic systems, including DA, NE, and 5-HT (e.g., bupropion or mazindol, see later), tend to exert their actions by simply blocking the reuptake mechanism.

Some amphetamines have neurotoxic effects on monoaminergic systems. This is well established for MDMA and serotoninergic systems in both humans and animals. Similarly, amphetamine derivatives with strong effects on monoamine release (typically methamphetamine and less so derivatives with simple monoamine reuptake inhibition effects, e.g., methylphenidate) have neurotoxic effects on DA systems at high dose in animal studies, especially in the context of repeated administration mimicking binges of stimulant abuse administration.

Presynaptic Modulation of the Dopaminergic System Primarily Mediates the Electroencephalographic Arousal Effects

Although amphetamine-like compounds are well known to stimulate catecholaminergic transmission, the exact mechanism by which they promote EEG arousal is still uncertain. A canine model of the sleep disorder narcolepsy has been used to explore its mechanism. Canine narcolepsy is a naturally occurring animal model of the human disorder.[7] Similar to human patients, narcoleptic dogs are excessively sleepy (i.e., short sleep latency), have fragmented sleep patterns, and display cataplexy.[7]

Using narcoleptic and control Doberman dogs, the effects of ligands specific for the DA (GBR-12909, bupropion, and amineptine), NE (nisoxetine and desipramine), or both the DAT and NET (mazindol and nomifensine), as well as amphetamine and a nonamphetamine stimulant, modafinil, were studied to dissect wake-promoting mechanisms.[8] The results indicate that prototypical DA uptake inhibitors such as GBR-12909 and bupropion, dose-dependently increased EEG arousal in narcoleptic dogs, whereas nisoxetine and desipramine, two potent NE uptake inhibitors, had no effect on EEG arousal at doses that almost completely suppressed REM sleep and cataplexy (Figure 43-3).[8] Furthermore, the EEG arousal potency of various DA uptake inhibitors correlated tightly with in vitro DAT-binding affinities (see Figure 43-3), whereas a reduction in REM sleep correlated with in vitro NET-binding affinities,[8] suggesting that DA uptake inhibition is critical for the EEG arousal effects of these compounds.

D-Amphetamine has a relatively low DAT-binding affinity but potently (i.e., need for a low mg/kg dose) promotes alertness (see Figure 43-3). It is also generally considered more efficacious (i.e., can produce more alertness with high dose) than pure DAT reuptake inhibitors in promoting wakefulness. As described in the pharmacology discussion, D-amphetamine not only inhibits DA reuptake but also enhances DA release (at lower dose by exchange diffusion and at higher dose by antagonistic action against VMAT2) and inhibits monoamine oxidation to prevent DA metabolism. The DA-releasing effects of amphetamine are likely to explain the unusually high potency and efficacy of amphetamine in promoting EEG arousal.

In vitro studies have demonstrated that the potency and selectivity for enhancing release or inhibiting uptake of DA and NE vary between amphetamine analogs and isomers.[9] Amphetamine derivatives thus offer a unique opportunity to study the pharmacologic control of alertness in vivo. To dissect wake-promoting effects of amphetamine, the effects of various amphetamine analogs (D-amphetamine, L-amphetamine, and L-methamphetamine) on EEG arousal and in vivo effects on brain extracellular DA levels were compared using narcoleptic dogs.[10] In canine narcolepsy, D-amphetamine is 3 times more potent than L-amphetamine and 12 times more potent than L-methamphetamine in increasing wakefulness and reducing slow wave sleep (see Figure 43-3, *A*).[10]

Microdialysis experiments in the same narcoleptic dogs suggest that wake-promoting effects of amphetamine derivatives correlate well with their effects on dopamine efflux (i.e., intracellular concentration, a net effect of dopamine release and dopamine uptake block). The local perfusion of D-amphetamine raised DA levels nine times above baseline (Figure 43-4, *B*).[10] D-Amphetamine also increased DA levels by up to seven times, but peak DA release was only obtained at the end of the 60-minute perfusion period. L-Methamphetamine did not change DA levels under these conditions. NE was also measured in the frontal cortex

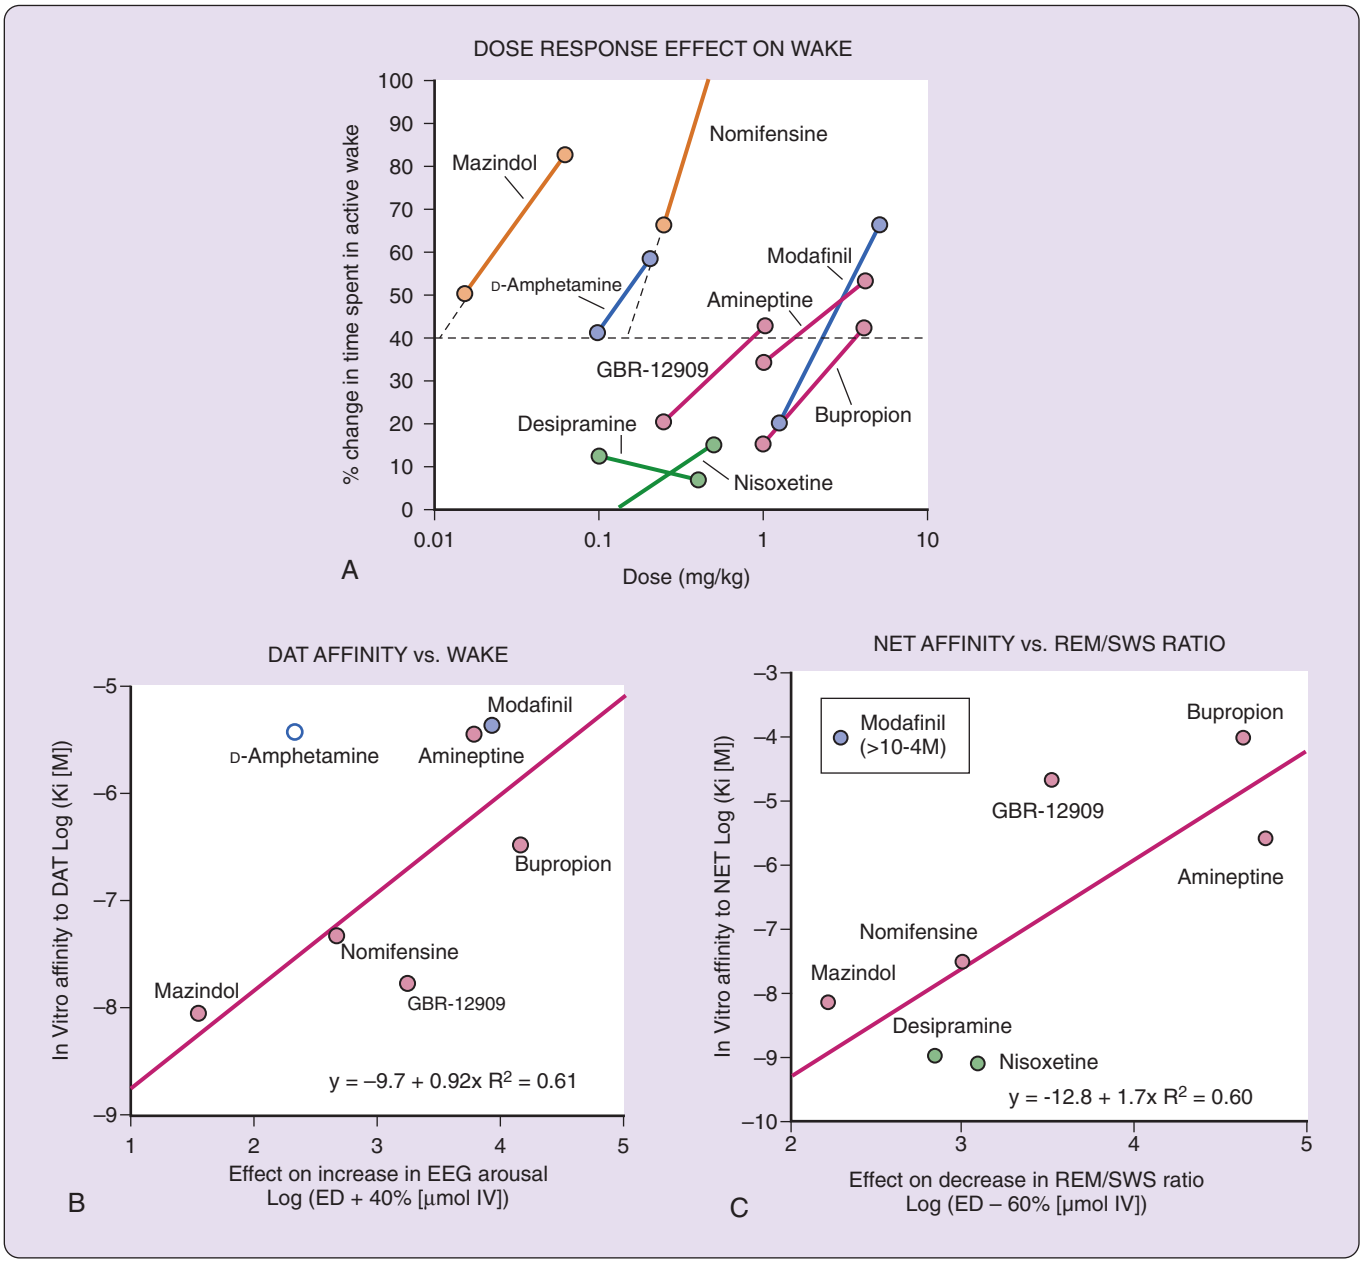

Figure 43-3 Effects of various dopamine (DA) and norepinephrine (NE) uptake inhibitors and amphetamine-like stimulants on the electroencephalographic (EEG) arousal of narcoleptic dogs and correlation between in vivo EEG arousal effects or REM sleep and in vitro DA or NE transporter binding affinities. **A,** The effects of various compounds on daytime sleepiness were studied using 4-hour daytime polygraphic recordings (10:00 to 14:00) in four to five narcoleptic animals. Two doses were studied for each compound. All DA uptake inhibitors and central nervous system (CNS) stimulants dose-dependently increased EEG arousal and reduced slow wave sleep (SWS) in comparison to vehicle treatment. In contrast, nisoxetine and desipramine, two potent NE uptake inhibitors, had no significant effect on EEG arousal at doses that completely suppressed cataplexy. Compounds with both adrenergic and dopaminergic effects (nomifensine, mazindol, D-amphetamine) were active on both EEG arousal and cataplexy. The effects of the two doses performed for each stimulant were used to approximate a dose-response curve; the drug dose that increased the time spent in wakefulness by 40% above baseline (vehicle session) was estimated for each compound. The order of potency of the compounds obtained was: mazindol > (amphetamine) > nomifensine > GBR-12909 > amineptine> (modafinil) > bupropion. **B,** In vitro DAT binding was performed using [^{3}H]-WIN 35,428 onto canine caudate membranes. Affinity for the various DA uptake inhibitors tested varied widely between 6.5 nM and 3.3 mM. In addition, it was found that both amphetamine and modafinil have low but significant affinity (same range as amineptine) for the DAT. A significant correlation between in vivo and in vitro effects was observed for all five DA uptake inhibitors and modafinil. Amphetamine, which had potent EEG arousal effects, has a relatively low DAT binding affinity, suggesting that other mechanisms, most probably monoamine-releasing effects or monoamine oxidase inhibition, are also involved. In contrast, there was no significant correlation between in vivo EEG arousal effects and in vitro NE transporter binding affinities for DA and NE uptake inhibitors. These results suggest that presynaptic enhancement of DA transmission is the key pharmacologic property mediating the EEG arousal effects of most wake-promoting CNS stimulants. **C,** In vitro NE transporter binding was performed using [^{3}H]-nisoxetine. A significant correlation between in vivo potencies on the REM/SWS and in vitro affinity to the NE transporter suggests that presynaptic modulation of NE transmission is important for the pharmacologic control of REM sleep. This may explain why most monoamine uptake inhibitors and monoamine oxidase inhibitors strongly reduce REM sleep in humans and experimental animals.

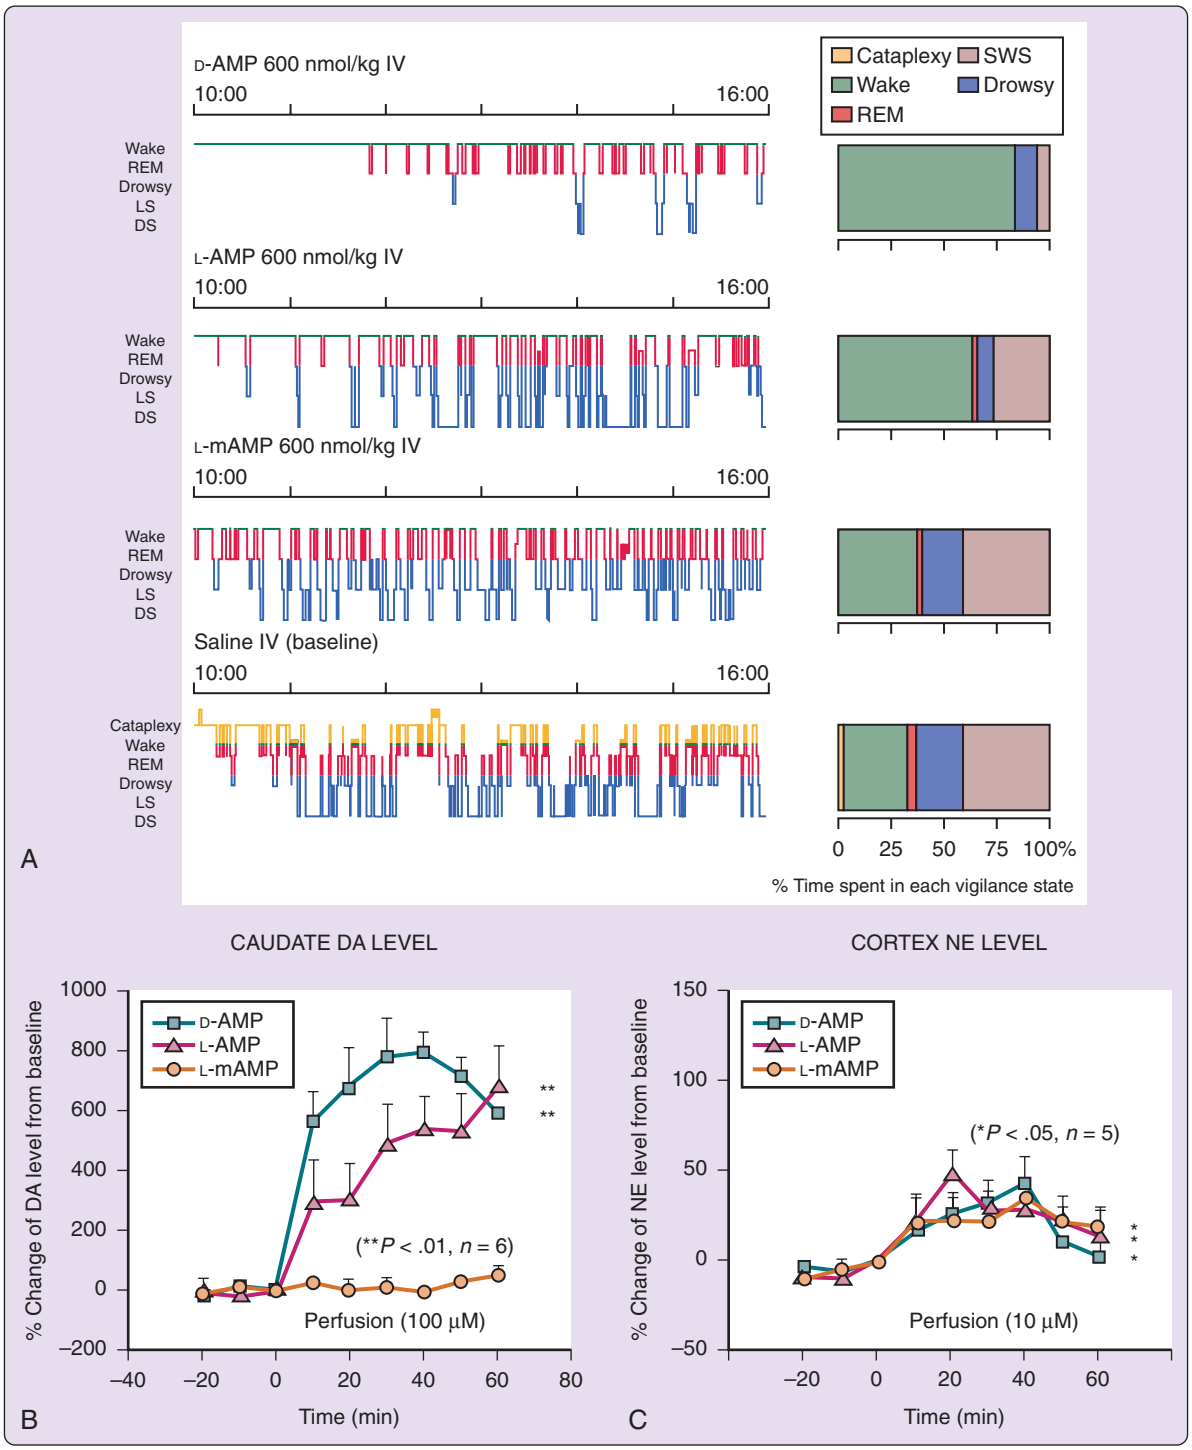

Figure 43-4 A, Effect of amphetamine derivatives on sleep parameters during 6-hour electroencephalogram (EEG) recordings in a narcoleptic dog (600 nmol/kg IV). Representative hypnograms with and without drug treatment are shown. Recordings lasted 6 hours, beginning at approximately 10:00 AM. Vigilance states are shown in the following order from top to bottom: cataplexy, wake, REM sleep, drowsy, light sleep (LS), and deep sleep (DS). The amount of time spent in each vigilance stage (expressed as % of recording time) is shown on the right side of each hypnogram. D-Amphetamine (D-AMP) was found to be more potent than L-amphetamine (L-AMP), and L-methamphetamine (L-mAMP) was found to be the least potent, whereas all isomers equipotently reduced REM sleep. **B,** Local perfusion of D-AMP (100 µM) raised dopamine (DA) levels eight times above baseline. L-AMP also increased DA levels up to seven times above baseline, but this level was obtained only at the end of the 60-minute perfusion period. L-mAMP did not change DA levels under these conditions. **C,** In contrast, all three amphetamine isomers had equipotent enhancements on norepinephrine (NE) release. These results suggest that the potency of these derivatives on EEG arousal correlated well with measurements of DA efflux in the caudate of narcoleptic dogs, whereas effects on NE release may be related to REM suppressant effects.

during perfusion of D-amphetamine, L-amphetamine, and L-methamphetamine. Although all compounds increased NE efflux, no significant difference in potency was detected among the three analogs.

The fact that the potency of amphetamine derivatives on EEG arousal correlates with effects on DA efflux in the caudate of narcoleptic dogs further confirms that the enhancement of DA transmission by presynaptic modulation mediates the wake-promoting effects of amphetamine analogs. This result is also consistent with data obtained with DAT blockers (see Figure 43-3). Considering the fact that other amphetamine-like stimulants, such as methylphenidate and pemoline, also inhibit DA uptake and enhance release of DA, presynaptic enhancement of DA transmission is likely to be the key pharmacologic property mediating wake promotion for all amphetamines and amphetamine-like stimulants. In contrast, there is little evidence that enhancing adrenergic transmission is wake promoting in animal studies.

The role of the DA system in sleep regulation was further assessed using mice, which genetically lacked the DAT gene. Consistent with a role of DA in the regulation of wakefulness, these animals have reduced non–rapid eye movement (NREM) sleep time and increased wakefulness consolidation (independently from locomotor effects).[11] The most striking finding was that DAT knockout mice were completely unresponsive to the wake-promoting effects of methamphetamine, GBR-12909, and modafinil. These results further confirm the critical role of DAT in mediating the wake-promoting effects of amphetamines and modafinil (see Figures 43-3 and 43-4)[11] (see Modafinil and Armodafinil section). Interestingly, DAT knockout animals were also found to be more sensitive to caffeine,[11] suggesting functional interactions between adenosinergic and DA systems in the control of sleep and wakefulness (see Caffeine section).

Anatomic Substrates Mediating Dopaminergic Effects on Wakefulness

Anatomic studies have demonstrated two major subdivisions of the ascending DA projections from mesencephalic DA nuclei (ventral tegmental area [VTA], substantia nigra [SN], and retrorubral field [A8]): (1) The mesostriatal system originates in the SN and retrorubral nucleus and terminates in the dorsal striatum (principally the caudate and putamen)[12]; and (2) The mesolimbocortical DA system consists of the mesocortical and mesolimbic DA systems. The mesocortical system originates in the VTA and the medial SN and terminates in the limbic cortex (medial prefrontal, anterior cingulated, and entorhinal cortices). Interestingly, DA reuptake is of physiologic importance for the elimination of DA in cortical hemispheres, limbic forebrain, and striatum, but not midbrain DA neurons.[13] It is thus possible that amphetamine, modafinil, and DA uptake inhibitors have greater effect on DA terminals of the cortical hemispheres, limbic forebrain, and striatum and that it is this effect that induces wakefulness. Local perfusion experiments of DA compounds in rats and canine narcolepsy have suggested that the VTA, but not the SN, is critically involved in EEG arousal regulation.[14] DA terminals of the mesolimbocortical DA system may thus be important in mediating wakefulness after DA-related CNS stimulant administration. The involvement of other, less studied dopaminergic cell groups, such as those located in the hypothalamus or in the ventral periaqueductal gray (recently suggested to be wake active),[15] is also possible and would be worth exploring further.

Dopamine agonists and L-DOPA (dopamine precursor) drugs typically used in the therapy of Parkinson disease are generally not strongly wake promoting in clinical practice but instead are mildly sedative. This has been explained by the primary presynaptic effect of these compounds at low dose, an effect that may in fact reduce DA transmission in some projection areas.[16]

Indications

Amphetamine and methylphenidate are primarily indicated for narcolepsy, idiopathic hypersomnia, and ADHD. Other therapeutic uses are controversial because of their abuse potential. This potential also imparts them a schedule II classification under the Controlled Substances Act of 1970. Moreover, certain states (e.g., Wisconsin) have passed even more restrictive legislation limiting the access and the use of these substances to specific indications.[17] The use of these compounds is highly regulated by federal policy and in some states requires triplicate prescription and monthly renewal.

Side Effects and Toxicology

Amphetamine releases not only DA but also NE. NE indirectly stimulates α- and β-adrenergic receptors, a profile common to all indirectly acting sympathomimetic compounds. This results in significant cardiovascular effects. α-Adrenergic stimulation produces vasoconstriction, thereby increasing both systolic and diastolic blood pressure. Heart rate may slightly slow down in reflex (this effect is more pronounced that indirect β-adrenergic stimulation on heart rate at low dose), but with large doses, tachycardia and cardiac arrhythmia may occur. Cardiac output is not modulated by therapeutic doses, and cerebral blood flow is unchanged. In general, smooth muscles respond to amphetamine as they do to other sympathomimetic drugs. There is a contractile effect on the urinary bladder sphincter. Pain and difficulty in micturition may occur.

Other acute side effects include mild gastrointestinal disturbance, anorexia, dryness of the mouth, tachycardia, cardiac arrhythmias, insomnia, restlessness, headaches, palpitations, dizziness, and vasomotor disturbances. Agitation, confusion, dysphoria, apprehension, and delirium may also occur. Other documented side effects include flushing, pallor, excessive sweating, and muscular pains. Tiredness and sleepiness, as well as lethargy and listlessness, may occur when the effects wear off, together with a mild depression of mood. For common side effects of CNS stimulant drugs in narcoleptics, refer to Table 43-1.

Common side effects occurring during long-term treatment in narcolepsy include irritability, headache, bad temper, and profuse sweating (reported by more than one third of subjects). Less common side effects are anorexia, gastric discomfort, nausea, talkativeness, insomnia, orofacial dyskinesia, nervousness, palpitations, muscle jerking, chorea, and tremor. Psychiatric symptoms, such as delusions or hallucinations, may also occur but are rather rare in narcoleptic patients who take amphetamine.

Methamphetamine (and to a lesser extent, amphetamine) can be neurotoxic at high dose. This effect is mediated by

a free radical increase, causing mitochondrial damage and decreasing adenosine triphosphate synthesis. In dopaminergic neurons, the neurotoxicity is mediated by formation of peroxynitrite, which can be reduced by antioxidants or L-carnitine. L-Carnitine is needed to transport long-chain fatty acids to mitochondria for fatty acid oxidation, preventing the generation of free radicals and peroxynitrite. MDMA, another amphetamine derivative with a preferential effect (and toxicity) on serotoninergic neurons, appears to also decrease glutathione and vitamin E in the brain. Mice deficient in vitamin E were found to have greater susceptibility to both MDMA neurotoxicity and hepatic necrosis, a finding further supporting a free radical mechanism for amphetamine toxicity.

The side-effect profile of methylphenidate is similar to that of amphetamine and includes nervousness, insomnia, and anorexia as well as dose-related systemic effects such as increased heart rate and blood pressure. Methylphenidate overdose may lead to seizures, dysrhythmias, or hyperthermia.

Abuse and Misuse of Amphetamine Stimulants

Methamphetamine, amphetamine, and methylphenidate all have clear street value for abusers. Whereas reinforcement occurs in the early stages of drug use, tolerance is common during long-term administration. Appetite-suppressing effects are also common. Interestingly, anecdotal data suggest that psychostimulant abuse in narcoleptic subjects is extremely rare,[18,19] a finding also supported by some animal data.[20] Nevertheless, there is a negative stigma associated with the administration of amphetamine-like compounds in patients with narcolepsy.

The mechanisms underlying abuse of amphetamine-like stimulants are complex but have been shown to primarily involve stimulation of the VTA-DA systems.[21] Downstream changes in adrenergic and serotoninergic systems, particularly through α_{1b}-adrenergic receptors and 5-HT_{2A}, may also be important.[22,23]

Drug-Drug Interactions

Drug-drug interactions with amphetamine and methylphenidate are generally pharmacodynamic or neurochemical in nature.[24] Small percentages of the metabolism of amphetamine and methylphenidate occurs through cytochrome P-450 2D6, and drugs that inhibit 2D6 metabolism can theoretically increase plasma levels of amphetamine. This is rarely, however, a significant problem with therapeutic doses. Tricyclic drugs inhibit the metabolism of amphetamine and amphetamine-like stimulants and enhance their behavioral effects. The combination of amphetamine with tricyclics could theoretically further blood pressure increases (because of the combined effects of NE reuptake and release), but in practice amphetamine 10 to 16 mg, methylphenidate 10 to 60 mg, and mazindol 2 to 12 mg have been given safely with imipramine and clomipramine, 10 to 100 mg, to treat narcolepsy-cataplexy. The dosage of amphetamine required to control narcolepsy may be reduced by one third with the simultaneous use of tricyclic drugs. MAO-A inhibitors (e.g., nialamide, pargyline, and tranylcypromine) inhibit the removal of amphetamine by the liver and greatly potentiate the behavioral effects of amphetamine.[25] Coadministration of MAO inhibitors and amphetamine derivatives is generally contraindicated. In contrast to tricyclics and MAO-A inhibitors, haloperidol, reserpine, and atropine have no effect on amphetamine hydroxylation in the animal liver, although they may reduce the central effects of amphetamine.[26] Chlorpromazine, trifluoperazine, perphenazine, and thioproperazine increase the half-life of amphetamine in the brain but inhibit central behavioral effects, such as stereotyped behavior in animals and euphoria in humans.[26] Hypnotic drugs will prevent many behavioral effects of amphetamines, although chlordiazepoxide and diazepam increase amphetamine tissue levels.[26]

MODAFINIL AND ARMODAFINIL

Racemic modafinil (2-[(diphenylmethyl)sulfinyl]acetamide; see Figure 43-1) was first developed in France and has been available in Europe since 1986. Modafinil was first approved in 1998 in the United States for the treatment of narcolepsy. More recently, it has been approved for shift work sleep disorder and for the treatment of residual sleepiness in treated with obstructive sleep apnea syndrome. Modafinil is a primary metabolite of adrafinil, a vigilance-promoting compound developed in France in the 1970s. Modafinil lacks adrafinil's terminal amide hydroxy group (see Figure 43-1) and is better tolerated.

Pharmacokinetics

Modafinil is rapidly absorbed but slowly cleared. It is approximately 60% bound to plasma proteins and a volume of distribution of 0.8 L/kg, suggesting that the compound is readily able to penetrate into tissues. Its half-life is 9 to 14 hours. Up to 60% of modafinil is converted into modafinil acid and modafinil sulfone, both of which are inactive metabolites. Metabolism primarily occurs through cytochrome P-450 3A4/5, but the compound has also been reported to induce P-450 2C19 in vitro.[27] Modafinil is currently available as a racemic mixture of two active isomers and as an r-isomer-only preparation (armodafinil). Importantly, the r-enantiomer of modafinil has a half-life of 10 to 15 hours, which is longer than that of the s-enantiomer (3 to 4 hours).[28] The dual pharmacokinetic properties of the racemic mixture may explain why modafinil is often more potent when taken twice per day at the beginning of therapy, during the period of drug accumulation.

Indications

Modafinil is one of the few compounds that have been specifically developed for the treatment of narcolepsy. Early clinical trials in France and Canada showed that modafinil 100 to 300 mg is effective in improving EDS in narcolepsy and hypersomnia without interfering with nocturnal sleep, but that it has limited efficacy in cataplexy and other symptoms of abnormal REM sleep.[29-31] Pharmacologic experiments in canine narcolepsy also demonstrated that modafinil has no effects on cataplexy, but it significantly increases time spent in wakefulness.[32] A double-blind trial of 283 narcoleptic subjects in 18 centers in the United States revealed that 200 mg and 400 mg of modafinil significantly reduced EDS and improved patients' overall clinical condition.

Armodafinil was approved by the FDA in 2007 for the treatment of sleepiness in association with narcolepsy, treated obstructive sleep apnea syndrome, and shift work sleep

disorder (i.e., for the same indications as those of racemic modafinil).[28] Armodafinil has been shown to be potent for a longer period of time after administration. In patients in whom once-daily modafinil does not cover the entire day, armodafinil may be useful. Further, lower doses of armodafinil, 150 mg and 250 mg, were used in a phase III trial, whereas earlier modafinil trials used 200 mg and 400 mg. Armodafinil is available at lower doses than modafinil, suggesting an improved safety profile. Although armodafinil may not be a revolutionary improvement compared with modafinil, it may have its place in the therapeutic arsenal.[28]

In addition to the FDA-approved indications for modafinil and armodafinil, several reports have suggested that modafinil is also effective for the treatment of ADHD, fatigue in multiple sclerosis, and EDS in myotonic dystrophy or Prader-Willi syndrome.[33] Modafinil is also being used in the treatment of periodic hypersomnia (Klein-Levin syndrome), for which treatment immediately after initiation of the episode may be critical.[34]

Side Effects

Modafinil is well tolerated. The most frequent reported side effects are headache and nausea.[35] In addition, however, modafinil, because of its dual hepatic and renal elimination profile, should be used at lower dose in hepatic and renal insufficiency cases, although dosage recommendations in such patients cannot be made.[33] Modafinil has a number of potential drug interactions. In vitro, modafinil produces a reversible inhibition of CYP2C19 in human liver microsomes. It also causes a small but concentration-dependent induction of CYP1A2, CYP2B6, and CYP3A4 activities and suppression of CYP2C9 activity in primary cultures of human hepatocytes. Clinical studies have been conducted to examine the potential for interactions with methylphenidate, dexamfetamine, warfarin, ethinylestradiol, and triazolam. The most substantive interactions observed were with ethinylestradiol and triazolam, apparently through induction of CYP3A4, primarily in the gastrointestinal system. For this reason, it is suggested that women taking low-estrogen contraception be informed of alternative or concomitant methods of contraception. Interestingly, modafinil has been shown to be safe and to have additive effects on alertness when administered with sodium oxybate in narcolepsy.

Several factors make modafinil an attractive alternative to amphetamine-like stimulants. First, animal studies suggest that the compound does not affect blood pressure as much as amphetamines do; only high doses (800 mg) have been found to be associated with higher rates of tachycardia and hypertension. Recent clinical studies showed only small average increases in mean systolic and diastolic blood pressure in patients receiving armodafinil compared with placebo. Increased monitoring of blood pressure may be appropriate in patients taking modafinil. Second, data obtained to date suggest that dependence is limited in humans with this compound,[29,36] although a recent animal study suggests that cocaine-like discriminative stimulus and reinforcing effects of modafinil in rats and monkeys. Most notably, modafinil is almost certainly used as a convenience drug by some to fight sleepiness resulting from sleep deprivation or jet lag. Modafinil is not attractive to cocaine or stimulant abusers and does not have a high street value. Third, modafinil has minimal effects on the neuroendocrine system. In a study of healthy volunteers who were sleep deprived for 36 hours, those who received modafinil did not differ from those who did not with respect to cortisol, melatonin, and growth hormone levels.[37] Fourth, clinical experience suggests that the pharmacologic profiles of modafinil might be qualitatively different from those observed with amphetamine.[29] In general, patients feel less irritable or agitated with modafinil than with amphetamines[29] and do not experience severe rebound hypersomnolence (seen in patients with amphetamine) after modafinil is eliminated. This differential profile is substantiated by animal experiments. In rats and dogs, modafinil does not increase locomotion beyond the effect expected in association with increased wakefulness.[32,38] Similarly, modafinil acutely decreases both REM and NREM sleep in rats for up to 5 to 6 hours, but the effect is not followed by a rebound hypersomnolence. This profile contrasts with the intense recovery sleep seen after amphetamine-induced wakefulness.[39] The safety profile of modafinil is likely the basis for the fact that it has replaced amphetamine-like stimulants as a first-line treatment for EDS in narcolepsy.[40]

Mechanism of Action

The mechanism of action of modafinil-armodafinil is the subject of controversy, although in our opinion, it is, as in the case of other stimulants, most likely related to DAT inhibition. Because there are a limited number of studies addressing the mode of action of armodafinil, this section mostly discusses the actions of the racemic modafinil mixture. Modafinil-armodafinil has not been shown to bind to or inhibit receptors or enzymes for most known neurotransmitters, with the exception of the DAT protein.[41,42] In vitro, modafinil-armodafinil binds to the DAT and inhibits dopamine reuptake.[28,41,42] These binding inhibitory effects have been shown to be associated with increased extracellular DA levels in the striatum of rats and dogs, suggesting functional effects. Finally and most important, modafinil effects on alertness are entirely abolished in mice without the DAT protein[11] and in animals lacking D1 and D2 receptors.[43] A similar abolition of wake promotion in DAT knockout mice is also observed with amphetamine and GBR-12909 (a selective DAT blocker), drugs known to work through the DAT. Modafinil promotes wakefulness in hypocretin-deficient narcolepsy. Modafinil also promote wakefulness in noradrenaline-depleted animals (by DSP-4 administration)[44] and in histamine-deficient animals (histidine decarboxylase knockout mice),[45] suggesting that the wake-promoting effects of modafinil are seen independent from the availability of these wake-promoting neurotransmitters.

Given these similarities in mechanism to other DAT inhibitors, it is puzzling that modafinil has a low potential for abuse, a property that we believe may be due to the insolubility of the compound (inability to use another formulation, e.g., intravenously), its low potency (impossibility to greatly increase the dose), its slow absorption (no rapid brain effects), or its atypical binding interaction with the DAT transporter.

Adrenergic effects have also been suggested to be involved in the wake promotion effects of modafinil, but we believe these to be insignificant in vivo. When first introduced, an involvement of α_1-adrenergic systems was suggested as the

primary mode of action of modafinil on wakefulness, based on the ability of the α_1 antagonist, prazosin, to antagonize modafinil-induced increases in motor activity in mice and wakefulness in cats. Problematically, however, modafinil does not bind α_1 receptors in vivo (Ki $>10^{-3}$ M, obtained from prazosin binding using canine cortex).[32] It also does not produce smooth muscle contraction in vas deferens preparations and is still wake promoting in noradrenaline-depleted animals (see earlier).[44] Further, the hyperlocomotion produced by amphetamine, like that of modafinil, also largely depends on α_{1b} receptors, a finding now explained by remodeling of the DA system in α_1 knockout mice.[46] Finally, previous studies in the canine model of narcolepsy have shown that α_1-adrenergic agonists are potent anticataplectic agents[47] and have significant acute hypertensive effect. Modafinil has neither anticataplectic activity nor hypertensive effects, suggesting that its alerting properties are unrelated to adrenergic α_1 stimulation.

Clinical observations provide even stronger evidence that modafinil is not a primarily adrenergic compound. Amphetamine and adrenergic reuptake blockers cause dilation of the pupils by increasing NE signaling, but modafinil has no effect on pupil size. Some studies have noted slight increases in heart rate or blood pressure with high doses of modafinil. However, these changes were small, and most clinical studies on modafinil, including a meta-analysis of six large clinical trials of modafinil (the most comprehensive study on this issue), have found no changes in heart rate or blood pressure. In contrast, adrenergic reuptake blockers are well known to slightly increase blood pressure and heart rate. These clinical observations suggest that at usual clinical doses, modafinil does not increase adrenergic signaling in humans.

Interestingly, Madras and colleagues[48] recently reported, in a study involving rhesus monkeys undergoing positron emission tomography (PET), that modafinil (given intravenously) occupied striatal DAT sites (5 mg/kg, 35%; 8 mg/kg, 54%). In the thalamus, modafinil occupied NET sites (5 mg/kg, 16%; 8 mg/kg, 44%) (Figure 43-5). The authors also showed that modafinil inhibited [^{3}H]-dopamine (IC_{50} = 6.4 M)

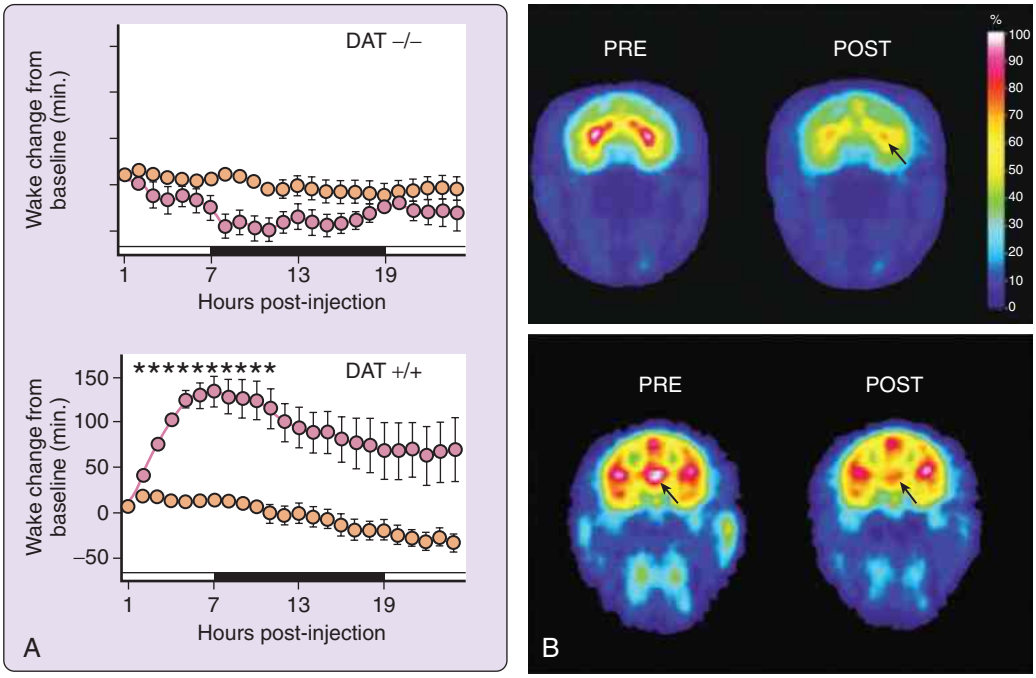

Figure 43-5 **A,** Wake-promoting effects of modafinil were completely abolished in dopamine transporter (DAT) knockout (KO) mice, suggesting that intact DAT function is required for the mediation of wake-promoting effects of modafinil. **B,** Modafinil (8 mg/kg) occupancy by the DAT in caudate putamen is shown as detected by positron emission tomography (PET) of the DAT with [^{11}C]CFT. *Left,* an adult rhesus monkey was injected with [^{11}C]CFT and scanned over 60 minutes to develop baseline measures of DAT-binding potential in the caudate putamen. Images were color-transformed to display occupancy of the DAT with [^{11}C]CFT, with highest levels detected in caudate putamen (*white-red*), as designated by the *arrow*, and lowest levels in *blue-purple*. Regions of interest are drawn over the caudate putamen. *Right,* After decay of [^{11}C]CFT radioactivity, modafinil was injected intravenously, and [^{11}C]CFT was injected again 1 hour later. [^{11}C]CFT accumulation was significantly lower compared with baseline levels of accumulation (*left*). **C,** Modafinil (8 mg/kg) occupancy by the norepinephrine transporter (NET) in the thalamus, as detected by PET imaging of the NET with [^{11}C]MeNER. *Left,* an adult rhesus monkey was injected with [^{11}C]MeNER and scanned over 60 minutes to develop baseline measures of NET binding potential in the thalamus. Images were color-transformed to display occupancy of the NET by [^{11}C]MeNER, with high levels detected in the thalamus (*white-red*), as designated by the *arrow*, and lowest levels in *blue-purple*. Regions of interest are drawn over the thalamus. *Right,* after decay of [^{11}C]MeNER radioactivity, modafinil was injected intravenously, and 1 hour later, [^{11}C]MeNER was injected. [^{11}C]MeNER accumulation was significantly lower compared with baseline levels of accumulation. (Modified from Wisor JP, Nishino S, Sora I, et al. Dopaminergic role in stimulant-induced wakefulness. *J Neurosci* 2001;21:1787–94; and Madras BK, Xie Z, Lin Z, et al. Modafinil occupies dopamine and norepinephrine transporters in vivo and modulates the transporters and trace amine activity in vitro. *J Pharmacol Exp Ther* 2006;319:561–9.).

transport 5 times and 80 times more potently than [^{3}H]-norepinephrine (IC_{50} = 35.6 M) and [^{3}H]-5-HT (IC_{50} = 500 M) transport, respectively, in cell lines that expressed the human DAT, NET, and 5-HT transporter. These data provide compelling evidence that modafinil occupies the DAT in the living brains of rhesus monkeys, consistent with the DAT hypothesis, but suggest that modafinil may also act on NET, depending on drug dose, brain structure, and other physiologic conditions.

Furthermore a recent human PET study in 10 healthy humans with [^{11}C]-cocaine (DAT radioligand) and [^{11}C]-raclopride (D2/D3 radioligand sensitive to changes in endogenous dopamine) also demonstrated that modafinil (200 mg and 400 mg given orally) decreased [^{11}C]-cocaine-binding potential in caudate (53.8%; $P < .001$), putamen (47.2%; $P < .001$), and nucleus accumbens (39.3%; $P = .001$),[49] the results being consistent with the DAT hypothesis. In addition, modafinil also reduced [^{11}C]-raclopride-binding potential in caudate (6.1%, $P = .02$), putamen (6.7%; $P = .002$), and nucleus accumbens (19.4%; $P = .02$) (see Figure 43-5), suggesting that the increases in extracellular dopamine were caused by DAT blockades.[49] These results are highly consistent with the previously mentioned results of the animal studies; the effects of modafinil on alertness are entirely abolished in mice without the DAT protein[11] and in animals lacking D1 and D2 receptors.[43]

MAZINDOL

Mazindol is a schedule IV controlled drug that is rarely used in the United States. At 2 to 8 mg daily, mazindol produces central stimulation, a reduction in appetite, and an increase in alertness but has little or no effect on mood or the cardiovascular system.[50] Mazindol is effective for the treatment of both EDS and cataplexy in humans[51] and in canine narcolepsy, possibly owing to its blocking properties of DA and NE reuptake.[42] This compound has a high affinity for DAT and NET,[42] yet interestingly this compounds has a low abuse potential. Problematically, however, mazindol often causes significant side effects, including anorexia, gastrointestinal discomfort, insomnia, nervousness, dry mouth, nausea, constipation, urinary retention, and occasionally angioneurotic edema, vomiting, and tremor.

BUPROPION

Bupropion is not scheduled by the U.S. Drug Enforcement Administration. Although the selectivity for the dopamine transporter is not absolute, bupropion blocks DA uptake. Bupropion shows a weak inhibition of NE reuptake and very limited serotoninergic effects. Although not indicated for these uses, bupropion may be useful for the treatment of EDS associated with narcolepsy at 100 mg three times daily.[42,52] It may be especially useful in cases associated with atypical depression.[52] Risk for convulsion increases dose dependently (0.1% at 100 to 300 mg; 0.4% at 400 mg).

SELEGILINE (L-DESPRENYL)

Selegiline is a methamphetamine derivative and a potent, irreversible, MAO-B selective inhibitor primarily used for the treatment of Parkinson disease.[53,54] Because it is often considered a simple MAO-B inhibitor, it is worth mentioning that selegiline is an amphetamine precursor. This compound is metabolized into L-amphetamine (20% to 60% in urine) and L-methamphetamine (9% to 30% in urine).[53]

In the canine model of narcolepsy, selegiline (2mg/kg given orally) was demonstrated to be an effective anticataplectic agent, but this effect was found to be mediated by its amphetamine metabolites rather than MAO-B inhibition.[55] Several trials in human narcolepsy have demonstrated a good therapeutic efficacy of selegiline in both sleepiness and cataplexy with relatively few side effects.[56,57] Selegiline 10 mg daily has no effect on the symptoms of narcolepsy, but 20 to 30 mg improves alertness and mood and reduces cataplexy, showing an effect comparable to D-amphetamine at the same dose. Selegiline may be an interesting alternative to the use of more classic stimulants because its potential for abuse has been reported to be very low.

ATOMOXETINE AND REBOXETINE

Atomoxetine and reboxetine (in Europe) are selective adrenergic reuptake inhibitors. Both compounds were developed as antidepressants, but atomoxetine is now mainly used in the therapy of ADHD.[58] Although these compounds are not stimulants per se, they are slightly wake promoting[59,60] and reduce REM sleep. These compounds can be helpful in some cases of narcolepsy and idiopathic hypersomnia. Atomoxetine needs twice-daily administration owing to its short half-life. Reboxetine was shown to reduce MSLT mean sleep latency in narcoleptic patients.[59] These compounds, however, increase heart rate and blood pressure. Sexual side effects are also common, but there is no risk for abuse.

CAFFEINE

Caffeine, a xanthine derivative isolated from plants, may be the most popular and widely consumed CNS stimulant in the world. An average cup of coffee contains 50 to 150 mg of caffeine. Tea, cola drinks, chocolate, and cocoa all contain significant amounts of caffeine. Caffeine can also be bought over the counter (No Doz, 100 mg caffeine; Vivarin, 200 mg caffeine) and is commonly used by narcoleptic patients before diagnosis.

Taken orally, caffeine is rapidly absorbed. The half-life of caffeine is 3.5 to 5 hours. The behavioral effects of caffeine include increased mental alertness, a faster and clearer flow of thought, wakefulness, and restlessness.[61] Fatigue is reduced and sleep-onset delayed.[61] The physical effects of caffeine include palpitations, hypertension, increased gastric acid secretion, and increased urine output.[61] Heavy consumption (12 or more cups/day, or 1.5 g of caffeine) causes agitation, anxiety, tremors, rapid breading, and insomnia.[61]

Adenosine has been proposed to be a sleep-promoting substance that accumulates in the brain during prolonged wakefulness[62] and possesses neuronal inhibitory effects. In animals, sleep can be induced after administration of adenosine A1 receptor (A1R) or A2A receptor (A2AR) agonists, such as N6-L-(phenylisopropyl)adenosine, adenosine-5′-*N*-ethylcarboxamide, and cyclohexyladenosine. Adenosine content is increased in the basal forebrain after sleep deprivation. Adenosine has thus been proposed to be a sleep-inducing substance accumulating in the brain during

prolonged wakefulness.[62] The mechanism of action of caffeine on wakefulness involves nonspecific adenosine receptor antagonism. In particular, Huang and colleagues[63] recently reported that wake-promoting effects of caffeine are abolished in A2AR knockout mice, whereas the effects were not altered in A1R knockout mice, suggesting a primary effect of caffeine through the A2AR, at least in this species. Interestingly, the A2AR interacts strongly with dopaminergic transmission. A2AR forms a heterodimer with dopamine D2 receptors, and 2AR knockout mice have been shown to have reduced amphetamine-induced locomotor simulation and reward.[64-66] Recently, Lazarus and colleagues demonstrated the specific neurons on which caffeine acts to produce arousal using selective gene deletion strategies for A2ARs in animals.[67] The authors reported that the A2ARs in the shell region of the nucleus accumbens (NAc) are responsible for the effect of caffeine on wakefulness. Caffeine-induced arousal was not affected in rats when A2ARs were focally removed from the NAc core or other A2AR-positive areas of the basal ganglia. The authors claim that caffeine promotes arousal by activating pathways that traditionally have been associated with motivational and motor responses in the brain.

Caffeine is metabolized into three active metabolites: paraxanthine, theobromine, and theophylline. We recently demonstrated that paraxanthine significantly promoted wakefulness and proportionally reduced NREM and REM sleep in both control and narcoleptic mice.[68] The wake-promoting potency of paraxanthine (100 mg/kg given orally) is greater than that of the parent compound, caffeine (92.8 mg/kg given orally), and comparable to that of modafinil (200 mg/kg given orally). High dose of caffeine and modafinil induced hypothermia and reduced locomotor activity, whereas paraxanthine did not. In addition, behavioral testing revealed that the compound possessed lesser anxiogenic effects than caffeine. Although further evaluation in humans should be needed, paraxanthine may be a better wake-promoting agent for normal individuals as well as patients who have hypersomnia associated with neurodegenerative diseases.

FUTURE STIMULANT TREATMENTS

Hypocretin-Based Therapies

Hypocretin deficiency is a main cause of human narcolepsy. Intracerebroventricular injections of hypocretin strongly promote wakefulness in dogs, mice, and rats. Animal experiments using ligand-deficient narcoleptic dogs show that very high systemic doses are required for hypocretin to penetrate the CNS and that only a short-lasting therapeutic effect is observed after intravenous administration of hypocretin. Stable and centrally active hypocretin analogs (possibly nonpeptidic synthetic hypocretin ligands) after peripheral administration will need to be developed.[69,70] Studies have also noted a normalization of the sleep-wake patterns and behavioral arrest episodes (equivalent to cataplexy and REM sleep onset) in hypocretin-deficient mice following the central administration of hypocretin-1.[71] Hypocretin may, therefore, one day prove to be effective in the treatment of both EDS (i.e., fragmented sleep-wake pattern) and cataplexy. Such studies also open the door to the possibility of cell transplantation–based and gene-based therapies.

To address whether hypocretin receptor function is intact after long-term hypocretin deficiency, Mishima and colleagues[72] recently studied hypocretin receptor gene expressions of ligand deficient narcolepsy in mice, dogs, and humans. A substantial decline (by 50% to 71%) in the expression of hypocretin receptor genes was observed in both ligand-deficient humans and dogs. Similar murine studies suggested that this decline is progressive over age. Importantly, however, about 50% of baseline expression was still observed in old ligand-deficient narcoleptic human subjects. Furthermore, because narcoleptic Doberman dogs heterozygous for the hypocretin receptor-2 mutation (with 50% receptor levels and normal levels of hypocretin) are asymptomatic, it is likely that an adequate ligand supplementation will prevent narcolepsy in hypocretin-deficient patients even if receptors are partially nonfunctional.

Histamine-3 Antagonists

Histamine has long been implicated in the control of vigilance because histamine-1 (H_1) antagonists are strongly sedative. The excitatory effects of hypocretins on the histaminergic system through hypocretin receptor-2 are likely to be important in mediating the wake-promoting properties of hypocretin.[73] In fact, brain histamine levels are reduced in narcoleptic dogs.[74] Reduction of histamine levels is also observed in human narcolepsy and other hypersomnias of central origin.[75,76] Although centrally injected histamine or histaminergic H_1 agonists promote wakefulness, the systemic administration of these compounds induces various unacceptable side effects through peripheral H_1 receptor stimulation. In contrast, the histaminergic H_3 receptors are regarded as inhibitory autoreceptors and are enriched in the CNS. H_3 antagonists enhance wakefulness in normal rats and cats[77] and in narcoleptic mice models.[78] Histaminergic H_3 antagonists might be useful as wake-promoting compounds for the treatment of EDS or as cognitive enhancers and are being studied by several pharmaceutical companies.[45]

Thyrotropin-Releasing Hormone

Another possible avenue of treatment, although one that currently enjoys less interest by pharmaceutical companies, is the use of thyrotropin-releasing hormone (TRH) direct or indirect agonists. TRH itself is a small peptide that penetrates the blood-brain barrier at very high doses. Small molecules with agonistic properties and increased blood-brain barrier penetration have been developed (i.e., CG3703, CG3509, or TA0910), thanks, in part, to the small nature of the starting peptide.[79] TRH (at the high dose of several mg/kg) and TRH agonists increase alertness, have been shown to be wake promoting and anticataplectic in the narcoleptic canine model,[80,81] and have excitatory effects on motoneurons. Initial studies demonstrated that TRH enhances DA and NE neurotransmission and that these properties may partially contribute to the wake-promoting and anticataplectic effects of TRH. Interestingly, recent studies have suggested that TRH may promote wakefulness by directly interacting with the thalamocortical network; TRH itself and TRH type 2 receptors are abundant in the reticular thalamic nucleus. Local application of TRH in the thalamus abolishes spindle wave activity,[82] and in the slice preparations, TRH depolarized thalamocortical and reticular-perigenuculate neurons by inhibition of leak K^+ conductance.[82] TRH injected in the lateral

hypothalamus induced locomotor activation in mice, but this effect was attenuated in hypocretin knockout mice, suggesting that the stimulant effects of TRH are partially mediated by stimulation of hypocretin neurons.[83] TRH also excites the histaminergic tuberomammillary nucleus.[84] Considering that TRH provokes arousal from hibernation,[85] TRH may be a potentially important wake-promoting system, although further studies are needed to disclose the roles of TRH in sleep-wake regulation.

Glutamatergic Compounds

Glutamatergic transmission is the major excitatory transmission of the mammalian brain and is increasingly believed to play a role in the generation of sleep homeostasis through changes in cortical synaptic plasticity.[86] Not surprisingly, therefore, compounds that are allosteric modulators of glutamatergic transmission, the ampakines, are being developed as wake-promoting compounds and may have counteracting effects on sleep deprivation.[87] Similarly, GluR subtype–specific compounds are likely to regulate sleep based on available knockout data and pharmacologic experiments.[88,89]

Among GluR subtypes, accumulating data support the therapeutic potential of glutamate metabotropic (mGluR2) receptors for treatment of psychiatric disorders such as depression, anxiety, and schizophrenia. The mGluR2 receptors are localized predominantly in presynaptic terminals of glutamate neurons, where they are inhibitory receptors and control glutamate release and glutamatergic neurotransmission on target networks.[90] Ahnaou and colleagues recently demonstrated that blockade of mGluR2, such as with the specific mGluR2 antagonist LY341495 or negative allosteric modulator Ro-4491533, in animals induced an immediate and endured desynchronized cortical activity associated with enhanced theta and gamma oscillations.[91] The wake-promoting effects are associated with marked lengthening of sleep-onset latency, an increased number of state transitions from light sleep to waking. The arousal response to mGluR2 blockade was not accompanied by sharp sleep rebound as found with the classic psychostimulant amphetamine, and further studies are needed to disclose the roles of mGluR2 receptors in sleep-wake regulation and their therapeutic use as new wake-promoting compounds.

CLINICAL PEARLS

- Almost all the currently available stimulants used to treat excessive daytime sleepiness in clinical practice (amphetamines, amphetamine-like stimulants, and modafinil-armodafinil) act presynaptically to increase dopaminergic transmission, either by stimulating dopamine release or by blocking dopamine reuptake. These effects are believed to be critically involved in the mediation of the wake-promoting effects of these compounds.
- Some (e.g., amphetamine) stimulants also increase adrenergic neurotransmission. Selective adrenergic uptake inhibitors have limited wake-promoting effects but potently reduce REM sleep or cataplexy. Increased adrenergic neurotransmission may play a minor role in stimulant-induced wake-promoting effects.
- Caffeine (as an over-the-counter supplement, coffee, tea, cola drinks, chocolate, and cocoa) is a nonselective adenosine receptor blocker. The potency and efficacy of caffeine are too low to provide substantial relief in the treatment of EDS associated with narcolepsy.
- Agents stimulating the hypocretinergic and histaminergic pathways may be promising future wake-promoting compounds but are not yet available.
- When using stimulants for the treatment of sleepiness, it is suggested to start with compounds that inhibit dopamine reuptake first (modafinil > methylphenidate) and then move on to the use of dopamine-releasing agents (e.g., amphetamines) only if the other compounds are not effective enough.

SUMMARY

Amphetamine-like stimulants have been used in the treatment of narcolepsy and various other conditions for decades, yet only recently has the mode of action of these drugs on vigilance been characterized. In almost all cases, the effects on vigilance were found to be mediated by effects on the DAT, leading to the widely accepted notion that the wake-promoting effects of these agents cannot be disentangled from their abuse potential. Importantly, however, the various medications available have differential effects and potency on the DAT and on monoamine storage and release. The various available stimulants are more or less selective for dopamine versus other amines. Although much work remains to be done in this area, it appears more and more likely that other properties, for example, the ability to release DA rather than simply block reuptake, plus the combined effects on other monoamines (such as serotonin) may be important to explain abuse potential. Differential binding properties on the DAT itself may also be involved, together with drug potency and compound solubility. The lack of solubility of some low-potency compounds may, for example, result in an inability to administer the drug by snorting or intravenously. Finally, lower abuse potential of these compounds has long been suspected in narcolepsy-cataplexy patients either because of the biochemical hypocretin abnormality or because of the social aspects of treating narcolepsy as a disease.

The mode of action of modafinil remains controversial and probably involves dopaminergic rather than nondopaminergic effects. Whatever its mode of action, the compound is generally found to be safer and to have a lower abuse potential than amphetamine stimulants. Its favorable side-effect profile has led to an increasing use outside the narcolepsy indication, most recently in the context of shift work sleep disorder and residual sleepiness in treated sleep apnea patients. This recent success exemplifies the need to develop novel wake-promoting compounds with low abuse potential. Other mechanisms of action involved in wake promotion include adenosine receptor antagonists, such as those found in caffeine. Novel classes of wake-promoting therapeutics are being developed, including glutamatergic and histaminergic modulators, and preclinical and clinical evaluations are in progress. A need for treating daytime sleepiness extends well beyond the relatively rare indication of narcolepsy-cataplexy.

Wake-Promoting Medications: Efficacy and Adverse Effects

Mihaela Bazalakova; Ruth M. Benca

Chapter Highlights

- A variety of wake-promoting medications are used to treat excessive sleepiness, ranging from over-the-counter caffeine to Schedule II amphetamine-like compounds. Each has a potential role in the clinical treatment of excessive sleepiness due to sleep disorders. Because their pharmacologic profiles are diverse, the clinician may guide selection of the agent based on a variety of factors: time of onset, length of activity, degree of tolerance in chronic use, expected side effects, and abuse liability. It is important to recognize that wake-promoting medications provide symptomatic treatment but do not modify the underlying etiology of sleepiness.[1]
- Although the traditional stimulants have been prescribed most widely for disorders such as narcolepsy, nonsympathomimetic compounds such as modafinil and its R-enantiomer armodafinil are now considered first-line wake-promoting agents for this disorder. These compounds have also been approved by the U.S. Food and Drug Administration (FDA) for treatment of excessive sleepiness due to shift work sleep disorder and in patients with obstructive sleep apnea whose sleepiness fails to remit despite optimal treatment with nasal continuous positive airway pressure.
- The rapid-acting hypnotic medication sodium oxybate also improves daytime alertness in people with narcolepsy and has received FDA approval for use in this patient population. Understanding the underlying pharmacology of the range of alerting agents available may clarify the qualitative aspects of wakefulness that they affect.

Wake-promoting medications fall into two categories: those that support wakefulness directly and are taken during the daytime and the hypnotic sodium oxybate, which gradually improves wakefulness over months of regular use at night. Of the daytime medications, there are three chemical classes: (1) direct-acting sympathomimetics, such as the α_1-adrenergic agonist phenylephrine; (2) indirect-acting sympathomimetics (frequently referred to as "stimulants" in clinical practice), such as methylphenidate and amphetamine; and (3) nonsympathomimetics (frequently referred to as "wake-promoting agents" in clinical practice), such as modafinil and caffeine. This chapter focuses on the clinical use of alerting medications.

THE HISTORY OF WAKE-PROMOTING MEDICATIONS

The known history of wake-promoting substances dates back to the early epochs of human civilization. Psychostimulants have been used for centuries in tonics and other preparations to allay fatigue and treat a variety of ailments (for reviews, see Haddad[2] and Angrist and Sudilovsky[3]).

Caffeine

Caffeine is the most widely consumed psychoactive substance in the world today—a testament to the apparently universal need for and widespread perceived benefit of an alertness-promoting agent.[4] Caffeine can be extracted from plants such as coffee and tea or synthetically produced. Caffeine is also an important central nervous system (CNS) active constituent of chocolate and "energy drinks." The most popular drinks in the world—coffee, tea, and many carbonated soft drinks—contain caffeine (Table 44-1), with carbonated beverages constituting the primary source of caffeine for children.[5]

Coffee's stimulant effects were likely first discovered in East Africa many centuries ago. Legends describe Ethiopian goat herders noticing the energizing effects of coffee beans on their herds, with the coffee plant eventually making its way to Yemen, where it has been cultivated since the 6th century, via the port city of Mocha or Mokha. Reports of coffee bean roasting date back to the 1400s, with writings by Abd al-Qadir al-Jaziri describing Sheikh Jamal-al-Din al-Dhabhani using coffee to "[drive] away fatigue and lethargy."[6] By the mid-1600s, coffee became popular in Europe, where it substituted alcohol-based staples, such as beer soup, at breakfast,[7] thus likely transforming European health and habits.[8] Today, 83% of U.S. adults report drinking coffee, with 63% consuming coffee daily and 75% reporting coffee intake at least once per week.[9]

Historical records suggest tea was first discovered as early as 2737 BCE by the Chinese Emperor Shen-Nung, who boiled the first pot of tea using bush leaves.[10] Like coffee, tea became popular in Europe in the 1600s. The tradition of the afternoon tea is ascribed to Anna, Duchess of Bedford, who introduced afternoon tea to Queen Victoria's court to "ward off that sinking feeling." Close to 80% of U.S. households reported tea consumption in 2012, totaling 3.6 billion gallons per year.[11]

Table 44-1 Caffeine per Serving and Product

Product	Serving Size	Caffeine Content (mg)
Coffees*		
Coffee, brewed	8 oz	110 (range, 100–200)
Coffee, decaf	8 oz	5 (range, 3–12)
Starbucks coffee, grande	16 oz	330 (range 260–560)
Starbucks coffee, tall	12 oz	260
Starbucks coffee, short	8 oz	180
Espresso	1 oz	64 (range 30–90)
Espresso, decaf	1 oz	10
Instant coffee	8 oz	75 (range 27–173)
Caffé latte	8 oz	120 (range 63–175)
Arizona Blue Luna iced coffees	8 oz	40–50
Arizona iced coffees	8 oz	40–50
Coffee ice cream	8 oz	58
Teas*		
Yerba Mate	8 oz	85
Arizona iced tea, black tea	8 oz	16
Arizona iced tea, green tea	8 oz	7.5
Arizona iced tea, Rx Power and Energy	8 oz	30
Brewed, imported brands	8 oz	60
Brewed, major U.S. brands	8 oz	40 (range 40–120)
Lipton Brisk iced tea	8 oz	6
Mistic teas	8 oz	17 (average)
Snapple iced tea, all kinds	8 oz	21
Soft Drinks		
Josta	12 oz	58
Mountain Dew	12 oz	55.5
Surge	12 oz	52.5
Diet Coke	12 oz	46.5
Coca-Cola	12 oz	34.5
Dr. Pepper, regular or diet	12 oz	42
Sunkist orange soda	12 oz	42
Pepsi-Cola	12 oz	37.5
Diet Pepsi	12 oz	36
Diet RC	12 oz	54
Barqs Root Beer	12 oz	22.5
Barqs Diet Root Beer	12 oz	0
7-Up or Diet 7-Up	12 oz	0
Sprite or Diet Sprite	12 oz	0
Mug Root Beer	12 oz	0
Caffeine-Free Coke or Diet Coke	12 oz	0
Caffeine-Free Pepsi or Diet Pepsi	12 oz	0
Minute Maid orange soda	12 oz	0

Continued

Table 44-1 Caffeine per Serving and Product—cont'd

Product	Serving Size	Caffeine Content (mg)
Caffeinated Waters and Energy Drinks		
Wired X344	16 oz	344
Spike Shooter	8.4 oz	300
5-Hour Energy	1.9 oz	200
Monster	16 oz	160
Full Throttle	16 oz	144
Java Water	500 mL	125
Krank 20	500 mL	100
Aqua Blast	500 mL	90
Red Bull	8.3 oz	80
Water Joe	500 mL	60–70
Aqua Java	500 mL	50–60
Chocolate		
Hershey's Chocolate Bar	1.55 oz	9
Hershey's Dark Chocolate Bar	1.45 oz	31
Baker's chocolate	1 oz	26
Chocolate milk beverage	8 oz	5
Chocolate-flavored syrup	1 oz	4
Cocoa beverage	8 oz	6
Dark chocolate, semi-sweet	1 oz	20
Milk chocolate	1 oz	6
Medications		
Anacin	2 tablets	26
Aqua Ban	1 tablet	100
Cafergot	1 tablet	100
Caffedrine	2 capsules	200
Coryban-D	1 tablet	30
Darvon Compound	1 tablet	32
Dexatrim	1 tablet	200
Dristan	1 tablet	30
Excedrin, max strength	2 tablets	130
Fiorinal	1 tablet	40
Midol	1 tablet	32
Migralam	1 tablet	100
Neo-Synephrine	1 tablet	15
NoDoz, maximum strength; Vivarin	1 tablet	200
NoDoz, regular strength	1 tablet	100
Percodan	1 tablet	32
Permathene Water Off	1 tablet	100
Pre-Mens Forte	1 tablet	50
Prolamine	1 tablet	140
Triaminicin	1 tablet	30
Vanquish	1 tablet	33

*The listed caffeine content is average for a standard brewed cup of coffee or tea; certain brewing methods may increase or decrease the average caffeine content per cup.

Together, coffee, tea, and energy drink consumption in 2011 totaled 30 gallons per capita per year in the United States (18.5, 10.3, and 1.2 gallons per person per year, respectively), exceeding bottled water consumption (28.3 gallons per capita per year) and only exceeded by yet another source of caffeine: carbonated soft drinks (44.7 gallons per capita per year).[12]

In a 7-day, diary-based population study of 42,851 consumers 2 years and older performed between October 2010 and September 2011, Mitchell and colleagues confirmed that 85% of the U.S. population consumes at least one caffeinated beverage daily, with mean and 90th percentile caffeine intake of 165 and 380 mg/day, or 2.2 and 5 mg/kg/day, respectively, for all ages.[5] Caffeine consumption increased with age, with highest levels found in adults 50 to 64 years old (226 mg/day), and women reported higher caffeine consumption than men when adjusted for body weight. A notable finding included increased caffeine consumption in all age groups, including children, compared with a similar survey from 1999. Although consumption of caffeinated carbonated soda drinks decreased over the same time period, there was a concomitant increase in coffee consumption, the main course of caffeine in adults. Interestingly, the yearly per capita consumption of coffee varies significantly around the globe, ranging from a high of 12 kg per person in Finland to less than 0.8 kg per person in Southeast Asia. Annual consumption in Canada (6.5 kg per person) and Brazil (5.6 kg per person) outpaces U.S. use (4.2 kg per person).[13]

Sympathomimetics

The native peoples of Peru and Bolivia used cocaine, a crystalline alkaloid derived from the leaves of the coca plant, for pleasure and to increase stamina. From 1886 to 1905, cocaine was an ingredient in Coca-Cola. The medicinal use of cocaine was advocated by Freud.[14] However, cocaine's profound potential for abuse and addiction soon limited the role of this stimulant in modern medicine. In 1931, Doyle and Daniels described the use of ephedrine to treat the sleepiness of narcolepsy.[15] Despite its clinically noteworthy efficacy, it was soon apparent that side effects, incomplete patient acceptance, rapid development of tolerance, and cost limited its usefulness. In 1935, Prinzmetal and Bloomberg suggested that amphetamine sulfate would be appropriate treatment for narcolepsy because of its close relationship to ephedrine and epinephrine, its low toxicity and low cost, its prolonged action, and its lack of pronounced sympathomimetic side effects.[16] By 1949, amphetamine (racemic B-phenylisopropylamine), in one or another of several oral preparations as a phosphate or sulfate, had become the treatment of choice for excessive sleepiness due to narcolepsy. Methylphenidate, a piperidine derivative, was introduced in 1959 by Yoss and Daly.[17] Pemoline, an oxazolidine compound, was later introduced as a mild CNS stimulant, whereas the mild stimulant mazindol, an imidazoline derivative, was marketed as an appetite suppressant. Neither pemoline nor mazindol are currently available as wake-promoting medications because of their adverse effects.

Nonsympathomimetics

Modafinil (2-iphenylmethylsulfinyl acetamide) is a racemic compound unrelated to the amphetamines or other CNS stimulants. Of all the alerting agents, modafinil has the most specific and selective wake-promoting properties and usually has minimal side effects. Modafinil appeared on the world market for the indication of narcolepsy and CNS hypersomnia in the early 1990s and is now considered a first-line agent for the treatment of these conditions.[18] Its R-enantiomer, armodafinil, was introduced in 2007. Additional U.S. Food and Drug Administration (FDA)–approved indications for modafinil and armodafinil took effect in the mid-2000s, including treatment of patients with excessive sleepiness due to shift work sleep disorder (SWSD) and treatment of patients with obstructive sleep apnea (OSA) to augment nasal continuous positive airway pressure (CPAP). These additional indications have helped fuel discussion of the more general need for assessment and treatment of pathologic sleepiness in clinical practice.

Hypnotics (Sodium Oxybate)

The most recent addition to the armamentarium of wake-promoting treatments is, paradoxically, a hypnotic, sodium oxybate, the sodium salt of γ-hydroxybutyrate (GHB). GHB, a naturally occurring inhibitory neurotransmitter that binds to γ-aminobutyric acid B (GABA-B) and GHB receptors, was first used as an anesthetic and neuroprotective agent in the 1960s. In 1979, Broughton and Mamelak described improvements in nighttime sleep, daytime alertness, and cataplexy symptoms in a group of 16 narcolepsy patients who took GHB at night, with sustained treatment effects over 20 months.[19] Subsequent research in the 1980s and 1990s confirmed GHB as an effective anticataplectic agent that also evoked improvements in daytime alertness,[20] although often patients required additional daytime use of traditional stimulant medication. GHB had previously been described as a "cataplexy antagonist and mild stimulant" but has more recently been recognized as a wake-promoting agent.[21] In 2002, sodium oxybate was granted an FDA indication for the treatment of cataplexy in narcolepsy, and an additional indication for the treatment of excessive sleepiness in narcolepsy was added in 2005.

WAKE-PROMOTING AGENTS: CAFFEINE

Mechanism of Action

Caffeine's main mechanism of action on the CNS is antagonism of adenosine receptors. Adenosine-releasing neurons are found in the hypothalamus and project to cells in the cortex, basal forebrain, and reticular activating system. It is known that endogenous adenosine levels rise with continued wakefulness and may be a fundamental part of the homeostatic sleep mechanism.[22] Exogenous adenosine promotes slow wave sleep, whereas xanthines, including caffeine, block the A1 adenosine receptors, thereby inhibiting sleep onset and maintenance. Caffeine inhibits sleep in other mammals and insects through similar mechanisms.[23]

Pharmacokinetics and Dynamics

Following oral ingestion caffeine reaches peak plasma levels within 30 to 120 minutes. Caffeine then undergoes hepatic metabolism, with metabolites excreted in the urine. The half-life of caffeine varies, ranging between 4 and 6 hours.[24] In smokers, clearance rate is increased by more than 50%.[25] In contrast, in women taking oral contraceptives and during pregnancy, caffeine's half-life may be prolonged twofold to threefold, possibly through CYP1A interactions.[26]

Alerting Effects and Clinical Efficacy

Caffeine improves alertness, mood, and cognitive performance. The usual dose in tablet form is 50 to 200 mg, and beverages contain amounts within this range as well (see Table 44-1). In standard daily practice, 85% of Americans use caffeine, many to foster wakefulness when arising from sleep.[27] This culturally accepted truism has been empirically examined, and it is clear that caffeine effectively eliminates the cognitive fog of sleep inertia on psychomotor tasks.[28] The combination of caffeine and naps, with caffeine intake immediately preceding a short 20-minute nap, appears to be especially effective in reducing subjective sleepiness and postnap sleep inertia, and improving objective performance in working memory tasks during the "midafternoon dip."[29]

Use in Sleep Deprivation

The sleepiness caused by sleep deprivation in young, healthy, non–caffeine-dependent volunteers can clearly be attenuated both subjectively and objectively using caffeine supplements. Using doses of 600 mg of a sustained-release preparation, caffeine reduced slow wave activity on the electroencephalogram and improved psychomotor performance tasks after up to 36 hours of sleep deprivation.[30] Similarly, two 300-mg doses of sustained-release caffeine significantly improved both vigilance and performance during 64 hours of continued wakefulness.[31] In a study of U.S. Navy SEALs randomly assigned to receive caffeine doses of 100, 200, or 300 mg or placebo after 72 hours of sleep deprivation and with continuous exposure to other stressors, caffeine at doses of 200 mg or above clearly improved tests of vigilance, alertness, and reaction time. However, it did not improve marksmanship, a task that requires fine motor control that tends to be worsened by caffeine.[32]

A more recent study demonstrated that caffeine (5 mg/kg) administered after 36 hours of sleep deprivation in normal subjects significantly improved reaction times as well as physical performance compared with placebo.[33] One of the few head-to-head studies comparing the effects of caffeine (600 mg), dextroamphetamine (20 mg), and modafinil (400 mg) on psychomotor vigilance after 44 hours of wakefulness found similar improvements in performance with all three stimulants, although caffeine had a shorter duration of action.[34]

Although caffeine can promote wakefulness, it should not be assumed that it will reverse all the effects of sleep loss on cognition and emotional regulation. Studies have begun to address this question and assess the effects of caffeine on restoring higher order executive function during sleep deprivation. In one study of extended sleep deprivation for 3 nights (77 hours), administration of 200 mg of caffeine every 2 hours from 1 AM to 7 AM each night (800 mg total dose per night) improved planning speed, response time, and throughput compared with placebo on a visuospatial planning and sequencing task known to be mediated by the dorsolateral prefrontal cortex.[35] Administration of caffeine was also reported to reduce the increases in a risk-taking behavior task produced by 75 hours of sleep deprivation.[36]

Use in Shift Work

Because it is such a widely available alerting agent, caffeine stands in a unique position to help improve the safety of shift workers and drivers, but not without caveats. Caffeine has been shown to substantially improve alertness in a simulated night shift.[37] In general, night shift workers tend to consume more caffeine than day workers, yet they continue to be at risk for accidents both on the road and at the workplace.[38] If used in sufficient doses (usually at least 200 mg), caffeine may significantly improve the alertness and cognitive skills that become impaired by sleepiness, especially in individuals who are not already moderately caffeine dependent. Caffeine's effectiveness is greater with the sustained-release form of a 600-mg daily dose, which has been demonstrated to extend the benefit of short naps following partial sleep deprivation in a driving simulation task.[39] Compared with subjects who had received a placebo, normally rested subjects who took 200 mg caffeine or a 30-minute nap 1 hour before driving 200 km at night (between 2 and 3:30 AM) in a driving simulator showed significantly lower incidence of impaired driving as indicated by inappropriate line crossings and subjective sleepiness.[40] Clearly, there are multiple factors, including tolerance or habituation and the timing of driving home in relation to the circadian nadir, that compromise the ability of caffeine (or any alerting agent) to mitigate severe sleepiness.

Potency

Compared with the potency of other alerting medications, caffeine is a moderately effective alerting agent when taken on an intermittent basis. Parkes and Dahlitz estimated that a dose of six cups of strong coffee has about the same alerting effect as 5 mg dextroamphetamine.[41] The duration of caffeine's effect on alertness appears to be dose dependent, with 75 to 150 mg of caffeine (1 cup of coffee) lasting up to 90 minutes after administration, 200 mg (approximately 2 cups of coffee) improving performance up to 4 hours after administration, and 300 to 400 mg (3 to 4 cups of coffee) sustaining alertness for up to 5.5 to 7.5 hours.[24] High doses of caffeine (200 to 600 mg) may approximate the efficacy of standard doses of modafinil (200 to 400 mg) in maintaining alertness and performance during long-term sleep deprivation.[42] Importantly, conditions of prolonged sustained sleep deprivation (24 to 44 hours) may dissociate the effect of caffeine on alertness from its effect on cognitive performance because decision making may remain impaired despite improved vigilance.[43]

Despite its documented ability to promote wakefulness, the potential benefits of caffeine to counteract sleep loss or shift work for alertness may be suboptimal because (1) it may not be consumed in adequate doses; (2) acute benefits are relatively short lived, and so it must be taken at the right time; and (3) development of tolerance leads to reduced efficacy overall. Caffeine may also be insufficiently potent in situations of new or worsening hypersomnia, and it is ineffective as monotherapy for the severe sleepiness of sleep disorders such as narcolepsy and idiopathic CNS hypersomnia.

Side Effects and Morbidity

The most common side effect of caffeine use is disrupted nighttime sleep. If taken before sleep, caffeine postpones sleep onset and reduces the amount of slow wave sleep.[44] The disruptive effects of caffeine on sleep maintenance are also well known; typically, if caffeine is consumed within a few hours of bedtime, sleep efficiency and total sleep time are both decreased. A recent study reported that 400 mg of caffeine

administered even 6 hours before bedtime in normal sleepers led to a reduction in total sleep time of more than 1 hour.[45] Individual sensitivity to caffeine's effects varies, likely based on multiple factors. Genetic studies in humans have demonstrated differential sensitivity to both wake-promoting and anxiety-eliciting effects of caffeine in relation to polymorphisms in the adenosine A2A receptor gene.[46] The decline in metabolic rate with age, leading to an increased half-life in older adults, is another factor that makes caffeine an increasingly likely contributor to sleep fragmentation in some, especially older, adults.

At high doses (above 4 mg/kg body weight), caffeine stimulates the medullary vagal, vasomotor, and respiratory centers,[47] as well as skeletal muscle,[48] giving rise to a variety of common side effects: nausea and diarrhea, flushing, sweating, increased heart and respiratory rates, muscle twitches and cramps, tremor, and nervousness. The lethal dose of caffeine is quite high—more than 10 g for an adult, or the equivalent of 100 cups of coffee.

Although coffee may exacerbate several disorders, such as osteoporosis, fibrocystic breast disease, irritable bowel syndrome, and peptic ulcer disease,[49] caffeine use in moderation appears to be generally safe. In fact, in 2012 the FDA stated that doses up to 400 mg/day do not appear to be associated with adverse health effects in healthy adults.[5]

Additional Health Benefits and Uses

Caffeine or coffee consumption has been associated with, among others, weight loss and insulin sensitization; lower risk for type 2 diabetes, hypertension, depression, symptomatic gallstones, and hepatocellular and colorectal malignancies; and possible neuroprotection, with lower incidence of Parkinson and Alzheimer disease.[50] Contrary to long-standing clinical suspicion, coffee consumption not only appears nonharmful but in fact also is possibly beneficial for cardiovascular morbidity and mortality. Although acute coffee intake does increase systolic blood pressure, habitual use of up to 6 cups of coffee per day was not associated with development of hypertension in the Nurses' Health Study. Caffeine doses as high as 500 mg/day did not precipitate or worsen ventricular arrhythmias, and increased coffee consumption (3 to 4 cups per day) is protective against atrial fibrillation and is associated with reduced incidence of stroke, heart failure, and coronary artery disease.[51]

Withdrawal

Caffeine in even moderate daily doses has been shown to produce a withdrawal syndrome after abrupt cessation. In one double-blind, placebo-controlled study, an average of 235 mg/day was consumed. On discontinuation, subjects reported headache, increased sleepiness and fatigue, fogginess and difficulty concentrating, and depressed mood, with symptoms emerging within 12 to 24 hours and peaking between 20 and 51 hours after caffeine cessation.[52] Although there are clearly both physical and mental changes associated with withdrawal, an expectation of symptoms may also increase the likelihood that they emerge.[53]

Tolerance

Although regular caffeine consumers frequently report decreased effectiveness of caffeine in the maintenance of subjective alertness, physiologic tolerance to caffeine may manifest in some (e.g., mood, response time) but not other (e.g., working memory) aspects of cognitive function.[24] Nevertheless, objectively measured sleep latencies on the Multiple Sleep Latency Test (MSLT) increase most notably on the first day of caffeine supplementation and subsequently decline, although values remain significantly higher than placebo, suggesting persistent benefit despite some possible development of tolerance.[54]

Dependence and Abuse Potential

Although caffeine discontinuation leads to withdrawal symptoms and cravings, lack of significant decrements in social, emotional, or physical well-being generally prevents substance abuse experts from considering caffeine dependence as a serious addiction.[51]

WAKE-PROMOTING AGENTS: SYMPATHOMIMETICS

Mechanism of Action

As discussed in detail elsewhere (see Chapter 44), the sympathomimetics directly or indirectly increase the activity in dopaminergic and noradrenergic pathways by blocking dopamine (DA) and norepinephrine (NE) reuptake and inducing DA/NE release through the dopamine (DAT) and norepinephrine (NET) transporters. The primary effect on alertness is mediated through the dopaminergic ventral tegmental area and the noradrenergic locus coeruleus, which both project widely throughout the brain. The additional activation of subcortical target areas (e.g., striatum, nucleus accumbens) accounts for the side effects typical of the sympathomimetics (e.g., tics) and abuse liability. It is important to recognize that wake-promoting medications provide symptomatic treatment but do not modify the underlying pathophysiologic processes leading to sleepiness, which are frequently not understood.[1]

Pharmacokinetics and Dynamics

Currently, there is a long list of immediate- and delayed-release sympathomimetic stimulants, whose development and use have been driven primarily by the attention deficit-hyperactivity disorder (ADHD) field. The available preparations offer a range of half-lives and therefore dosing strategies to treat sleepiness. Immediate-release amphetamines are absorbed rapidly and, on average, reach peak plasma levels within 2 hours of oral ingestion and have half-lives in the range of 4 to 6 hours. They undergo hepatic metabolism and renal excretion, the latter significantly increased at low urinary pH. Therefore urine acidification (e.g., with orange juice or ascorbic acid consumption) significantly reduces the elimination half-life and, thus, efficacy of amphetamines and methylphenidate, whereas urine alkalinization (e.g., with sodium bicarbonate or acetazolamide) prolongs their elimination half-life and may cause toxicity.[55]

Several preparations of amphetamine have been developed as oral compounds that vary in terms of the concentration of the dextro-isomer and whether a phosphate or sulfate salt is used. Although most methylphenidate preparations include racemic mixtures, Focalin consists of D-methylphenidate alone. Immediate-release methylphenidate has a rapid onset and shorter half-life on average (3 to 4 hours) compared with the amphetamines and thus can be administered two to four times daily. Sustained-release formulations of

methylphenidate and amphetamine have longer half-lives (8 to 16 hours). Even the pharmacokinetics of different formulations of the same stimulant vary and may affect a patient's level of alertness throughout the day. For instance, two commercial preparations of sustained-release methylphenidate (Ritalin LA and Concerta ER)[56] compared across several subjects exhibit similarly timed bimodal peaks in plasma levels after dosing but significantly different blood levels between formulations.

Combination of sympathomimetics with monoamine oxidase inhibitors (MAOIs, such as tranylcypromine, pargyline, phenelzine, and high-dose selegiline) is contraindicated because MAOIs inhibit hepatic metabolism of amphetamine and may result in hypertension or hyperthermia. However, coadministration of sympathomimetics and low-dose tricyclic antidepressants (TCAs) used as anticataplectic agents (e.g., imipramine, protriptyline, and clomipramine at 10 to 100 mg) appears generally safe, although TCAs also inhibit amphetamine and methylphenidate metabolism and thus may lead to reduced dosing requirements of the sympathomimetics.[57] Synergistic effects between methylphenidate and selective serotonin reuptake inhibitors (SSRIs) have been reported, possibly owing to increased monoaminergic tone at the synapse or decreased SSRI metabolism, with at least one case report of serotonin syndrome in a patient taking sertraline and methylphenidate.[58]

Alerting Effects and Clinical Efficacy

The clinical treatment of excessive sleepiness due to narcolepsy originated with the traditional stimulants, and the dosing guidelines have changed little since their development in the first part of the last century. Clinical practice parameters are thus based on a few small trials, without effective assessment of risk-benefit ratios, long-term efficacy, and side-effect profiles.[1]

In one double-blind, randomized protocol comparing 8 narcoleptics with cataplexy to matched controls, MSLT sleep latencies increased from 4.3 minutes (placebo) to 9.3 minutes (methamphetamine 60 mg) in narcoleptics and from 10.3 minutes (placebo) to 17.1 minutes (methamphetamine 10 mg) in controls.[59] Thus although mean sleep latencies increased with high-dose methamphetamine in narcoleptics, they did not completely normalize compared with controls, remaining pathologically low (less than 10 minutes). Importantly, functional improvement accompanied the reduction in sleepiness, with significantly fewer objects hit on a driving stimulator test following amphetamine administration both in the narcoleptics (0.3 versus 3) as well as in the controls (0.16 versus 0.8).

In another randomized controlled trial, Mitler and colleagues compared 13 narcoleptic patients given methylphenidate at 10, 30, or 60 mg total daily dose (taken in divided doses three times per day) to 5 narcoleptic patients taking dextroamphetamine 10, 30, or 60 mg maximum total daily dose (also taken divided into three doses over the day) and 9 control subjects taking placebo.[60] After 7 days of drug or placebo administration, participants underwent objective (Maintenance of Wakefulness Test [MWT]) and subjective evaluation of sleepiness as well as cognitive testing (Wilkinson Addition and Digit-Symbol Substitution Tests). Both methylphenidate and dextroamphetamine showed dose-dependent improvements in mean sleep latency on MWT. However, dextroamphetamine 60 mg showed significantly greater relative improvement, with mean latency improving from 35% to 70% of control values (18.9 minutes), compared with an increase from 55% to 80% of control with methylphenidate 60 mg. The difference in baseline sleep latency values between dextroamphetamine and methylphenidate treatment groups may partially be related to the small sample size and additional factors such as mean age (50 years old in the methylphenidate group versus 39 years old in the dextroamphetamine group). Subjective improvement in sleepiness and cognitive testing was only seen at the maximum daily dose of 60 mg methylphenidate but was seen with all doses of dextroamphetamine, including the lowest 10-mg dose.

Current commonly used sympathomimetics for the treatment of hypersomnia include immediate-release amphetamines, D-amphetamine (Dexedrine), racemic D/L amphetamine (Benzedrine), and methamphetamine (Methadrine); delayed-release amphetamine formulations Adderall and Vyvanse; short-acting racemic methylphenidate (Ritalin); and the bioactive d-methylphenidate formulation (Focalin), supplemented by the osmotic release oral system (Concerta) (Table 44-2). In general, the specific pharmacokinetic profile must be considered when prescribing stimulants because it is often the most important element in shaping a patient's wakefulness throughout the day and ability to tolerate one formulation of a medication better than others.

Potency

A useful distinction is one between the amphetamine derivatives and the piperazine derivative methylphenidate. Although both amphetamines and methylphenidate block DA and NE reuptake and induce catecholamine release through interactions with DAT and NET, amphetamine also binds the intracellular vesicular monoamine transporter, thus additionally potentiating catecholamine release compared with methylphenidate, which does not bind vesicular monoamine transporter.

Additionally, the dextro-isomer d-amphetamine appears to increase DA release preferentially to NE release compared with L-amphetamine and induces wakefulness more potently. Methamphetamine, which has an additional methyl group attached to the amine, has increased CNS penetration and is thus more potent than amphetamine. These subtle molecular differences may account for the differing clinical efficacy and side-effect profiles of the sympathomimetics such that, for example, methylphenidate may be less efficacious but also easier to tolerate.

Side Effects and Morbidity

Common stimulant side effects include irritability, nervousness or tremulousness, insomnia, orofacial dyskinesias, and headache. Sympathomimetic activation may cause palpitations, tachycardia and hypertension, diaphoresis, anorexia, and vomiting.[17,61] The reported frequency of side effects of stimulants in clinical practice and in clinical trials varies from 0% to 73%; the extreme variation reflects, at least in part, differences in methods of determining side effects and the definitions of side effects. Studies show that at high doses, most patients experience side effects, including disturbed nocturnal sleep.[59]

Cardiac and vascular complications due to prescribed sympathomimetics have been reported only rarely in people with narcolepsy. These drugs do not appear to cause clinically significant increases in blood pressure at commonly used doses

Table 44-2 Medication and Dosage

Medication	Dose	Onset to Peak Concentration	Half-Life	Common Side Effects	Serious Side Effects	Important Drug Interactions	Contraindications and Precautions	Comments
Amphetamine/Dextroamphetamine								
Amphetamine/dextroamphetamine IR (Adderall)	5–60 mg	2–3 hr	7–34 hr (average 10 hr)	Weight loss, headache, insomnia, tremor, abdominal pain, anorexia, xerostomia, dysphoria, euphoria, anxiety, restlessness	Cardiomyopathy, chest pain, sudden death, MI, irregular heart rate, immune hypersensitivity reaction, CVA, Tourette syndrome, seizure, hypertension, palpitations, psychotic disorder with prolonged use	MAO inhibitors: hypertensive crisis SSRIs, SNRIs: increased risk for serotonin syndrome Sodium bicarbonate: amphetamine toxicity by decreasing urinary excretion/increasing half-life Ascorbic acid: increased urinary excretion/decreased half-life	Advanced atherosclerosis, cardiovascular disease, concomitant use of MAOIs or within 14 days of MAOI use, drug dependence, structural cardiac abnormalities, hyperthyroidism, moderate to severe hypertension Can lower seizure threshold	Black box warning: high potential for abuse
Dextroamphetamine IR (Dexedrine)	5–60 mg	2–3 hr	10 hr					
Lisdexamphetamine (Vyvanse)	30–70 mg	1 hr	4 hr					
Methamphetamine (Desoxyn)	5–60 mg	30–60 min	4–5 hr					
Amphetamine/dextroamphetamine XR (Adderall XR)	10–60 mg	7 hr	12 hr					
Dextroamphetamine SR	5–60 mg	8 hr	12 hr					
Methylphenidate								
Methylphenidate hydrochloride (Ritalin, Concerta)	10–80 mg	1–2 hr (food slows absorption)	3 hr	Loss of appetite, irritability, anxiety, restlessness	Hypertension (frequent), tachyarrhythmia (frequent), thrombocytopenia, hallucinations	Warfarin: increased plasma concentrations and an increased risk for bleeding	Caution in patients with a history of drug dependence or alcoholism	Black box warning: high potential for abuse
Methylphenidate hydrochloride ER (Ritalin ER, Concerta ER, Metadate CD, Methylin ER)	10–60 mg	1.3–4 hr (food slows absorption)	3.5 hr (6–12 hr)			Warfarin: increased plasma concentrations and increased risk for bleeding MAO inhibitors: hypertensive crisis Phenytoin, phenobarbital increased serum levels	Caution in patients with a history of drug dependence or alcoholism Contraindicated in patients taking MAOIs and patients with glaucoma, motor tics, Tourette syndrome	
Other Drugs								
Modafinil (Provigil)	100–800 mg	2–4 hr	9–14 hr (R isomer 15 hr, S isomer 4–5 hr	Headache, nausea, anxiety, insomnia, dizziness	Drug hypersensitivity syndrome, Stevens-Johnson syndrome, toxic epidermal necrolysis due to drug hypersensitivity reaction, hypertension	OCPs: decreased bioavailability and reduced effectiveness Other interactions: diazepam, propranolol, phenytoin, cyclosporine, carbamazepine, clomipramine	Angioedema, hypersensitivity reaction, anaphylactoid (rare)	Low abuse potential, Schedule IV
Armodafinil (Nuvigil)	50–300 mg	2–4 hr	10–15 hr, plasma levels remain elevated significantly longer compared with modafinil					

Continued

Table 44-2 Medication and Dosage—cont'd

Medication	Dose	Onset to Peak Concentration	Half-Life	Common Side Effects	Serious Side Effects	Important Drug Interactions	Contraindications and Precautions	Comments
Ritanserin	10–30 mg	140 min	40 hr	Constipation	Prolongation of the QTc interval	Droperidol: increased risk for cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)	Patients concurrently receiving class III antiarrhythmic agents or drugs known to cause hypokalemia, prolongation of QT interval arrhythmias	Some improvement in daytime sleepiness in patients with narcolepsy
Selegiline	5–10 mg	40–90 min	10 hr	Decreased systolic arterial pressure, orthostatic hypotension, weight loss, diarrhea, indigestion, headache, insomnia, xerostomia	Hypertensive crisis, suicidal thoughts	Meperidine, methadone, propoxyphene, tramadol: severe hypertension or hypotension, hyperpyrexia, coma, death SSRIs: increased risk for serotonin syndrome Albuterol: increased risk for tachycardia, agitation, or hypomania TCAs: hyperpyrexia, convulsions, death Fentanyl: severe and unpredictable potentiation of opioid analgesic effects	Meperidine, methadone, propoxyphene, tramadol, carbamazepine, oxcarbazepine, cyclobenzaprine, bupropion, mirtazapine, St. John's wort, SSRIs, albuterol TCAs, fentanyl: contraindicated Concomitant use of dextromethorphan: can cause psychosis or unusual behavior Pheochromocytoma Caution with tyramine-rich foods, increased risk of hypertensive crisis	Black box warning: increased the risk for suicidal thinking and behavior in children, adolescents, and young adults with major psychiatric disorders Very few data to support use for daytime sleepiness
Sodium oxybate (γ-hydroxybutyrate [GHB]) (Xyrem)	2.25–9 g in divided doses	15–30 min to peak concentration Fatty food delays absorption	30–60 min	Nausea, vomiting, enuresis, dyspepsia, abdominal pain, confusion, dizziness, somnolence, headache, incontinence	Respiratory suppression, sleepwalking, depression	Benzodiazepines Opiates may have additive CNS and respiratory depressant effects	Succinic semialdehyde dehydrogenase deficiency, concurrent treatment with sedative-hypnotics, alone or combined with alcohol, has a high propensity to induce a comatose state	Can be used as drug of abuse Need to be registered to prescribe in the United States

CNS, Central nervous system; CVA, cerebrovascular accident; MAO, monoamine oxidase; MAOI, monoamine oxidase inhibitor; MI, myocardial infarction; OCP, oral contraceptive pill; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

in normotensive individuals.[17,61] Isolated cases of severe disease such as stroke, cardiomyopathy, and ischemic vascular complications have been reported in the context of chronic use of sympathomimetics, especially at high doses. Although advanced cardiovascular disease is a reasonable contraindication to sympathomimetic therapy, there are no systematic studies indicating that well-controlled hypertension is exacerbated by moderate doses of stimulants. Again, methylphenidate appears to result in less hypertension (as well as appetite reduction, another common side effect) compared with the amphetamines.[62]

Psychiatric complications with the use of sympathomimetics, including delusions, paranoia, and mania, are dose dependent and more likely to occur in patients with coexisting or preexisting psychiatric conditions.[63] Psychosis and hallucinations are rare in narcoleptic patients treated with stimulants. There is no evidence that different agents confer a greater or lesser risk for psychotic symptoms, although the use of short-acting forms is associated with mood swings and irritability. Methylphenidate 20 to 60 mg does not appear to worsen clinical measures of impulsivity or addictive behaviors in narcoleptic patients.[64]

A variety of complications can occur with intravenous, intranasal, or oral amphetamine or methamphetamine abuse. In healthy volunteers, repetitive oral administration of 5 to 10 mg of dextroamphetamine produces paranoid delusions, often with blunted effects, after a cumulative dose of 55 to 75 mg.[65] Other symptoms of amphetamine abuse are motor tics, stereotypic movements, and perseveration: repetitive thoughts or organized, goal-directed, but meaningless activity, such as repetitive cleaning or elaborate sorting of small objects.[66] In young adults, the relative risk for stroke is estimated to be 6.5 times greater for drug abusers compared with nonabusers, with amphetamines implicated in a substantial proportion of young drug abusers with strokes.[67]

Additional Health Benefits and Uses

Sympathomimetic stimulants appear effective in treatment-resistant depression, although no controlled trials have been performed to confirm this effect and to investigate true antidepressant qualities rather than fatigue reduction or increased motivation as a result of amphetamine intake.[55] Bronchodilation and weight loss are known side effects of the sympathomimetics, which may be beneficial in certain clinical scenarios.

Withdrawal

Abrupt discontinuation of amphetamines can result in prolonged bouts of recovery sleep, disrupted sleep including vivid or unpleasant dreams, depressive mood, and worsening of daytime sleepiness.[68]

Tolerance

In people with narcolepsy, tolerance to alerting effects appears to occur with variable frequency. In one review, 10 of 100 patients had discontinued stimulants owing to failure to respond, tolerance, or side effects, and 31 others had required doubling of dosage over a 1-year period for the same control of symptoms.[61] Other studies have found a similar or higher amount of tolerance evident clinically in patients using sympathomimetic agents.[69] Tolerance to stimulants appears to be more likely, or at least more evident, in patients taking high doses. There is little evidence that the incidence of tolerance and side effects is less in people with narcolepsy than in others taking sympathomimetics. Furthermore, it does not appear that tolerance reported by some patients is an effect of inadequate nocturnal sleep rather than true tolerance, nor does tolerance appear less likely to occur with methylphenidate than with dextroamphetamine.[70]

Dependence and Abuse Potential

Amphetamines and related compounds have a high abuse potential and can produce dependence. Although most users do not become addicted, controlled use may become compulsive use, especially when high doses or rapid route of administration are used.[71] A sequence of euphoria, dysphoria, paranoia, and psychosis can occur after a single exposure to a high dose or with chronic exposure to low doses. Because of its increased lipophilicity and thus rapid CNS penetration and onset of action, methamphetamine has the greatest abuse potential.

WAKE-PROMOTING AGENTS: MODAFINIL AND ARMODAFINIL

Mechanism of Action

Modafinil (the racemic mixture of R- and S-enantiomers) and armodafinil (the R-enantiomer preparation) are chemically unrelated to the sympathomimetics agents and are sometimes referred to as somnolytics rather than stimulants.[72] The precise mechanism through which modafinil enhances wakefulness remains unclear. A comprehensive discussion of modafinil's mechanism of action is included elsewhere (see Chapter 43). However, modafinil likely blocks dopamine reuptake predominantly, through differential involvement of the dopamine rather than norepinephrine transporters,[55] possibly accounting for its more benign cardiovascular and tolerance and abuse side-effect profiles compared with the sympathomimetics.[73] It has been postulated that modafinil exerts its effects by modulating the homeostatic sleep drive (e.g., by decreasing recovery sleep duration following prolonged sleep deprivation). However, studies have not demonstrated clear effects on sleep homeostasis, such as increased homeostatic sleep pressure inducing rebound sleepiness following discontinuation of the drug. Furthermore, beyond the initial acclimatization period, modafinil's alerting effects do not appear to disrupt the evolution of normal sleep architecture. Thus modafinil likely exerts its alerting effects through activation of dopaminergic wake-promoting mesocortical pathways.[74]

Pharmacokinetics and Dynamics

Modafinil is absorbed quickly and reaches peak plasma levels within 2 to 4 hours, with a half-life of 9 to 14 hours. The onset of action and half-life of armodafinil are similar to those of modafinil, but the pharmacokinetics of the two drugs are quite different, partially owing to the much shorter half-life of the S-enantiomer (3 to 4 hours), which is present in modafinil but not armodafinil.[75] Thus armodafinil plasma levels remain elevated significantly later in the day compared with modafinil, allowing once-daily armodafinil dosing, whereas modafinil is frequently used in divided doses. Modafinil is primarily metabolized by CYP3A4 and is renally excreted; lower doses should be used in patients with renal and hepatic dysfunction. Modafinil is a CYP3A4 inducer and thus may increase metabolism, thereby decreasing efficacy of oral contraceptives as well as triazolam, diazepam, and phenytoin. Alternative contraceptive methods should be used by women

of childbearing age. Armodafinil is also a moderate inhibitor of CYP2C19, which metabolizes coumadin, and thus potential dose reductions may be necessary.

Alerting Effects and Clinical Efficacy

Use in Narcolepsy

Although in some individuals 100 mg of modafinil is sufficient to sustain alertness for several hours, most patients with excessive sleepiness require doses of 200 mg per day or higher. In two large populations of narcoleptic patients taking 200 to 400 mg per day, alertness measures (MWT, Epworth Sleepiness Scale [ESS], Clinical Global Impression of Change) gradually increased over 9 weeks of double-blind treatment.[76,77] In one study, mean latencies on the MSLT improved by 1.8 and 19.9 minutes with modafinil 200 and 400 mg, respectively (from baseline of 2.9 and 3.3 minutes), and ESS score declined by 3.5 and 4.1 points from 17.9 and 17.1, respectively.[76] Some individuals with severe sleepiness may require modafinil at 600 to 800 mg per day in divided doses (morning and no later than early afternoon to avoid insomnia) for effective control of their symptoms.[78,79] Although these doses are significantly above the FDA-indicated guidelines, if lower doses are well tolerated but ineffective, then it is reasonable to titrate up to higher doses. Armodafinil's potency is estimated at approximately twice that of modafinil; thus initial dosing may start as low as 50 mg, increasing to as much as 250 mg in the morning. Armodafinil was found to increase mean sleep latencies on MWT of narcoleptics by 1.3 minutes (from baseline of 12.1 minutes) and 2.6 minutes (from baseline of 9.5 minutes) at 150 mg versus 250 mg respectively.[80]

Use in Idiopathic Hypersomnia

Both sympathomimetics (methylphenidate) and modafinil have been used in the treatment of idiopathic hypersomnia (IH), although no large randomized and controlled trials have been performed. A recent cohort study compared modafinil (50 to 600 mg/day) in patients with diagnoses of IH with ($n = 59$) and without ($n = 45$) long sleep time and in patients with diagnoses of narcolepsy with cataplexy ($n = 126$). This study found similar improvements in subjective sleepiness in IH (ESS, −2.6) and narcolepsy and cataplexy (ESS, −3) patients. As a group, IH patients without long sleep time appeared more impaired at baseline (ESS, 18) and showed greater benefit with modafinil (ESS, 12) compared with the IH patients with long sleep time (ESS, 15 at baseline and 13.7 following modafinil treatment). The side-effect profile was similar, with more frequent side effects reported in the IH groups (nervousness 14%, palpitations 13%, headache 11%) compared with the narcolepsy and cataplexy group.[81] A small randomized crossover double-blind placebo-controlled trial showed objective improvement with higher MWT mean sleep latencies in 13 patients with narcolepsy and 14 patients with IH who took modafinil 400 mg/day for 5 days (30.8 minutes) compared with narcolepsy and IH patients taking placebo (19.7 minutes; controls = 39.6 minutes); this improvement was also correlated with better performance on an open highway driving test.[82]

Use in Sleep-Disordered Breathing

Modafinil and armodafinil are approved by the FDA for patients with OSA who have disabling sleepiness despite OSA-specific treatments such as nasal CPAP. Nasal CPAP treatment has been clearly demonstrated to improve alertness in patients with OSA,[83] but even with optimal mechanical therapy, chronic sleepiness remains a problem for some patients with sleep-disordered breathing. Indeed, a recent study of patients with OSA demonstrated a clear dose-response relationship between hours of CPAP use during sleep and both subjective and objective daytime sleepiness. However, about 20% of those study subjects with an average of 8 hours of use of CPAP per night remained excessively sleepy by self-report.[84] It has been hypothesized that this residual sleepiness in OSA patients is a long-term effect of the intermittent hypoxic episodes that their wake-promoting brain areas were exposed to before therapy.[85]

Whatever the underlying cause, it is clear that a subset of patients with OSA experience chronic residual sleepiness despite their compliance with mechanical treatments during sleep. For these patients, the adjunctive use of modafinil appears to be a reasonable and safe measure to improve their safety and quality of life. In a large, double-blind placebo-controlled study of patients with OSA reporting residual excessive sleepiness while on CPAP, modafinil at doses of 400 mg improved alertness by 2.6 points on the ESS above placebo-treated patients, and more than half the modafinil-treated patients reported normal ESS values (score of less than10) by the study end point.[86] Further, in a 12-week follow-up open-label study, adjunct modafinil treatment improved objective measures of alertness on the MSLT (8.6 minutes compared with 7.4 minutes at baseline). However, a small drop in CPAP use was also noted (5.9 hours/night in modafinil group compared to 6.3 hours/night during double-blind baseline). Subsequent studies have demonstrated the efficacy of modafinil in daily doses of 200 to 400 mg for improving alertness in CPAP-treated patients with OSA and residual sleepiness and confirmed a relative absence of adverse consequences in this patient population.[87]

Use in Shift Work

Millions of adults keep nonstandard work hours, with many experiencing chronic, problematic sleepiness as a result. Although many shift workers adapt adequately to the constraints of their schedules, there are many more who suffer at least transiently from the effects of both sleep deprivation and circadian misalignment. Furthermore, it is estimated that approximately 10% of the adults working nonstandard hours have persistent complaints of excessive sleepiness or insomnia consistent with the diagnosis of SWSD.[88] A double-blind placebo-controlled study of more than 200 night-shift workers demonstrated this group to be pathologically sleepy at baseline (MSLT average sleep latencies approximately 2 minutes), with significant cognitive impairment on a psychomotor vigilance task, as well as numerous mistakes, near misses, or accidents at work or while driving home after work. All of these measures improved substantially after treatment with 200 mg modafinil taken at the beginning of their night shift; for example, MSLT mean sleep latencies improved by +1.7 with modafinil versus 0.3 minutes with placebo. Furthermore, this treatment did not interfere with their ability to sleep during time off duty.[89] Armodafinil 150 mg increased MSLT-measured mean sleep latencies by 3 minutes from 2.3 minutes at baseline in shift work disorder.[90] On the basis of this and other evidence, the FDA approved modafinil for the treatment of excessive sleepiness due to SWSD in 2004. Together with a program

of nonpharmacologic measures to protect sleep time and sleep ability in this patient population, modafinil or armodafinil is a potentially life-saving treatment for these adults.

Potency

In a paradigm comparing modafinil 100 to 400 mg to caffeine 300 mg ingested at 10 PM during an overnight work period spanning 7 PM to 8:45 AM, healthy non–sleep-deprived subjects reported less subjective sleepiness and performed better in vigilance, attention, and recall tasks at all doses of modafinil and caffeine compared with placebo, but modafinil at 300 and 400 mg outperformed caffeine 300 mg.[74]

Side Effects

Side effects are fewer with modafinil than with sympathomimetics. The most common adverse events in the initial modafinil and armodafinil trials were headache, nausea, and anxiety, which increased in frequency if the dose was high or increased too quickly; side effects were usually transient, resolving with acclimatization.[76] Insomnia has not been reported widely and again appears to be dose-related and transient. In one study, modafinil 300 to 400 mg was shown to disrupt recovery daytime sleep following acute overnight sleep deprivation when ingested 11 hours before recovery sleep, with increased sleep latency, reduced sleep efficiency, and greater wake time after sleep onset compared with placebo, caffeine 300 mg, or modafinil 100 to 200 mg.[74] Modafinil 100 to 600 mg does not appear to worsen clinical measures of impulsivity or addictive behaviors in narcoleptic patients.[64]

There have been no clinically significant cardiovascular adverse effects from modafinil or armodafinil treatment in the clinical trials to date, including among patients with OSA.[86] However, at least one small study in 12 healthy volunteers showed increases in resting heart rate (+9 beats/minute on average) and systolic blood pressure (+7.3 mm Hg on average) following ingestion of 400 mg of modafinil on 3 consecutive days. Interestingly, this was not reflected in measures of peripheral sympathoexcitation, namely peroneal microneurographic activation, and 33% of the participants were presyncopal with tilt table testing with either placebo or modafinil ingestion, thus raising a question of underlying pathophysiologic confounders.[91] So far, it appears that only patients with a history of sensitivity to activating medications (e.g., those with mitral valve prolapse) experienced cardiovascular side effects from modafinil (e.g., palpitations, chest pain), and these symptoms reversed when the medication was discontinued. Psychotic symptoms have developed rarely and only at high doses of modafinil.[92] Cases of modafinil-induced hypersensitivity reactions, including rare cases of life-threatening Stevens-Johnson syndrome, have also been reported.

Additional Uses

In randomized placebo controlled trials, modafinil (200 to 300 mg) showed equal or superior efficacy compared to methylphenidate (20 to 30 mg/day) in improving ADHD symptoms in children.[71] However FDA approval for ADD treatment was not granted because of rare cases of Stevens-Johnson syndrome.[93] Modafinil has also been used in Parkinson disease, myotonic dystrophy, multiple sclerosis, traumatic brain injury, depression, and chronic fatigue syndrome. Studies in Parkinson disease have been somewhat contradictory, with smaller studies showing reduction in subjective (ESS), but not objective (MWT), measures of sleepiness at 100 to 200 mg/day,[94] with no significant improvement in ESS or MSLT (–0.16 vs. –0.7 in placebo vs. modafinil 400 mg) in a larger study of 37 patients.[95] Modafinil appears to reduce sleepiness in MD.[71] It was not found to be efficacious in MS patients or patients with chronic fatigue, whereas subjective improvement in sleepiness and fatigue was reported by patients with major depression, but the effect did not extend beyond the first 2 weeks of treatment. Two trials have shown benefit with modafinil 200 to 400 mg for fatigue but not sleepiness in patients with traumatic brain injury.[96]

Withdrawal

In large clinical trials of patients taking stable doses of modafinil for sleepiness, abrupt discontinuation did not elicit specific symptoms of withdrawal with rebound hypersomnia; rather, patients simply returned to their initial level of sleepiness. Patients who discontinue modafinil will typically experience a full return of sleepiness symptoms within 2 to 3 days of cessation. There are generally no obvious recovery changes to nighttime sleep because modafinil does not appear to significantly alter nighttime sleep architecture during treatment. This lack of rebound following discontinuation is a significant advantage for patients already on modafinil requiring diagnostic polysomnography and daytime sleep testing because it significantly reduces the time patients need off medication before testing. Patients withdrawn from modafinil can be expected to be fully back to baseline within 5 days, whereas patients withdrawn from chronic stimulants will generally need at least several weeks before sleep testing to allow normalization of sleep architecture patterns and recovery from rebound hypersomnolence.

Tolerance

Modafinil appears to have a very low, or idiosyncratic, occurrence of tolerance. Clinical and subjective self-assessments of efficacy remained stable for most of those patients who enrolled in open-label studies taking the same dose of modafinil for 3 years.[97,98]

Dependence and Abuse Potential

Modafinil is a Schedule IV medication, with limited potential for abuse and dependence. In abuse liability studies conducted with seasoned substance abusers, modafinil was similar to caffeine in its rating as producing some "good effects" on a subjective rating scale, and it did not elicit any desire to procure more (i.e., "amount willing to pay" was $0).[99] These and other studies demonstrate that the effects of modafinil are clearly different from predictably dose-dependent euphoria and the desire to have more drug that is seen with traditional stimulants like amphetamine. Moreover, modafinil has a slower onset of action, and its water-insoluble properties make it impossible to snort or inject, so it is not pharmacokinetically amenable to abuse. Postmarketing surveys and medical literature to date have identified only idiosyncratic cases of people developing addictions or cravings for modafinil. However, there are some reports that at doses as high as 800 mg, polysubstance abusers described a "high" similar to methylphenidate, while healthy users reported "liking" similar to d-amphetamine.[71] Some feared that modafinil would be abused to extend the wake period by college students or others

in similar situations, but this abuse has so far not been reported to be a widespread phenomenon. This form of abuse of wake-promoting medication is likely limited by the ultimate need to sleep—no medication is really an effective substitute for sleep—and more likely to occur with the more robustly arousing, traditional stimulants.

ADDITIONAL DAYTIME WAKE-PROMOTING AGENTS

Atomoxetine (Strattera) is a nonstimulant NET-specific inhibitor, originally developed as an antidepressant but currently used primarily in ADHD. It has modest wake-promoting as well as anticataplectic effects, but tachycardia, hypertension, and sexual dysfunction are limiting side effects.

Bupropion, a low-potency nonspecific monoamine reuptake inhibitor that also has DAT- inhibitory properties, is sometimes used to combat excessive sleepiness.[100] Bupropion may be especially effective when depression is a major comorbidity. Dose-dependent risk for seizures has been reported.

Finally, selegiline, a methamphetamine derivative, is an MAO-B inhibitor with wake- promoting and anticataplectic properties, the former effect likely owing to its metabolites L-amphetamine and L-methamphetamine. Doses of 20 to 30 mg appear clinically effective in comparison to similar doses of D-amphetamine, with lower potential for abuse.[55]

FUTURE WAKE-PROMOTING CANDIDATE AGENTS

Histamine-3 (H_3) receptor antagonists or inverse agonists, both enhancing histamine release, have been proposed as wake-promoting agents. At least one randomized controlled crossover trial compared a one-time dose of an H_3 receptor inverse agonist to modafinil (200 mg) or placebo in 56 subjects with diagnosis of OSA (apnea-hypoxia index greater than 15), compliant with positive airway pressure and with self-reported regular bedtimes and nightly sleep opportunity of 6.5 to 8 hours. The study showed efficacy of the new agent but no improvement over modafinil (MWT sleep latencies were 8.1 and 10.2 minutes longer than placebo values for H_3 receptor inverse agonist and modafinil), with higher incidence of insomnia (29% for H_3 receptor inverse agonist versus 9% for modafinil and 6% for placebo).[101]

The report of a GABA-A receptor activating compound identified in the cerebrospinal fluid of 32 hypersomnolent patients points to GABA-A receptor antagonists, such as flumazenil, as possible wake-promoting agents.[102] Unfortunately, flumazenil is not currently available in an oral formulation, but a case report of continuous subcutaneous administration of flumazenil for 26 days in one subject with idiopathic hypersomnia described a decrease in self-reported sleep time from 13.5 hours/day at baseline to 9.5 hours/day. ESS score decreased from 21 to 11 as well.[103] Sixty-four percent of the hypersomnolent patients whose cerebrospinal fluid increased GABA-A receptor activity reported subjective reduction in sleepiness and showed improved psychomotor vigilance with clarithromycin treatment (mean dose 1098 mg), presumably through clarithromycin's GABA-A receptor antagonist function, which has been demonstrated in vitro.[104] However, case reports of clarithromycin-induced hypersomnia in children exist as well.[105]

Finally, thyrotropin-releasing hormone agonists and hypocretin replacement, either through delivery of a synthetic ligand or gene therapy, have been proposed as wake-promoting treatments, but no human clinical trials have been done at this time.[55]

SODIUM OXYBATE

Mechanism of Action

Commercially available sodium oxybate, Xyrem, is the sodium salt of GHB. It is a rapidly acting sedative-hypnotic medication used for the treatment of daytime sleepiness and cataplexy in narcolepsy patients. Although the precise mechanism of action is unknown, the effects may be mediated in part through interaction with GABA-B and GHB receptors[106] because GHB is a GABA derivative present endogenously in the mammalian brain.[107] Its highest concentration is in the dopaminergic regions such as the substantia nigra and ventral tegmental area, suggesting that endogenous GHB may also modulate the activity of dopamine neurons.[108] What is interesting, and unknown, is how GHB reduces sleepiness—or elevates wakefulness—in patients, although it could be related to increases in delta power during sleep; sodium oxybate leads to dramatic increases in the density and duration of slow wave sleep each night.[109] Patients with narcolepsy frequently experience side effects as soon as GHB treatment is initiated, but much like antidepressant therapy, improvements in daytime functioning become robustly evident only after sustained use for weeks to months. Indeed, most patients must initially remain on daytime wake-promoting and anticataplectic medications. Although it is unclear how sodium oxybate effects improvements in alertness and reduces cataplexy, it seems reasonable to suppose the mechanism may be related to (or a consequence of) the changes to sleep it evokes each night.

Pharmacokinetics and Dynamics

GHB is rapidly absorbed after oral administration with nonlinear pharmacokinetics such that increases in dosing result in disproportionately higher plasma levels and thus a narrow safety margin.[107] The drug is metabolized rapidly to succinic semialdehyde, then oxidized to succinic acid and ultimately metabolized to carbon dioxide in the Krebs cycle. Onset of action is as fast as 15 minutes and the half-life is as short as 30 to 60 minutes, potentially resulting in sleep maintenance insomnia and necessitating a second dose within 2.5 to 4 hours from the first nightly dose. Oral bioavailability is affected by food, especially high-fat food; therefore administration should remain as consistent as possible and meals should ideally be consumed several hours before bedtime. Sodium oxybate is contraindicated in patients with succinic semialdehyde dehydrogenase deficiency, owing to inability of these patients to metabolize the drug.

Alerting Effects and Clinical Efficacy

The first report that GHB could be an effective treatment for excessive sleepiness in narcolepsy was published in 1979 by Broughton and Mamelak.[19] This study, along with follow-up reports demonstrating use of GHB for treatment of cataplexy in narcolepsy, led to larger research protocols to confirm its effects. FDA approval of sodium oxybate for cataplexy was based on two randomized, double-blind, placebo-controlled trials in patients with narcolepsy who were also being treated

with traditional stimulants.[110,111] Subsequent large trials demonstrated the efficacy of sodium oxybate for the treatment of sleepiness associated with narcolepsy, allowing an expanded indication for the use of this medication in narcolepsy.

In one placebo-controlled, randomized study involving 136 narcoleptic patients with cataplexy, sodium oxybate improved subjective sleepiness as determined by the ESS in a dose-related manner, but the effect was only statistically significant at a dose of 9 g per night.[110] At this dose, the median ESS dropped from 17 to 12, with some patients falling in the normal range (ESS lower than 10). There was also a significant reduction in the number of unintended naps or sleep attacks seen at doses of 6 and 9 g. In another multicenter, randomized, double-blind, placebo-controlled, parallel-arm trial study of 228 patients with narcolepsy with moderate to severe excessive daytime sleepiness and cataplexy symptoms, sodium oxybate demonstrated a significant median increase of more than 10 minutes in the MWT, significant reduction in median ESS, and reduction in weekly unintended naps.[112] In both these studies, most patients remained on wake-promoting medications at stable doses during the study.

Sodium oxybate is taken nightly, in divided doses on an empty stomach (no food within 2 to 4 hours of bedtime). As discussed earlier, food will mitigate absorption of sodium oxybate, so a variable eating schedule is a common source of adverse effects and inconsistent efficacy of similar dosing in patients. The usual effective dose range is 4.5 to 9 g per night, with half the total dose taken immediately before lying down to go to sleep and the second half 2.5 to 4 hours later. Although some patients will respond to this medication at lower doses, often patients will require the recommended dose of 6 to 9 g per night. To minimize side effects, for some patients it may be necessary to begin at much lower doses (e.g., 1 to 2 g per night) and increase sodium oxybate by 0.5- to 1.0-g increments once every several nights. At the 6-g/day dose sleep paralysis appears to be decreased more consistently than hypnagogic hallucinations.

Potency

In a multicenter, double-blind, placebo-controlled study of subjects with narcolepsy who had been taking modafinil, the effects on sleepiness of switching them to sodium oxybate, modafinil, the combination of sodium oxybate with modafinil, or placebo for 8 weeks were assessed.[111] Patients treated with sodium oxybate alone (6 g for 4 weeks and then 9 g for the subsequent 4 weeks) were compared with patients treated with modafinil (200 to 600 mg daily); both of these wake-promoting medications caused similar improvements in the patients' alertness on the MWT compared with the placebo treatment group. The greatest improvement in the MWT was seen in the group of patients taking both sodium oxybate and modafinil, suggesting an additive effect of each medication. ESS scores and weekly inadvertent naps and sleep attacks were also significantly reduced in the sodium oxybate and sodium oxybate–modafinil groups but not in the modafinil group. A limitation of the study was that the modafinil-treated patients remained on doses established before the study and were not further titrated to a maximally effective dose during the study. Additionally, to date there have been no studies that directly compare sodium oxybate to traditional stimulant medications. Furthermore, there have been no randomized, placebo-controlled trials using sodium oxybate for the treatment of excessive daytime sleepiness in patients other than those with narcolepsy.

Side Effects and Morbidity

The most commonly reported adverse events associated with the use of sodium oxybate in placebo-controlled trials (n = 655) and post-marketing use in 26,000 patients between 2002 and 2008 included nausea (2.2%), insomnia (1.4%), headache (1.4%), dizziness (1.3%), vomiting (1%), and somnolence (0.9%).[113] Enuresis and sleep walking have been reported as well, presumably related to increased slow wave sleep. Paradoxical sleep initiation insomnia (0.8%) has been reported with initial administration of GHB. Side effects appear to be dose dependent.

Psychiatric side effects of sodium oxybate are increasingly recognized and include emergent depression (0.6%), suicidal ideation, confusion, and psychosis.[113] Symptoms or pre-existing or new onset major depression and suicidality thus need to be monitored carefully and addressed immediately prior to initiation of and during use of sodium oxybate. Given the potent CNS depressant effects, care must be taken to prevent accidental access to the medication by young children or other household members, as accidental or intentional overdose can result in death.

Sodium oxybate has the potential to impair respiratory drive and thus should be used with great caution or not at all in patients being treated with sedative hypnotic agents or other CNS depressants, and should not be combined with alcohol. Sleep disordered breathing should be ruled out or adequately treated with CPAP or oral appliances prior to initiation of sodium oxybate,[114] and patients should be monitored for worsening of OSA or emergent central sleep apnea. Because impaired motor or cognitive function may occur when taking sodium oxybate, the elderly may be at higher risk of falls and injury. Patients should not drive or operate machinery for at least 6 hours after taking sodium oxybate.

Additional Health Benefits and Uses

Sodium oxybate has been investigated for treatment of alcohol withdrawal, fibromyalgia, and rapid eye movement (REM) behavior disorder, among other conditions.[113] Sleep-deprived normal subjects who took sodium oxybate before a 3-hour nap following a night of sleep deprivation slept a similar amount of time as the placebo group, but they also had a higher percentage of slow wave sleep during and longer MSLTs following the nap, reported less subjective sleepiness, and had faster reaction times on the psychomotor vigilance test.[115] Findings such as these suggest that sodium oxybate may exert its effects by increasing slow wave sleep.

Withdrawal

The discontinuation effects of sodium oxybate have not been systematically evaluated in controlled clinical trials, but an abstinence syndrome has not been reported in clinical investigations. After cessation of treatment, patients can expect a gradual return to baseline levels of sleepiness and recurrence of cataplexy symptoms over days to weeks.[112]

Tolerance

Tolerance development to sodium oxybate has not been reported.

Dependence and Abuse Potential

Sodium oxybate was available over the counter as a food supplement for many years, and it became popular with weightlifters who discovered that it accelerated muscle growth and recovery (no doubt secondary to its effect on growth hormone release during sleep). After reports of overdosing by weightlifters, increasing recreational abuse, and reported use as a "date-rape" drug given its sedative and anterograde amnesia side effects, GHB supplements were banned in 1990. Popular pressure to make sodium oxybate illegal was countered by lobbying efforts on the part of narcolepsy patients who testified to the drug's benefits when used appropriately for sleepiness and cataplexy. The end result was a unique dual-schedule mechanism such that sodium oxybate may be prescribed as a Schedule III drug through a centralized pharmacy, and abuse or diversion of sodium oxybate is prosecuted under Schedule I felony charges.

Sodium oxybate continues to have high street value because of its ability to induce euphoria and craving in users. There have been case reports of dependence after illicit use of sodium oxybate at frequent repeated doses in excess of the therapeutic dose range (18 to 250 g/day). Careful monitoring of patients for dependence and abuse is necessary, although as with sympathomimetic stimulants, addiction has not been described in narcoleptics.

IS ALL WAKEFULNESS THE SAME?

An additional aspect of efficacy is the subjective experience of wakefulness that each medication produces. That is, sympathomimetic-induced wakefulness may not feel the same, or in fact be the same, as the wakefulness produced by caffeine, modafinil, or sodium oxybate. It has been suggested that although several neurotransmitter systems facilitate alertness through their extensive projections throughout the cortex, these systems may not be simply redundant, but rather support different aspects of wakefulness.[116] In particular, the monoaminergic projections of the ascending reticular activating system may mediate a sort of "guard duty"—an externally directed vigilance or awareness of one's surroundings—whereas the hypothalamic arousal regions (tuberomammillary nucleus and orexin systems) may perhaps support a form of internally directed vigilance—attention, motivation, insight, and planning. Normally, a healthy balance of activity from these systems should allow a person to focus on a task while being aware of the surrounding milieu. This hypothesis stems in part from the observation that the excess dopamine and norepinephrine release after administration of high-dose amphetamines provokes a state of exaggerated hypervigilance, or paranoia, and impairs executive functions, including judgment, insight, and planning.[65]

The comparison of relative efficacy on cognitive benefits may be more difficult, however, because sleepy patients frequently judge their level of wakefulness not by the degree of mental alertness present but rather by the autonomic arousal that sympathomimetics generate. Conversely, it is important to distinguish wakefulness from cognitive enhancement as the desired clinical end point guiding titration, especially of sympathomimetics. Thus although subjective or objectively measured sleepiness may appear to be well controlled, patients may request increases in stimulant dosing based on perceived cognitive benefits in concentration, attention, and memory abilities. The coexistence in narcolepsy of sleepiness and deficits of attention and concentration is increasingly appreciated. However, no guidelines are currently available to inform dosing of psychostimulants or GHB for cognitive rather than wakefulness enhancement in narcolepsy or hypersomnia patients. Nevertheless, consideration of the varied mechanisms of alerting medications may be useful in understanding clinical outcomes.

SPECIFIC USE OF WAKE-PROMOTING MEDICATIONS

In Children

Side effects of sympathomimetics in children with narcolepsy have not been studied in detail; much of the available data concern the use of these agents for children with ADHD. The potential side effect of greatest concern is growth restriction.[117] For example, deficits in weight gain and height increase may occur after treatment of ADHD with dextroamphetamine or methylphenidate.[118,119] The growth restriction effects of the sympathomimetic agents are due to drug-induced anorexia and the reduction of slow wave sleep and attendant suppression of growth hormone release. The growth deficits may be reversed during summers off medication,[119,120] and with these drug holidays, there is little or no evidence of long-term effects on growth. Obviously, the need for drug holidays to circumvent the effects on growth means that, during treatment interruptions, the child may suffer disabling symptoms that hamper functioning socially and at home. Motor tics can also occur in children taking sympathomimetics,[121] and these may limit dosing. Typical initial doses of these agents for treatment of ADHD in children are methylphenidate 0.3 mg/kg or dextroamphetamine 0.15 mg/kg, followed by dose titration to achieve optimal effects. The safety of higher doses (e.g., methylphenidate 60 mg/day) for children with narcolepsy, compared with doses currently recommended for ADHD, is unknown.

Neither modafinil nor sodium oxybate is currently indicated for patients younger than 16 years. Both medications have potential advantages for use in children because neither medication degrades nighttime sleep or interferes with appetite, so growth restriction may be less likely to occur compared with the sympathomimetic agents. Indeed, phase III studies of modafinil in children with ADHD revealed equal or superior efficacy of modafinil 400 to 600 mg/day compared with sympathomimetics. However, there was increased risk for rash, including one case reported as Stevens-Johnson syndrome.[93] However, in clinical practice modafinil is commonly used off-label for treatment of sleepiness due to narcolepsy in children either as a first-line agent or, more commonly, following failed trials of sympathomimetics. Further safety and efficacy studies are also needed for sodium oxybate, although this medication is frequently used off-label for narcolepsy in children.

In Sustained Military Operations

During the 1991 Persian Gulf War and during the American-led occupation of Iraq, armed forces were issued modafinil and dextroamphetamines for vigilance during sustained operations (S. Lubin, personal communication). Although there are few controlled studies, in a study of U.S. Army helicopter pilots

engaged in flight simulation after prolonged periods of wakefulness, 10 mg of dextroamphetamine, compared with placebo, improved aviator simulator control on descents and turns. Performance was facilitated most noticeably after 22, 26, and 34 hours of continuous wakefulness. Alertness was sustained significantly by dextroamphetamine—there was reduced slow wave electroencephalographic activity and improved rating of vigor and fatigue. No adverse behavioral or physiologic effects were observed.[122,123] Comparable results on performance have also been demonstrated with modafinil during 64 hours of sustained mental work.[124] Interestingly, the recovery sleep after extended periods of modafinil treatment shows a lack of the rebound hypersomnolence characteristic of recovery sleep following amphetamine treatment.[72,125] This difference suggests that modafinil may exert its alerting effects in a novel way, without invoking a rise in the homeostatic sleep drive.

In Sleepiness Due to Insufficient Sleep

Insufficient sleep, beyond the military situation, arises in many circumstances. Common among these circumstances are jet lag and shift work. Modafinil has recently been approved for the treatment of sleepiness in SWSD. The prospective use of alerting agents to enhance the alertness and performance among resident physicians has become a focus of discussion.[126,127] This use of alerting medications is problematic for many physicians, and active debate continues. The key points of this debate center on the relative importance of the potential benefit for safety and performance, especially when a high degree of vigilance is required, and the potential for abuse and dependency associated with these agents. The demand for alerting medications is likely to increase as our society continues to depend on 24-hour operations in the manufacturing, transportation, and service industries, underlining the importance of a careful risk-benefit analysis, currently limited by absence of large controlled clinical studies.

In Circadian Misalignment

SWSD presents a special case of a frequently shortened sleep zone, in which circadian mismatch results in wakefulness required at the natural circadian nadir and insomnia naturally ensuing at the peak of circadian wake, further exacerbating insufficient sleep. The contribution of circadian mismatch, rather than a contracted sleep zone that is purely behavioral in source, cannot be overemphasized in cases of SWSD. Whereas modafinil has shown limited benefit in studies of prolonged partial sleep deprivation, it may play a particularly important role in counteracting the sleepiness associated with the circadian nadir. However, the importance of obtaining sufficient sleep should be emphasized to patients, and the addition of a hypnotic to counteract sleep initiation and maintenance insomnia attributed to circadian mismatch may be indicated as well. The role of sympathomimetics may be more limited by their extensive side-effect profile, including cardiovascular side effects.

Wake-Promoting Agents as "Smart Pills"

Both sympathomimetics and modafinil have been explored as possible "neuroenhancement" agents in healthy people, either in the rested state or following sleep deprivation. Surveys in the mid to late 2000s have reported pervasive "academic doping" using nonmedical stimulants (typically amphetamine and methylphenidate) ,with the goal of cognitive enhancement or "staying awake," that ranges between 8% and 34% in college student populations.[71] The 2008 National Survey on Drug Use and Health reported a prevalence of 12.3% nonmedical stimulant use in 21- to 25-year-olds in the United States.[128] Surprisingly, controlled studies have not always substantiated robust and sustained cognitive benefits, especially for sympathomimetics. Smith and Farah reviewed placebo-controlled studies of sympathomimetic effects on cognition in healthy nonelderly adults and found inconclusive results, suggestive of enhanced long-term declarative memory consolidation and varied effects on executive function. Not only was improvement of working memory and cognitive control not always seen, some subjects were impaired, most notably high performers at baseline as well as those homozygous for the met allele of the catechol-*O*-methyl transferase gene.[128] Another recent meta-analysis suggested that a single dose of methylphenidate may improve motivation and memory, whereas repeated doses bolster subjective energy and attention during a partial-sleep-deprivation protocol (4 hours of sleep) but do not reduce sleepiness or improve cognitive measures during sustained sleep deprivation (64 hours) (for review, see Repantis and colleagues[129]).

A single dose of modafinil improved wakefulness and attention in both rested and sleep-deprived individuals, whereas repeated administration during 4 days of sleep deprivation improved wakefulness, but not cognitive measures.[129] Two important limitations were seen with modafinil administration in healthy individuals. First, repeated daily administration of 400 mg of modafinil increased scores on both positive (elevated mood) and negative (anxiety) affect scales. Second, after 64 (but not 24 or 40) hours of sustained sleep deprivation, there was an "overconfidence" mismatch between subjects' retrospective, self-reported cognitive performance and objective cognitive measures. In addition, there appears to be a narrow therapeutic range, with smaller (100 mg) but not larger (200 mg) doses showing cognitive enhancement properties following single administration in healthy rested people.[130]

In summary it appears that, although potentially helpful during limited bouts of partial sleep deprivation, wake-promoting agents are not adequate for counteracting the effects of sustained, complete sleep loss. Caution should be exercised with modafinil in particular, given reported potential for subjective overestimation of performance following sleep deprivation. Additionally, enhanced alertness and cognitive processes appear beneficial in a dose-dependent manner but only up to a point, beyond which wake-promoting agent efficacy is limited by side effects. Indeed, Lyon and Robbins have described the efficacy of sympathomimetics as an inverted U-shaped curve, with optimal "psychostimulant activation" at intermediate doses, whereas high doses remain limited by undesirable side effects, including stereotypic behaviors, cognitive inflexibility, psychosis, and addiction.[71,131] In addition, an emerging literature suggests that some of the perceived benefits of sympathomimetics may ensue from their mood-modifying[132] or motivation-modifying properties, rather than strictly cognitive (learning and memory or executive function) effects as previously expected.[128]

RECOMMENDATIONS AND TREATMENT PLANNING

Current practices in the use of alerting medications vary considerably. On the whole, patients who are medicated for

excessive sleepiness are still monitored primarily by clinical assessment of their ability to remain alert during sedentary activities, with medication selection and dosing decisions adjusted accordingly with consideration of medication side-effect profiles. Few studies directly compare the relative efficacies of wake-promoting medications, although an earlier comparison of the studies assessing the effects of various medications on MSLT and MWT measures suggested that classic stimulants may be most potent for the majority of sleepy narcoleptics.[133] All prescription wake-promoting medications produce clinically significant improvements in alertness in narcolepsy, but based on the available published data, only a small proportion of very sleepy patients will achieve normal levels of alertness with medication.[134] Clinicians should treat individual patients based on their profile of sleepiness throughout the day and their ability to tolerate side effects. Although many authorities recommend temporary withdrawal of sympathomimetic medications or reduction of dose if tolerance occurs (i.e., drug holidays[135,136]), there are no published studies demonstrating the efficacy of drug holidays. The effect of drug holidays on patient safety and quality of life must also be considered. Another factor that probably influences clinical practice is whether an alerting medication has been placed on Schedule II by the U.S. Drug Enforcement Administration. Because of the extra paperwork required in some states to prescribe Schedule II agents, Schedule IV drugs such as modafinil may be preferentially prescribed. Similarly, the risks for abuse or diversion may deter some clinicians from prescribing sodium oxybate.

Alerting medications, however prescribed, represent only part of a comprehensive therapeutic approach to excessive somnolence. Sound sleep hygiene, attention to other substances and drugs that may disrupt the sleep-wake cycle, and periodic reassessment of symptom severity and the need for and adequacy of treatment modalities are other important aspects of management. The physician should consider the following points in establishing the proper dose of an alerting drug and structuring a management plan:

1. *Diagnosis*. It is important to define as carefully as possible the factors that contribute to a patient's excessive sleepiness. Differentiating an insidious and lifelong condition such as narcolepsy from sleepiness due to sleep-related breathing disorders, for example, is essential for both the patient and the clinician.
2. *Education*. Clarify the goals of treatment, side effects, risks, and benefits. This process involves discussions with the patient and, perhaps, the patient's family members or companions. Normal alertness throughout the day may not be attainable in many patients because of the disease process, drug side effects, work schedules, or other idiosyncratic circumstances.

   In cases of SWSD, advocating for a work schedule change (such as a switch to daytime work hours) may be the ideal alternative to fully restore alertness. Unfortunately, many people do not have the ability to control their schedules directly and must continue to cope with their current situation. In this case, the clinician must support the patient's need for alertness without imposing judgment about the need for lifestyle changes.

   The importance of obtaining sufficient sleep whenever possible should always be emphasized, however, because stimulants promote wakefulness but cannot substitute for sleep.
3. *Dosing*. Begin with a low to moderate dose of a wake-promoting agent and match the drug and dosage to the patient. For most patients, aim to provide even alertness throughout the wake period. Modafinil or long-acting sympathomimetics provide advantages in this respect. Short-acting sympathomimetics may be useful especially for someone who needs rapid alertness on arising from sleep (e.g., in order to drive). Short-acting medications also provide opportunities for napping between doses but can produce unprotected sleepiness. Recommendations for starting and maximal doses of commonly used wake-promoting medications are summarized in Table 44-2.
4. *Follow-up*. Initially, pharmacologic management should be guided by regular (e.g., weekly) contact with the patient. If prescribing sympathomimetics, it is wise to periodically measure growth (height and weight) in children and weight, pulse, and blood pressure in adults. Patients should be monitored frequently to determine the effective dose and preparation for their symptoms and for side effects. After the dose is stable, patients should be seen every 6 to 12 months. Under circumstances in which the patient's safety or the safety of others depends on adequate control of excessive somnolence, laboratory confirmation of therapeutic efficacy with the MSLT or MWT is helpful.
5. *Emphasize sleep hygiene*. Consider short (30-minute), prophylactic naps. The effect of sleep inertia must be factored in if naps are used in the work setting or are prolonged, and may be counteracted by caffeine administration (100 to 200 mg) immediately preceding a 30-minute nap. Consider the use of light therapy, melatonin, or other modalities if circadian factors affect the ability to sleep (see Chapter 40).
6. *Adjust medication dosages* based on clinical information. Narcolepsy and idiopathic hypersomnia are usually stable conditions that do not progressively worsen. For a patient who has been on a stable dose for some time (years) and now appears to require more medication, consider other possible causes of increased sleepiness, such as: (1) interval development of sleep apnea or other primary sleep disorder that can contribute to sleepiness; (2) tolerance to medication; (3) change in schedule (e.g., a change in job shift, causing less sleep at night); (4) change in life situation (e.g., a new baby causing sleep disruption or a new job that requires greater vigilance); (5) stress, anxiety, or depression; and (6) unrealistic expectations. Evaluation should include a detailed history covering the not only these possibilities but also a review of the patient's sleep schedule and napping.
7. *Recommend counseling and long-term support*. A person with pathologic sleepiness who suddenly becomes more alert and energetic during the daytime may evoke strong feelings from family members not used to their active participation. Patients may become depressed or grieve the time "lost to sleep" before treatment after the degree of their prior impairment becomes clear to them. Available evidence suggests that over time, patients tend to take less, not more, of their prescribed stimulant.[137] Although the reasons for this are undoubtedly complex and incompletely understood, it is important that the patient understand the long-term nature of his or her condition and the

benefits that can be obtained with regular use of alerting medications.

CHANGING OR COMBINING MEDICATIONS

For most patients, replacement of one alerting agent with another should present few problems. However, for patients taking high doses of sympathomimetic medications, a gradual weaning period may be prudent. Furthermore, if the patient is switching from a sympathomimetic stimulant to modafinil, the qualitative difference in their alerting effects—and the difference in peripheral side effects—usually necessitates a 3- to 4-week adjustment period during which the stimulant withdrawal effects dissipate and the patient begins to experience what he or she feels like on modafinil alone. Titration toward optimal control of alertness can then be done more clearly. By combining stimulants with different durations of action, it may be possible to maintain wakefulness during the day, allow for periods for napping, and promote long periods of sleep at night without producing medication-induced insomnia.

Except for studies with sodium oxybate and modafinil, there are no systematic studies of chronic treatment with more than one alerting agent at a time. Some patients report satisfactory results on combinations such as modafinil or extended-release sympathomimetics (for long-lasting effects) combined with small doses of short-acting sympathomimetics such as methylphenidate IR, taken on an as-needed basis. There are no known drug interactions that would preclude this practice, which is indeed common. However, in some patients, hypertension may develop or be exacerbated by the coadministration of multiple wake-promoting medications, so appropriate blood pressure monitoring is indicated during treatment. All of the available wake-promoting medications can be safely combined with nonsedating antidepressants used as anticataplectic agents, including TCAs, SSRIs, and serotonin-norepinephrine reuptake inhibitors.

CLINICAL PEARL

The main goal of the treatment of pathologic sleepiness is to address and correct the underlying sleep disorder. When sleepiness remains an issue despite nonpharmacologic treatment—such as in patients with narcolepsy, other central nervous system hypersomnias, or SWSD, and in some patients with OSA using CPAP—prescription alerting medications should be considered for the patient's safety and quality of life, with the recognition that these medications offer symptomatic rather than disease-modifying treatment. Modafinil and armodafinil are first-line agents in patients with excessive sleepiness due to these disorders because it prompts wakefulness without many side effects or rebound hypersomnia. A broad array of sympathomimetic compounds are also available to treat sleepiness and may be required in patients who do not respond adequately to modafinil, but the risks for abuse, tolerance, and side effects makes them second-line agents in treating narcolepsy or for off-label treatment of other sleep disorders. Caffeine is a useful alerting agent in situations of mild sleepiness, such as with shift work, following mild sleep deprivation, or to overcome sleep inertia, but tolerance can develop when taken daily. Sodium oxybate may be helpful in reducing excessive sleepiness when used in patients with narcolepsy and cataplexy.

SUMMARY

The potentially disabling symptom of sleepiness occurs in many sleep disorders. When this sleepiness does not resolve with nonpharmacologic approaches, the use of alerting medications is appropriate.[138] Caffeine is widely available and is consumed by most of the world's population. As an alerting agent, caffeine is most effective when used intermittently at doses of 200 mg or more; tolerance develops with chronic use, however. Severe or chronic sleepiness is best treated with one of the variety of prescription alerting medications. Treatment with alerting medications of excessive sleepiness associated with narcolepsy or idiopathic hypersomnia is almost always indicated to allow wakefulness when sustained vigilance is necessary, for the safety of both the individual and the public. Pharmacologic treatment with modafinil is now also indicated for severe sleepiness in patients with SWSD and in patients with OSA who remain sleepy despite compliance with nasal CPAP. Sodium oxybate may be indicated in patients with narcolepsy and cataplexy. Because the risk for teratogenicity associated with the use of alerting agents is uncertain, these drugs in general should be avoided in pregnancy unless the benefits associated with their use are likely to outweigh the risks.

Drugs that Disturb Sleep and Wakefulness

Paula K. Schweitzer; Angela C. Randazzo

Chapter Highlights

- Disturbed sleep and daytime sedation are common side effects of many medications. Sedating drugs may impair waking function if the sedating action occurs during waking hours, from either prolonged duration of action or administration during waking hours. Drugs that disrupt sleep can lead to impaired waking function and daytime sleepiness, whereas drugs that promote alertness may disrupt sleep.
- Principal pharmacologic mechanisms promoting sedation include antagonism of histamine-1 (H_1) receptors, norepinephrine α_1 receptors, muscarinic cholinergic receptors, serotonin type 2 receptors (5-HT_2), or dopamine receptors.
- Principal pharmacologic mechanisms promoting wakefulness include reuptake inhibition of norepinephrine, serotonin, and dopamine, as well as inhibition of monoamine oxidase.
- A number of drugs have pharmacologic effects at the receptors involved in sleep-wake regulation and thus have the potential to disrupt sleep or impair waking function. Psychotherapeutic drugs are the principal drugs with the potential for these negative effects. However, a variety of other drugs may produce negative effects on sleep-wake function, including antiepileptics as well as drugs used in the treatment of cardiovascular disease, Parkinson disease, and pain.

Research on the neural mechanisms involved in sleep-wake regulation suggests that sleep-wake state is controlled by a complex interaction between wakefulness-promoting and sleep-promoting nuclei in the hypothalamus and brainstem.[1-3] Wake-promoting neurons include orexinergic and histaminergic nuclei in the hypothalamus, cholinergic nuclei in the brainstem, adrenergic nuclei in the locus coeruleus, serotonergic nuclei in the raphe nuclei, and dopaminergic nuclei in the midbrain ventral tegmental area. Sleep is promoted by nuclei in the basal forebrain, ventrolateral preoptic area, and anterior hypothalamus through the inhibitory neurotransmitters gamma-aminobutyric acid (GABA) and galanin. Adenosine, which has been proposed to be involved in homeostatic regulation of sleep, may promote sleep through anticholinergic activity in the basal forebrain and brainstem. Drugs with pharmacologic effects at receptors involved in sleep-wake regulation may therefore have effects on sleep-wake behavior. These effects may be therapeutic (e.g., improve sleep or enhance wakefulness) or impairing (e.g., cause sleep disturbance or daytime sedation).

Table 45-1 summarizes pharmacologic mechanisms of drug effects on sleep and waking behavior.[4] Drugs can cause sedation by multiple mechanisms, either by increasing the activity of the sleep-promoting system through GABA enhancement (e.g., benzodiazepine receptor agonists, ethanol) or by inhibiting the wake-promoting system through antagonism of central histamine-1 (H_1) receptors (e.g., first-generation antihistamines, tricyclic antidepressants), norepinephrine α_1 receptors (e.g., certain antidepressant and antipsychotic medications), muscarinic cholinergic receptors (e.g., some antidepressants), serotonin-2 (5-HT_2) receptors (e.g., trazodone, mirtazapine, olanzapine, quetiapine), or dopamine receptors (e.g., certain antipsychotics). Similarly, drugs can disrupt sleep through effects on either the sleep-promoting system or the wake-promoting system. More specifically, wake promotion may occur through blockade of the reuptake of serotonin (5-HT; e.g., fluoxetine), norepinephrine (e.g., venlafaxine), or dopamine (e.g., bupropion), or by inhibition of monoamine oxidase (MAO; e.g., phenelzine), thereby increasing the available amount of norepinephrine, serotonin, and dopamine.

Drugs may also affect homeostatic and circadian processes involved in sleep-wake regulation. Effects on neurotransmitters and neuronal systems involved in the generation of slow wave sleep (SWS) and rapid eye movement (REM) sleep can affect sleep architecture. REM suppression may occur with blockade of cholinergic receptors and increased 5-HT binding to 5-HT_{1A} receptors. SWS may increase through blockade of 5-HT_2 receptors. Drugs can also impair sleep or wakefulness by causing or exacerbating restless legs syndrome (RLS) and periodic limb movements during sleep (PLMS). The mechanism by which this occurs is not clear but may be associated with increasing availability of 5-HT and blockade of dopamine receptors. Dose, half-life, and time to peak concentration are additional important factors that may determine the effects of drugs on behavior. Pharmacologic effects may vary with drug dose. For example, doxepin at low doses is predominantly a histamine antagonist, whereas at higher doses it also inhibits serotonin transporter (5-HTT) and norepinephrine transporter (NET), in addition to having α-adrenergic and

Table 45-1 Pharmacologic Mechanisms of Drug Effects on Sleep and Wake Behavior

Mechanism	Promotes Sleep	Promotes Wake	Suppresses REM Sleep	Increases SWS	Promotes RLS/PLMS

anticholinergic effects. Half-life, combined with drug dose, determines the duration of clinical effects. Time to peak concentration affects the speed with which clinical effects may occur.

Sedating drugs may impair waking function if the sedating action occurs during waking hours, from either prolonged duration of action or administration during waking hours. Drugs that disrupt sleep can lead to impaired waking function and daytime sleepiness, whereas drugs that promote alertness may disrupt sleep. Thus the desired action of a drug may become an undesirable action when its effect occurs at the "wrong" time of day or night. In addition, drugs often act at multiple neural sites involved in sleep-wake regulation. Thus the desired action of a drug may be produced by effects at specific receptor sites, and undesired actions may occur because of concomitant effects at other receptor sites.

This chapter reviews drugs that are used for common medical and psychiatric conditions and that have unintended effects on sleep or wakefulness. Drugs used as hypnotics, stimulants, and drugs of abuse are reviewed elsewhere in this volume.

PSYCHOTHERAPEUTIC DRUGS

Psychotherapeutic drugs have a variety of pharmacologic effects on sleep-wake function. Table 45-1 summarizes the pharmacologic mechanisms likely responsible for the effects of antidepressant and antipsychotic drugs on sleep-wake behavior. Table 45-2 summarizes the effects of psychotherapeutic drugs on sleep-wake behavior. Figure 45-1 displays receptor binding affinity data for many of these drugs.[6]

Antidepressants

Drugs classified as antidepressants are used in a variety of disorders, including depression, obsessive-compulsive disorder, anxiety disorders, neuropathic pain, and others. Sedating antidepressants used as hypnotics are covered elsewhere in this volume.

Antidepressant drugs can improve or disturb sleep as well as affect waking function. Evaluation of the effects of these drugs on sleep and wakefulness is complicated by the fact that many individuals with depression have disturbed sleep[7] as well as daytime complaints such as fatigue, sleepiness, somatic complaints, and decreased cognitive and psychomotor functioning.[8-10]

Tricyclic Antidepressants

Most tricyclic antidepressants (TCAs) are used in the treatment of depression. However, clomipramine and doxepin have U.S. Food and Drug Administration (FDA) indications for obsessive-compulsive disorder. These drugs differ from one another in their relative effects in blocking reuptake of 5-HT compared with norepinephrine as well as in the degree of antagonism of muscarinic cholinergic receptors and H_1 receptors[11] (see Figure 45-1). The more sedating TCAs tend to be more anticholinergic (amitriptyline) and more antihistaminergic (doxepin, trimipramine) but also exhibit proportionately greater inhibition of 5-HT reuptake than norepinephrine reuptake.

Generally, these drugs decrease sleep latency, increase total sleep time (TST), and decrease REM sleep while increasing phasic eye movements during REM.[12,13] TCAs that are more adrenergic (e.g., desipramine, nortriptyline) may decrease TST and increase awakenings.[14] TCAs may increase PLMS and symptoms of RLS.[13] Multiple Sleep Latency Test (MSLT) latency was significantly decreased following a single evening 75-mg dose of amitriptyline.[15] Cognitive, psychomotor, and driving performance are impaired with acute use in normal subjects, but there is evidence that these effects lessen with time.[16-18]

Table 45-2 Effects of Psychotherapeutic Drugs on Sleep and Wake Behavior

Drug or Class	U.S. Trade Name	FDA Indication	Primary Mechanism of Action	Subjective Data	PSG Data	MSLT Data	Cognitive and Performance Data
Antidepressants							
Tricyclic Antidepressants (TCAs)							
Amitriptyline Amoxapine Imipramine Trimipramine Clomipramine	Elavil Asendin Tofranil Surmontil Anafranil	Depression OCD	5-HT > NE reuptake inhibition; α_1, M, H_1, 5-HT_2 antagonism	Somnolence +++ Insomnia + Nightmares ?RBD	↑TST, ↓W, ↓↓REM, ↑PLMS	↓SL	Mild to moderate impairment acutely
Doxepin	Anafranil Sinequan	OCD	5-HT = NE reuptake inhibition; α_1, M, H_1, 5-HT_2 antagonism	Somnolence +		No data	
Desipramine Nortriptyline Protriptyline	Norpramin Pamelor Vivactil	Depression	NE > 5-HT reuptake inhibition; M antagonism	Insomnia + Nightmares	↑W, ↓TST, ↓↓REM, ↑PLMS		
Selective Serotonin Reuptake Inhibitors (SSRIs)							
Citalopram	Celexa	Depression	5-HT reuptake inhibition	Insomnia + Somnolence +	↓TST, ↑W, ↓REM, ↑PLMS	No data	No impairment
Escitalopram	Lexapro	Depression, GAD, OCD	5-HT reuptake inhibition	Insomnia + Somnolence + Nightmares, RLS	↓REM ? ↑PLMS	No change in MSLT	Improved
Fluoxetine	Prozac, Sarafem	Depression, bulimia nervosa, OCD, panic disorder, PMDD	5-HT reuptake inhibition	Insomnia ++ Somnolence + Nightmares, RLS	↓TST, ↑W, ↓REM,↓SWS, ↑SEMs, ↑PLMS	↑ SL on modified MSLT	Generally no change or mild improvement
Fluvoxamine	Luvox	OCD	5-HT reuptake inhibition	Insomnia ++ Somnolence +	↓TST, ↑W, ↑SL, ↓REM	No change in MSLT	No impairment
Paroxetine	Paxil	Depression, GAD, OCD, panic disorder, PMDD, PTSD, social anxiety	5-HT reuptake inhibition	Insomnia ++ Somnolence ++ Nightmares	↑W, ↓TST, ↑SL, ↓REM ↑PLMS	No data	Mixed results
Sertraline	Zoloft	Depression, OCD, panic disorder, PMDD, PTSD, social anxiety	5-HT reuptake inhibition	Insomnia ++ Somnolence ++	↑SL, ↓TST, ↓REM, ↑REM latency, ↑PLMS		No change or mild improvement
Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)							
Desvenlafaxine	Pristiq	Depression	5-HT and NE reuptake inhibition	Insomnia ++ Somnolence +	No data	No data	No data
Duloxetine	Cymbalta	Depression, diabetic neuropathy, fibromyalgia, GAD, chronic musculoskeletal pain	5-HT and NE reuptake inhibition; weak D reuptake inhibition	Insomnia ++ Somnolence + Nightmares	↓REM, may ↑SWS, variable effects on sleep efficiency	No data	Improvement
Levomilnacipran	Fetzima	Depression	NE, 5-HT reuptake inhibition		No data	No data	No data

Milnacipran	Savella	Fibromyalgia	NE >5-HT reuptake inhibition	Insomnia +	↑W, ↓SL, ↓NREM, ↓REM	No data	No effects
Venlafaxine	Effexor	Depression, GAD, panic disorder, social anxiety	5-HT reuptake inhibition at low doses; NE reuptake inhibition at high doses; weak D reuptake inhibition	Insomnia +++ Somnolence +++ RLS Nightmares	↓TST, ↑W, ↓↓REM ↑PLMs	No data	↑ Performance in normals
Serotonin Antagonist Reuptake Inhibitors (SARIs)							
Nefazodone (no longer available in the U.S.)	Serzone	Depression	5-HT_2 antagonism; weak 5-HT and NE reuptake inhibition	Somnolence +++ Insomnia +++ Nightmares	↑TST		Mixed effects
Trazodone	Desyrel, Oleptro	Depression	5-HT_{2A} antagonism; 5-HT reuptake inhibition; α_1, H_1 antagonism	Somnolence ++	↑TST, ↓SL, ↓W, ↑SWS, ↓REM		↓ Function
Norepinephrine Dopamine Reuptake Inhibitors (NDRIs)							
Bupropion	Wellbutrin, Zyban, Aplenzin	Depression, smoking cessation, seasonal affective disorder	NE and D reuptake inhibition	Insomnia ++ Somnolence + Vivid dreaming, nightmares	↑REM, ↓SWS, ↑PLMS	No data	No impairment
Norepinephrine and Specific Serotonergic Antidepressants							
Mirtazapine	Remeron	Depression	α_1, α_2, H_1, 5-HT_2, 5-HT_3 antagonism	Somnolence +++ Insomnia + Nightmares, RLS	↑TST, ↓SL, ↑SWS, ↑PLMS	No data	↓ Performance acutely
Selective Norepinephrine Reuptake Inhibitors (NRIs)							
Atomoxetine	Strattera	ADHD	NE reuptake inhibition	Somnolence in children + Insomnia in adults +	↑REM latency, ?↓W in ADHD children	No data	?Improvement
Reboxetine (not available in the U.S.)			NE reuptake inhibition	Insomnia +	↓REM, acute ↑W, ↑REM latency		No impairment, ?improvement
Serotonin Partial Agonist Reuptake Inhibitor							
Vilazodone	Viibryd	Depression	5-HT reuptake inhibition; 5-HT_{1A} partial agonism	Insomnia + Abnormal dreams +	↓↓REM, ↑SWS, ↑W	No data	Improvement
Multimodal Antidepressant							
Vortioxetine	Brintellix	Depression	5-HT reuptake inhibition; 5-HT_3, 5-HT_7, 5-HT_{1D} antagonism; 5-HT_{1B} partial agonism; 5-HT_{1A} agonism	Abnormal dreams +	No data	No data	Improvement

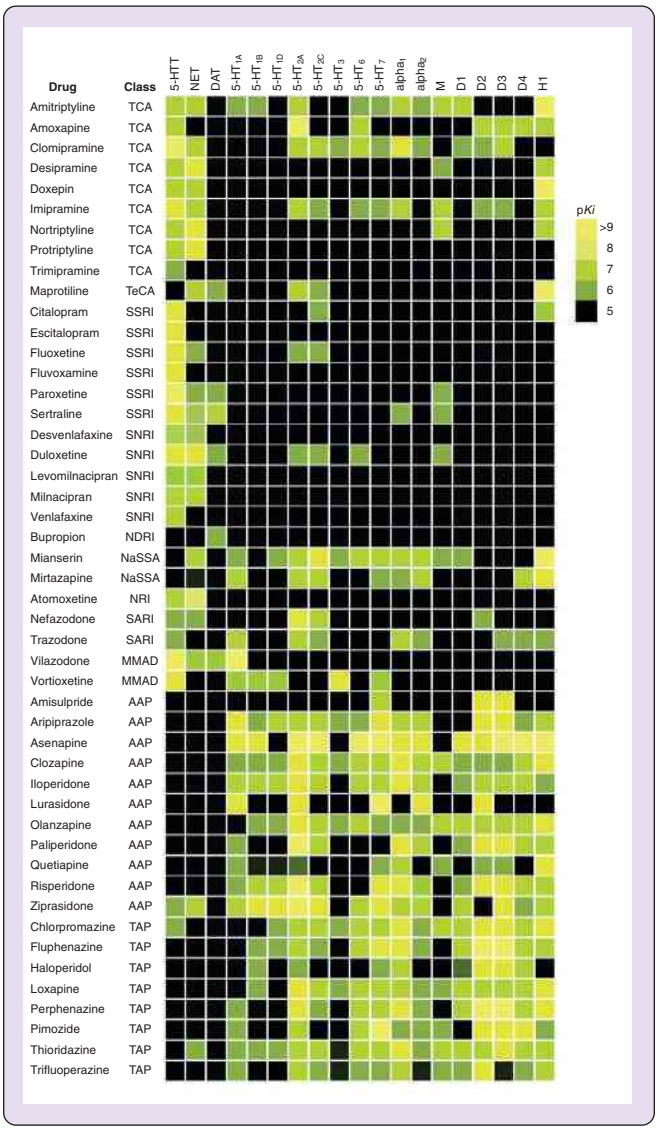

Figure 45-1 Heat map representation of receptor binding affinities for select psychotropic medications. Binding affinities (in p*Ki* values) range from 5 (inactive, *black*) to >9 (highly active, *yellow*). Binding affinity data were retrieved from the Psychoactive Drugs Screening Program (PDSP) database (http://pdsp.med.unc.edu)[5] and from Michl and colleagues.[6] 5-HT, Serotonin; 5-HTT, serotonin transporter; AAP, atypical antipsychotic; alpha, α-adrenergic; D, dopamine; DAT, dopamine transporter; H, histamine; M, muscarinic cholinergic; MMAD, multimodal antidepressant; NaSSA, noradrenergic and specific serotonergic antidepressant; NDRI, norepinephrine-dopamine reuptake inhibitor; NET, norepinephrine transporter; NRI, selective norepinephrine reuptake inhibitor; SARI, serotonin antagonist and reuptake inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TAP, typical antipsychotic; TCA, tricyclic antidepressant; TeCA, tetracyclic antidepressant. (Modified from Michl J, Scharinger C, Zauner M, et al. A multivariate approach linking reported side effects of clinical antidepressant and antipsychotic trials to in vitro binding affinities. *Eur Neuropsychopharmacol* 2014;24:1463–74.)

Selective Serotonin Reuptake Inhibitors

The primary mechanism of action of selective serotonin reuptake inhibitors (SSRIs) is potent inhibition of 5-HTT. With the exception of escitalopram, however, these drugs are not entirely selective. Citalopram has mild antihistamine properties; fluoxetine blocks the 5-HT_{2C} receptor, likely enhancing both norepinephrine and dopamine release; sertraline weakly inhibits the dopamine transporter (DAT); both sertraline and fluvoxamine are active at the σ_1 receptor, which may account for their anxiolytic effects; and paroxetine weakly inhibits NET. These diverse actions may explain why SSRIs may differentially be associated with insomnia[12,19] and daytime sedation.[8,12,20] Polysomnography (PSG) studies of SSRIs generally indicate disruption of sleep continuity and suppression of REM.[14,15,21] SSRIs are also associated with increased frequency of PLMS, RLS,[22] and REM sleep without atonia.[23]

Fluoxetine, which has been studied most extensively, decreases TST and increases wake time in normal subjects during single-night studies with doses of 20 to 60 mg[24] and in depressed patients with doses of 20 to 80 mg for up to 1 year.[25] Fluoxetine has been associated with the presence of prominent slow eye movements in non–rapid eye movement (NREM) sleep.[26] Paroxetine decreases TST and increases awakenings in normal subjects.[27] Escitalopram showed decreased TST, increased wake time, decreased REM sleep, and increased PLMS following a single 10-mg dose in healthy males.[15] In depressed patients, there is evidence of increased awakenings and sleep fragmentation with paroxetine and fluvoxamine.[28,29] Citalopram produced the typical decrease in REM sleep but no changes in sleep latency or TST in depressed patients during 5 weeks of treatment.[30] Sertraline prolonged both sleep latency and REM latency while decreasing REM sleep, but had no effects on sleep efficiency or wake after 12 weeks of treatment in depressed patients.[31]

SSRIs usually do not negatively affect daytime performance or cognitive functioning and may actually improve functioning in some patients, but data are limited. One placebo-controlled study reported memory impairment with paroxetine but improvement in a verbal task with sertraline.[32] A single nighttime dose of fluvoxamine in healthy subjects showed increased daytime sleep latencies compared with dothiepin but no change compared with placebo in a modified MSLT.[33]

Serotonin-Norepinephrine Reuptake Inhibitors

Serotonin-norepinephrine reuptake inhibitor (SNRI) drugs combine 5-HTT inhibition with varying degrees of NET inhibition, which reportedly results in improved cognitive and physical pain symptoms.[34] These drugs increase 5-HT and norepinephrine throughout the brain as well as increasing dopamine in the prefrontal cortex. Venlafaxine exhibits dose-dependent variability in NET inhibition, such that 5-HT reuptake predominates at low doses and NET inhibition progressively increases as dose increases. Duloxetine, in addition to 5-HTT and NET inhibition, also weakly inhibits DAT and has weak antagonistic activity at 5-HT_{2A}, 5-HT_{2C}, 5-HT_6, and muscarinic receptors.[5] With the exception of milnacipran (approved for treatment of fibromyalgia), all of these drugs have FDA indication for the treatment of depression. Duloxetine has, in addition, been approved for treatment of neuropathic pain, fibromyalgia, generalized anxiety disorder, and chronic musculoskeletal pain. Venlafaxine is additionally approved for use in anxiety and panic disorders and has been studied for use in obsessive-compulsive disorder and posttraumatic stress disorder.

Both insomnia and somnolence are common with venlafaxine (placebo-corrected rates in clinical trials of 14% and 8%, respectively), desvenlafaxine (5% to 8% and 3% to 9%),

and duloxetine (4% and 5%) but rare with milnacipran and levomilnacipran.[35] In normal subjects, 75 to 150 mg of venlafaxine produced increased wake and stage 1 sleep; in addition, in six of the eight subjects, frequent PLMS (more than 25 per hour) were noted.[36] In depressed inpatients treated for 1 month, venlafaxine (maximum dose 225 mg/day) increased PSG-recorded wake after sleep onset.[37] In one study of normal subjects, sleep efficiency was decreased with duloxetine 60 mg twice daily but increased by duloxetine 80 mg daily.[38] In a study of depressed patients, duloxetine 60 to 90 mg daily had no effect on sleep continuity but increased stage 3 sleep.[39] REM was suppressed in both studies. In a non–placebo-controlled study of depressed patients, milnacipran increased TST and decreased REM sleep.[40] There are no studies that objectively evaluate daytime sleepiness and alertness. Neurocognitive function is either unchanged or improved with these drugs.

Serotonin Antagonist and Reuptake Inhibitors

Trazodone weakly inhibits 5-HTT and blocks 5-HT_{2A} receptors at antidepressant doses. However, at the low doses typically used off-label for treatment of insomnia, it does not antagonize 5-HT_{2A} receptors. It shows moderate H_1 antagonism, also inhibits 5-HT_{1A} and 5-HT_{1C} receptors, and demonstrates weak α_1 and α_2 antagonism.[41] Nefazodone (no longer available in the United States) is also a 5-HT_{2A} antagonist and a weak inhibitor of 5-HTT, NET, and DAT but has little affinity for 5-HT_{1A}, α_1, α_2, or H_1 receptors.[41]

Trazodone is currently more likely to be used as a hypnotic than as an antidepressant in doses lower than those used for depression. Drowsiness is the most commonly-reported side effect.[35] PSG studies are limited by small sample sizes, lack of placebo control, and other methodologic factors. These studies indicate that trazodone likely decreases sleep latency, increases SWS, and does not affect REM sleep, but effects on sleep continuity are equivocal.[42] Nefazodone may increase TST but has no consistent effect on sleep latency, SWS, or REM sleep.[12,43] Trazodone impairs performance in healthy individuals,[44] but data on depressed individuals are inconclusive. In a placebo-controlled study, low-dose trazodone (50 mg) administered as a hypnotic before sleep for a week in primary insomniacs resulted in next-day impairment of memory, equilibrium, and muscle endurance but no decrease in MSLT latency.[45]

Norepinephrine and Dopamine Reuptake Inhibitor

Bupropion weakly inhibits DAT and NET.[5] It is approved for the treatment of depression, smoking cessation, and seasonal affective disorder. The low degree of DAT occupancy likely accounts for this drug being activating or stimulating without the abuse potential seen in stimulants that are also NET and DAT inhibitors. Bupropion is associated with insomnia in 5% to 19% of patients in clinical trials.[46] In a PSG study of seven depressed patients, after 4 weeks of treatment bupropion did not affect sleep latency or TST but did decrease REM latency and increase REM sleep percentage.[47] Bupropion is not usually associated with cognitive or psychomotor performance impairment.[44]

Norepinephrine and Specific Serotonin Antagonists

Mirtazapine disinhibits both 5-HT and norepinephrine through blockade of α_2 receptors.[48] It is a potent antagonist of H_1 and 5-HT_2 receptors, which likely accounts for its highly sedating activity and the reason for its use off-label as a hypnotic. PSG studies indicate improvements in sleep latency and sleep continuity.[49] One study suggests RLS symptoms develop or worsen in up to 28% of patients.[50] Mirtazapine impairs driving performance, attention, reaction time, and verbal memory, at least acutely, in normal subjects.[51,52] Bedtime dosing of mirtazapine 15 mg impaired next day road-tracking performance acutely but not after 9 days.[53]

Selective Norepinephrine Reuptake Inhibitors

Atomoxetine, although classified as a norepinephrine inhibitor because of its potent inhibition of NET, also inhibits both 5-HTT and DAT, although much less effectively.[5] This drug was not developed as an antidepressant; it is approved for treatment of attention-deficit/hyperactivity disorder (ADHD). Clinical trials indicate somnolence in ADHD children (2% incidence) but insomnia in ADHD adults (8% incidence).[35] A PSG study in ADHD children showed that atomoxetine increased REM latency but did not adversely affect sleep latency.[54]

Clinical trials of reboxetine, not available in the United States, indicate an incidence of insomnia of approximately 10%.[55] PSG studies in depressed patients showed acute increases in wake and persistent suppression of REM.[56] In healthy normal subjects, reboxetine was subjectively sedating but did not impair cognitive function.[57]

Serotonin Partial Agonist Reuptake Inhibitor

The only drug currently in this category is vilazodone, which is a 5-HTT inhibitor and a partial agonist at 5-HT_{1A} receptors. Insomnia and abnormal dreams have been reported in clinical trials with placebo-corrected incidence rates of 4% and 3%, respectively.[35] A single 20-mg dose of vilazodone in healthy young males resulted in near abolishment of REM sleep, increase in SWS and delta power, and increased wake time, probably a result of 5-HT_{1A} agonism.[58]

Multimodal Antidepressant

Vortioxetine is a multimodal antidepressant that inhibits 5-HTT and is also a 5-HT_3, 5-HT_{1D}, and 5-HT_7 receptor antagonist as well as a 5-HT_{1B} partial agonist and a 5-HT_{1A} agonist. Neither insomnia nor sedation has been reported in clinical trials. However, abnormal dreams occurred at a rate of 1% to 2% (placebo corrected).[35] There are no PSG studies in humans. However, in the rat, vortioxetine increased wakefulness and frontal cortical activity, likely because of 5-HT_7 and 5-HT_3 antagonism and 5-HT_{1A} agonism.[59] Neurocognitive function, including driving performance, does not appear to be impaired and may be improved independent of the improvement in depression.[60,61]

Monoamine Oxidase Inhibitors

Drugs of this type include moclobemide (not available in the United States) and selegeline. MAO inhibitors inhibit the action of MAO enzymes, resulting in increased concentrations of 5-HT, norepinephrine, and dopamine. MAO type A (MAO-A) is primarily involved in the metabolism of 5-HT, norepinephrine, epinephrine, melatonin, and dopamine, whereas MAO type B primarily metabolizes dopamine. The classic MAO inhibitors (e.g., isocarboxazid, phenelzine, tranylcypromine) irreversibly inhibit both MAO-A and MAO-B enzymes. Insomnia and daytime sedation are

commonly-reported side effects (up to 62% and 42% of patients, respectively),[62] but there are no placebo-controlled studies. The most impressive PSG finding is a marked decrease in REM sleep, including almost complete abolishment of REM sleep.[63] TST is also decreased. Although MSLT studies are lacking, actigraphic monitoring in a small group of patients confirmed periods of decreased daytime activity coincident with reported episodes of napping, possibly associated with poor nighttime sleep. Cognitive and psychomotor performance data are limited. Subjective and PSG data suggest that insomnia is more likely with higher doses.[64,65]

Melatonergic Antidepressant

Agomelatine, approved for treatment of depression in Europe but not available in the United States, is a potent agonist at both melatonin-1 (MT_1) and MT_2 receptors as well as an antagonist at 5-HT_{2C} receptors.[5] A single placebo-controlled PSG study showed phase shifts in body temperature and hormonal rhythms in healthy older men but no changes in sleep variables.[66] Studies without placebo control show variable effects on sleep.

Antipsychotic Drugs

Antipsychotic drugs were initially developed for the treatment of schizophrenia. However, many drugs now have clinical approval for the treatment of other disorders such as bipolar disorder, autism, obsessive-compulsive disorder, and major depressive disorder. In addition, these drugs have been used off-label in the treatment of dementia, depression, borderline personality disorder, posttraumatic stress disorder, substance abuse, eating disorders, anxiety, and insomnia.[67] Antipsychotics used as hypnotics (e.g., olanzapine, quetiapine) are covered more fully elsewhere in this volume.

Antipsychotic drugs have complex pharmacologic profiles (see Figure 45-1). Their antipsychotic effects are thought to be mediated primarily by antagonism of dopamine-2 (D_2) receptors in the mesolimbic dopamine pathway.[68] These drugs also block dopamine receptors in other neural pathways, leading to unwanted effects such as anhedonia, extrapyramidal symptoms, and hyperprolactinemia, which are commonly seen with the older or "typical" antipsychotics (e.g., chlorpromazine, haloperidol, thioridazine). These effects are decreased with the second-generation or "atypical" antipsychotic drugs that, in addition to blockade of dopamine receptors, also antagonize serotonin receptors (especially 5-HT_{2A}), have the ability to dissociate from D_2 receptors, may have partial agonist activity at D_2 receptors, or may act as partial agonists at 5-HT_{1A} receptors.[48] These drugs differ in their specificity for D_2 versus D_1 receptors. Typical antipsychotics also have some degree of 5-HT antagonism. Antipsychotics in general, whether typical or atypical, differ in the degree to which they block muscarinic cholinergic, H_1, and α-adrenergic receptors.[5,68] Sedation is more likely in drugs with relatively more potent antagonism of histamine, α-adrenergic, or 5-HT_2 receptors compared with antagonism of dopamine receptors. See Table 45-1 for a summary of the effects of these drugs on sleep and waking behavior.

Patients with schizophrenia commonly have insomnia and circadian rhythm disturbances.[69] Sedation is a common side effect of antipsychotic drugs, but insomnia has also been reported. Among the older drugs, chlorpromazine and thioridazine have very high rates of somnolence (33% to 57%), as does haloperidol (23%).[68] Among the atypical drugs, sedation is very frequent with clozapine (transient sedation 54%, persistent sedation 46%, and sedation requiring drug discontinuation 24%),[70] frequent with risperidone (30%) and olanzapine (29%), and moderately frequent with quetiapine and ziprasidone (12%).[68] Although ziprasidone and quetiapine would be expected to be sedating given their pharmacologic profiles, they appear less sedating than other drugs, possibly because of their short half-lives. Aripiprazole is least sedating (12%) but more likely to cause insomnia.

Insomnia is frequent with the typical antipsychotics haloperidol and thioridazine.[68] Among atypical drugs insomnia is highest with aripiprazole but also frequent with risperidone and olanzapine and moderately frequent with quetiapine and ziprasidone.[68] Although the mechanism is not clear, options include 5-HT_{1A} receptor agonism and RLS symptoms secondary to dopaminergic antagonism.[68] RLS symptoms have been reported in case reports for olanzapine, risperidone, quetiapine, and clozapine.[71-73] Drugs with high potency for blocking dopamine receptors are more likely to trigger RLS and PLMS.[4]

Double blind placebo-controlled PSG studies of healthy normal subjects and schizophrenia patients indicate that olanzapine markedly increases SWS, likely because of 5-HT_2 antagonism. Haloperidol, risperidone, and likely ziprasidone also increase SWS. Olanzapine also increases REM sleep; quetiapine and risperidone decrease REM sleep; and haloperidol and ziprasidone have variable effects on REM sleep. Clozapine, haloperidol, olanzapine, quetiapine, and ziprasidone all increase sleep continuity.[68,71,74-79] The relatively high cholinergic antagonism of chlorpromazine and thioridazine may lead to REM suppression, but PSG data are lacking.

Objective measures of daytime sleepiness are rare. However, both clozapine and olanzapine reduce MSLT latencies in schizophrenic patients.[80] A placebo-controlled study showed increased Epworth Sleepiness Scale scores with quetiapine but not with lurasidone in patients with acute schizophrenia.[81]

Although antipsychotics cause cognitive impairment in healthy subjects,[82] these drugs may have no negative effects in patients, who generally have mild to moderate cognitive impairment when untreated.[83] Although there is evidence that treatment with some atypical antipsychotics may remediate impairment of cognitive function,[84,85] results from large randomized trials have not supported this conclusion.[86] One exception is a study showing superior cognitive performance compared with placebo in patients receiving lurasidone.[87] Risperidone decreased cognitive performance while increasing sleepiness in a study in healthy normal subjects, and paliperidone was no different from placebo in the same study.[88]

Lithium

Lithium, which is used primarily in the treatment of bipolar disorder, is subjectively associated with improved nocturnal sleep and increased daytime sleepiness, at least initially.[89] Sleep disturbance is a prominent feature of mania and similar polysomnographically to that observed in major depression.[90] In healthy volunteers lithium increases SWS, decreases REM sleep,[91] and produces cognitive and psychomotor deficits, including prolonged reaction times, decreased vigilance, and

impairment of semantic reasoning.[90] Similar deficits have been shown in psychiatric patients taking lithium for periods of time ranging from 2 weeks to longer than 3 months,[92] although it is difficult to determine whether the deficits seen in the patient population are caused by the medication or their psychiatric illness. Degree of cognitive deficit increases with age, severity of disease, and lithium concentration.

Anxiolytic Drugs

The primary drugs used in the treatment of anxiety disorders include antidepressants (particularly SSRIs and SNRIs), benzodiazepines, and buspirone, a 5-HT_{1A} partial agonist. Antiepileptics and atypical antipsychotics are also sometimes used off-label, particularly pregabalin, quetiapine, and aripiprazole.[93,94] Prazosin, an antihypertensive with α_1-adrenergic antagonism, has been used to treat nightmares in posttraumatic stress disorder.[95]

Antidepressants, antiepileptics, and antipsychotics are covered elsewhere in this chapter. Benzodiazepines approved for treatment of anxiety disorders (e.g., alprazolam, clonazepam, diazepam, lorazepam) have similar pharmacologic profiles to benzodiazepines used to treat insomnia and thus similar side effects. Given that these drugs enhance GABA at the $GABA_A$ receptor, their most common side effect is sedation.[89] In nonanxious subjects, daytime administration of alprazolam and diazepam produced decreased MSLT latencies on both day 1 and day 7 of treatment, with alprazolam producing greater sleepiness than diazepam on the first day of treatment.[96] Performance impairment, including impairment of actual driving performance,[97] is common with daytime administration of benzodiazepines in studies of normal subjects and patient groups for treatment periods of up to 3 weeks, particularly at higher doses. Well-controlled studies are needed to determine whether longer-term use of benzodiazepine anxiolytics results in tolerance to these performance-impairing effects and whether there are differential effects between younger and older individuals.

Buspirone does not have the hypnotic, anticonvulsant, and muscle relaxant properties of the benzodiazepines. The anxiolytic efficacy of buspirone is similar to that of the benzodiazepines, but its onset of action is much slower, requiring up to 3 to 4 weeks.[98] Buspirone appears to act primarily as a 5-HT_{1A} partial agonist but also has effects on D_2 receptors.[99] It has no affinity for the benzodiazepine receptors and does not affect GABA binding. In clinical studies of anxious patients, buspirone was comparable with placebo in the frequency of subjective reports of sedation.[100] In a study of 12 patients with chronic insomnia, alertness as measured by MSLT was not impaired by 20 mg/day in divided doses over a 3-day period.[101] Compared with benzodiazepine anxiolytics, buspirone appears to have few negative effects on psychomotor, cognitive, or driving performance in healthy volunteers receiving short-term treatment or in patients treated for up to 4 weeks.[101,102]

ANTIEPILEPTIC DRUGS

Antiepileptic drugs (Table 45-3) include compounds with diverse pharmacology and chemistry that share the common property of ability to decrease neuronal excitability. Although these drugs are used to treat epilepsy, a number of them are used in the treatment of neurologic and psychiatric disease, including neuropathic pain, hyperkinetic movement disorders, migraine, RLS, bipolar disorder and schizophrenia.[103] For example, gabapentin is more frequently used for postherpetic neuralgia and RLS than for epilepsy, whereas pregabalin is more frequently used in the treatment of neuropathic pain and fibromyalgia than for seizure control. Both drugs, along with tiagabine, have been evaluated for insomnia. Lamotrigine and carbamazepine are used in the treatment of bipolar disorder, and eslicarbazepine is under study for bipolar treatment. Divalproex sodium and valproic acid are used for migraine prophylaxis.

Primary mechanisms of action of these drugs include (1) blockade of voltage-dependent sodium channels; (2) GABA-mediated enhancement through interaction with specific $GABA_A$ binding sites, inhibition of GABA metabolism, or reduction of neuronal uptake of GABA; and (3) blockade of voltage-gated calcium channels.[104] Many of the newer drugs have more specific mechanisms of action including (1) blockade of glutamate *N*-methyl-D-aspartate (NMDA; e.g., felbamate); (2) blockade of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainite receptors (e.g., topiramate, perampanel); (3) synaptic vesicle 2A binding (levetiracetam); and (4) enhancement of transmembrane potassium currents mediated by KCNQ ion channels (ezogabine).[104] Conventional or "older" antiepileptics are mostly likely to involve GABA neurotransmission, whereas most of the newer compounds are more likely to have other or multiple mechanisms of action; the exceptions are tiagabine and vigabatrin, whose mechanisms involve GABA inhibition.

Sleepiness is one of the most commonly-reported adverse effects of antiepileptic drugs. In general, drugs acting on GABAergic neurotransmission (benzodiazepines, barbiturates, tiagabine, vigabatrin) have the highest incidence of sleepiness or fatigue (15% to 30% or more). Interestingly, although placebo-controlled trials showed no difference between tiagabine and placebo in the incidence of sedation, open-label, long-term studies showed a 25% incidence of sedation with tiagabine.[105] The incidence of sedation with drugs acting primarily via sodium channel blockade (e.g., carbemazepine, phenytoin, eslicarbazepine) is 5% to 10%, while the incidence of sedation with drugs acting via calcium channel blockade or with multiple mechanisms of action varies substantially, being 5% to 15% for gabapentin, lamotrigine, perampanel, pregabalin, zonisamide, and 15% to 27% for levetiracetam and topirimate.[35,104,106-109]

PSG studies of established antiepileptic drugs in general show these drugs produce shorter sleep latency and increase TST.[110] The newer drugs show variable effects on sleep latency and sleep continuity (see Table 45-3). However, gabapentin, pregabalin, and tiagabine increase SWS, whereas lamotrigine decreases SWS.[111-114]

A placebo-controlled study in healthy normal subjects reported no decrement in MSLT latencies with levetiracetam.[114] However, results have been mixed in patient groups. One study of patients with partial epilepsy showed no decrement in MSLT latencies but an increase in Epworth Sleepiness Scale ratings,[115] whereas another reported decreased Maintenance of Wakefulness Test latencies.[116] Neither gabapentin nor topiramate showed increased sleepiness on a 6-minute "awake maintenance test," although gabapentin produced electroencephalogram slowing.[117] In studies without placebo control, patients treated with phenobarbital[118] or

Table 45-3 Effects of Antiepileptic Drugs on Sleep and Wake Behavior

Drug or Class	U.S. Trade Name	FDA Indication Other than Seizure Control	Primary Mechanism of Action	Subjective Data	PSG Data	MSLT / MWT Data	Cognitive / Performance Data
Conventional Antiepileptics							
Benzodiazepines: Clonazepam Diazepam Lorazepam	Klonopin Valium Ativan	Anxiety	$GABA_A$ receptor modulation	Somnolence +++	↓SL, ↓SWS, ↓REM	↓SL	Mild impairment
Carbamazepine	Tegretol	Bipolar disorder, trigeminal or glossopharyngeal neuralgia	Sodium channel blockade	Somnolence ++	?↓SL, ↑TST, ?↓REM, ↑SWS	↓SL	Mild impairment
Ethosuximide	Zarontin		Calcium channel blockade	Somnolence +		No data	No data
Phenobarbital	Phenobarbital		$GABA_A$ receptor modulation	Somnolence +++	↓SL, ↓#W, ↑TST, ↓REM	↓SL	Significant impairment
Phenytoin	Dilantin		Sodium channel blockade	Somnolence ++	↓SL, ↑S1, ↓SWS	No data	Moderate impairment
Primidone	Mysoline		$GABA_A$ receptor modulation	Somnolence +	↓SL	No data	No data
Valproate, valproic acid	Depakote Depakene	Mania Migraine prophylaxis	GABA synthesis, sodium channel blockade	Somnolence ++	↑TST, ↓#W, ↑S1	No change	Mild to moderate impairment
Atypical Antiepileptics							
Brivaracetam	Not approved	Under study for neuropathic pain	Synaptic vesicle SV2A binding, sodium channel blockade	Somnolence +	No data	No data	No impairment
Eslicarbazepine	Aptiom	Under study for bipolar disorder	Sodium channel blockade	Somnolence +	No data	No data	No impairment
Ezogabine	Potiga		Interaction with voltage-gated potassium KCNQ channels and with GABA receptors	Somnolence +			
Felbamate	Felbatol		Blockade of sodium and calcium channels and NMDA	Insomnia + Somnolence +	No data	No data	No data
Fosphenytoin	Cerebyx		Sodium channel blockade	Somnolence ++	No data	No data	No data
Gabapentin	Neurontin Gralise Horizant	Postherpetic neuralgia RLS	GABA turnover and calcium channel blockade	Somnolence ++	↑SWS, ↑REM, ↑TST,	↓MWT	No to moderate impairment
Lacosamide	Vimpat		Sodium channel slow inactivation	Somnolence +	No data	No data	No impairment

Table 45-3 Effects of Antiepileptic Drugs on Sleep and Wake Behavior—cont'd

Drug or Class	U.S. Trade Name	FDA Indication Other than Seizure Control	Primary Mechanism of Action	Subjective Data	PSG Data	MSLT / MWT Data	Cognitive / Performance Data
Lamotrigine	Lamictal	Bipolar disorder	Sodium channel blockade, possible increase of GABAergic activity	Somnolence + Insomnia +	?↓SWS	No change	No impairment
Levetiracetam	Keppra		Acutely: calcium channel blockade Chronically: synaptic vesicle SV2A binding	Somnolence ++	↑TST ↑SWS	No change in healthy normals, mixed findings in patients	Mild impairment
Oxcarbazepine	Trileptal Oxtellar XR		Sodium and calcium channel blockade, possibly potassium channel effects	Somnolence ++	No data	No data	Driving impairment
Perampanel	Fycompa		Antagonism on AMPA/kainite glutamate receptors	Somnolence ++			
Pregabalin	Lyrica	Fibromyalgia, neuropathic pain, postherpetic neuralgia, under study for anxiety	Selective binding to alpha-2-delta subunits of voltage-gated calcium channels	Somnolence ++	↓SL, ↓W, ↑SWS, ?↓REM	No data	Mild impairment
Rufinamide	Banzel		Probably sodium channel blockade	Somnolence ++	No data	No data	No impairment
Tiagabine	Gabitril		GABA uptake inhibition	Somnolence + to ++++	↑TST, ↑SWS	No data	Mild impairment
Topiramate	Topamax	Migraine prophylaxis	GABA increase, sodium blockade, antagonism of AMPA/kainite glutamate receptors, inhibition of brain carbonic anhydrase activity	Somnolence +++ RLS	No data	No impairment on MWT	Dose-dependent moderate to significant Impairment
Vigabatrin	Sabril	Infantile spasms	GABA transaminase inhibition	Somnolence ++	No data	No change?	No impairment
Zonisamide	Zonegran		Sodium and calcium channel blockade	Somnolence ++	No change	No change	Dose-dependent impairment

#W, Number of awakenings; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; GABA, gamma-aminobutyric acid; MAO, monoamine oxidase; MSLT, Multiple Sleep Latency Test; MWT, Maintenance of Wakefulness Test; NMDA, *N*-methyl-D-aspartate; REM, rapid eye movement; TST, total sleep time.

carbamazepine[119] had lower mean MSLT latencies, and patients on carbamazepine, phenytoin, phenobarbital, or valproate demonstrated increased drowsiness on the "awake maintenance test" compared with healthy control subjects and untreated patients with epilepsy.[106] Drug-naive patients with partial epilepsy on topiramate showed no change in MSLT latencies compared with healthy control subjects either at baseline or 2 months later.[120] Neither lamotrigine nor zonisamide showed change in MSLT when used as add-on therapy in patients with focal epilepsy.[121,122]

Cognitive impairment appears to be more common with phenobarbital and possibly with primidone than with other drugs, more common when multiple medications are used, and more common in children than in adults. Phenobarbital and phenytoin have most frequently been associated with significantly impaired neuropsychological function, particularly in the areas of short-term memory, concentration, and attention.[123] Carbamazepine is moderately impairing.[124] Among the newer antiepileptic drugs, topiramate demonstrates dose-dependent persistent impairment on multiple cognitive domains.[123,125,126] Most of the other newer drugs appear to have fewer and less severe negative cognitive effects. In particular, gabapentin, lamotrigine, vigabatrin, and levetiracetam appear to have few negative effects, although placebo-controlled studies are rare.[127-129] Driving impairment was less with oxcarbazepine than with carbamazepine.[130] A placebo-controlled study of pregabalin showed no driving impairment in healthy individuals but, unlike placebo, there was failure to improve skills with training.[131] It should be noted that well-controlled studies evaluating cognitive function are rare, and methodologic problems include subject composition, choice of neuropsychological test, lack of placebo control, and sample size. Because a number of these drugs are being increasingly used in nonepilepsy disorders, the need for carefully-controlled studies evaluating the effects of these drugs on daytime function is increased.

DRUGS USED IN THE TREATMENT OF PARKINSON DISEASE

Sleep disorders are extremely common in Parkinson disease, the most frequent being insomnia, sleep apnea, REM behavior disorder, RLS, and disorders of daytime alertness.[132] Sleep-related complaints, which tend to worsen with disease progression, may be the result of abnormalities in sleep-wake regulation caused by the disease, accompanying symptoms such as nocturnal motor disturbance, other sleep disorders such as sleep apnea or PLMS, concurrent medical or psychiatric illness, or the medications used for treatment. PSG studies of patients with Parkinson disease show increased sleep fragmentation[133] and decreased REM sleep and SWS,[132] along with increased incidence of REM behavior disorder.[134] PLMS and sleep apnea are also common. MSLT studies indicate a high prevalence of excessive daytime sleepiness.[135] Dopamine replacement is the primary treatment for Parkinson disease. Because sleep is significantly disrupted in Parkinson disease, it is difficult to determine whether changes in sleep and waking behavior following drug administration are due to direct effects of drug or effects of drug on disease.

The principle drugs used to treat Parkinson disease are levodopa/carbidopa and dopamine agonists, which include ergot agonists (apomorphine, bromocriptine, cabergoline, lisuride, piribedil, and pergolide) and nonergot agonists (pramipexole, ropinirole, and rotigotine). Amantadine is less commonly used. Adjunctive treatments include catechol-*O*-methyltransferase inhibitors (e.g., entacapone, tolcapone), which prolong the duration of the effect of levodopa,[136] anticholinergics (e.g., hyoscyamine, benztropine), and selective irreversible MAO-B inhibitors (selegiline, rasagiline) which presumably result in increased dopamine through blocking dopamine catabolism. Selegiline is metabolized to methamphetamine and amphetamine.[137]

Dopamine agonists differ somewhat in their selectivity for dopamine receptor subtypes. There are five subtypes of dopamine receptors divided into two major classes, D_1 (D_1 and D_5 subtypes) and D_2 (D_2, D_3, D_4 subtypes).[138] The nonergot drugs have higher selectivity than the ergot agonists.[139] Pergolide and apomorphine have both D_1 and D_2 agonist activity, whereas pramipexole, ropinirole, and rotigotine are D_2 selective. All three have higher specificity for the D_3 receptor subtype than for the D_2 subtype; however, pramipexole exhibits the highest specificity. Ergot-derived drugs also demonstrate 5-HT_{2A} and 5-HT_{2B} agonism. Long-term use of the ergot agonists cabergoline and pergolide have been associated with valvular heart disease, possibly associated with 5-HT_{2B} (and perhaps 5-HT_{2A}) agonism.[139]

Some data suggest that low doses of dopaminergic medications tend to improve sleep, whereas higher doses are likely to disrupt sleep.[132,139] PSG studies have shown mixed results, including both increased and decreased REM sleep and decreased SWS. Nightmares and visual hallucinations may be increased. Improvement in parkinsonian symptoms may independently improve sleep.

Although sleepiness is a common symptom in Parkinson disease, with prevalence rates of 15.5% to 74%,[140] there is controversy as to whether the sleepiness is related to the pathologic process of the disease itself (due to loss of neurons involved in the control of the sleep-wake cycle), use of specific drugs, or other factors, including comorbid disorders such as sleep apnea. Parkinson disease itself is associated with loss of orexin neurons,[141] and objective sleepiness in Parkinson disease correlates with decrease of cerebrospinal fluid hypocretin levels.[142] Subjective daytime sleepiness measured by Epworth Sleepiness Scale has been associated with nigrostriatal dopaminergic degeneration.[143]

Dopaminergic agonists have been associated with increases in daytime sleepiness, including sudden "sleep attacks."[144] Studies in rats[145] and humans[146] suggest that sleepiness may be a drug effect in that nonergot dopamine D_2 receptor agonists cause selective loss of orexin-immunoreactive neurons, possibly through suppression of glutamatergic inputs to orexin neurons. Although initial reports suggested that unintentional sleep episodes were related specifically to the nonergot dopamine agonists, subsequent data have indicated no difference in sleepiness or unintentional sleep episodes between ergot and nonergot agonists.[147,148] MSLT studies of Parkinson disease patients indicate no differences in sleepiness among various dopamine agonists, including pramipexole, ropinirole, bromocriptine, or pergolide, taken alone or in combination with levodopa,[149,150] or compared with levodopa alone.[151] On the other hand, a study in healthy individuals showed reduced MSLT latency with pramipexole but no differences among L-dopa, bromocriptine, and placebo.[152] (See Ataide and

Table 45-4 β-Adrenergic Antagonists: Selected Pharmacologic Characteristics and Risk for Insomnia

Drug	Lipid Solubility	β Selectivity*	Relative Affinity for 5-HT Receptors	Other Effects	Risk for Insomnia†
Bisoprolol	Moderate	β_1	Low		Low
Atenolol	Low	β_1	Low		Low
Betaxolol	Low	β_1			Low
Acebutolol	Moderate	β_1	Low	ISA‡	Low
Nebivolol	High	β_1	Low	Nitric oxide–mediated vasodilating activity	Low
Nadolol	Low	Nonselective	High		Low?
Sotalol	Low	Nonselective	High		Moderate?
Timolol	High	Nonselective	High		Moderate?
Pindolol	Moderate	Nonselective	High	ISA‡	Moderate
Carvedilol	Moderate	Nonselective	High	α_1 Antagonism	Moderate
Labetalol	Moderate	Nonselective	Low	α_1 Antagonism	High
Metoprolol	Moderate	β_1	Low		High
Propranolol	High	Nonselective	High		High

*Nonselective β antagonists appear to have more central nervous system–related side effects. They also have higher affinity for 5-HT receptors.
†High 5-HT receptor occupancy and high β_2 affinity may be more important factors in disrupting sleep than degree of lipophilicity although lipophilic compounds appear to be more disruptive of sleep than hydrophilic compounds.
‡β antagonists with intrinsic sympathomimetic activity (ISA) act as partial agonists at β_2 receptors.

colleagues[153] for a review of MSLT studies in Parkinson disease.) The association of sleepiness with dopaminergic drugs may be related to dose, with lower doses more likely to improve sleep through D_2 autoreceptor activation, whereas higher doses may impair wake through differential activation of D_1 receptors. Indeed, several studies suggest that higher doses of dopaminergic drugs are more likely to be associated with increased sleepiness.[154-156]

Cognitive and motor deficits are common in Parkinson disease. Anticholinergic drugs have been demonstrated to produce worsening of cognitive function, primarily in the areas of memory function.[157] In healthy subjects, pramipexole impaired cognitive performance while increasing subjective sedation,[158] pergolide impaired delayed response tasks but not memory or executive function,[159] while ropinirole resulted in improved fine motor activity and reaction time.[160] In patients with mild Parkinson disease, pramipexole worsened verbal fluency, but pergolide and L-dopa did not.[161] Evaluation of the effects of these drugs on cognitive function is complicated by the frequent presence of behavioral symptoms that may affect performance. Moreover, the interaction of disease-related severity of dopamine depletion with distinct dopamine replacement therapies may produce different cognitive profiles at various stages of disease.[162]

Dopaminergic medications are also used in the treatment of RLS (covered more fully elsewhere in this volume). Somnolence and fatigue have been reported with pramipexole and ropinirole.[163] PSG data on pramipexole, ropinirole, and cabergoline generally show improvements in sleep in this population.[160,164,165] However, these improvements are likely the result of treatment of symptoms rather than the sedating effect of the drug. In a single MSLT study in healthy normal subjects, ropinirole decreased mean MSLT latency.[166]

CARDIOVASCULAR DRUGS

β-Adrenergic Antagonists

Information on pharmacologic characteristics of β antagonists relevant to central nervous system (CNS) sleep-wake function is given in Table 45-4. CNS side effects reported with β blockers include tiredness, fatigue, insomnia, nightmares and vivid dreams, depression, mental confusion, and psychomotor impairment.[167] There have also been case reports of REM behavior disorder with lipophilic β blockers.[168] Although sleep disturbance appears to be more common with the more lipophilic drugs, high β_2 or 5-HT receptor occupancy may be a more important factor in causing sleep disruption.[169] Plasma concentration (degree of β antagonism) may also be a factor.[170] Drugs that are more selective for β_1 receptors have lower affinity for 5-HT receptors. On the other hand, β antagonists decrease melatonin release through inhibition of β_1 receptors, which could affect sleep.[171] Among these drugs, propranolol, which has high lipid solubility and high 5-HT affinity, is most commonly associated with disturbed sleep. A study of new-onset insomnia following treatment for newly diagnosed hypertension in patients 65 years and older suggests that both selectivity and lipophilicity influence the risk for insomnia because atenolol and bisoprolol were associated with low risk for insomnia, whereas carvedilol, metoprolol, labetalol, and propranolol were associated with high risk.[172] Nebivolol, a highly selective and lipophilic compound with endothelial nitric oxide–mediated vasodilation,

appears to be less disruptive of sleep.[173] β blockers with vasodilating properties through blockade of α_1 receptors (e.g., carvedilol, labetalol) have been associated with fatigue and somnolence.[174] One placebo-controlled study[175] in normal subjects demonstrated increased wake with propranolol, metoprolol, and pindolol, but not with atenolol. However, REM sleep was decreased by all four drugs. Reviews of the effects of β blockers on cognitive and psychomotor performance indicate that these drugs produce few consistent neuropsychological deficits.[167,169]

α_2-Adrenergic Agonists

Sedation is the most common side effect of both clonidine and methyldopa, occurring in 30% to 75% of patients, but the severity apparently diminishes with time.[176] There are also reports of insomnia and nightmares with these drugs. In a double-blind placebo-controlled crossover study, hypertensive men aged 31 to 59 years who were given 0.1 to 0.3 mg of clonidine twice daily showed significantly decreased TST compared with placebo after 3 months of use.[177] Healthy subjects, however, given clonidine acutely showed increases in TST.[178] No MSLT studies exist to quantify daytime sedation objectively. However, one study of a single morning dose of clonidine in young healthy subjects demonstrated microsleeps in six of eight subjects.[179] Few well-controlled studies exist that evaluate the effects of these drugs on performance. Verbal memory impairment and poorer workplace performance[180] have been reported in patients receiving methyldopa.

Hypolipidemic Drugs

Data mining studies indicate that statins, particularly the more lipophilic compounds, are associated with a higher reporting rate of insomnia in comparison with other drugs.[181,182] One PSG study in normal subjects showed increased wake after sleep onset with lovastatin, whereas pravastatin did not differ from placebo.[183] Subsequent placebo-controlled clinical trials and PSG studies of lovastatin, simvastatin, and pravastatin have in general failed to show increased sleep disturbance even with the more lipophilic compounds.[184,185] However, Roth and colleagues[186] reported performance decrements with lovastatin even though nocturnal sleep and daytime sleep tendency (measured by MSLT) were not affected. There have been case reports of short-term memory loss associated with statin use, but randomized studies using neuropsychological testing and a meta-analysis of observational studies suggest that these drugs may actually lower the odds for development of cognitive impairment.[187,188]

Other Cardiovascular Drugs

The α_1 antagonists (e.g., prazosin, terazosin) are sometimes associated with transient sedation. Prazosin has been used in the treatment of nightmares and sleep disturbance in combat-related posttraumatic stress disorder.[95] In placebo-controlled studies prazosin increased TST, REM, and subjective sleep quality and reduced nightmares.[189,190] There are no reports of sleep disturbance or wake dysfunction with the calcium channel blockers (e.g., verapamil, nifedipine); however, these drugs decrease the effectiveness of hypnotics and potentiate the effects of stimulants, at least in studies in animals.[191] Angiotensin-converting enzyme inhibitors (e.g., captopril, cilazapril) reportedly have a low incidence of central side effects. However, a dry, irritating cough is a common side effect,[192] which may contribute to sleep apnea, possibly related to rhinopharyngeal inflammation.[193]

HISTAMINE ANTAGONISTS

Histamine-1 Receptor Antagonists

The first-generation H_1 antihistamines (e.g., diphenhydramine, hydroxyzine) are lipophilic and easily cross the blood–brain barrier, demonstrating H_1 receptor occupancy of up to 60% or more.[194,195] In addition to H_1 antagonism, these drugs demonstrate muscarinic anticholinergic antagonism and may also have α-adrenergic and serotonergic effects. They cause decrements in alertness and performance.[196,197] Because of their sedating effects, these drugs (in particular, diphenhydramine) are widely used as over-the-counter hypnotics. Subjectively, these drugs decrease sleep latency and increase sleep continuity, but PSG data are mixed. Diphenhydramine increases physiologic sleep tendency as measured by MSLT and decreases performance acutely, but tolerance may develop within 3 to 4 days,[198,199] although driving may continue to be impaired.[200] A single presleep dose of diphenhydramine 50 mg resulted in decreased REM and next-day impairment in psychomotor performance as well as increased subjective sleepiness and a trend toward decreased latency on MSLT.[201]

The second-generation H_1 antihistamines (cetirizine, desloratadine, fexofenadine, levocetirizine, loratadine) are hydrophilic molecules that do not easily penetrate the CNS. Although they are much more selective than the first-generation antihistamines, H_1 receptor occupancy varies from almost negligible (e.g., fexofenadine) to 30% (cetirizine).[188,200] Most studies in normal subjects and atopic individuals generally confirm that these drugs are not sedating and do not impair performance when used in recommended doses.[197] Although MSLT studies indicate that cetirizine is nonsedating,[198] it has been classified as sedating by the FDA, and a number of studies suggest it is more subjectively sedating and more likely to impair performance than other second-generation H_1 antagonists.[202,203] Meta-analysis of 18 studies concluded that although second-generation antihistamines caused less performance impairment than the first-generation antihistamine diphenhydramine, mild impairment was still present.[204] There is some evidence that fexofenadine and levocetirzine may be less impairing than other second-generation drugs,[195,205] although sedation may emerge with increase in dose.[206]

Histamine-2 Receptor Antagonists

H_2 antagonists (e.g., cimetidine, ranitidine, famotidine, and nizatidine) are unlikely to impair CNS function because these compounds do not easily cross the blood–brain barrier. However, cimetidine slows the clearance of some benzodiazepine receptor agonists, which may make carryover effects of hypnotics more of a problem.[207] Similarly, cimetidine has been shown to increase levels of theophylline, carbamazepine, and β blockers with resultant increases in the CNS effects of these drugs. Ranitidine has produced some of the same effects, although not to the extent seen with cimetidine.

One crossover study comparing 1-week administration of cimetidine, famotidine, ranitidine, and placebo in normal subjects reported no differences in nocturnal sleep or daytime MSLT latencies although cimetidine produced a slight

increase in subjective estimates of sleepiness.[208] H_2 antagonists do not appear to affect psychomotor performance. However, both cimetidine[209] and ranitidine, administered in conventional doses, have been associated with an increased incidence of lethargy, somnolence, and confusion in patients with renal impairment. In addition, benzodiazepine-produced impairment of psychomotor and cognitive function was prolonged with concomitant administration of cimetidine and ranitidine in healthy volunteers.[210]

DRUGS USED FOR THE TREATMENT OF PAIN

The neurobiology of pain is complex and involves both peripheral and central mechanisms. Simplistically, activation of peripheral nociceptors (by inflammation or tissue damage) is modulated by central mechanisms that affect pain perception. Pain disrupts sleep, whereas sleep loss may increase pain sensitivity.[211] Multiple neurotransmitters modulate pain processing, including substance P, endorphins (through μ-opioid receptors), norepinephrine (α_2 adrenoceptors), and serotonin (5-HT_{1B}, 5-$HT_{1D,}$ 5-HT_3 receptors).[212] Drugs used in the treatment of pain include analgesics (opiates and nonsteroidal antiinflammatory drugs [NSAIDs]), muscle relaxants, antidepressants (particularly TCAs and SNRIs), and antiepileptics.[211,213] The SNRI duloxetine has been approved for treatment of diabetic neuropathy, fibromyalgia, and chronic musculoskeletal pain; the SNRI milnacipran has been approved for fibromyalgia. Among antiepileptics, gabapentin is approved for treatment of postherpetic neuralgia and used frequently off-label for other neuropathic pain. Pregabalin is approved for treatment of neuropathic pain, postherpetic neuralgia, and fibromyalgia. These drugs are discussed in the sections on antidepressants and antiepileptics. In addition, pain and sleep are discussed more fully elsewhere in this volume.

Opioids act at a variety of CNS receptors, including μ, κ, δ, and nociceptin/orphanin FQ.[214] All of these receptor subtypes appear to be involved in the analgesic effect of opioids, whereas the μ subtype plays a prominent role in respiratory control. Sedation is mediated by both μ and κ receptors.[212] The most common clinically-used opioids are relatively selective for μ receptors. Opioid peptides (enkephalins, endorphins, dynorphins) are involved in the regulation of a number of biologic activities, including blood pressure, respiration, mood, pain perception, and possibly sleep.[215] Somnolence is a common side effect of opioid medication.[216] Degree of sedation may depend on the specific drug, dosage, and duration of use as well as severity of the underlying disease.[217] Chronic use in cancer or chronic pain patients is associated with both insomnia and daytime sleepiness and fatigue, but this may be secondary to disease or psychological function.[218] One case-controlled study showed increased subjective sleepiness (measured by Epworth Sleepiness Scale) in patients on stable methadone compared with normal controls, but mean Epworth values for the group were within the normal range; daytime function was impaired (as measured by the Functional Outcomes of Sleep Questionnaire), however.[219] Older adults appear to have increased pharmacodynamic sensitivity to opioids.[220]

The limited PSG data available indicate that opioids used acutely in young healthy volunteers markedly decrease SWS and may decrease stage 2 and REM, particularly at higher doses.[221,222] In current or former addicts, opioids also decrease TST and increase wake after sleep onset.[223] Subjective quality of sleep may be improved, presumably because of improved pain control.[224]

In healthy normal subjects, cognitive and psychomotor function are impaired in a dose-related fashion with parenteral administration of opioids, but findings are mixed with oral dosing.[225] Acute administration in pain patients results in dose-related impairment in cognitive functioning.[217,226] Both acute and chronic opioid use have been associated with deficits in attention, recall, visuospatial skills, and psychomotor speed, whereas long-term use appears to have the greatest effect on executive function.[227] Comorbid medical or psychiatric disease may be more predictive of cognitive impairment than frequency or dose of medication.[228]

The most serious adverse effect of opioids is respiratory depression, particularly during sleep or after surgery. Opioids act directly on the brainstem respiratory centers through μ and δ receptors and at chemoreceptors through μ receptors, resulting in a shift to the right and a change in slope of the carbon dioxide response curve.[229] Opioids depress the pontine and medullary centers involved in the regulation of respiratory rhythmicity, resulting in increased respiratory pauses, irregular breathing, and decreased tidal volume.[230] Respiratory depression increases with increase in opioid dose. Limited data suggest that clinically significant respiratory depression rarely occurs with standard opioid doses used acutely in healthy individuals.[231,232] However, chronic opioid use is a risk factor for the development of central sleep apnea and hypoxemia.[233] Individuals with pulmonary disease or obstructive sleep apnea are at greater risk for sustained hypoxemia during sleep.[234] Concomitant use of other sedatives, including sleep aids, increases the risk for potentially fatal respiratory depression. After surgery, individuals with obstructive sleep apnea receiving intravenous morphine have been shown to have pronounced oxygen desaturation, paradoxical breathing, and slow ventilation.[235]

Centrally-acting α_2 agonists used in the management of pain include clonidine, tizanidine, and dexmedetomidine. Somnolence is common with these drugs.[236] Tizanidine also negatively affects psychomotor performance and neurocognitive function.[237]

Triptans, which are selective 5-$HT_{1B/1D}$ agonists, are currently the primary treatment for acute migraine. Somnolence is a common side effect, but incidence varies among drugs, likely the result of differences in lipophilicity and the presence of active metabolites. Somnolence is highest with eletriptan, zolmitriptan, and rizatriptan, all of which are highly lipophilic and have active metabolites, and lowest with almotriptan, sumatriptan, and naratriptan, which are weakly lipophilic and have no active metabolites.[238] There are no studies which report PSG or MSLT data or which evaluate cognitive function.

NSAIDs may affect sleep because they decrease the synthesis of prostaglandin D_2, suppress the normal nocturnal surge in melatonin synthesis, and attenuate the normal nocturnal decrease in body temperature.[239] Prostaglandin D_2 increases proportionately with increased duration of wake and may be involved in sleep initiation.[240] NSAIDs inhibit cyclooxygenase (COX), blocking the synthesis of inflammatory prostaglandins. The classic NSAIDs inhibit both COX-1 (thereby accounting for their gastrointestinal toxicity) and COX-2 isoenzymes, whereas the newer NSAIDs selectively inhibit COX-2 (found primarily in the CNS, renal cortex, and

vas deferens).[241] Limited PSG data are mixed and have shown both no effect[242] and decreased sleep efficiency with acutely-administered aspirin and ibuprofen in healthy subjects.[239,243] One placebo-controlled study of tenoxicam (not available in the United States) in rheumatoid arthritis patients improved clinical symptoms but did not affect PSG measures.[244] Subjective reports suggest an improvement in sleep quality with use of NSAIDs, presumably because of a reduction in pain. Cognitive deficits are apparently rare with NSAIDs but may be a problem in older adults.[245]

DRUGS USED FOR THE TREATMENT OF ALZHEIMER DISEASE

Drugs used in the treatment of dementia of the Alzheimer type include centrally-acting cholinesterase inhibitors (tacrine, donepezil, rivastigmine, galantamine) and NMDA receptor antagonists (memantine). Insomnia and nightmares have been reported in 1% to 5% (placebo-adjusted rate) of patients in clinical trials of donepezil.[246,247] In contrast, there was no indication of insomnia based on adverse-event reporting in clinical trials of rivastigmine or galantamine.[248,249] Clinical trials of memantine report variable rates of insomnia (placebo-adjusted rate, 0% to 3%) and sleepiness (placebo-adjusted rate, 0% to 6%).[250]

PSG studies in normal subjects and Alzheimer disease patients show an increase in REM percent with donepezil but no effect on TST or other sleep architecture measures.[251,252] However, donepezil in healthy older adults, rivastigmine in healthy older adults and young normal subjects, and galantamine in young normal subjects produced no change in REM percent, although REM latency decreased and REM density increased.[253-256]

OTHER DRUGS

Corticosteroids

Corticosteroids are widely believed to disrupt sleep, but the results of objective studies are inconsistent. Differences in receptor affinities between synthetic and endogenous corticosteroids, dosage, methodologic issues associated with the study of patient populations, and the variety of organ systems affected by corticosteroids, as well as the variety of side effects reported,[257] all contribute to this confusion.

In patient populations, corticosteroids have frequently been associated with sleep disturbance. Approximately 50% of patients treated with prednisone for optic neuritis reported sleep disturbance, compared with 20% on placebo.[258] Patients taking prednisone for oral inflammatory ulcerative disease reported a dose-related incidence of insomnia ranging from 12% to 71%.[259] Parent ratings of sleep disturbance increased when steroids were added to the chemotherapy regimen of children with leukemia or other types of cancer.[260] Insomnia has also been reported more frequently in patients with asthma receiving steroid medications.[261] In addition, numerous anecdotal and case reports implicate systemic corticosteroid use with insomnia.[262] Behavioral observations of 12 healthy subjects given prednisone 80 mg/day for 5 days showed decreased sleep in 25% and mild hypomania in 67%.[263] Inhaled glucocorticoids do not appear to have the same negative effects, but there have been case reports of hyperactivity, insomnia, and psychosis with these drugs as well.

The most consistent effect of corticosteroids on PSG-recorded sleep in normal subjects is a marked decrease in REM sleep.[264] Although less consistent, there is good evidence for increased waking during the night with cortisol, dexamethasone, and prednisone. Dexamethasone, administered before bedtime, resulted in increased daytime alertness the next day as measured with MSLT.[265]

In a single study evaluating performance in healthy subjects, prednisone 80 mg/day given for 5 days produced increased frequency of errors of commission on a verbal memory task.[266] Prednisone was associated with decreased cognitive functioning in a study of patients with systemic lupus erythematosus.[267]

Pseudoephedrine and Phenylpropanolamine

Pseudoephedrine and phenylpropanolamine share the pharmacologic properties of ephedrine but have less potent CNS-stimulating effects. These drugs are used extensively as nasal decongestants and are available in a variety of over-the-counter cold preparations; phenylpropanolamine is also available in over-the-counter diet aids. Although similar in chemical structure to amphetamine, phenylpropanolamine is much less lipophilic and thus has much less potent CNS effects. Phenylpropanolamine, however, has been reported to increase plasma caffeine levels,[268] possibly adding to the stimulant effect of caffeine. These drugs have been reported to cause insomnia. In one study, 27% of patients given 120 mg of extended-release pseudoephedrine for 2 weeks for the treatment of allergic or vasomotor rhinitis complained of insomnia. In a PSG study, the administration of pseudoephedrine in the evening (as part of either a 60-mg four-times-daily or 120-mg sustained-release twice-daily dosing regimen) produced increased wake time during sleep compared with the morning administration of a once-daily controlled-release formulation (240 mg).[269] Further objective evaluation of dosage, timing, and duration of treatment of these drugs would be useful.

Stimulants

Stimulant medications are covered more fully elsewhere in this volume. Stimulants are the primary treatment for both narcolepsy and ADHD. Their use in ADHD has increased significantly over the past 20 years. Sleep problems are common in both children and adults with ADHD.[270,271] Although actigraphic, PSG, and MSLT data in children do not yield consistent findings, it appears likely that ADHD children have decreased sleep efficiency, decreased REM, increased daytime sleepiness, and possibly an increased prevalence of PLMS in sleep.[270] Limited actigraphic and PSG data in adults also indicate decreased sleep efficiency.[271,272] Stimulant medications used in the treatment of ADHD include immediate-release compounds (dextroamphetamine, methylphenidate) as well as extended-release formulations (methylphenidate [Concerta], dextroamphetamine-levoamphetamine [Adderall XR], and lisdexamphetamine [Vyvanse]). Modafinil has been studied in both children and adults but is not currently approved by the FDA for ADHD treatment.[273] Clinical trials and subjective reports indicate increased incidence of insomnia with these drugs. Parental reports, in particular, indicate significant sleep disturbance, which may be higher with the modified-release drugs. However, limited PSG and actigraphic data have yielded conflicting results. Cognitive

function may improve as a result of symptom improvement rather than a direct drug effect.

Theophylline

Theophylline, a respiratory stimulant and bronchodilator, is chemically related to caffeine. Peak plasma concentration is usually reached within 2 hours, but the half-life varies by preparation and is typically shorter in children (3.5 hours) and longer in adults (8 to 9 hours). Absorption is lower at night than in the morning[274] and may be greatly affected by food.[275]

Disturbed sleep is a common complaint among patients taking theophylline. In a prospective study, patients with asthma treated with theophylline were more likely to complain of sleep maintenance difficulty (55%) than were patients treated with other asthma medications (31%),[276] and in a retrospective study of treated patients with asthma, 46% of whom complained of insomnia, only theophylline or corticosteroid therapy was associated with the complaint of insomnia.[261] Most of the studies purporting that theophylline does not adversely affect sleep are limited by the lack of a placebo control or other methodologic difficulties. Because theophylline improves asthma-related symptoms, there have also been reports of improved sleep continuity and decreased nocturnal awakenings associated with its use.[277]

Theophylline, administered for up to 3 weeks, has been shown to disturb PSG-recorded sleep in healthy subjects,[278,279] patients with asthma,[280] children with cystic fibrosis,[281] and patients with sleep apnea[282] or chronic obstructive pulmonary disease.[283] Dose-dependent increase in MSLT latency and performance was noted with short-term administration of theophylline in normals.[279] In a double-blinded study, asthmatic children were more likely to exhibit behavioral or attentional problems when receiving sustained-release theophylline for 4 weeks than when on placebo.[284] However, a meta-analysis of 12 studies of theophylline did not indicate impairment in cognition or behavior.[285] Furthermore, academic achievement did not differ between 72 asthmatic patients who were treated with theophylline and siblings without asthma.[286]

Drugs Used for the Treatment of Obesity

Weight loss drugs with CNS activity include the sympathetic amines phentermine and diethylpropion; lorcaserin, a selective 5-HT_{2C} agonist; and the combination drugs phentermine-topiramate (Qsymia) and naltrexone-bupropion (Contrave). Bupropion, as well as the anticonvulsants zonisamide and topiramate, is used off-label for obesity. Insomnia is a common side effect of phentermine and diethylpropion because these drugs have pharmacologic activity similar to amphetamine. Insomnia has also been reported with lorcaserin, phentermine-topiramate, and naltrexone-bupropion. Impairment of attention and memory has been reported with lorcaserin.[287,288]

CLINICAL PEARL

Drugs that block the activity of wake-promoting neurotransmitters are likely to be sedating. Drugs that inhibit the reuptake or metabolism of wake-promoting neurotransmitters are likely to disrupt sleep. Knowledge of receptor pharmacology and pharmacokinetics is helpful in determining the likelihood of negative effects on sleep or waking function.

SUMMARY

Disturbed sleep, daytime sleepiness, and impaired cognitive functioning are common side effects of many medications. Negative effects may be the result of a direct action of a drug (e.g., disturbed sleep from an activating compound or carry-over sedation from a long-acting hypnotic) or an indirect action (e.g., daytime sleepiness as a result of drug-induced sleep disruption). Sleep-wake regulation involves multiple neuronal systems and neurotransmitters. Drugs that increase the activity of the sleep-promoting system or decrease the activity of the wake-promoting system will be sedating, whereas drugs that act in a reciprocal fashion will be alerting. Whether these effects are considered side effects depends on when they occur. Knowledge of receptor mechanisms and pharmacokinetics can help predict which drugs will negatively affect sleep or wake function. Drugs most likely to affect sleep-wake behavior negatively include psychotherapeutic drugs, antiepileptics, dopaminergic medications used in the treatment of Parkinson disease, first-generation antihistamines, and centrally-acting pain medications. A number of other drugs with CNS effects may produce unwanted sedation or sleep disruption.

Effects of Hypnotic Drugs on Driving Performance

Chapter 46

Joris C. Verster; Aurora J.A.E. van de Loo; Thomas Roth

Chapter Highlights

- There are a variety of methodologies to examine whether it is safe to drive a car the day after being treated with hypnotic drugs. This chapter discusses epidemiologic evidence and explains the experimental methodology and results of the standardized on-the-road highway driving test to determine the effects of hypnotic drugs on driving ability.
- Most classic benzodiazepine hypnotics and zopiclone, when administered at bedtime, significantly impair next-morning driving ability. The magnitude of driving impairment depends on variables such as gender and age, drug dosage, half-life, and the time between drug intake and driving. Depending on dose and half-life, impairment of some benzodiazepines may last until the afternoon, that is, 16 to 17 hours after bedtime administration.
- When allowing a full night of sleep, next-morning driving ability was not impaired after bedtime administration of zolpidem (10 mg) and zaleplon (10 mg). Middle-of-the-night administration of zolpidem (10 mg), however, significantly impaired driving performance 4 hours after that time.
- Currently the only drugs that showed no significant driving impairment 4 hours after middle-of-the-night administration are zaleplon (10 and 20 mg) and sublingual zolpidem tartrate (3.5 mg).
- Despite its short half-life, the melatonin receptor agonist hypnotic ramelteon impairs next-day driving performance. Hence the development of safer yet effective hypnotic drugs is needed.

For most people, driving a car is a daily activity (e.g., to commute to and from work). Typically people with insomnia and other sleep disorders are outpatients; thus it is likely that they routinely drive a car. Driver sleepiness (reduced alertness) accounts for 10% to 30% of accidents.[1] Because a number of patients with insomnia report daytime sleepiness, it is important to determine whether sleep disorders or their pharmacologic treatments negatively affect driving.

Data on driving ability in untreated insomniacs is inconsistent as to whether insomnia impairs driving. The fact that only some insomniacs report daytime sleepiness, and objective assays of sleepiness show them to be alert, probably accounts for the negative findings in insomnia. Surprisingly little research has been conducted to examine the effect of insomnia on driving ability under controlled conditions. One on-the-road driving study found no impairment in patients with insomnia, but these patients used hypnotic drugs infrequently, so they may have benefited from treatment.[2]

To be effective, hypnotic drugs need to put patients to sleep and maintain sleep during the night. However, this induction of sedation needs to dissipate across the night because the patient wants to wake up refreshed without residual daytime sleepiness. The challenge is to find the right balance between efficacy into the later portion of the night and safety of hypnotic drugs. This chapter focuses on the effects of hypnotic drugs on next-day driving.

EPIDEMIOLOGIC EVIDENCE

Several epidemiologic studies examined the effect of hypnotic drug use on driving. Neutel selected 78,070 patients using the benzodiazepine hypnotics triazolam or flurazepam from the Saskatchewan Health Database and compared the risk for traffic accident injury with data from 97,862 "healthy control" subjects.[3] The use of benzodiazepine hypnotics was associated with a significantly increased (3.9 times) risk for traffic accident injury. The data further revealed that the risk for accident injury is highest after treatment initiation and then gradually decreases with continued use. Similarly, Barbone and colleagues reported an increased traffic accident risk for users of benzodiazepine hypnotics (odds ratio [OR] = 1.19; 95% confidence interval [CI], 0.83 to 170).[4] In contrast, McGwin and associates did not find a significant increase in traffic accident risk patients using benzodiazepine hypnotics (OR = 5.2; 95% CI, 0.9 to 30).[5] Importantly, researchers have shown that the risk was, in part, dependent on the half-life of the drug. Surprisingly, whereas classic benzodiazepine hypnotics with a long (>24 hours) or intermediate (6 to 24 hours) half-life showed no significant effect on accident risk, users of other benzodiazepine receptor agonist hypnotics with shorter half-lives (i.e., <8 hours) showed a significantly increased traffic accident risk (OR = 4.00; 95% CI, 1.31 to 12.2). Interestingly, in the latter study 14 drivers were all treated with zopiclone.[4]

For a number of reasons it is hard to draw conclusions on fitness to drive of individual patients from these population-based studies. Importantly these studies provide little information on if, when, and to what extent a drug impairs driving.[6] This is because this type of database research only compares medication distribution files with accident records of patients. It is often not possible to verify whether the drug was actually used on the day of the accident, nor are data collected on actual drug dosage, the specific type of hypnotic drug taken, its half-life, the time between intake and driving, and important accident-related issues (e.g., whether the driver was actually at fault of causing the accident or if it was due to other traffic). Also, sometimes it is unclear whether benzodiazepines were being used for hypnotic or anxiolytic purposes.[7-9] This likely has an effect on the risk for traffic accidents because sleep medication is usually taken at bedtime and anxiolytics during the day, causing a large difference between time of drug intake and driving between the two clinical use patterns. Taken together, current epidemiologic data suggest a potentially increased traffic accident risk in patients treated with hypnotic drugs. However, these data provide little information to the user or the clinician about relative risk associated with different drugs, drugs with different half-lives, and dose for a given drug.

THE ON-THE-ROAD DRIVING TEST

Because of possible ethical restrictions and legislation most countries do not allow the investigation of drug effects on driving in normal traffic. An exception is the Netherlands, where a standardized on-the-road driving test has been used over the past 30 years to examine the effects of drugs on driving.[10-12] The 100-km driving test is conducted on a public highway in normal traffic. Subjects are instructed to drive with a steady lateral position of their own choice within the right (slower) traffic lane while maintaining a constant speed of 95 km/hour. This allows them to drive along with the regular traffic flow. A driving instructor with dual controls guards the safety of the subjects, and the investigator in the back seat monitors the recording equipment. Lateral position data and mean speed are recorded two times per second. The mean lateral position (MLP) and mean speed (MS) are control variables, showing whether the subject conducted the test according to the instructions. These data further allow calculating the traditional primary parameter of the driving test, the Standard Deviation of Lateral Position (SDLP). The weaving of the car (i.e., SDLP) has proved to be an excellent measure of vehicle control. Dose-dependent driving impairment (i.e., SDLP increment) has been shown for alcohol and drugs of abuse[13] as well as for pharmacotherapeutic drugs such as antidepressants, hypnotics, anxiolytics, and antihistamines.[14] Alternatively, driving improvement has also been shown, illustrated by a reduction in SDLP, for example, in patients with attention deficit/hyperactivity disorder who were treated with methylphenidate.[15] The effect of driver sleepiness (e.g., that caused by sedative drugs) on vehicle control is illustrated in Figure 46-1.

Drivers are normally capable of keeping the car within the lane boundaries, and loss of vehicle control by drivers after taking a sedative increases SDLP values. This loss of control may also result in having out-of-lane excursions, but these are a poor predictor of vehicle control (SDLP) because they depend in great part on the choice of lateral position within the right traffic lane.[16] Drivers who choose a lateral position close to the lane boundary are much more likely to have excursions out of lane than those driving in the middle of the road,

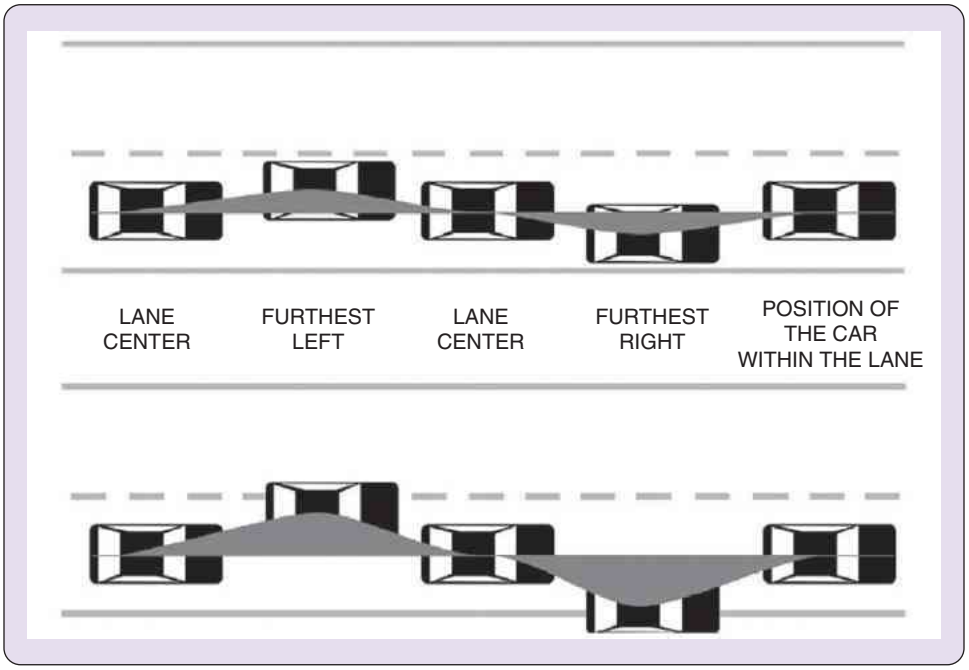

Figure 46-1 Standard Deviation of Lateral Position (SDLP). The *top figure* represents a regular SDLP under placebo condition. If weaving increases (*bottom figure*), the SDLP value becomes higher. (Modified from Verster JC, Veldhuijzen DS, Volkerts ER. Residual effects of sleep medication on driving ability. *Sleep Med Rev* 2004;8:309–25.)

independently from a possible drug effect on driving. A secondary outcome measure of the driving test, the standard deviation of speed, can also provide an indication of loss of vehicle control, but this measure has been shown to be much less sensitive than SDLP.[17]

When interpreting SDLP as an outcome measure it is important to keep in mind that the differences between drug and placebo (ΔSDLP) is the key end point. Absolute SDLP is not as sensitive because values under placebo vary significantly between individual drivers (mean, 18 to 20 cm; range, 10 to 30 cm). However, SDLP values are very stable within individuals (e.g., test-retest reliability above 0.80 have been shown).[12] Aside from demonstrating a significant difference it is also important to determine whether the impairment is clinically relevant as well as how many individuals show a clinically relevant impairment. To determine what should be regarded as clinical relevant impairment, researchers have looked at the ΔSDLP observed after administering alcohol to reach a blood alcohol concentration (BAC) of 0.05%. The driving data indicated that ΔSDLP of greater than 2.4 cm should be regarded as illustrative of clinically relevant driving impairment (Box 46-1).

In many instances in which the driving performance impairment is clinically relevant (i.e., ΔSDLP >2.4 cm), the standard deviation of speed after drug treatment does not differ significantly from placebo.[17] The same is also true for the number of excursions out of lane.[16] Therefore the standard deviation of speed and the number of excursions out of lane are generally not considered as important factors to determine whether driving is safe. Also, the number of collisions and stopped driving tests are poor indicators of a drug's effect on driving (Box 46-2).

An important aspect of the driving test is time on task. The standardized driving test takes about 1 hour to complete. This is necessary to get a good sample of the drug's effect on driving. Research has shown that shortening the driving test makes it less sensitive in showing a true difference between drug and placebo.[21] The latter is caused by the fact that in tests of short duration motivated drivers may successfully counteract impairment by investing more effort to perform the test. Vigilance decrement (i.e., increased performance impairment over distance driven or duration of driving time) is an essential characteristic of the driving test.[21] Hence, on the driving test its gets harder and harder to compensate for drug-induced impairment with increasing time on task. Increased effort sometimes can be effective for short duration (e.g., a 10-minute driving test) but does not last for the full 1 hour.

It has been suggested that on-the-road driving tests can be replaced by psychometric tests measuring driving-related skills and abilities or by driving simulators. At first this seems a safer alternative, and it would be less effortful if on-the-road driving performance and fitness to drive could be predicted by a short test battery that could be conducted at any place of choice (e.g., the physician's office). Unfortunately, comparative research showed that cognitive and psychomotor tests poorly predict on-the-road driving performance.[22,23] The primary reason for this poor correlation is the fact that driving-related skills and abilities are tested in isolation, whereas when on the road these are integrated (e.g., judgment, vision, reaction time). Importantly, overall driving performance is not simply the sum of its components (e.g., tracking, reaction speed, attention) but rather is the integration of these various skills to produce optimal safe driving. Driving simulators attempt to mimic actual driving, and these machines have become more sophisticated over the years. Whereas in the past, driving simulators were often simple computerized divided-attention tasks using a steering wheel instead of a respond box,

Box 46-1 CLINICALLY RELEVANT STANDARD DEVIATION OF LATERAL POSITION INCREMENT

There is only indirect evidence that Standard Deviation of Lateral Position (SDLP) is related to the risk for having car crashes.[18] Hence, to determine whether the magnitude of driving impairment has clinical relevance, often the comparison with impairment seen after different dosages of alcohol is made. Louwerens and colleagues examined driving performance after different dosages of alcohol.[19] The results are depicted in Figure 46-2 and show a clear dose-dependent relationship between SDLP and blood alcohol concentration (BAC).

From these historical data, it was inferred that the cutoff for clinically relevant impairment is an SDLP increment relative to placebo of +2.4 cm, corresponding to a BAC of 0.05%, which is the most commonly reported legal limit for driving a car.

Box 46-2 CRASHES AND STOPPED DRIVING TESTS

At first, the occurrence of crashes may be regarded as the ultimate evidence that a drug negatively affects driving; however, this premise can be debated. First, crashes can be caused by many factors; the effect of hypnotic drugs is only one. For example, a crash may be caused by another driver without any blame to the patient. In the on-the-road driving test, crashes do not occur because the driver is accompanied by a licensed driving instructor. If safety becomes compromised, the driving instructor intervenes and prevents a crash from happening. In driving simulators, crashes are more commonly seen. This likely has to do with increased sleepiness scores and the fact that participants know that having a crash has no real-life consequences in terms of injury or death. Crashes are infrequent and uncommon events during normal driving. Even when driving is significantly impaired, usually crashes do not occur. Therefore counting the number of crashes as an indicator of drug-induced driving impairment is not useful.

Driving tests can be stopped for many reasons. For example, the driver experiences adverse events such as stomach pain or drowsiness and requests to stop the test before completion. Alternatively, the driving instructor may abort the test if he or she feels it is unsafe to continue. In both instances, these are subjective decisions that by no means imply that driving is actually impaired. A comparative analysis of more than 7000 driving tests revealed that stopped driving tests occur both after drug treatment (4.1%) and, although to a lesser extent, in placebo conditions (0.7%).[20] Further analyses revealed that 39.6% of stopped drivers had a lower and 60.4% had a higher SDLP than 35 cm, a cutoff sometimes used to indicate unsafe driving. Because SDLP values of stopped and completed driving tests often do not significantly differ, the number of stopped tests should be regarded as a poor predictor of a drug's effect on driving performance.

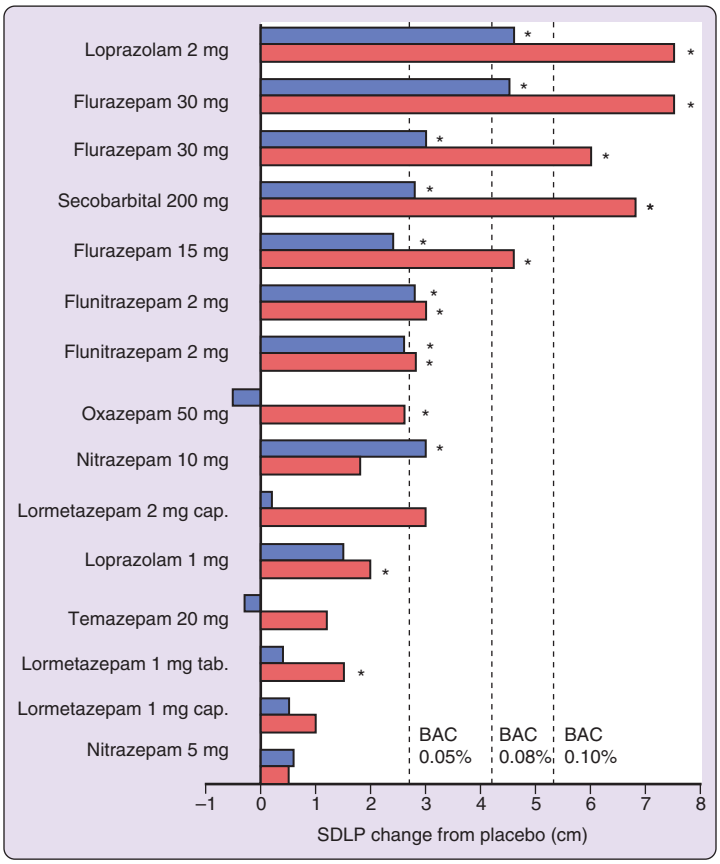

Figure 46-2 Effects of benzodiazepine hypnotics on driving. All treatments were administered at bedtime. Driving tests were performed in the morning, 9 to 10 hours after intake (*red bars*), and the afternoon, 16 to 17 hours after intake (*blue bars*), representing the times many people drive to and from work. Significant differences from placebo ($P < .05$) are indicated by an asterisk (*). (Modified from Verster JC, Veldhuijzen DS, Volkerts ER. Residual effects of sleep medication on driving ability. *Sleep Med Rev* 2004;8:309–25.)

nowadays real cars including car motion and sound are used with realistic scenery projected on a large surrounding screen, including other traffic. Few researchers have directly compared on-the-road and simulated driving. These studies found that SDLP values and sleepiness scores are generally significantly higher in driving simulators.[24] The difference between driving simulator environments and actual driving in terms of risks for having an accident is essential and may account for the observed differences. In many simulators, number of accidents is used as an end point. However, having an accident in a simulator has no consequences in terms of injury or death, whereas these risks are evident during on-the-road driving. Hence a number of people may regard driving in the simulator as a game and thus have a different mindset compared with on-the-road driving. Nevertheless, driving simulators and psychometric tests are useful to determine fitness to drive in general and to examine performance impairment. The decision about whether driving is safe should always be based on the overall available evidence gathered with different research methodologies and thus should include performance on both cognitive and psychomotor tests, driving simulators, and an on-the-road driving test.

The purpose of hypnotic drugs is to make you fall asleep and maintain sleep. It is critical, however, that after waking up 7 to 8 hours later, people who use these drugs are not sedated and can participate safely in activities of daily living such as driving. The next sections of this chapter summarize findings from on-the-road driving studies examining the effects of hypnotic drugs on driving.

EFFECTS OF HYPNOTICS ON DRIVING

The usual design of studies examining the effects of hypnotic drugs on driving performance is a double-blind placebo- and active drug–controlled trial. Treatments are administered at bedtime, and driving tests are typically conducted the following morning and sometimes afternoon (about 9 and 16 hours after intake), occasions that are coincidental with the times people usually drive to and from work. Since the 1980s, the effects on driving of a great number of benzodiazepine and nonbenzodiazepine hypnotic drugs have been examined by applying the standardized on-the-road driving test.[25,26] An overview of the results for benzodiazepine hypnotics is given in Figure 46-3.

It is evident from Figure 46-3 that benzodiazepine hypnotics significantly impair next-morning driving. In the afternoon, impairment is less pronounced, but for several drugs the magnitude of impairment (SDLP increment relative to placebo) still is higher than that seen with a BAC of 0.05%. A recent meta-analysis of these data revealed that driving

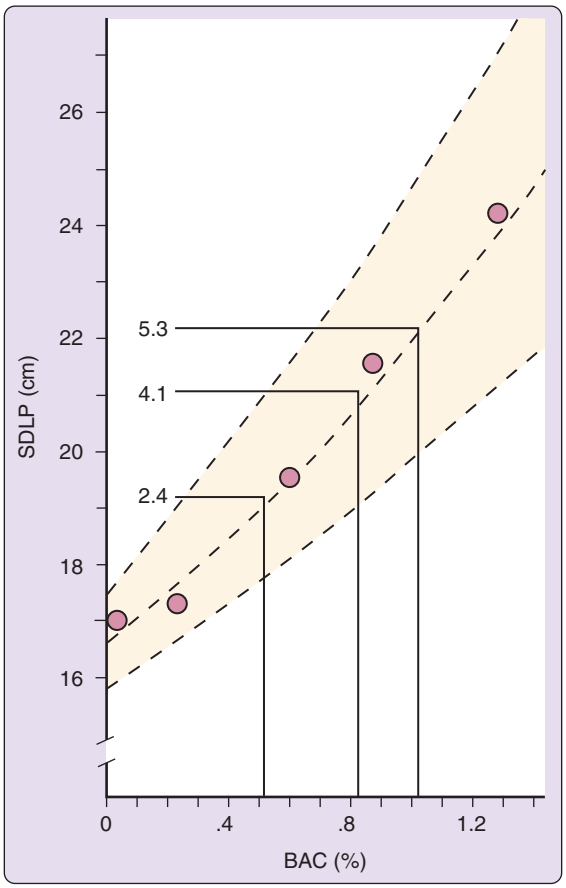

Figure 46-3 Standard Deviation of Lateral Position (SDLP) relative to baseline (no alcohol) at different breath alcohol concentration (BAC) levels.

impairment is dose dependent and is more pronounced with drugs with a longer half-life and when the time between drug intake and driving is shortened.[26] Both intermediate- (6 to 12 hours) and long-acting (>12 hours) drugs cause significant impairment the morning after bedtime administration, whereas short-acting hypnotics (<6 hours) generally do not. Interestingly, interindividual blood drug concentrations at a given time point correlate poorly with an individual's driving impairment.[27] For some benzodiazepine hypnotics, sex differences were seen in the magnitude of driving impairment,[28] emphasizing the importance of including both male and female participants in driving studies. It should be noted that the effects shown in Figure 46-3 were all found after one or two nights of treatment. Up to now, long-term effects of the use of benzodiazepine hypnotics on driving performance have not been extensively examined using the on-the-road driving test. However, given the epidemiologic evidence discussed in this chapter and driving data from studies examining long-term benzodiazepine anxiolytics use (e.g., diazepam for 4 weeks),[29] it can be assumed that at least partial tolerance to the impairing effects can be expected if the drugs are used on a nightly basis over a period of time. However, the rate the development of this tolerance is not currently defined. Importantly, the mechanism that mediates this tolerance has not been investigated. For drugs with a half-life greater than 15 hours, impairment may worsen because of drug accumulation. As a result of the lack of clear data, there is currently no consensus among sleep experts as to whether and when driving is safe after initiating treatment with medications known to impair driving acutely.[30]

The "z-drugs" (i.e., zopiclone, eszopiclone, zolpidem, and zaleplon) also act at the benzodiazepine receptor of the gamma-aminobutyric acid A ($GABA_A$) complex but do so more specifically and have a relatively shorter half-life. Hence, it was anticipated at their introduction that these drugs would be devoid of the next-morning adverse effects seen with benzodiazepine hypnotics. Zopiclone, the first of the z-drugs introduced and commonly prescribed in Europe, is one of the most frequently studied drugs used in hypnotic clinical studies. Bedtime administration of zopiclone (7.5 mg) consistently results in next-morning driving impairment. The magnitude of impairment is about +2 to +3 cm, roughly comparable to that seen with a BAC of 0.05%.[31] For this reason, zopiclone is typically used as positive control in on-the-road hypnotic driving studies. In the afternoon, however, driving after zopiclone (7.5 mg) is not impaired. In contrast, bedtime administration of zolpidem (10 mg) or zaleplon (10 mg) does not impair next-morning driving.[32,33] This is attributable to the short (<3 hours) half-life of these two drugs.

MIDDLE-OF-THE-NIGHT ADMINISTRATION

Because sleep maintenance problems are commonly reported by patients with insomnia, treatments enabling patients to fall asleep more rapidly after middle-of-the-night (MOTN) awakenings have been developed, to be taken in the middle of the night. In addition, many drugs (e.g., zolpidem) are taken off label in the middle of the night. Thus the effects of hypnotics taken in the middle of the night need to be investigated in terms of driving performance the next day. To date, four such on-the-road driving studies have been conducted.[34] In these studies, treatments were administered during the night, 4 to 6 hours before the driving test. Driving performance after MOTN administration of traditional benzodiazepine hypnotics has not been examined, presumably because they already impair next-morning driving after bedtime administration. Zolpidem (10 mg and 20 mg, oral immediate-release tablets) significantly impaired driving in a dose-dependent manner when tested 4 hours after MOTN administration.[35] Also, gaboxadol (15 mg) and zopiclone (7.5 mg) significantly impaired next-morning driving after MOTN administration.[36] In contrast, buffered sublingual zolpidem (3.5 mg) and zaleplon (10 mg and 20 mg) did not significantly affect driving 4 hours after MOTN administration.[36-38]

NON–GAMMA-AMINOBUTYRIC ACID HYPNOTICS

In the search for hypnotic drugs without next-day sedation, development has focused on drugs that do not act at the $GABA_A$ receptor complex. In this context, histamine-1 and orexin receptor antagonists are under investigation. Also, melatonin agonists are considered. For example, the effects on driving of ramelteon (8 mg), a melatonin receptor agonist, have been investigated.[39] Significant driving impairment was observed 8.5 hours after bedtime administration. Significant next-day impairment was also found on reaction time in the Sternberg Memory Scanning Test, reaction speed and

tracking in a divided attention test, and delayed recall in a word learning test. No significant impairment was found on the Digit Symbol Substitution Test and a balance test, which was performed during the night, 2 hours after treatment administration. The magnitude of performance impairment seen with ramelteon (8 mg) was comparable to that of zopiclone (7.5 mg). This is an important finding because ramelteon has a short half-life. Thus the question arises as to the mechanism of this impairment. The two possibilities are that the impairment is due the effect of a long-acting ramelteon metabolite or the effect of ramelteon on shifting circadian phase.

FUTURE DIRECTIONS

Although the effects of drugs on mean SDLP has been the standard measure of impaired driving, the nature of the risk and extent of the risk are not fully defined with this single analytic approach. In the recent past, two modifications to the traditional analysis of on-the-road driving have been investigated. The first is the use of alternate end points to SDLP. Lapses have traditionally been used to assess the impairing effects of sleep deprivation on laboratory-based performance. Recently, lapses have been introduced as an outcome measure of the on-the-road driving test.[40] A lapse in driving is defined as a continuous change in lateral position of greater than 100 cm, lasting for at least 8 seconds. In contrast to weaving (SDLP), a unique feature of lapses is that they occur during short periods of inattention. That is, the presence or absence of lapses may differentiate drivers who are aware of driving impairment from those who are not aware of loss of vehicle control (SDLP increment). If correct, having a lapse may have serious consequences in terms of traffic safety because this period of inattention may increase the risk for having a sleepiness-related accident. Moving forward, research using lapses as an outcome measure is needed to determine the degree of overlap between lapses and SDLP and to what extent lapses and SDLP provide unique information regarding impaired driving and traffic accident risks.

The second innovation involves an alternate method to analyze SDLP data. Although mean SDLP contrasts (drug vs. placebo) provide useful information, they do not address the primary issue of putting individuals at increased risk for having a traffic accident. A large sample size or small variance can lead to statistically significant mean differences that do not correspond to meaningful driver impairment (i.e., nonclinically relevant SDLP increments, less than +2.4 cm). A small sample size or large variance can result in failure to find a difference that in fact corresponds to increased accident risk. Indeed, a large variance may be the result of outlying individuals with impaired driving skills who are the very group of interest. As is the case with all safety data parameters, it is more important to discover whether a treatment produces a large effect in a subset of subjects than whether it produces a relatively clinically meaningless shift across the entire sample. This problem can be addressed by a responder analysis that assesses the proportion of patients on drug versus placebo who exceed a predetermined threshold for clinically meaningful impairment or other thresholds, larger and smaller, that are of interest in understanding the degree of impairment. The statistical test used for such an analysis has been called symmetry analysis because it tests whether the distribution of changes (drug minus placebo) above the threshold and below the threshold is symmetrical around zero.

CLINICAL PEARLS

- Drug type, dosage, time of driving after drug intake, drug half-life, and patient characteristics all have a significant effect on the magnitude of next-day driving impairment.
- Impairment is more pronounced when time between drug intake and driving is shorter, with higher drug dosages, and with drugs with a longer half-life.
- More research is needed to determine effects of chronic drug use on driving and to explore gender, age, and disease differences associated with these effects.

SUMMARY

The World Health Organization has identified traffic accidents as one of the major causes of injury and death around the world. An important factor contributing to traffic accidents is inattention of the driver due to reduced alertness or increased sleepiness. It is therefore important to understand the effects of sedating drugs on driving and their impact on the risk for crashes. A standardized method to examine ability to drive is the on-the-road driving test. Results from 30 years of Dutch on-the-road driving research have demonstrated that some hypnotic drugs are safe whereas others impair driving performance, thereby influencing drug labeling. In addition, differences between drugs in degree of impairment also vary as a function of dosage, half-life, and time since drug ingestion, demonstrating the importance of treatment compliance with directions for use of the drug to ensure driving safety.

DISCLAIMER

Although the information presented in this chapter has been gathered and evaluated with great care, the authors will not accept any liability after use of the information by patients taking the medicines discussed. Patients should always consult their physician concerning whether or not it is safe to drive a car.

DISCLOSURE OF INTEREST

Joris Verster has received grants and research support from The Dutch Ministry of Infrastructure and the Environment, Janssen Research and Development, Takeda, and Red Bull and has acted as a consultant for Canadian Beverage Association, Centraal Bureau Drogisterijbedrijven, Coleman Frost, Deenox, Eisai, Purdue Pharma, Red Bull, Sanofi-Aventis, Sepracor, Takeda, Transcept, and Trimbos Institute.

Section 7

Psychobiology and Dreaming

Chapter 47

Introduction

Robert Stickgold

The study of dreams and dreaming has made remarkably slow progress over the past century. In defense of this slow progress, it is worth noting that it shares with the study of consciousness several unenviable features: (1) it is only poorly defined, and there is no consensus on a definition; (2) it has no clear physiologic correlates; and, hence (3) its biologic basis is largely unknown; (4) it has no behavioral correlates; and, hence (5) has no known function; and, finally, (6) its existence in species other than humans is a matter of conjecture. In short, we do not know the cause, nature, or consequence of dreaming, a remarkably sad state of affairs! What is, however, absolutely clear is that dreaming is a highly robust human occurrence that is most likely experienced by most humans every night.

DEFINITION

Given our ignorance of underlying biologic mechanisms and functions, it is perhaps not surprising that a clear, agreed-on definition of dreaming has evaded us. Most definitions in science refer either to physical objects to or processes that are defined by their underlying mechanisms or measurable consequences. We have none of these for dreaming. Indeed, a discussion group of the Association of Professional Sleep Societies and the Association for the Study of Dreams concluded that a "single definition for dreaming is most likely impossible given . . . the diversity in currently applied definitions."[1] What all discussants did agree on is that its definition must be phenomenologic; that is, dreaming refers to a state of mind. Although most discussants argued that dreaming should be restricted to mentation occurring during sleep, others argued that daydreaming should be included. Some demanded hallucinatory perceptions, thoughts, and emotions that are altered from normal, but others required one but not another, and some included any reported mental activity during sleep, even something as simple as a report of "I was wondering when you would wake me up."

For these reasons, some authors have eschewed the use of the term altogether, talking instead about *sleep mentation*. Unlike the term *dreaming*, this phrase can be simply defined. Sleep mentation is defined as (1) all mental experiences—perceptions, thoughts, and emotions—occurring during sleep, or (2) the process of experiencing perceptions, thoughts, and emotions during sleep. Thus it combines the sense of the words *dream* and *dreaming*. It is this concept, sleep mentation, that is more properly the subject of this section on dreaming.

METHODOLOGY

It is important to understand that researchers do not study dreams directly. Rather, they study dream reports, written, dictated, or on rare occasions, drawn or acted out, after the subject has awakened from sleep, along with their physiologic and psychological correlates.

In one sense, this is not as big a problem as it is often considered. All scientific measurements are derivative. We measure blood pressure with the aid of a pressure cuff applied externally, listening with a stethoscope for the sounds produced by the movement of blood through the brachial artery, depending on our conscious perception of the moment at

which the intensity of these sounds drops below our threshold of perception. Yet no one questions the legitimacy of the technique. It certainly is not accurate to more than 2 mm Hg at best, but it is good enough.

The difference between dream reports and blood pressure measurements is in the concept of "good enough." Researchers have confirmed the validity of using pressure cuffs by monitoring blood pressure with indwelling catheters in parallel with pressure cuff measurements and confirming the reliability of the pressure cuff technique. There is no way to tell whether a given dream report, or dream reports in general, are good enough, and it is not clear that it will ever be possible to record dreams (or any other conscious experiences) with the same level of confidence and reliability as exists for most other measurements in the biologic sciences.

If we make the presumption that dream reports are a good enough representation of the mental experience during the prior period of sleep, the next question is how our data collection procedures affect the data. Table 47-1 outlines some of the parameters of dream collection that vary from one study to the next.

For each of these parameters, changes in the methodology of report collection are known to affect report content, with differences most notable in report frequency, length, bizarreness, and emotional content. But arguments continue in most cases over whether these differences reflect differences in dreaming or just in accuracy and completeness of the dream reports. Even in the case of laboratory awakenings from rapid eye movement (REM) and non–rapid eye movement (NREM) sleep, arguments continue over how much of the difference seen in reports from the two sleep stages reflects diminished dreaming, as opposed to diminished recall, in NREM. Because a given pair of studies can conceivably differ on all nine of these parameters (allowing more than 3000 distinct protocols), it is not surprising that disputes over report frequencies, lengths, and features are as common as they are.

Table 47-1 Parameters of Dream Collection

Parameter	Common Values
Location	Home (monitored or unmonitored) Laboratory (monitored)
Awakening	Spontaneous Evoked
Timing	Morning Nocturnal
Sleep stage	REM N1 N2 N3
Time in stage	Constant Random Spontaneous Later in stage (esp. REM) later in the night
Time of night	Constant Variable
Nights	One Several (consecutive, fixed schedule, or ad libitum)
Report style	Written Audio recording
Probes	None Fixed Semistructured

DESCRIPTION

A proper description of dreaming (defined now as sleep mentation) should describe the nature of the perceptions, thoughts, and emotions experienced by the dreamer and how these change with condition. Several chapters in this section focus on this question. Unfortunately, dreaming remains incompletely characterized even at the descriptive level. Most studies of dreaming focus on dream perceptions— the highly visual, narratively complex, and delusional hallucinations that we all think of when we think of dreaming. A smaller body of research has looked at the emotions of dreams, and a much smaller body has looked at the thoughts of dreams.

Even in the area of dream perceptions, what is studied varies dramatically: from word counts to counts of characters and objects; to classification of characters, objects, and actions as familiar or novel; to identification of bizarreness (on any of a number of ad hoc scales); to measures of "latent content." Thus it is not uncommon for two studies of "dream content" to lack a single outcome measure reported in both.

Individual and group differences are also poorly understood. Aside from clinical populations and very limited case studies (often from a psychoanalytic perspective), the best comparative data relate to dreaming in children and to the question of whether some individuals dream at all.

Probably the greatest amount of investigation of variability in dreaming relates to the question of REM versus NREM dreaming, and even here huge disagreements exist. At this time, all that can be safely stated is that the two extreme positions, namely that dreaming occurs only during REM or, conversely, that there is no difference between REM and NREM dreaming, no longer appear to have any champions. But between these two extremes, almost every imaginable niche is occupied.

MECHANISMS

Efforts to explain the mechanisms that produce dreams date back to antiquity, when gods and indigestion were major contenders for the origins of dreams. Over the past 150 years, efforts at finding a brain or mind basis for dreaming have progressed slowly. At the moment, one can discern several schools of thought, which generally fall into the fields of neurophysiology, psychology, psychoanalysis, and, more recently, cognitive neuroscience. At their best, each of these takes an inclusive view, acknowledging the contributions of the other fields but focusing on their own. At their worst, they reject the usefulness of each other, with the usefulness of at least neurophysiology and psychoanalysis explicitly rejected by some groups. All of these, except psychoanalysis, are represented in the chapters that follow.

FUNCTIONS

Theories of the function of dreaming often are unclear as to what is actually being discussed, whether it is the

phenomenologic experience of dreaming or the biologic processes that underlie it. This is only important because some researchers state their belief that dreaming per se has no function, but that the biologic processes that underlie it have very important functions. For example, they would argue that the activation of neural networks within association cortex during REM might lead to important, long-term changes in network connectivity and may also fleetingly create a dream, but the dream and the process of dreaming itself are irrelevant to the production of these cortical modifications. Other researchers believe that the phenomenologic dream experience (with or without subsequent waking recall) is the critical element in the functionality of the dream and that the underlying biology is important only insofar as it is necessary to create the dream experience. Still others find the distinction unimportant or even meaningless.

This should not be surprising. It exactly parallels discussions of the functionality of consciousness. Philosophers and neurobiologists alike struggle to understand how to even think and talk about such functionality. Some reject any such functionality, others take it as a given, and others believe the distinction reflects a poorly formed question, that consciousness cannot be separated from its underlying brain basis. For the purpose of this section, we will collapse the two questions, talking about the function of dreaming and its underlying brain mechanisms as if they were interchangeable. While not claiming that they actually are interchangeable, it appears safe to say that we do not know how to measure their effects independently.

Theories of the function of dreaming (or lack thereof) go hand in hand with the approaches taken to studying the mechanisms underlying dreaming. Thus physiologic models tend to see little function in dreaming, whereas psychoanalytic models ascribe highly complex functions to dreaming. Psychological and cognitive neuroscience models tend to lie somewhere in between, ascribing various levels of complexity to dream function.

SUMMARY

In the end, we are left with a field that is very much a work in progress. There is no more than a hint of an even close to complete brain-based model for dream construction, and there is limited experimental evidence that dreaming plays any functional role. With that being said, the past 10 years have shown a resurgence of interest and research on dreaming, and brain imaging studies during sleep have fueled the development of new models of dream construction and function. It is hoped that this section will provide a snapshot of the state of the field at this time, a warning of the questions unanswered, and a guide to how dream research will progress over the next decade.

Chapter 48

Why We Dream

Robert Stickgold; Erin J. Wamsley

Chapter Highlights

- Sixty years after the discovery of rapid eye movement sleep launched the field of sleep research, we still have surprisingly little insight into the most fundamental question about the sleeping mind: why do we dream?
- In this chapter, we focus on data suggesting that dreaming reflects the activity of brain mechanisms that perform off-line memory consolidation during sleep. We then describe studies suggesting that a multiplicity of memory functions are reflected in the formal properties and content of conscious experience across stages of sleep and wakefulness.
- Together, these findings suggest both a mechanism and function for dreaming.

The search for an understanding of dreaming is thousands of years old. During the past 100 years, three publications have formed the core of most of the scientific discussion of this question: Freud's *Interpretation of Dreams,*[1] published at the end of the 19th century; the report of a correlation between dreaming and the newly discovered rapid eye movement (REM) sleep,[2] in the 1950s; and the proposal of the activation-synthesis model of dreams[3] in the 1970s, which argued that dreaming is initiated by random neural activity in the brainstem during REM sleep. Yet now, in the twenty-first century, there is precious little on which dream researchers agree.

One relatively new approach has been to consider dreaming within a larger neurocognitive framework of off-line memory consolidation during sleep. The rationale of this approach is that dreaming reflects the activity of the brain and that this activity necessarily includes the reactivation of memories and emotions from earlier experiences. Because any neural activity in the brain invariably leaves the activated networks altered, dreaming must modify the networks storing memories and emotions. Dreaming then becomes the conscious experiencing of these activated networks in the process of being modified.

BRAIN ACTIVITY DURING SLEEP

To understand how dreams might be produced and the functions they may serve, it is important to understand how brain activity in REM and non–rapid eye movement (NREM) sleep differs from that in wakefulness. During the past decades, neuroimaging studies have begun to describe how patterns of human brain activity differ across the states of waking, REM sleep, and NREM sleep.[4] In the 1990s, positron emission tomography (PET) studies initially demonstrated that whereas regional cerebral blood flow is generally decreased during slow wave sleep, entry into REM sleep leads to reactivation of some regions along with further deactivation of others.[5-7] The pattern seen suggests a shift in global brain function in REM sleep away from conscious executive control (further decrease in dorsolateral prefrontal cortex activity) and toward hallucinatory (increased activity in sensory association cortices) and emotional (increased amygdala, anterior cingulate, and medial orbitofrontal cortex activity) processing, which might relate to the features of REM dreaming.[6,7] Yet dreams are also commonly recalled from NREM sleep as well. Given this, the fundamental neural substrate for dream experience must be common to all stages of sleep.

More recent imaging studies stressed that activation remains relatively high in certain regions during NREM when controlling for the global decrease in activity, including within several memory-related areas.[8,9] Relative hippocampal activation, for example, has been reported to peak during slow wave sleep, exceeding even that seen during wakefulness.[9] Functional magnetic resonance imaging studies (with vastly superior temporal resolution compared with PET) confirm that NREM sleep is not a homogenous state of "decreased activation"; during NREM sleep, there are in fact brief, transient increases in local brain activation during sleep spindles and slow waves.[4] Fast spindles (>13 Hz) in particular have been associated with increased activity in the hippocampus and medial prefrontal cortex. Both fast spindles[10] and these specific brain regions[11] have been implicated in sleep-dependent memory consolidation.

In both humans and rats, patterns of brain activity observed during waking appear to be "replayed" during NREM sleep (for the most part; one study has reported a similar effect during REM[12]). In rats, recordings of single-unit activity demonstrate that sequences of neuronal firing seen as rats explore an environment are later statistically reiterated during sleep.[13,14] First observed in the hippocampus, this effect also occurs in cortical regions.[15,16] Meanwhile, in humans, PET studies have shown that brain regions activated during the learning of a task are selectively reactivated during the next night's sleep, both in REM and NREM sleep.[9,17] This reactivation of patterned activity in the sleeping brain is thought to support the consolidation of memory during sleep. Indeed, reactivation has recently been reported to promote the

formation of dendritic spines,[18] and disrupting reactivation impairs learning.[19] This discovery, that brain networks involved in prior waking experience are reactivated during later sleep, has been paralleled by a growing body of evidence for sleep-dependent memory consolidation.

SLEEP-DEPENDENT MEMORY CONSOLIDATION

One interpretation of neural changes during sleep is that they reflect a *homeostatic* process working to restore the brain to its state at the start of the previous day. These "rest" or "restorative" models of sleep argue that sleep serves to reverse deleterious changes that inevitably accrue across the day. A current example of such theories is the synaptic homeostasis model of sleep function.[20,21] In contrast, a more powerful, *progressive* model suggests that these changes reflect *off-line processing* of information obtained during the prior day—consolidating, integrating, and sometimes even reversing changes that occurred during waking. Dreaming, as well, might serve either a *homeostatic* or *progressive* function. Freud, for example, proposed a restorative model of dreaming, specifically considering but then rejecting any progressive model.[1] In contrast, others have questioned[22] or rejected[23] the notion of any sort of evolutionary function for dreams.

Although the question of the function of dreaming remains unresolved, there is a growing consensus that sleep serves a function of off-line memory consolidation (for reviews, see Diekelmann and Born[24] and Stickgold[25]). Sleep has been shown to enhance prior learning of perceptual and motor skills,[26,27] paired word associates,[28,29] and emotional memories,[30,31] and even to enhance insight[32] and creativity.[33,34] As with dreaming, memory consolidation appears to vary across sleep stages. In humans, hippocampus-dependent memory has most strongly been associated with slow wave sleep.[9,24,35–37] In contrast, other forms of memory have variously been associated with REM sleep (emotional memory[31,38,39]) or stage 2 sleep (motor learning[27,40]). The particular model of dream function presented here, then, proposes that dreaming relates to this memory function of sleep, participating in, or at least reflecting, the processing of memories for recent daytime experiences.

SLEEP STAGES AND DREAM CONTENT

If memory processing is differentially activated across sleep stages, and dreaming at least parallels and possibly contributes to these memory processes, one would expect to see changes in the content of dream reports collected from different sleep states. In its simplest form, this is exactly what is seen. Reports are more frequent after awakenings from REM sleep,[2,22,41,42] and both REM and NREM sleep reports are more common when awakenings occur later in the night.[42] Reports obtained from REM tend to be longer, more vivid, more storylike, and more bizarre than NREM reports.[22,42] Whereas it has been suggested that some of these differences merely reflect poorer recall after NREM awakenings, little objective evidence supports such a claim, and other REM and NREM differences are not amenable to such an explanation. For example, hallucinations are more prevalent in reports from REM sleep, whereas directed thinking is more common in NREM sleep, a pattern that cannot be explained simply by poorer recall from one stage or another.[43]

Even at this level of analysis, there is the suggestion of homology between dream content and memory function in sleep. In REM sleep, dreams are hallucinatory, emotional, and narrative, with frequent fictive movements (for review, see Hobson and colleagues[22]). Congruently, REM sleep is thought to facilitate consolidation of visual perceptual and emotional memories.[31,38,39] In contrast, NREM sleep (particularly slow wave sleep) has been associated with sleep-dependent improvement on a range of hippocampus-dependent tasks, including the memorization of declarative information[28,29,35] and navigation through spatial environments.[9] Paralleling this mnemonic function, dream reports from NREM sleep tend to be more "realistic" and draw more on material from recent episodic memory.[44] There are notable exceptions (e.g., improvement on a motor task correlates with stage 2 sleep,[27] but REM sleep dreams are decidedly more motoric), but the argument can be made that differences in memory functions across sleep stages are reflected in differences in dream content.

That the mechanisms underlying REM and NREM dreaming may be qualitatively different can be inferred from REM behavior disorder.[45] In this disorder, the inhibition of movement that produces the atonia of REM breaks down, and as a result, patients physically act out their dreams, often with violent consequences. In contrast, no such atonia exists in NREM sleep. Yet there is no equivalent acting out of dream content, suggesting that the neural mechanisms underlying NREM dreaming differ from those of REM dreaming in at least the engagement of motor systems.

DREAMS AND MEMORY SYSTEMS

Most models of dreaming implicitly assume that dreams are constructed from our memories, but they also recognize that this construction need not involve the transparent, direct incorporation of specific memories into the dream scenario. Freud, for example, emphasized that actual memories, events, and their associated emotions underwent "condensation" and "displacement" before appearing in dreams. Whereas he elaborated a complex theory of "dream work" to explain these alterations, modern cognitive neuroscience allows the formation of much simpler, evidence-based explanations. Specifically, dream construction does not include the veridical replay of complete "episodic" memories, whose recall is normally mediated by the hippocampus in waking life. Instead, dreams appear to be constructed from unbound *fragments* of various recent episodes,[46] intermixed with remote memories, semantic memories (facts and general information), and representational memories (sensorimotor images), all stored in and directly accessible in the neocortex.

Within dream content, the distribution of these various types of memory sources appears to differ by sleep stage. Subjects identify episodic memory sources for dream elements more frequently after awakenings from NREM sleep (including sleep onset) than after REM awakenings.[44] This differential rate parallels the decline in directed thinking reported as subjects move from sleep onset to stage 2 NREM sleep and then into REM sleep.[43] At the same time, the frequency of "generic semantic memory sources" is greatest in REM sleep.[44]

Episodic memories are clearly a *source* for the construction of dreams in both REM and NREM sleep, but these episodes are not "replayed" during dreaming in their original form. In

one study, subjects identified waking antecedents for 364 dream elements in 299 dream reports. When the extent of congruence between these dreams and their purported waking sources were analyzed, only 3% of dream elements were judged to have the same location, characters, and actions as the identified waking memory source.[46] For this small percentage of reports, dream content may reflect the same hippocampus-mediated process of episodic recall that characterizes waking recall, allowing identification of particular episodes as the source of their dream elements. What, then, is the basis of this association in the remaining 97% of dreams? The features that showed highest congruence between dream element and putative waking source were theme, emotion, and characters.[46] Whereas the last of these is consistent with the reiteration of a specific episode, the first two are decidedly not. Thematic congruence might instead reflect the activity of nonhippocampal semantic memory systems. As discussed later, evidence from the dreams of amnesiac patients also suggests that the hippocampus is not required for the brain to generate dreams related to recent experience. At the same time, there is increasingly strong evidence that the hippocampal memory system is active during sleep[9,15,15,47,48] and may contribute to dreaming in healthy individuals.[49] Below we turn our attention to the activity of hippocampus-dependent declarative memory systems in sleep.

DREAMING AND DECLARATIVE MEMORY CONSOLIDATION DURING SLEEP

A mounting body of evidence suggests that sleep is critically involved in a wide range of types of memory consolidation, ranging from the consolidation of simple visual and motor skills[26,27,40,50] to the consolidation, integration, and extraction of complex, hippocampus-dependent declarative memories.[28,29,47,48,51-53]

Several studies have employed the "paired associate" learning paradigm to assess the contribution of sleep to declarative memory performance. In this task, subjects are presented with a series of word pairs, and after the entire list has been presented, they are shown the first word of each pair and asked to recall the second. An early study by Plihal and Born[29] suggested that the deeper, slow wave sleep of NREM sleep early in the night is particularly beneficial for the consolidation of such word pair memory compared with the benefits of wake or late-night, REM-rich sleep. Subsequent studies have consistently confirmed that a period of sleep, relative to wakefulness, benefits the retention of this type of memory[11,28,53] and that experimental enhancement of slow wave activity enhances word pair recall.[36,54]

Although most of the literature on sleep and declarative memory focuses on the memorization of verbal or visual stimuli, other research highlights the equally important role of sleep in the *reorganization and transformation* of declarative memories across time. For example, several studies have now reported that sleep aids in the development of transitive inference in a paradigm in which subjects are asked to make judgments extending beyond material learned before sleep.[52,55,56] Payne and colleagues[57] have meanwhile observed that sleep facilitates extraction of the general theme of semantically related word lists. Other studies demonstrate that sleep enhances hippocampus-dependent spatial memory.[47,51,58,59]

In sum, a rapidly accumulating body of research demonstrates that complex, hippocampus-dependent learning is processed during human sleep. Might this reactivation and transformation of declarative memory be expressed within the content of dreams? In partial answer to this question, we later discuss evidence that intensive, engaging learning experiences *are* reliably expressed in the content of dreams during post-training sleep.

INCORPORATION OF WAKING EVENTS INTO DREAMS

Although many of the studies of dreaming described earlier reflect the incorporation of waking events into dreams, few involved experimental manipulations of waking events with the goal of influencing subsequent dream content (for review, see Wamsley and colleagues[60]). A newer line of research investigating this process has focused on hypnagogic dreams, which occur at sleep onset. In the first of these studies,[61] subjects spent 2 to 3 hours per day playing the video game *Tetris* across 2 or 3 days. Three groups of subjects were studied: 12 subjects with no prior *Tetris* experience (novices), 10 with extensive *Tetris* experience (experts), and 5 dense amnesiacs with extensive medial temporal lobe damage resulting from anoxia or encephalitis (amnesiacs). The game involves manipulating game pieces as they "fall" from the top of the computer screen to the bottom in a central "play window." Players can move pieces to the left or right and rotate them as they fall. Their goal is to rotate and position the pieces so that they fill the space at the bottom of the screen without leaving gaps between pieces. On each day of game play, subjects were awakened repeatedly during the first hour of their regular overnight sleep, always within 3 minutes of sleep onset, and asked to report any thoughts, feelings, or images from the prior sleep period. Nine of the novices (75%) and five of the experts (50%) reported visual images of the game in 9.8% and 4.8% of their sleep-onset reports, respectively. Taken together, 64% of the subjects reported instances of game imagery during the hypnagogic period, with images reported in 7.2% of their reports.

Subjects reported remarkably similar imagery, seeing *Tetris* pieces falling in front of their eyes, occasionally rotating and fitting them into empty spaces. Among the 27 reports of imagery, there were no reports of seeing the larger picture surrounding the play window, the scoreboard, or the keyboard or of typing on the keyboard. There were only two reports of seeing a computer screen and none of seeing the desk or room. Thus the imagery was limited to those aspects of the experience that were most salient and to which subjects presumably paid the most attention. As described before, here again we see that dreams are not exact "replays" of waking experience but rather are composed of *fragments* of recent episodic material, often intermingled with other content.

Remarkably, three of five amnesiac patients also reported hypnagogic *Tetris* images, despite being unable to recall playing the game before or after the night's sleep. This observation clearly indicates that the hippocampal memory system, which supports the encoding and recall of episodic memories during wakefulness, is *not* necessary for the construction of sleep-onset imagery related to recent experience. Indeed, the similarity of amnesiacs' reports to those of control subjects was striking. Although unable to recall having played the game (or

even to recognize the experimenter from session to session), patients nonetheless reported, for example, "little squares coming down on a screen," and in one case, the subject explicitly stated that she had no knowledge of the source of the images. Thus she was able to produce dream images of events for which she had no declarative knowledge.

An additional point of note is that two of the five *Tetris* experts reported *Tetris* images explicitly described as being from earlier versions of the game, which they had not played in the last year. One subject reported imagery from a game version that she had not played since high school, 5 years earlier. Thus sleep-onset dream imagery need not be determined only by recent sensory input but additionally can incorporate older, strongly associated memories. Here again, we see that rather than an exact reiteration of waking experience, dreams incorporate salient elements of recent experience into a novel scenario.

This fact is driven home even more forcefully by a study in which subjects were taught three nonsense sentences across a night, one immediately before going to sleep and two more after awakening from REM sleep.[62] The nonsense sentences (translated from the original Italian) are as follows:

> In the bathroom the raven is painting a fish on a radio and spinning a bust on the custard.
>
> In the embers a poster is fining a parcel along the bridge and betting a tooth in the game.
>
> In a liter a cock is tricking a ruble from a palm and nursing a ball in a tub.

Subjects were instructed to memorize the sentences, and after hearing one twice, they repeated it back as accurately as possible. When dream reports were collected after awakening from the next REM period, dream content was frequently judged as related to the previously memorized sentence. For example, after hearing the first sentence, with its reference to "painting a fish," one subject reported "walking with a friend on the seashore."

Of course, such apparent associations can be spurious. Indeed, when judges scored dream reports from a control night, before subjects had heard any of the sentences, apparent associations were again found. However, the experimental design allowed one to use these rates of "pseudoincorporation," obtained from the control night, to correct for such spurious associations, and when this is done, more than one third of all REM reports collected on the experimental night contained actual incorporations of elements from the learned sentence (72% of reports on the experimental night versus 39% on the control night).

Two features of these results are particularly striking. First, the simple act of intentional memorization seems to be sufficient to tag a memory for potential incorporation into subsequent dream content, even when the memory itself has no apparent meaning. Second, as with the previously described study of the incorporation of waking memories into nocturnal dreams,[46] these incorporations are never in the form of an exact replay of the episode, that is, a report of memorizing a sentence. Instead, the brain seems to simply extract specific elements of the memorized sentence (single words or phrases) and to incorporate them into an unrelated scenario. In fact, not only is the scenario changed, but the object is as well, so that the actual word from the memorized sentence (e.g., the fish) is replaced by a semantically related word (e.g., the seashore).

In another study, after training intensively on the downhill skiing arcade game *Alpine Racer II,* 65% of subjects reported images from the game in their subsequent hypnagogic dreams.[63] These sleep-onset dream reports sometimes included places where they frequently crashed or a particularly steep slope, but the game images were again devoid of their original context, always being reported without the arcade game itself being seen or themselves playing it.[63] In agreement with the findings of the *Tetris* study, subjects with prior downhill skiing experience also reported seeing images related not to the arcade game but to actual skiing experiences from their past. These observations thus extend the *Tetris* findings to a second learning paradigm.

In the case of *Alpine Racer II,* it was additionally observed that the nature of game-related sleep-onset imagery became more abstracted from the original experience across the course of the night. A subset of participants were allowed 2 hours of uninterrupted sleep at the start of each night, before being awakened and then, as they fell back asleep, reporting hypnagogic imagery at this later time. In this "delayed awakening" protocol, subjects reported dramatically fewer skiing images. Instead, they reported imagery more indirectly related to the game, for example, of "falling down a hill" or of "moving through some kind of forest" with their "entire upper body incredibly straight."[63] Thus imagery related to recent experience appears to become more abstracted from the original memory source later in the night, a phenomenon also suggested in the transformation of "fish" into "seashore" in the study described previously.[64]

Finally, there is evidence that the incorporation of recent experiences into dream content directly reflects the process of memory consolidation. When newly learned information is incorporated into dream content, even in abstracted form, this is associated with enhanced memory for that information. In fact, such evidence dates back to the 1970s. Fiss and colleagues, for example, found that after reading the text of a short story, participants who reported dreams related to the story exhibited superior memory for the text the following morning.[65] De Koninck and colleagues also examined dreams and verbal learning, exploring dream content as a corollary of language learning in an academic setting.[66] Among students enrolled in a French-immersion class, those with the strongest language acquisition across the 6-week course incorporated French into dream content more often than students who were less successful in the class. Most recently, our laboratory has demonstrated that dreaming of a virtual maze navigation task is associated with enhanced consolidation of spatial memory both across a nap[67] and across a full night of sleep.[68]

EMOTION IN THE SLEEPING BRAIN

REM dreaming is commonly associated with the experience of intense emotion.[22,42] As such, literature suggesting that sleep supports the reactivation and transformation of *emotional* memories, in particular, may be relevant to our understanding of the dreaming process. In one study,[31] the recall of emotionally charged stories was selectively enhanced after REM. In this protocol, subjects learned both neutral and emotional texts before sleep. Relative to wakefulness, periods

of posttraining sleep rich in REM were particularly beneficial for these memories. Furthermore, memory for the *emotional* texts benefited from this REM-rich sleep to a greater degree than did neutral material. Remarkably, when the same research participants were again tested 4 years later,[69] the beneficial influence of REM versus wakefulness on memory for the original emotional (but not neutral) texts was maintained. Similarly, a study from Payne and colleagues[30] demonstrated that sleep selectively enhances memory for emotional objects in the foreground of visual scenes, suggesting that sleep selects the information most relevant to an individual for further processing while allowing memory for less salient aspects of an experience to decay. These observations are also in line with other literature suggesting that sleep modulates emotional responsiveness more generally.[70]

The most well-known example of emotional processing during sleep is perhaps also the least well understood. This is the phenomenon of "sleeping on a problem," involving situations in which a difficult decision must be made. Anecdotal reports indicate that people can go to bed at night with such a problem on their mind and wake up the next morning with a clear solution in their mind. There are several features of this phenomenon that are worth noting. First, it is a remarkably robust effect, with most people casually surveyed believing that, as often as not, it successfully yields results over a single night. Second, the decision normally becomes apparent without an explicit rationale. People report knowing at a "gut level" that they have come to the correct decision but without a clear and rational justification for it. Third, there is usually considerable confidence that the decision reached is the correct one and little sense that further deliberation would be of any added benefit. At the same time, the process does not appear to be useful for the recall of forgotten information, such as a phone number or address. Rather, it serves to analyze available information to come to a decision on the basis of some unknown algorithm that appropriately weights the relevant information. Whereas these features of the process are clear from anecdotal observations, few objective studies of the phenomenon have been made. Still, several studies do suggest that laboratory-induced problems are solved more easily following a period of sleep compared with a period of waking incubation.[34,71,72]

A NEUROCOGNITIVE MODEL OF DREAM CONSTRUCTION AND FUNCTION

When memory networks are activated in the brain, they are inevitably altered. This is one of the most striking findings of cognitive neuroscience in the past decade. Indeed, it might be true that no neural circuits are ever activated without being at least subtly altered. This is true whether the activity of a particular circuit is perceived by the conscious mind or not. Thus every time a young child hears a sentence spoken, neural circuits are activated that over time will extract rules of grammar that will allow her to speak with nearly perfect grammar without explicitly knowing those rules or even that they exist. This is a hallmark of the brain's construction—that it extracts similarities and rules without conscious knowledge that they exist. In addition, studies of mathematical insight[32] and transitive inference[52] have shown that sleep dramatically facilitates this process.

Of course, the activation of memory networks can also be accompanied by conscious experience, as is the case now, as you read and consider the arguments presented here. As there are distinct memory systems in the brain, some accessible to consciousness and some not, so also are there distinct mechanisms for activating and manipulating these memories, some of which are accessible to consciousness and some of which are not. So it should come as no surprise when we suggest, first, that dreaming must inevitably alter the memories accessed in the process of dream construction and, perhaps more important, that dreaming may be a byproduct of mechanisms that evolved to facilitate sleep-dependent memory consolidation and integration.

As in wake, these mechanisms would often activate systems that remain outside of our awareness. This perhaps is the case when a visual texture discrimination skill[23] or a finger-tapping motor sequence[22] is consolidated during sleep. At other times, the sleep-dependent reactivation of memory networks might occur in a manner that brings the patterns of activation in these networks into conscious awareness. Thus, after training on a hippocampus-dependent virtual maze navigation task, participants dream of the maze, observing the flow of images, thoughts, and feelings that occur during this memory reactivation process, which ultimately leads to improved memory performance following sleep. Critically, we do not necessarily *see* the changes in the memory systems that result from this process, and thus we see the content of dreams but neither their underlying purpose nor their ultimate effects. In short, the content of recalled dreams does not in itself reveal any obvious function; as we saw earlier, dreams typically do not appear to be a rehearsal of things that are important to remember.

The question of the function of dreaming may be reducible to a question of the function of the sleep-dependent memory processes that result in the conscious experience of dreaming. Accumulating evidence suggests that sleep has, as one of its most critical functions, the incremental modification of cortical networks. Such a model has been put forward in some detail elsewhere.[24,25] Because sleep has been shown to enhance (1) the experientially controlled modification of visual circuitry during early development[73,74]; (2) visual, auditory, and motor skill learning[26,27,75]; (3) emotional memories[30,31,39,70,76]; (4) declarative and hippocampus-dependent memories[28,29,47,51-53,77]; and (5) creative insight,[32-34] it is clear that sleep's role in memory consolidation spans an impressively wide range of brain circuits and functions. The question of dream function now becomes two questions: For which of these circuits and functions does activity during sleep enter our conscious awareness? and Does this conscious awareness in turn have an effect on these brain circuits? As described earlier, there is evidence that the consolidation of memory in the sleeping brain does, in some cases, directly affect dream content. However, there are still no ways to address the question of whether actual conscious experience can ever alter brain activity, either in waking or in sleep.

CLINICAL PEARL

Emerging data suggest that dream experiences reflect the offline consolidation, integration, and analysis of recent memories during sleep. As such, studying dreaming may facilitate a greater understanding of the sleep-related processes underlying long-term memory formation, as well as the dysfunction of these processes seen in pathologic conditions such as posttraumatic stress disorder.

SUMMARY

In the end, then, we propose that dreaming is simply the conscious perception of the stream of images, thoughts, and feelings evoked in the brain by one or more of the many forms of off-line learning and memory processing that occur during sleep. At the same time, it reflects one of the most sophisticated forms of processing that the brain performs: the analysis and interpretation of the events of our lives in a manner that provides meaning to these events and can guide our future behavior.

Chapter 49

Dream Content: Quantitative Findings

Antonio Zadra; G. William Domhoff

Chapter Highlights

- Researchers and clinicians have long been fascinated by the content of dreams, and considerable progress has been made in the systematic study of dream content. The most frequently used methods for collecting dream reports, laboratory awakenings, home dream logs, questionnaires, and most recent dreams collected in group settings, all have their uses and inherent advantages and disadvantages. However, reliable, comprehensive, and validated instruments for the actual analysis of dream content reports have been developed, and complementary tools are now available to all researchers on the Internet.
- Quantitative data on dream content from laboratory and nonlaboratory settings generally converge in depicting a reliable picture about the nature of dream content in the general adult population. Both data sets indicate that, for the most part, dreams are a reasonable simulation of waking life characters, social interactions, activities, and settings and that dreams show systematic relationships to various dimensions of the dreamer's waking life but not to day-to-day events.
- Results from a variety of studies show that developmental changes occur in dream content until late adolescence, when dream content becomes generally stable and consistent throughout adulthood and old age. In addition, clinically oriented investigations suggest that affect and social interactions are two key dream content variables that are most strongly related to measures of psychological well-being.
- The findings presented in this chapter have several implications for theories of dreaming and provide convincing evidence that dreams are a unique and meaningful psychological product of the mind.

Researchers and clinicians have long been fascinated by the content of dreams. Although many contemporary dream researchers suggest that dreaming is functionally significant and may subserve a biologically important function, some argue that dreams are a by-product of neurophysiologic activity during rapid eye movement (REM) sleep and have no value in and of themselves even though evidence suggests they have psychological meaning.

There is no consensus on what distinguishes "dreaming" from other cognitive processes, such as thinking or daydreaming, nor on what constitutes "dream content." Interdisciplinary groups from the International Association for the Study of Dreams and the American Academy of Sleep Medicine concluded that "a single definition for dreaming is most likely impossible given the wide spectrum of fields engaged in the study of dreaming, and the diversity in currently applied definitions."[1] Thus, depending on one's perspective, dreaming can be synonymous with the term *sleep mentation*, which refers to the experience of *any mental activity* (e.g., perceptions, bodily feelings, thoughts) during sleep, or can be restricted to more elaborate, vivid, and storylike experiences recalled on awakening. As highlighted by others,[2] using a broadly inclusive versus more restrictive definition of dreaming has a direct and significant effect on the nature and sense of empiric data and theoretical modeling in the field.

In this chapter, the term *dream* is conceptualized as having four interrelated meanings. First, a dream is a form of thinking during sleep that occurs when there is a certain, as yet undetermined, minimal level of brain activation in a context in which external stimuli are typically occluded and the cognitive system that keeps us aware of our surroundings is shut down. Second, a dream is something people experience as a series of actual events (e.g., a sequence of perceptions, thoughts, and emotions) because the thought patterns simulate waking reality in a manner that is now often called *embodied simulation*. Third, a dream is what people remember on awakening, so it is a memory of the dreaming experience. Finally, a dream is the spoken or written report provided to investigators based on the memory of the dreaming experience. The empiric studies discussed in this chapter reveal that the events of a dream always include the dreamer as an observer or participant and that they almost always include at least one other character besides the dreamer (either a person or an animal). In addition, the dreamer or the other characters in the dreams are invariably engaged in one or another activity (e.g., looking, walking, running) or a social interaction. Thus the sense of participation in an event, along with characters, activities, and social interactions, is what distinguishes dreams from the more fleeting, fragmented, and thoughtlike forms of sleep mentation.

METHODS FOR COLLECTING DREAM REPORTS

Researchers never study dream experiences directly. Instead, they collect and have access to descriptions of the experience, the dream report. The nature and content of the verbal or written report obtained can be influenced by a number of factors. These include the setting (e.g., home, laboratory, classroom, psychotherapy), method of awakening (e.g., spontaneous, induced), time of awakening (e.g., early, middle, or late in the sleep period), sleep stage before awakening (e.g., REM, non–rapid eye movement [NREM] sleep), type of collection instrument (e.g., questionnaire, dream journal), reporting method (e.g., written by the subject, written by the experimenter, audio recording), instructions provided (e.g., report anything that was going through your mind before your awakening, not only your dreams), probes on reported content (none, fixed, or semistructured questions), interpersonal situation (e.g., reporting directly to an experimenter, clinician), time delay between when the dream was experienced and when it is reported, study duration, and subject characteristics (e.g., gender, personality, habitual level of dream recall).

The degree to which the content of dream reports is influenced by these various factors either individually or in combination varies as a function of the collection method used. The principal sources of dream reports are the sleep laboratory, home dream journals, questionnaires, psychotherapy sessions, and classroom or other group settings where a most recent dream can be collected from everyone willing to participate. Although there is convincing evidence that working with patients' dreams can be clinically useful,[3] dream reports from the psychotherapy relationship are rarely used in systematic studies and thus this source is not covered here.

Sleep Laboratory

Sleep laboratories are an excellent source of dream reports because they provide the opportunity for collecting a representative sample of a subject's dream life, both within and across nights, under controlled conditions. Awakening subjects from several REM or NREM periods results in the collection of dream reports that may have been otherwise forgotten by the participants on normal awakening in the morning. Awakenings during REM or from stage II NREM sleep late in the sleep period maximize the probability of recall and make it possible to collect as many as four or five dreams in a single night. On the other hand, frequent awakenings can be difficult for participants, and factors such as sleep inertia and one's desire to return to sleep may interfere with the quality of the dream reports. However, a complementary cued morning report of dreams recalled during the night can yield new and reliable information as to the dreams' original contents.[4]

The main problem with the laboratory collection of dream reports is that it is a very costly and time-consuming process, and even though several dreams can be collected each night, it still can take many months to obtain 10 or more dreams from each of a dozen participants. Furthermore, some types of dreams, including nightmares and sexual dreams, rarely occur in the sleep laboratory, presumably because of sociocognitive factors. In addition, approximately 20% of laboratory REM dream reports will reflect direct incorporations of the laboratory environment, even when collected over several consecutive nights. For our purposes, the most important outcome of detailed laboratory studies is that they provide a baseline for assessing the quality of dream reports collected by other methods.

Dream Logs

Prospective daily logs are used by an increasing number of dream researchers even though they require a greater investment of time and resources than do questionnaires. In fields like nightmare research, home journals are considered the gold standard for the measurement of nightmare frequency.[5] Although limitations associated with longer-term retrospective assessments of dream recall and dream content are increasingly recognized, variations in home logs have received little attention. Prospective logs can take two different forms. The first is the checklist format in which participants indicate if there was dream recall and, if so, the number and type of dreams recalled (e.g., nightmare). The second is the narrative log, in which participants are requested to provide a complete written transcript of each dream recalled. Findings from one comparison[6] of these two methods of data collection suggest that narrative log participants, having a more time-consuming task, do not take the required time to provide a complete narrative of all of their recalled dreams, as Strauch[7] found with teenage boys. Instead, they may choose to focus on their more memorable, exciting, or salient dreams, which would typically include bad dreams and nightmares. By comparison, people completing checklist logs would be more likely to record all of their dreams (including relatively banal or poorly recalled ones) because each entry is just as quickly completed regardless of dream type.

Although writing down one's dreams remains the most frequently used method to collect dream content, participants may also use tape recorders to dictate their reports. This approach may be particularly useful with children and younger adolescents. It also proved highly useful in a study of blind participants.[8]

Questionnaires

In questionnaire studies, participants' retrospective self-reported information concerning their dream experiences is viewed as a modest but acceptable way of assessing different aspects of the dream experiences themselves, but research suggests they are of limited value in assessing the frequency or content of dreams. Three types of information are generally collected.

First, subjects can be queried about the frequency with which they experience certain kinds of dreams (e.g., everyday dreams, nightmares) over a determined period of time. There is increasing evidence, however, that data obtained with retrospective estimates differ considerably from daily prospective home logs. For instance, compared with results from daily home logs, retrospective self-reports significantly underestimate current nightmare frequency,[9,10] and this rate of underestimation is not attributable to an increase in recalled dreams caused by keeping a dream log.[10] Similarly, one study[9] found that the magnitude of the association between trait anxiety and nightmare frequency decreased significantly when daily logs were used to measure nightmare frequency instead of retrospective self-reports. This led the authors to suggest that anxious individuals do not necessarily have more nightmares, but rather are more likely to remember and report nightmares retrospectively. Finally, a meta-analysis[11] of studies examining the relationship between dream recall frequency and various

personality dimensions found that scores on personality measures were not related to dream recall frequency per se, but rather to people's tendency to retrospectively underestimate or overestimate their dream recall. Taken together, these findings indicate that correlates of retrospective measures of dream recall should not be assumed to be correlates of log measures of dream recall. Contrary to prospective log measures, retrospective indexes of dream recall are best viewed as measures of peoples' cognitive representations of their dream life.

A second kind of information sometimes elicited by questionnaires focuses on specific dimensions of people's dreams or their beliefs about their general dream life. This approach assumes that there exists a valid relationship between self-reported information on the content of one's everyday dreams and the dream experiences themselves. However, comparisons of self-report measures and log-based data indicate that this assumption may be unwarranted. For instance, one[12] comparison of participants' questionnaires and 2-week logs found no relationship between estimated frequency for the appearance of aggressive, friendly, and sexual elements and their frequency in the dream reports. Similarly, a subsequent study[13] showed that when people's level of dream recall is poor, their beliefs about the level of anxiety in their dreams is not related to the actual affective content of their everyday dreams as recorded prospectively in home logs. These findings suggest that the relation between beliefs people hold about the content of their dreams and their actual dream experiences is mediated by autobiographic memory and that these beliefs are particularly inaccurate when dream recall is low (i.e., when memories of one's dreams are not readily available).

Lastly, questionnaires are used to investigate whether participants ever experienced a specific type of dream and, if so, to report the most recent occurrence as best recalled. This approach allows for the investigation of certain types of dreams that, because of their infrequency, are difficult to capture in laboratory settings or with home dream logs (e.g., recurrent dreams, existential dreams) or dreams that stand out in the person's past (e.g., earliest dream recalled, most terrifying nightmare). Although useful in some research settings, the resulting dream content findings must be treated cautiously because of possible memory distortions and biases.

In sum, although some dream questionnaires have good internal consistency and test-retest reliability,[14] studies of their relationship to dream content and frequency findings obtained from dream journals reveal important discrepancies and raise questions as to their validity.

Classroom and Other Group Settings

Settings such as classrooms provide an objective and structured context for the efficient and inexpensive collection of dream reports. Anonymous participants are instructed to write down the most recent dream that they can recall on a standardized form while revealing only basic background information such as age and gender. The Most Recent Dream method has been used with children as young as ages 10 to 11 years in different countries with surprisingly similar cross-national results.[15] A more recent study[16] using the Most Recent Dream method with Greek children (ages 8 to 12 years) and adolescents (ages 13 to 18 years) also showed consistent age changes along with ongoing gender differences similar to those for children studied in the other countries. However, there is reason to believe that young children up to ages 10 to 11 years are using their waking imaginations to provide a report that fits cultural stereotypes about the nature of dreams. The main drawback with this method is that there is not usually time to collect any personality or cognitive measures on the people providing the reports.

ANALYZING DREAM CONTENT: INSTRUMENTS AND ISSUES

Most past dream research used either rating scales at the ordinal level of measurement ("more" or "less" of a characteristic) or discrete categories at the nominal level of measurement (an element is "present" or "absent"). Rating scales are most useful for those characteristics of dream reports that have degrees of intensity in waking life. Cohen[17] reports that four dimensions of dream salience can be rated by participants in dream studies: emotionality, bizarreness, activity, and vividness. A factor analysis of the ratings of 100 REM dream reports suggests that rating scales boil down to five basic dimensions: (1) degree of vividness and distortion, (2) degree of hostility and anxiety, (3) degree of initiative and striving, (4) level of activity, and (5) amount of sexuality.[18] However, it is often difficult to establish reliability with some scales, and much of the specific information in dream reports is lost or unused with general rating scales.

Of the 150 dream rating and content analysis scales reviewed by Winget and Kramer,[19] the Hall and Van de Castle (hereafter HVDC) coding system[20] is the best validated and remains the most widely used system for analyzing dream content. The HVDC system, which provides many of the findings presented in the rest of this chapter, rests on the nominal level of measurement and uses percentages and ratios as content indicators that can correct for the varying length of dream reports from sample to sample. The dream reports used in the original normative sample, as well as the coding of them, are available to researchers through www.dreambank.net.[21] The normative findings reveal a pattern of gender differences that needs to be taken into account when doing studies of individuals. The coding system employs nonparametric statistics for determining *P* values and effect sizes, which can be obtained instantly after entering codes into the DreamSAT spreadsheet available to all researchers on www.dreamresearch.net.[22] The general HVDC norms can be used with confidence for a variety of purposes because they have been replicated in several studies.[23,24] The coding system and the norms also have been found to be useful in studies of college students in several different countries.[25]

As documented by Winget and Kramer,[19] there exist numerous other coding systems, and many new ones have been created since their comprehensive review. However, unlike the HVDC system, most of these instruments have only been used by the original investigators (limiting potential for comparisons across laboratories), many use weighting systems of questionable validity, and few are based on clearly defined and objective scoring criteria that yield good interrater reliability. Moreover, as detailed elsewhere,[23] many of these scoring systems can be duplicated by combining two or more elements of the HVDC system.

Some research questions (e.g., self-reflectiveness in dreams,[26] contextualizing images in dreams[27]) have necessitated the creation of new instruments. The DreamThreat rating scale[28] was developed to test an evolutionary theory of

dreams that stipulates that the function of dreaming is to simulate threatening events with the intent of improving the subject's capability to recognize and avoid diverse threats in real life. Although this rating scale has been criticized, it is noteworthy in that it has been used by different groups to assess various kinds of dreams[28,29] and that it yields good to excellent interrater agreement. Taken together, findings indicate that a significant proportion of dreams contain a wide range of threats, but few of these dreams present realistic life-threatening events, and the dreamer rarely succeeds in escaping the threat.

Finally, because of the time-consuming nature of traditional coding systems, programs for word and phrase searches have been created to study specific characters (e.g., "my mother) or activities (e.g., "making love"), and lengthy word strings have been developed for coding concepts characterized by a relatively circumscribed set of terms (e.g., specific emotions). The program for single words, phrases, and word strings on www.dreambank.net calculates frequencies, percentages, *P* values, and effect sizes when two sets of dream reports are compared.[21] A comprehensive and carefully constructed set of 40 word strings covers classes of characters, types of activities, natural settings, and much else.[30,31] These 40 word strings have normative findings based on the same dream reports used to create the HVDC norms, and they provide results comparable to the HVDC findings for several categories.

Problems in Studying Emotions and Bizarreness in Dreams

Although both rating scales and the HVDC nominal coding categories have proved useful for most dimensions and elements of dream content, there are methodologic problems relating to the study of both emotions and bizarreness in dreaming. Several different studies using blind coders find that negative emotions outnumber positive ones.[20,32] Further, a laboratory study that compared ratings of emotions by independent judges with similar ratings by participants immediately after each awakening showed no differences.[33] However, different results emerge when the participants themselves make a global rating of each of their dream reports on a pleasant-unpleasant dimension. Such studies regularly find that the dreamers rate the emotions in their dreams as at least equally pleasant and unpleasant, and sometimes as more pleasant.[34,35] Furthermore, some studies[36] show that a greater proportion of laboratory as well as home dream reports are rated as containing emotions when these are scored by the dreamer compared with external raters. More recently, one study[37] of emotional experiences in REM dream reports found that self-ratings of emotions provided by the dreamer on awakening differed from ratings given by external judges using the same rating scales, with self-ratings resulting in greater estimates of emotional dreams, positively valenced dreams, and positive and negative emotions per dream.

Dreamers also tend to attribute many more emotions to their home dreams than do blind judges when they are later asked to recall the emotions that accompanied reports they wrote down at an earlier time. However, it is an open question in need of further study as to why dreamers often say their dreams are more pleasant than might be expected based on judges' ratings and attribute more emotions to their home dream reports than judges do. These differences may result from two extrinsic factors, namely the demand characteristics of such a rating task and the waking-life assumption that certain emotions would logically be present in many of the situations experienced in the dreams. It is also likely that the use of different rating scales and instructions for the scoring of emotions in dreams (e.g., dream's overall emotional tone versus number of emotions reported per dream narrative, frequency versus intensity of emotions, number of discrete positive and negative emotions to be rated, scoring of inferred versus explicitly reported emotions) affects the ratings obtained, whether they are self-reported by the dreamer or scored by external judges.

There is also lack of agreement on how to assess unusual or bizarre elements in dreams, which leads to widely varying prevalence and frequent estimates. In studies that focus on clearly impossible events, the figure is 10% or below for large samples of both REM and home dreams.[38,39] When sudden scene changes, uncertainties, and small distortions are included, the figure rises to between 30% and 60%.[40,41] Using a rating scale based on the degree to which any dimension of the dream differs from waking experience and behavior, it was found that 75% of 500 REM reports from adult men and women had at least one bizarre aspect, as compared with 7% to 8% that were bizarre in three or more ways.[42] In addition, other than for one study[43] showing that scene changes can be similar in REM dream reports and waking mentation, studies of bizarreness in dreams have been handicapped by the fact that there have been no other adequate studies comparing the nature and frequency of bizarre elements in dreams and waking thought samples from the same participants, which seems to be an essential step given the evidence that waking thought often contains unexpected and anomalous elements.[44]

The Importance of Adequate Sample Sizes and Minimum Report Lengths

One important variable that is all too often overlooked when investigating dream content is the sample size required to detect changes in various content variables. The use of an approximate randomization algorithm provides evidence that it takes 100 to 125 dream reports to detect significant content differences for many of the HVDC content indicators because some dream elements appear in half or less of dream reports; in addition, effect sizes are often modest.[45] It should also be noted, as detailed elsewhere,[23] that it is unlikely that repeatable and scientifically useful results can be obtained with dream reports much shorter than 50 words, especially when using HVDC content categories.

Finally, although coefficients of internal consistency for dream diaries indicate that everyday dream recall is relatively stable over time,[6,46] several dream content variables appear infrequently in dream reports and show large intraindividual fluctuations. For this reason, it is suggested that correlational studies involving relatively rare or unstable dream content variables be based on at least 20 dream reports from any given participant.[14]

Quantitative Findings on Dream Content

Dream Reports from Laboratory Awakenings

The best starting point for the systematic study of dream content remains the classic studies completed by dream researchers during the heyday of laboratory dream research in the 1960s and early 1970s. They show that dream content simulates everyday life to a far greater degree than had been

anticipated based on the clinical cases that had been the basis for theorizing before the laboratory era of dream research.[47] They characterize a prototypical REM dream report as a "clear, coherent, and detailed account of a realistic situation involving the dreamer and other people caught up in very ordinary activities and preoccupations, and usually talking about them."[47]

For example, of all the dream settings that were described, only 5% were "exotic," in the sense of highly unusual or out of the ordinary, and less than 1% were "fantastic," in the sense of unrealistic.[47] Using a conservative standard to guard against imputing any emotions to the dreamers, specific emotions were judged to be present in only 30% to 35% of the reports, with unpleasant emotions outnumbering pleasant ones by 2 to 1. Anxiety and anger were the most frequent types of emotions; erotic feelings occurred in only 8 of the 635 reports (1.3%).[47] The dreams were rated as having a low degree of bizarreness. Focusing here on the longest reports because they were more frequently rated as bizarre, 50% were rated as having no bizarreness, 30% as having a low degree of bizarreness, 8% as having a medium degree, and 2% as having a high degree.[47]

A low degree of bizarreness was also reported in a highly detailed laboratory study of that issue.[39] The authors "emphasize the rarity of the bizarre in dreams" because major distortions of actual waking experiences reach a high of only 17% of all the activities and social interactions and of 6% and 8% for all characters and physical surroundings.[39] When they carried out global ratings of each dream for overall novelty, they found that most of them contained very little novelty: only 9% were highly improbable by waking standards; another 26% showed large but plausible differences from previous waking experiences.

The issue of emotions in REM dream reports was first investigated in great depth in the sleep laboratory where participants were quizzed in detail after each awakening as to the presence of emotions and the appropriateness of the emotion to the content. Drawing on ratings by both participants and naïve judges, it was concluded that about 70% of the dream reports had at least some affect.[48] The study further found that there were no differences in the ratings of emotions by the independent judges and the participants.[33] A study in a Swiss sleep laboratory came to very similar conclusions about the frequency and intensity of emotions in dreams.[42]

Several early laboratory studies probed for any changes that might occur in dream content from REM period to REM period, uncovering very few replicable differences. Employing categories for settings, characters, activities, social interactions, and emotions, both quantitative and qualitative analyses find few or no differences from REM to REM when corrections are made for the length of report.[34] In the most comprehensive study of this issue, there were two minor differences among 26 analyses employing HVDC categories for the first four REM periods, whether they were nights with single or multiple awakenings, and there were no differences with spontaneously recalled dreams that came from night or morning REM self-awakenings.[49] However, there may be some degree of thematic continuity from REM to REM on a few nights.[42]

REM and NREM Dream Reports

Although there were indications in early laboratory studies that dreaming occurs almost exclusively in REM sleep and that there were differences in the content of REM and NREM reports, many later studies suggest that the differences in recall are not black and white, especially late in the sleep period, and that some of the content differences disappear when there is a control for word length.[50,51] Still, most studies conclude that dreams are more frequent and longer during REM periods and that many NREM reports seem to be "thoughts," not dreams. In fact, NREM reports are more often a continuation of waking thoughts and memories, whereas there are few episodic memories in REM or home dream reports.[52,53]

The differences in content relate to a greater character density in REM reports, which in turn leads to the possibility of social interactions.[38,50] Then, too, there is evidence that NREM reports late in the sleep period are more similar to REM reports than are NREM reports from the first few hours of sleep.[54] In the most recent studies of this issue, the thought-like nature of NREM decreased by 56% and the hallucinatory nature increased by 62% over the course of the night, leading to the conclusion that "as the night progresses, NREM approaches the neurocognitive characteristics of REM."[55] In two separate studies it was found that the major difference between late-night REM and NREM dreams is on aggressive interactions.[56]

Laboratory and Home Dream Comparisons

Several careful investigations reveal that there are relatively few differences between home and laboratory dream reports even when the dreams are obtained by tape recorders in the sleep laboratory and by written reports at home.[38,42] Furthermore, most of these differences disappear when the proper controls are introduced.[57,58] The one exception to this generalization seems to be hostile and aggressive dream elements, which occur more frequently in the home dream reports of young adults in three different studies.[38,58]

These findings on the relatively small differences between home and laboratory dreams may be explainable in terms of the results from laboratory studies that compare what is reported from REM awakenings with what is still remembered in the morning.[59,60] Such studies reveal that recency and length of report are the primary factors in later recall, which at home would lead to a representative sample of nightly dream content given the lack of content differences from REM to REM and between REM and late-night NREM. However, some of these studies also show that intensity can be a tertiary factor in morning recall, which suggests there is some selection bias toward the everyday recall of more emotionally salient content.

Normative Dream Content in Home Dreams

As might be expected from the results of the laboratory-home comparisons, studies of large samples of dream content collected from young college-educated adults outside the laboratory show many similarities with the laboratory results when the same or comparable content categories are employed. Dreams mostly occur in commonplace settings, contain a large number of familiar characters, and revolve around family concerns, love interests, and activities engaged in during waking life.[61] This point is best seen in a study of several hundred dream reports from German college men and women in which the dream content was coded for at least one instance of several simple ad hoc categories constructed to determine the degree to which the dreams involve people and activities

from everyday life.[62] There were four categories for familiar characters, five categories for commonplace leisure activities, and a single category for involvement in work, school, or politics. The everyday nature of most of these dreams is seen in the fact that 75% of the women's dreams and 62% of the men's have at least one instance of one of the four categories of familiar characters. Similarly, 42% of the women's dreams and 27% of the men's have at least one instance from one of the five leisure-time categories. The routine matters of work, school, or politics appear in 20% of the women's dreams and 29% of the men's dreams. Overall, only 13% of the women's dreams and 20% of the men's have no instance of any of the above categories. In keeping with other findings on gender differences in dream content, the men's dreams are less likely to have familiar characters and familiar leisure time activities and more likely to have instances of school, work, or politics, but the important point for purposes of this chapter is that only a minority of dreams for either gender involves unknown characters and activities that are out of the ordinary.

Given the longstanding clinical and popular interest in dreams with erotic or sexual content, this dream content category has received surprisingly little attention. Questionnaire studies indicate that approximately 80% of adults answer positively to the question, "Have you ever dreamed of sexual experiences?"[63] with men reporting sexual dreams more often than women. The normative data from HVDC indicates that 12% of mens' dreams and 4% of women's dreams contained sexual content, including having or attempting intercourse, petting, kissing, sexual overtures, and fantasies. However, one study[64] of more than 3500 dream reports found no gender differences, with approximately 8% of dream reports from both men and women containing sexually related activity. The differences with the HVDC data may be partially due to sample composition (college students versus student and nonstudent adults). Alternatively, it is also possible that women actually experience more sexual dreams now than they did 40 years ago, or that they now feel more comfortable reporting such dreams because of changing social roles and attitudes, or both.

Age Differences

There appear to be major changes in dream content from the preschool to teen years, but few changes from the late teens to old age. Dream content thus seems to parallel cognitive and emotional development during childhood as well as the stability of adult personality. Much of what is known in a systematic way about children's dreams comes from a classic longitudinal laboratory study of children between the ages of 3 and 15 years, supplemented by a cross-sectional laboratory replication a few years later with children ages 5 to 8 years.[65] More recently, a 5-year longitudinal laboratory study of Swiss children ages 9 to 15 years has provided additional supporting information.[7,66] Detailed summaries of the methods, samples, and findings can be found elsewhere.[22]

The most unexpected finding in the first study was the low amount of recall from REM periods in the 3- to 5-year-olds (only 27% of the REM awakenings yielded any recall that could reasonably be called a dream), and the static, bland, and underdeveloped content of the few reports that were obtained. The reports became more "dreamlike" (in terms of characters, themes, and actions) in the 5- to 7-year-olds, but it was not until the children were 11 to 13 years old that their dreams began to resemble those of adult laboratory participants in frequency, length, emotions, and overall structure, or to show any relationship to personality.[67]

A cross-sectional replication of these results[65] with children ages 5to 8 years supported all of the main original findings. The median rate of reporting was only 20% for all age groups. The imagery in the dreams was more static than dynamic until age 7 years, and the child's "self" character did not tend to take an active role in the dreams until age 8 years.[65] As with young adult dreams, there were more characters in the girls' dreams, and there was the same gender difference in the percentage of male and female characters. There were no failures, few negative emotions, and very few misfortunes. There were few aggressive or friendly interactions, with more friendliness in the girls' reports.[23]

The results from the longitudinal study of Swiss children ages 9 to 15 years were generally similar to those for preadolescents and adolescents in the earlier longitudinal study, and there were only relatively small changes in most categories over the 6-year period. The largest change was a decline in bizarreness for both boys and girls, as defined by degrees of deviation from waking experience and social norms; just over 60% of dream reports had at least some degree of bizarreness at ages 9 to 11 and 11 to 13 years, but the figure fell to 41% at ages 13 to 15 years.[7]

In contrast to the changes in dream content from childhood to adolescence, dream content is extremely stable in terms of characters, social interactions, and most other dream elements after age 18 years according to cross-sectional studies in the United States, Canada, and Switzerland that are summarized in Domhoff.[23] Elderly people recalled fewer dreams in one large longitudinal study,[68] but separate studies suggest their dream content remained generally the same—except perhaps for aggression, where studies suggest a decline.[69,70]

Dream Content and Well-Being

Considerable research efforts have been expended trying to establish dream content correlates of standardized personality variables, measures of psychological well-being in nonclinical samples, and indexes of psychopathology in clinical populations. Taken as a whole, there is mixed evidence that psychometrically defined personality traits (e.g., neuroticism, extraversion) are related to everyday dream content.[71] Robust relations, however, have been demonstrated between waking levels of well-being and specific types of dreams such as nightmares[5] and recurrent dreams,[72] as well as between dream content and various dimensions of waking life, including people's general waking concerns.[24,45,73] Several studies[74,75] have shown that dream content is reactive to the experience of naturalistic and experimental stressors, but whether or not dreams play a role in people's actual adaptation to stress remains an open question. In a series of longitudinal studies of REM dream reports from depressed and nondepressed adults undergoing marital separation or divorce, Cartwright and her collaborators[73,76] provide suggestive evidence that dream content variables centered around affect and the representation of the ex-spouse are associated with how well people adapt to their situation over time. Similarly, one longitudinal study[77] of normal adults found that participants' dream content from home logs was moderately to strongly correlated to their scores on measures of psychological well-being both at fixed points in time and over a 6- to 10-year period, with content variables of dream affect and social

interactions showing the strongest relations. Dream content in severe psychopathologic conditions such as schizophrenia has been reviewed elsewhere,[78,79] and with few exceptions, little by way of consistent findings has emerged from this literature. In addition, many studies in this field suffer from methodologic problems, including unclear diagnoses, inadequate controls, unknown effects of medications, few dream reports per patient, and the use of untested coding systems. However, the HVDC system has been shown to be useful in studies of patients with Parkinson disease and those with REM sleep behavior disorder[80,81] as well as women who have had mastectomies.[82]

In addition, unique features of dream content have also been better documented in relation to conditions typically accompanied by distinct waking thoughts and concerns, such as pregnancy,[83] bereavement,[84] and exposure to trauma.[85] A better understanding is also emerging regarding the frequency and contents of specific kinds of dreams, including typical dreams[63,86] as bad dreams and nightmares.[87]

Individual Case Studies

Within the context of the many well-established group findings, individual case studies can be of great value for both research and possible clinical applications. The dream journals on which such studies are based have value as nonreactive measures that have not been influenced by the purposes of the investigators who later analyze them. The conclusions drawn from nonreactive archival data are considered most reliable and useful when they are based on a diversity of archives likely to have different sources of potential biases.[23]

Studies of more than a dozen different dream journals first proved their usefulness for scientific purposes by revealing an unexpected consistency in dream content when several hundred dream reports were studied.[23] This consistency begins in the late teens and continues to old age. Two studies of discontinuous dream series show that the consistency revealed in continuous dream journals is not the result of practice effects.[23,88]

Individual dream journals also provided the basis for the most rigorous work to date on the lawfulness of dreams and their relationship to waking conceptual processes. This work[89] shows that the social networks in dreams—that is, the pattern of direct and indirect relationships among the characters—have the same properties as waking social networks in that the paths between characters are short and the clustering of characters is high. Moreover, the frequency distribution of the characters is consistent with Zipf's law, a power law for describing frequency distributions in which the top few entities occur very frequently and most other entities appear very rarely. In a recent extension of this work,[90] the dream and waking-life social networks of a middle-aged woman were compared using 4254 dream reports and information from the dreamer concerning her relationships with her dream characters in waking life. Results showed that people important in one network tend to be important in the other, but that people with different relationships to the dreamer (e.g., family, friends, and coworkers) are mixed together much more in the dream than the waking network.

Blind analyses of dream journals[23,91] also have led, through the formulation of inferences that can be accepted or rejected by the dreamer and other respondents, to the conclusion that some dream content is continuous with the dreamers' waking conceptions, concerns, and interests. The most direct continuities involve the main people in a dreamer's life and the nature of the social interactions with them. There also is good continuity for many of the dreamer's main interests and activities. However, these findings on continuity have to be qualified in two ways. First, the continuity is with general concerns, not day-to-day events, as shown by three studies (two based on REM awakenings, one based on morning recall at home) in which judges could not match detailed waking reports of daily concerns with dream reports.[92] This finding is consistent with studies showing low levels of episodic memory in dreams.[52,93] Second, the continuity usually is with both thought and behavior, but sometimes it is only with waking thought. For example, people who have highly aggressive dreams are not always aggressive people in waking life, but they usually admit to many aggressive thoughts and fantasies during the day.[23]

Sensory Experiences and Dreams of Blind Subjects

Although the overwhelming majority of dream reports contain visual and, to a lesser extent, kinesthetic elements, the presence of other sensory modalities has also been noted in both laboratory and home dream reports.[47,94] More than 50% of dream reports contain auditory experiences, whereas explicit references to olfactory, gustatory, and pain sensations occur in less than 1% of all dream reports. One study[94] found that women's dream reports were more likely to contain olfactory or gustatory sensations, whereas references to auditory and pain experiences occurred in a higher percentage of men's dreams. That the more infrequent modalities of smell, taste, and pain occur at all in dreams is an important demonstration of the representational capacities of dreaming.

Perhaps because of the highly visual nature of dreaming, people always have wondered if blind people dream, so some of the earliest systematic interview studies on dreams dealt with this topic, showing that people who are born blind or become blind before age 4 or 5 years do dream even though they do not see images in their dreams,[95] a finding that was then supported by laboratory studies.[96] Nor is there much if any difference in dream content, except that there may be less aggression in their dreams.[8,95] There is also much greater mention of touch, taste, and smell in blind people's dreams.[8] It is noteworthy that people who become blind after age 5 or 6 years often have visual imagery in their dreams, which suggests that there is a window for the development of the capacity to have visual dreams that parallels what was found in longitudinal studies of children aged 3 to 7 years.[97]

Implications for Theories of Dreaming

The array of systematic results presented here suggests that a considerable amount of psychological information can be extracted from dream reports. This conclusion provides support for the core idea of all twentieth century dream theories, but it must be stressed that much dream content is not yet understood. The findings also suggest that most dreams focus on a handful of personal concerns revolving around social interactions with family, friends, and coworkers. The greatest variability in dream content seems to concern the appearance of aggression, especially physical aggression.

Despite the originality and creativity that is displayed in the cognitive production of dreams, and even given the aspects

of dream content that are not understood, most dreams are more realistic and based in everyday life than is suggested by most traditional dream theories. In addition, much dream content seems more transparent than might be expected by older clinical theories that emphasize disguise or symbolism in understanding dreams. Finally, a significant minority of dreams may not be as emotionally based as theories imply, especially before the adolescent years.

As a starting point, perhaps dreams are best understood as embodied simulations that enact the person's main conceptions and concerns, including emotionally salient interpersonal preoccupations. This type of conceptualization is at the heart of the continuity hypothesis, which posits a relationship between everyday dream content and general waking states and concerns. Although most of the research findings reviewed here are consistent with the continuity hypothesis, much work remains to be done to clarify which specific dimensions of waking life (e.g., particular learning tasks, daily mood, major life events, ingrained behaviors, sustained fantasies, cognitive styles) are most robustly associated to what kind of dream content and the nature of these relationships over time.[52] In fact, instead of referring to *the* continuity hypothesis, it may be more appropriate to consider multiple levels of continuity between various waking and dream parameters and to be alert for discontinuities as well. The observations that dreams rarely depict episodic memories and that the nature of temporal references in dreams can take many forms add a layer of complexity to an already difficult problem. In the end, dreaming may or may not have a function, but data convincingly show that dream content is a unique and meaningful psychological product of the human brain, and as such, dreams will continue to interest and challenge clinicians and researchers alike.

CLINICAL PEARLS

- Examining a series of dreams often yields more meaningful information about a patient's psychological state than focusing solely on one particularly salient dream.
- Changes over time in the frequency and content of repetitive dream themes, especially those involving strong affect and social interactions, are most likely to reflect a patient's clinical progress or deterioration.

SUMMARY

This chapter reviews methodologic issues in dream research and systematic findings on the content of people's dreams, and it presents the implications of key findings on normative dream content. Quantitative data on the content of laboratory and home dream reports converge in depicting a reliable picture about the nature of dream content in the general adult population as well as its development in children. At the most general level, these findings indicate that dreams show systematic relationships to various dimensions of the dreamer's waking life and suggest that many dreams are the embodiment of thoughts through dramatizations of life concerns and interests. That a wide range of psychological information can be extracted from dream reports has implications for clinical, theoretical, and empirical approaches to the study of dreams.

Brain Correlates of Successful Dream Recall

Luigi De Gennaro; Michele Ferrara

Chapter 50

Chapter Highlights

- The scientific study of dreaming grew up rapidly in the 1950s, after the discovery of rapid eye movement sleep, which was considered to be a neurophysiologic marker of dreaming. Subsequent and more accurate investigations, however, showed that qualitatively different mental experiences are developed during all sleep stages.
- The recent progress with electrophysiologic (high-density electroencephalogram) and imaging techniques seems promising to elucidate the functioning of the brain structures presumably involved in the elaboration of dreaming, both in healthy subjects and in patients with acute or chronic brain damage, neurodegenerative diseases, or sleep disorders.
- This chapter summarizes the established findings and emerging knowledge on the neural correlates of successful dream recall. Lines of recent evidence converge in indicating that dream recall is related to specific electroencephalographic frequencies and to particular topographic features of the scalp electroencephalogram. These results are consistent with neuropsychological data, pointing to an overlap between functional and structural cerebral substrates of waking and rapid eye movement sleep mental imagery.

This chapter surveys the main findings and the rising knowledge of the neural correlates of successful dream recall. Owing to the intrinsic impossibility of direct access to dream *generation*, necessity forces recourse to indirect access through the collection of data on dream *recall*. In this context, the specific question to be addressed in this chapter is twofold. On the one hand, a common *general* question in cognitive neuroscience concerns the definition of the neural substrates of a specific cognitive process (in this case, dreaming). On the other hand, a second focus is on the *specific* problem of how tight the association is between functional/structural brain measures and dream experience itself. The lack of a direct measurement of the physiologic scenario in which dreams are generated implies that correlative findings on successful recall may be interpreted in terms of basic individual characteristics—defined in this chapter as *trait-like* differences—or as a direct consequence of neural functioning in a specific physiologic state—that is, *state-like* differences. For these reasons, different approaches to the question may be useful and produce different insights on the general issue: (1) quantitative scalp electroencephalogram (EEG) studies provide elecctrophysiologic data, with good temporal resolution; (2) intracerebral recordings in patients with pharmacoresistant epilepsy are informative regarding the spatiotemporal dynamics of subcortical electrencephalographic correlates; (3) microstructural analyses by magnetic resonance imaging (MRI) brain scans and by diffusion tensor imaging (DTI) analysis of MR images allow measurement of interindividual differences in brain tissue; and (4) these last measures can be considered as a sort of counterpart, in healthy subjects, of the neuropsychologic evidence, which describes behavioral and cognitive changes in patients with brain injury. Converging evidence and new research techniques from across the neurosciences can be expected to contribute strategies to overcome some intrinsic difficulties in directly accessing dream generation.

ELECTROENCEPHALOGRAPHIC CORRELATES

Scalp Measures

The study of neural correlates of dream recall has coincided for a long time with evaluating the association between the presence or absence of recall on awakening and the cortical electrophysiologic findings in sleep intervals preceding the awakening, as measured by quantitative scalp EEG studies. The assumption is that dream reports and failure to recall after awakening are linked by temporal contiguity to the scenario in which the dream experience happens, supporting the correlative hypothesis. On the other hand, no independent control study has confirmed that sleep mentation, as evaluated by a postawakening protocol, actually refers to a dream experience obtained in close temporal proximity to the awakening. As a further limitation of this approach, the empiric findings have been obtained both during naps and during nocturnal sleep. Independently from the actual evidence of chronobiologic effects on dream production,[1,2] this aspect of the study undoubtedly implies a possible confounding role of circadian/ultradian factors.

Given these caveats, in recent years multielectrode recordings have allowed a gain in spatial resolution, along with the possibility of comparing EEG findings with those provided by other neuroimaging techniques. Accordingly, the

investigation of EEG correlates of successful dream recall has evolved by addressing two general questions:

1. Are differences in dream recall–no recall related to specific EEG frequencies?
2. Does dream recall–no recall show scalp EEG topographic differences?

The alpha EEG activity on the one hand in the temporoparietal area on the other turned out to provide a plausible answer to these questions. Accordingly, increased EEG activity in the alpha range (between 11.72 and 13.67 Hz) is associated with the absence of sleep-onset rapid eye movement (REM) period dreams and the appearance of sleep-onset non-REM (NREM) period dreams.[3] Moreover, a negative correlation between alpha activity at the right central site and a measure of visual activity in dream reports has been reported after nocturnal awakenings, irrespective of sleep stage of awakening.[4] This association was partly confirmed in nocturnal NREM and REM awakenings.[5] In both sleep stages, dream recall was associated with lower alpha power, although of lesser magnitude in REM sleep. Independently from sleep stage, the alpha reduction was mainly localized over temporoparietal areas temporoparietal areas. The specific involvement of alpha activity in stage 2 NREM dream mentation was subsequently confirmed by Marzano and colleagues,[6] who also found that frequency of dream recall after awakenings from stage 2 was linearly correlated with a lower level of alpha oscillatory activity in the right temporal area (Figure 50-1, *left*). On awakening from REM sleep, a higher level of frontal theta activity was linearly correlated with dream recall rate (Figure 50-1, *right*). By this evidence, two stage-specific EEG activities were predictive of a successful dream recall at morning awakening, and the relations were topographically specific.

One of the limitations of the quantitative EEG approach is that the presence of a spectral peak resulting from a fast Fourier transform analysis of the EEG signal does not necessarily imply an underlying oscillatory activity at that frequency.

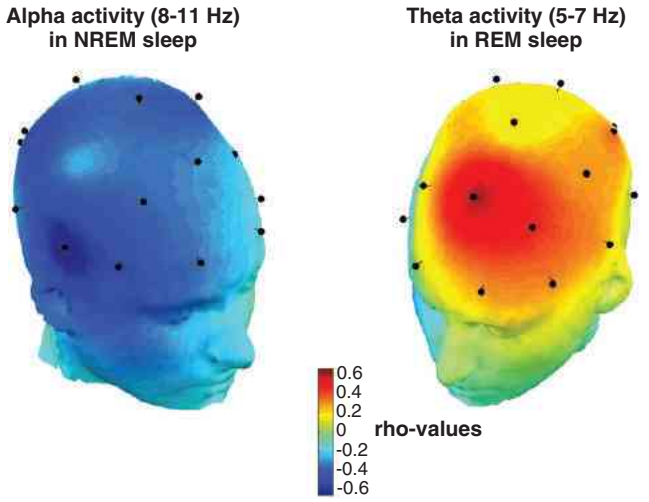

Figure 50-1 A three-dimensional topographic distribution of correlation values (rho) between the number of dreams recalled upon morning awakenings and (1) the amount of EEG theta activity in REM sleep (*right side*) and (2) the amount of EEG alpha activity in NREM sleep (*left side*). EEG, Electroencephalogram. (Data from Marzano C, Ferrara M, Mauro F, et al. Recalling and forgetting dreams: theta and alpha oscillations during sleep predict subsequent dream recall. *J Neurosci* 2011;31:6674–83.)

This limitation may indeed be relevant in light of findings, obtained by scalp recordings during wakefulness, showing that low-frequency brain oscillations increase during encoding of episodic memories.[7-9] The hypothesis that the encoding of dream content during sleep shares some electrophysiologic mechanisms with the successful encoding of episodic information during wakefulness implies a further (different) approach to scalp EEG during sleep. The application to the EEG signals of a method (Better OSCillation [BOSC][10]) to detect oscillatory activity within a signal containing a nonrhythmic portion provided empiric support for that notion. The results of Marzano and associates[6] showed an involvement in dreaming of those regions that control successful memory encoding in waking by detecting higher oscillatory theta activity at frontal areas after awakening from REM sleep and lower temporo-occipital alpha oscillations after awakening from stage 2 sleep. It is intriguing that the cortical regions whose oscillatory activity predicts dream recall are reminiscent of those involved in the global cessation of dreaming after brain injuries (see later under Neuropsychological Correlates).

Although predictive relationships between EEG oscillations and dream recall have been reported as a function of the proximity to the time of awakening, the possibility that stable interindividual EEG patterns characterizing particular subjects explain these findings cannot be ruled out completely. In fact, high recallers are characacterized by larger neurophysiologic responses, as assessed by evoked potentials to auditory stimuli, than low recallers.[11] Of interest, this larger brain reactivity was found during both wakefulness and REM and NREM sleep stages, somehow with the general notion that brain correlates of dream recall share some electrophysiologic mechanisms of the awake brain. However, a definitive response to the question of whether EEG correlates of successful dream recall reflect state- or trait-like differences can be provided only by multinight within-subject studies, whereby preawakening sleep periods followed by successful versus failed dream recall could be compared.

In conclusion, most empiric evidence goes in the direction of a frequency- and topography-specific relation between EEG oscillations in the minutes preceding awakening and dream recall. Some evidence suggests that successful dream recall is associated with the specific electrophysiologic pattern in the minutes preceding awakening.[6] Theta and alpha oscillations are correlated with successful recall, with involvement of temporoparietal and frontal areas. This evidence is consistent with models of episodic memory in which theta oscillations allow a top-down control from the frontal cortex to the hippocampus, modulating the encoding and retrieval of episodic memories,[12] whereas the alpha activity may be functionally related to the activation of stored information.[13]

Therefore EEG studies suggest that the neurophysiologic mechanisms underlying the encoding and recall of episodic memories are the same across different states of consciousness.

Intracerebral Measures

If the EEG correlates of dream recall point to a crucial role for the temporoparietal and frontal cortices, the available knowledge on subcortical areas is limited. The recent application of intracerebral recordings (using stereo EEG) obtained in patients with pharmacoresistant epilepsy has provided some

insights regarding the spatiotemporal dynamics of subcortical EEG correlates of dream recall. In particular, mediotemporal lobe activity associated with dream recall has been investigated under the assumption that dream recall is a peculiar form of episodic memory encoded during sleep.[14] Thus the encoding of dream content could share some electrophysiologic mechanisms with successful episodic memory encoding of the awake brain, because phase synchronization of rhinal-hippocampal EEG activity in the gamma range and increased EEG coherence in the theta range are predictive of successful memory formation.[15,16] Actually, comparison of rhinal-hippocampal and intrahippocampal EEG connectivity between good and poor dream recallers awakened from REM sleep shows a strong relationship between rhinal-hippocampal and intrahippocampal EEG connectivity and the capability to recall dreams.[14] In particular, patients who recollected dreams showed a higher EEG coherence for all of the frequency bands investigated (from 1 to 44 Hz) than that in patients who did not, and this difference holds across wakefulness and NREM and REM sleep. Indeed, this higher connectivity was more evident in the low-frequency theta range, confirming previous data on waking memory formation.[15,16] Thus successful dream memorization and declarative memory formation seem to be associated with increased mediotemporal connectivity, independent of the physiologic state (i.e., wakefulness and REM and NREM sleep). Again, the question of whether a higher EEG connectivity associated with successful dream recall reflects state- or trait-like differences remains open.

Morphologic-Anatomic Measures

Individual volumetric and ultrastructural measures of subcortical nuclei, as determined by DTI, are stable over time and refelct interindividual differences in brain tissue.[17,18] Such measures may permit evaluation of the existence of trait-like individual characteristics of dream experience. Microstructural analyses—that is, of volume and diffusivity (magnitude of neuronal water diffusion)—by MRI brain scans and by DTI analysis of MR images have been used to investigate relationships between deep gray matter structures and dreaming.[19] In particular, this novel approach has been introduced for evaluating the relationships between dreaming and some anatomic measures of the hippocampus and amygdala, according to their possible role in the processing of mnestic and emotional sources of dream content. Although the hippocampus should mediate the partial reproduction of memories of events occurring during wakefulness for inclusion in dream content,[19] concomitant interest in the amygdala is justified by its involvement both in control of the encoding and retrieval of emotional memories and in the physical expression of emotions during wakefulness.[20] Furthermore, hippocampus and amygdala seem likely to affect the emotional quality of dream mentation, because they are involved in the processing and execution of fear memories,[21] and specific forms of learning involve the amygdala and hippocampus at different stages.[22-25] Finally, MRI/DTI analyses in subjects capable of reporting a dream on awakening from REM sleep show bilateral amygdalar activation.[26]

Volume of gray matter and microstructural alterations of gray matter in the hippocampus and in the amygdala, as expressed by reduced cellular barriers that restrict the free diffusion of water molecules in tissues, are not associated with successful dream recall. DTI measures of these nuclei do not show any correlation with dream recall rate.[19] Neuroanatomic measures are indeed related to some *qualitative* features of the recalled dreams (emotional load, bizarreness, and vividness) and, to some extent, with the length of dream reports. A decreased microstructural integrity of the left amygdala is associated with shorter dream reports and decreased emotional load, whereas that of the right amygdala with a lower index of bizzarreness. Left amygdala volume also is related to a lower bizarreness index. Although indeed significant, relationships with ultrastructural measures of hippocampus are weaker.[19]

The main point is that functional neuroanatomy of the amygdala and the hippocampus indicates a dissociation between some quantitative and qualitative aspects of dream reports. Although the mean number of dreams recalled per day does not show any significant relationship with the aforementioned neuroanatomic measures, significant associations with some qualitative features of the recalled dreams are observed.[19] Within this framework, successful dream recall does not reflect trait-like differences, at least with respect to gray matter of the amygdala and hippocampus.

NEUROPSYCHOLOGICAL CORRELATES

The study of behavioral and cognitive changes after accidental brain injury or neurosurgery, or associated with neurologic diseases that affect particular brain regions, represents the classical method for establishing brain-mind relationships in humans. This approach, as applied to the phenomenology of dreaming, has been called the "neuropsychology of dreaming." Although initial observations focused on the brainstem structures, on the basis of the erroneous assumption that the high correlation between REM sleep and dream recall rate necessarily implied that brainstem mechanisms also were responsible for dream generation, in the past several decades investigations have been directed at the consequences of cortical damage.

Subcortical Lesions

Because REM sleep is controlled by pontine brainstem areas,[27] and their lesions suppress or reduce human REM sleep,[28] a concomitant suppression or reduction of dream experience was expected. Solms[29] reviewed the published cases of brainstem lesions, which provided some information on the dream experience. In only one case was a drastic reduction in REM sleep accompanied by a cessation of dreaming.[30] In the other 25 cases, the hypothesized correlation was not found (or it was not taken into account).[28,31-34]

However, the preservation of dreaming in cases with obliteration of REM sleep due to brainstem lesions has not been satisfactorily demonstrated. In fact, preserved dreaming after brain trauma involving large pontine lesions has been reported in only four patients, in the absence of polygraphic monitoring.[35] This approach is partly limited by the fact that pontine lesions extensive enough to significantly affect REM sleep usually do not preserve consciousness in the affected subject.[36]

A reasonable conclusion, therefore, is that pontine brainstem lesions in humans do not abolish dreaming, and that REM sleep is not a necessary prerequisite for the occurrence of dreams. This conclusion also is consistent with findings on pharmacologic suppression of REM sleep. Indeed, phenelzine therapy for depressed patients, which eliminates REM sleep

without altering slow wave sleep, does not abolish or coherently affect the frequency of dream recall.[37]

Cortical Lesions

The first indications of a complete (or nearly complete) loss of dreaming, associated with localized lesions in the forebrain with complete preservation of brainstem, date back to approximately 125 years ago. These clinical reports described two patients who dreamed "almost not at all anymore" after sustaining, respectively, a bilateral occipital-temporal[38] and a bilateral occipital[39] lesion.

A century later, subsequent reevaluation of data for 104 patients with brain lesions who reported information about their dreams[40] indicated that the presence of frontal lobe damage was not systematically associated with loss of dreaming, whereas lesions in the parietal lobes and lesions associated with disconnective syndromes could cause a loss of dreaming without notable hemispheric asymmetry. Moreover, dream cessation after unilateral left or right brain damage was as frequent as after bilateral damage. Because a lesion in either hemisphere could be sufficient to cause dream loss, no simple relation between either hemisphere (i.e., unilateral brain lesions) and dreams could be postulated. Accordingly, it was proposed that the right hemisphere provides the core material for the dreams, whereas the left hemisphere provides the means of decoding it.[40]

The foundation of the neuropsychology of dreaming, however, should be ascribed to Mark Solms, who examined 361 patients with brain injuries.[29,35] He found that cessation of dreaming (called *global anoneria*) follows damage to two different systems: (1) a posterior system, centered in or near the parieto-temporo-occipital (PTO) junction, and (2) an anterior system, mostly bilateral, located in the ventromedial prefrontal cortex and including the white matter surrounding the anterior horns of the lateral ventricles. Lesions of this second system, however, were not invariably associated with dreaming cessation.

As far as the posterior system is concerned, unilateral (or, in a few cases, bilateral) injuries in or near the PTO junction were associated with a complete loss of dreaming, suggesting that this area might be essential for dreaming itself.[29] This finding is crucial, because it has been long recognized that the cortical network for spatial representation is centered in the inferior parietal lobe. The PTO junction supports various cognitive processes that are crucial for visual memory and mental imagery.[41]

Of note, lesions of the posterior system may affect dreaming,[35] waking visual mental imagery,[42] and waking visuospatial abilities.[43] Also of note, visual imagery, in turn, shares approximately two thirds of activated brain areas with visual perception.[42,44] Finally, a complete "anoneria" (see further on) with preservation of REM sleep also has been reported, in a case of deep occipital lobe damage (including the right inferior lingual gyrus) secondary to bilateral occipital artery infarction,[45] as well as after left temporo-occipital injuries.[46] These findings suggest that global cessation of dreaming can be associated with temporo-occipital lesions, even without parietal involvement.

The basic idea that dream experience, mental imagery, and late stages of visual perception may share some neural mechanisms also is strengthened by the notion that lesions of more specific regions, such as V4 or V5, may selectively affect dream representation of color[29] or movement.[43] Specifically, patients who are unable to generate facial and color imagery in waking life (as a consequence of V4 lesions) also cannot generate faces or colors in their dreams[29,47-54]; a decrease in the "vivacity" of dreaming was reported by two patients with damage to areas V3, V3a, and V4.[35]

With specific reference to the visual component of dreams, Doricchi and Violani[40] first proposed a second nosologic syndrome, *nonvisual dreaming,* subsequently termed "visual anoneria" by Solms.[35] In this entity, complete or partial loss of visual dream imagery occurs only with lesions in visual association cortex (with preservation of normal waking vision). Of interest, visual anoneria is accompanied by the inability to produce mental imagery in waking (irreminiscence), further supporting the existence of a common neural substrate. Lesions in primary visual cortex, however, have no effect on dreams. For example, visual dream imagery is intact in cortically blind patients (with V1 or V2 lesions). In addition, partial variants of visual anoneria have been described, characterized by selective loss of specific visual elements (e.g., kinematic anoneria, facial anoneria).

By contrast, dream imagery seems unaffected by lesions of primary unimodal sensomotor cortices.[29] Hemiplegic patients (with unilateral perirolandic lesions) show preserved somatosensory and motor imagery in their dreams.[35,55,56] Similarly, aphasic patients (with left perisylvian lesions) experience normal audioverbal and motor speech imagery in their dreams.[35,57,58] These findings suggest that somatosensory, motor, audioverbal, and speech imagery in dreams is generated outside of the respective unimodal cortices, probably in heteromodal paralimbic or PTO cortex.[29]

Lesions of the second (anterior) system are less frequently associated with global cessation of dreaming. Typically, global anoneria is a consequence of bilateral damage to white matter tracts that surround the anterior horns of the lateral ventricles, underlying ventromedial prefrontal cortex. Many of these nerve fibers originate or terminate in the limbic system. The ventromedial white matter contains dopaminergic projections to the frontal lobe, which are disconnected as a consequence of prefrontal leukotomy.[59] Thus a 70% to 90% incidence of global (or near-complete) cessation of dreaming has been reported in patients who underwent prefrontal leukotomy.[29] On the other hand, lesions in the dorsolateral prefrontal cortex that cause waking deficits of self-monitoring and decision making have no effect on dreaming.[60]

Finally, two types of "dreaming excess" also have been described.[35] Lesions in medial prefrontal cortex, the anterior cingulate cortex, and the basal forebrain are associated with increased frequency and vividness of dreams, with intrusion of content into waking life. In particular, patients with frontal-limbic lesions may exhibit the syndrome referred to as *anoneirognosis,* characterized by difficulty in distinguishing between internally generated experiences, such as dreams, from externally driven perceptions. Second, the syndrome of "recurring nightmares" is characterized by frequent nightmares with a repetitive theme. Increased frequency of nightmares often was associated with temporal-limbic seizure activity, with stereotypical nightmares accompanying complex partial seizures in some cases.

To summarize, the evaluation of brain-damaged patients seems to support the hypothesis that dreaming is not an intrinsic function of REM sleep (or of the brainstem

mechanisms that control it). Moreover, neuropsychological evidence confirms that the neural network supporting dreaming has considerable specificity. In fact, the posterior and anterior systems just described are crucial to dream imagery production, whereas brain-damaged patients do not show significant changes in dreaming when lesions are located outside those systems.

The crucial involvement of the PTO junction and of the ventromedial prefrontal cortex in dreaming generation is further supported by recent neuroimaging findings.[61] Regional cerebral blood flow (rCBF), measured with $[^{15}O]H_2O$ positron emission tomography, was higher in the temporoparietal junction in subjects with high dream recall frequencies (HRs) than in "low recallers" (LRs) during REM sleep and deep NREM sleep (stage N3). Moreover, HRs showed a higher rCBF than LRs in the medial prefrontal cortex during REM sleep. These neurofunctional correlates of dream recall in healthy humans are consistent with the aforementioned neuropsychological findings showing that lesions involving the PTO junction and the ventromedial parts of the prefrontal cortex lead to a global anoneria.[35]

Of interest, a different functional organization of the brain in HRs and LRs also was shown while subjects were resting in the scanner, when the rCBF was higher in HRs than in LRs in both the temporoparietal junction and medial prefrontal cortex. Because both of these regions are part of the default mode network,[62] it has been suggested that the neural substrate of dreaming could be a subsystem of this network.[61,63] In particular, the higher level of temporoparietal junction and medial prefrontal cortex activity in HRs may be associated with increased wandering of the mind and increased involvement in episodic memory recall and evaluative processing.[64] In keeping with this notion, an event-related potential study pointed out that HRs might be more reactive to the environment than LRs.[11] Specifically, the amplitude of the cortical response to first names, an attention-orienting brain response known to recruit temporoparietal junction, was higher in HRs and correlated with the total duration of intrasleep wakefulness. The increased duration of intrasleep wakefulness in HRs could in turn explain their high dream recall frequency, as already suggested by Koulack and Goodenough.[65]

Therefore differences in spontaneous brain activity in the temporoparietal junction and medial prefrontal cortex during both sleep and wakefulness may be the neurophysiologic substrate of a low or a high frequency of dream recall. The increased activity in the temporoparietal junction seen in HRs may facilitate the orienting of attention toward external stimuli and promote intrasleep wakefulness, facilitating by that means dream production and/or dream memory.

In conclusion, neuropsychological data suggest that dream experience and waking mental imagery may share a common neural substrate. Although the continuity between neural mechanisms of waking and sleep mentation is particularly clear if the characteristics of the posterior system, directly linked to an advanced stage of visual (and, more generally, sensory) processing, are taken into account, it may appear less evident in considering the involvement of the mesocortical-mesolimbic dopamine system (i.e., the anterior system), which also seems to play a causal role in the generation of dreams. Nevertheless, the increased activation of medial prefrontal cortex, occipitotemporal visual cortex, and anterior cingulate cortex during REM sleep reported by the (few) functional neuroimaging studies of REM sleep[6] is consistent with the results of the previously discussed lesion studies, supporting the importance of those brain areas in dream generation. Moreover, a large portion of the dorsolateral prefrontal cortex is deactivated during REM,[26,60,66] and lesions in this region do not affect dreaming.[35,40] Taken together, these findings are consistent with a continuity model of the cerebral substrates of waking and REM sleep mental imagery (see Chapter 54).

CONCLUSIONS AND FUTURE DIRECTIONS

Within the specific methodologic limits of dream research, successful recall is associated with a relatively well-defined series of functional and anatomic changes. Cortical EEG oscillations in the minutes preceding the awakening can predict dream recall rate, suggesting that the electrophysiologic changes underlying the encoding and recall of episodic memories are the same across different states of consciousness.[6] Similar conclusions can be derived from intracerebral recordings showing an increased mediotemporal connectivity associated with dream recall, as well as with successful declarative memory formation in waking.[14] In addition, evidence coming from studies in patients with cerebral lesions strengthens the view of an overlap between the cerebral substrates of waking and REM sleep mental imagery.[29,35]

Nevertheless, electrophysiologic and neuropsychological findings do not disentangle the state-/trait-like aspects of these neural correlates. Preliminary evidence from structural MRI scans[19] does not support the structural hypothesis, that is, the hypothesis of basic neural ("trait-like") differences, because no relation is evident between dream recall rate and morphologic-anatomic measures of the hippocampus and the amygdala. Longitudinal studies or, at least, multiawakening observations in the same subject are needed to respond to the functional-structural question.

CLINICAL PEARL

Limited evidence is available to support the view of involvement of the dopaminergic system in dream recall. This lack of substantiation should be taken into consideration by physicians otherwise inclined to prescribe compounds such as varenicline (i.e., for smoking cessation) or dopaminergic agents (i.e., in Parkinson disease). In both cases, dream experiences may be exacerbated, and nightmares can be induced. When possible, alternative treatments are preferred.

SUMMARY

Successful dream recall is associated with the specific electrophysiologic patterns during the minutes preceding the subject's awakening. Quantitative EEG analyses indicate that theta oscillations in REM sleep and alpha oscillations in NREM sleep are related to successful recall, with crucial involvement of temporoparietal and frontal areas. Moreover, analysis of intracerebral recordings in patients with pharmacoresistant epilepsy confirmed that phase synchronization of rhinal-hippocampal EEG activity characterizes both successful dream memorization and declarative memory formation. Therefore the encoding of dream content during sleep evidently shares some electrophysiologic mechanisms

with the successful encoding of episodic information during wakefulness.

The continuity between neural mechanisms of waking and sleep mentation is further supported by neuropsychological evidence. The evaluation of brain-damaged patients indicates that a "posterior system," centered in or near the PTO junction, and an "anterior system," located in the ventromedial prefrontal cortex, are crucial to dream imagery production. The critical involvement of the PTO junction and of the ventromedial prefrontal cortex in dream generation is further supported by recent neuroimaging findings showing that differences in spontaneous brain activity in the temporoparietal junction and medial prefrontal cortex during both sleep and wakefulness may be the neurophysiologic substrate of a low or high frequency of dream recall. Altogether, the available evidence is consistent with a continuity model of the cerebral substrates of waking and REM sleep mental imagery.

Chapter 51

Neurobiology of Dreaming

Edward F. Pace-Schott; Dante Picchioni

Chapter Highlights

- This chapter reviews the sleep stage, electrophysiologic, and regional brain activity correlates of dreaming, with a focus on rapid eye movement (REM) sleep observations. REM sleep differs from non–rapid eye movement (NREM) sleep in ways that suggest bases for its enhanced dreaming, including increased fast electroencephalography oscillation and decreased anteroposterior electroencephalography coherence. Neuroimaging studies show widespread decrease in brain activity with the transition from waking to NREM, followed by reactivation, in REM, of midline limbic and paralimbic brain areas to levels that equal and even exceed those of waking. Notably, however, lateral multimodal association cortices retain NREM-like low activity in REM, suggesting possible bases for the unique nature of dream cognition.
- The chapter also reviews functional connectivity methods and the relationship between dreaming and internally cued cognition during wakefulness. Key sleep studies, with an emphasis on REM sleep studies, are presented under the relevant network. This is important because information integration across a large number of brain regions has become a central tenet in theories of consciousness, and alterations in this integration resulting from the absence of core nodes or increased randomness may explain the alterations in consciousness that accompany sleep and dreaming.
- Striking changes in the forebrain neuromodulation take place in the transition from wake to NREM and thence to REM. Levels of cholinergic and aminergic modulators diminish from waking to NREM, whereas the levels of acetylcholine alone return to waking levels during REM. Observation of these changes contributed to the first neurobiologic theory of dreaming, activation synthesis, in which an elevated cholinergic-to-aminergic ratio accounts in part for differences between dreaming and waking cognition. Other dream theories focus on dopamine and activation of reward networks in concert with other midline regions in REM.
- Dreaming shares phenomenology with abnormal waking states such as spontaneous confabulation, in which imagined scenarios are accepted as veridical memories, and complex hallucinosis, in which fully formed fictive visual images are perceived. Examinations of underlying neuroanatomy and neurochemistry of these conditions reveal overlap with those of REM sleep.
- Observations from neuroimaging of sleep, cognitive neuroscience, and clinical neuropsychology allow us to construct a putative model of neurobiologic processes that generate dream phenomena, including restored conscious awareness, altered emotion and memory, fictive movement, complex visual hallucinations, fictive space, and impaired executive function.

Dreaming is a universal human experience occurring during sleep in which fictive events follow one another in an organized, storylike manner and into which are woven hallucinatory, primarily visual, images that are largely congruent with an ongoing confabulated plot. Most often, this wholly imaginary experience is uncritically accepted in the same manner as are veridical waking percepts and events.

THE ASSOCIATION OF DREAMING WITH BEHAVIORAL STATE

Early speculation that rapid eye movement (REM) sleep was the exclusive physiologic substrate of dreaming[1] was soon followed by awakening studies showing substantial recall of mental experiences from non–rapid eye movement (NREM) sleep.[2] Nonetheless, REM sleep reports are more frequent, longer, more bizarre, more visual, more motoric, and more emotional than are NREM sleep reports.[3] In an extensive review, Nielsen estimates an NREM sleep mental experience recall rate of 42.5%, contrasting with 81.8% from REM sleep, and suggests that brain activation processes occurring outside polysomnographically scored REM sleep ("covert REM") may account for NREM-sleep dreaming.[4]

Recent Electrophysiologic Findings

Fast and Slow Oscillations and Dreaming

REM sleep shows much more gamma frequency (30 to 80 Hz) fast brain waves ("oscillations" or "rhythms") than does

NREM sleep as measured by scalp electroencephalography (EEG),[5] intracranial EEG,[6] and magnetoencephalography (MEG).[5] In waking, these fast oscillations are associated with attention to stimuli and other forms of active or effortful cognition.[7] During REM-sleep dreaming, fast oscillations have been hypothetically associated with cognitive and perceptual processing,[8] memory processing,[9] and the temporal binding of dream imagery.[10]

NREM sleep is instead associated with slower oscillations produced by recurrent interactions between the thalamus and cortex (intrinsic "corticothalamocortical" rhythms) such as sleep spindles and delta waves and with the cortical slow (<1 Hz) oscillation that groups the other corticothalamocortical oscillations in time.[11,12] The slow oscillation consists of periods of neuronal quiescence (hyperpolarized or "down" states) that alternate with shorter periods of rapid neuronal firing (depolarized or "up" states).[13] Slow intrinsic oscillations may interfere with ongoing mental activity and lead to a lower frequency of dreams in NREM sleep.[3] Although human slow wave sleep (SWS) shows less sustained gamma activity compared to REM sleep and waking, intracranial EEG has shown that gamma oscillations appear during the transient "up" state of the slow oscillation.[14,15]

Electrophysiologic Connectivity in Sleep

Declines in phase synchrony ("coherence") of EEG rhythms between different brain regions occurring during sleep relative to waking may reflect functional disconnections that contribute to the cognitive features of dreaming. Gamma oscillations in REM sleep become desynchronized between anterior and posterior regions of the brain; a disconnection that may contribute to the hypofrontal and bizarre features of REM-sleep dreaming.[5]

Dreaming and Phasic Activity in Sleep

In cats, a close temporal association exists between REM-sleep rapid eye movements (REM-sleep saccades) and ascending potentials that originate in the brainstem and are termed *ponto-geniculo-occipital* (PGO) *waves*.[3] In the activation-synthesis hypothesis of dreaming,[16] Hobson and McCarley suggest that the brainstem's activation of the forebrain in REM sleep allows the forebrain to synthesize dream scenarios based on currently available information. They suggest that the PGO wave, originating in the pons and arriving at primary visual cortex by the dedicated visual pathway through the thalamic lateral geniculate nucleus, might be interpreted by the brain as visual information, thereby leading to the visual hallucinosis of dreams.

Early evidence of human PGO waves was derived from scalp EEG recordings temporally locked to REM-sleep saccades.[3,17] Subsequently, positron emission tomography (PET)[18] and function magnetic resonance imaging (fMRI)[19] studies also correlated REM-sleep saccades with activation of structures corresponding to the feline PGO wave. Compelling evidence for human PGO waves has recently emerged. First, using MEG, Ioannides and colleagues[20] showed that correlated phasic activity in the pons and frontal eye fields begins before an REM-sleep saccade and intensifies with increasing temporal proximity to saccade onset. Second, using depth electrodes in a patient with Parkinson disease, Lim and colleagues[21] described phasic signals, with waveform and temporal characteristics very similar to the feline PGO, originating in the pedunculopontine nucleus—a structure at the pons-midbrain (mesopontine) junction crucial for generating the feline PGO.[3] Third, using fMRI, Miyauchi and colleagues[22] demonstrated that activity in the pontine tegmentum, ventroposterior thalamus, and visual cortex takes place in the few seconds before REM-sleep saccades. Activation in these regions, relative to the REM-sleep saccade, corresponded both to the neural pathway and time course of the feline PGO wave, that is, pontine tegmentum (–4.7 seconds), ventroposterior thalamus (–3.8 seconds), and primary visual cortex (–2.8 seconds).

The scanning hypothesis, which posits a correlation between REM-sleep saccades and the direction of hallucinated gaze in dreams,[23] continues to generate interesting but conflicting findings. For example, in an event-related potentials study, REM-sleep saccades occurred without the readiness potential that preceded waking saccades, whereas a wakelike potential reflecting visual engagement persisted, suggesting that REM-sleep saccades may trigger rather than follow visual experiences.[24] However, Miyauchi and colleagues[22] observed primary visual cortex activation *before* REM-sleep saccades that, therefore, could not have been triggered by efferent copies from neural activity in the frontal eye fields associated with the saccade, as an alternate explanation might suggest, but rather that REM saccades may have been in response to PGO-initiated dreamed visual imagery.

Convergent evidence does, however, suggest activation of limbic structures in concert with REM-sleep saccades. For example, using low-resolution brain electromagnetic tomography, Abe and colleagues[25] observed a pre-REM-sleep saccade potential with current sources estimated to lie in anterior limbic regions. Using MEG, Ioannides and colleagues[20] also described REM-sleep saccade onset linked current sources estimated to lie in the amygdala and orbitofrontal and parahippocampal cortices. Both groups suggest that this pre-saccade limbic activity reflects phasically enhanced emotional processing.[20,25]

In summary, EEG and MEG studies suggest that brain activity accompanying phasic REM sleep may be related to dream phenomena. Such phenomena include visual imagery,[21,22,24,26] enhanced cognitive activity and attention,[5,8] decoupling of executive control and perception,[5] and enhanced emotional processing.[5,20,25]

Dreaming and Brain Activity

Deactivation of frontal cortices is one of the first signs of human sleep observed using EEG, MEG, and functional neuroimaging.[17,27] PET studies of NREM sleep show declines in brain activity relative to waking both globally[27] and in many specific regions of the subcortex and cortex,[28,29] findings now replicated using fMRI.[30] Global and regional cerebral activity further declines with the deepening of NREM sleep.[27,29-31] Following sleep onset, EEG studies show greater slow wave spectral power in frontal versus posterior sites.[32] Synchronization of slow waves then spreads progressively to posterior regions,[33] a trajectory also traveled by the slow (<1 Hz) oscillation.[34]

Compared with these deactivated NREM sleep conditions, in REM sleep there is a prominent increase of neural activity in subcortical brain regions, including the pons and midbrain,[28,35] thalamus,[28,35] basal ganglia,[28] and limbic subcortex comprising the amygdala,[35] hypothalamus, and ventral

striatum.[28] Increases are also seen in limbic-related cortices anteriorly in the rostral and subcallosal anterior cingulate,[28,35] anterior insula, more posterior orbitofrontal and paracingulate Brodmann area (BA) 32 cortices, BA 10 in medial prefrontal cortex (PFC),[28] and more posteriorly in the parahippocampal gyrus and temporal pole.[28] Certain visual association cortices (regions that process higher-order aspects of vision) are also active.[28,36] However, multiple neuroimaging modalities show that lateral prefrontal cortices remain deactivated after the transition from NREM to REM sleep.[28,35-37]

When REM sleep is directly compared with waking, there is relative deactivation of the lateral PFC.[28,35,37] Maquet and colleagues[37] showed that regions most consistently hypoactive in REM sleep compared with waking include middle and inferior frontal gyri as well as inferior parietal and temporal-parietal junction association cortices. However, compared with waking, in REM sleep there is *greater* activation of limbic and paralimbic regions.[28,35,38-40] Nofzinger and colleagues[39,40] have termed this region the "anterior paralimbic REM activation area" and describe it as a "bilateral confluent paramedian zone which extends from the septal area into ventral striatum, infralimbic, prelimbic, orbitofrontal, and anterior cingulate cortex" (p. 192)[40] and includes the hypothalamus, ventral pallidum, hippocampus, and uncus as well as supplementary motor, pregenual and subgenual anterior cingulate, and insular cortices.[39]

Neuroimaging Has Renewed Interest in Lucid Dreaming

Lucid dreaming[41] has reemerged as an exciting new tool in fMRI studies by offering a degree of real-time access to the dreaming brain. Because, unlike skeletal muscles, oculomotor muscles maintain tonus in REM sleep, eye movements can still be produced, allowing the lucid dreamer to "signal out" of the dreaming state.[41] This technique was recently exploited to demonstrate that dreamed hand clenching activated the corresponding sensorimotor cortex.[42] Prior speculation that lateral PFC deactivation in REM-sleep dreaming contributes to the characteristic lack of insight in dreaming was supported by a recent study, using quantitative EEG, that showed a return of wakelike, gamma activity in the lateral PFC when lucidity was achieved.[43] A recent fMRI study has shown activation, during lucidity, of many regions that normally remain deactivated in nonlucid REM, including posterior midline, lateral parietal, prefrontal, and occipitotemporal regions.[44] A number of these regions are associated with self-reflection, self-evaluation, and volition, functions normally weak in dreams[45] but restored with lucidity.[44] Most recently, a remarkable study showed that the level of self-reflective insight could be increased during sleep in lucid dreamers by applying transcranial direct current stimulation to scalp areas overlying frontal regions of the brain.[46] Hence, in addition to emerging as a unique experimental tool, there now is strong evidence that lucid dreaming is indeed a state intermediate between normal REM-sleep dreaming and wakefulness.[43,44,46]

DREAMING AND BRAIN FUNCTIONAL CONNECTIVITY

When you observe the simultaneous activation of more than one region, those regions can be labeled as a functional network. However, mean changes in two regions' activities can occur independently from changes in the correlation between them. One can perform a "seed" region connectivity analysis. Activity in the seed region is correlated with all other voxels in the brain, so the resulting color map represents the strength and direction of each correlation with the seed region. It is critical to remember that a negative correlation indicates the same magnitude of connectivity as the equivalent positive correlation; a negative correlation is not disconnectivity. One can repeat the seed-region approach with many regions and present all pairwise correlations in a cross-correlation matrix. When considering the entire brain, one can statistically separate activity into spatially independent components or quantify the connectedness of the network as a whole using graph theory.[47]

Functional connectivity is typically measured during "rest" (i.e., unconstrained quiet wakefulness) and using blood oxygen level–dependent fMRI because it has greater temporal resolution than PET. When analyzing the spectral power of the spontaneous fluctuations that appear during rest, less than 0.1-Hz oscillations contribute most to functional connectivity correlations.[48] Functional connectivity networks have been shown to bear close correspondence with anatomic networks identified in nonhuman primates, postmortem studies, and MRI-based imaging of fiber tracts using diffusion-tensor imaging.[49-51] They also overlap with the same regions that are activated during execution of the corresponding task.[52] For example, during rest and in the absence of a language production task, a seed region in Broca's area will correlate with other nodes in the language network.

Obtaining REM sleep during fMRI is difficult, largely because of the acoustic noise associated with fMRI,[53,54] so there are only four fMRI studies of functional connectivity during REM sleep, and they all have relatively small sample sizes. The first study ($n = 3$) is unique because the investigators analyzed connectivity differences between tonic and phasic REM sleep.[53] Investigators from the second study ($n = 2$) used a seed in the posterior cingulate cortex.[55] The third study had the largest sample size ($n = 12$) and is unique because the investigators employed an adaptation night and simultaneous eyelid video monitoring to aid REM-sleep scoring.[56] Investigators from the fourth study ($n = 4$) used a seed in the posterior cingulate cortex and a thalamic seed defined by its connectivity with the posterior cingulate cortex during REM sleep.[57] The results from these studies indicate that connectivity during REM-sleep dreaming exists but may differ from the connectivity observed during waking cognition.

Default-Mode Network

During rest, the same regions exhibit decreased activity across a wide variety of tasks. These experiments were designed to use rest as the baseline, so if we instead conceptualize the task as our baseline, these regions exhibit increased activity at rest. Hence these regions were labeled the *default-mode network*.[58] This network includes posteromedial parietal regions (posterior cingulate, precuneus, and retrosplenial cortices), lateral-inferior-parietal/superior-temporal regions, hippocampal formation (hippocampus and parahippocampal cortex) regions, and medial PFC regions.[59,60]

Functional connectivity networks are not merely resting-state networks. Internally cued cognition replaces externally cued cognition, and the former is another adaptive task.[61,62] This is best measured with comparisons of internally versus

externally cued cognition in response to the same stimuli. For example, increased activity in the nodes of the default-mode network is observed when investigators contrast unconstrained quiet wakefulness to an externally cued task, but the same result is obtained when investigators contrast the judgment of whether a picture was pleasant or unpleasant to the judgment of whether the picture was an indoor or outdoor scene.[59] Therefore these networks can be labeled simply as *intrinsic connectivity networks*. Dreaming is another type of internally cued cognition, so it naturally shares many features with waking internally cued cognition.[63,64]

Default-Mode Network (Simulation Subsystem)

The default-mode network includes two subsystems: one centered on the hippocampal formation (the medial temporal lobe subsystem, henceforth referred to as the *simulation subsystem*) and one centered on the dorsal medial PFC (the dorsal medial PFC subsystem, henceforth referred to as the *self-referential subsystem*), activity in both of which correlates strongly with a core network (anterior-medial PFC and posterior cingulate cortex) but weakly with each other.[65,66] The simulation subsystem is active in both retrospective simulation (remembering the past) and prospective simulation (imagining the future),[60] whereas the self-referential subsystem is active during self-relevant tasks and social cognition, including imagining what others are thinking and feeling (i.e., theory of mind).[67]

During SWS, core default-mode network regions are disconnected.[68-70] During REM sleep, these regions become reconnected,[55,57] and simulation subsystem regions show higher connectivity compared with SWS.[56] The overall similarity in default-mode network connectivity during wakefulness and REM sleep was confirmed using meta-analytic techniques,[63] so the default-mode network simulation subsystem is a primary candidate to explain the dreaming that predominates in REM sleep.[17,63,64,71-73]

Default-Mode Network (Self-Referential Subsystem)

Although internally cued cognitions in dreaming and waking share many features, they have notable dissimilarities. Koike and colleagues[56] discovered incomplete reconnectivity in the self-referential subsystem during REM sleep as evidenced by a lack of anterior-posterior connectivity with the dorsal medial PFC. This difference in connectivity in the self-referential network may underlie the high delusional acceptance of dreaming compared with waking internally cued cognition. Combining data from this study with newer data, Watanabe and colleagues[74] discovered that overall default-mode network connectivity progressively decreases within a single bout of REM sleep, and this reaffirms the heterogeneous and dynamic nature of connectivity during REM sleep.

During dreaming, alterations in default-mode network connectivity may cause the simulation to be perceived as occurring in the present.[17] Without a perception of the self, the dreamer may also confabulate the simulations into a story-like theme as an attempt to interpret them.[73,75] This idea is consistent with the importance of the temporal-parietal junction (BA 40) in dreaming. This is another node in the self-referential subsystem,[65] and its damage causes cessation of dreaming.[76] Similarly to how Damasio describes alterations in the dream self,[77] perhaps the lack of the integration of the self into cognition is the reason that we cannot properly perceive events experienced during dreaming as a simulation.

Executive Control and Dorsal Attention Networks

Aside from the default-mode network, several other cortical networks have been identified. The dorsal attention network includes the intraparietal sulci and frontal eye fields. This network and the executive control network are negatively correlated with the default-mode network. As mentioned previously, because a correlation can be positive or negative, a negative correlation indicates the same magnitude of connectivity. Therefore these three networks can be considered part of a larger network in which activity both increases and decreases during internally cued cognition. During NREM sleep stage 1, the connectivity (i.e., the negative correlation) between these three seemingly separate networks decreases,[69,70,78] and the same phenomenon is observed in REM sleep.[57] The decrease in the negative correlation between these networks during NREM sleep stage 1 and REM sleep could therefore be related to features of mentation during sleep onset (e.g., hypnagogic imagery) and REM-sleep dreaming. Perhaps during wakefulness, the switch from externally cued cognition to internally cued cognition requires unique networks based on unique information processing requirements, but during sleep, unique networks may be less important to support cognition because it is typically internally cued.

Salience Network

The salience network—the anterior insula, anterior cingulate cortex, and ventral striatum—is involved in the interoception of the feelings associated with reward.[79] In addition to the internally cued versus externally cued distinction, paying attention to dreamed characters and objects is, in theory, executed by similar networks compared with waking cognition. Interoception could then apply in either waking or sleep cognition to the sensing of bodily states. The salience network has been implicated in drug craving and the associated relapse in addiction.[80] Dreams and the duration and number of REM-sleep periods increase during drug withdrawal.[81] Although the default-mode network may be important for normal dreaming, perhaps the salience network exhibits altered connectivity during this period of dream rebound and perhaps such alterations predict relapse.

Visual Network

The visual network is composed of primary visual cortex and visual association cortices in inferior temporal cortex and posterior parietal cortex. Unlike the paucity of incorporations of waking visual material into REM-sleep mentation,[3] presleep visual stimuli are reliably incorporated into sleep-onset mentation,[82] and this incorporation is correlated with sleep-dependent improvements in visuospatial memory.[83] Connectivity in the visual network increases during NREM sleep stage 1.[84] Further, increased connectivity between visual association and PFC is correlated with sleep-dependent improvements on a paired-associate face/scene task.[84] Although sleep-onset mentation was not measured, the results from this study indicate that visual network connectivity, sleep-onset mentation, and memory consolidation may be tightly linked.

Large-Scale Networks

A regular network has many nodes with short-distance connections (similar to a local train). This is inefficient because the average number of jumps needed to travel between all possible pairs of nodes in the network is very high. A random network has more nodes with long-distance connections (similar to an express train), and in such a network, the probability that two nodes are connected is unrelated to distance. This is inefficient because it results in more total wiring, and information may need to travel a long distance to traverse two nodes despite the fact that they are close to each other. The brain resembles an ideal "small-world" network,[85] which is a compromise between a regular and random network. The importance of information integration across a large number of brain regions has become a central tenet in theories of consciousness,[86,87] and alterations in this integration resulting from the absence of core nodes or increased randomness may explain the alterations in consciousness that accompany sleep and dreaming.[88,89]

During NREM sleep stages 1 and 2, there is a shift from an ideal small-world network to a more random network, and during SWS, there is a shift from an ideal small-world network to a more regular network,[90] although a shift to a more regular network has also been observed in NREM sleep stage 2.[69] The shift to a more random network during sleep onset may be correlated with sleep-onset mention.

Although portions of the thalamus are sometimes included in the default-mode network, it may be more appropriate to consider them part of a larger network because many thalamic nuclei project diffusely throughout the brain. Thalamocortical connectivity is weaker in NREM sleep stage 2 and SWS compared with wakefulness[91] and stronger in REM sleep compared with wakefulness and SWS.[57] Heightened thalamocortical connectivity during REM sleep may orchestrate dissociated heteromodal cortical regions and, correspondingly, the forced, confabulatory narrative in dreams.[57] Phasic REM-sleep episodes arising from a tonic REM sleep background showed characteristic changes in forebrain activity that include increased functional connectivity between the thalamus and a broad cortical-limbic-striatal network.[53] Wehrle and colleagues[53] suggest that these changes represent activation, during phasic REM sleep, of networks important to memory and emotion processing. Therefore like the EEG and MEG studies detailed previously, functional connectivity indicates that phasic REM sleep is associated with brain activity that might reflect intensified dream imagery, attention, and emotion but in the context of network connectivity that differs from wakefulness.

THE NEUROCHEMISTRY OF DREAMING

Three major neurochemical hypotheses have been advanced to explain differences between dreaming and waking consciousness. First, the activation-synthesis and activation-input-modulation models of Hobson and colleagues suggest that the massive increase in cholinergic (relative to noradrenergic and serotonergic) activation from the ascending reticular activating system (ARAS) during REM sleep contributes strongly to the unique nature of dream consciousness.[3,16] Second, Solms[76] suggests that stimulation of limbic and prefrontal reward networks by dopaminergic projections from the midbrain ventral tegmental area (VTA) generates motivational impulses that initiate dreaming, a hypothesis recently expanded in the reward activation model.[92,93] Third, Gottesmann suggests that dopaminergic stimulation of the cortex during REM sleep, in the absence of waking's inhibitory serotonergic and noradrenergic modulation, allows emergence of psychotomimetic (psychosis-like) aspects of dream consciousness.[94]

Acetylcholine

The activation-synthesis[16] and activation-input-modulation[3] models suggest that forebrain activation in REM-sleep dreaming originates in ascending activation of the thalamus by mesopontine cholinergic nuclei. Much evidence exists for cholinergic enhancement of both REM-sleep and dreaming. Higher mesopontine- and brainstem-derived acetylcholine concentrations during wake and REM versus NREM sleep are seen in the thalamus, including the lateral geniculate nucleus.[95] Cholinergic stimulation potentiates REM sleep when microinjected into the animal brainstem or when systemically administered to humans.[3] Cholinesterase inhibitors can induce REM sleep with dreaming[96] and increase nightmares[97] and hypnagogic hallucinations.[98] Transdermal nicotine[99] and the nicotinic receptor partial agonist varenicline[100] intensify dreams.

Dopamine

A key role is assigned to dopamine in psychotomimetic[94] and reward-based[76] theories of dreaming. The latter was recently expanded in the reward activation model, which posits that high-saliency memories are selectively processed during dreaming following their replay and prioritization by hippocampal-ventral striatal circuits in NREM sleep.[92,93] Support for this model comes from selective consolidation of salient memories during sleep[101,102] and the fact that administration of a dopamine agonist eliminated this selectivity.[103] In addition, L-dopa and certain other dopaminergic agents can enhance dreaming in patients with Parkinson disease.[76,104,105] However, psychostimulants are not associated with dream enhancement, neuroleptics do not prevent dreaming, some dopamine agonists reduce dreaming, and some dopamine antagonists enhance dreaming.[105] Thus dopamine's dream effects may depend on dosage as well as receptor type and location.

Roles for dopamine in REM sleep have also emerged from animal studies. For example, enhancing REM sleep intensity increases c-Fos expression in the VTA,[106] and dopamine concentrations in the medial PFC and nucleus accumbens are greater during REM sleep than during NREM sleep.[107] In addition, increased burst firing in the VTA has been observed during REM sleep[108] and may result from increased cholinergic excitation of the VTA by the pedunculopontine nucleus.[109]

Serotonin

Selective serotonin (5-HT) reuptake inhibitors and other serotonergic drugs can intensify dreaming.[110] Animal studies of serotonergic hallucinogens by Aghajanian and colleagues suggest that low or fluctuating cortical 5-HT levels may induce cortical output conducive to hallucinosis.[111] Serotonergic hallucinogens act presynaptically as partial 5-HT_{2A} (serotonin-2A) receptor agonists at glutamatergic inputs to apical

dendrites of layer V cortical pyramidal neurons, causing an "asynchronous" release of glutamate to follow the larger action-potential-mediated ("synchronous") release.[111] This late, slow release of glutamate induces prolonged excitatory postsynaptic potentials (EPSPs) that are hypothesized to underlie the cognitive-perceptual effects of the hallucinogens.[111] Such potentials do not normally occur because of inhibitory effects at 5-HT_1 autoreceptors.[111] However, under conditions of decreasing 5-HT concentration, such synchronous transmitter release–evoked EPSPs do emerge.[111] The naturally occurring lowest levels of 5-HT occur during REM sleep, and fluctuations of 5-HT release occur during sleep-stage transitions.[3] Thus these conditions may promote the natural occurrence of hallucinosis during dreaming.

NEUROPSYCHIATRIC SYNDROMES THAT INFORM THE STUDY OF DREAMING

Confabulation Shares Neural Substrate with Dreaming

Like the dreamer, patients with spontaneous behavioral confabulation believe they have experienced false events and act on false beliefs, believing them with unshakable conviction.[112-114] Confabulation results from lesions of the ventral medial PFC (vmPFC), the orbitofrontal cortex, and their connections with the basal forebrain, amygdala, thalamic mediodorsal nucleus, and hypothalamus.[113-115] These regions broadly overlap with the anterior paralimbic REM sleep activation region.[39]

One theory on the cognitive deficit resulting in confabulation suggests that vmPFC lesions disrupt a reality-monitoring function that preconsciously suppresses spontaneously activated memories not pertaining to present circumstances.[115] Memories of past experiences are thus perceived as related to the present.[115] An alternative theory posits temporal deficits to be a subset of a more general deficit in strategic retrieval and verification of memories.[114]

Moskovitch and Winocur[116] suggest vmPFC regions subserve an early stage in memory verification—a "feeling-of-rightness"—after which further evaluation of a retrieved memory takes place in dorsal lateral PFC (dlPFC). Gilboa and colleagues[114] suggest impaired feeling-of-rightness resulting from lesions to the vmPFC and orbitofrontal cortex is crucial and sufficient for producing confabulation.

Dreaming may represent a potent form of confabulation in which imaginary events are not only created and believed but also vividly experienced as organized, multimodal hallucinations.[17,73,105] For example, confabulators create plausible but false explanations for inconsistencies in their stories[113] that closely resemble ad hoc explanations for improbable dream occurrences.[117] Similarly, "pathological false recognition"[113] in confabulation parallels dreamers' assigning a known identity to dream characters perceptually dissimilar to their waking counterpart,[118] a phenomenon Schwartz and Maquet[119] liken to Fregoli syndrome. In both confabulation[113] and dreaming, altered function of the vmPFC and the orbitofrontal cortex may release from normal inhibitory, reality-monitoring, and executive constraints, innate human tendencies to represent both imagined and experienced events within a narrative structure.[73] Notably, medial PFC regions have also been associated with the production of normal narrative.[120]

Visual Hallucinosis in Waking and Dreaming

Anatomic regions associated with dreaming and with hallucinosis also overlap. Manford and Andermann[121] suggest that hallucinations result when inferior occipital and temporal visual association cortices that identify objects and scenes (the "ventral processing stream") are released from normal restraints under three conditions: (1) loss of exogenous visual input, (2) ARAS damage that alters serotonergic and cholinergic modulation of the cortex, or (3) abnormally excitatory input.[121] Conditions corresponding to each mechanism may contribute to REM-sleep hallucinosis.

First, in conditions such as Charles Bonnet syndrome, waking hallucinosis results when perceptual input to the visual association cortex is lost because of lesions of the primary visual pathway.[121] In REM-sleep dreaming, there is no retinal input. Moreover, primary visual cortices are deactivated,[36] a phenomenon that perhaps decreases their regulatory input on downstream association cortices. (Interestingly, visual deprivation is able to produce hallucinations similar to Charles Bonnet syndrome in normal subjects.[122]) Second, in peduncular hallucinosis, lesions of the rostral brainstem disrupt the amount and balance of serotonergic and cholinergic input to the forebrain.[121] Serotonergic raphe neurons normally fire at their minimum during REM sleep, whereas mesopontine cholinergic systems are reactivated to near-waking levels.[3] Therefore an altered serotonergic-cholinergic balance during REM sleep may also favor hallucinosis. Third, abnormal excitation of visual association cortices (the regions active during hallucinations in Charles Bonnet syndrome[123]) can produce epileptic hallucinosis.[121] Ventral-processing-stream visual association cortices are more active in REM sleep than in either NREM sleep or postsleep waking[28,36] and are a hypothesized source of dream imagery.[3,76] During REM sleep, PGO waves originating in the mesopontine brainstem[3,21] excite many cortical regions, including visual association regions.[124]

Collerton and colleagues[125] suggest that hallucinations result from combined sensory impairment, attentional deficit, and relatively intact scene perception that allows poorly formed "proto-objects" to resolve into erroneous percepts. In REM-sleep dreaming, ascending activation of visual association cortices may evoke hallucinatory proto-objects that, under the attentionally unstable conditions of REM sleep, resolve into hallucinatory percepts congruent with the ongoing dream plot. Internal consistency of dream plots may then arise because the evolving dream context itself biases resolution of ambiguous percepts into plot-congruent images. Dreams may thus evolve by a "boot-strapping" process whereby current images provide the context that, in turn, determines succeeding dream imagery.[126] In the absence of working memory capacities that provide continuity to waking experience, the evolving dream plot can be strongly influenced by immediately prior dream experiences. In a similar manner, top-down influences from limbic cortices may bias posterior association cortices toward generating, attending to, or disambiguating imagery in a manner that is congruent with ongoing dream emotion.[17]

A DESCRIPTIVE NEURAL MODEL OF DREAM PHENOMENOLOGY AND FUNCTION

Behavioral states and cognitive capacities are physically instantiated in widely distributed networks with distinct

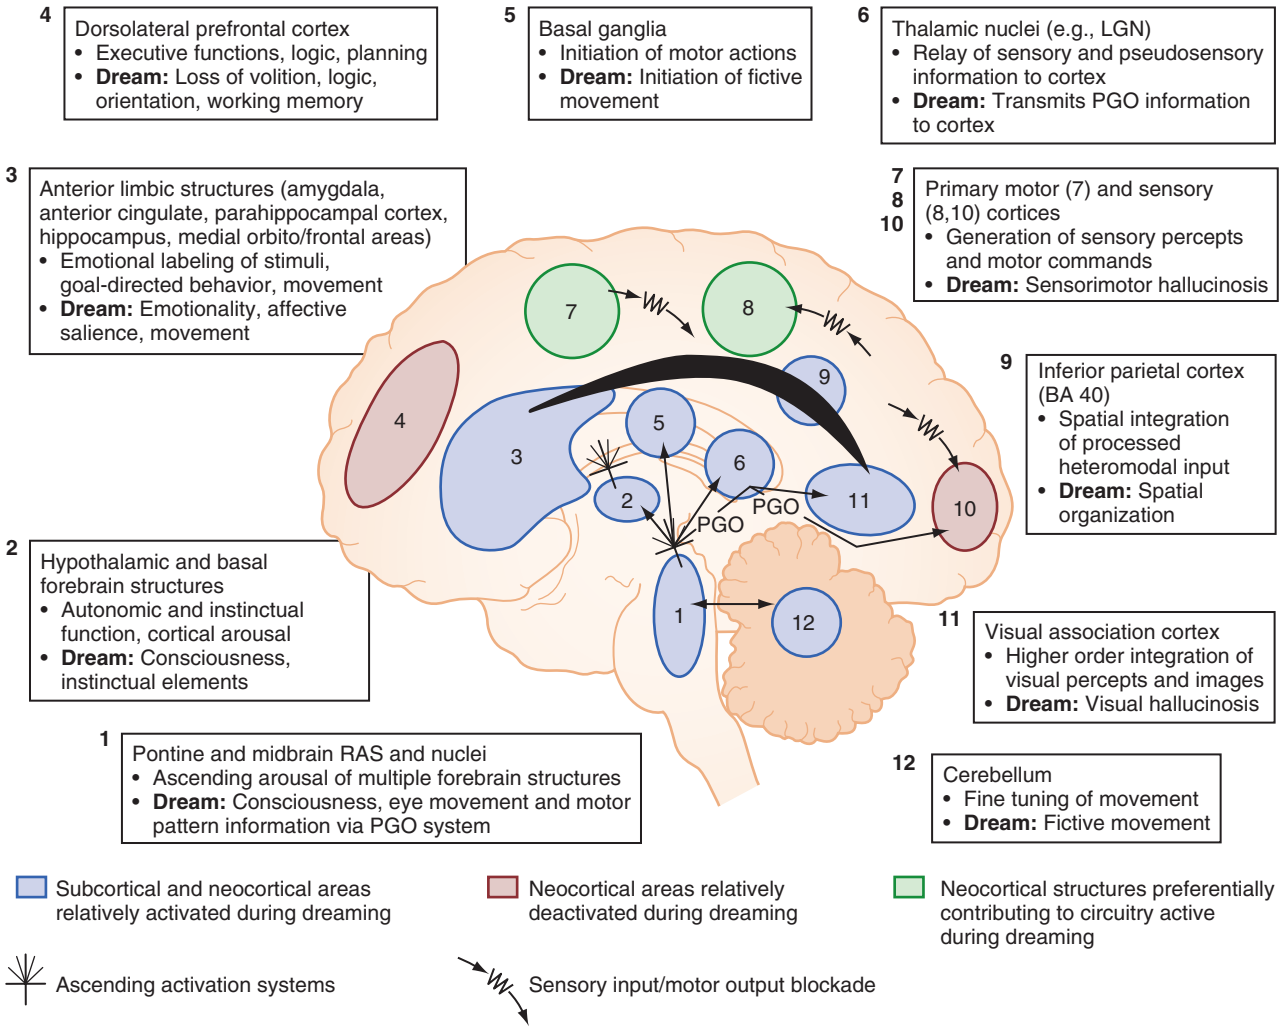

Figure 51-1 Forebrain processes in normal dreaming—an integration of neurophysiologic, neuropsychological, and neuroimaging data. Regions 1 and 2, ascending arousal systems; region 3, subcortical and cortical limbic and paralimbic structures; region 4, dorsal lateral prefrontal executive association cortex; region 5, motor initiation and control centers; region 6, thalamocortical relay centers and thalamic subcortical circuitry; region 7, primary motor cortex; region 8, primary sensory cortex; region 9, inferior parietal lobe; region 10, primary visual cortex; region 11, visual association cortex; region 12, cerebellum. BA 40, Brodmann area 40, the temporal-parietal junction; LGN, lateral geniculate nucleus; PGO, ponto-geniculo-occipital waves; RAS, reticular activating system. (From Hobson JA, Pace-Schott EF, Stickgold R. Dreaming and the brain: toward a cognitive neuroscience of conscious states. *Behav Brain Sci* 2000;23:793–842; discussion 904–1121.)

epicenters of critical control in a pattern of "selectively distributed processing."[127] Recent findings on intrinsic connectivity networks described previously have begun to assign distinct neural networks and key nodes to many of these functions. The following working model of neurobiologic structures and networks subserving REM-sleep-dream phenomenology refers to brain regions depicted in Figure 51-1.[3]

Ascending Arousal Systems

Activation of the forebrain in REM sleep, as in waking, occurs through the ascending arousal systems of the brainstem,[12] basal forebrain,[128] and hypothalamus[129] (regions 1 and 2 in Figure 51-1). However, unlike in waking, ascending activation in REM sleep is primarily facilitated by cholinergic systems, whereas aminergic neuromodulation is attenuated.[3] Pedunculopontine nucleus and laterodorsal tegmental cholinergic neurons project to the thalamus and basal forebrain but not the cortex.[130] Therefore cortical activation in REM sleep is preceded by cholinergic activation of the diencephalon[12] and basal forebrain,[128,131] which in turn activate the cortex with glutamate[12] and acetylcholine,[128,131] respectively. In NREM sleep, phasic increases in ARAS activity due to endogenous or exogenous stimulation may transiently stimulate the same forebrain networks activated in REM, the subjective manifestation of which may be NREM-sleep dreaming. The effect of cortical arousal on dream production is always confounded by the effects of such arousal during postsleep wakefulness on dream recall. A recent PET study suggests, however, that forebrain activation during preawakening REM sleep is directly related to dream recall on awakening.[132]

Thalamocortical Relay Centers and Thalamic Subcortical Circuitry

During REM sleep, thalamocortical signaling (region 6 in Figure 51-1) may be interpreted as incoming sensory information by primary and secondary association sensory cortices[16] (region 11) and evoke local activation of stored cognitive representations (hallucinosis of known entities) or novel representations (as in dream bizarreness). The PGO wave may be only one of many pathways for ARAS phasic activation of the cortex by thalamic or basal forebrain intermediaries during REM sleep. For example, in the rat, the pontine p-wave in REM sleep impinges directly on limbic structures such as the amygdala, hippocampus, and entorhinal cortex as well as the visual cortex.[133] Other pathways through the thalamus might include a nonrelay sensory route through the pulvinar nucleus directly to the visual association cortex[36] or to limbic prefrontal regions through magnocellular portions of the mediodorsal nucleus.

During NREM sleep, intrinsic thalamocortical oscillations suppress but do not completely extinguish perception and mentation.[45] NREM sleep oscillatory rhythms reflect endogenous activity of corticocortical and corticothalamocortical circuits grouped by the slow oscillation, the "up" state of which briefly returns cortical neurons to levels of high activity.[12,13,134,135] Steriade[135] has suggested that when this oscillatory pattern is impinged on by phasic thalamocortical bursts, such as the isolated PGO waves in the NREM-REM sleep transitional state, phasic elevation of regional activity may lead to vivid visual imagery. Notably, activation in NREM sleep of primary visual[31,36] and visual association[136] regions may also generate NREM-sleep imagery.

Subcortical and Cortical Limbic and Paralimbic Structures

In REM sleep, selective activation of limbic and paralimbic cortex and subcortex[28,35,36,39,40] (region 3 in Figure 51-1) suggested to PET researchers a role for REM sleep in the processing of emotionally influenced memories,[37,137] integration of neocortical functions with basal forebrain and hypothalamic motivational and reward mechanisms,[40] or internal information processing between visual association and limbic regions.[36] Such processes may underlie the emotionality[3,28,137] and social nature of dreaming.[17,118]

Emotion Regulation and Dreaming

It is often hypothesized that sleep and dreaming play an emotion regulatory function[138-140] that is disrupted in mood and anxiety disorders that, in turn, can alter dreaming, as in nightmares.[139] Indeed, the anterior paralimbic REM sleep activation region includes many of the structures implicated in the experience and expression of emotion.[141] Although dreams may aid in resolution of intrapersonal conflict (e.g., see Cartwright and colleagues[138]), dreaming may also moderate emotional extremes by universal mammalian learning processes such as habituation and extinction.[139,142]

Nielsen and Levin[139] have suggested that, in normal REM sleep, activity in the anterior paralimbic REM-sleep activation region regulates emotion through formation of extinction memories when emotionally salient memories appear in safer contexts during dreaming. Human[143] as well as animal[144] studies link formation, retention, and expression of extinction learning to circuitry linking the amygdala, vmPFC, and hippocampus. Notably, a night's sleep promotes generalization of extinction learning.[145,146] Whereas such circuitry may be recruited by cognitive processes subserved by dlPFC in waking,[147] it may function autonomously during REM-sleep dreaming.[139]

Reward systems are also activated in REM sleep during which positive and negative emotions may be modulated. VTA sources of mesolimbic and mesocortical dopamine are recruited by ascending cholinergic activation[109] and, like their ventral striatal and medial PFC targets, lie well within the anterior paralimbic REM-sleep activation region.[39,40,92,93] In dreaming, hypothalamic-brainstem circuits may initiate instinctively salient behavior[148] that may, in turn, recruit additional forebrain regions to enact appetitive[76] or other adaptive behaviors.[148]

Altered Memory Processing in Dreams

A cholinergically mediated informational barrier between cortex and hippocampus in REM sleep has been proposed to underlie the paucity of episodic memories in dreams.[149] However, despite the inaccessibility of episodic memory, another aspect of declarative memory, "familiarity" or "recognition,"[150] is ubiquitous in dreams. For example, 40% of dream characters may be identified on the basis of "just knowing."[118] Schwartz and Maquet[119] suggest such phenomena result from the sleep-related disconnection of temporal lobe face recognition from prefrontal reality monitoring regions. Alternatively, frequent experiences of familiarity in the absence of accurate replay of episodic memories in dreams may reflect activity of recognition memory mechanisms in anterior perirhinal cortices (BA 35, BA 36) dissociated from hippocampally mediated recall. Indeed, double dissociations between recognition and knowing have been shown in human fMRI studies.[150] Because perirhinal regions of the anterior-medial temporal lobe are proximal to the anterior paralimbic REM sleep activation region,[40] altered interactions of this region with other portions of the hippocampal formation during REM sleep may produce this dissociation.

During dreaming, frontal contributions to memory retrieval may also be altered. Ventral lateral and dlPFC regions that are deactivated in REM sleep[37] subserve cue-specification and search strategies, respectively.[116] In contrast, posterior vmPFC, which is active in REM sleep,[28,35,39,40] subserves "feeling-of-rightness"[116] and "feeling-of-knowing,"[151] for which more anterior PFC regions only later provide cognitive verification.[116] Therefore, during REM sleep, greater activation of posterior-ventral-medial than anterior-lateral PFC regions relative to waking may favor an indiscriminate, emotional confirmation of accuracy for any item in consciousness without the benefit of strategic volitional search or critical verification. In combination, studies of mental simulation,[60] confabulation,[114,115] and memory verification[116,151] predict that restriction of frontal activation to vmPFC would favor an emotionally salient state prone to producing mental simulations that evoke a powerful sense of veracity and familiarity and are uncritically believed.

As discussed previously, a shift to a more random network has been observed during NREM sleep stage 1.[90] This shift could underlie the discontinuous and incongruous memory associations of dreaming in this stage. Sleep-onset mentation is typically short, so it would be difficult to measure the

correlation between these bizarre associations and small-world network changes. No similar studies exist for REM sleep, but the data from NREM sleep stage 1 might lead one to predict a similar change, and these changes could be correlated with the bizarreness of the corresponding dream.

Dreaming as a Simulation

Default-mode network simulation subsystem connectivity during REM sleep as it is related to dreaming could support the memory function of sleep.[72,152] Although entire memories are often not incorporated into REM-sleep mentation, memory elements may be incorporated depending on their emotional salience and/or cued reward value for subsequent memory consolidation,[150] as discussed previously. In addition to consolidating memories, activity in the default-mode network during dreaming would support the idea that dreams rehearse or simulate potential future events so as to prepare for them.[153,154] Imagining future events increases goal-directed actions when the corresponding opportunity later presents itself,[155] so simulation subsystem connectivity and the associated dreaming may increase adaptive behavior, similar to proposals on the functions of waking internally cued cognition.[65]

Social Cognition and Dreams

Brain regions most consistently activated in neuroimaging studies of social cognition include regions that are components of the default-mode network self-referential subsystem: medial PFC (especially the paracingulate cortex, BA 32), superior temporal sulcus, and temporal poles including the amygdala.[156] Incomplete reconnectivity of this subsystem during REM sleep[56] may underlie the high degree of delusional acceptance of dreams compared with waking cognition, and this may depend on an altered integration of the self into cognition. However, theory of mind, a complex aspect of social cognition,[156] is preserved in dreaming despite notable degradation of reasoning about the physical world.[157,158] This may seem like a contradiction, but social cognition has two components: an ability to perceive ourselves as social agents and an ability to perceive the intentions of others.[159] Subtle disconnections in the self-referential subsystem may disrupt the former and lead to delusional acceptance of dreams, whereas residual connectivity in the self-referential subsystem may preserve the latter and produce the ubiquity of interpersonal interactions and emotions in dreams.[17,37,73,157,160]

The function of residual self-referential subsystem activation as it is related to dreaming could be connected to the development and refinement of social skills. The interpretation of existing and new characters during dreaming may serve as practice for the application of social skills during wakefulness. Patients with autism have alterations in default-mode network activity,[161] and it would be interesting to examine whether these alterations persist in REM sleep because these patients exhibit sleep disturbances.[162,163]

Motor Initiation and Control Centers

Strong activation of the basal ganglia[28] (region 5 in Figure 51-1) may mediate the ubiquitous fictive motion of dreams.[164] The basal ganglia are extensively connected not only with motor cortex but also with mesopontine (e.g., pedunculopontine) nuclei[165] that contain gait circuitry and other motor pattern generators as well as REM-sleep regulatory regions.[3] Activation of brainstem vestibular nuclei and the associated cerebellar vermis[28] during REM sleep may additionally contribute vestibular sensations interpreted as flying or falling as well as a sense of motor control.

Visual Association Cortex

Medial occipitotemporal cortices (region 11 in Figure 51-1) are activated in REM sleep.[28,36] These and other visual association regions may generate the visual imagery of dreams.[3,76] As in waking, specific regions of the visual association cortex may process specific visual characteristics of dreaming. For example, the fusiform gyrus both mediates waking face recognition and is activated in REM sleep.[28,36,40] Braun and colleagues[36] suggest that REM sleep constitutes a unique cortical condition of internal information processing (between visual association and limbic cortices), functionally isolated from input from (through primary visual cortex) or output to (through frontal cortex) the external world. Dream image formation may arise as ascending activation impinges on visual and multimodal association regions in occipital, temporal, and inferior parietal cortices.

Inferior Parietal Lobe

The supramarginal and angular gyri of the inferior parietal lobe (BA 39 and 40; region 9 in Figure 51-1), especially in the right hemisphere, are essential for visuospatial awareness.[127] These regions may generate the fictive dream space necessary for the organized hallucinatory experience of dreaming.[76] Destruction of these regions is alone sufficient to produce global cessation of reported dreaming.[76,166] Maquet and colleagues have found right inferior parietal cortex to be relatively activated during REM sleep in some[35] but not all[38] PET studies. In REM sleep, both the previously described visual association cortex and the vmPFC are simultaneously active.[36] Therefore, in REM sleep, self-centric reality simulation, a putative function of the vmPFC,[60] and hallucinatory imagery may arise in concert. Inferior parietal multimodal association cortices may integrate different unimodal inputs and facilitate their incorporation into the emerging plot in the virtual proscenium where the dream is experienced.

Dorsolateral Prefrontal Executive Association Cortex

Lesions of the dlPFC (region 4 in Figure 51-1) do not cause cessation or attenuation of dreaming, an observation that suggests that they are nonessential for the generation of dreaming.[76,166] Unlike vmPFC regions that reactivate, these dorsal lateral prefrontal regions remain deactivated in REM sleep,[28,35-37] and this may explain dream mentation executive deficiencies that include disorientation, illogic, impaired working memory, and amnesia for dreams.[3] Additionally, because the PFC regulates posterior sensory cortices,[167] deactivation of the dlPFC in REM sleep[28,35,37] may promote dreaming by disconnection, release, or disinhibition of sensory association cortices (as also suggested by EEG and MEG[5,168,169]).

This may be consistent with the absence of the dorsal medial PFC from the default-mode network self-referential subsystem during REM sleep.[56] In addition to considering the dorsal medial PFC as part of the default-mode network self-referential subsystem, it and the lateral portions of the PFC can be considered as part of executive association cortex that includes the superior parietal gyrus, and the disruption of this

network may, again, promote dreaming by disinhibition of sensory association cortices.[170] The incomplete reconnectivity of this node in REM sleep might contribute to the bizarre nature of dreaming compared with waking cognition and is closely related to the reconnectivity of the simulation subsystem in REM sleep. Because this reconnectivity co-occurs with a reduction in sensory input, this may elicit the spontaneous and involuntary cognitions of dreaming.[72]

The PFC maintains an online representation of a goal, the means to achieve it, and the ongoing context relevant to this goal to "bias" the functioning of networks elsewhere in the brain toward this particular outcome.[171] For example, top-down influence can sensitize primary and association perceptual cortices to particular stimuli while simultaneously attenuating their sensitivity to competing stimuli.[172] With diminished frontal activation during sleep, goal-directed biases in the regulation of circuits subserving working memory and attention (frontoparietal) and memory encoding and retrieval (frontotemporal) may be impaired during dreaming.[3,17] Nonetheless, top-down influence in REM sleep may bias sensitivity of sensory cortices to hallucinatory percepts related to affective and social processing subserved by the vmPFC, whereas nonemotional imagery may fail to persist in the face of weakened working memory. Additionally, diminished activity in lateral frontal cortices in REM sleep[37] may weaken the ability of frontal, top-down influence to modulate emotional responses to dream imagery.[147] Alteration in dreaming of specific frontal-subcortical networks may underlie dream emotional salience and executive weakness. For example, the "cognitive" fronto-striatal-thalamo-cortical circuit (linking dlPFC with dorsal striatum) may be less active than "affective" (orbito-frontal-ventral caudate) and "motivational" (anterior cingulate–nucleus accumbens) circuits.[173]

CLINICAL PEARL

The physician prescribing selective serotonin reuptake inhibitors, transdermal nicotine, varenicline, beta blockers, dopaminergic agents, or a variety of other medications[97,99,100,104,110] should be alert for possible dream intensification or nightmare induction. Other choices within the same class or a different class of medications may need to be considered if such side effects are intolerable to the patient.

SUMMARY

ARAS, thalamocortical, and basal forebrain-cortical arousal systems activate the forebrain regions involved in dream construction in a manner that is chemically and anatomically different from waking. In REM sleep, such activation may be more frequent and sustained and, perhaps, may proceed through different or more diverse pathways than in NREM sleep. Cortical circuits activated in REM-sleep dreaming are medial circuits linking visual association and paralimbic regions (central crescent in Figure 51-1), but not the primary sensory and lateral frontal executive cortical regions that are active in waking.[36] Therefore dreaming is both positively and negatively emotionally salient (amygdala, ventral striatum, vmPFC), often conflictual (anterior cingulate) and social (vmPFC), while also displaying profoundly deficient working memory, orientation, and logic (lateral prefrontal and parietal deactivation). Subcortical circuits involving the limbic structures, striatum, diencephalon, and brainstem regions are selectively activated in REM sleep. They may contribute to dreaming's emotional (limbic subcortex), motoric (striatum, brainstem, cerebellum), instinctual (hypothalamus), and motivational (midbrain-ventral striatum) properties. Preserved connectivity in default-mode network simulation subsystem during REM sleep may be the neural substrate of dream simulations, whereas altered connectivity in default-mode network self-referential subsystem may underlie the high degree of delusional acceptance of dreams compared to waking cognition.

Chapter 52

Lucid Dreaming

Martin Dresler; Daniel Erlacher; Michael Czisch; Victor I. Spoormaker

Chapter Highlights

- During lucid dreaming, the dreamer is fully aware of his or her current dream state. This metacognitive insight often leads to full access to memory and increased volitional control over the dream narrative.
- Lucid dreaming is a rare natural phenomenon; however, several strategies are available to induce dream lucidity or increase the frequency of this sleep state.
- Lucid dreaming is associated with increased neural activity in several neocortical regions, particularly lateral prefrontal, frontopolar, and medial parietal cortices. On the electroencephalogram, 40-Hz gamma power over dorsolateral prefrontal areas is increased during lucid dreaming, and 40-Hz transcranial alternating current stimulation of this region induces dream lucidity.
- Lucid dreaming has a potential clinical application in the therapy of nightmares. In keeping with the view that dreaming can serve as a model for psychosis, lucid dreaming may potentially be of value for the therapy of metacognitive deficits in psychosis.

Conscious experience varies strikingly across the sleep-wake cycle. During wakefulness, humans are alert, aware of external and internal stimuli, able to reflect on their perceptions, emotions, and thoughts, and capable of acting volitionally according to their intentions. Most of these properties of waking consciousness fade during the process of falling asleep; however, they partly reappear during sleep mentation. Conscious experience during sleep is manifold. If not absent as in dreamless sleep, it can include abstract thought fragments, intense emotions, and sensory imagery, up to fully immersive visuomotor hallucinations with a complex interactive dream plot.[1] From the perspective of the dreamer, this virtual reality often feels indistinguishable from waking life. Dream experiences, however, typically show many cognitive peculiarities, with delusional thought, diminished volition, and a complete lack of insight into the true state of mind even in the face of a bizarre dream plot. In this regard, dreaming resembles the psychosis of mental diseases such as schizophrenia, characterized by hallucinations, loosening of associations, incongruity of personal experience, and a loss of self-reflective capacity.[2,3]

In contrast with normal dreaming, the rare phenomenon of lucid dreaming is characterized by the reappearance of many wake-like cognitive capabilities. Minimally defined by the criterion that the sleeper is aware of the current dream state as such,[4] lucid dreaming often leads to full insight into the delusional nature of the dream environment, access to short- and long-term memory, and sometimes even volitional control over the dream narrative.[5] Despite this wake-like cognitive capability, lucid rapid eye movement (REM) sleep comprises all defining markers of REM sleep[4] and all basal dream features such as visuomotor hallucinations[1]—in fact, prototypical aspects of dream phenomenology such as bizarreness might even be more pronounced in lucid dreams.[6] Lucid dreaming is not an all-or-nothing phenomenon but can occur in different degrees.[7,8] Questionnaires such as the Metacognitive, Affective, Cognitive Experience (MACE) questionnaire[9] and the Lucidity and Consciousness in Dreams scale[10] aim to assess this continuum ranging from single-minded sleep mentation over prelucid reflections to full-blown lucid control dreams.

Despite being described in ancient scripture and reported in early modern research literature, lucid dreaming faced considerable skepticism in mainstream sleep research during most of the twentieth century. In the late 1970s, the first systematic validation of lucid dreaming as an objective phenomenon occurring during otherwise normal REM sleep was achieved. In accordance with the scanning hypothesis, according to which rapid eye movements during REM sleep are related to gaze direction during dreaming,[11] lucid dreamers were asked to move their eyes in a left-right-left-right fashion during dreaming as soon as they became aware of their dreaming state.[4] Through this technique, which has since become the gold standard in lucid dream research, lucid dream reports could be objectively verified by eye movement patterns as recorded in the electrooculogram. By providing objective temporal markers of dream content, this method has allowed, for example, investigations into neural correlates of dreamed behaviors[12-14] and comparisons of the passage of time as experienced during dreaming with objective measurements in the real world.[15] Nevertheless, the rarity of lucid dreams and the difficulties of observing them under laboratory conditions hamper research with considerable sample sizes, rendering many results from lucid dreaming studies preliminary. In

addition, lucid dreams documented in the laboratory tend to be much shorter than at home, which further restricts the possibilities of lucid dream research.[16,17]

PREVALENCE AND INDUCTION METHODS

Generally, lucid dreaming is quite rare. Only one half of the general population know the phenomenon from personal experience, approximately 20% have lucid dreams on a monthly basis, and only a minority of approximately 1% have lucid dreams several times a week.[18,19] Some differences across different populations and cultures seem to exist—for example, German students reported a much higher lucid dream frequency than Japanese students,[20,12] and even when representative population samples are surveyed, Germans report more lucid dreams than Austrians.[19,21] Also, age-related differences in lucid dreaming prevalence have been recognized, with young children and adolescents reporting lucid dreams more frequently than adults.[22,17]

Quite often, lucid dreaming spontaneously emerges from nightmares, recurrent dreams, or some peculiarities within a dream. However, lucid dreaming also can be intentionally induced by applying various induction or relaxation techniques, by engaging with topics of dreaming and lucid dreaming, and with use of other deliberate training strategies.[23,24] Sleep-specific circumstances, such as short awakening in the morning or an afternoon nap, as well as stress also can initiate the first lucid dream experience.[17]

Since the onset of lucid dream research, possible induction techniques have always been a pertinent concern. A plethora of strategies to induce lucid dreams have been suggested in the literature, which can be loosely classified into three broad categories: cognitive techniques, external stimulation, and miscellaneous.[25] The first category encompasses all cognitive activities that are carried out to increase the likelihood of achieving lucidity in a dream state. For this category, a large number of different methods have been suggested that can be further divided into methods whereby lucidity is initiated from within a dream, so that the person becomes lucid during a dream (*dream-initiated lucid dreaming*), and methods whereby lucidity is initiated from wakefulness, so that the person retains conscious awareness when falling asleep (*wake-initiated lucid dreaming*). The rationale behind the second category is that an external stimulus presented to a sleeping person can be incorporated into the dream (e.g., spraying water on the sleeping person's face may promote the incorporation of sudden rainfalls in the dream) and that the incorporated stimuli serve as a cue to remind the dreamer about being in the dream state (e.g., someone squirting water signals the dreamer that he or she is dreaming) and thereby triggers dream lucidity.[26] The third category includes miscellaneous aids to gain lucidity, such as drugs (e.g., Donepezil) but also specific practices involving sleep-wake patterns—for example, waking up in early-morning hours and then, after a certain period, going back to bed to take a nap, known as *wake-back-to-bed* (WBTB).[27] WBTB is not a technique per se, because it was empirically tested only in combination with other techniques (*mnemonic induction of lucid dreams* [MILD]) and may boost their efficacy.

Most lucidity induction strategies described in the literature are based on personal and anecdotal accounts. A recent systematic review of evidence found 27 studies that experimentally tested the efficacy of lucidity induction techniques,[25] of which 5 were conducted as sleep laboratory studies and the other 22 were done as field experiments, in some cases with low methodologic quality. None of the induction techniques was verified to induce lucid dreams reliably, consistently, and with a high success rate; some methods, however, proved to be promising—for example, the MILD/WBTB combination. More recently, noninvasive brain stimulation methods yielded encouraging results. Although transcranial direct current stimulation of the dorsolateral prefrontal cortex during REM sleep showed rather modest success in inducing dream lucidity as assessed by the eye signaling technique,[27] transcranial alternating current stimulation in the low gamma range (25 Hz and 40 Hz) led to a robust increase in retrospectively reported dream lucidity as measured by the Lucidity and Consciousness in Dreams questionnaire.[28]

NEUROBIOLOGY

Dream-like mental activity can be observed during all sleep stages; REM sleep dreams, however, are particularly vivid and intense. The specific phenomenologic characteristics of dreaming frequently have been associated with neural activation patterns observed during REM sleep. For example, higher visual areas show strong metabolic activity during REM sleep,[29] which is in line with visuospatial hallucinations as the hallmark of typical dreaming.[1] The amygdala, medial prefrontal cortex, and anterior cingulate cortex also show increased activity during REM sleep.[30,31] All of these brain areas have been implicated in emotional processing, nicely mirroring the intense emotions experienced in many dreams. By contrast, the dorsolateral prefrontal cortex, frontopolar cortex, and parietal areas including the supramarginal cortex and precuneus show low metabolic rates during normal REM sleep.[30,31] In particular, prefrontal deactivations have been postulated to underlie cognitive deficiencies typical of ordinary dreaming such as impaired critical thinking, diminished metacognitive ability, and restricted volitional control.[32]

Although lucid REM sleep dreaming is characterized by the full range of coarse electroencephalographic features of REM sleep according to the classical Rechtschaffen and Kales (1968)[33] or new American Association of Sleep Medicine (AASM)[34] sleep stage scoring, it does incorporate some subtle physiologic changes relative to nonlucid REM sleep, such as higher eye movement density and increases in respiration, heart rate, and skin potential.[16] In addition, brain activity during lucid REM sleep shows distinctive changes from that during nonlucid REM sleep. Early electroelectrogram (EEG) studies observed higher alpha activity,[35,37] and increased beta-1 activity (13 to 19 Hz) over parietal regions during lucid dreaming.[36] A more recent high-density EEG study demonstrated that lucid dreaming is associated with higher activity in the gamma band—the between-states-difference peaking at approximately 40 Hz—and overall EEG coherence compared with nonlucid REM sleep.[37] Both power in the 40-Hz band and coherence levels were observed to be strongest over the dorsolateral prefrontal cortex (Figure 52-1), which has been associated with metacognitive evaluation.[38]

In a combined functional magnetic resonance imaging (fMRI)-EEG approach, activations in a network of purely neocortical regions including the dorsolateral and frontopolar prefrontal cortex were observed during lucid dreaming as

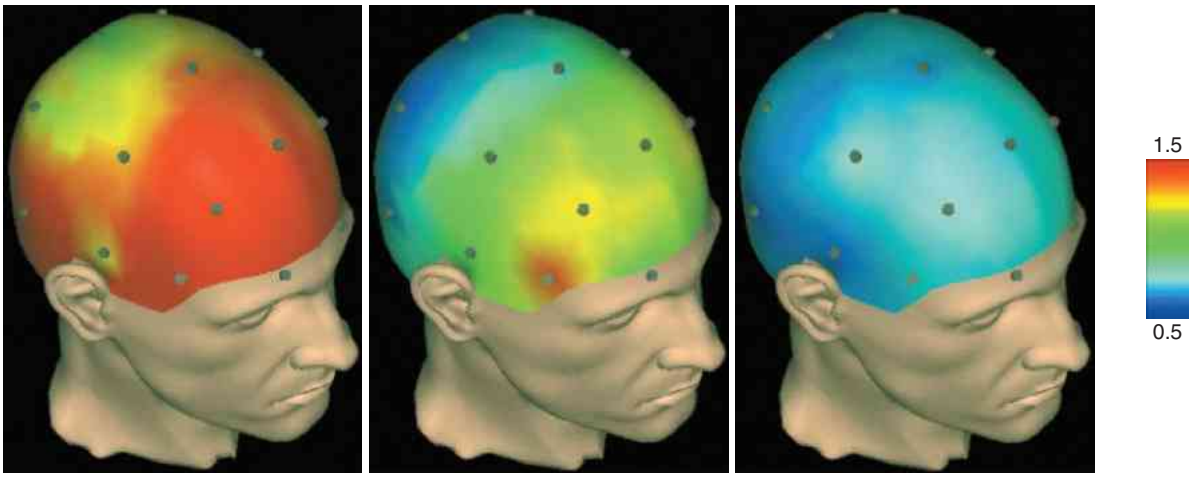

Figure 52-1 **Quantitative EEG Data for Lucid Dreaming.** Shown is gamma 40-Hz standardized current source density power during wakefulness, lucid REM sleep, and nonlucid REM sleep. The dorsolateral prefrontal cortex during lucid dreaming shows similar 40-Hz power to that during wakefulness. EEG, Electroencephalogram. (From Voss U, Holzmann R, Tuin I, Hobson JA. Lucid dreaming: a state of consciousness with features of both waking and non-lucid dreaming. *Sleep* 2009;32:119–200, with permission of the American Academy of Sleep Medicine from Voss et al. 2008; permission conveyed through Copyright Clearance Center, Inc.)

compared with nonlucid REM sleep background (Figure 52-2),[39] thus confirming earlier EEG data. Of note, recent anatomic analyses have demonstrated larger gray matter volume in the frontopolar cortex in dreamers with high self-reported dream lucidity.[40] The frontopolar cortex has been related to the processing of internal states, such as self-evaluation of thoughts and feelings,[41] metacognitive ability,[42] and supervisory modes,[43] which are impaired in normal dreaming but reinstated in lucid dreaming. Strong activation increases during lucid dreaming also were observed in parietal regions including the precuneus, inferior parietal lobules, and supramarginal gyrus.[44] Prefrontal-parietal interactions are involved in many higher-level cognitive processes such as intelligence or working memory,[45] whereas the precuneus has been implicated in self-referential processing such as first-person perspective taking and experience of agency.[46] These findings are in line with the notion that dream lucidity provides increased availability of self-related information, leading to a much higher degree of coherence and stability of the phenomenologic self during lucid dreaming.[47] Taken together, the frontoparietal activation patterns observed during lucid REM sleep nicely mirror the reinstatement of cognitive capabilities experienced during lucid dreaming. Activation increases during lucid dreaming also were found in some occipital and inferior-medial temporal regions.[44] These cortical areas are part of the ventral stream of visual processing, which is involved in several aspects of conscious awareness in visual perception.[48] Although such activations initially may seem puzzling—nonlucid dreams also are characterized by vivid dream imagery—they are consistent with reports of lucid dreamers stating that lucidity is associated with an exceptional brightness and visual clarity of the dream scenery.[49]

In recent years, network analyses of neuroimaging data have been introduced into sleep research.[50,51] Particular interest has been directed at the *default mode network,*[52] which during wakefulness shows increased activity in the absence of processing related to external tasks. Because this activity increase appears to be related to stimulus-independent thought such as internal awareness and daydreaming during wakefulness,[53,54] the default mode network has been proposed to be associated with nonlucid dreaming during sleep.[55,56] A second network shows activation anticorrelated with the default mode system in resting state fMRI analyses: the *dorsal attention system,* which is mainly involved in externally directed perceptual processes.[57] A third network, dubbed the *frontoparietal control system,* has been postulated to integrate information coming from both the default mode and the dorsal attention network by switching between competing internally and externally directed processes.[58,59,60] Phenomenologically, this might be interpreted as a monitoring of and control over mind-wandering and perception by metacognitive processes.[61] Owing to this role as a kind of meta-network, the frontoparietal control system might be seen as an ideal candidate subserving metacognitive aspects of consciousness that are the hallmark of lucid dreaming.[51] Brain regions activated during lucid dreaming indeed comprise substantial parts of the frontoparietal control network.[44]

LUCID DREAMING AS HIGHER-ORDER CONSCIOUSNESS

The contrast between lucid and nonlucid dreaming has been suggested to mirror the conceptual contrast between basal (primary) and higher-order (secondary) aspects of consciousness.[62,63] Although all basal features of consciousness, such as perceptions and emotions, are present in normal dreaming, metacognitive reflections and the insight into the current state of consciousness are, by definition, bound to dream lucidity. Because some reflective thoughts have been reported in nonlucid dreaming, and also because active reflections frequently are absent during daydreaming and other phases of wakefulness, it has been argued that metacognitive activity differs only quantitatively and not qualitatively between dreaming and waking consciousness.[64] This absence, however, is only a

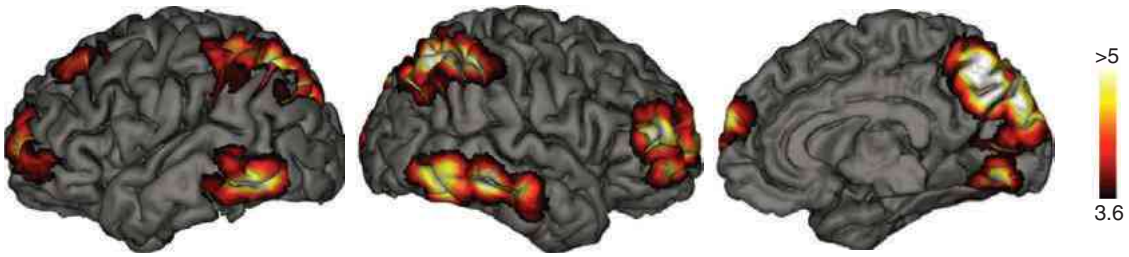

Figure 52-2 Functional MRI Data for Lucid Dreaming. During lucid REM sleep, strong activation is seen for dorsolateral prefrontal and frontopolar regions including the inferior, middle, and superior frontal gyri; parietal regions including the precuneus, inferior parietal lobule, and supramarginal gyrus; and temporal regions including the inferior and middle temporal gyri, as compared with nonlucid REM sleep. The *color bar* represents T-values. MRI, Magnetic resonance imaging. (From Dresler M, Wehrle R, Spoormaker VI, et al. Neural correlates of dream lucidity obtained from contrasting lucid versus non-lucid REM sleep: a combined EEG/fMRI case study. *Sleep* 2012;35:1017–20, with permission of the American Academy of Sleep Medicine; permission conveyed through Copyright Clearance Center, Inc.)

"local," not global feature of such phases. It is hardly imaginable, at least in nonpathologic cases, that the daydreaming subject misinterprets the daydream for reality, with full recognition of his or her current state prevailing. In the dreaming state, by contrast, this misperceived "reality" is completely normal—unless the dreamer eventually achieves lucidity by means of such prelucid reflection.[7]

Lucid dreaming may even be critical to achieve full understanding of the neural correlates of higher-order consciousness, because in contrast with coma-wake, anesthesia-wake, or sleep-wake comparisons, no major shift occurs in the vigilance state as defined by formal neurophysiologic criteria. Lucid REM sleep still is REM sleep proper, according to the classical Rechtschaffen and Kales (1968) or newer AASM[34] sleep scoring criteria. When compared with wakefulness, pathologic or pharmaceutically induced loss of consciousness also reduces the brain's basal metabolism, as does deep sleep. Lucid dreaming therefore provides the only known phenomenon that can contrast basal consciousness with full-blown higher-order consciousness within the same arousal level, allowing for comparison of cerebral activity by means of EEG, positron emission tomography, or fMRI without differences in the basal activity state.[51]

Higher-order aspects of consciousness are traditionally thought to be most pronounced in humans.[65,66] If the contrast between ordinary and lucid dreaming mirrors that between basal and higher-order consciousness, data on the neural correlates of dream lucidity might shed new light on this debate. Indeed, it turns out that cerebral regions showing increased activity during lucid dreaming also show extensive volumetric expansion in humans as compared with nonhuman primates.[67,68] In particular, the frontopolar cortex is significantly larger in humans than in other primate species[69] and has even been suggested to be a distinctly human brain structure.[70,71]

CLINICAL APPLICATIONS

Lucid dreaming has been suggested as a therapeutic approach for several clinical conditions, including nightmares, posttraumatic stress disorder, and schizophrenia. Lucid dreaming frequency is moderately correlated with nightmare frequency,[20] and people with frequent lucid dreams have incidentally reported that their nightmares have triggered lucidity. Theoretically, dream lucidity seems a logical solution to the main problem of nightmares, which encompasses a real emotional response to a nonexistent threat.[72] Becoming lucid in a nightmare should therefore take the sting out of it, and once the person realizes the threat is not real, it should disappear—along with the emotional response. Neurocognitive models of disturbed dreaming emphasize a hyperresponsivity of the amygdala in nightmare generation, coupled with a failure of medial prefrontal regions to dampen this activation.[73] Lateral prefrontal regions have been shown to be capable of influencing amygdala function through connections to the medial prefrontal cortex.[74] The neurobiology of lucid dreaming with increased lateral prefrontal activation therefore fits well with potential therapeutic effects of lucid dreaming on nightmares.[14]

Thus far, the theory holds—but does it work as readily in practice? Patients with narcolepsy who frequently suffer from nightmares report that dream lucidity intervention indeed provides relief during nightmares,[75] and a few case studies[76] and one small controlled pilot study[76] have indicated that lucid dreaming therapy was effective in reducing nightmare frequency. In the controlled pilot study, lucid dreaming therapy was superior to a waiting list regarding nightmare frequency but did not have an effect on secondary anxiety and sleep measures; its efficacy was much higher in individual patients than in a group therapy setting, suggesting confounding therapist effects.[77] A larger online self-help study did not find any additional effect of lucid dreaming therapy as an add-on to other effective cognitive-behavioral techniques such as imagery rehearsal therapy,[78] although low power and high dropout rates (>50%) limited the scope of the conclusions.

Lucid dreaming therapy raised some unexpected issues. An important consideration was that people with frequent nightmares may report becoming lucid but then find themselves unable to change the nightmare,[76] presumably because the expectations about the storyline may be too strongly engrained into the brain.[79] Moreover, realizing that one is dreaming does not automatically erase the threat and accompanying (intense) emotions, which could be expected to take some time after complete threat removal. As in all lucid dreams, lucidity in nightmares is not precisely an all-or-none phenomenon but rather a staged process, and a prelucid or half-lucid stage may not suffice to fully tackle a seemingly real threat. Moreover, many subjects with frequent nightmares reported a spontaneous change in their nightmares even without obtaining

lucidity.[77] This finding suggests that control over the nightmare, not lucidity, may be the therapeutic factor in successful nightmare treatment. Last but not least, even if the promising initial findings (which are only partly corroborated in controlled pilot studies) are sustained, the effects of lucid dreaming therapy tend to be stronger on nightmare aspects (frequency, intensity) than on general sleep quality or mental health characteristics. By contrast, the effects of imagery rehearsal have been much broader in scope.[80]

However, one disadvantage of the nightmare treatments that are currently best supported by experimental evidence, such as imagery rehearsal,[81] exposure therapy,[82] and combinations of both,[83] is that they also require a repetitive nightmare or theme to work with. If nightmares are too different from night to night, no story lines are available to rescript, as in imagery rehearsal, nor are repetitive images to systematically desensitize, as in exposure. Here, lucid dreaming therapy has the advantage that although having a repetitive nightmare or theme is beneficial (to allow recognition of the dream state in a future nightmare), it is not a sine qua non, because people can train themselves to become lucid without having nightmares.[72] Moreover, appropriate training can help patients link lucidity with feeling anxiety and fear in therapy and thereby prepare themselves for the next time they feel threatened—as it is likely to occur during a future nightmare. In this manner, lucid dreaming therapy can be useful for people with idiopathic nightmares with very different contents.

One important caveat is that lucid dreaming therapy may not be optimal for treating posttraumatic nightmares, besides being less evidence-based than imagery rehearsal. Because many posttraumatic nightmares may constitute a replication of an original event or parts of an original event,[84] changing the nightmare "on-line" during its occurrence may be much harder to achieve than changing it "off-line" in mentation, and even this issue typically raises questions concerning guilt and "undoing the past." Lucidity may thus have the adverse consequence that patients with posttraumatic stress disorder relive their original traumatic event with full consciousness but without the possibility to change anything.[76] Such an occurrence would be retraumatizing rather than empowering, and although solutions to this inability to change the nightmares have been proposed (e.g., starting by changing small background objects in color and then proceeding from there in small steps), it appears better to avoid experimenting with such inflammable material and to first try the treatments that may work in a majority of cases.

Besides nightmares, lucid dreaming also has been suggested as a therapeutic strategy in the treatment of schizophrenia.[3,28] The idea that normal dreaming can serve as a model for psychosis has a long and honorable tradition; however, it is notoriously speculative. One of the most interesting aspects of the dreaming-psychosis model is the issue of insight. Between 50% and 80% of patients diagnosed with schizophrenia have poor insight into the presence of their disorder,[85] probably owing to ineffective self-reflection processes.[86] Because such deficits are thought to lead to more relapses and rehospitalizations and poorer therapy success in general,[87] the concept of insight is becoming an increasingly important area of investigation in schizophrenia research.[88] On the dreaming side of the model, lack of insight into the current state characterizes almost any dream experience—with the obvious exception of lucid dreaming. This suggests that dream lucidity may be a good model for insight in the dreaming-psychosis model. Of interest, historical approaches to psychosis used the term "lucidity" to denote the patient's awareness of his or her illness.[89] Although the specific composition of the multiple facets of insight in psychosis is still under discussion,[90,91] two crucial dimensions are classically considered to be (1) the affected person's recognition that he or she has a mental illness and (2) the ability to recognize unusual mental events (delusions and hallucinations) as pathologic.[92] Hence, in the dreaming-psychosis model, lucidity during dreaming represents what patients in psychosis lack: full insight into the delusional nature of the current state of consciousness.

In neurobiologic studies, in particular, prefrontal, medial parietal, and inferior temporal cortical regions that are linked to insight problems in psychosis show striking overlap with brain regions associated with dream lucidity.[5] It has been demonstrated that prefrontal cortex function in schizophrenic patients can be improved through cognitive training.[93] Metacognitive training approaches are of particular interest, because skilled lucid dreamers typically gained their frequent insight into the dreaming state by metacognitive training, in particular by developing autosuggestions and the habit of frequently contemplating about their state of consciousness.[24,25] By teaching schizophrenia patients such training regimens, enhancing insight-related prefrontal and medial parietal functions might well lead to enhanced insight capabilities during acute psychosis. In addition, recent advances in dream lucidity induction by electrical brain stimulation methods[94,28] may show generalization effects to insight processes during psychotic wakefulness, or they may potentially serve as direct tools to improve insight during acute psychosis. Of note, a recent case study provides evidence that brain stimulation might indeed transiently attenuate insight problems in psychosis.[95] Lucid dreaming as a model for the successful treatment of psychotic symptoms also may be helpful for developing and testing new antipsychotic medication. If a given pharmacologic agent increases the frequency of lucid dreams in healthy subjects, it can be considered as a promising candidate to enhance insight in psychotic patients as well.[68] Lucid dreaming, therefore, transforms the dreaming-psychosis model from an interesting idea with a long history into a testable scientific hypothesis and a promising new therapeutic approach.

NONCLINICAL APPLICATIONS

Lucid dreaming also is used for several nonclinical purposes. A recognized strategy is to maximize certain behaviors or patterns within the dream state. Among the most popular intended dream behaviors are flying, communication with dream characters, and sexual encounters during dreaming, with lucid dreaming frequency appearing to predict how successful such intentions are recalled and executed in lucid dreams.[17] Besides such purely recreational applications within dreams, use of lucid dreaming also has been reported by many persons to influence aspects of waking life.[96] Two examples for which at least some scientific data are available are creative problem solving and practicing motor skills.

Anecdotal reports on scientific discovery, inventive originality, and artistic productivity suggest that creativity can be triggered or enhanced by sleeping and dreaming. In addition, theoretical considerations and experimental studies suggest that dreams can improve waking-life creativity.[44] Theoretically,

sleep has been suggested to provide an ideal state for creative incubation. The internally generated dream narrative, in the absence of external sensory data, leads to a much more radical renunciation from unsuccessful problem-solving attempts, leading to coactivations of cognitive data that are highly remote in waking life, and both dreaming and creativity have been characterized with primary process thinking, flat associative hierarchies, and defocused attention. In contrast with the more random flow of nonlucid dream narratives, dream lucidity allows for a more goal-oriented use of these creativity-related dream characteristics. Surveys among lucid dreamers and experimental studies demonstrate that lucid dreaming can indeed be used to improve creative thinking and problem solving.[97,96]

Motor practice during lucid dreaming is a novel type of mental rehearsal in which the person uses the dream state to consciously practice specific tasks without waking up.[98] It can be compared to mental practice, which is well established in sports theory and sports practice.[99] For both mental and dream rehearsal, movements are simulated with an imagined body on a purely cognitive level, while the physical body remains still. One advantage that lucid dreaming has over both mental practice and modern virtual reality simulators is that it offers the potential for practice with all kinesthetic sensations of the dream body in an environment that is experienced with as much vividness and realism as would be encountered in waking experience. In addition, the lucid dreamer, being limited only by imagination and attentional stability, has far greater potential for control over his or her own body, actions, and environment than in mental rehearsal, virtual reality environments, or waking life. In contrast with the vast amount of research on mental practice, however, empiric data on practice in lucid dreams are rather sparse.

In several anecdotal reports, amateur and professional athletes have described using lucid dreaming to improve their waking performance, such as in long distance running, tennis, skating, alpine skiing, or martial arts.[100,72] In a more systematic questionnaire study, 840 German athletes from a variety of sports were surveyed about their experiences with lucid dreams.[101] Although lucid dreaming in athletes was similar in prevalence to that in the general population,[19] the percentage of lucid dreams relative to all recalled dreams was found to be nearly doubled in athletes. Approximately 1 in 10 athletes who had lucid dreams (5% of the total sample) used lucid dreaming to practice sports skills, with most of them reporting improved performance.

Few studies have tested possible effects of practice in lucid dreams in controlled experiments. In a qualitative study, subjects were instructed to perform different complex sports skills familiar to them in waking life, such as skiing or gymnastics, in their lucid dreams.[102] Participants reported that they had no difficulties performing these sports skills in their lucid dreams and that their movements improved both in the dream and the waking state. In a quasiexperimental pre-/postdesign study, participants were asked to practice a coin-tossing task in their lucid dreams.[103] Results showed a significant increase in hitting the target from pretest to posttest evaluations for the group that practiced the coin-tossing task in lucid dreams, but no increase was found for the control group. More recently, these results could be replicated with a different motor task (sequential finger tapping). Improvements after lucid dream practice seem to be similar to or slightly less in degree than those obtained with actual physical practice, and similar to or slightly better than those with mental practice in wakefulness.[104]

CONCLUSIONS AND FUTURE DIRECTIONS

Up until the late 1970s, lucid dreaming met much skepticism or was completely ignored by mainstream sleep research, and even in the late 1990s, studying lucid dreaming was not considered to be experimentally advantageous for the neuroscience of consciousness.[105] Since then, an increasing number of studies have elucidated the neurobiologic basis of lucid dreaming and demonstrated its value for clinical and nonclinical applications. Nevertheless, owing to the rarity of the phenomenon, the study of lucid dreaming is still in its infancy, with many preliminary data demanding further confirmation and many details of the neural mechanisms underlying lucid dreaming and its therapeutic effects awaiting thorough investigation. In particular, reliable lucidity induction strategies are needed to boost lucid dream therapy and the relevant research.

CLINICAL PEARL

Lucid dreaming has been proposed as a natural therapy for nightmares, because the insight into the illusional nature of the dreamed threat could prevent the emotional response to it. Lucid dreaming as a therapy for nightmares has indeed some clinical support. It might be particularly suited for addressing nonrecurring nightmares but less so for managing posttraumatic nightmares. Because lucid insight into dreaming and insight into psychosis appear to largely share the same brain basis, lucid dreaming also may potentially be of value in schizophrenia therapy or in the development of novel antipsychotics.

SUMMARY

In contrast with the metacognitive impairments of normal dream mentation, lucid dreaming is characterized by awareness of the current state of mind, often leading to considerable volitional control of the dream narrative. Lucid dreaming is a rare skill; however, it can be learned and reinforced with training using a variety of induction strategies ranging from autosuggestion to transcranial current stimulation. Lucid dreaming as a research topic has faced much skepticism during most of the past century; in recent years, however, interest is acquiring increasing momentum. Lucid dreaming is associated with specific changes in neural activity when compared to nonlucid dreaming, with lateral prefrontal, frontopolar, and medial parietal activation as proposed neural correlates of the increased metacognitive capacity that defines dream lucidity. Lucid dreaming has clinical and nonclinical applications, ranging from nightmare therapy to mental motor skills training and creative problem solving. Reliable induction methods are strongly needed to further explore the potential of lucid dreaming and for its scientific study.

Nightmares and Nightmare Function

Tore Nielsen; Michelle Carr

Chapter Highlights

- The definition of *nightmare disorder* as a clinical entity by the *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition (DSM-5) and the *International Classification of Sleep Disorders,* third edition (ICSD3) suggests that nightmares are symptomatic but not functional.
- The nearly ubiquitous nature of nightmares and dysphoric dreaming in the general population is consistent with the claim that they serve a function related to cognitive-emotional regulation or emotional memory consolidation.
- Theories of nightmare function vary in their emphasis on mechanisms for dealing with emotional regulation and include stress mastery, affect desomatization, fear memory extinction, emotional contextualization, and others.

WHAT IS THE FUNCTION OF NIGHTMARES?

There are diverse opinions—but little consensus—about why dreaming so frequently turns dark and interrupts sleep with fear-filled awakenings. Are these nightmares simply symptomatic of an underlying clinical condition? Or do they serve a homeostatic or cognitive function related to the processing of intense emotion? Or might some nightmares serve a function while others are symptomatic, and if so, how are these nightmare types to be distinguished? The characterization of nightmares remains a major unresolved issue of modern sleep medicine and one with important ramifications for our understanding of mental health and cognitive development. The present chapter addresses the problem of nightmares from the perspective of their possible functionality and reviews new findings that bear on the problem.

We first consider literature demonstrating that nightmares have been, and continue to be, widely accepted as a clinical symptom and thus, possibly, have no adaptive function. We then review studies showing that nightmares and a wide spectrum of other types of negative dreams are highly prevalent in the general population and thus that some nightmares—especially those that are infrequent, or not severe or recurrent in nature—may well play a functional role. After touching briefly on polysomnographic studies, which are inconclusive on nightmares' functionality, and neurocognitive studies, which are too scarce to permit drawing firm conclusions, we review the principal theories that address whether nightmares serve an adaptive function. These theories are multifaceted, propose a variety of hypothetical mechanisms, and for the most part support the notion that nightmares are, indeed, functional.

In the present context we consider the term *nightmare* to refer to dreaming during which intense negative emotion is in play. In this definition we subsume dreams with a variety of dysphoric emotions as well as dreams that do not immediately awaken the dreamer. This broad definition, although not shared by all writers, corresponds closely with current clinical definitions (Table 53-1) as well as with earlier DSM-III and DSM-III-R definitions of *dream anxiety attacks* and *anxiety dreams* and is employed so that a wide swath of nightmare theories may be included in the discussion.

NIGHTMARES ARE A RECOGNIZED CLINICAL ENTITY

Nightmares have for centuries been viewed as pathologic; accordingly, clues to their possible functionality may be found in how they are described clinically. Nightmares are, according to the most authoritative sources, the DSM-5[1] and ICSD3,[2] powerful unpleasant dreams associated with feelings of threat, anxiety, fear, or other negative emotions that occur during late-night REM sleep and that are clearly recalled on awakening (see Table 53-1). The implication of basic fear expression in nightmare genesis is indicated by the fact that fear manifests in 65% to 85% of nightmares, whereas other dysphoric emotions such as anger and sadness prevail in the remainder.[3,4] This clear predominance of fear may mean that nightmares are akin to the symptoms of other fear-dysfunction disorders, such as phobias, generalized anxiety, or social anxiety, but it may also point to a deeper involvement of fear memory, fear extinction, and fear regulation systems that underlie the normal functions of emotional learning and emotional memory consolidation.[5-7] These are not mutually exclusive possibilities of course.

The pathologic context of nightmares is striking and has been reviewed in detail elsewhere.[6,8] Pathologic conditions that are comorbid with nightmares range from the mild to the severe, but causality between nightmares and other pathologies has not yet been clearly established. Nightmares are more frequent among those suffering from impaired sleep quality,[9-11] a variety of sleep disorders,[11,12] depressive and anxiety symptoms and neuroticism,[6,8] and posttraumatic stress disorder (PTSD)[13] than they are among healthy individuals. Nightmares are also reliably associated with suicidal ideation,[14] suicide attempts,[15] and death by suicide[16]—independent of other psychopathologies.[14,17,18] Frequent nightmares are also associated with the eveningness chronotype.[19,20]

Table 53-1 Diagnostic Criteria for Nightmare Disorder from the DSM-5 and ICSD3*

	DSM-5	ICSD3
A. Nature of recalled dream	Repeated occurrence of extremely dysphoric, well-remembered dreams, usually involving threat and occurring in the second half of sleep	Repeated occurrence of extremely dysphoric, well-remembered dreams, usually involving threat and occurring in the second half of sleep
B. Nature of awakening	Becomes alert and oriented on awakening	Becomes alert and oriented on awakening
C. Nature of distress	Causes clinically significant distress or impairment	Causes clinically significant distress or impairment in one of the following areas: mood, sleep, cognition, family, behavior, daytime sleepiness, fatigue, occupation, social
D. Differential diagnosis	Not substance derived	N/A
E. Differential diagnosis	Not due to other mental or medical disorder	N/A
Duration	Acute: <1 mo Subacute: <6 mo Persistent: >6 mo	N/A Note: Nightmare disorder only diagnosed in children in cases of persistent distress
Severity	Mild: <1 per wk Moderate: 1-6 per wk Severe: ≥7 per wk	

**International Classification of Sleep Disorders,* third edition (ICSD3) criteria have changed only slightly from the ICSD2. *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) criteria have changed from DSM-IV-TR in several respects. DSM-5 introduces categorization of subtypes according to duration and severity (used in ICSD2), whereas ICSD3 drops them. Terrifying hypnagogic hallucinations in DSM-IV-TR are subsumed in DSM-5 as sleep-onset subtype of nightmares. In DSM-5, nightmare disorder may be diagnosed in cases of REM sleep behavior disorder, posttraumatic stress disorder, and acute stress disorder if nightmares preceded the condition and their frequency or severity necessitates independent clinical attention. Both manuals now include any dysphoric emotional tone and recognize the frequent depiction of threat-related content. Awakening from sleep is no longer a defining criterion of a nightmare.

Nightmare-focused treatments can alleviate comorbid symptoms such as anxiety, depression, and PTSD symptoms[21,22] suggesting that nightmares may contribute to the pathology of these conditions.

Altogether, the continued description of nightmare disorder in the DSM-5 and ICSD3 as a primarily fear-based disorder, as well as accumulating evidence linking nightmares to various comorbid affective conditions, supports the position that frequent nightmares reflect a pathologic breakdown in the normal functioning of processes governing fear expression, fear memory, or fear regulation. Nonetheless, despite the distress and suffering caused by nightmares, it remains possible that they also signify—at least up to a certain degree of severity—innate adaptive responses over the long term. Both possibilities, the dysfunctional and functional theories of nightmares, remain viable, albeit unproven, ideas. Nevertheless, in both cases, the presence of multiple comorbid conditions among nightmare sufferers substantially complicates the determination of whether nightmares are a primary contributor to these clinical conditions and whether they support some kind of adaptive function.

NIGHTMARES ARE UBIQUITOUS

Large population studies indicate that nightmares are a prevalent clinical problem but also that dysphoric dreaming is much more ubiquitous than is generally appreciated. Nightmare prevalence at a clinically significant frequency (i.e., about 1/week or more[1]) varies from 0.9% to 6.8% of individuals.[23] The two largest cohort studies (i.e., 69,813 participants from the general Finnish population[23] and 87,408 7th- to 12th-graders from Japan[24]) provide consistent estimates. The former study found that 4.2% reported "frequent" nightmares in the past 30 days; the latter that 6% reported nightmares "always" or "often" in the same time period. However, this is not the complete picture. For one thing, in most of these studies the definition of a nightmare included the requirement that the dream lead to an awakening. In addition, nightmares occur at lower frequencies among many more people (e.g., 40% of the Finnish cohort reported "occasional" nightmares during the past 30 days). A full 85% of adults report at least one nightmare per year.[6] Occasional nightmares are not generally considered pathologic; they may well be evidence of nightmares sustaining a normal, adaptive response. The widespread occurrence of nightmares is also supported by the finding that prospective measures, such as home dream logs, estimate them to be 3 to 10 times more frequent than do retrospective measures, such as questionnaires.[25-27] In addition, there is a much wider spectrum of disturbed and dysphoric dreams, of which nightmares are clearly a part and from which they have not been clearly distinguished.[6,28] To illustrate, many types of disturbed dreams have been described during bereavement,[29] during pregnancy,[30] following trauma or brain surgery,[31] after consuming or withdrawing from various drugs, or in tandem with many mental, physical, and sleep disorders.[28,31] Bad dreams, in particular, have been distinguished from nightmares in that they do not lead to awakenings, are less emotionally intense, but are as likely to contain negative emotions.[32] Bad dreams occur up to four times more frequently than do nightmares.[27,32] Bad dreams and nightmares together occur on average at a rate of about 40 per year among healthy university students[27] and constitute 13.7% of all dreams reported by 572 subjects (9796 dreams).[32] That bad dreams are thematically similar to nightmares (e.g., depict physical aggression) yet more likely to resolve positively (38%) than nightmares (22%),[32] suggests that they may be more functional in

regulating emotions than are nightmares. Beyond bad dreams, negative emotions constitute from 66% to 80% of all dream emotions in home dreams.[33,34]

In sum, although nightmares are clearly recognized as a clinical entity, the ubiquity of nightmares as part of a wider, still insufficiently articulated, spectrum of disturbed and dysphoric dreams supports the possibility that they may play a role in cognitive-emotional regulation or processing of emotional memories; a role that may diminish as the nightmares become more severe and disruptive.

SLEEP POLYSOMNOGRAPHY FINDINGS FOR NIGHTMARE SUFFERERS ARE INCONCLUSIVE

Polysomnography (PSG) has revealed several sleep-dependent memory functions, with memory improvements having been linked to both proportions of sleep stages and microstructural sleep features such as spindles and rapid eye movement (REM) density.[35] REM sleep, in particular, has been linked to the processing of emotional stimuli, such as consolidation of fear and safety memories[36] or of the negative component of complex pictures,[37] and to modulation of emotional reactivity.[35] In light of such advances, the PSG features characterizing nightmare sufferers—and their REM sleep features in particular—may provide clues to nightmare functionality.

Unfortunately, PSG studies pertaining to nightmares and nightmare sufferers are few and inconclusive. Two studies of nightmare episodes[38,39] both revealed signs of REM sleep activation (e.g., heart rate increase), which can be attributed to autonomic arousal that would be expected to accompany fear. On the other hand, in a surprising 60% of cases[39] this expected autonomic arousal was not observed, raising the possibility of a dampening of affect expression during nightmares (see later). Other studies have found more eye movements per minute and shorter respiration rates for dreams that are high compared with low in anxiety.[40] For the habitual sleep of nightmare sufferers, no consistent patterns of PSG abnormalities in either microstructure or macrostructure have been established. Some studies find REM-specific abnormalities, such as increased skipping of early REM periods, increased REM latency and cycle length, more REM periods,[41] and increased spectral power in the high alpha range (10 to 14.5 Hz),[42] whereas others report changes in non–rapid eye movement (NREM) sleep such as low alpha power,[42] reduced cyclic alternating pattern (CAP) A1 but increased CAP A2 and A3 subtypes,[43] and reduced slow wave sleep.[44] Yet other studies report global changes such as more frequent periodic leg movements,[45] more fragmented sleep,[39,46] longer sleep latency, more nocturnal awakenings,[44] and increases in the normalized low-frequency component of the heart rate during recovery sleep after REM sleep deprivation.[47] These findings are discrepant but could be considered to reflect an increase in arousal during the sleep of nightmare sufferers, whether expressed as leg movements, nocturnal awakenings, or alpha oscillations. This notion fits with the subjective experience of increased emotional and physical arousal during nightmares. However, increased arousal in sleep is not a highly specific correlate of known sleep-related functions and also does not account for why sometimes nightmares are triggered and sometimes they are not.

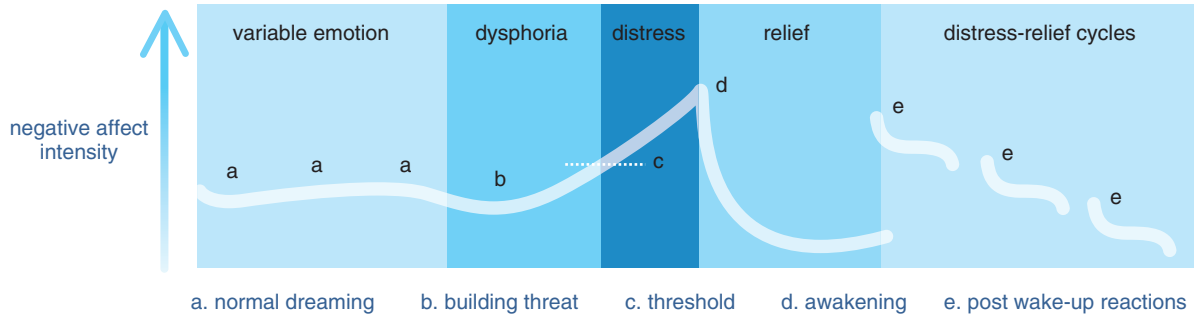
Overall, the inconsistencies and lack of replication studies in the sleep literature do not yet allow reliable links to be made between nightmares and known memory or emotion regulation functions of sleep.

NEUROPSYCHOLOGICAL STUDIES OF NIGHTMARE SUFFERERS ARE SCARCE

The testing of cognitive or neuropsychological attributes might illuminate the functional status of nightmares by revealing specific waking state deficits or advantages that are characteristic of this population. This is analogous to how such testing has revealed relationships between sleep-related memory consolidation and brain conditions like functional memory impairment[48] or mild cognitive impairment[49] or between cognitive competency (IQ) and sleep spindles.[50] However, research on nightmares is scarce. One study[51] of nightmare sufferers and controls revealed some performance deficits and some advantages on prefrontal and frontal-limbic measures of executive functions and emotion regulation. Nightmare sufferers showed general slowing on the Emotional Stroop, longer reaction times on the Emotional Go/NoGo, and slightly lower fluency and substantially higher perseveration on Verbal Fluency. On the Color-Word Stroop, however, nightmare subjects committed *fewer* errors than controls for incongruent word/color pairings, suggesting superior functioning on tasks implicating dorsolateral prefrontal and dorsal anterior cingulate regions.[51] Our attempt to replicate the elevated Verbal Fluency perseveration finding[52] was only partially successful; we failed to find a difference between nightmare and control groups, but we did show a positive correlation between perseveration and nightmare severity. These findings are thus consistent with the possibility of a dose-response relationship between frontal deficits and nightmare severity. Finally, neuropsychological studies of brain injuries and disease[31,53] reveal that nightmares with recurrent stereotypical themes are often associated with seizure disorders and usually involve lesions in the right temporal lobe.[31] Recurrently themed nightmares that replay the trauma are also characteristic of PTSD patients.[54] This particular type of nightmare, then, may reflect a fundamental neural dysfunction.

THERE IS A SPECTRUM OF NIGHTMARE FUNCTIONALITY THEORIES

In the present work we use the term *functional* to refer to a biologic, adaptive advantage attributed to nightmares (see review in Revonsuo[55]). The question of whether nightmares are functional has remained contentious since at least the time of Freud[56] and continues to divide opinion today. Freud, in fact, supported both points of view. He initially considered nightmares ("anxiety-dreams") to conform to his theory that dream function in general is to repress expressions of unacceptable unconscious impulses.[56] However, he also admitted that nightmares challenge this theory by recognizing a repetition compulsion in the more severe "war neurosis" nightmares and, later, other "immoral" dreams for which the dream work mechanisms of censorship had broken down.[57] In more recent times, with growing emphasis on the medicalization of nightmares (DSM),[1] as well as evidence linking nightmares to psychopathologic conditions, beliefs that nightmares have no function or are dysfunctional are widespread. Two such theories[58,59] single out nightmare awakenings as evidence that



Function step(s)	a	b	c	d	e
1. All nonfunctional	✗	✗	✗	✗	✗
2. Normal dreaming	✓	✗	✗	✗	✗
3. Normal dreaming/threat	✓	✓	✗	✗	✗
4. Threat	✗	✓	✗	✗	✗
5. Threat/distress	✗	✓	✓	✗	✗
6. Distress	✗	✗	✓	✗	✗
7. Normal dreaming/threat/distress	✓	✓	✓	✗	✗
8. Wake-up	✗	✗	✗	✓	✗
9. Recall	✗	✗	✗	✗	✓
10. All functional	✓	✓	✓	✓	✓
✗ = nonfunctional; ✓ = functional					

Figure 53-1 *Upper panel:* Five phenomenologic steps of a threat-based nightmare displaying increases in negative affect intensity (*pale solid lines*) and specific affective reactions (*top row of text*). The steps consist of a period of normal dreaming with variable emotions (a); a period of dreaming with building threat and concomitant increases in dysphoria (b) to an arbitrary threshold where the experience evokes increasing distress (c); an awakening, which brings relief and other feelings (d); and a series of postawakening reactions (e) when the nightmare emotions may be recalled, followed by progressively more relief. The latter step may last for minutes, hours, or longer. *Lower panel:* Ten possible theories classified according to where in the five-step sequence functionality is hypothesized to occur (✓) or not occur (✗). *Nonfunctional* theories (1)—at one hypothetical extreme—stipulate that all steps of a nightmare, including prior dreaming, distress threshold, waking up, and postwaking reactions, have no functional value, whereas *all functional* theories (10)—at the other extreme—stipulate that every step is functional. Other, less extreme theories (2 to 9) correspond to most published theories in stipulating that some step or combination of steps of the sequence may be functional. Not all of the 32 possible theories for this five-step sequence are shown. The content of dreaming does not figure in this hypothetical sequence but may nonetheless be decisive; in particular, if the dream replicates a prior trauma, a given step may be hypothesized to be nonfunctional.

dreaming's function has failed. A third[7] considers failures to regulate fear extinction during dreaming as responsible for dysfunction. Apart from these, however, theories formally describing nightmares as a functional failure are few. On the other hand, several functional theories invoke processes of emotion regulation (see later).

Although it may be tempting to view existing theories of nightmare functionality as dichotomous (i.e., that nightmares either are or are not functional), a closer consideration of the literature and of the dynamic phenomenology of nightmares suggests that a number of gradations of functionality falling between these two extremes have been described. As Figure 53-1 illustrates for the case of a simplified typical threat-nightmare, at least five phenomenologic steps with five accompanying emotional reactions unfold during a nightmare experience. These include a phase of normal dreaming, a period of building dysphoric emotion, an arbitrary threshold at which the dream passes over into a realm of distress, an awakening, and postawakening reactions. Theories may attribute functionality or a lack of it to any one or combination of these steps. The lower panel of Figure 53-1 details 10 hypothetical theories, some of which have analogues described in the literature (see later). For example, a theory that considers threatening dreams and nightmares to be functional regardless of affect intensity, such as theory 5,[55] would include steps b and c but not steps a, d, or e. In contrast, a theory that sees nightmares as wholly dysfunctional, such as theory 2, might include steps a or b, but not c, d, or e.[58] Even this detailed breakdown is not exhaustive; functionality or a lack of it can be attributed to specific types of dream content, such as problem-solving (functional) versus recurrent (dysfunctional) content.

Altogether, the empiric literature provides a poor basis on which to determine whether nightmares are functional and, if they are, what parts of the nightmare sequence sustain this function. Problems with how nightmares are conceived and categorized complicate the clear formulation of questions about functionality. The many types of nightmares and other disturbed dreams may or may not all serve the same function—if any at all. Without further taxonomic progress in the field, questions about nightmare function remain very speculative (see Nielsen[59a] for discussion).

A REVIEW OF NIGHTMARE FUNCTION THEORIES

In the following section, we discuss how several nightmare theories pertain to the question of function. Although a number of studies report evidence for genetic[60] and personality risk factors for nightmares, such findings typically have not been formalized into theories of nightmares with implications for function and so will not be considered further here. Also, *The Interpretation of Dreams*[56] heavily influenced many later nightmare theorists (e.g., Jones'[61] theory that anxiety-dreams contain unconscious sexual impulses) and remained influential among psychoanalytic thinkers for half a century. Only three theories that diverge in important respects from classical psychoanalytic thinking—by Kellerman,[62] Fisher,[39] and Palombo,[63]—are reviewed here. Most of the theories we consider share a general assumption that nightmares are implicated in the adaptive modification of emotional responses over time. We present these theories separately to highlight the more specific mechanisms of emotion regulation that they bring forward and to summarize the available empiric findings that support or refute each mechanism.

Emotion-Defense Regulation

One neo-psychoanalytic theory[62] diverged from Freud (1900) in attributing nightmare awakenings to ego defense mechanisms that fail to contain the overactivation of specific types of emotions—and thus fail in the dream's function. Nightmare awakenings are purportedly triggered by eight basic emotion types: joy, acceptance, surprise, expectation, anger, disgust, sorrow, or fear,[64] each of which produces a distinctive nightmare theme and, frequently, its own characteristic behaviors on awakening. For example, fear could lead to a terror nightmare with overt locomotion or speech on awakening; anger could lead to a rage nightmare with fist clenching; sorrow could lead to a grief nightmare with copious crying; and joy—paradoxically perhaps—could lead to a "pleasure" nightmare with nocturnal orgasm. This eightfold structure of nightmare themes was extended to include not only ego defense mechanisms—one type per theme—but also more general attributes of, for example, personality structure, cognitive orientation, and psychosomatic organ systems.[62] An intriguing component of this theory is that every nightmare is thought to contain an element of fear to the extent that there is resistance to fully express a predominant emotion while dreaming, such as a fear of letting anger amplify to overt rage or of letting joy or pleasure amplify to the point of orgasm.

Despite its clarity and accessibility, this theory has not been tested empirically and has fostered surprisingly little research; Google Scholar identified only 10 citations of the work over 27 years, and none was an empiric test of the theory. The theory is, however, generally consistent with current definitions of nightmares as including emotions other than fear as well as studies showing that awakenings from nightmares and other dysphoric dreams are often accompanied by dream-enacting behaviors in both parasomnias like REM sleep behavior disorder[65] and among the general population.[66]

Adaptation to Stress

Although early theories of dream function emphasized roles for REM sleep and dreaming in facilitating adaptation to stress, most of these dealt only marginally with nightmares. Thus, despite evidence that presleep stressors are incorporated into dream content or followed by an increase in dysphoric dream emotions,[67-70] findings were generally interpreted to indicate how normal dreaming was able to "master"[67] or "assimilate"[71] daytime stress rather than to explain how stress might trigger nightmares or how nightmares might modify stress. One exception to this trend was a focus on the possible role of nightmares in "war neurosis,"[72] now known as PTSD, which considered dream function to be mastery of stress and nightmares to reflect continuing attempts to master a trauma.

Another exception was the disruption-avoidance-adaptation theory,[73,74] which hypothesized that dreaming enables stress adaptation by its oscillation between two distinct functions: mastery and avoidance. Dreams about unresolved disturbing events are considered *mastery dreams* and have the potential to disrupt sleep—as in the case of awakenings from nightmares. Mastery is hypothesized to occur by a type of creative emotional problem solving that draws on memories of similar, yet successfully resolved, past situations. Emotional mastery is favored by the lack of interruption, disregard for social acceptability, and free-flow of ideas, thoughts, and emotions unique to dreaming. If dreams are too disruptive, however, awakenings and other sleep disturbances may result. *Avoidance dreams* prevent mastery attempts and thus sleep disruption by various processes (e.g., presenting dream emotions or specific contents that have no apparent relationship to the waking stressor). Oscillation between mastery and avoidance dreams continues, within and across nights, until adaptation is attained. Nightmares, because they disrupt sleep, are evidence of failure of both mastery and avoidance functions.

Evidence supporting stress adaptation theories is mixed. Some studies[75] found that dreaming about a stressful presleep stimulus led to improved mood in the morning, whereas others[76] found essentially the opposite. The disruption-avoidance-adaptation theory was presented specifically to deal with such inconsistencies. However, suggesting that post-stressor dreams may be either related or not to prior stressors amounts almost to an unfalsifiable theory. More detailed predictions are needed about precisely when, and in which sequence, mastery and avoidance dreams are expected following stress.

Desomatization

Fisher and colleagues[39] found that some REM sleep nightmares were not accompanied by the autonomic activation that would be expected for the degree of negative emotion reported in the nightmare. In 60% (12 of 20) of their recorded nightmares, emotion-related autonomic activation, as measured by heart rate, respiratory rate, and eye movement activity, were not seen. In other nightmares, such activity occurred only in the last few minutes of the REM episode. Similar findings were reported in a more recent study.[38] This apparent separation of seemingly fearful dream imagery from its expected autonomic correlates prompted the notion of REM dreaming as a mechanism for "tempering and modulating anxiety, for desomatizing the physiological response to it … [for] abolishing or diminishing the physiological concomitants" (p. 770).[39] This desomatization mechanism was thought to help protect REM sleep, to assuage anxiety during dreaming, and to decrease the degree of disruption that occurs after an awakening. This serves to prevent the self-perpetuation of anxiety and assist in the mastery of traumatic memories—even after

awakening.[39] A breakdown of the mechanism is suggested by intense autonomic activity while dreaming, as occurred in 40% of their recorded nightmares.

Similar desomatization notions have occurred sporadically in the literature, and slightly different desomatizing mechanisms have been proposed. A short note on a desensitization function of dreaming[77] and an empiric study on an anxiety-extinction function of nightmares[78] were both published shortly after Fisher and colleagues' work.[39] These authors suggested that nightmares facilitate extinction through repeated exposure to fear-inducing stimuli (like implosive therapy), but their own findings did not support the hypothesis.[78] Others have pointed to specific physiologic mechanisms of REM sleep that might be responsible for desomatization. These include REM sleep eye movements desensitizing affect by a mechanism similar to that of eye movement desensitization and reprocessing[79,80]; REM sleep atonia desensitizing the somatic component of negative affect by repeatedly blocking kinesthetic feedback during negative dream imagery[81,82]; and, in a related theory, the repeated pairing of dysphoric dream imagery and REM sleep atonia desensitizing anxiety in a manner analogous to systematic desensitization therapy.[83] In all such models, negative affect is considered to be implicated in desensitization up to a certain threshold; this threshold is clear when it is the point of waking up (analogous with flooding therapy) but otherwise remains undefined in most cases.

In addition to evidence replicating Fisher and colleagues' observation of desomatized nightmares,[38] there is evidence that dream emotion may be inhibited by REM sleep processes related to the orienting response[81] or modulated by two REM sleep mechanisms associated with threat-fear and loss-sadness.[29] Desomatization theories imply that negative emotion should be progressively reduced over time, especially within a single dreaming episode. Two studies suggest, in fact, that dream emotion becomes more negative over time.[84,85]

In sum, desomatization theories propose mechanisms of emotion regulation during dreaming and nightmares by which strong emotion is downregulated by its repeated pairing with processes such as autonomic inhibition, muscle atonia, eye movements, or orienting reactions.

Regulation of Negative Moods

The mood regulatory theory posits an emotion regulation function for dreaming[58,86] and is similar in many respects to desomatization approaches. It assumes that a cardinal characteristic of REM sleep is a surge of affective arousal that unfolds over the REM episode. The surge consists of a progressive increase and subsequent plateau in autonomic arousal as indicated by heart and respiratory rates, eye movement amplitude and density, and limbic system activity, among other markers. Dream content "contains" these surges by reducing the intensity and variability of the associated emotions. This is achieved by *progressive-sequential* patterns of dream content that unfold over successive REM periods and that facilitate emotional problem solving. The progressive-sequential dream pattern is distinguished from a *repetitive-traumatic* pattern during which an emotional conflict is simply stated and restated without evidence of adaptive change. Nightmares contribute to problem solving up to a point where the capacity for assimilation of emotional surges is exceeded. Similar mood regulation theories that consider nightmares to function as a coping mechanism for stress have been proposed by others.[87,88]

The physiologic assumption that REM sleep is surgelike in nature remains to be demonstrated empirically. However, dreams are influenced by presleep thoughts and emotions[89] and are related to the next day's mood[90]; the frequency and intensity of nightmares is associated with both increasing daily stress and increasing coping efforts.[88] Stress that is induced either experimentally (e.g., difficult intelligence test[76]) or naturally (e.g., earthquake[91]) leads to an increase in incorporation of the stressor in later dreams and nightmares. Moreover, overnight reductions in negative mood (e.g., unhappiness) correlate with intervening dream content, especially with the number of characters in a dream.[86] Consistent findings were also reported[92,93] by which high presleep depression scores were associated with more dysphoric dreams from the first REM period, but not with sleep physiology variables. Other supporting evidence from this group[87,94] shows that subjects in a marital breakup who report a predominance of early-night negative dreams are more likely to be in remission a year later than are those with more late-night negative dreams. Negative dreams occurring early in sleep may thus reflect a within-sleep mood regulation process similar to the problem-solving pattern that is triggered by a major emotional conflict; a predominance of negative dreams late in sleep may reflect a failure of this regulation function.

In sum, mood regulation models posit mechanisms for downregulating intense emotions by the nature and structure of dream content; this may implicate the regular coupling of emotional surges with a problem-solving dream structure that unfolds over time or the timing of negative dream emotion to occur early in the night.

Sleep to Forget and Sleep to Remember

The sleep to forget and sleep to remember theory[95,96] proposes that REM sleep serves a dual function in prioritizing consolidation of emotional memories and reducing the "affective blanket" that surrounds them. Emotion reduction prevents an unwanted build-up of anxiety in associated memories and thus helps prevent development of affective disorders. Dreaming consciousness is hypothesized to play a role in this function, and recurrent nightmares indicate repeated attempts (and failures) in this process of separating affective tone from emotional memory. The theory is supported by evidence that memory is better for emotional than for neutral experiences,[97] but also by observations that emotional arousal accompanying the remembering of experiences decreases over time. A central claim is that REM sleep reduces amygdala reactivity to memories while retaining the hippocampally held memory, possibly through the theta oscillations characteristic of REM sleep. Downregulation of emotion is attributed to reduced aminergic activity during REM sleep,[98] allowing a decoupling of a memory trace from its associated autonomic reaction.

The sleep to forget and sleep to remember theory is presented as complementing previous dream-based theories of emotion regulation[92,99] with a neurophysiologic explanation. It thus postulates a possible role for dreaming in completing this function, but does not specify the precise dream mechanism. Nonetheless, it is suggested that if emotion depotentiation is unsuccessful on a given night, further attempts on subsequent nights will appear in a pattern of recurrent REM

nightmares, as is characteristic of PTSD.[95] This theory thus associates recurrent nightmares with a failure of dream function.

Corroborating research for the theory is that REM sleep plays a role in emotional memory consolidation[100,101] and the fact that brain regions active during REM sleep overlap with regions implicated in emotional functioning, particularly the amygdala, the anterior cingulate, and the ventromedial prefrontal cortex.[102,103] A key study[104] demonstrates that participants deprived of sleep after memorizing emotional pictures show both reduced recall 72 hours later (poor memory) and lack of reduction in amygdala reactivity (increased emotion) when viewing the pictures a second time. Our recent study of an REM-sleep priming effect[105] supports the theory in that the presence of REM sleep predicts more priming to emotion cue words, although time in REM predicts less priming.

Fear Extinction

A recent theory[6,7] ascribes a fear memory extinction function to dreaming and explains nightmares as a perturbation of this function. Cognitive and neural levels of description are articulated.

Cognitive-Level Explanation

Fear extinction by this theory entails: the activation of fear memory elements such that they are isolated and removed from their episodic contexts, the recombination of these into novel here-and-now simulations of reality, the expression of alternate emotional reactions to this virtual context, and ultimately the production of new *fear extinction memories*. Fear extinction memories provide a sense of safety and thus compete with and, if consolidated, supersede the original fear memories. Fear extinction memories are realized by coupling fear memory elements with realistic nonaversive contexts that are incompatible with fear by a mechanism obeying Pavlov's[106] principles of fear memory learning and extinction.[107] Nightmares occur as a result of disruption of this mechanism. For example, if an entrenched fear memory resists recombining with new contexts, as might be the case for nightmares with recurrent themes, new extinction memories may not be formed. Or, if an extinction memory is not properly consolidated, an original fear memory may be reinstated.[108] Temperament may also interact with these basic extinction processes, especially one's susceptibility to *affect distress,* which could amplify the emotional responses produced.

Neural-Level Explanation

At the neural level, fear extinction is supported by a network of at least four regions that control the representation and expression of emotions in both sleeping and waking states: the amygdala, the medial prefrontal cortex (mPFC), the hippocampal complex, and the anterior cingulate cortex (ACC). Normally, these regions interact with larger integrated networks such as the default mode network[109] or the extended mirror neuron system.[110] Each region controls a set of extinction processes defined at the cognitive level of explanation. During nightmares, the amygdala may be hyperresponsive to fear-related memory elements portrayed in the dream, whereas processes in the mPFC, the hippocampal complex, or the ACC that normally downregulate amygdala activity may be disrupted. The result is the abnormally intense activation of fear. This situation parallels empirically supported models of PTSD pathology.[111] Affect distress, linked to ACC activity, is shaped by the emotional history of the individual (e.g., early adversity) but also by pain-related distress, social rejection, and difficulties with emotional expression.[112]

The fear extinction theory is grounded in a considerable amount of neuroscience research but has not yet generated a great deal of new findings. One test of the theory[51] used neuropsychological tests to assess involvement of frontal brain regions and supported the theory to the extent that frequent nightmare sufferers showed poorer performance on verbal fluency perseverations. These findings were partially replicated with a cohort of French-speaking participants.[52]

Cognitive Avoidance and the Limits of Fear Extinction: Recurrent Nightmares

Spoormaker[113] proposed a variation of the preceding theory to explain fear extinction failures in the subclass of nightmares with recurrent themes. The recurring storylines are stipulated to be "scripts" in memory that are easily activated by ongoing, neutrally toned dreaming and whose specific contents vary as a function of this prior dreaming. Recurring nightmare scripts may be based on real traumatic memories or may develop over time with repeated emotional stress, particularly if stressors are habitually responded to in a way that develops and reinforces the underlying script. Cognitive avoidance is the key mechanism by which occasional distressful nightmares may become recurrent. After awakening from such a nonpathologic nightmare, avoidance strategies (e.g., trying not to think about or remember the nightmare) lead to a failure of fear extinction as well as a reduced likelihood that the root script will be integrated into autobiographical memory or that alternative responses to the nightmare script will be discovered. In detailing the limits of fear extinction processes, this model clarifies the pathologic aspect of nightmare experience.

The theory's emphasis on recurrent themes fits well with the fact that the plot lines of many nightmares are, indeed, recurrent. An unpublished study found that of all nightmares reported by 188 college students, including those that were only occasional, 60% contained a recurrent storyline.[113] Among participants with a clinical nightmare problem (at least 1 per week), 91% claimed that their nightmares possessed recurrent storylines. The inherent dysfunctionality of recurrent nightmares also fits well with the finding that recurrent dreaming more generally is associated with poorer well-being.[114]

Image Contextualization

The image contextualization theory[115,116] highlights the role of emotion in dream formation and considers nightmares—as it does dreaming more generally—to play a role in adaptation to emotional experiences. Dream images are proposed to be driven by the emotions associated with current concerns; the more powerful an emotion, the more powerful and salient the central image of the dream. Recurrent and posttraumatic nightmares are among the clearest examples, but dreams of intense emotions of any type are included. The basic role of dreaming is to *contextualize* the imagery metaphorically within a safe context, that is, during REM sleep when muscular inhibition prevents acting out of the dream. An example of a central contextualizing dream image is the "tidal wave" dream, in which a powerful wave contextualizes feelings of overwhelming fear or helplessness stemming from a waking concern with similarly intense feelings. Contextualizing

depends on a hyperassociativity of neural networks during dreaming, that is, increased cross-connectivity among elements of the emotional concern and past similar experiences. As mnemonic connections increase, emotions become less intense and the concern is progressively integrated. The dream's adaptive function is likened to psychotherapy following trauma in that the therapist provides a safe context within which intense emotions may be expressed and linked constructively to other memories.[117]

Supporting evidence includes findings that powerful and salient central images are more frequent following trauma or abuse,[118] that REM sleep participates in the forming of hippocampus-dependent memories,[119] and that the hippocampus is central to the consolidation of memory for context.[120]

Threat Simulation

The evolutionary theory of threat simulation[55] suggests that the purpose of dreaming—including nightmares—is to provide a realistic (virtual) environment for confronting threatening situations and practicing threat perception and threat-avoidance skills. Repeated threat simulation over time increases the probability of successfully coping with real threats in wakefulness and confers a survival advantage to our species. The threat simulation mechanism is fully activated and thus produces more dreams with threats when the individual is exposed to heightened levels of daytime threat (e.g., living in a war zone). The high prevalence of dysphoric dreams and nightmares supports the theory because these commonly portray threats. Thus nightmares of being attacked or chased are considered functional to the extent that these provide opportunities to identify threatening situations that might be met in real life and to practice adaptive reactions to them. Research supporting the theory includes dream content analyses showing that college students report frequent threatening dreams that are both severe and realistic (e.g., aggression, misfortune themes) and during which appropriate responses are enacted by the dreamer.[121] Further, children subjected to high levels of threat (trauma), in fact, do dream more often and more intensely of threatening events.[122] Arguments against threat simulation theory claim that the threats created in dreams are too often unrealistic[123] and that the dreamer is too often unable to react successfully to the threat.[124] Realistic threats appear in less than 15% of recurrent dreams[125] and in only 8% of undergraduates' home dreams.[123] The experiencing of threat dreams also does not correlate with actual adaption to threatening events, as in the case of PTSD, in which reexperiencing nightmares are often debilitating. Further, the occurrence of nightmares before or after trauma exposure is often a risk factor for developing PTSD.[54]

POSTAWAKENING ADAPTATIONS

A number of approaches consider nightmares to be functional to the extent that reactions after waking up may play a homeostatic or adaptive role. One type of theory suggests that a postawakening function can be automatic. The *information-processing* or *memory cycle* theory[63,126] is a neo-psychoanalytic approach based on the notion that dreaming's function is the incorporation of important new experiences into long-term memory, that is, the affective integration of new with old memories. Anxiety dreams that produce awakenings have a particular functionality in that they signal a failure of normal affective integration but allow waking state processes to modify memory sources of the original anxiety dream. This leads to a modified *correction* dream the following night. Associating an anxiety dream with other thoughts, feelings, and memories essentially integrates the latter new sources of information with the original sources and provides new, more adaptive, memory sources for the correction dream. This postawakening integrative function may be automatic and preconscious, resulting simply from "having the dream in mind" during the day, or it may be deliberate, either by intentional reflection on the dream during waking or by the aid of a therapist. In either case, the corrective feedback leads to a permanent, adaptive reorganization of emotional memory structures. Recurrent anxiety dreams are thought to reflect a failure of affective integration *and* a failure of the correction dream to correct it. The theory has been subjected to very little empiric investigation and is supported only generally by evidence that REM sleep is linked to emotional regulation.

A second type of postawakening theory also considers that using dreams in a self-reflection or therapeutic context leads to biologic adaptations, but the mechanisms for such adaptations are not typically specified. One general goal of some such approaches is to alleviate the suffering associated with the nightmares using pharmacologic or behavioral approaches,[127] but another common goal is to use the nightmares as a source for uncovering focal emotional conflicts that can then be addressed therapeutically. In this case, nightmare-focused therapies have been documented for a diversity of emotional conditions, such as bereavement,[128] drug dependencies,[129] and general psychotherapy.[130]

CONCLUSIONS

Science still remains divided in many ways on whether the darker side of dream experience serves a purpose. Nightmares and other disturbing dreams have been clearly delineated as a pathologic condition that is comorbid with many other illnesses, a view that is broadly consistent with the notion that nightmares are either nonfunctional or dysfunctional symptoms. However, their nearly ubiquitous existence in the general population, including evidence for a much wider spectrum of disturbed and dysphoric dreams (e.g., bad dreams), points to the likelihood that some nightmares may, in fact, be a component of cognitive-emotional regulation or emotional memory processing functions. Nightmares that are neither too frequent, nor too severe, nor too recurrent in nature may be those that play a functional role.

Unfortunately, inconsistent and unreplicated findings from the sleep literature have not yet allowed consistent PSG profiles of either nightmare episodes or the typical sleep of nightmare sufferers to be claimed; reliable links to memory or emotion functions of sleep have thus not emerged. Similarly, a scarcity of neuropsychological findings provides few clues as to whether or how specific brain regions are implicated in nightmare formation or function.

Theories of nightmare function fall along a spectrum varying between functional and nonfunctional, with many differences in which parts of a nightmare progression should be considered as functional. Our analysis of the structure of typical nightmares dovetails well with the multifaceted nature of hypothesized nightmare functionality and demonstrates

how these hypotheses might readily be operationalized. Most functional theories consider nightmares to enable some type of emotion regulation function. Several of these were influenced by Freud's early work. Others attempted to incorporate findings from early investigations of REM sleep physiology. Yet others attempted to found their assumptions on both sleep laboratory findings and a wider understanding of the cognitive neuroscience of emotion. Postawakening theories of function also share the notion of emotion regulation; waking reactions to the nightmare—either spontaneous or therapist assisted—feed back into the nightmare production system with adaptive outcomes. The evolutionary threat simulation theory of nightmares is distinct from these theories in claiming that nightmares enable development of threat perception and threat coping skills.

Many of the theories propose a function for nightmares that is a simple extension of a more general function for dreaming and thus they more easily account for the wider spectrum of dysphoric dreams observed. Most theories differ in the nature of the hypothesized regulatory mechanism. Although they are often lumped together under a single category of emotion regulation, the mechanisms vary, including stress mastery, desomatization of affect, fear memory extinction, emotional contextualization, and others. Despite this variety, however, many nightmare theories remain relatively vague as to the key functional mechanism; for example, it is rare to find cellular- or systems-level explanations, and predictions are as a result not clear. For those theories that propose more detailed explanations, supportive evidence is either still controversial or lacking altogether. Some of the theories are applicable only to certain types of nightmare experience, such as recurrent nightmares,[31,113] fear nightmares,[6,7] or threat nightmares,[55] whereas others[62] deal with such a wide swath of emotions that, paradoxically, even intensely positive dreams are included. All of the theories could benefit greatly from an increase in empiric and comparative investigations.

CLINICAL PEARL

That nightmares are comorbid with many pathologic conditions, such as anxiety, neuroticism, and PTSD, indicates that they are symptomatic, but their ubiquity in the general population suggests that they may serve some functional purpose. If nightmares do facilitate emotional regulation or emotional memory consolidation as suggested by some theorists, they may need to be treated only when they are frequent, severe, and disruptive of daily functioning.

SUMMARY

Opinion is divided on whether nightmares have a function. Although the clinical definition of nightmares as pathologic suggests that they do not, epidemiologic evidence of the widespread occurrence of nightmares and other dysphoric dreams in the general population suggest that they do—at least if they are not frequent, severe, or recurrent in nature. PSG and neuropsychological studies are too inconsistent or scarce to permit drawing conclusions about nightmare function. Theories of nightmare function are multifaceted, attributing functionality to several of the phenomenologic steps of typical nightmares (e.g., preawakening vs. postawakening). Such theories vary in the mechanisms they propose to account for emotion regulation and include stress mastery, desomatization of affect, fear memory extinction, and emotional contextualization. However, supportive evidence is either controversial or absent.

Incorporation of Waking Experiences into Dreams

Michael Schredl

Chapter 54

Chapter Highlights

- Research on the continuity between waking and dreaming has clearly identified factors that affect the chances that waking-life experiences will be incorporated into subsequent dreams, such as emotional intensity, time interval between waking event and dreaming, and type of daytime activity.
- Because direct empiric tests of possible functions of dreaming are difficult to carry out, research on the continuity hypothesis may potentially provide hints about the functions of dreaming.
- Still unclear is whether dreaming is involved in sleep-dependent memory consolidation.
- The finding that social interactions seem to be integral ingredients of dreams that are closely associated with the waking-life social environment may point to the importance of dreaming in regulating and maintaining social relationships that have been essential for survival in hunter-gatherer societies over the history of mankind.
- Interesting yet unresolved is the question of why people dream about things they have never experienced in waking life.

The question of why people dream has fascinated humankind for centuries. Even though many hypotheses have been formulated over the years, starting from dreams as guardians of sleep[1] to theories that dreaming is a training field for consciousness,[2] the empiric testing of possible functions of dreams faces certain insurmountable obstacles. To elicit the content of a dream, the participant has to report the dream, but if the dream is reported in the waking state, it is not possible to differentiate between the effects of the dream within sleeping and the effects of the narration of the dream, for example, in obtaining creative ideas. In other words, it is not possible to study the effects of nonremembered dreams and, correspondingly, the possible benefits of dreams per se directly. In view of these difficulties, the empiric studies reviewed in this chapter are based on the question of whether the function of dreaming can be elucidated by examining reported dream content and its relation to waking life.

DEFINITION OF CONTINUITY

The occurrence of waking-life experiences in dreams was termed "day-residues" by Freud,[1] whereas the notion of the continuity hypothesis was introduced by Hall and Bell[3] and expanded by Hall and Nordby.[4] The following quotation illustrates the basic idea:

> This [continuity] hypothesis states that dreams are continuous with waking life; the world of dreaming and the world of waking are one . . . . The continuity may be between dreams and covert behavior (thoughts, feelings, and fantasies) or it may be between dreams and overt behavior ("acting out") (p. 104).[4]

Although the definition of dreams as recollections of subjective experiences that occur while sleeping[5] is widely accepted, a controversy has emerged over the years about what aspects of waking life are continuous with dreaming (discussed more fully elsewhere[6]). First, it should kept in mind that dreaming only very rarely includes exact replays of episodic memories[7]—that is, the continuity between waking and dreaming is seldom one-to-one. Second, in the original definition of the continuity hypothesis, Hall and Nordby[4] already specified two areas of waking life that presumably affect dream content, and subsequent researchers elaborated on this notion and studied various aspects of waking in relation to dreaming (Table 54-1). These aspects can be grouped into the two broad categories of "covert" and "overt" behavior, as mentioned earlier. These areas do not exclude each other; according to the model, they contribute together to the relationship between waking and dreaming. Thus, according to Hall[8]: "If the dreamer feels that the world presents a cold, bleak face, he may materialize this conception in the form of a cold climate and a bleak, rocky setting (in the dream)." This example illustrates how conceptions of the world might be reflected in dreams. If you look at the experiential level in waking life, it might be expected that such a person might have very few positive social relationships and feels miserable, so the dream could be seen as a reflection of these waking-life experiences. That is, the conception of the world is mirrored in the daytime experiences of the dreamer.

A similar argument can be made for emotions; feelings of loneliness in the waking state can be directly reflected in dream images of being alone. Stumbrys[9] emphasized a type of continuity rarely looked at by other dream researchers: the

Table 54-1 Aspects of Waking Life that May Affect Dreams the Continuity Hypothesis

Aspect of Waking Life	
Concerns	Actions
Conceptions	Interests
Thoughts	Unfinished business
Emotions	Psychological issues
Experiences	Worries
Preoccupations	Personal significant events
Fantasies	Meta-awareness

aspect of *meta-awareness*. The induction of lucid dreaming by means of the reflection technique ("Am I dreaming or am I awake?") is based on this continuity. Increasing reflective awareness about one's state of consciousness during wakefulness increases the awareness while dreaming and thus can increase lucidity.

Even though empiric research supports the continuity hypothesis of dreaming,[10] a point worthy of mention in this context is that a considerable number of dreams clearly are discontinuous with waking life—for example, flying dreams[11] or walking dreams in congenital paraplegics.[12] The first line of thinking is that such dreams presumably reflect waking-life thoughts, daydreams, and so on. But if the dreamer had never experienced something in waking life, such as with sight in congenital blind persons, it also should be difficult to imagine such experience in the waking state. Even though some continuity might be retained at the emotional level (waking-life emotions and dream emotions)—for example, flying dreams were associated with personality traits associated with positive emotions, whereas falling dreams were associated with traits associated with negative emotions[13]—the concept of discontinuity is still not well understood. Of interest, research in amputees[14] seems to indicate that dreams may reflect innate body images that are not based on experience. In addition, studies looking at pain in dreams,[15] for example, suggest that dreams also may reflect experiences based on mirror neurons, as with seeing someone in pain versus direct experience of the pain. Overall, studies carefully relating waking-life thoughts and fantasies in relation to bizarre dream content can be expected to help clarify whether these topics are still explained within the framework of the continuity hypothesis (reflecting waking-life thoughts) or whether it is necessary to expand this theory by elaborating the concept of discontinuity.

STUDYING THE CONTINUITY BETWEEN WAKING AND DREAMING

Over the years, different approaches have been applied for studying the continuity between waking and dreaming (Box 54-1). Because the methods can have a marked effect on the findings (see further on), a brief outline of the basic ideas of these approaches, with reviews of exemplary studies, is presented next.

The most detailed study looking at temporal references of dream elements was carried out by Strauch and Meier.[16] Fifty dreams stemming from REM sleep awakenings of five

Box 54-1 PARADIGMS FOR STUDYING THE RELATIONSHIP BETWEEN WAKING AND DREAMING

- Assessing temporal references of dream elements
- "Blind" analysis of dream series
- Diary studies
  - Within-subject approach
  - Between-subject approach
- Experimental manipulation of daytime experiences
- Lucid dreaming

subjects included 80 key role characters, 39 "extras" (persons playing a minor role in the dream), 74 settings, and 298 objects. The ability to relate these elements to waking life by the dreamer varied considerably: 25.6% (extras), 30.9% (objects), and 76.3% (key role characters). Thus, for 76.3% of the key role characters, the participants were able to find correspondences to their own waking life—they thought about a particular person, for example, or encountered the person in the workplace. Even though this method seems straightforward (and has also been used in clinical settings), several problems have been recognized. With inclusion of inner processes like waking thoughts, memory restrictions presumably would constitute a major limitation, because it is very difficult to recall all of the thoughts of the previous day, let alone of the previous week. Another issue is that of multiple correspondences of dream elements. Dreaming about one's mother, for instance, might correspond to a telephone conversation a few days ago or to a childhood experience. Owing to these difficulties, the findings obtained by the retrospective approach are necessarily limited in their interpretation regarding the continuity between waking and dreaming.

A very interesting approach called "blind" analysis was developed by Hall[17] and further pursued by Domhoff[18] and others.[19] Dream series are quantitatively analyzed by rating systems[20] or word search algorithms[19] and predictions are then derived as to what should be prominent in the dreamer's waking life. Analyzing the dream series of one subject, for example, Domhoff[18] found strong correspondences between the social interactions within the dream and the real-life social interactions with the person encountered by the subject (mother, sister, brother, friend). That is, if the relationship was full of conflicts in waking life, the aggressiveness/friendliness index for this dream character was high (i.e., many more aggressive interactions than friendly interactions). The major problem with this approach is that the matching between dream content and waking life of the dreamer is rather vague, depending on the data obtained through interviews carried out with the dreamer. If, for example, the participant is a student, false positives would be likely because the waking lives of students are in several aspects very similar.

A simple approach is using a diary in which the participants fill in daytime events and their dreams. In the study of Schredl and Reinhard,[21] the participants were asked after each dream whether the dream had any correspondences with the previous day(s), whereas in the study of Blagrove and colleagues,[22] the participants matched dreams and day reports after the 2-week period during which they kept diaries. The problem with this approach is that the subjectivity of each participant doing the matches can heavily influence the

findings, depending on how correspondences were defined (thematic, literal, metaphorical, and so on).

The diary method also can be used for testing whether interindividual differences in waking life are reflected in corresponding differences in dreaming. Schredl and Hofmann,[23] for example, correlated the amount of time spent engaged in specific activities during the day with the frequency of these activities in dreams. Persons who often drove in their waking lives also had driving dreams more often. The diary approach has the problem, though, that recording daytime experience (and dreams) can affect subsequent dreams and can therefore bias the results of this kind of study. A simplified version was applied by Schredl and Erlacher[24] using a questionnaire eliciting the amount of time spent in particular activities such as sports and reading and correlated these figures with the percentage of dreams including these topics. As expected, the amount of time spent in sports activities during the day correlated directly with the percentage of sports dreams, irrespective of whether the participants were sports or psychology students.[24]

Another option for studying interindividual differences in dreams is to look at specific populations—for example, comparing men and women, or patients with mental disorders and healthy control subjects. The basic idea is that the paired groups differ in some aspects of their waking life and thus should also differ in their dreams. For example, men dream more often about sex than women do,[20] reflecting the greater frequency of sexual fantasies in waking life typical of men.[25]

A further option is to study the effects of experimental manipulations of waking-life experiences on dreams. De Koninck and Brunette,[26] for example, exposed phobic participants to a snake (in a terrarium) and read them different stories before sleep onset. Of interest, the emotional tone of the story affected the participants' dream emotions but not the dream content. In addition, real-life stressors such as awaiting major surgery or an intensive group therapy session[27] also were studied and showed stronger effects than the experimental stressors. Within this context, it should be mentioned that the high percentage of laboratory references in dreams (approximately 20% in more than 2000 dreams collected in 12 studies) obtained on REM or NREM awakenings in the sleep laboratory clearly supports the notion of continuity between waking and dreaming.[28]

The last paradigm included in this brief review is lucid dreaming. Proficient lucid dreamers can carry out prearranged tasks in their dreams.[29] Remembering the instructions received while awake clearly indicates the continuity between waking and dreaming.[30]

EMPIRIC FINDINGS REGARDING THE CONTINUITY BETWEEN WAKING AND DREAMING

Time Course

Freud[1] summarized his own experiences and his literature review regarding the time course of dreams as follows: "Dreams show a clear preference for the impression of the immediately preceding days." This "preference" is embodied by the so-called day-residue effect. Subsequent studies[16,31,32] confirmed that events from the previous day are more often incorporated into dreams compared with events from past days, weeks, or years. Even though a diary study[33] confirmed this decrease in dream incorporation rates with increasing time intervals between waking-life event and dream, it should be considered that the aforementioned studies—as with Freud's observations and the literature he reviewed—applied the approach of assessing in reverse order the temporal references of the reported dream elements. If thoughts, emotions, and the like are included, it then becomes obvious that this approach is limited by the memory capacity of the dreamer; thus the decrease in more remote references might be explained by lack of recalling the corresponding waking experiences.

Several diary studies[22,34-38] found a *day residue effect*—that is, the highest incorporation rates were for events of the previous day. Also observed was a so-called *dream lag effect*, whereby the incorporation rate for events that happened 5 to 7 days before the dreams was higher than for events of the previous 2 to 4 days or those occurring more than 8 days earlier. These data have been interpreted as reflecting adaptive processes, especially in regard to social stressors and processes of memory consolidation.[38]

Of note, however, the study findings should be interpreted with caution, because diary studies are most likely to identify REM sleep dreams before awakening in the morning and thus are not representative for all dreams. Available evidence indicates that the first REM dreams of the night are more often affected by experimental manipulations applied before sleep[39,40] when compared with REM dreams later in the same night, and that dream elements of late-night REM dreams contain more remote references to waking life than do dream elements of early REM dreams.[41,42]

Studying the dream lag in laboratory dreams has shown that the dream lag effect was not present in NREM dreams but was seen only in REM dreams, but the mean time between sleep onset and these REM dreams was 6.16 hours; that is, on average, these were dreams of the latter part of the night. To follow up this line of thinking, it would be necessary to collect larger samples of REM dreams stemming from the first part of the night.

To summarize, according to the available evidence, the time course of incorporating daytime events may not follow a simple exponential function (with lower incorporation rates of more remote waking-life experience). Rather, processes related to memory consolidation or adaption to stressful social events apparently mediate the incorporation of waking-life experiences into dreams.

Effect of Experimental Manipulation of the Presleep Situation on Dream Content

Several studies[39,43-47] showed their subjects different films before the laboratory study night for the recollection of REM dreams. Of interest, in these studies, direct incorporation of the film topics into dreams occurred very rarely. By telling the participants a positively toned version versus a negatively toned version of the same story, De Koninck and Brunette[26] were able to manipulate the emotional tone of the dreams but not the content—that is, neither the phobic object (a snake) nor the control animal (a squirrel) showed up in the dreams, even though the participants were exposed to a snake before bedtime. Formal characteristics of dreams such as colors also have been successfully manipulated by having the subjects wear red goggles during the day, for example.[40]

Using the technique of dream incubation (dating back to ancient Greek traditions), the topics the dreamer wanted to dream about before sleep onset did not show up in the

dreams.[48,49] If, however, the participants were instructed to think about a current personal problem before sleep, the probability of dreaming about this problem increased from 20% to 40%.[16] Similarly, focusing on discrepancies between ideal self and current personality traits before sleep onset increased the probability of dreaming about this trait.[50] In contrast with the findings regarding dream incubation, a carefully designed study[51] indicated that the instruction to not think about the target person yielded more occurrences in subsequent dreams than thinking about the person—supporting the so-called ironic-process theory. Subsequent studies[52-54] using idiosyncratic intrusive thoughts as targets that should be suppressed (not thought about) replicated the findings of the first study. In a sleep laboratory study,[55] the same effect was found for sleep onset dreams, this time using an image of three white bears and the presleep instruction not to think about them.

Research using experimental manipulation of the presleep situation showed that stimuli that are not related to the personal life of the dreamer, even if they are not pleasant, do not exert a strong effect on subsequent dream content. The emotional tone of dreams is more sensitive to stressful stimuli, in keeping with the research findings that nightmare frequency is positively related to current waking-life stress.[56] The closer the topic is related to the personal issues of the dreamer, the higher the chance of an effect of presleep manipulation on dreams.

Effect of Waking Life on Dream Content: Field Studies

The effects of a large variety of waking-life activities and events on dreaming, ranging from media consumption to traumatic experiences, have been studied and are reviewed briefly here.

Approximately 50% to 70% of participants stated that TV viewing or reading books has affected their dreams.[57] In children and adolescents, media figures have been found in nightmares quite frequently.[58,59] Computer games such as Tetris or Alpine Racer and others have shown an effect on subsequent dreams.[60-62]

Spending time in everyday activities such as reading, driving a car, playing sports, or engaging in political discussion is directly related to the percentage of dreams that include these topics.[23,24,63] Similarly, the time spent with people of both sexes during the day is reflected in the ratio of male and female dream characters.[64,65] The romantic partner also plays a major role in dreams.[66,67] Of interest, daytime emotions related to encounters with friends had the strongest correlations with dream emotions, compared with academic studies or personal issues[21]—indicating that social interactions during the day have a considerable impact on nighttime dreaming.

One specific life event that shows a strong influence on dreaming is pregnancy.[68-70] Of interest, the overall emotional tone of dreams in pregnant women is negative, reflecting the fact that pregnancy can be quite stressful to mothers-to-be.[71] Even the dreams reported by the expectant fathers are affected by this life-changing event.[72] Divorce also has a negative effect on dreaming, for both the divorced parents and the children.[73,74]

In patients with insomnia, the occurrence of waking-life problems was correlated with the number of problems within the dream.[75] Overall, the dream studies in patients with mental disorders have shown that psychopathologic symptoms experienced during the day also were present in their dreams.[76-79] For example, the severity of depressive symptoms correlated with negative dream emotions,[80] and dream bizarreness was related to the severity of psychotic symptoms in schizophrenic patients.[81] Patients with eating disorders dreamed more about rejecting food (patients with anorexia nervosa) or more about food in general (patients with bulimia).[82]

Very stressful, traumatic events also affect subsequent dream content very strongly; recurrent nightmares of the trauma are a hallmark symptom of posttraumatic stress disorder (see also Chapter 56).[83] The effects of experiences related to the 9/11 terror attacks,[84] sexual assault,[85] childhood sexual abuse,[86] kidnapping,[87,88] accidents,[89,90] and war[91-93] on dreams can be detected even decades after such experiences in waking life.

Overall, trauma studies indicate that emotional intensity may be one of the factors affecting continuity between waking and dreaming—that is, emotionally more intense waking-life experiences are more likely to be incorporated into subsequent dreams than less intense experiences. Of interest, this plausible hypothesis has rarely been studied directly. From a methodologic standpoint, it seems to be important to use a design in which the emotional intensity of the waking-life event will be rated before the dream occurs; otherwise, the approach of retrospectively rating the emotionality of events that resurfaced in the dream presumably could be biased by hindsight: "I dreamed about this; therefore, it must be important."

In a diary study,[33] this problem was addressed by instructing the participants to keep a diary over a 2-week period to record the five most important events of the day and then to rate the emotional intensity and valence for each. The participants also recorded their dreams and checked whether any of the recorded events of the previous days showed up in the dream. The emotional intensity and valence of the incorporated event were compared with those for the other recorded events of the same day. The findings indicated that emotional intensity was higher for incorporated events, but emotional valence was similar for the events not incorporated.[33] That is, no bias toward incorporating more negatively toned waking life events was detected. The study of Malinowski and Horton[94] replicated this finding: Emotional intensity but not stressfulness was crucial for incorporation of content into subsequent dreams.

TYPE OF WAKING-LIFE EXPERIENCE

Already in 1909, Meumann[95] observed that reading and writing occurred very rarely in his dreams, although he was engaged in these activities up to 6 hours/day. Hartmann[96] compared the frequencies of reading, writing, and typing with other waking activities like walking, talking with friends, and sexuality-related behaviors and also found that the so-called three R's are less likely than other activities to be found in dreams. On the basis of his findings that emotional intensity of the waking-life activity does not necessarily explain these differences (e.g., comparing walking with reading), Hartmann[96] formulated the hypothesis that during cholinergic-driven REM sleep, focused thinking processes are not that easy for the brain to handle compared with the waking state. As a point of interest, "thinking" in general, such as about what other people think or what to do next, is quite common in dreams.[97]

The findings of Hartmann[96] were confirmed by several studies.[23,24,98] In a diary study[23] the so-called cognitive activities (reading, writing, calculating, working with a computer) accounted for 41.6% of the elicited waking-life activities (including talking with friends, driving a car, watching TV, using the phone, and being in nature), whereas only 18.6% of the dream activities fell into this cognitive area. The hypothesis of Schredl[98] that dreams are more likely to reflect "archaic" themes such as social interactions or being in nature was not supported by subsequent work from Schredl and Hofmann,[23] who found that driving a car, for example, was significantly overrepresented in dreams. The additional finding that talking with friends was also very common in dreams is in line with evidence showing briefer lag times for persons or characters and emotions until their incorporation into dreams[16,99] and might point to a preference of dreamers for social topics.

IMPLICATIONS FOR POSSIBLE FUNCTIONS OF DREAMING

Based on the well-documented findings that sleep contributes to memory consolidation,[100] the first question regarding the potential functions of dreaming that comes to mind is whether dreaming is reflecting the processes involved in sleep-dependent memory consolidation. In a nap study using a maze learning paradigm, performance gains were higher if task-related dreams were reported.[101] However, an overnight study[102] using mirror tracing as a procedural learning task did not show any relation between task-related dreams and next-day performance gain in the participants. In view of the fact that memory consolidation involves processes on both cellular (long-term potentiation) and network levels, the second question is whether dreaming (as experience that can be recalled on awaking) is connected to or can reflect these processes—similar to waking life, in that the brain is doing much more than thinking and experiencing. Of interest, training in a specific task during a lucid dream can enhance performance in the morning,[103] although this finding should be viewed with caution because it is uncertain whether simply recalling a dream of training for the task might enhance performance as opposed to the training within the dream (as described early in this chapter). In any case, whether dreaming is associated with or reflecting processes crucial to sleep-dependent memory consolidation has not yet been ascertained.

The research regarding the temporal references of dream elements (see earlier) indicates that new information is mixed with experiences from the distant past. In addition, dreams are creative—that is, they form new associations instead of just replaying daytime experiences.[104] This scenario parallels processes typically involved in problem solving. First, compare the new incident with previous successfully handled experiences, and second, if no strategy is already available, try something new (brainstorming). In view of this analogy, proposing problem solving and adaptation as possible dream functions[105] seems plausible.

The finding that emotional intensity but not emotional tone or stressfulness affects the incorporation of daytime events into dreams[33,94] renders unlikely those dream functions that are focused solely on negative dream emotions such as the threat simulation theory,[106] even though it does not exclude learning about places that might be dangerous as one of the functions of dreaming.

Finally, several findings indicate a strong continuity between the social environment of the dreamer in the waking state and social interactions in dreams. Emotionally "close" persons often play an important part in dreams,[66] emotions related to close persons have strong effects on dreams,[21] and social interactions are overrepresented compared with academic activities.[23] This continuity may point to another evolutionary aspect of dreaming (in addition to avoidance of being eaten before producing offspring): the importance of the social network for survival in hunter-gatherer societies. That is, it is essential to (1) get along with other group members and (2) not be ostracized by the group.[107]

To summarize, all of these ideas about dream function are, of course, highly speculative, but studying the continuity between waking and dreaming may potentially shed light on this still-unanswered question about the function of dreaming.

FUTURE DIRECTIONS

The review of the evidence presented in this chapter clearly shows that research into the factors that have an effect on the continuity between waking and dreaming is still in its infancy. Schredl[10] proposed a mathematical model to promote more systematic research on the effects of time, emotional intensity, and so on on the incorporation rates of waking-life experiences into subsequent dreams. Methodologic problems concerning how to measure waking-life experiences (e.g., type, frequency, intensity) and how to relate these measures to dream content are not yet solved and require more empiric testing. Another line of research was suggested by Schredl and Reinhard[21] reporting on the so-called second-order effect of continuity—that is, dreams that were affected by the previous day are more likely to affect the mood of the following day. A plausible interpretation of this finding would be that some themes, topics, and concerns are processes that day and night occupy the affected person's consciousness. Finally, studying dreams that are clearly not continuous with waking life (such as, for example, flying dreams) would be most beneficial in elucidating why people can dream about things, such as pain,[15] never experienced in waking life, or in explaining the occurrence of walking dreams in congenital paraplegics.[108]

CLINICAL PEARL

In clinical encounters in which the patient relates the specifics of a dream, it is important to identify the basic pattern of the dream, because this pattern is most likely to be continuous with the person's waking life. For example, if dream content includes being chased by a monster, the basic pattern is one of anxiety and avoidance. The question is then whether avoidance of something or someone is an issue for the patient in his or her waking life.

SUMMARY

Research on the continuity between waking and dreaming has clearly identified factors that affect the chances of incorporating waking-life experiences into subsequent dreams. Because direct empiric tests of possible functions of dreaming are difficult to carry out, the question arises as to whether the research on continuity may provide hints about the functions

of dreaming. Still unclear at this stage is whether dreaming is involved in sleep-dependent memory consolidation. The finding that social interactions seem to be integral ingredients of dreams that are closely associated with the waking-life social environment may point to the importance of dreaming in regulating and maintaining social relationships that have been essential for survival in hunter-gatherer societies over the history of humankind. An interesting yet unresolved issue is the question of why people dream about things they have never experienced in waking life (discontinuity).

Dreams and Nightmares in Posttraumatic Stress Disorder

Chapter 55

Wilfred R. Pigeon; Thomas A. Mellman

Chapter Highlights

- Posttraumatic stress disorder (PTSD) develops in a significant minority of persons who are exposed to severely threatening trauma. Trauma-related nightmares appear to be specific to PTSD and can be a persisting and distressing symptom, although not all dream content reported by persons with PTSD is a direct representation of trauma memories.
- Stress and trauma appear to acutely affect the thematic content of dreams irrespective of whether the dreamer goes on to experience continuing emotional distress. Dreams that more specifically replicate the memory of the trauma during the early aftermath of exposure have been associated with the development of PTSD. Findings from experimental and naturalistic studies suggest that dreams can positively influence adaptation to stress and trauma, also suggesting that persisting trauma-related nightmares may represent a failure of adaptive mechanisms.
- Findings from polysomnographic studies of PTSD have not been entirely consistent. Generally, a majority of nightmare episodes of study subjects with PTSD arise in rapid eye movement sleep, although they also can be accompanied by non–rapid eye movement sleep. Additionally, the rapid eye movement sleep of PTSD subjects tends to be more fragmented than that of healthy sleepers, and this pattern may be predictive of PTSD in the acute aftermath of trauma.
- In contrast with normal dreams, dreams in persons with PTSD often incorporate actual memories of frightening experiences. These features have implications for understanding neurocognitive substrates of dreaming and the development of integrative PTSD pathophysiology models.
- Evidence supports that pharmacologic antagonism of noradrenergic receptors ameliorates nightmares in PTSD, as do psychological treatments that use exposure to, and/or cognitive restructuring of, nightmares.

REPLICATIVE-TRAUMA NIGHTMARES: HALLMARK OF A DISORDER?

Posttraumatic stress disorder (PTSD) is a psychiatric condition that develops in approximately 10% of persons who experience severely threatening traumatic experiences.[1] The diagnosis is based on a set of four persisting symptom clusters: intrusive symptoms such as reexperiencing the trauma with intrusive images, flashbacks, or nightmares; avoidance of trauma-related stimuli; negative alterations in mood or cognition; and heightened arousal and reactivity. The course of PTSD can be self-limited, but in approximately a third of cases the disorder persists for many years, and it often manifests with comorbid psychiatric conditions (see also Chapter 136). The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* specifically delineates "recurrent distressing dreams in which the content and/or affect are related to the traumatic event" among the intrusive symptoms.[2] In an influential review and theoretical paper, Ross and colleagues emphasized the occurrence of "repetitive replicas" of trauma scenes as a feature of dreams that is virtually specific to PTSD, further referring to rapid eye movement (REM) sleep disturbance and trauma nightmares as a "hallmark of the disorder."[3] A recent review of this hypothesis maintains that nightmares constitute a signature feature of PTSD.[4]

Whereas the overall rate of frequent nightmares (one or more per week) is 2% to 5% in the general adult population,[5-7] approximately half of all patients with PTSD have frequent trauma-replicating nightmares, and another 20% to 25% experience nightmares that are thematically or symbolically related to their traumatic event.[8-10] Among children, rates of nightmares range widely, from 7% to 20% in the general population and 20% to 81% in trauma-exposed samples, with the highest rates observed among those with diagnosed PTSD[11] and extreme living situations such as in war zones.[12] In addition, even compared with patients with idiopathic nightmares, patients with PTSD have an elevated frequency of nightmares.[8,9,13] Treating patients who have PTSD often leaves the clinician impressed with the impact of distressing dreams featuring traumatic experiences. Recurrent dreams, in general, are associated with more negative dream content, increased distress, and a lower degree of psychological well-being compared with nonrecurrent dreams[14]; the content of PTSD nightmares, however, also tends to

be more replicative of traumatic experiences and even more distressing.[15]

Several studies support the specificity of the relationship between trauma-related nightmares and PTSD. Van der Kolk and colleagues[16] reported that patients with combat-related PTSD were more likely to indicate that their nightmares exactly or almost exactly replicated an actual event, as compared with nightmare sufferers who did not have PTSD. Mellman and associates[17] surveyed combat veterans from clinical and nonclinical settings and found that nightmares about combat experiences were more specifically associated with PTSD than were nightmares on other topics. In an analysis of a large epidemiologic database on Vietnam veterans, a measure that combined instances of nightmares related to military experiences and of distress from dreaming was strongly associated with PTSD.[18] The relationship between replicative nightmares and higher PTSD severity has been observed in patients as long as 40 years after a traumatic event.[19]

The available evidence thus provides consistent support for the theory that continuing representation of trauma memories in dreams is a feature of PTSD but not necessarily of trauma exposure absent the diagnosis. The aforementioned studies relied on retrospective and global, categorical assessments of dreams. Esposito and coworkers[20] performed content analysis of dreams elicited from morning diaries in a group of combat veterans receiving treatment for PTSD. Approximately half of the subjects' dreams contained direct references to combat experiences, and almost all of the dreams featured threat. A majority of these reported dreams also were similar to normal dreams in that they contained implausible elements that were not representations of actual memories. Similarly, among a group of combat veterans experiencing PTSD symptomology, approximately half of the dreams elicited after awakenings in the laboratory setting referred to military experiences.[21] These studies all focused on data for combat veterans many years after their combat experiences.

Several studies have examined the influence of trauma on dream content during an acute phase after the traumatic event. In the 2 months subsequent to a hurricane, dream questionnaires from 22 primary care patients were compared with those for a larger sample surveyed before the hurricane (n = 265). A significantly higher percentage of the posthurricane subjects reported that their dreams were related to general stressors (74% versus 48%) and to "especially stressful life experiences" (67% versus 37%), although only 13% reported dreams specific to the hurricane.[22] Similarly, evacuees of an urban fire were more likely than control subjects to have recorded dreams in their home diaries with content related to death, disasters, and fires.[23] Among children and adolescents, a similar pattern of trauma event incorporation into early posttrauma dreams has been observed. This pattern was seen among all 23 children kidnapped and buried underground in a trailer,[24] in 8 of 10 children who witnessed rapes,[25] and in 63% of those on a playground during a sniper attack,[26] with higher rates of trauma dreams correlated with proximity to the threat or reflecting direct versus indirect association with the trauma.[26,27] In review of the pediatric literature, these types of findings are more mixed among children than among adult studies.[11,28] In both the children and adult studies, most reports do not relate dream content to PTSD status. In a sample of 13- to 18-year-old Afghan unaccompanied youths seeking asylum in the United Kingdom, PTSD symptoms were measured and found to be correlated with nightmare frequency, although dream content was not assessed.[29]

Mellman's group elicited dream content from study participants during the acute aftermath of traumatic injury.[30] A subgroup of the sample described dreams that were distressing and "highly similar" to the traumatic experience (17% of the sample; 56% of those who reported dreams). Subjects in this group had more severe concurrent PTSD symptom ratings than those in the groups with other categories of dreams, and they had higher subsequent PTSD severity than the subjects who did not recall dream content.[30] Wittman and colleagues observed a similar pattern in children immediately after motor vehicle accidents, with acute replicative nightmares predicting PTSD symptoms 2 and 6 months later.[31]

Thus, in trauma-exposed populations, dreams with specific trauma-related or thematically related content are typically reported during the acute aftermath of disasters and other traumas, and dreams that are similar to the memory of the actual traumatic event are associated with the development of PTSD. Chronic PTSD is associated with recurring dreams that represent specific memories of a traumatic experience. However, the more comprehensive evaluations of dreams during chronic phases of PTSD document that salient dream content is not limited to representations of traumatic memories.

DREAM CONTENT WITH STRESS AND TRAUMA: BEYOND REPLICATION

Although the issue of trauma replication has received considerable attention, other aspects of content have been described in the literature on dreaming, nightmares, and PTSD. The boundaries of traumatic stress are not always clear, and the topic seems embedded in broader questions of stress and dreaming, including observations of the impact of stressful experiences on dreams, the influence of dreams on adaptation to stressful experiences, and content themes related to trauma exposure and PTSD beyond replication of trauma.

Stress and Dream Content

It has been consistently observed that dream narratives incorporate elements of current concerns including the incorporation of daily stressors as distressing dream content.[32] Studies of naturalistic stressors have suggested an impact of stressful waking experiences on dream content. For example, health-related stressors have been evidenced in the home dream content of patients awaiting surgery,[33] in hospitalized burn-injured patients,[34] and in pregnant women.[35,36] In addition, the dreams of women with stressful menstruation are more likely to contain emotional content and relationship themes during the peak hormonal phase than those during other days in the menstrual cycle.[37] Academic and occupational stresses also have been associated with dream content, including increased dream recall in college students a week before final examinations compared with that during a control week.[38] Correlations also have been found between recurrent nightmares, dreams of being chased, and dreams of falling with both graduate students' financial stress[39] and stockbrokers' stress levels during market downturns.[40] Living in threatening

environments is correlated with increased threatening dreams in traumatized Kurdish children.[41] However, dream reports of South African people living in areas of high crime did not differ in the frequency of threatening content from that for a control Welsh sample.[42] Of interest, several dream-reporting studies were undertaken around the time of the September 11, 2011 terrorist attacks in the United States. Although their methodologies varied, each study concluded that the attacks were associated with increased intensity of dreams compared to pre-9/11 dreams,[43-45] but only two of the studies found that post-9/11 dream narratives contained explicit references to the terror attacks.[45,46]

It has been noted that recurring dreams, which have more negative content than nonrecurring dreams, tend to be activated by stressful life experiences.[14,47,48] In a community sample, subjects with active recurring dreams reported greater life stress in the previous 6 months and had more negative dream content than both former recurrent dreamers and dreamers who had never had recurrent dreams.[49] These findings were replicated in two college student samples.[38,50] In addition to these naturalistic observations, several older studies used experimental induction of stress and examined dream content. Disturbing movies,[51,52] sham intelligence examinations,[53,54] and experimentally induced pain[55] all have been incorporated into dreams collected in the sleep laboratory. Overall, experimental stressors are associated with subsequent dreams that are characterized by a negative tone. Although difficult to quantify across studies, both naturalistic and experimental stressors are incorporated into dream content with several caveats. If they are not severe enough and/or salient to the dreamer, they may not appear as precisely replicative of the stressor, and their incorporation is likely to be influenced by individual subjects' characteristics.

Although available evidence suggests that relatively innocuous daytime events and concerns can be incorporated into dreams, it seems reasonable to infer from the studies just reviewed that stressful waking experiences are more likely to be incorporated into dreams and have an impact on dream emotional content. This relationship of dream incorporation to emotional saliency has led several dream theorists to invoke an emotional information processing function for dreaming.[33,56-58] The threat simulation theory of dreaming further posits an evolutionary function of dreaming, one that simulates realistic threats within the safe space of the dream world to permit adequate rehearsal and preparation for future threats in waking life.[59] Although it has been difficult to confirm that threat rehearsal occurs in dreams, several lines of evidence support a relationship between dreams and adaptations to emotional stress.

Dreams and Adaptation to Stress

In one of the experiments that used viewing a disturbing film as a probe, volunteer subjects experimentally deprived of REM sleep were subsequently more distressed by the film than either an non–rapid eye movement (NREM) sleep interruption group or an uninterrupted sleep group.[52] Naturalistic studies suggesting that dream incorporation can aid adaptive processing include several that found that references to drugs and alcohol in dreams are a positive predictor of abstinence.[60-64] Cartwright and colleagues[56] elicited dream reports after laboratory awakenings from REM sleep in men and women going through divorce, the first near the time of the initial breakup and a second 1 year later. Those who incorporated the ex-spouse into their dreams at the time of the breakup were less depressed and better adjusted at the 12-month follow-up evaluation than those who did not. These two sets of observations initially might seem to contradict the observations reviewed earlier of an association between trauma-replicating dreams and the outcome of PTSD. The observations just reviewed, however, refer to incorporation of a reference or representation of a stressful situation and not necessarily to the replication of events.

For dreaming to influence emotional adaptation to stress, the neurocognitive activity of sleep must have an enduring influence on memory representations. Support does exist for sleep's role in the consolidation and reprocessing of memory (i.e., learning), which is reviewed in Chapter 22.

Trauma, Posttraumatic Stress Disorder, and Content Themes

Dow and colleagues[65] studied depressed combat veterans with and without PTSD. They examined dreams collected from both groups in the sleep laboratory after awakenings from REM sleep. The PTSD group's dreams were rated higher for anxiety and were more likely to be set in the past. Another laboratory study of veterans found more frequent aggression in the dreams of subjects with combat-related PTSD compared with the dreams of healthy control subjects.[66] Ratings for anxiety, aggression, and interpersonal conflicts were greater in the dreams of a symptomatic subgroup of Holocaust survivors.[67] In a study of combat-related PTSD in which dream recall was stimulated using diary records filled out in the morning, threatening content was observed in a majority of dreams (83%) with and without the presence of combat references.[20]

Studies relating dream content to trauma exposure in children also have described content themes beyond representation of the trauma. The dreams of Palestinian children exposed to ongoing civil and military violence, elicited by home diaries, contained more themes of aggression, persecution, and negative emotions than dreams recorded by children living in a more peaceful region.[68] Kurdish children with trauma exposure evidenced more dreams with threat and aggression than either those in a nonexposed group or children in a control group from a peaceful country. Unfortunately, neither of these studies determined the PTSD status of their subjects.[41]

In a study of patients with recent traumatic injuries, dreams of those in whom PTSD subsequently developed had more content related to general and physical misfortune, as well as more negative emotions, than those in whom PTSD did not develop.[69] Thus, compared with other dreams, dreams after trauma have more general negative emotions, anxiety, threat, and aggression, and these appear to be most pronounced with PTSD.

POLYSOMNOGRAPHIC CORRELATES OF NIGHTMARES IN POSTTRAUMATIC STRESS DISORDER

An association, albeit not an absolute one, between dreams—particularly those with content that is more elaborate, visual,

emotional, and bizarre—and REM sleep stage has been recognized.[70] Other sleep phenomena, such as night terrors and related parasomnias, arise in NREM sleep stages, particularly slow wave sleep.[71] Owing to the atypical aspects of dreams from patients with PTSD, interest has emerged in determining their relationships to stages of sleep. It has been asserted that nightmares in PTSD are associated with NREM sleep. In one study, body movement occurred during stage 2 sleep when nightmares were reported in the morning.[16] In another study in a group of 24 subjects evaluated in the sleep laboratory, Kramer and Kinney[72] identified a subgroup of 8 combat veterans with nightmare symptoms who reported a majority of their nightmares after awakening from stage 2 sleep.

By contrast, the one spontaneous nightmare awakening that occurred during sleep recordings in a study by Ross and coworkers[3] and three recorded by Mellman's group were preceded by REM sleep.[73] Hefez and colleagues[74] described a pattern of REM interruption insomnia in a group of patients with PTSD reporting nightmares. The largest sample of polysomnographically recorded spontaneous nightmares ($n = 17$) for patients with PTSD was reported in an abstract by Woodward and colleagues.[75] These workers indicated that the probability of REM sleep occurring in the 10 minutes preceding spontaneous awakenings with nightmares was 57%, whereas only 17% of total sleep was REM. The probability of sleep preceding nightmares featuring stage 2 (27%) was less than its percentage of total sleep. None of the nightmares emerged during slow wave sleep. Thus, on balance it seems that nightmares in PTSD tend to be preceded by REM sleep, but they sometimes emerge in other sleep stages (1 and 2). The characteristics of nightmares in PTSD, however, can contrast with normative features of dreams associated with REM sleep, such as a lack of correspondence with actual events, bizarreness, and mixing of time frames and contexts.[70,76]

The observations reviewed in previous sections of this chapter suggest that associative memory functions linked to REM sleep may facilitate emotional adaptation. As previously mentioned, a relationship has been noted between the development of PTSD and dreams that were rated as being very similar to the trauma memory.[30] In a subsequent study of patients hospitalized for traumatic injuries, polysomnographic recordings were obtained close to the time of medical and surgical stabilization. Patients in whom PTSD subsequently developed did not differ from those in whom PTSD did not develop with respect to general measures of sleep maintenance, amount of REM sleep, and increased eye movement density (compared with uninjured control subjects). The group in which PTSD developed, however, spent significantly less uninterrupted time in REM sleep before shifting to waking or other EEG sleep stages,[73,77] which also was observed among a community sample of subjects with PTSD.[78] Other disrupted sleep characteristics reported during REM sleep of persons with PTSD are hypothesized to be indices of the heightened arousal that is symptomatic of PTSD and include higher sympathetic heart rate variability indices,[79] more periodic leg movements,[80] higher beta frequency power,[77] and lower theta frequency power.[81,82] The most consistent polysomnographic finding in patients with PTSD, however, appears to be one of increased REM fragmentation.[83] We hypothesized that this observed fragmentation of REM sleep may compromise REM sleep's potentially adaptive memory-processing functions.[73]

CONCLUSIONS AND THEORETICAL IMPLICATIONS

The representation of the memory of a traumatic experience in dreams is a distinguishing feature of PTSD. Although having characteristics different from those generally ascribed to dreams arising in the REM sleep stage, PTSD dreams appear most often to be associated with REM sleep, although they can emerge in stages 1 and 2 as well. Traumatic and stressful experiences appear to influence dream content whether or not the affected person is successfully adapting emotionally.

Findings suggest that nightmares that are replicative of the actual memory of the trauma experience are associated with the development of PTSD. When PTSD enters a chronic phase, trauma memories continue to be represented in recurring nightmares. Dream content of patients with established PTSD is not limited to trauma memories, however, and it might reflect the negative and restricted emotional state of the dreamer in other ways as well. The literature on stress and dreaming suggests that dream content reflects the emotional processing of the dreamer and that dreams potentially have a positive influence on emotional adaptation. By contrast, recurring nightmares in patients with PTSD appear to reinforce the memory of the trauma and contribute to the dreamer's distress. The distinguishing feature of replicating or representing the memory of the trauma over time might provide important clues regarding what is not working in the dream life and the more general emotional memory processing in people with PTSD.

Fosse and colleagues[84] have found that dreams recalled by healthy college students often contain references to recent experiences, but the events' representation in the dreams rarely corresponds to actual events. The researchers concluded that normal dreams are not episodic memories. Noncorrespondence to coherent whole-memory representations and other characteristics of dream mentation are thought to be consequent to the selective activation of neural structures during REM sleep. In the generally accepted model of sleep state regulation, neural activation during REM sleep is mediated by firing of cholinergic brainstem nuclei and is further facilitated by inhibition of noradrenergic firing.[76]

As has been discussed, the dreams that characterize PTSD are not necessarily unaltered replays of the traumatic event. Yet a tendency has been noted for dreams occurring with PTSD to contain more representations of events that include or are closer to unaltered memories (of traumatic events) than in normal dreams. Experimental evidence indicates that declarative memory for emotionally arousing stimuli is mediated by noradrenergic mechanisms.[85] Impaired inhibition of noradrenergic tone during sleep, therefore, could be a mechanism underlying the presence of episodic-specific, fear-enhanced memories in dreams. Direct support for this hypothesis comes from evidence that pharmacologic blockade of noradrenergic stimulation with prazosin, an $alpha_1$-noradrenergic antagonist, ameliorates nightmares in PTSD.[86]

A further consideration regards an adaptive memory-processing function for REM sleep and REM dreaming that may be impaired with PTSD. Normal dream mentation has a hyperassociative quality. Characters, places, and sequences that typically are not linked in waking conscious thought tend to be juxtaposed in dreams.[76] Foa and colleagues[87] have

suggested that one of the mechanisms of successful emotional processing during exposure therapy is the development of a new network of associations with the traumatic memories. Such a process may be facilitated by the normal neurocognitive characteristics of REM sleep and impaired by a more selective activation of trauma memories.

More recent neurocircuitry models of PTSD posit that the ventromedial prefrontal cortex fails to inhibit the amygdala, leading to attentional bias toward threat, increased fear responses, impaired extinction of traumatic memories, and deficits in emotion regulation.[88,89] These models inform, and can be informed by, the growing specificity of theories and models of how sleep neurobiology contributes to adaptive and maladaptive emotional processing of traumatic memories. This area of investigation includes an interesting proposition that eye movement desensitization reprocessing, a successful form of PTSD treatment, may have as a mechanism of action induction of an optimal REM sleep–like state in which hippocampal mediation of episodic trauma memories and their amygdala-dependent affective valence can be integrated into broader cortical networks.[90] Nielsen and Levin have updated a neurocognitive model of nightmare production incorporating findings from sleep and PTSD neurobiology to explain how extinction (and consolidation) of fear memories can occur.[91,92] Finally, Germain and colleagues have proposed that amygdala hyperactivity and attenuated medial prefrontal cortex activity are tied to whole-brain neuronal activity in NREM sleep, which would be permissive of insomnia,[93] and that REM sleep amplifies activity of the amygdala and the medial prefrontal cortex, which would be permissive of nightmares.[93] Conceptual models such as these, which integrate new neurobiologic findings from both the sleep and PTSD fields as well as their respective clinical research findings, will be needed to guide empirical inquiry into the role of recurrent traumatic dreams in PTSD pathophysiology. At the same time, trauma-related nightmares, as well as their response to various treatment strategies, can inform models of central PTSD mechanisms.

TREATMENT OF POSTTRAUMATIC NIGHTMARES AND RELATED SLEEP DISTURBANCES

A number of treatments, particularly selective serotonin reuptake inhibitor antidepressant therapy and cognitive-behavioral psychotherapeutic techniques, have been documented to be effective for treating PTSD and are included in treatment guidelines.[94-96] Reports of the treatment studies typically indicate reduction in the severity of reexperiencing symptoms but do not specifically parcel out the treatment effects on nightmares. It is likely that nightmares tend to decrease in frequency and intensity as PTSD generally abates. Clinical experience and literature on the treatment of residual sleep symptoms, however, suggest that especially insomnia and/or nightmares can be inadequately responsive to first-line interventions for PTSD.[97-101]

Formulations discussed in preceding sections suggest pharmacologic and psychotherapeutic approaches for targeting PTSD nightmares. Clinical research evidence now supports efficacy of treatment strategies that are consistent with the previously stated theoretical formulations. For instance, a therapeutic effect of postsynaptic blockade of noradrenergic neurotransmission is consistent with the role for noradrenergic activity in mediating traumatic nightmares that was postulated in the previous section. In this regard, prazosin has now been demonstrated to have a placebo-controlled effect on nightmares in several populations.[102-105] Evaluations of other pharmacologic approaches to target nightmare symptoms of PTSD have mostly not been controlled or not been promising in double-blind trials. The 2010 American Academy of Sleep Medicine's best practice guide for the treatment of nightmare disorders recommends only prazosin based on its designation of "level A" evidence; a number of agents (atypical antipsychotic medications, cyproheptadine, fluvoxamine, gabapentin, low-dose cortisol, nitrazepam, phenelzine, topiramate, trazodone, triazolam, and tricyclic antidepressants) were deemed to have "level C" evidence for their use.[106] A meta-analysis confirmed that prazosin is an effective agent for nightmare treatment, with a moderate effect size similar to that of psychological therapies.[107]

In addition, the idea that dreams are related to both successful and impaired patterns of emotional processing suggests that recurrent nightmares related to trauma might respond to psychotherapeutic interventions. In fact, several clinical trials have demonstrated good efficacy for nightmare interventions that are based on principles of exposure therapy or cognitive restructuring. Imagery rehearsal therapy (IRT) has the largest evidence base to date.[108] In this technique, patients first learn cognitive-behavioral strategies to manage unpleasant images during wakefulness before writing out the content of a distressing dream, rescripting the content any way they wish, and then rehearsing the images of the altered dream scenario. Successful variations on this approach include combining relaxation training and direct, repeated exposure to disturbing dream content with rescripting of the dreams (exposure, relaxation, and rescripting therapy [ERRT]),[109] relaxation and exposure without rescripting,[110] and an approach that uses lucid dreaming techniques wherein patients learn to alter dream content as the dream actually occurs.[111] Overall, this set of interventions results in significant reductions in nightmare severity and frequency, with more modest improvements in insomnia and other symptoms of PTSD. A meta-analysis found that less complex approaches such as relaxation alone were not effective, but that psychological interventions for nightmares were effective overall, with a moderate effect size comparable to that for pharmacologic interventions.[107] At present, none of these related approaches can be recommended as a first-line comprehensive treatment for PTSD. However, IRT and ERRT appear to be particularly effective in targeting nightmare symptoms and can be applied as stand-alone interventions for nightmares with moderate to large effects.[107,112-114] IRT also has been combined with cognitive-behavioral therapy for insomnia, with good success.[115-117] It also may be a useful adjunct to first-line PTSD treatments.

These psychotherapeutic nightmare interventions are consistent with principles from the established cognitive-behavioral treatments of PTSD that apply exposure or cognitive restructuring, or both, to trauma memories.[64] That such techniques can be effectively applied directly to nightmare content (which in PTSD often features trauma memories) has important implications. One is that clinicians can be realistically hopeful about the potential for alleviating distressing nightmare symptoms. As previously mentioned, an apparent paradox is that stress-related references in dreams

are associated with positive outcome, whereas trauma-replicating nightmares are associated with PTSD. This paradox may be reconciled if the former dreams represent an adaptive emotional processing, possibly related to modification of associative networks, and the latter represent a failure of such a process. Studies of imagery rehearsal suggest that conscious exposure to the content of recurring distressing dreams, along with instruction to modify the dream scenario, facilitates movement toward the more adaptive response.

That benefits of nightmare-focused interventions are generalizable to other symptom domains lends support to the idea of continuity between waking emotional life and dreaming. Dreams also may offer clinicians a unique window into patients' emotional adaptation to trauma and stress, along with the status of their processing of traumatic memories. The apparently robust association between PTSD and replays or representations of trauma memories in dreams further provides an important clue to understanding abnormalities of emotional memory processing that differentiate those who suffer with PTSD from those who are more resilient to adverse psychobiological consequences of trauma.

It has been shown that poor sleep quality has a negative impact on the severity and trajectory of PTSD symptoms[118,119] and that sleep disturbance, including nightmares specifically, may even contribute to suicidal thoughts and behaviors.[120,121] The growing evidence from the literature, as reviewed in this chapter, indicates that treatment of nightmares not only can ameliorate sleep disturbances but also can reduce overall symptoms of PTSD, although not to the point of remission.

CLINICAL PEARL

The phenomenon of trauma replication in dreams is a distinguishing feature of PTSD. Recurrent trauma nightmares contribute to considerable distress in patients with PTSD. Evidence supports the use of prazosin as a pharmacologic treatment for PTSD-related nightmares. Psychological treatments recommended for such nightmares include IRT and EERT.

SUMMARY

Trauma-related nightmares continue to warrant their designation as a hallmark of PTSD. Although not entirely consistent or linear, the preponderance of evidence indicates that stressors of increasing strength are incorporated into dream narratives with severe traumas and PTSD nightmares occupying the extreme end of a possible continuum. Evidence also suggests that dreaming of life stressors and traumatic events may be emotionally adaptive in acute post-trauma periods, but that persistent and trauma-replicating dreams are maladaptive. Findings from sleep neurobiology, PTSD neurobiology, and polysomnographic studies of trauma and PTSD patients have informed increasing refinements in neurocognitive models of nightmares. At the same time, during the past decade efficacy of some pharmacologic and nonpharmacologic nightmare treatments have been established, which are consistent with the contention that incorporation of actual trauma memories and their affective components into dreams is indicative of neurocognitive substrates.

Emotion, Motivation, and Reward in Relation to Dreaming

Chapter 56

Sophie Schwartz; Lampros Perogamvros

Chapter Highlights

- The activation of emotional and reward brain networks during non–rapid eye movement and rapid eye movement sleep is supported by robust evidence.
- Specific patterns of brain activity during sleep probably determine key features of dream content. Conversely, dream characteristics such as intense emotional experiences offer valuable insights into information processing during sleep.
- The activation of limbic regions, in particular, the amygdala, and of the reward system during sleep seems to promote the reactivation of affectively relevant memories, as well as the experience of emotions and the expression of approach and avoidance behaviors in dreams.
- Emotional and reward processing during dreaming may explain its contribution to waking cognitive and emotional processes, including emotion regulation and performance improvement. This hypothesis is supported by recent experimental evidence.

Recent neuroimaging, neurophysiological, and clinical studies converge to suggest that emotional and reward networks are activated during sleep. Because these networks are active primarily while the organism interacts with its external environment, of critical relevance is how and why such systems are also activated during sleep. A main hypothesis is that their recruitment during sleep relates to the affective and motivational components of the dreaming experience and has beneficial consequences on waking behavior and emotional well-being. This chapter examines how the activation of emotional and reward circuits during sleep may determine the affective and motivational attributes and functions of dreaming.

DREAMING AND EMOTIONAL PROCESSING

Sleep is an active yet variable and heterogeneous state of the brain. Over the past two decades or so, neuroimaging studies in humans have demonstrated that distinct brain regions display specific patterns of activity during rapid eye movement (REM) sleep and non–REM (NREM) sleep. As briefly reviewed subsequently, these new data provide unprecedented insights into the neural circuits whose recruitment during human sleep plausibly determines typical features in dreams. In particular, the activation of limbic and mesolimbic systems presumably promotes affective and memory processing during sleep and dreams.

REM sleep is characterized by the activation of brain regions involved in sensory-motor, memory, and emotion processing, including associative visual areas, motor cortex, medial temporal regions, amygdala, anterior cingulate cortex, and medial prefrontal cortex.[1-4] During wakefulness, the amygdala is involved in the detection of emotional stimuli and also contributes to emotional learning and extinction, in close interaction with the medial prefrontal cortex.[5] In addition, amygdala activity was found to correlate with heart rate variability during REM sleep, suggesting a role for the amygdala in autonomic regulation during this sleep state.[6] The particular recruitment of the amygdala and medial prefrontal cortex during REM sleep would thus provide a favorable condition for the reprocessing and regulation of emotionally relevant information during sleep and may elicit intense emotions in dreams.[7-11] Furthermore, a recent brain structural study in humans demonstrated that preserved microstructural integrity in the left amygdala was associated with longer and more emotional dream reports.[12]

By contrast, several regions implicated in executive and attentional functions during wakefulness are significantly deactivated during REM sleep, including the dorsolateral prefrontal cortex, orbitofrontal cortex, and inferior parietal cortex.[1,2] These deactivations are compatible with several cognitive characteristics of dream reports such as illogical thinking, disorientation, impaired working memory, and limited cognitive control.[13,14] Reduced activity in medial prefrontal regions is also consistent with relatively poor and labile dream recall, whereas an increase in frontal theta activity (5 to 7 Hz) during REM sleep underlies successful dream recall.[15] Moreover, limited monitoring from frontal and parietal regions may explain the intriguing tolerance to bizarre aspects in dreams. Objects, places, or characters are recognized despite their modified physical appearance in dreams,[14] and discontinuities in the dream plot or events that are highly unlikely or

impossible during wakefulness may not be identified as such[16]; furthermore, full-blown basic and social emotions (e.g., fear, sadness, sexual emotions, embarrassment) may be experienced without disrupting the dreamer's sleep. Dreaming may thus involve this particular conjunction of reduced control and criticism over the illusory nature and peculiarities of the dream world. Recent experimental evidence has shown that transcranial alternating current stimulation in the low gamma range (25 to 40 Hz) applied to frontotemporal regions during REM sleep could enhance "executive ego functions" such as self-reflective awareness in dreams by promoting insight into the fact that one is currently dreaming, third-person perspective-taking, and control over the dream plot.[17]

Early neuroimaging studies of human NREM sleep consistently reported decreases in regional brain activity, in accordance with a homeostatic need for brain energy recovery. In particular, activity is decreased in the brainstem, basal ganglia, and several cortical areas including the prefrontal cortex (as reviewed by Dang-Vu and associates[18]). Recent functional magnetic resonance imaging studies, however, have started to unveil transient increases in neural activity across emotion and memory circuits during this sleep stage. Specifically, NREM sleep spindles have been associated with increased activity in the insula, anterior cingulate cortex, and superior temporal gyrus,[19] while slow waves have been associated with increased activity in the precuneus, parahippocampal gyrus, and posterior cingulate cortex.[20] Bilateral increases in regional metabolism from waking to NREM have also been found in the ventral striatum, anterior cingulate cortex, amygdala, and hippocampus.[21] Increased activity in memory-related regions, in particular, those time-locked to slow oscillations, supports the hypothesis that memories are reactivated during NREM sleep.[22]

Overall, existing neuroimaging data suggest that emotional networks are activated during all stages of sleep, especially during REM sleep. These activations may explain the emotional characteristics of REM and NREM dreams. Indeed, dream content analyses most often report a general intensification of emotions and predominance of negative emotions in REM compared with NREM dreams.[23] More than 50 years ago, the French neurophysiologist Michel Jouvet observed that when muscle atonia was abolished during REM sleep, cats displayed negatively toned behaviors (e.g., those corresponding with anger or fear).[24] Similarly, aggressive behaviors are frequent in patients with REM sleep behavior disorder, who act out their dreams.[25] On the other hand, positive emotional states like friendliness are frequent in NREM dreams.[26] Dream data thus confirm that emotional processes may be active during both REM and NREM sleep stages. They also suggest, however, that distinct emotions may prevail during specific sleep stages, with more intense negative emotions and aggressiveness predominating in REM dreams. The possible implications related to the processing of emotions during sleep are considered further on, under Implications for Emotion Regulation and Learning.

DREAMING AND REWARD PROCESSING

It has been suggested that an elevated dopamine level in the mesolimbic dopaminergic (ML-DA) system during sleep plays an important role in the generation of dreams.[27] Lesions in the white matter surrounding the frontal horns of the lateral ventricles can cause a total cessation of dreaming, without affecting REM sleep.[27,28] These lesions disrupt the mesolimbic circuit, which connects dopaminergic neurons of the ventral tegmental area (VTA)—the source of dopamine activity—with the nucleus accumbens (NAcc), amygdala, hippocampus, anterior cingulate cortex, and frontal cortex (insular and medial orbitofrontal cortex, medial frontal cortex, ventromedial prefrontal cortex), and which forms the so-called SEEKING system. Introduced in the 1980s by the neuroscientist Jaak Panksepp, the SEEKING system is a "curiosity-interest-expectancy" command system related to instinctual appetitive states.[29,30] It was proposed that this psychobehavioral emotional and motivational system may be implicated in the generation of dreams.[28,31] Activation of the ML-DA system would induce a SEEKING disposition, which could promote approach-like behaviors and emotional anticipation during both wakefulness and in dreams. Of note, Panksepp's conceptualization of the SEEKING system is compatible with other models of the reward system subserving reward prediction error,[32] reinforcement-learning,[33] or "incentive salience."[34]

Pharmacological studies have provided further evidence that dreaming relates to the activation of the ML-DA system (and associated SEEKING disposition) by showing that the administration of dopaminergic (D_2) antagonists is associated with a reduction in dreaming[35] and in nightmares,[36-38] whereas the administration of dopaminergic agents (e.g., pramipexole) causes vivid dreams.[39-41] Furthermore, total or partial sleep deprivation leads to disturbed reward brain functions.[42-44]

Activation of reward networks in sleep (and not necessarily in dreaming) also is suggested by some recent human studies showing that the consolidation of declarative memory benefits from NREM sleep and is influenced by motivational biases.[45-47] For instance, recently learned declarative memories (word-pair associates) are better retrieved after a period of sleep, but only if the participants had been informed that a retrieval test would occur.[46] Thus increasing the future relevance of memories enhances their consolidation, and this enhancement is correlated with NREM oscillatory activity (slow waves and spindles). Such a preferential consolidation of highly rewarded memories during sleep seems to involve the activation of the dopaminergic reward system in human sleep.[47] More specifically, in a placebo group, memory consolidation was enhanced after sleep only for those memories associated with high reward; after administration of the dopaminergic agonist pramipexole, memory was improved for both high and low reward conditions. These observations converge with findings in animal studies showing that during sleep, a spontaneous reactivation (replay) of neuronal firing patterns occurs in neurons of the ventral striatum after reward-searching behavior.[48,49] This "off-line" replay is orchestrated by hippocampal ripples and may strengthen the association between a memory trace and a specific motivational value.[50,51] The spontaneous reactivation of reward-related neuronal firing patterns in the ventral striatum during NREM sleep may involve a transfer of novelty or relevance signal from the hippocampus to the VTA,[49] and contribute to the activation of the VTA in REM sleep.[31,52]

Indeed, during REM sleep as well, key structures of the ML-DA reward system are activated, including the VTA and the NAcc. In rodents, VTA bursting activity is elevated during REM sleep,[52,53] up to levels observed during reward or

punisher anticipation at waking.[54] This activity is significantly higher in REM sleep than in the awake state or in NREM sleep; it is comparable in intensity and duration to activations during waking behaviors such as feeding, punishment, or sex.[52] Moreover, extracellular levels of dopamine are increased in the NAcc during REM sleep in rats.[55] In both animal and human studies, other reward-related regions, including the ventromedial prefrontal cortex and the anterior cingulate cortex, are activated during REM sleep.[2,3,55] Finally, the orexin neurons in the lateral hypothalamus, which are involved in the regulation of sleep-wake states and in reward-seeking behaviors,[56-58] display bursts of activity during REM sleep.[59,60] Further support for an activation of reward-related circuits during REM sleep comes from the observation, in both animals and humans, that the hippocampus exhibits a theta rhythm,[61,62] which is associated with novelty-seeking, exploratory, and instinctual behaviors during wakefulness.[30]

How does the activation of reward-seeking mechanisms during sleep influence, at least partly, the content of dreams? Recent research has shown that approach behaviors (e.g., behaviors of exploration, curiosity, or engagement) may be as frequent as "avoidance" behaviors (e.g., avoiding a threat through fleeing, freezing, or hiding) both in dreams[63] and as overtly expressed in parasomnias.[64,65] Moreover, dream reports are biased toward content with strong motivational value (e.g., socializing, fighting, sexual content) and less oriented toward content with no such particular value (e.g., typing, washing dishes, buying food at the supermarket).[66] Of importance, frequent approach behaviors are not incompatible with the high prevalence of negative affect in dreams,[67] because both the ML-DA system and the amygdala-limbic system are activated during sleep.[68]

IMPLICATIONS FOR EMOTION REGULATION AND LEARNING

The links between dreaming and emotional or motivational processes, as previously expounded, offer new insights into the possible functions of dreaming. NREM and REM dreams appear to encompass specific emotional/motivational states; NREM dreaming would predominantly simulate friendly interactions, self-related information, and actual waking life events, whereas REM dreams contain comparatively more aggressive social interactions[26] and less integration between self-referential and social cognitive reasoning with autobiographical memory.[69] It has been proposed that the variety of emotions that the dreamer experiences may contribute to emotion regulation processes. Evidence in favor of this claim comes from the demonstration that different REM dream characteristics relate to specific daytime affective functions, such as protection against depression after divorce[70,71] and response to antidepressant treatment.[72] Moreover, being exposed to diverse emotional stimuli (objects, situations, thoughts, memories, and physical sensations) during dreaming, including feared ones, in a safe context that the dream state represents, resembles and may act like desensitization therapy.[73] This assumption is indirectly supported by studies demonstrating that sleep, in general, promotes the retention and generalization of extinction learning.[74]

Along the same lines, the Finnish psychologist and philosopher Antti Revonsuo proposed the threat simulation theory, according to which dreaming promotes the development and maintenance of threat-avoidance skills during wakefulness by simulating threatening events during sleep.[10,67] This mechanism would rely on the activation of limbic regions, in particular the amygdala, during REM sleep. Consistent with this hypothesis, persons suffering from posttraumatic stress disorder simulate threatening events in their dreams more often than controls.[75] Moreover, REM sleep deprivation impairs threat avoidance skills in waking life,[76] whereas sleep selectively prioritizes the consolidation of perceptual features of aversively conditioned stimuli, ultimately enhancing the detection of potential dangers in the environment.[77] Also, recent experimental evidence demonstrated that sleep does not only protect memory for emotional pictures but also preserves emotional reactivity, as measured by subjective ratings of valence and arousal elicited by the pictures.[9] Of note, the latter results relate to the effects of sleep on emotional processing; whether they illuminate a possible function of dreaming still remains speculative. On the other hand, nightmares may correspond to the failure of fear memory extinction, when temporary (e.g., daily concerns) or more persistent (e.g., trauma) emotionally disturbing memories are being reactivated in sleep.[78]

Extending the threat simulation theory, we recently put forward the reward activation model for sleep and dreaming,[31] which supports that dreaming favors the activation of stimulus representations or behaviors of high emotional and motivational relevance, including instinctual and approach/avoidance behaviors (such as feeding, mating, fighting, or fleeing). In this model, emotionally relevant experiences have a higher probability of being activated during dreaming and exhibit a preferential access to sleep-related memory consolidation processes. Plausible functions of dreaming may thus implicate off-line emotion regulation processes by exposing the sleeper to aversive or rewarding stimuli, as well as enhanced memory consolidation during sleep, and improved performance in real life situations.

Indeed, a second major contribution of dreaming, apart from emotion regulation, seems to pertain to memory processes. Dreaming is a particular state of consciousness during which some memory representations are reexperienced and then potentially reorganized. Evidence for the role of dreaming in the consolidation of memory was recently demonstrated by Wamsley and associates.[79] In this study, participants first were trained on a virtual navigation task and then either took a nap or rested while awake. Task-related imagery during the sleep/rest period improved subsequent task performance significantly more than when task-related thoughts occurred during wakefulness. Such off-line processes of memory reactivation and reorganization would also explain why sleep may favor creative insights.[80] Using a semantic priming task, Stickgold and colleagues[81] demonstrated that participants awakened from REM sleep showed greater priming by weak primes (than by both unrelated primes and strong primes), consistent with a hyperassociative state of the sleeping mind, reminiscent of the unusual associations of features or events in REM dreams.[14] In a similar experiment, Walker and coworkers[82] demonstrated that subjects awakened from REM sleep exhibited a 32% advantage on an anagram-solving task, compared with the number of correct responses after NREM awakenings. In line with these observations, compared with quiet rest and NREM sleep, REM sleep (but not necessarily dreaming) enhances the integration of initially unassociated information

resulting in more creative problem solving.[83] More experimental studies are needed in order to better delineate how dreaming per se influences memory consolidation, creativity, and insight.

Taken together, these findings demonstrate that distinct sleep stages contribute to the remodeling of memory stores, and that memory reprocessing may be enhanced in the dream state, with important implications for waking performance. On the basis of robust neurophysiological evidence of reward activation during sleep, it has been suggested that dreams relate not only to known past events but also to an unexpected, novel, or probabilistic future.[31,69] Dream content analysis provides support for this idea by showing that although past and current waking concerns are common in dreams,[71,84] dreams rarely provide exact replicates of past events; instead they most often represent novel combinations of memory elements.[85,86] Dreaming would thus offer an off-line cognitive and emotional preparation of the dreamer for future waking life events. By suggesting that subjective experiences in dreams fulfill important biological and psychological functions, this theoretical proposal also has clinical implications because dream characteristics may represent biomarkers of important brain functions, such as emotion regulation processes.[7]

METHODOLOGICAL ISSUES

The difficulty of understanding the functions of dreams is related in part to the fact that the neural correlates of the dreaming state still remain largely undetermined. This shortcoming may be due to methodological difficulties pertaining to the commonly used techniques in dream research (e.g., limited number of EEG electrodes, neuroimaging studies specific to sleep but not to dreams) and the lack of studies correlating the dreaming experience, which is by definition subjective, with its neurobiological substrates. Moreover, studying dreams implies that subjective parameters are collected *after* the experience (i.e., the dreamer remembers of the dream after being awakened). Therefore recent methodological improvements in the integration of self-report data with neuroimaging data, with the potential for decoding mental content from ongoing brain activity, represent a promising avenue for future developments in the science of dreaming.[87-89]

Although it is tempting to relate some aspects of dreaming to motivational and emotional functions, as in work summarized in this chapter and elsewhere (threat simulation theory,[67] protoconsciousness theory,[90] default-mode activation theory[91]), more studies specifically addressing such functional relationship are needed.[71,72,79,92] Moreover, distinct sleep stages and dream states (associated with NREM or REM sleep) may differ in their contribution to off-line reprocessing of emotional and reward information. NREM sleep and dreams may be more specialized in linking memory traces with motivational values,[46,49] whereas REM sleep and dreams may be responsible for emotional memory consolidation and synaptic consolidation.[93] Nevertheless, studies combining dream content analysis, sleep recordings, and an assessment of emotion and/or memory functions are still very scarce.[79]

Progress in dream research will thus benefit both from new neuroimaging techniques that allow the identification of brain states associated with specific mental contents ("brain decoding" methods) and from a better integration of these physiological data with subjective dream data.

CLINICAL PEARL

The demonstration that dreaming affects emotion regulation processes may be useful to promote measures preventing sleep (and dream) restriction. This is particularly important for the most vulnerable populations, such as psychiatric patients or children, whose brains may be in elevated need of the reprocessing and simulation of emotions occurring during dreaming. Conversely, dream characteristics constitute biomarkers of important brain functions, such as emotion-regulating processes.[92]

SUMMARY

This chapter summarizes the evidence for activation of emotional-limbic and reward-related circuits during sleep. Dreaming seems to be closely related to these specific patterns of neural and behavioral activations, a link that may explain its contribution to important functions such as emotion regulation, associative learning, and social cognition. By simulating defense and approach behaviors, subserved by limbic regions and the mesolimbic dopaminergic reward system, dreaming provides a virtual and safe environment, in which the dreamer can be exposed to an important load of aversive or rewarding stimuli. This mechanism provides the person with enhanced learning capacities, which can be potentially used in the waking life. However, more empirical studies are needed to better characterize these proposed roles of dreaming.

Impact, Presentation, and Diagnosis

Chapter 57

Approach to the Patient with Disordered Sleep

Beth A. Malow

Chapter Highlights

- This chapter emphasizes the clinical approach to the patient with disordered sleep, focusing on specific aspects of the history and physical examination.
- Patients who complain of disturbed sleep usually describe one or more of three types of problems: insomnia; abnormal movements, behaviors, or sensations during sleep or during nocturnal awakenings; or excessive daytime sleepiness.
- Taking a systematic history that includes medication use, family history, social history, and review of systems can provide important clues regarding the diagnosis.

Patients who complain of disturbed sleep usually describe one or more of three types of problems: insomnia; abnormal movements, behaviors, or sensations during sleep or during nocturnal awakenings; or excessive daytime sleepiness. These sleep complaints are not mutually exclusive, and a given sleep disorder may be associated with more than one type. For example, patients with sleep apnea may complain of insomnia, excessive daytime sleepiness, choking or gasping during the night, or all three. Those with narcolepsy may complain of sleep paralysis and hallucinations at sleep onset or on awakening, disrupted sleep, and daytime sleepiness.

CHIEF COMPLAINT AND HISTORY

Evaluation begins with the chief complaint, which provides a focus for delineating the patient's concerns and eliciting the history. It is often useful to ask why the patient is seeking help at the present time, particularly if the problem has been of long standing. If the chief complaint is from the spouse or bed partner, it is important to determine whether the patient recognizes the problem, is unaware of it, or denies its existence. Many clinicians also obtain a brief patient profile during the interview that includes the patient's age, sex, occupational or academic status, marital status, and living arrangements. The profile often includes valuable information about how the sleep concern is affecting the patient's daily functioning (e.g., difficulty performing job responsibilities or participating in leisure activities with family). After the chief complaint is delineated, details concerning the sleep problem are sought, including its duration, the circumstances at its onset, the factors that lead to exacerbation or improvement, and any associated symptoms.

The patient's daily schedule is reviewed, including the usual bedtime and estimated time to sleep onset, the number and timing of awakenings, and the time of final awakening. Morning symptoms should be elicited, such as increased nasal congestion, dry mouth, or morning headaches. These symptoms may support a diagnosis of obstructive sleep apnea.

Daytime symptoms, including during passive or repetitious activities (e.g., watching television or riding in a car), should be investigated to characterize the severity of sleepiness. A comprehensive sleep history also includes questions about the frequency and duration of daytime naps and the presence or absence of cataplexy, hypnic hallucinations, sleep paralysis, and automatic behavior.

Insomnia

Patients with insomnia usually complain that their nocturnal sleep is inadequate in some way. They may describe difficulty falling asleep, frequent awakening, or early morning awakening with inability to return to sleep. It is important to distinguish among these patterns of insomnia because they may have different causes. For example, awakenings from sleep because of obstructive sleep apnea may result in sleep maintenance insomnia but would not result in a patient's complaining of lying awake for hours not being able to fall asleep. The description of insomnia and its course may help determine cause, as outlined in Chapter 84.

Excessive Sleepiness

Patients with daytime sleepiness typically complain of drowsiness that interferes with daytime activities, unavoidable napping, or both. Falling asleep while driving or at other particularly inappropriate or dangerous times is often the impetus that brings the patient to the clinician. Some of these patients complain that they need more sleep at night or that daytime drowsiness occurs regardless of how much sleep is obtained at night. Patients may also complain of difficulty with concentration or memory or increased irritability. Children may exhibit hyperactivity rather than sleepiness.

The differential diagnosis of excessive daytime sleepiness ranges from insufficient sleep to sufficient sleep that is disrupted by pathologic events, such as apneas, or neurologic disorders, such as narcolepsy. Inquiring about sleep routines and bedtimes and wake times is essential in excluding insufficient sleep as a cause of sleepiness. Asking patients who complain of sleepiness about other associated symptoms provides essential information. Loud snoring, gasping, snorting, and episodes of apnea suggest the diagnosis of obstructive sleep apnea syndrome (see Chapter 116). A history of episodic muscle weakness with buckling of the knees, laxity of the neck or jaw muscles, or complete loss of muscle tone associated with laughter, anger, or hearing or telling a joke suggests cataplexy and a diagnosis of narcolepsy (see Chapter 92). Questions assessing mood are needed to identify patients with sleep disorders associated with depression (see Chapter 140). Circadian rhythm sleep disorders should be considered in patients with complaints of nocturnal insomnia and daytime sleepiness (see Chapter 41).

Nocturnal Movements, Behaviors, and Sensations

Information from collateral sources is needed for evaluation of episodic movements and behaviors during sleep. The bed partner should be asked to describe behaviors and vocalizations during the episodes, to relate episodes to sleep onset and time of night, and to note the degree of the patient's responsiveness during the episode. The patient's ability to recall the events is also significant. Episodes of inconsolable screaming and amnesia during the first third of the night suggest sleep terrors (see Chapter 104); episodes of dream-enactment behavior associated with dream recall that occur toward the end of the sleep cycle REM sleep behavior disorder (see Chapter 105). Epileptic seizures may occur at any time of the night and should be strongly considered if a history of stereotyped behavior or dystonic posturing is elicited (see Chapter 99).

MEDICATION USE AND MEDICAL HISTORY

Assessment of medication use, including nonprescription medications, herbal supplements, and illicit drugs, is critical because of the wide variety of medications that alter sleep, wakefulness, and sleep disorders (see Chapter 46).

The history of current or past medical, surgical, and psychiatric illnesses is a source of important information. Seizure disorders, parkinsonism and dementia, arthritic conditions, asthma, ischemic heart disease, migraine or cluster headache, compressive neuropathies, and almost any painful illness can cause significant sleep disturbance. Anemia, renal disease, and pregnancy may cause or exacerbate restless legs syndrome or periodic limb movement disorder. Anxiety disorders, including panic disorder, and mood disorders are psychiatric disturbances that are often accompanied by insomnia, and some patients with depression complain of excessive daytime sleepiness.

FAMILY HISTORY

A history of disordered sleep in family members is important information. Specific inquiry should be made about the existence in family members of previously diagnosed sleep disorders or symptoms suggestive of narcolepsy, obstructive sleep apnea, periodic limb movements, enuresis, sleep terrors or sleepwalking, or insomnia. There is a strong genetic contribution to the development of narcolepsy (see Chapter 91), and genetic and familial influences sometimes have a role in the development and expression of obstructive sleep apnea (see Chapter 115) and some of the parasomnias.

SOCIAL HISTORY

Assessment of psychosocial, occupational, and academic functioning as well as of satisfaction with personal relationships can yield valuable information about the impact of disordered sleep on the patient's life. Alcohol, caffeine, nicotine, and illicit drug use should be determined. Alcohol use or abuse may intensify snoring and obstructive sleep apnea, may be a contributor to insomnia, or may produce long-lasting changes in sleep patterns. Caffeine use produces significant sleep disturbance in susceptible persons, and nicotine dependency may lead to nocturnal awakenings.

REVIEW OF SYSTEMS

The review of systems may uncover symptoms of medical illnesses that can cause or contribute to sleep disorders (Box 57-1). Recent weight gain or increase in collar size increases the likelihood of obstructive sleep apnea. Particular attention should be paid to the cardiovascular and pulmonary systems because of their relation to breathing and oxygenation during sleep. Angina, orthopnea, paroxysmal nocturnal dyspnea, and wheezing may indicate that sleep disturbance is

Box 57-1 SAMPLE SLEEP REVIEW OF SYSTEMS

Sleep Habits
Bedtime on weekdays
Bedtime on weekends
Wake time on weekdays
Wake time on weekends
Time it takes to fall asleep
Awakenings during the night
Time it takes to fall back asleep

Morning Symptoms

due to cardiac or pulmonary disease. Heartburn and reflux of gastric contents into the throat when the patient is recumbent may cause nocturnal choking episodes. Leg cramps and neuropathic pain may be accompanied by sleep disruption. Nocturia is a common cause of disturbed sleep, particularly in older men. Depression or anxiety can contribute to insomnia.

PHYSICAL EXAMINATION

Examination of the head and neck is particularly important in patients with suspected obstructive sleep apnea. Auscultation of the chest may reveal expiratory wheezes in patients with nocturnal asthma attacks. Thoracic abnormalities such as kyphoscoliosis may compromise ventilatory capacity, leading to hypoventilation and nocturnal breathing difficulties. Auscultation may reveal a prominent fourth heart sound originating from the enlarged right ventricle and murmurs related to pulmonary or tricuspid valve insufficiency. On abdominal examination, hepatomegaly may suggest that alcohol abuse is contributing to sleep disturbance or, in conjunction with other findings, that congestive heart failure is a factor. Examination of the extremities may reveal joint swelling or deformity, decreased range of motion across affected joints, and thickening of synovial tissue in patients with disordered sleep due to arthritis.

Findings on mental status testing and neurologic examination may indicate the presence of a psychiatric or neurologic disease that causes or contributes to disturbed sleep. Impairment of short-term memory, judgment, language functions, and abstract reasoning suggests the presence of a dementing illness that may cause insomnia or nocturnal confusion. Assessment of mood may suggest the presence of mania or depression, either of which may be associated with insomnia. Delusional thoughts and agitation may indicate that acute psychosis is the cause of insomnia. Reduced alertness with slurred speech and nystagmus may be signs of hypnotic or sedative abuse. Impaired sensation and reduced or absent tendon reflexes may indicate peripheral neuropathy, sometimes accompanied by nocturnal paresthesias or burning pain. Elements of the physical examination relevant to the sleep patient are covered in greater detail in Chapter 59.

CLINICAL PEARL

A complete sleep and medical history often yields a specific cause of the patient's sleep complaint. For example, in patients complaining of excessive daytime sleepiness, the cause can often be pinpointed by close attention to the patient's (and bed partner's) account of nighttime symptoms, bedtime and wake time schedules, medications, and coexisting medical disorders.

SUMMARY

The evaluation of a patient with disordered sleep begins with the chief complaint, which can be classified as insomnia, daytime sleepiness, episodic nocturnal movements or behaviors, or a combination of these concerns. A thorough characterization of these concerns, coupled with a comprehensive sleep history that includes the daily schedule, bedtime routine, and morning and daytime symptoms, forms the foundation for diagnosis. As in other fields of medicine, it is essential to consider other medical and psychiatric conditions, medication use, family history, social history including the psychosocial situation, review of systems, and physical examination before formulating a differential diagnosis and performing diagnostic studies. This systematic approach allows accurate diagnosis and specific interventions for many treatable sleep disorders.

Chapter
58

Cardinal Manifestations of Sleep Disorders

Bradley V. Vaughn; O'Neill F. D'Cruz

Chapter Highlights

- Sleep disorders include a wide range of conditions that impair health and quality of life. To identify patients afflicted with these disorders, to institute effective treatment, and to optimize patients' health and quality of life, early clinical recognition of the fundamental symptoms (insomnia, hypersomnia, and unusual sleep-related behaviors), as well as the more subtle signs of these conditions, is essential.
- Insomnia is a common symptom, and as a diagnostic entity it can be related to many contributing factors. Features that predispose to, precipitate, and perpetuate the insomnia can be identified in persons who suffer from chronic insomnias. Insomnia can have an intricate relationship with other medical and psychiatric disorders.
- Hypersomnia often is a presenting feature of other sleep disorders or may reflect lifestyle choices. The difficulty in diagnosis is in distinguishing sleepiness from fatigue, and in determining the underlying contributing features. The pattern of sleepiness, characteristics of the sleep period including length, and response to these sleep periods give clear clues. Other manifestations, such as snoring, witnessed apnea, unrefreshing sleep, and morning headache, may indicate potential sleep-related breathing disorders or cataplexy, prompting an evaluation for narcolepsy.
- Unusual nocturnal sensations or events can provide a window into sleep issues. Features of restless legs syndrome, periodic limb movements in sleep, and parasomnias, such as sleepwalking, sleep terrors, and dream enactment, require detailed description of the sleep-related behaviors to help differentiate among potential causes. These events may indicate other underlying sleep disorders and brain disease.
- Sleep issues also may manifest as systemic problems. Findings of hypertension, unexplained weight gain, or mood or cognitive issues may be important flags signaling a need to inquire about underlying sleep issues. In addition, sleep issues may be early signs of brain disease.

Sleep is essential to health, restoring properties that promote wakefulness and a sense of well-being. Sleep disturbance, however, frequently disrupts this sense of well-being and can result in a wide range of systemic and neuropsychological symptoms. Sleep disruption due to intrusion of components of the sleep state into periods of wakefulness may manifest as hypersomnia. Similarly, intrusion of components of wakefulness into the sleep period may manifest as insomnia. Beyond the medical manifestations, sleep disruption also has consequences for societal and public health issues by impairing work performance and psychosocial interactions. As the connection of sleep to good health is increasingly appreciated, sleep disruption is now recognized to exacerbate symptoms of other diseases. These pathologic effects may manifest as worsening of a preexisting disorder or as impairment of the patient's ability to cope with its symptoms. The challenge for physicians is to recognize these manifestations and appropriately delineate them as being related to dysfunction of sleep.

Most patients referred to sleep centers present with one or a combination of three classic complaints: excessive sleepiness, difficulty attaining or sustaining sleep, or unusual events associated with sleep. These symptoms can be easily recognized as related to sleep and are not mutually exclusive in nature. Patients may note more than one problem, such as difficulty sleeping at night and excessive sleepiness during the day. Others may complain of unusual events at night with daytime sleepiness or inability to sleep. Each of these symptoms conveys clues to the underlying pathologic process (Figures 58-1 to 58-3). This chapter reviews the cardinal manifestations of sleep disorders and describes some of the key features that guide the clinician to pursue further diagnostic evaluations.

INSOMNIA

The diagnosis of insomnia is dependent on the complaint of difficulty initiating or maintaining sleep combined with daytime sequelae. This combination of poor nighttime sleep with an adverse effect on daytime activities is important to establishment of the complaint as insomnia. The daytime manifestations of insomnia may take the form of excessive fatigue, impairment of performance, or emotional change. Individual sleep need may vary significantly. Some people may feel fine and note no impairment of performance with 5 hours

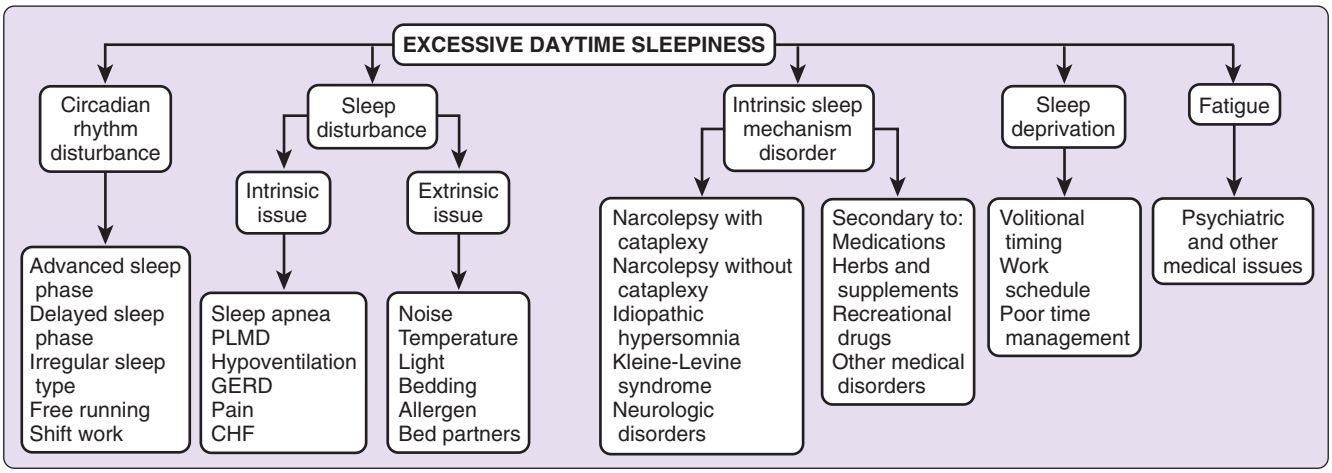

Figure 58-1 Diagnostic flow chart to approach excessive daytime sleepiness. CHF, Congestive heart failure; GERD, gastroesophageal reflux disease; PLMD, periodic limb movement disorder.

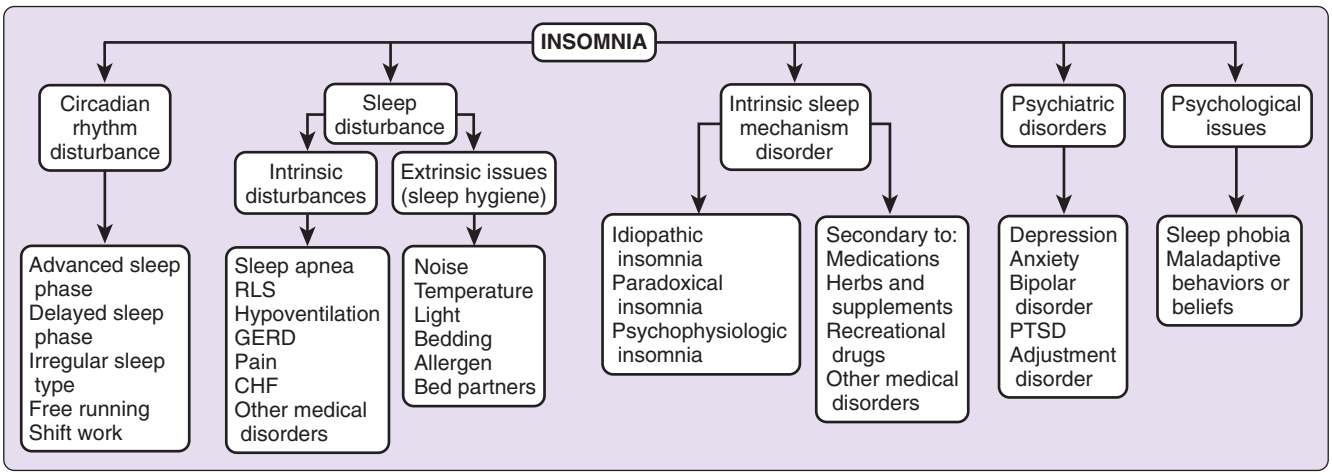

Figure 58-2 Diagnostic flow chart to approach insomnia. CHF, Congestive heart failure; GERD, gastroesophageal reflux disease; PTSD, posttraumatic stress disorder; RLS, restless legs syndrome.

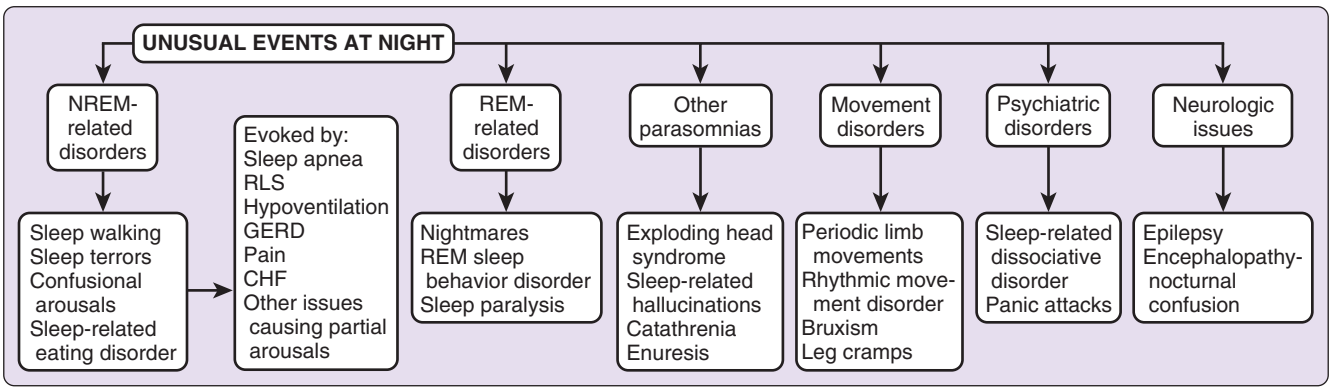

Figure 58-3 Diagnostic flow chart to approach unusual nocturnal events. CHF, Congestive heart failure; GERD, gastroesophageal reflux disease; RLS, restless legs syndrome.

of sleep per night, whereas others may need more than 9 hours to preserve daytime functioning. Thus the requirement of daytime sequelae differentiates individual sleep need from the complaint of insomnia.

Most people have an occasional night fraught with difficulty falling asleep or trouble maintaining sleep. These occasional nights may be closely linked to the surrounding events of the day, psychological challenges, or sudden changes in environment or onset or exacerbation of a medical condition. Surveys have shown that approximately one third of people complain that their sleep is disrupted on occasion and that a smaller group, of approximately 1 in 10, have a more persistent insomnia.[1] For these patients, lack of "good-quality" sleep produces a greater disruption of life and may lead to more significant medical or psychological symptoms.

As a symptom, insomnia is directly related to the patient's perception of poor sleep. Patients with insomnia believe that the sleep disruption produces their excessive sleepiness, fatigue, lack of concentration, muscle aches, and depression, and that a good night's sleep would reverse these symptoms. Patients with insomnia frequently describe themselves as tense, anxious, nervous, tired, irritable, unable to relax, obsessively worried, and depressed. Many of these traits may predate the onset of the insomnia, but others may arise after the onset of the poor sleep. Patients with insomnia frequently give historical clues directed toward the mechanisms behind their insomnia. The symptom complex may indicate an underlying disorder related to primary failure of sleep mechanics or one in which sleep disruption is the byproduct of another disorder. Because sleep is an active process, neuronal networks involved with sleep induction must be engaged and networks involved in wakefulness must be diminished for sleep to occur. Rarely is just one factor responsible for chronic insomnia (defined as lasting longer than 3 months). In most patients, multiple factors contribute to the risk of developing and maintaining insomnia. The presence of predisposing, precipitating, and perpetuating factors emphasizes the nature of insomnia as an ongoing process, and clinicians need to search for these contributing factors to outline an effective treatment course (see Chapters 80 to 88).

As indicated by epidemiologic studies, insomnia appears to be more common in women, older persons, and those with psychiatric or chronic medical illness. Insomnia also is more common in persons of lower socioeconomic status and with less education. Behavioral traits such as obsessive-compulsive nature, frequent rumination, and poor coping strategies and a "hyperalert" baseline state are correlated with greater risk for insomnia. So-called hyperarousal documented on recent neuroimaging studies may explain the neurophysiologic basis for these associated factors predisposing to chronic insomnia.[1]

Insomnia may be initiated by sudden changes in environment or challenges to the body or mind. These challenges may come in the form of acute medical illness, psychological or psychiatric events, shift in schedule, or changes in medications or diet, including supplements. Although these events provide good clues to preventing further recurrence of insomnia, initiating events may play little role in the patient's current, ongoing process..

Many patients, in attempting to improve their sleep, may adopt behaviors that actually perpetuate the insomnia. Patients may employ rituals and "remedies" that convert the short-term insomnia into a chronic form. During this evolution, the patient may institute changes in sleep schedule, resort to certain somnogenic substances, or develop secondary medical or psychological issues. Many of these behaviors conflict with typical sleep hygiene practices, producing an environment detrimental to sleep. Such maladaptive habits may occur during the day or night and include issues such as heavy caffeine or alcohol use, watching television or playing video games while in bed, and even eating or exercising during the usual sleep period. Some patients may claim that television or radio distracts them from intrusive thoughts. In others, the development of sleep associations may be a mechanism to counterbalance negative experiences. A subgroup of patients actually fear going to bed or experience performance anxiety over the oncoming sleep period. This expectation of poor sleep promotes apprehension toward sleep and may perpetuate counterproductive sleep rituals. These maladaptive behaviors become the predominant feature of psychophysiologic insomnia. Many patients with these types of negative associations temporarily improve once placed in a new environment.

The timing of the insomnia during the sleep period also may be helpful in the evaluation. Circadian rhythm sleep-wake disorders can masquerade as complaints of insomnia or excessive sleepiness, and patients with insomnia may develop dysfunction of their circadian rhythm. Difficulty with the onset of sleep suggests an underlying delayed sleep phase or occasionally depression in younger adults. Insomnia with early-morning arousal raises the possibility of underlying depression or advanced sleep phase. Schedule changes, such as from jet lag or shift work, are important clues, and sleep diaries of bedtime and wake time can be useful in determining potential links to schedule or circadian rhythm issues. Timing also may correlate with other issues such as restless legs syndrome or medication or caffeine intake. Specific questions should explore the patient's daily routine including the timing of activities that may be stimulating, such as exercise or work or gaming on a computer.

Perception of good sleep is an important factor in evaluating the complaint of insomnia. Some patients exaggerate their symptoms; still other patients may not even recognize that sleep is occurring. Paradoxical insomnia is one subtype of chronic insomnia in which people do not recognize that they have slept despite the recording of normal physiologic parameters of sleep. Other patients may endorse unrealistic expectations or unobtainable goals. Patients may assume that sleep should not be interrupted by any arousals or that it is essential to sleep for a set number of hours. These beliefs can be easily addressed with appropriate education about these issues.

For some people, insomnia may start in childhood and be lifelong. The subtype of chronic insomnia known as idiopathic insomnia is not associated with clear inciting factors. In affected persons, insomnia persists despite a change in environment or other measures, and significant family history may be identified. These factors are discussed further in Chapters 82 and 83.

Medical or neurologic disorders may precipitate and perpetuate insomnia. Derangement of almost any system in the body can disrupt sleep. Patients with heart, liver, or renal failure or disturbances of the gastrointestinal system or pulmonary disease commonly complain of insomnia. Patients with fulminant rash or significant burns frequently note disturbed sleep, and urologic issues such as nocturia may provoke frequent arousals. Neurologic disorders also promote sleep

disruption. Neuromuscular disorders, for example, may be associated with discomfort or inadequate ventilation at night that provokes insomnia. Some patients who suffered a stroke have noted insomnia or sleep disruption after the vascular event. Paralysis from central or peripheral nervous system disorders can result in nighttime discomfort from inability to move. Patients with Parkinson disease may exhibit akinesis, tremor, or medication effects, and patients with dementia may have circadian rhythm abnormalities that promote awakenings at night.

Pain can disturb sleep and promotes insomnia. Musculoskeletal discomfort may become worse with periods of rest. Arthritis and other rheumatologic disorders frequently can disrupt sleep with increasing nighttime pain and stiffness. Pain from headaches, such as cluster headache, and even pain related to increased intracranial pressure or brain mass lesions can become more intense during sleep, and symptoms from entrapment neuropathies, such as carpal tunnel syndrome, typically are worse at night. Restless legs syndrome produces a classic urge to move that is worse in the evening.

Nearly all the psychiatric illnesses have some link to poor sleep. Patients with depression or anxiety disorders may endure insomnia for years before presentation of the affective component. Although the cause and effect are still in debate, the association is clear. Insomnia may herald the onset of psychosis or mania.

The clinician may uncover few physical findings in patients with insomnia. Anxious or hyperalert persons may demonstrate mild tachycardia or rapid respiratory rate; cold hands may be an associated feature. These patients may easily startle or be distracted during the interview. The clinician should look carefully for signs of obstructive sleep apnea, narrow airway, and obesity because these too can be manifested as insomnia. Signs of Cushing syndrome (round face and buffalo hump) or hyperthyroidism (tachycardia and excessive sweating) are important clues to an endocrine disorder. Each patient with a complaint of insomnia should undergo a complete neurologic examination to look for potential neurologic lesions impairing sleep. This examination should include an assessment of cognition, mood, and affect. Insomnia or interrupted sleep can occur in many neurologic disease states, including several forms of dementia. The Mini Mental State Examination is a tool that helps assess cognitive abilities, with findings monitored for follow-up over time.[2] Clinicians also can use the Minnesota Multiphasic Personality Inventory to identify personality and affect issues, and the Hamilton Anxiety and Depression Scales may be helpful tools in clinical follow-up for persons so affected.

EXCESSIVE DAYTIME SLEEPINESS

Sleepiness is a common symptom noted by 5% to 20% of people.[3,4] Most people can relate some instances of falling asleep when they intended to be awake. Sleepiness is a normal feeling on approaching a typical sleep period or after prolonged wakefulness. Excessive sleepiness may manifest as sleep in an inappropriate setting or as episodes of unintentional sleep. Excessive sleepiness can occur in various degrees of severity. In mild sleepiness, the affected person may fall asleep while reading a book or while sitting quietly. This degree of sleepiness may produce only limited impairment in the person's perceived quality of life. Greater degrees of sleepiness may be associated with bouts of irresistible sleep or sleep attacks intruding on such activities as driving, participating in a conversation, or eating meals. This degree of sleepiness may place the patient at significant risk for accidents and have a major impact on the person's health and sense of well-being.

As with other subjective symptoms, the person's perception of sleepiness influences the nature of the complaint. Some patients may overreport the degree of sleepiness and note this feeling even during periods of normal wakefulness. Others may underreport and not recognize periods of daytime sleepiness. For some people in the latter group, sleepiness may be described as periods of lapse of attention or diminished cognitive abilities, such as missing an exit on the highway or brief delay in performing a task. Perception of sleepiness also is reduced with continued sleep deprivation. People who are chronically sleep-deprived become accustomed to their impairment and are less likely to recognize their degree of sleepiness.

Clinicians should always question their hypersomnic patients for clues of potential sleep debt, dyssomnia, or medical or psychiatric causes. Sleep deprivation is common in today's society, and patients should be queried about their schedule during the week and weekends. Information elicited about sleep habits and environment may disclose important factors contributing to the sleepiness.

Excessive sleepiness may result from a wide range of medical disorders and medication. Patients with heart, kidney, or liver failure and rheumatologic or endocrinologic disorders such as hypothyroidism and diabetes may note sleepiness and fatigue. Similarly, a wide range of medications may cause daytime sleepiness even when taken at night. Neurologic disorders, such as strokes, tumors, demyelinating diseases, and head trauma, can be associated with excessive sleepiness. Sleepiness frequently is the cardinal symptom of many sleep disorders. Patients with sleep apnea, narcolepsy, idiopathic hypersomnia, or even parasomnias may identify excessive daytime sleepiness as their main complaint. Historical features of snoring, observed apneas, morning headaches, cataplexy, sleep paralysis, hypnagogic hallucinations, and confusion on arousals suggest contributions of a specific sleep disorder. Persons with idiopathic hypersomnolence experience unrelenting daytime sleepiness despite prolonged periods of sleep, which differentiates this disorder from sleep deprivation. Many adults with idiopathic hypersomnia find naps are not refreshing, whereas patients with narcolepsy (type 1 and type 2) note that brief naps actually improve their daytime sleepiness.

Physical findings are few in patients with sleepiness. Frequent pauses, slowed responses, drooping eyelids, and repetitive yawning support the complaint of sleepiness. Patients may be asleep when the clinician enters the examination room, and some patients may show signs of chronic sleepiness, such as dark circles under the eyes. The neurologic examination may yield findings of inattentiveness or even brief "microsleeps."

Sleepiness can be quantified subjectively by questionnaires or by objective assessments such as a multiple sleep latency test. The Epworth Sleepiness Scale is one example of a quantifiable subjective measure of sleepiness and has been translated into several languages (Table 58-1).[5] For scoring on this scale, the patient is asked to rate on a scale of 0 to 3 (0, no chance; 3, high likelihood) the chance of dozing in a series of eight situations. This score has a modest correlation with

physiologic measures of sleep but has a better correlation with the respiratory disturbance index in patients with obstructive sleep apnea (Table 58-2).

Two quantitative tests are available to measure ability to fall asleep and to stay awake: the Multiple Sleep Latency Test (MSLT) and the Maintenance of Wakefulness Test. The MSLT quantifies objective sleepiness on the basis of the time to onset of physiologic changes associated with sleep across five trials separated by 2 hours each across the typical wake period. Sleep is determined by the loss of the posterior dominant rhythm on the electroencephalogram or, in the absence of posterior dominant rhythm, slow eye movements, vertex sharp waves, and slowing of the background electroencephalographic activity. The MSLT uses these physiologic markers to quantify the time to sleep. Unfortunately, the MSLT is not well correlated with daytime function, and significant overlap has been documented between persons deemed "normal" and those deemed to have sleep disruption. Although the MSLT can "quantify" the degree of sleepiness on a particular day, the test is validated only for the diagnosis of narcolepsy (type 1 and type 2). The Maintenance of Wakefulness Test quantifies the propensity to stay awake during four attempts in a dimly lit room. This test has not been extensively tested in relationship to daytime function. These tests are covered in greater detail in Chapter 169.

Table 58-1 The Epworth Sleepiness Scale

Name: _____
Today's date: _____ **Your age (years):** _____
Your sex (male = M; female = F): _____
How likely are you to doze off or fall asleep in the following situations, in contrast with feeling just tired? This refers to your usual way of life in recent times. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation:
0 = would never doze
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

Situation*	Chance of Dozing
Sitting and reading	_____
Watching TV	_____
Sitting, inactive in a public place (e.g., a theater or a meeting)	_____
As a passenger in a car for an hour without a break	_____
Lying down to rest in the afternoon when circumstances permit	_____
Sitting and talking to someone	_____
Sitting quietly after a lunch without alcohol	_____
In a car, while stopped for a few minutes in traffic	_____
Thank you for your cooperation.	

*The numbers for the eight situations are added together to give a global score between 0 and 24.
From Johns MW. A new method for measuring daytime sleepiness: the Epworth Sleepiness Scale. *Sleep* 1991;14:540–5.

FATIGUE

The complaint of fatigue is a complex symptom typically related to the perception of lack of energy. Many patients with excessive daytime sleepiness note fatigue or decreased energy. Patients may be aware of the lack of energy but not perceive the degree of sleepiness, or may confuse the symptom of fatigue with excessive sleepiness. Although frequently noted in combination, fatigue is distinct from excessive sleepiness. Patients with fatigue alone may not have an increased ability to fall asleep but believe that a good night's sleep would correct their lack of energy. Distinguishing sleepiness from fatigue can be difficult even for the most astute clinician. Detailed questioning regarding ability to fall asleep can be helpful. Patients with insomnia also frequently complain of fatigue related to disrupted sleep, as may patients with immunologic, endocrinologic, or organ failure. Similarly, patients with depression frequently have associated fatigue without sleepiness.

SNORING

Snoring is the sound created by turbulent airflow vibrating upper airway soft tissue. Usually more prominent during

Table 58-2 Sleep-Related Conditions and Sleepiness: Epworth Sleepiness Scale Score in Experimental Subjects

Condition/Diagnosis	Total No. of Subjects (Males/Females)	Age (Years): Mean ± SD	Epworth Sleepiness Scale Score	
			Mean ± SD	Range
Healthy control subjects	30 (14/16)	36.4 ± 9.9	5.9 ± 2.2	2–10
Primary snoring	32 (29/3)	45.7 ± 10.7	6.5 ± 3.0	0–11
Obstructive sleep apnea syndrome	55 (53/2)	48.4 ± 10.7	11.7 ± 4.6	4–23
Narcolepsy	13 (8/5)	46.6 ± 12.0	17.5 ± 3.5	13–23
Idiopathic hypersomnia	14 (8/6)	41.4 ± 14.0	17.9 ± 3.1	12–24
Insomnia	16 (6/12)	40.3 ± 14.6	2.2 ± 2.0	0–6
Periodic limb movement disorder	18 (16/2)	52.5 ± 10.3	9.2 ± 4.0	2–16

SD, Standard deviation.
From Johns MW. A new method for measuring daytime sleepiness: the Epworth Sleepiness Scale. *Sleep* 1991;14:540–5.

inspiration, snoring occurs in approximately 32% of adults and in more than 7% of children.[6,7] Many adults have little knowledge or recognition of their snoring habits, and accounts from bed partners may be more helpful for the clinician.

Snoring usually is worse with the patient in the supine position, after sleep deprivation or alcohol ingestion. Loud snoring may not disturb sound sleepers, but some patients may report complaints from family members and even neighbors. Snoring may continue for decades. Persistent loud snoring is a classic symptom of obstructive sleep apnea syndrome, but the absence of snoring does not exclude the diagnosis of apnea. In some cases, the airway dynamics are not conducive to snoring. This is especially true in patients who have had upper airway surgical procedures that eliminated flaccid tissue. Other patients, such as those with neuromuscular disorders, may not generate enough force to produce turbulent airflow.

Snoring, for many people, produces little disruption in their lives, but snoring may have implications for overall health. People who snore are at greater risk for vascular disease. Witnesses may describe the snoring occurring in bursts or associated with snorts, gasps, choking, body jerks, and movements. Patients may recall being awoken by their own gasps and relate symptoms of gastroesophageal reflux. These associated symptoms raise the clinical suspicion of obstructive sleep apnea.

SLEEP APNEA

Apnea is the absence of ventilation. In the sleep laboratory, an apneic event is defined as the cessation of breathing for more than 10 seconds and usually is associated with oxygen desaturation and arousal.[8] Although snoring is very common, witnessed apneic events and nocturnal gasping or choking are the most reliable subjective indicators of sleep apnea.[9] Some patients may experience hundreds of events in a single night and are unable to obtain good-quality sleep because of the frequent arousals. These patients typically are unaware of the arousals, but some may report being aware of occasional awakening with a gasp or snort. Sleep apnea is classified in two major forms: obstructive and central.

Obstructive apnea is the most common form of sleep apnea. These apneas are due to obstruction in the upper airway and more commonly are noted during stage N1 or N2 or rapid eye movement (REM) sleep. Snoring is a frequent associated complaint, but a wide variety of symptoms may be present. Some questionnaires, such as the Sleep Apnea section of the Sleep Disorder Questionnaire, Berlin Questionnaire, or the STOPBANG, a combination of items regarding snoring, witnessed apneas, body habitus, and associated disorders such as hypertension[10,11] (Table 58-3), provide a summary score that correlates with presence of obstructive sleep apnea, but the questionnaires have been tested only in selected populations. Thus the questionnaires themselves serve as rough guides and do not confirm the diagnosis of sleep apnea. Astute clinicians should not rule out the presence of apnea on the basis of a low score on a questionnaire. The physical examination may show structural evidence for airway obstruction. Many patients are obese, with a thick neck or crowded upper airway, yet some have a normal body habitus. Common structural abnormalities, such as a narrow nasal passage, long soft palate, large tonsils, or retroflexed mandible leading to a small airway, contribute to airway obstruction. Sleep apnea is associated with significant health risks and lowers the quality of life of both patient and bed partner. Mounting evidence from multiple studies such as the Sleep Heart Health Study indicates that hypopneas with oxygen desaturation correlate with greater risk of vascular disease.[12] These are discussed in greater detail in Chapters 126 to 128.

Central apnea is the absence of ventilation due to an absence of contraction of the lower respiratory musculature.

Table 58-3 Key Features of the Berlin Questionnaire

Height _____	**Age** _____
Weight _____	**Gender** _____
Has your weight changed in the last 5 years?	Increased Decreased No change
Do you snore?	Yes No Do not know
Your snoring is:	Slightly louder than breathing As loud as talking Louder than talking Very loud
How often do you snore?	Nearly every day 3 to 4 times per week 1 to 2 times per week 1 to 2 times per month Never or almost never
Has your snoring bothered other people?	Yes No
Has anyone noticed that you quit breathing during your sleep?	Almost every day 3 to 4 times per week 1 to 2 times per week 1 to 2 times per month Never or almost never
Are you tired or fatigued after your sleep?	Nearly every day 3 to 4 times per week 1 to 2 times per week 1 to 2 times per month Never or almost never
During your wake time, do you feel tired, fatigued, or not up to par?	Nearly every day 3 to 4 times per week 1 to 2 times per week 1 to 2 times per month Never or almost never
Have you ever fallen asleep while driving?	Yes No If so, how often does it occur? Nearly every day 3 to 4 times per week 1 to 2 times per week 1 to 2 times per month Never or almost never
Do you have high blood pressure?	Yes No Do not know

Modified from Reprinting of the Berlin questionnaire. *Sleep Breath* 2000;4(4): 187–92, with the permission of Kingman P. Strohl.

Affected patients experience pauses in respiration, also associated with oxygen desaturation and arousals. Central apneas can be caused by narcotics or a neurologic abnormality in the brainstem or other areas involved in regulation of respiration. Cheyne-Stokes breathing can manifest features of both central and obstructive apnea. The classic pattern of crescendo-decrescendo breathing with a central apnea can be seen in persons with heart failure, neurologic lesions, and metabolic or toxic encephalopathies. This pattern may be present only in sleep and may signal underlying disease. Apneic episodes may follow other neurologic events, such as nocturnal seizures, and are more prevalent after acute strokes and seizures. Central apnea is reviewed in Chapters 109 and 110.

CATAPLEXY

Cataplexy is the abrupt loss of muscle tone triggered by strong emotional stimuli or physical exercise.[13] Patients are aware of their surroundings and have clear memory for the complete events. Events can be triggered by a joke, surprise, anger, fear, or enthusiastic athletic endeavors. Individual experiences range in intensity from a mild feeling of weakness to severe weakness precipitating a fall. Cataplectic attacks arise over several seconds and may start with brief waves of loss of tone that may appear like jerks initially. In most cases, symptoms initially affect the face and neck and then progress to involve the rest of the body. Patients may describe more subtle events as a feeling of slowness to respond or slurring or speech. The attacks generally are brief, lasting less than a few minutes. Patients then regain muscle control and exhibit no postictal confusion or memory deficits. More prolonged attacks may be ended with the patient's entering sleep and then awakening. Examination of the patient during the cataplectic attack will demonstrate paralysis with diffuse hypotonia, absence of deep tendon reflexes, diminished corneal reflexes, preservation of pupillary responses, and in many instances, phasic muscle twitching. Phasic muscle twitching can occur as single jerks or repetitive muscle twitching and most frequently is seen in the face, sometimes being confused with seizure activity.

The combination of excessive daytime sleepiness and cataplexy is nearly always related to narcolepsy type 1. Cataplexy can rarely be seen as an isolated symptom suggestive of an underlying neurologic lesion in the brainstem. Maintenance of consciousness and memory helps differentiate these events from most seizures and syncope. The historical feature of clear emotional triggers differentiates cataplexy from vertebral basilar insufficiency and the group of neuromuscular disorders known to produce periodic paralysis. Cataplexy also is differentiated from myasthenia gravis by the abrupt onset and absence of muscle fatigue with repetitive stimulation that is typical of myasthenia gravis.

SLEEP PARALYSIS

Sleep paralysis is an inability to move during the transition into or out of sleep. The association with intentional sleep distinguishes these events from cataplexy. Patients may describe complete awareness of their surroundings or feeling partially asleep with awareness but being unable to move even the fingers or to vocalize. Patients may try to scream but produce only a whisper. Some affected persons may describe a feeling of suffocation, with resumption of breathing only when the event has passed. Patients frequently describe a strong feeling of impending doom, being chased, or having to escape imminent danger. On occasion, patients may note the feeling that someone else is in the bedroom. Auditory and tactile hallucinations may accompany the events, and patients may recount dramatic stories. These events can be emotionally profound and leave a lasting memory that patients vividly recall years later. Most sleep paralysis episodes last a few minutes and usually end after the patient is touched or is alerted. If the event is allowed to persist, the patient usually reenters sleep and awakens later. These events are experienced by many people in association with severe sleep deprivation, schedule disruption, or ingestion of alcohol and may be more frequent in patients with narcolepsy.

HYPNAGOGIC AND HYPNOPOMPIC HALLUCINATIONS

Hallucinations can occur with sleep onset (hypnagogic) or at the end of sleep (hypnopompic). Such hallucinations may include visual, auditory, or tactile components and may last seconds to minutes. The events occur at the transition between wake and sleep and incorporate some dream-like features. They can be relatively pleasant or very terrifying and difficult to distinguish from reality. Patients may note a feeling of weightlessness, falling, or flying or describe an out-of-body experience; the episode may sometimes terminate with a sudden jerk (hypnic jerk). Visual hallucinations may be described as poorly formed colors and shapes or well-formed images of people and animals. The events are terminated once the patient awakens.

Exploding head syndrome is characterized by the subjective experience of a loud, painless explosion that occurs near sleep onset. This parasomnia is benign and may be associated with a hallucinatory flash of light.

In the face of excessive daytime sleepiness, patients with hypnagogic hallucinations should be evaluated for narcolepsy. These events may be repetitive but usually are not stereotypical. This lack of stereotypical features distinguishes these events from seizures. Affected patients may experience these events after sleep deprivation or a change in the sleep schedule. Alcohol ingestion or withdrawal of REM suppressants may also provoke these events. The relationship of sleep to these hallucinations distinguishes them from hallucinations of psychosis and dementia. Hypnagogic hallucinations are shorter in duration than peduncular hallucinations. Some people with dementia experience hallucinations at night. These types of hallucinations are associated with cognitive impairment during the day and most commonly are seen in patients with Lewy body dementia but can occur with other forms of dementia. Small people or animals predominate in these hallucinations, and many patients experience these events while awake.

AUTOMATIC BEHAVIOR

Automatic behavior consists of purposeful but inappropriate activities that occur with the patient partially asleep. Patients relay stories of putting milk containers in the microwave oven, cereal bowls in the dryer, or even missing an exit on the highway. Sleep-deprived soldiers have been reported to

continue marching in the wrong direction. Patients appear drowsy or groggy during the event and usually are partially or totally amnestic for the actual happenings. Events may last minutes to up to an hour. Automatic behavior and "sleep inertia," the persistence of profound sleepiness into the awake state, are more common in persons with idiopathic hypersomnolence but also are common in patients with a delayed sleep phase.

These events are distinguished from seizures by the lack of stereotypical behavior. Automatisms associated with seizures usually are stereotypical and repetitive, such as picking, rubbing, or lip smacking. Patients with sleep-related automatic behavior appear sleepy but can be alerted and answer questions appropriately, in contrast with those with postictal confusion and metabolic or toxic encephalopathy. The quick return of orientation with lack of bewilderment and anxiety also differentiates this entity from transient global amnesia.

EXCESSIVE MOVEMENT IN SLEEP OR PARASOMNIA

Patients and their bed partners may complain of frequent movement during the sleep period. This complaint may be more concerning to the bed partner than to the patient. Excessive sleep movement also is a common complaint among patients who complain of insomnia and in persons with sleep apnea. Some patients may complain of being active sleepers and describe a corresponding high level of mental activity or an inability to turn off their mind. These patients need an evaluation focusing on features of insomnia. Those who are physically active need evaluation for the movements or a parasomnia.

Parasomnia refers to undesirable physical or behavioral phenomena that occur predominantly during sleep. They include disorders of arousals, such as sleepwalking and night terrors; sleep-wake transition disorders, such as bruxism or rhythmic movement disorder (e.g., head banging); and REM parasomnias, such as REM sleep behavior disorder. These behavioral events may mimic epileptic seizures or other psychiatric events, and a clear description from a keen observer is very helpful in leading to the correct diagnosis. The parasomnias are covered in greater detail in Chapters 101 to 106.

Key features of age at onset, time of night of the events, memory for the events, and family history are important in determining the etiology of parasomnias. Stereotypical behavior—recurrence of the same behavior with each event—also can help in categorizing the events. Events such as periodic limb movements, rhythmic movement disorder, and epileptic seizures are associated with stereotypical behavior, whereas sleeptalking, sleepwalking, night terrors, and dream enactment incur different behavior with each event. Although historical features can be useful in distinguishing among these disorders, most patients require polysomnographic recording to delineate the cause.

Sleeptalking

Sleeptalking is a relatively frequent event, ranging from occasional utterances to coherent conversation during sleep. This usually occurs in the lighter stages of NREM sleep but can occur in REM ("stage R") sleep. Patients have no memory for such events, during which they may convey information that may have little resemblance to the truth. Many people talk in their sleep, and this is considered a normal variant. In the absence of other sleep disturbances, sleeptalking is of little medical concern.

Sleepwalking

Sleepwalking events usually are part of the disorders of arousal, indicating incomplete arousal typically from slow wave sleep (stage N3) occurring during the first half of the sleep period. The events can consist of minor behaviors and movement or elaborate behaviors including dressing, unlocking locks, minor housekeeping or work tasks, and even driving. Patients usually have little or no memory of the event. They typically can recall various associated feelings or impressions, however, and some imagery is more common in adults. Affected patients do not exhibit significant tachycardia, sweating, or manifestations of fear. The lack of screaming and autonomic features differentiates sleepwalking from sleep terrors. Both children and adults with a history of recent sleepwalking should be questioned regarding signs of other sleep disorders. Any disorder evoking arousals may increase the likelihood of these events, so a careful assessment to uncover symptoms of other sleep disorders is essential. Patients typically exhibit normal neurologic examination findings during wakefulness.

Sleep Terrors

Sleep terrors are a more intense form of disorder of arousal with a predominance of autonomic expression. Witnesses rarely forget the patient's sudden arousal accompanied by a piercing scream or cry, autonomic output, and behavioral manifestation of intense fear, but the patient has little to no memory of the event. The onset of the episode is abrupt, accompanied by tachycardia, tachypnea, flushing, diaphoresis, and mydriasis. The affected patient is confused and disoriented, and attempts to intercede may result in prolongation of the event and potential harm to the person trying to wake the patient. Patients can become violent, resulting in injury to the patient and bed partners. Less than 1% of adults may experience these events.[14] They usually occur in the first third of the night, and the events are nonstereotypical. Diurnal neurologic examination typically yields normal findings, and as with sleepwalking, a careful assessment for the presence of other sleep disorders is indicated.

Confusional Arousals

Confusional arousals can occur during any arousal from NREM sleep. These events are characterized by disorientation, slowed speech and mentation, or inappropriate behavior. Affected patients have memory impairment for the event, and the events can be induced with forced arousal. These events usually become less frequent with age, but rate of occurrence may remain stable in adulthood.

Patients may exhibit other complex sleep-related behaviors. In a well-characterized variant of such behavior, eating is the sleep-related event, as seen in sleep-related eating disorder. Affected persons consume quanitities of high-calorie, sometimes bizarre foods and have no or little memory of the episode. Morning anorexia and unexplained weight gain are typical. Another reported complex sleep behavior consists of engaging in multiple episodes of sexual intercourse during sleep. Again, the affected person relates no memory of the event.

Sleep-Related Groaning (Catathrenia)

Rarely, patients or families may present because of repetitive nocturnal groaning. Bed partners usually express concern because the patients voice long expiratory groans that sound mournful. Patients usually have no recollection of the sound or feeling distressed but may have morning hoarseness. No other detectable abnormalities are found on physical examination. These groaning events have been compared with central apneas, and the disorder is now classified under sleep-related breathing disorders.[15]

Dream Enactment

REM sleep ("stage R") is characterized by diffuse muscle atonia. Normally, only brief phasic muscle activity is noted during REM sleep, but pathologic dream enactment behavior can include punching, kicking, leaping, running, talking, yelling, and any behavior that could occur during a dream. Bed partners frequently are injured, and patients may go to great lengths to protect themselves and bed partners. This dream enactment commonly is seen as part of REM sleep behavior disorder (RBD). Patients usually have a vivid recall of the actual dreams that correlates with the witnessed behavior, and many dreams involve fleeing or defending themes. Dream recall is not uniformly noted, and patients may not be willing to talk about the dream that led them to seek medical attention. These events occur more commonly in the latter half of the night but can occur any time on entry into REM sleep. Patients may experience multiple events during a single night. In most cases, the dream enactment behavior begins in late adulthood, but children with symptoms of RBD have been described. RBD can be induced by medication, and tricyclic antidepressants, monoamine oxidase inhibitors, and serotonin reuptake inhibitors all have been implicated in causing RBD-like behavior. Acute forms of RBD also can occur during alcohol withdrawal and potentially benzodiazepine withdrawal. In the more chronic form of RBD, behaviors may occurr for years before the patient presents for medical evaluation. RBD has been linked to alpha-synucleinopathies. This group of disorders includes Parkinson disease, multiple system atrophy, and Lewy body dementia. Patients need a complete neurologic evaluation to look for signs of degenerative disorders. Other identifiable neurologic disorders, such as strokes, posterior fossa tumors, and demyelination, have been reported in association with RBD.[16]

Nightmares

Nightmares or recurrent disturbing dream mentation can be a presenting symptom of sleep disturbance. The hallmark of nightmares is emotionally intense dreaming associated with fear, anxiety, anger, sadness, or other negative emotions. Affected persons awaken from stage R or light NREM sleep to full alertness and usually recall the event immediately. Nightmares most commonly are associated with a psychologically disturbing event but may also be a result of medications, such as antihypertensives, antidepressants, or dopamine agonists. Nightmares can occur in patients with narcolepsy as well as in patients with sleep apnea.

Sleep-Related Rhythmic Movement Disorder

Rhythmic movement disorder can be manifested as a variety of distracting behaviors that occur before sleep onset. The movements are stereotypical, usually involving large muscles, and are sustained into light sleep. Movements and related behaviors may include head banging, body rocking, leg rolling, humming, and chanting and frequently are more concerning to the bed partner and family than to the patient. Many patients are relatively unaware of the movement, and others may describe such movement as inducing a calming effect or as a compulsion before sleep. This behavior frequently is seen in infants and young children, and the prevalence diminishes with age. It is more commonly seen in persons with mental challenges or autism and is more prevalent in males. Emotional stress may provoke it. Patients can be easily alerted during the events, which helps differentiate these events from seizures.

Sleep-Related Bruxism

Sleep bruxism also can occur as a rhythmic or repetitive movement during sleep.[17] Grinding or clenching of the teeth during sleep may produce bizarre sounds, and patients rarely may even vocalize with the episodes. Patients may exhibit abnormal wear of the teeth and complain of jaw pain, headache, facial pain, or tooth pain. They may experience hundreds of events per night, and the events increase with emotional stress. Some studies suggest that as many as 85% of the population grinds the teeth to some degree during the day or night. These events often occur in children, and persistence of symptoms occasionally is associated with a familial tendency.

RESTLESS LEGS SYNDROME AND PERIODIC MOVEMENTS OF SLEEP

Patients may complain of an unpleasant crawling, deep aching sensation in the legs or arms that is relieved in some measure by motion of the extremities. Diagnostic criteria focus on four main symptoms: the sensation or urge to move the limbs, worsening of symptoms with rest, improvement with movement, and higher frequency in the evening.[18] In addition, the patient must note a symptom of concern, distress, sleep disturbance, or some impairment related to the sensations. Patients with restless legs syndrome may relay that the discomfort can be debilitating at times, and some people are driven to pursue extreme measures to decrease the symptoms. Most patients experience the symptoms while sitting or lying down and may complain of the need to walk or to have continuous movement of their legs. These symptoms can lead to the affected person's walking until the early morning hours or trying to sleep despite the continuous leg motion. Other afflicted persons may use a combination of medication and alcohol to reduce the symptoms. Some patients note that their legs move or dance on their own, indicating periodic limb movements in wakefulness. Restless legs syndrome usually occurs along with periodic movements of sleep.

Periodic movements of sleep are repetitive stereotypical movements, typically of the lower extremities, that occur during sleep; in the legs, they consist of the extension of the great toe with dorsiflexion of the ankle and flexion of the knee and hip. The patient or a bed partner may complain of kicking or arm movements at night. These movements may occur as periodic events or appear random. Movements also can occur in the arms and axial muscles. The individual movements are relatively brief, lasting 0.5 to 5.0 seconds, and occur at 5- to

90-second intervals. Although a majority of people with restless legs also experience periodic limb movements of sleep, only a minority of patients with periodic movements of sleep will experience excessive daytime sleepiness or insomnia. Patients may be unaware of the movements, but bed partners usually are unable to ignore them. Similar factors that provoke periodic limb movements increase the likelihood of restless legs syndrome. Periodic movements of sleep have been associated with uremia, peripheral vascular disease, anemia, arthritis, peripheral neuropathy, spinal cord lesions, antidepressants, antiemetics, and caffeine use.

MORNING HEADACHE

Morning headache is a common symptom.[19] Almost three fourths of the population has occasional headache; this symptom is relatively nonspecific. Morning headache is more specifically linked to sleep dysfunction but also may indicate elevated blood pressure at night. Characteristics of the headache, such as location, quality, and nature of pain, and potential associations can aid in determining the etiology. Approximately one half of the patients with obstructive sleep apnea and hypoventilation note morning headache, typically dull and generalized in nature, which usually clears within an hour of waking. Patients with chronic obstructive pulmonary disease and obstructive sleep apnea may develop morning headache from the increase in carbon dioxide, low oxygen saturation, or vascular changes. Patients with sinus disorders, muscle contraction headache, post–alcohol intake, and withdrawal from medication (rebound headaches) may have distinct patterns. Cluster headaches are noted to occur in REM sleep. Hypnic headaches, or "alarm clock headaches," so called because of their regularity, are throbbing or sharp pains lasting 15 to 60 minutes that awaken the patient typically between 1 A.M. and 3 A.M. Headaches that routinely awaken patients from sleep should be further evaluated, potentially including head imaging. Patients with brain tumors frequently note worsening of headache at night. Headaches in sleep are discussed in greater detail in Chapter 98.

SYSTEMIC FEATURES

Recognition of the connection of good sleep to good health continues to expand the current understanding of the importance of sleep. Sleep plays a role in endocrine regulation, weight maintenance, and metabolism and has been hypothesized to improve neuronal network proficiency and function. Therefore sleep disorders may influence both regulatory processes and compensatory mechanisms.

Sleep disorders may influence systemic disorders by three general mechanisms: (1) they may directly cause the primary physiologic changes that result in systemic disease; (2) they may exacerbate a preexisting disorder by altering a normal compensatory mechanism; or (3) they may be the hallmark symptom of the systemic disease, sharing a common pathophysiologic mechanism. Sleep disorders may result in systemic manifestations, as noted in sleep-related breathing disorders. Sleep-related disordered breathing can result in a variety of vascular and autonomic changes that increase the likelihood of hypertension and other vascular disorders.

In patients with high-risk disorders, including those with hypertension, vascular disease, heart disease, diabetes mellitus, and obesity, the clinical assessment should include specific evaluation for symptoms of sleep dysfunction that may indicate sleep disorders acting as a cofactor. Sleep disorders (e.g., obstructive sleep apnea or hypoventilation) may exacerbate underlying conditions such as hypertension, diabetes mellitus, congestive heart failure, epilepsy, and depression. Thus the clinician must pay attention to aggravation of symptoms of medical, neurologic, or psychiatric dysfunction as a clue to disordered sleep. The interplay of sleep and brain function makes symptoms of neurologic and psychiatric disease natural manifestations of sleep dysfunction. This association has been documented in persons with epilepsy as well as in those with symptoms of depression and anxiety. Patients may not be aware of the connection of sleep to their other medical problems or may not place emphasis on their sleep symptoms. Therefore the clinician needs to consider the potential of sleep disturbance as an aggravating factor and to recognize the relationship of systemic findings to sleep disruption. Patients also may present with a systemic illness that may share a common pathophysiologic mechanism with a sleep disorder. In persons with anemia and restless legs, iron deficiency may be the common link, so appropriate treatment of the underlying cause may address the symptoms of both. Finally, the sleep symptom may be the hallmark of another process, as observed with REM sleep behavior disorder preceding the development of other neurologic disorders such as Parkinson disease. Although these symptoms may not be considered the typical cardinal manifestations of sleep disorders, their clinical identification does represent an important aspect of diagnosis and may constitute an appropriate entry point for patients into the medical system. Recognition of the systemic manifestations of sleep disorders is an important step in understanding the full relationship of sleep to the body.

PEDIATRIC CARDINAL MANIFESTATIONS

Symptoms of sleep disorders in children can be strikingly different from those in adults and are likely to be overlooked or misinterpreted.[20] Moreover, disruption of family dynamics, psychosocial factors that influence the family unit, and temperamental differences between parent-child pairs may be reported as childhood sleep disorders. Sleep-onset associations, cultural norms, and parental expectations can influence the perception of sleep problems in infants and toddlers. Children can present with a range of physical and behavioral manifestations. In young children, sleep disturbances may manifest as poor growth, learning difficulties, persistent fussiness, inconsolability, or increased oppositional behavior. School-aged children may exhibit suboptimal academic performance, inattention or hyperactivity, or daydreaming behavior in sedentary settings. Adolescents typically fall asleep in class and may present with affective symptoms that need to be differentiated from primary psychiatric disorders. In children with symptoms of RLS (often reported as "growing pains"), a strong family history often is present, suggesting a hereditary predisposition with age-dependent expression. In all pediatric age groups, unrefreshing nocturnal sleep often is a clue to sleep disturbance. Although many of these symptoms are nonspecific, the clinician must be aware of the potential role of sleep dysfunction in the genesis of the symptoms.

CLINICAL PEARL

Patients may present with initial complaints that may seem unrelated to sleep, such as morning headache, "fogginess" during the day, or elevated blood pressure. The patient initially may not have any concerns about his or her sleep or may not even be aware of sleep symptoms. Clarifying functional questions (e.g., asking patients to describe how they feel during certain activities such as on getting up in the morning or after lunch) may give additional clues. Also, family members may be aware of sleep issues before the patient notices a problem, thus lending insight into the impact of sleep on the clinical picture.

SUMMARY

Sleep provides the benchmark for many aspects of daily life. The restorative powers of sleep improve baseline status in wakefulness and maximize the ability to attain higher levels of functioning, whereas poor sleep has a negative impact on health, sense of well-being, and performance. Obvious manifestations of poor sleep, such as daytime sleepiness, insomnia, and sleep-related events, are the hallmark signs indicating the need for further investigation. A proper understanding of the intricate relationship of sleep and health must go beyond the most apparent manifestations of sleepiness. The astute clinician should be alert to less obvious and discrete signs. Predominance of negative over positive memories, trouble with creative solutions, obesity, and poor healing all may suggest sleep disruption. In both research and clinical practice, it is essential to continue to search for more clues that delineate the connection of sleep to health. The insights thus obtained can be expected to expand the clinical recognition of these cardinal manifestations of sleep disorders. Identification of persons who need further evaluation and application of appropriate therapies, as described in the following chapters of Section 8, will lead to optimal management of individual patients and also address the societal and public health issues associated with these disorders.

Chapter 59

Physical Examination in Sleep Medicine

Alon Y. Avidan; Meir Kryger

Chapter Highlights

- Because many patients who present with sleep disorders have sleep-disordered breathing, assessment of vital signs (heart rate, blood pressure, pulse rate), along with height and weight to calculate the body mass index (BMI), is key.
- Head and neck physical examination is critical for evaluation of any directly visualized anatomic factors that could hinder airflow at the level of the upper airway. This chapter reviews the Mallampati and Friedman classification systems used to assess upper airway patency.
- In addition to increased BMI, other factors that predispose to sleep apnea include increased neck circumference, macroglossia, retrognathia, tonsillar adenoid hypertrophy, overjet, and decreased cricomental space. This chapter provides some specific examples of how these factors are measured and contribute to sleep apnea.
- Specific phenotypes that contribute to sleep-disordered breathing include systemic diseases such as systemic amyloidosis and mucopolysaccharidosis, which lead to abnormal upper airway tissue infiltration and airway restriction.
- Craniofacial disorders related to Down syndrome, acromegaly, and primary mandibular deficiency result in abnormal reduction of upper airway size and contribute directly to obstructive sleep apnea.
- Facial and body habitus phenotype in specific endocrinopathies such Graves disease, Cushing disease, and polycystic ovarian syndrome can predispose patients to both sleep apnea and insomnia and should prompt the clinician to review for these complaints in the appropriate patients.
- Patients with neurologic disorders have significant sleep comorbidities. For example, those with neuromuscular disorders and motor neuron disease are especially vulnerable to nocturnal hypoventilation. Specific neurologic signs such as bulbar weakness, Gower maneuver from sitting to standing, and hypophonia are critical and should prompt the clinician to ask about breathing patterns, sleepiness, and nighttime sleep disruption.
- Patients with parasomnias and nocturnal seizures may present with unexplained bruises, ecchymosis, and nonspecific injuries the next day.
- Symptoms of rapid eye movement sleep behavior disorder often precede the onset of Parkinson disease. Patients with Parkinson disease present with neurologic examination findings of bradykinesia, cogwheel rigidity, masked facies, and resting tremor.
- Patients with bruxism, when severe, often demonstrate dental consequences, including teeth fractures and masseter muscle hypertrophy.
- Patients with narcolepsy often lack characteristic features on physical examination. However, cataplectic facies is a physical finding that was recently used to describe facial weakness and grimaces among patients with cataplexy in the setting of narcolepsy type 1.

The physical examination of the patient presenting with sleep complaints often provides important supporting information for the diagnosis of a sleep disorder. In this chapter, the examination findings characteristic of the major categories of sleep disorders are described and illustrated. These include findings observed in obstructive sleep apnea (OSA), central sleep apnea, hypoventilation syndromes, narcolepsy, Willis-Ekbom disease (WED), parasomnias, and bruxism.

After obtaining the narrative medical history, the sleep care provider performs the physical examination, a key and necessary element in evaluating patients with sleep disorders. The examination may provide important clues that lead to elucidation of the etiology and pathophysiology of the sleep disorder. These will help guide the clinician in determining what diagnostic tests will be ordered, what comorbidities require management, and ultimately what therapy will be

employed. The sleep physical examination is a critical component of monitoring outcome of treatment of many sleep disorders. See also Chapter 143, Oropharyngeal Growth and Skeletal Malformations.

SLEEP APNEA

OSA is associated with multiple anatomic and physical risk factors. Some of these require elaborate measurements of nasopharyngeal anatomy using fiberoptic visualization or cephalometric radiographic techniques, whereas others measure changes in response to maneuvers. The most commonly used signs are static, anthropometric measurements from simple examination of oropharyngeal and craniofacial structure.[1] However, at the time of the initial evaluation of the sleep apnea patient, the main ones are obesity, as reflected by elevated body mass index (BMI), and increased neck circumference.[2]

Figure 59-1 summarizes the key anatomic changes that result from increasing age and BMI. The airways become restricted, and the soft palate, which becomes longer and thicker, is now closer to the posterior and lateral pharyngeal walls, restricting the retropalatal space even further.[2] Increased adipose volume in the floor of the mouth displaces the tongue superiorly and posteriorly, thus decreasing the retroglossal airway space. Chronic allergic rhinitis expands the turbinate tissue, leading to diminished intranasal airway space (see Figure 59-1). The spread of adipose volume in the submental triangle and in the supraplatysmal regions produces the so-called double-chin appearance with a full neck phenotype.[2]

Anthropometric Measurements in Patients with Suspected Sleep Apnea

Obesity, as measurement of BMI, is strongly associated with OSA. However, recent data indicate that general body adiposity and regional adiposity are also important risk factors in the evolution of OSA. Besides BMI, other anthropometric obesity indexes, such as increased waist circumference and neck circumference, are significant risk factors for the evolution of OSA.[3]

Body Mass Index Calculations

The following BMI criteria are used to quantitate weight phenotype[4]: Patients with a BMI below 18.5 are considered underweight, those between 18.5 and 24.9 are classified as normal weight, those between 25.0 and 29.9 are classified a overweight, and those with a BMI higher than 30.0 are obese (Table 59-1).

Figure 59-2 illustrates the obesity phenotype in two brothers. Visceral fat accumulation, as depicted in Figures 59-3 and 59-4, is an important risk indicator for sleep apnea, particularly in male patients.[1,2,4] Expansion of regional fat deposition is believed to compromise airway space, whereas visceral or

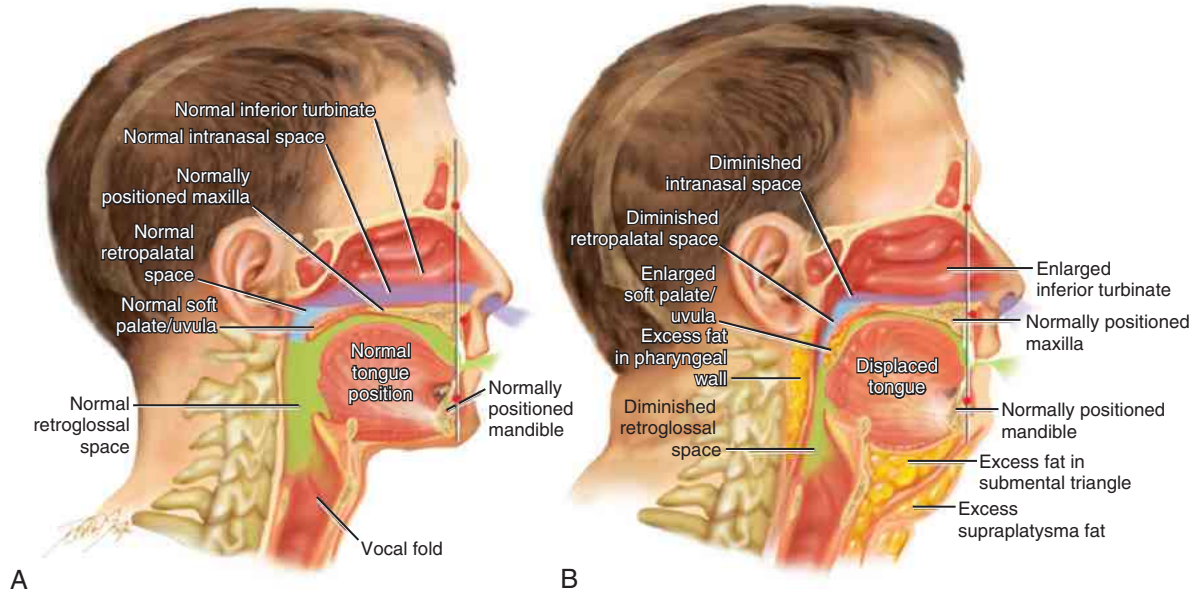

Figure 59-1 Normal and abnormal airway anatomy. **A,** This illustrated midline sagittal cross-section of the head and neck depicts the normal upper airway and maxillofacial spaces and anatomy of a healthy, normal-weight 20-year-old man. The patient has a normal upper and lower facial skeleton and normal soft tissue indicators (soft palate, tongue, tonsils, and adenoids), without any compromise of the intranasal cavity. **B,** With increasing age and weight gain, the same individual, three decades later has an elevated body mass index. Although the anatomy of the upper and lower facial skeleton remains fixed without any changes, fatty tissue consisting of adipose cells has expanded and infiltrated the crevices and space in the upper airway. Particularly compromised are the retropharyngeal and the lateral pharyngeal tissues, the soft palate, and the floor of the mouth, culminating in restricted airflow. At age 20 years, the patient had normal upper airway space (the intranasal, retropalatal, and the retroglossal sites were all well visualized and with appropriate space for air flow to proceed smoothly and unimpeded. At age 50 years, he has developed obstructive sleep apnea: The normal airspace (*green*) is severely compromised because of restriction of the upper airway, intranasal space, and retropalatal and the retroglossal spaces. A *perfect storm* indeed. (From Posnick JC. Obstructive sleep apnea: evaluation and treatment. In: Posnick JC, editor. *Orthognathic surgery: principles and practice.* Philadelphia: Elsevier; 2014. p. 992–1058.)

abdominal obesity reduces lung volume and therefore caudal traction on the pharynx.[5]

Neck circumference at the superior border of the cricothyroid membrane can be measured to evaluate excessive adiposity in the upper body. This measurement is performed with the patient in the upright position (Figure 59-5). Recent data suggest that in adults with metabolic syndrome, measurement of neck circumference is associated with OSA and should be considered in the definition of metabolic syndrome (Figure 59-6).[6] In pediatric and adolescent patients, neck circumference percentile, particularly that greater than the 95th percentile for age and sex, may be an additional screening tool for OSA.[7] In adults, having a large neck circumference in the context of OSA can predict difficult intubations in the anesthesia setting[8] and has been documented in several metabolic derangements, as in the patients presented in Figure 59-7.[9]

Table 59-1 Body Mass Index Calculations

Measurement Units	Formula and Calculation
Kilograms and meters (or centimeters)	Formula: Weight (kg)/height (m^2) Using the metric system, the formula for body mass index (BMI) is weight (expressed in kilograms) divided by height in meters squared. Because height is commonly measured in centimeters, divide height in centimeters by 100 to obtain height in meters For example: Weight = 68 kg, height = 165 cm (1.65 m) Calculation: $68 \div 1.65^2 = 24.98$
Pounds and inches	Formula: weight (lb)/height (in^2) × 703 Calculate BMI by dividing weight in pounds (lb) by height in inches squared (in^2) and multiplying by a conversion factor of 703 Example: Weight = 150 lb, height = 5′5″ (65″) Calculation: $[150 \div 65^2] \times 703 = 24.96$

However, many patients with OSA are not obese but may exhibit reduced oropharyngeal airspace, retrognathia, or micrognathia, which put patients are risk for OSA (Figure 59-8). In contrast, central sleep apnea usually presents with abnormalities reflective of impaired respiratory effort, including the manifestations of heart failure, central nervous system (CNS) disease, or neuromuscular disease. Hypoventilation may be secondary to obesity but may also reflect pulmonary disease or neuromuscular and chest wall disorders. We review the manifestations of sleep apnea on the basis of anatomic site.

Overall Inspection

As noted in the previous section, sleep apnea often presents in association with obesity, which increases the prevalence 10-fold (20% to 40%).[10] Obesity and, in particular, the central type of obesity (see Figure 59-4) are significant risk factors for OSA.[11] They impose increased pharyngeal collapsibility through mechanical compression of the pharyngeal soft

Figure 59-2 Obesity is strongly associated by body mass index (BMI). The example depicts two brothers with sleep apnea with elevated BMI, in the morbidly obese range. (From Kryger MH. *Atlas of clinical sleep medicine*. 2nd ed. Philadelphia: Saunders; 2014: Fig. 13.1-3, A.)

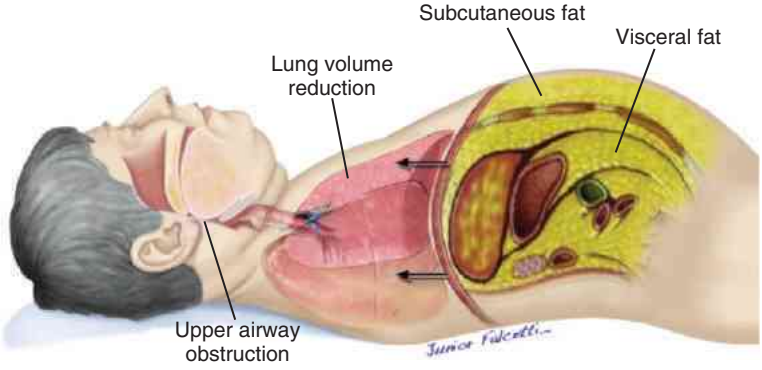

Figure 59-3 The contribution of obesity to obstructive sleep apnea. The illustration depicts the principle anatomic factors that place obese patients at significant risk for obstructive sleep apnea. (From Drager L, Togeiro SM, Polotsky VY, Lorenzi-Filho G. Obstructive sleep apnea: a cardiometabolic risk in obesity and the metabolic syndrome. *J Am Coll Cardiol* 2013;62[7]:569–576.)

Figure 59-5 Measuring neck collar size. Neck circumference (NC) values of 17 inches or greater in men and 16 inches or greater in women are strongly correlated with the risk for obstructive sleep apnea. (From Kryger MH. *Atlas of clinical sleep medicine*. 2nd ed. Philadelphia: Saunders; 2014: Fig. 13.1-40.)

tissues and decreased lung volume through CNS-acting signaling proteins (adipokines) that may alter airway neuromuscular control.[11,12] OSA may independently predispose individuals to worsening obesity as a result of sleep deprivation, hypersomnia, and disrupted metabolism.[13]

Sleep apnea is also associated with endocrinopathies such as hypothyroidism[14,15] and acromegaly.[16] Hypothyroidism is a known cause of secondary OSA; oropharyngeal airway myopathy, edema, and obesity predispose patients to upper airway collapse and obstruction. Acromegaly as depicted in Figure 59-9 results from excessive growth hormone, resulting in enlarged growth of the craniofacial bones, enlargement of the tongue (macroglossia as shown in Figure 59-10), and thickening and enlargement of the laryngeal region; all of these factors can contribute to upper airway obstruction.[17] Goiter, which is associated with acromegaly and hypothyroidism as well as a euthyroid state,[18] can contribute to OSA (Figure 59-11). Patients with Down syndrome (Figure 59-12) regularly experience snoring and obstructive apneas, two common manifestations of upper airway obstruction in this condition, which independently predict neurocognitive impairment.[19] Recent data show significant prevalence of OSA in Down

Figure 59-6 The typical facial features of a patient with obstructive sleep apnea. Notice the width of the neck. (From Venn PJH. Obstructive sleep apnoea and anaesthesia. *Anaesth Intens Care Med* 2014;12:313–8.)

syndrome patients, conferred through several factors, including craniofacial anatomy, high BMI, adenotonsillar hypertrophy, and muscle hypotonia.[20]

Metabolic derangement such as deposition disorders, including mucopolysaccharidosis (Figure 59-13) and amyloidosis (Figure 59-14),[21] are strongly correlated to OSA. In fact, in patients with mucopolysaccharidosis the prevalence of OSA syndrome can be as high as 70%.[22]

Specific endocrinopathies, in particular polycystic ovarian syndrome, are extremely common among women of reproductive age but often go undiagnosed.[23] Polycystic ovarian

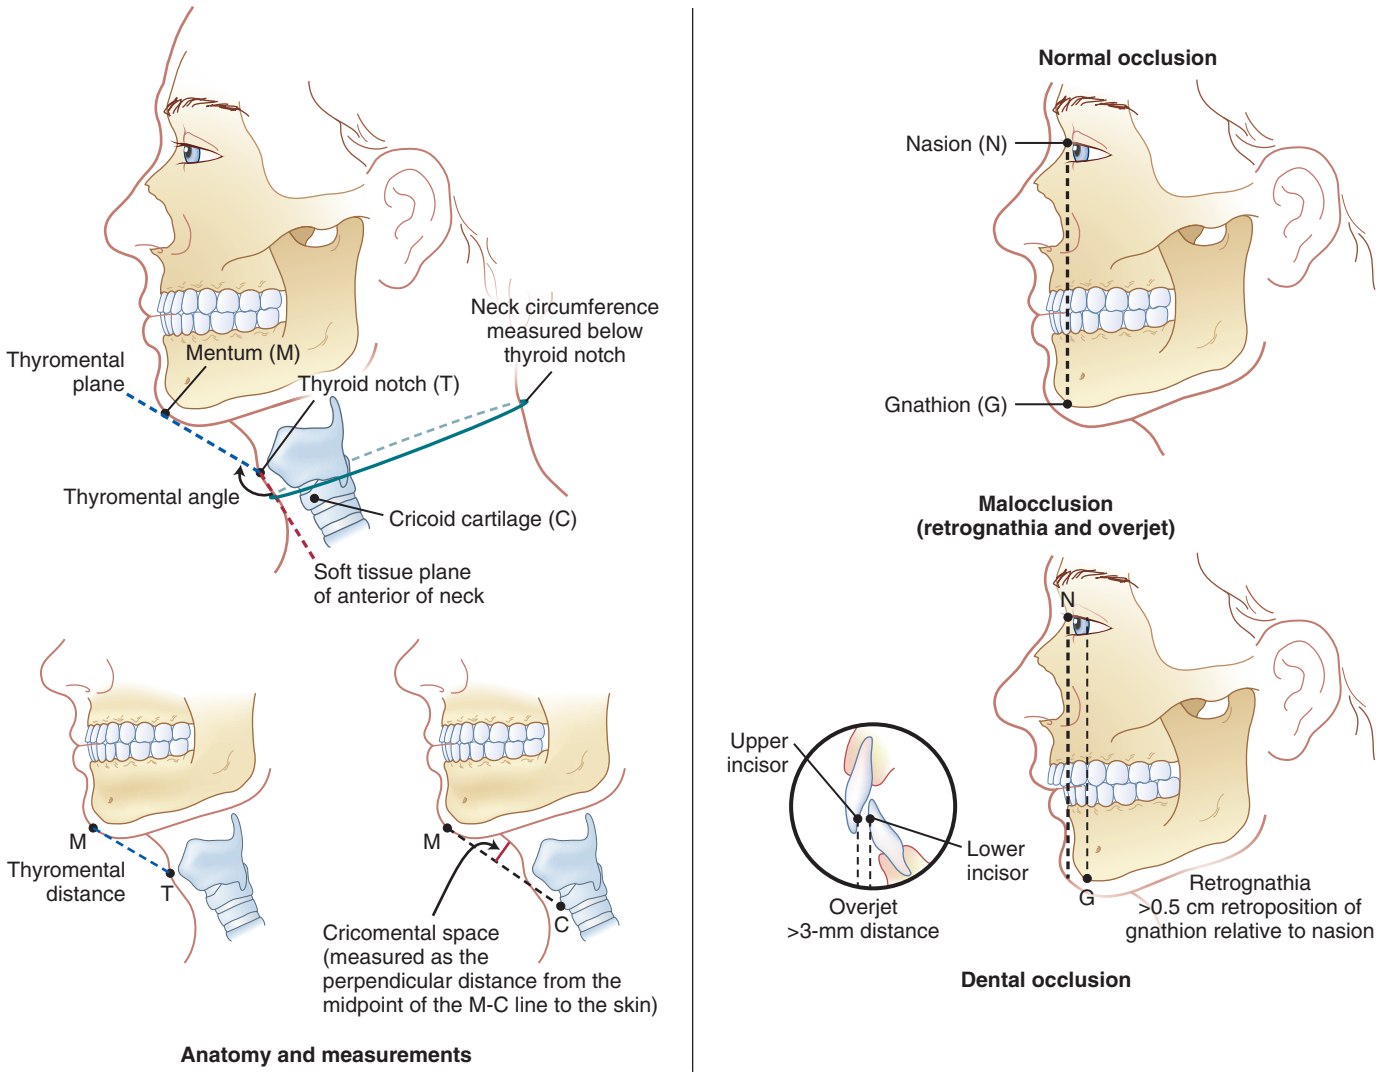

Figure 59-8 Anatomy and surface measurements in the assessment of a patient with suspected obstructive sleep apnea (OSA). Retrognathia, overjet, and reduced cricomental space are key craniofacial properties that are predictive of OSA. (From Myers KA, Mrkobrada M, Simel DL. Does this patient have obstructive sleep apnea? The rational clinical examination systematic review. *JAMA* 2013;310:731–41.)

Figure 59-9 Progressive change in facial features in a patient with acromegaly. The onset of physical changes is sometime insidious, and patients may not present with specific complaints relating directly to these distinguishing signs of acromegaly. However, patients may be more likely to present with symptoms referred to other conditions such as diabetes, hypertension, and obstructive sleep apnea. At the advanced stages of the condition, patients exhibit more dramatic physical characteristics, such as enlarged hands, feet, lips, and tongue; prominent supraorbital ridges; and lower jaw protrusion. (From Molitch ME. Clinical manifestations of acromegaly. *Endocrinol Metab Clin North Am* 1992;21[3]:597–614.)

Figure 59-13 Hunter syndrome (mucopolysaccharidosis type II) depicting significant macroglossia, a risk factor for OSA. In this 8-year-old boy with Hunter syndrome, infiltration of the macroglossia can be seen. Other features include macrocephaly, coarse hair, abnormally short neck, hairy face, puffy eyelids, depressed nasal bridge, upturned nose, full lips, and thick skin texture. (From Chou W-C, Weng C-Y, Lin S-P, Chu S-Y. Postenzyme replacement therapy era for type 2 mucopolysaccharidosis. *Tzu Chi Med J* 2013;25:128–9.)

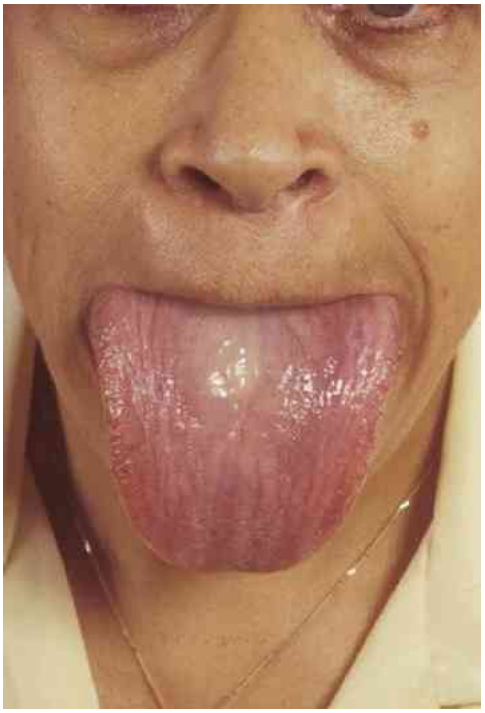

Figure 59-14 Profound enlargement of the tongue (macroglossia) as a result of amyloid infiltration. The patient had severe obstructive sleep apnea. The tongue fills the oral cavity completely, contributing to profound hypopharyngeal and oropharyngeal airway blockade. (From Hoffman R, Benz EJ, Silberstein LE, et al. *Hematology: diagnosis and treatment*. Philadelphia: Elsevier Science; 2013. p. 1352, Figure 87-3.)

syndrome is associated with metabolic syndrome and carries a greatly increased risk for obesity with metabolic syndrome, OSA, impaired glucose tolerance, type 2 diabetes mellitus, and cardiovascular disease (Figure 59-15).[23]

Craniofacial Factors

As summarized in Figure 59-8, cephalometric measurements reveal that subjects with OSA have significant changes in the size and position of the soft palate and uvula, volume and position of the tongue, hyoid position, and mandibulomaxillary protrusion compared with controls. Mandibular retrognathia (Figure 59-16) and micrognathia (Figure 59-17), which cause the tongue to rest in a more superior and posterior position, impinging on the upper airway, can be detected on examination, especially by observing the patient from the side. As seen in Figure 59-17, *B*, the cricomentalis space defined by the distance between the neck and the bisection of a line from the chin to the cricoid membrane, when the head is in a neutral position, is extremely limited.[24] A scalloped tongue (Figure 59-18) may accompany micrognathia. Men with retrognathia or micrognathia may grow a beard to compensate for this anatomic variant. Crowded teeth (Figure 59-19) and overjet (Figure 59-20), with the mandibular teeth excessively posterior to the maxillary teeth (Figure 59-20, *B*), often accompany retrognathia or micrognathia. Figure 59-21 depicts the global consequences of primary mandibular insufficiency on the patency of the upper airways, leading to compromised retronasal, retropalatal, and retroglossal spaces.[2] Commonly encountered craniofacial features predisposing to sleep apnea consist of mandibular deficiency syndrome, an inferiorly placed hyoid bone relative to the mandibular plane, narrowing of the posterior airspace, and elongation of the soft

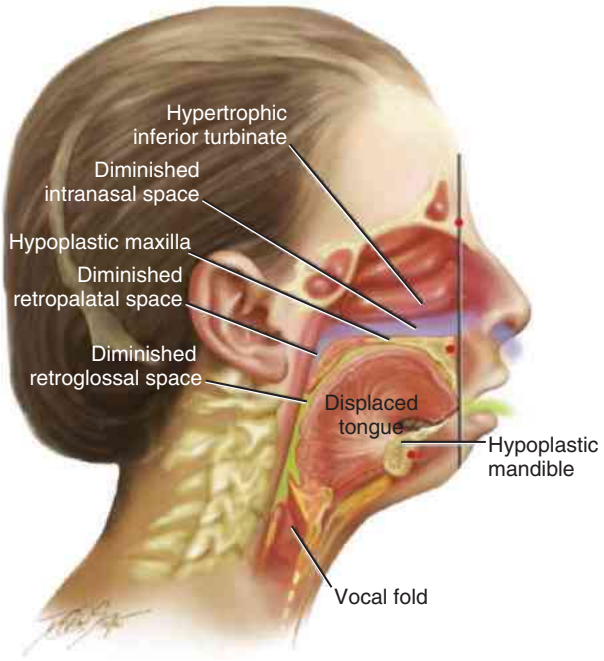

Figure 59-21 An illustration of a sagittal cross-sectional head and neck view from a 16-year-old patient with primary mandibular deficiency and overjet malocclusion predisposing to obstructive sleep apnea. (Courtesy Dr. Meir H. Kryger.)

Figure 59-22 A patient with the long face syndrome, a well-established risk for obstructive sleep apnea, that is conferred through an increase of anterior facial height generally associated with retrognathia. (Courtesy Dr. Meir H. Kryger.)

palate.[25] In addition, marfanoid habitus, including the long face phenotype (Figure 59-22), leads to upper airway restriction, thereby predisposing to OSA.[26] Indeed when the well-established role of obesity in the development of OSA is taken into account, a model of OSA emerges in which the degree of craniofacial abnormalities determines the extent of obesity required to produce OSA in a given individual.

Racial differences in cephalometric properties probably play a major role in conferring risk for OSA in the absence of obesity. For example, in Chinese patients with OSA, a more retropositioned mandible was associated with more severe OSA, after controlling for obesity.[27] In Japanese patients with OSA, micrognathia was a major risk factor.[28] Children and adults with Down syndrome (see Figure 59-12) frequently have sleep apnea most likely related to a combination of craniofacial abnormality and macroglossia.

Patients with OSA have an increased pharyngeal narrowing ratio, which is defined as a ratio between the airway cross section at the hard palate level and the narrowest cross section from the hard palate to the epiglottis.[29]

Nasal Factors

Examination of the nasal airway should focus on anatomic abnormalities that may contribute to nasal obstruction. These may be congenital, traumatic, infectious, or neoplastic in etiology (Figure 59-23).

Neck Circumference

Increased neck circumference (see Figure 59-6) is an important risk factor for OSA. Patients with a neck circumference

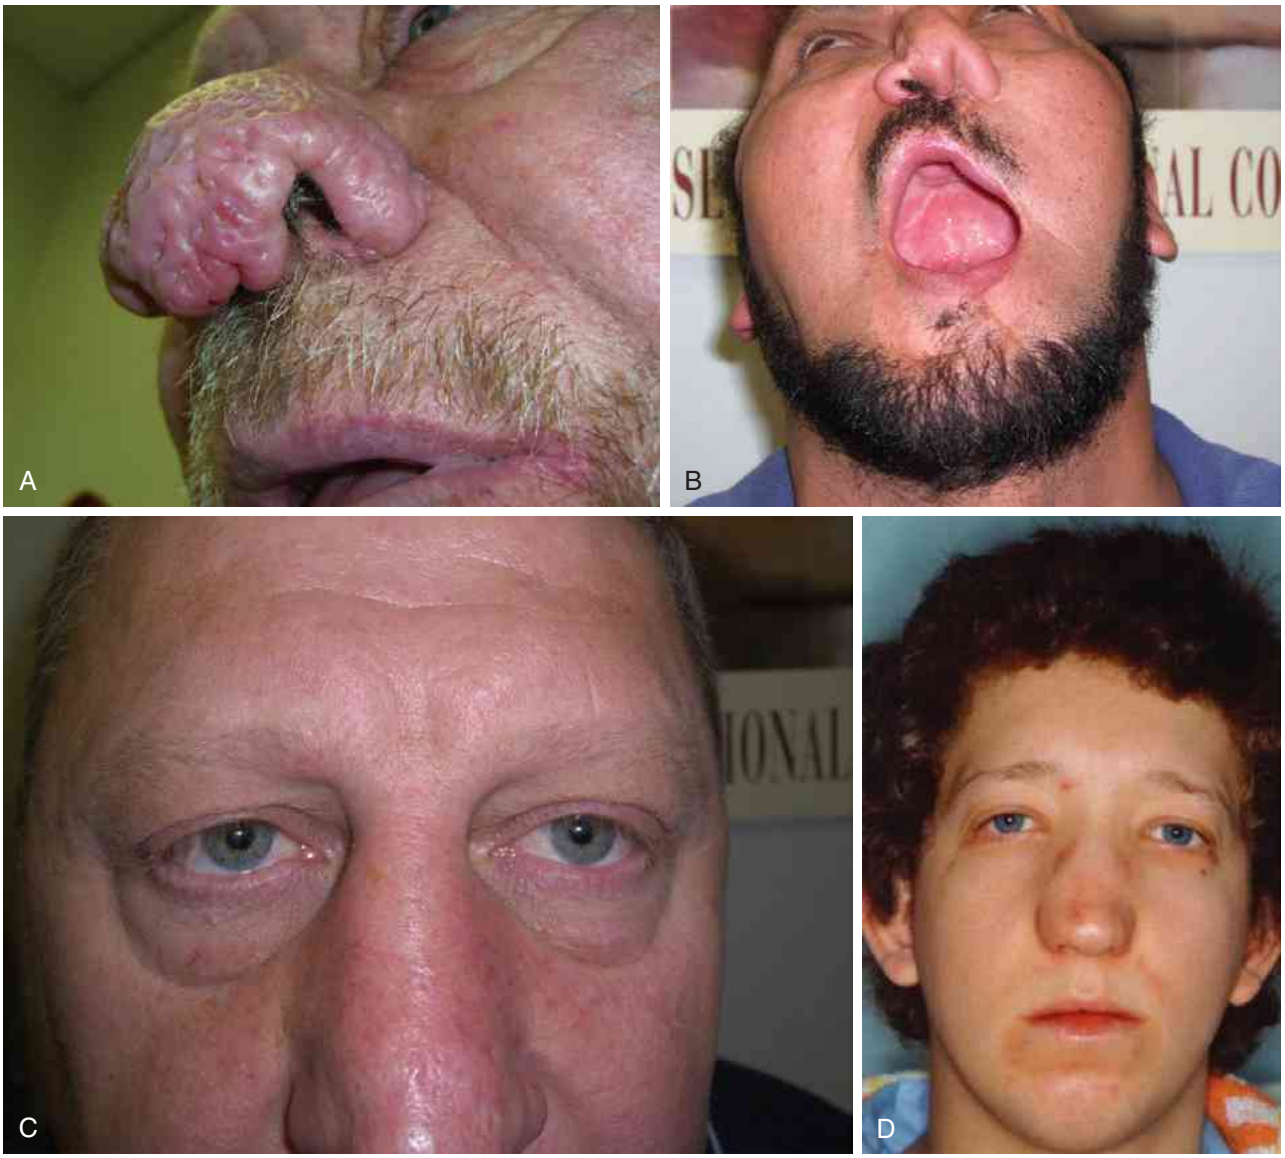

Figure 59-23 Deformity of the nose can be a very important contributor to sleep disordered breathing. **A,** Rhinophyma ("bulbous nose" or "phymatous rosacea") is a nodular hypertrophy characterized by progressive thickening of the nose and leading to compromise of the nasal orifice airflow. **B,** Gun shot wound leading to significant facial injury and nasal collapse, requiring maxillomandibular reconstruction and plastic surgery. **C,** Nasal deviations due to remote fool injury. **D,** Nasal deformity due to the presence of nasal polyps. (**A, B,** and **D,** Courtesy Dr. Meir H. Kryger. **C,** From McGurk M. ENT disorders. In: Sprout C, Burke G, McGurk M, editors. *Essential human disease for dentists.* Edinburgh: Churchill Livingstone; 2006. p. 195–204.)

greater than 48 cm (19.2 inches) have a 20-fold increased risk for OSA.[30]

Examination of the Pharynx

There are two well-established classifications to determine the relation of the tongue to the pharynx. The Mallampati classification was first described as a method for anesthesiologists to predict difficult tracheal intubation (Figure 59-24).[31] The Friedman classification identifies prognostic indicators for successful surgery for sleep-disordered breathing, combining palate position with tonsillar size.[32] The Mallampati classification can be seen in Table 59-2 and Figures 59-25 through 59-28. The Friedman classification is illustrated in Figure 59-29.

Table 59-2 Mallampati Classification

Class I	Soft palate, fauces, uvula, and posterior and anterior pillars are visible (Figure 59-25)
Class II	Soft palate, fauces, and uvula are visible (Figure 59-26)
Class III	Soft palate, fauces, and only base of uvula are visible (Figure 59-27)
Class IV	Soft palate is not visible (Figure 59-28)

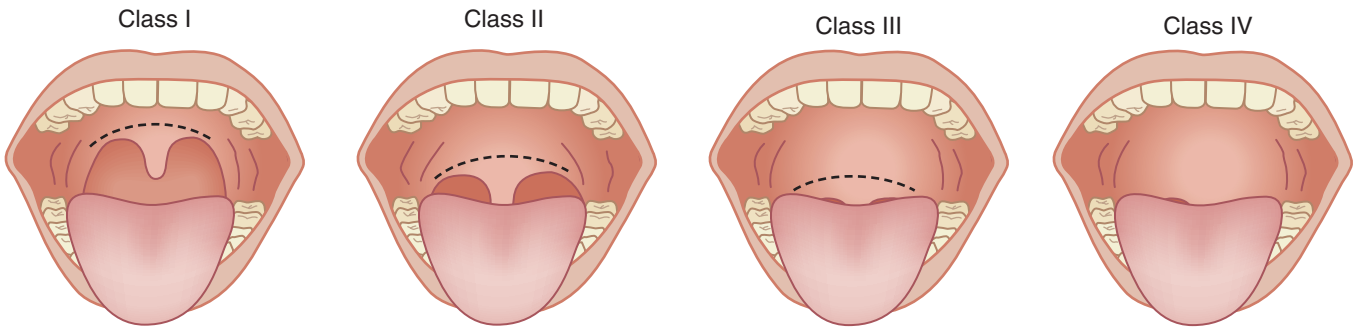

Figure 59-24 The Mallampati classification system is visualized with the tongue protruded, but without the patient phonating. A *modified* form of the Mallampati system is measured with the tongue remaining on the floor of the mouth. The system was initially developed to predict ease of intubation but was later adopted by sleep medicine to help forecast the severity of obstructive sleep apnea in the ambulatory setting. It can also be used to help predict the appropriateness of upper airway surgery in certain patients by delineating the relationship of the various upper airway structures and noting the tongue size in relation to the uvula, tonsils, soft palate, and oropharyngeal wall. The standard for tongue size measurement involved the patient holding his or her head in a neutral position, opening the mouth as wide as possible, and sticking out the tongue. Class I is characterized by direct visualization of the soft palate, uvula, palatine tonsils, and pillars. However, as these structures become obscured, so does the Mallampati class, until only the hard palate is visible (class IV). (From Townsend CM Jr, Beauchamp RD, Evers BM, et al. *Sabiston textbook of surgery*. 19th ed. Philadelphia: Elsevier; 2012.)

Figure 59-27 Mallampati class III. (From Kryger MH. *Atlas of clinical sleep medicine*. 2nd ed. Philadelphia: Saunders; 2014: Fig. 13.1-30, A.)

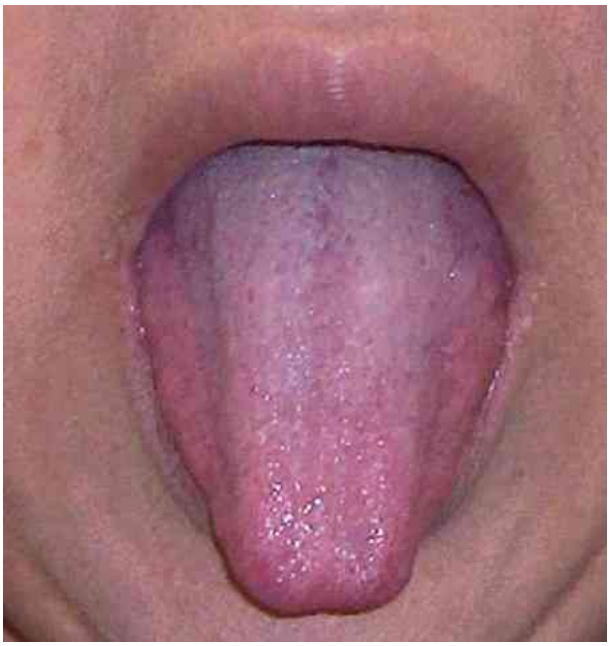

Figure 59-28 Mallampati class IV. (From Kryger MH. *Atlas of clinical sleep medicine*. 2nd ed. Philadelphia: Saunders; 2014: Fig. 13.1-31.)

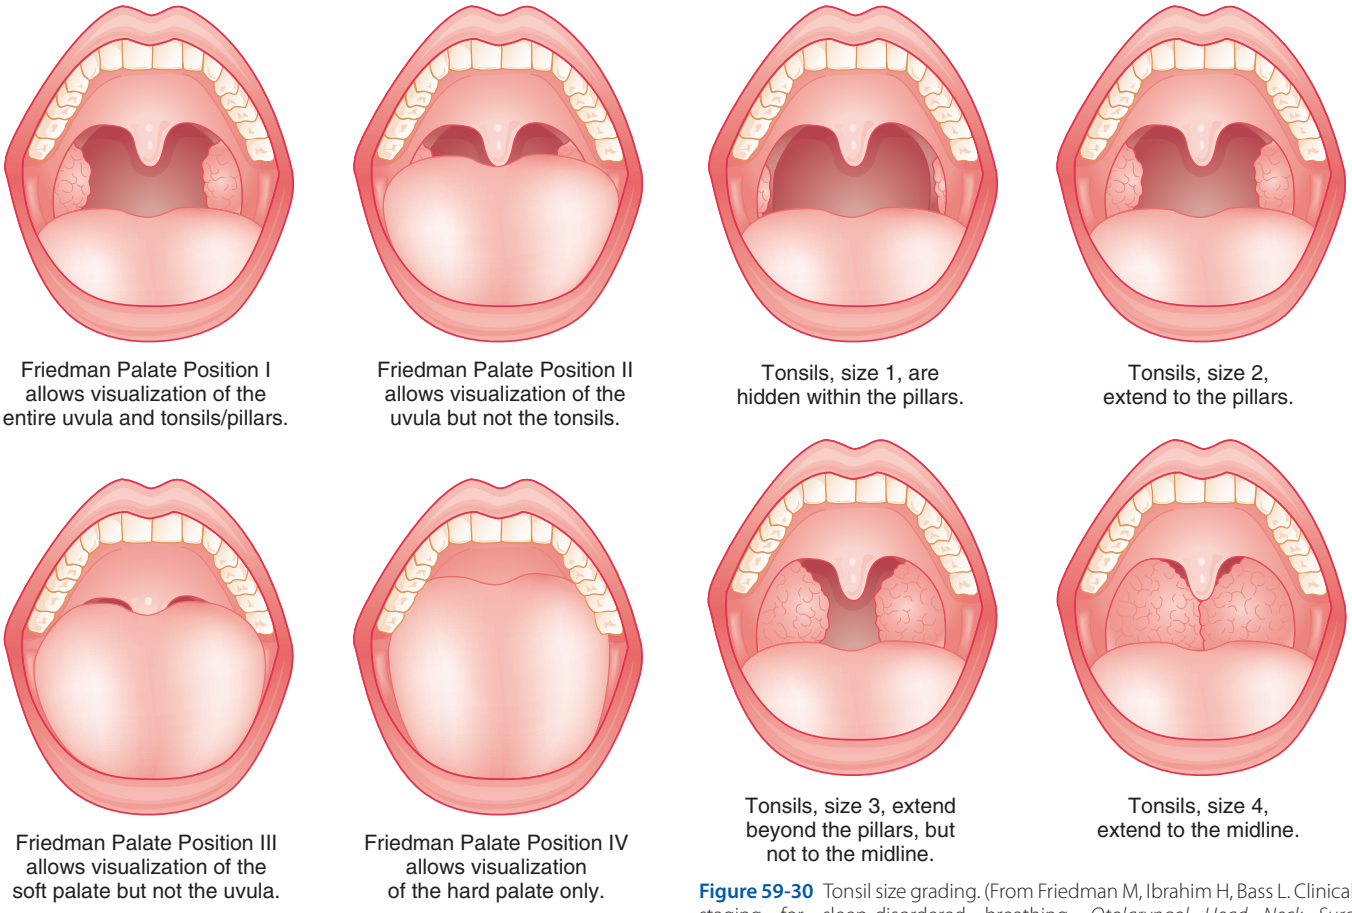

Figure 59-29 Friedman classification. This grading is based on the tongue in a natural position inside the mouth (I). Palate grade I allows the observer to visualize the entire uvula and tonsils or pillars. Palate grade II allows visualization of the uvula but not the tonsils. Palate grade III allows visualization of the soft palate but not the uvula. Palate grade IV allows visualization of the hard palate only. (From Friedman M, Ibrahim H, Bass L. Clinical staging for sleep-disordered breathing. *Otolaryngol Head Neck Surg* 2002;127:13–21.)

Figure 59-30 Tonsil size grading. (From Friedman M, Ibrahim H, Bass L. Clinical staging for sleep-disordered breathing. *Otolaryngol Head Neck Surg* 2002;127:13–21.)

Examination of the Tonsils

Enlarged tonsils and adenoids are a major cause of airway obstruction and sleep apnea in children, but a minority of adults may also have enlargement of these structures contributing to airway obstruction.[33] Adenoids cannot be visualized in a routine physical examination, and the examination of tonsils may require use of a tongue blade. Tonsillar size is graded on a scale of 1 to 4 (Figure 59-30). Children with marked adenotonsillar hypertrophy and nasal obstruction have been noted to have a peculiar "dull" expression (i.e., "adenoid facies"), as shown in Figure 59-31, *A* and *B*. Children with chronic sinus allergies may present with an "allergic salute" sign (see Figure 59-31, *C*).

Neurologic Examination

The neurologic examination may hold important clues to the presence of obstructive or central sleep apnea and hypoventilation syndromes. Features of neuromuscular disease evident on physical examination may indicate these syndromes. For example, progressive muscle atrophy and fasciculations of the hand (Figure 59-32) or tongue may indicate amyotrophic lateral sclerosis. In amyotrophic lateral sclerosis, phrenic nerve dysfunction is common and results in diaphragmatic paralysis, with prominent hypoventilation during rapid eye movement (REM) sleep. In addition, coexisting OSA may occur in amyotrophic lateral sclerosis with bulbar involvement. Weakness of thoracoabdominal or respiratory accessory muscles, often with accompanying kyphoscoliosis, may be observed in poliomyelitis. Postpolio syndrome, muscular dystrophies, myasthenia gravis, and metabolic myopathies may also manifest with weakness of the chest wall musculature[34] and diaphragm weakness. Myasthenia gravis (Figure 59-33) may also involve facial structures, resulting in OSA. Craniofacial abnormalities may occur in myotonic dystrophy (Figure 59-34) or muscular dystrophy; macroglossia may also occur (e.g., Duchenne muscular dystrophy).[35]

Figure 59-35 depicts a patient with facial weakness in the setting of progressive muscular dystrophy. Figure 59-36 shows a patient with myotonic dystrophy with tightness of the muscles (called myotonia), leading to difficulty relaxing certain muscles after using them, such as being able to release grip in a handshake or on a doorknob, or as in the example provided. Figure 59-37 depicts the classic Gower maneuver in Becker muscular dystrophy. Defects in upper airway neuromuscular control in many of the patients with dystrophinopathies play a critical role in sleep apnea pathogenesis, and the sleep care provider must maintain a vigil eye on sleep disturbances in this group of patients.[36]

Finally, obesity (e.g., from steroid use, as in Figure 59-38, or inactivity) may also contribute to sleep apnea in neuromuscular disease.

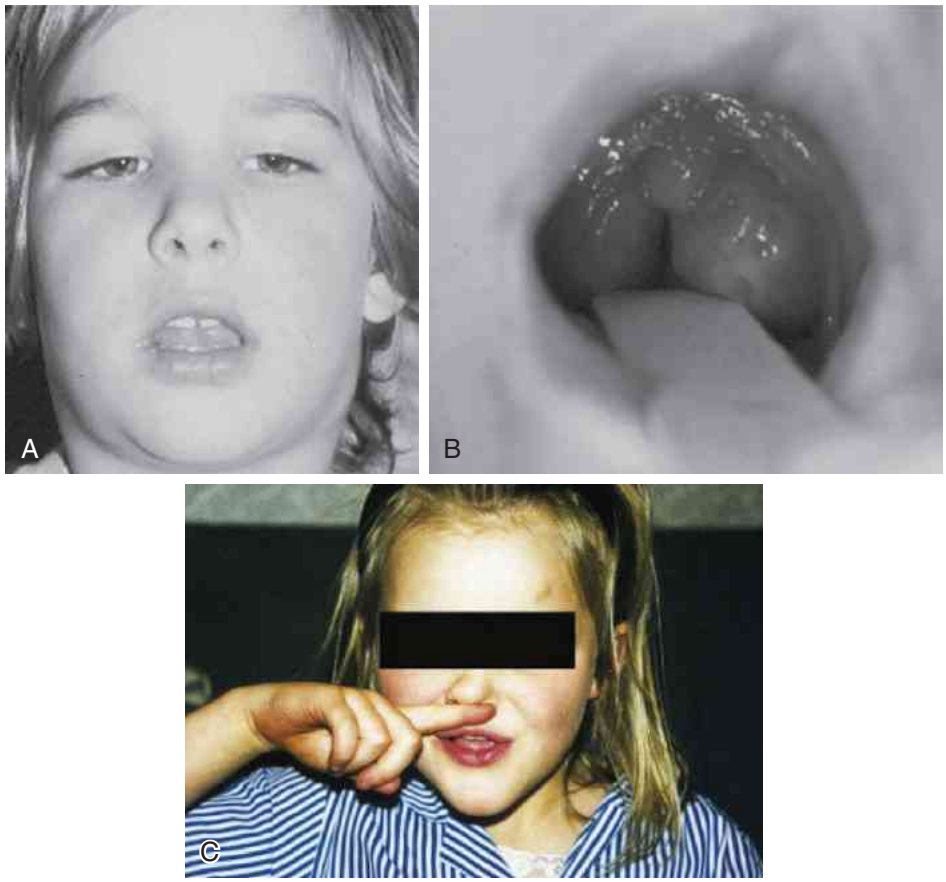

Figure 59-31 A pediatric patient with adenoidal and tonsillar hypertrophy and sinus allergies. **A,** The patient has a "dull expression" of a child with marked adenotonsillar hypertrophy and nasal obstruction (i.e., "adenoid facies"). He must keep his mouth open to breathe and shows signs of fatigue as a result of the result of sleep disruption as a consequence of obstructive sleep apnea. **B,** A severely crowded oropharynx due to tonsillar hypertrophy. **C,** Allergic salute in a patient with chronic allergic rhinitis. Figure 59-33 Facial muscle weakness in myasthenia gravis. (From Goldman L, Ausiello DA, editors. *Cecil medicine*. 23rd ed. Philadelphia: Elsevier; 2008.)

Cardiopulmonary Examination

The presence of congestive heart failure (see Chapter 129) indicates a high likelihood of central sleep apnea. Peripheral edema (Figure 59-39) is a common finding in patients with obesity-hypoventilation syndrome (as a manifestation of cor pulmonale) and in some patients with OSA who also have left ventricular cardiac failure. Resolution of peripheral edema with treatment correlates with clinical improvement. Chronic obstructive pulmonary disease (see Chapter 111) and asthma (see Chapter 111) are also seen in association with OSA. In patients with cardiopulmonary insufficiency, clubbing of digits and nails may be a cardinal sign (Figure 59-40).

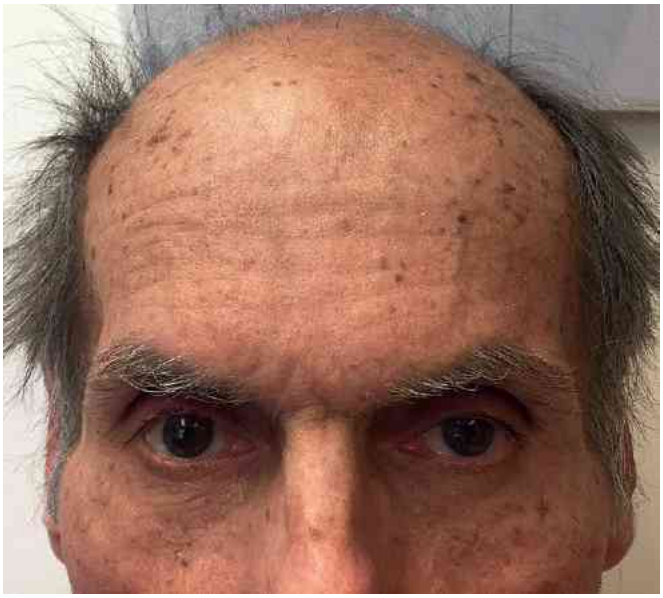

Figure 59-34 Myotonic muscular dystrophy (DM1). Findings in a patient with myotonic muscular dystrophy include wasting of the temporal muscles (shown) and male-pattern baldness that began at an early age. These patients may also have weakness of other facial muscles and mycrognathia. (Courtesy Dr. Meir H. Kryger.)

CENTRAL NERVOUS SYSTEM HYPERSOMNIA

Narcolepsy

Physical findings in patients with narcolepsy are nonspecific and may be subtle, infrequent, and absent during the clinic visit. During cataplectic spells, patients present with muscle atonia, absence of deep tendon reflexes, and decrease in the H-reflex.[37] Cataplexy attacks may range from partial episodes characterized by sagging of the jaw and mild dropping of the head and shoulders, to generalized spells leading to loss of muscle tone with unbuckling of the knee. However, it is rare to encounter cataplexy during the actual clinic visit or physical examination, which makes it difficult to describe during routine clinic visits. In general patients with narcolepsy tend to be obese, with increased predilection to type 2 diabetes mellitus, and have a lower basal metabolism compared with controls.[38,39] Children with obesity and precocious puberty should be screened for narcolepsy and cataplexy.[40]

Narcolepsy related to medical conditions (symptomatic narcolepsy) is seen in disorders such as CNS tumors, head trauma, multiple sclerosis, neurosarcoidosis, acute disseminated encephalomyelitis, CNS vascular disorders, encephalitis, and neurodegeneration.[41] An abnormal neurologic examination can be an important sign that hypersomnia may be due

Figure 59-35 A and **B,** Bilateral facial weakness due to progressive muscular dystrophy. The patient exhibits the classic signs, including bilateral ptosis. Facial weakness involves the orbicularis oculi, orbicularis oris, and zygomaticus muscle, producing the characteristic myopathic facial. Weakness of muscles of the thoracic region often leads to respiratory insufficiency, and many patients also present with bulbar symptoms (dysarthria, dysphagia). (From Laina V, Orlando A. Bilateral facial palsy and oral incompetence due to muscular dystrophy treated with a palmaris longus tendon graft. *J Plast Reconstr Aesthet Surg* 2009;62[11]:e479–81.)

to a CNS etiology. In lesions of the diencephalon due to inflammatory changes such as neurosarcoidosis, one finds additional physical findings associated with panhypopituitarism such as orthostatic hypotension, temperature fluctuations, and other finding of autonomic dysregulation.

Patients with narcolepsy type 1 who experience cataplexy are sometimes observed to have a state of peculiar semipermanent ptosis and jaw weakness, on which partial and complete cataplectic attacks were superimposed cataplectic facies,[42,43] as depicted in Figure 59-41.

Figure 59-41 **A,** Patients with cataplexy are shown responding to the trigger stimulus (a cartoon). The facial weakness is also present during normal activity without stimulus. **B,** The patient experiences facial muscle weakness, as noted by bilateral, facial grimaces while attempting to keep the eyes open. Facial slackening and tongue protrusion with the mouth opened and a quasi "drunken or droopy look" phenotype, characterize the "cataplectic facies." (From Leonardo S, Pasquale M, Emmanuel M, et al. Cataplexy features in childhood narcolepsy. *Mov Disord* 2008;23:858–65.)

PARASOMNIAS

Nocturnal Eating Disorder and Sleep-Related Eating Disorder

In nocturnal eating disorder, patients often manifest compulsive food-searching behaviors and a return to sleep after food ingestion. Body mass index was abnormally high in 6 of 10 patients after careful exclusion of both anorexia nervosa and bulimia.[44] Sleep-related eating disorder, which also occurs in the setting of WED, is characterized by recurrent episodes of eating after an arousal from nighttime sleep with or without amnesia[45] and may also result in obesity.

REM Sleep Behavior Disorder

Patients with idiopathic REM sleep behavior disorder (RBD) can develop dramatic and aggressive dream enactment events sometimes leading to serious injury. Figure 59-42 depicts a patient who presented at the author's sleep clinic together with his wife who complained that he was dreaming about golfing, was in an argument, and fell to the floor. In the process he hit his neck on the corner of the bedside table and bruised his ear and cheek on bedside table. Although the condition is unlikely to produce severe injury to the patient, the bed partner paradoxically ends up suffering severe sleep interruptions, is more likely to experience sleepiness, and is at risk for injury. Patients with RBD are frequently at risk for development of α-synucleinopathies such as Parkinson disease, and most present with hyposmia (impaired smell), which is a potential preclinical nonmotor sign of the disease.[46] Odor identification was also found impaired in Japanese patients with idiopathic RBD and Parkinson disease.[47]

Cardinal features of Parkinson disease are shown in Figure 59-43. Patients with multiple system atrophy may present with inspiratory stridor, which along with RBD may serve as a clue to the disease in a patient with autonomic failure.[48]

SLEEP-RELATED MOVEMENT DISORDERS

Willis-Ekbom Disease

The prevalence of WED, also known as restless legs syndrome, in patients with type 2 diabetes is 17.7%,[49] and the prevalence may be higher in patients with hereditary neuropathy.[50] WED occurs in about one third of patients with polyneuropathy,[51] with preferential involvement of small sensory fibers. Electrophysiologic studies demonstrate that axonal neuropathy is common in WED, which further necessitates comprehensive peripheral nerve evaluations in these patients.[52]

Reduced iron stores can also cause WED. With iron deficiency, examination of the pharynx may reveal inflammation (redness) or loss or atrophy of the lingual mucosa, indicating glossitis (Figure 59-44). The patient may complain of a sore or tender tongue.

On neurologic examination, symptoms include sensory loss, often described by patients as a sense of numbness or tingling. In the generalized polyneuropathies, symptoms frequently begin in the most distal aspect of the longest sensory fibers, which produce disturbances in sensation in the toes and feet. In addition to sensory loss, patients frequently complain of paresthesias and dysesthesias, often characterized by numbness, tingling, prickling, and pins-and-needles sensations. The sensory examination will often disclose a distal to proximal loss of the various sensory modalities. In certain polyneuropathies, pain predominates in the clinical picture, and the sensory examination tends to disclose deficits predominantly of pain and thermal sensation. When significant proprioceptive deafferentation occurs, patients may present with altered joint position sense that can manifest as an ataxia or tremor of the affected limbs and an imbalance of gait and station.

Pain may be a significant symptom for many patients with WED in which the etiology is related to a polyneuropathy. It

may be described as a dull aching sensation, an intense burning sensation, or, occasionally, intermittent lancinating pulses of pain. On occasion, patients notice that their skin is hypersensitive to tactile stimulation, such as from the touch of bed sheets or clothing or standing on the feet. Some patients note an exaggerated painful sensation resulting from any stimulus to the affected area, a form of pain termed allodynia. Various limb deformities and trophic changes may be observed in chronic polyneuropathies. Pes cavus, characterized by high arches and hammertoes, and the clawfoot deformity are typical foot deformities in hereditary polyneuropathies with childhood onset. These deformities are due to progressive weakness and atrophy of intrinsic foot muscles. A similar clawlike deformity may be observed in the hand. Autonomic involvement of a limb may cause the affected area to appear warm, red, and swollen at times and pale and cold at other times owing to dysregulation of small vessels due to autonomic denervation. Various trophic changes, including tight, shiny skin, may occur. In patients who have had severe sensory

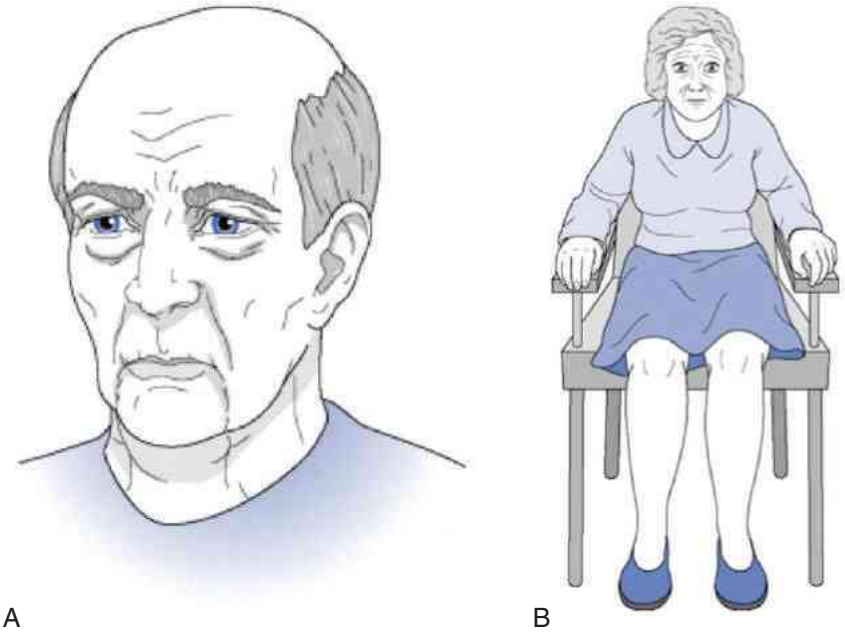

Figure 59-43 A, Patients with Parkinson disease (PD) blink less frequently and make fewer facial expressions, with less frequent head movements ("masked facies"). **B,** Patients with PD rarely participate in normal gestures or repositioning movements. They are observed to sit motionless with their legs uncrossed and their feet flat. The upper extremities remain motionless on the chair or in their lap. (From Kaufman DM: Involuntary movement disorders. In: Kaufman DM, editor. *Clinical neurology for psychiatrists.* 6th ed. Philadelphia: Elsevier; 2007. p. 401–64.)

loss in the limbs, the affected areas may be subject to incidental traumas, including burns, pressure sores, and other injuries that are not perceived by the patient, in whom repeated injuries and traumas may result in chronic infections and, when severe, lead to osteomyelitis. A clinical evaluation of peripheral neuropathy is provided by Kelly.[53,54]

Bruxism

Bruxism (see Chapters 144 and 145) represents a stereotyped movement disorder clinically characterized by grinding or clenching of the teeth during sleep. The sounds made by friction of the teeth are usually perceived by a bed partner as very unpleasant.[55] The condition is typically brought to the attention of the medical or dental practitioner in efforts to eliminate the disturbing sounds. Bruxism can lead to abnormal wear of the teeth (Figure 59-45), periodontal tissue damage, or jaw pain. Other symptoms include facial muscle and tooth pain and headache. Bruxism induces dental damage with abnormal wear to the teeth and damage to the structures surrounding the teeth. Chronically, over time and when untreated, this leads to recession and inflammation of the gums, alveolar bone resorption, muscles of mastication hypertrophy (Figure 59-46), and temporomandibular joint disorders, often associated with facial pain. Additional physical findings include tenderness of the muscles of mastication (masseter, temporalis, pterygoid, sternocleidal), temporomandibular disorders, tongue indentation, subjective appreciation of a tense personality, and hypervigilant patient.[56]

Case reports in patients with bruxism demonstrate bilateral enlargement in the region of the mandibular angle, corresponding with the masseter hypertrophy (see Figure 59-46).[57] Children with bruxism have a significantly longer and higher palate in the sagittal plane and bigger dental arches compared with normal children.[58] Psychiatric patients have a higher prevalence of bruxism and signs of temporomandibular disorders, possibly related to neuroleptic-induced phenomenon.[59]

Figure 59-45 Bruxism with abnormal wear of the teeth.

Insomnia

Insomnia, especially comorbid in type, is often seen in the context of endocrinopathies, mood disorders, anxiety disorders (Figure 59-47), rheumatologic conditions, pain, and a

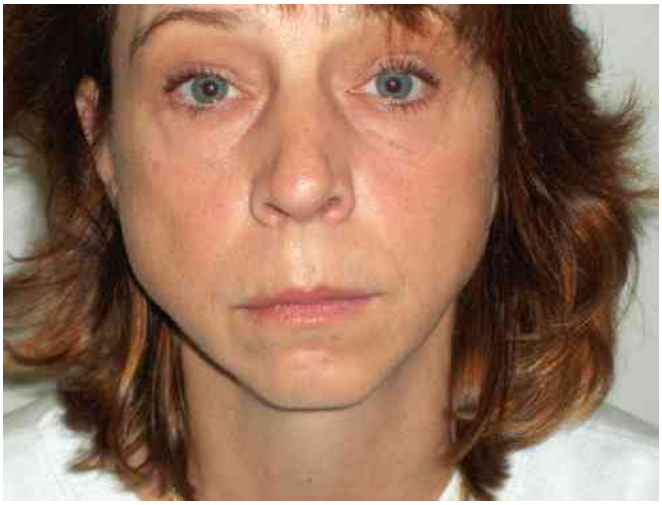

Figure 59-46 Hypertrophic masseter in bruxism. The masseter muscle bulk is markedly increased over the mandibular angle region. (Courtesy Dr. Meir H. Kryger.)

Figure 59-47 The painting of anxiety, a common comorbidity in chronic insomnia. (From Gross M. Shining new light on the brain. *Curr Biol* 2011;21[20]:R831–3.)

long list of other medical, psychiatric, and primary sleep disorders. Patients with Graves disease (Figure 59-48), an autoimmune disorder and a common cause of hyperthyroidism, is characterized by the presence of autoantibodies that bind and stimulate the thyroid-stimulating hormone receptor, resulting in hyperfunction of the thyroid. Graves disease is characterized by a phenotype of heat intolerance, involuntary weight loss, thyromegaly, tremor, and hyperactivity manifesting as restless sleep and insomnia.[60] Finally, floppy eyelid syndrome (Figure 59-49) is sometimes confused with tiredness, a thyroid disorder, or a neuromuscular disorder and is characterized by flaccid and easily everted upper lids, occurring spontaneously or with minimal manipulation.[61] It is can seen in middle-aged men who are overweight and has been associated with OSA.

CLINICAL PEARLS

- Overall inspection of the patient, coupled with observation of craniofacial, nasal, and pharyngeal factors, allows detection of key risk factors for sleep apnea.
- Examination of patients with insomnia should focus on the potential associated comorbidities, including hypothyroidism and rheumatologic disorders.
- Patients with motor disorders of sleep and parasomnias also have clinical findings conferred by the underlying medical, neurologic, and associated psychiatric comorbidities. For example, anosmia, orthostatic fluctuations in the setting of dream enactment behavior, and loss of electromyographic tone on polysomnogram may be predictive of an evolving α-synucleinopathy.
- Clues to the presence of abnormal nocturnal events such as parasomnias or nocturnal seizures may include unexplained bruising, lacerations in the former, and tongue laceration in the latter. However, even tongue biting, which is believed to be a clinical sign of epilepsy, can occur in syncope and nonepileptic seizures. These difficulties highlight the importance of a well-tailored approach in which the clinical history, physical examination, and supportive laboratory and polysomnographic data are used to arrive the most plausible clinical diagnosis.

SUMMARY

The physical examination of any patient with sleep disorders is the cornerstone for making critical decisions about the possible clinical diagnosis, determining the need for formal polysomnography, and ensuring that treatment is successful. Given that medial trainees often do not receive formalized sleep medicine education in medical school, appreciating the fundamental phenotypical patterns responsible for sleep-disordered breathing is critical. A basic appreciation of the abnormal neurologic examination is important for nonneurologists who may encounter patients with parasomnias and motor and movement disorders of sleep. Finally, no clinical examination of a sleepy patient should conclude without a comprehensive review of the patient's medical, endocrine, metabolic, genetic, and disease background, given that may phenotypes contribute directly to disruptive sleep.

Use of Clinical Tools and Tests in Sleep Medicine

Chapter 60

Cathy A. Goldstein; Ronald D. Chervin

Chapter Highlights

- A clinician confronted with a sleep-related complaint combines symptoms, signs, and test results to make a diagnostic assessment.
- Information about test performance characteristics, such as sensitivity, specificity, and predictive value, can be used more formally to decide on optimal approaches.
- In addition to the history and physical examination, tools and tests used in the evaluation of a patient with sleep-related symptoms may include questionnaires, sleep diaries or logs, actigraphy, nocturnal polysomnography, an out-of-center sleep test, or a multiple sleep latency test.

This chapter focuses on the comparative value of different approaches to clinical assessment of sleep-related problems. The symptoms, signs, and test results relevant to particular sleep disorders are described in detail in chapters that focus on specific clinical entities. This chapter, instead, highlights the clinical reasoning process by which a clinician challenged with a sleep complaint can combine information from different sources, appropriately weigh available evidence, and arrive at sound diagnoses and treatment plans. Here we review the value of tests in evaluations of suspected obstructive sleep-disordered breathing, hypersomnolence, insomnia, suspected circadian rhythm sleep-wake disorders, restless legs syndrome (RLS), and suspected parasomnias. A selection of evidence-based practice parameters and reviews produced by the American Academy of Sleep Medicine (AASM) can be accessed at http://aasmnet.org/practiceguidelines.aspx (Table 60-1) to supplement overviews presented in this chapter.

EVALUATION FOR SLEEP-RELATED BREATHING DISORDERS

History and Questionnaires

Sleep-related breathing disorders are by far the most common disorders diagnosed at sleep centers, and obstructive sleep apnea (OSA) alone accounts for nearly 70% of all patients evaluated.[1]

Subjective clinical impressions of OSA tend to have inadequate sensitivity (probability of a positive test result or assessment given that the disorder is present) and specificity (probability of a negative test result given that the disorder is absent).[2] Combinations of some signs and symptoms can have sensitivity above 0.90, but specificity is usually poor. Performance of these models in clinical practice can be worse than originally reported.[3] However, sensitivity and specificity data suggest that the negative predictive value (NPV) of some symptom combinations may be good, whereas the positive predictive value (PPV) is probably poor, especially when the prevalence of OSA in the tested population is not high.[4] Accordingly, patients without a history suggestive of OSA usually do not receive further testing for it. Among patients referred for suspected OSA, models based on historical information may accurately classify a minority as apnea free without further tests.[5] In practice, patients who do have symptoms of OSA generally are tested.

Although, in general, the PPV of symptoms alone is not high, a minority of patients have a clinical presentation so convincing as to be essentially diagnostic. However, the *International Classification of Sleep Disorders*, third edition (ICSD3), requires minimal objective criteria, in addition to symptoms, to establish a diagnosis of OSA.[6] Tests in such cases may also serve to define the severity of OSA. In a patient with a history strongly suggestive of OSA, the diagnosis must still be suspected when it is not confirmed by a single polysomnogram (PSG) and especially when it is not confirmed by a more abbreviated home sleep test.[7]

The diagnostic values of specific symptoms are difficult to judge on the basis of studies with significant methodologic differences. For example, among patients referred specifically for possible OSA, the symptom of excessive daytime sleepiness may[8] or may not[9] be useful in making the diagnosis, and a history of hypertension may be better than a report of snoring as an indication that OSA is present.[10] Among patients referred to a sleep center, snoring has high sensitivity (80% to 90%) and low specificity (20% to 50%) for the diagnosis of OSA, whereas nocturnal choking or gasping is less sensitive (52%) and more specific (84%).[2] In patients referred for suspected sleep-disordered breathing, the presence of nocturnal choking or gasping yields a PPV for OSA of 35%, which is greater than the PPV for morning headache, reported apnea, excessive daytime sleepiness, or snoring.[2] In contrast, in the community, the symptom with the highest predictive value for OSA is habitual snoring, although excessive daytime sleepiness and observed apneas are also useful.[11]

Physical Examination

In the community, among variables related to body weight, neck circumference and body mass index (BMI) correlate well with the presence and severity of OSA.[12] Among patients referred for possible OSA, these variables still may be useful, but their predictive value is not large except in extreme

MSLT, Multiple Sleep Latency Test; MWT, Maintenance of Wakefulness Test.
Practice guidelines are written by the Standards of Practice Committee of the AASM. Practice Parameters (P), Systematic Reviews (R), Clinical Guidelines (CG), and Best Practice Guides (BPG) are generally available at http://aasmnet.org/practiceguidelines.aspx.

ranges.[9,13,14] Patients with OSA who are not obese often have pharyngeal crowding, obstructed nasal passages, or other craniofacial abnormalities associated with narrowing of the upper airway.[15] The predictive value of such findings may differ somewhat between men and women.[16] The Mallampati score, which reflects oropharyngeal crowding on a 4-point scale, was found to predict OSA.[17] Each 1-point increase in the score was associated with an odds ratio of 2.5 (95% confidence interval [CI] [1.2, 5.0]) for OSA and predicted a 5-point higher apnea-hypopnea index (coefficient = 5.3 [0.2 to 10]), independent of many other physical findings and symptoms.

Physical findings can also be combined into predictive quantitative models to aid in the diagnosis of OSA. Models based on measures that can be obtained during the physical examination, such as BMI, neck circumference, craniofacial measurements, pharyngeal scores, and tonsil size, demonstrate excellent PPV (90% to 100%) but less strong NPV (49% to 89%).[18-20] Other physical findings may also have value in the diagnosis of OSA. High blood pressure increases the chance that OSA will be present, especially among persons who are less obese.[21] Signs of neuropathy or neuromuscular disease also may increase the likelihood of OSA.

Table 60-2 Value of Specific Questionnaire Instruments that Combine Symptoms and Physical Findings to Diagnose Obstructive Sleep Apnea

Instrument	Study	Subjects	Gold Standard	Sensitivity	Specificity	Predictive Value
Berlin Questionnaire	Subramanian et al., 2011[154]	Referral based	PSG RDI ≥15	0.93	0.14	
			PSG RDI ≥5	0.92	0.18	
	Hrubos-Strøm et al., 2011[155]	Population based	PSG AHI ≥15	0.43	0.80	PPV = 0.34, NPV = 0.86
			PSG AHI ≥5	0.37	0.84	PPV = 0.61, NPV = 0.66
	Sun et al., 2011[156]	Referral based	PSG AHI ≥15	0.97	0.48	
	Kang et al., 2013[157]	Population based	PSG AHI ≥5	0.69	0.83	
	Cowan et al., 2014[158]	Referral based	Home PG AHI ≥15	0.94	0.08	PPV = 0.44, NPV = 0.67
			Home PG AHI ≥5	0.93	0.06	PPV = 0.75, NPV = 0.22
STOP-BANG	Chung et al., 2008[159]	Preoperative population	PSG AHI ≥15	0.93	0.43	PPV = 0.52, NPV = 0.90
			PSG AHI ≥5	0.84	0.56	PPV = 0.81, NPV = 0.61
	Ong et al., 2010[160]	Referral based	PSG AHI ≥15	0.91	0.40	PPV = 0.61, NPV = 0.82
			PSG AHI ≥5	0.85	0.53	PPV = 0.84, NPV = 0.53
	Cowan et al., 2014[158]	Referral based	Home PG AHI ≥15	1.0	0.21	PPV = 0.5, NPV = 1.0
			Home PG AHI ≥5	0.95	0.3	PPV = 0.81, NPV = 0.64
NAMES	Subramanian et al., 2011[154]	Referral based	PSG RDI ≥15	0.91	0.23	PPV = 0.62, NPV = 0.63
			PSG RDI ≥5	0.88	0.29	
NAMES2	Subramanian et al., 2011[154]	Referral based	PSG RDI ≥15	0.92	0.34	
			PSG RDI ≥5	0.85	0.42	
Snoring Severity Scale with BMI	Morris et al., 2008[161]	Referral based	PSG RDI ≥15	0.97	0.40	PPV = 0.82, NPV = 0.84

AHI, Apnea-hypopnea index (number of apneas or hypopneas per hour of sleep); BMI, body mass index; RDI, respiratory disturbance index (number of apneas, hypopneas, or respiratory effort related arousals per hour of sleep); NPV, negative predictive value; PPV, positive predictive value; PSG, polysomnography; SDB, sleep-disordered breathing.
The NAMES instrument assesses neck circumference, airway classification, comorbidities, Epworth scale, and snoring. The NAMES2 instrument contains the same variables in NAMES with the addition of BMI and gender. The STOP-BANG instrument assesses snoring, tiredness, observed apneas, blood pressure, BMI, age, neck circumference, and gender. The Snoring Severity Scale (SSS) assesses snoring loudness, frequency, and duration.

Instruments that use a combination of symptoms, comorbidities, and physical findings to assess risk for OSA include the Berlin Questionnaire, STOP-BANG, NAMES, NAMES2, and the Snoring Severity Scale combined with BMI. Table 60-2 shows sensitivity, specificity, and predictive values for these tools. Of these tools, the Berlin Questionnaire and the STOP-BANG instrument (Figure 60-1) are most frequently encountered in clinical practice.

Nocturnal Polysomnography

A nocturnal, laboratory-based PSG is commonly used to objectively test for OSA. The PSG often is considered a gold standard for OSA diagnosis, assessment of severity, and identification of some other sleep disorders that can accompany OSA. The PSG allows direct monitoring and quantification of respiratory events and physiologic consequences—such as hypoxemia, arousals, and awakenings—that are suspected to cause daytime symptoms. A single-night PSG is usually sufficient to diagnose or to exclude OSA. However, the test is not infallible. Accuracy may be reduced by variability in biologic severity, laboratory equipment, human scoring, or scoring protocols. Night-to-night variability may be particularly high in subjects with low but clinically significant rates of apneas and hypopneas during sleep. A repeat PSG may confirm OSA in 20% to 50% of individuals who have symptoms suggestive of OSA but initial PSG negative for OSA.[22,23]

SNORING?
Do you **snore loudly** (louder than talking or loud enough to be heard through closed doors)? Yes No

TIRED?
Do you often feel **tired, fatigued, or sleepy** during the daytime? Yes No

OBSERVED?
Has anyone **observed** you **stop breathing** during your sleep? Yes No

PRESSURE?
Do you have or are you being treated for **high blood pressure?** Yes No

BODY MASS INDEX more than 35 kg/m²? Yes No

AGE older than 50 years? Yes No

NECK circumference?
Neck circumference greater than 40 cm? Yes No

Gender=male? Yes No

Figure 60-1 The STOP-BANG questionnaire. Low risk for OSA: yes to 0 to 2 questions. High risk for OSA: yes to 3 or more questions. (From Chung F, Yegneswaran B, Liao P, et al. STOP questionnaire: a tool to screen patients for obstructive sleep apnea. *Anesthesiology* 2008;108[5]:812–21, with permission.)

Publication by the AASM in 2007 (since updated twice) of new sleep scoring guidelines also included recommendations for polysomnographic equipment; scoring of abnormal respiratory events, electrocardiographic findings, movements, and arousals during sleep; and modifications necessary for children.[24] These guidelines serve to improve uniformity of procedures between laboratories.

Arguably, the change in the updated manual with the highest potential to influence clinical practice is the modification to the scoring rules for hypopneas. The scoring manual recommends that the technician scores a hypopnea when the nasal pressure transducer signal (or positive airway pressure flow during a titration study) drops by at least 30% from the preevent baseline, the duration of this amplitude reduction is at least 10 seconds, and the event results in either an arousal or oxygen desaturation of at least 3%.[25] The recommended hypopnea definition aims to increase the sensitivity of PSG to detect OSA in patients with sleep fragmentation and daytime impairment but without significant oxygen desaturations.[25] The scoring manual also defines an acceptable rule as an alternative method to score hypopneas that requires an oxygen desaturation of 4%.[25]

The distinction between the recommended rule and acceptable rule for scoring hypopneas is important from a diagnostic standpoint. For example, PSGs were rescored in a group of lean patients with known OSA based on use of a scoring rule that did not require oxygen desaturation to score hypopneas.[26] The PSGs were rescored with a hypopnea definition that required a 4% oxygen desaturation but not necessarily an arousal. This change resulted in a reduction of the apnea-hypopnea index (AHI) and classified 40% of these symptomatic patients as negative for OSA.[26] These findings highlight the potential benefits of the recommended hypopnea definition set forth in the 2012 scoring manual.

Most laboratories report an AHI that represents the sum total of apneas and hypopneas per hour of sleep. Additionally, the respiratory disturbance index (RDI) calculates the sum total of apneas, hypopneas, and respiratory effort related arousals (RERAs) per hour of sleep. Nasal or esophageal pressure monitoring allows for the scoring of RERAs. Although additional data are still needed, the importance of scoring RERAs is likely to depend in part on which hypopnea definition is used. With the less sensitive definition that focuses on 4% desaturations and ignores arousals, scoring RERAs makes a much larger difference in the computed total rate of respiratory events and may frequently make the difference between diagnosis and failure to diagnose OSA. If the more sensitive definition for hypopneas is used that includes arousal but does not require oxygen desaturation, fewer additional events are detected when RERAs are scored; RERAs then have less impact on the total rates of apneic events and therefore less clinical impact.

As a result of these challenges and the imperfect reliability of PSGs, interpretation of PSG reports remains more complicated and may not be definitive, particularly in borderline cases. The patient's clinical presentation should be considered when interpreting the PSG to help mitigate underdiagnosis and overdiagnosis. Although many clinicians believe that an AHI above 5 indicates OSA, the PSG finding of an AHI greater than 5 may not be associated with symptoms. For example, a large population-based epidemiologic study found that only 22.6% of women and 15.5% of men who met this criterion clearly complained of daytime hypersomnolence.[12] Conversely, some patients with an AHI less than 5 may still have OSA that merits treatment to improve symptoms and morbidity.[27,28]

Further research is needed to define and to improve the ability of PSGs to measure those aspects of sleep-disordered breathing that most affect health and daytime sleepiness. The AHI and minimum oxygen saturation do not correlate strongly with daytime sleepiness,[29] although the AHI may correlate better with cardiovascular morbidity.[22] Esophageal pressure monitoring is the gold standard to assess respiratory effort and may identify increased respiratory effort and RERAs in patients without significant apneas and hypopneas.[30,31] However, criteria for abnormal esophageal pressure recordings, as defined by association with poor outcomes, remain to be studied more definitively. Nasal pressure monitoring may provide a well-tolerated alternative; however, despite increased sensitivity, studies have yet to demonstrate improved prediction of outcomes, and initial comparisons to thermistor results show correlations high enough (e.g., 0.90 or higher)[32,33] to suggest redundancy of information. Other polysomnographic measures that may (or may not) prove to enhance the ability of PSGs to predict outcomes of sleep-disordered breathing include end-tidal or transcutaneous carbon dioxide monitoring,[34] pulse transit time,[35] peripheral arterial tonometry,[36] scoring of arousals,[37,38] and analysis of respiratory cycle–related electroencephalographic changes.[38,39]

In short, the PSG is the single most useful and definitive test in the diagnosis of sleep-related breathing disorders, but the information it provides cannot be reliably interpreted by persons without experience in sleep medicine, summarized by any single number, or applied to patient care without careful use of additional clinical data. Failure to recognize these limitations, by health care policy makers or clinicians, could trigger unnecessary intervention or deprive a patient of effective treatment.

Modified Forms of the Polysomnogram

In comparison to the standard PSG, daytime and split-night studies may reduce costs and expedite evaluation. Studies of daytime PSGs have sometimes found a high NPV, with lower PPV, but inconsistent results and the lack of sufficient data explain why daytime PSGs have not generally been recommended.[4] A successful split-night study may save a patient from a second night in the sleep laboratory. Studies of diagnostic accuracy and treatment outcomes appear promising.[40] Concordance is high between AHI measured in the first 2 hours of PSG recording and AHI measured in a full-night PSG (concordance correlation coefficient = 0.93).[41] Although the traditional gold standard has been separate, full-night studies for diagnostic assessment and then positive airway pressure titration, split-night studies may be adequate alternatives in most cases.[42,43]

Home Sleep Tests

Many different devices exist to assess OSA at home, although most do not record sleep. These "portable" recordings usually are less costly than laboratory-based PSGs, and patients often prefer home studies to laboratory studies. However, the diagnostic value of unattended portable monitoring is often reduced by the inability to make behavioral observations, standardize recording conditions, address technical problems,

make interventions during the night, or monitor variables equivalent to those recorded in the laboratory setting. Home sleep tests that do not monitor signals necessary to identify sleep stages or leg movements only evaluate for sleep apnea. Additionally, scored respiratory events may not have occurred during sleep and thus may result in inaccurate sleep apnea severity.

A Portable Monitoring Task Force of the AASM recommended home studies only after a comprehensive sleep evaluation by a clinician board-eligible or certified in sleep medicine, and then interpreted by someone with the same level of specialty training.[7] This recommendation is based on the fact that studies demonstrating effectiveness of home sleep tests were conducted in the context of thorough clinical evaluations by sleep specialists. Further, home studies have significant limitations and therefore must be interpreted by specialists aware of these constraints. Under these conditions, home studies can be used as an alternative to laboratory-based PSGs when clinical judgment suggests that pretest probability of moderate to severe OSA is high. Home studies should generally not be used when the patient is a child or older person, has significant health comorbidities (e.g., severe pulmonary disease, neuromuscular disease, or congestive heart failure), or in whom other additional sleep disorders are suspected.[7] Home studies may be indicated for patients who do not have access to laboratory-based PSG, cannot tolerate the procedure, or need follow-up assessment of response to non–positive airway pressure treatments of OSA.

Published guidelines for home studies recommend that at minimum they monitor airflow, respiratory effort, and blood oxygenation and that the equipment should be applied by a sleep technologist or health care practitioner with appropriate training.[7] Home studies can underestimate sleep-disordered breathing. Many home studies do not monitor an electroencephalogram (EEG) and as such do not allow for hypopneas to be scored when they terminate in cortical arousal but do not result in oxygen desaturation. Additionally, the AHI on a home study that does not monitor sleep is calculated with total recording time (as opposed to total sleep time) as the denominator.[42] Therefore, if a home study in an appropriately selected individual does not demonstrate OSA, a more definitive laboratory-based sleep study should be considered. A suggested algorithm for use of home studies is shown in Figure 60-2.

In carefully selected patients, portable recording devices are effective tools to diagnose OSA. A meta-analysis of level 3 portable monitoring devices demonstrated sensitivity from 0.79 to 0.97 and specificity from 0.60 to 0.93 for OSA, depending on AHI cutoffs.[44] However, these validation studies, generally performed in a controlled laboratory setting, do not take into account the potential for technical failure of portable devices in an ambulatory environment. Despite these limitations, initial investigations demonstrate similar outcomes in patients randomized to home sleep tests versus attended PSG.[45,46] Portable devices that have low costs, high sensitivities, and high specificities have the potential to be cost-effective in comparison to PSGs. However, cost-effectiveness analyses thus far suggest that full-night PSG is superior to portable tests for OSA[47,48] (discussed under Beyond Sensitivity, Specificity, and Predictive Value in this chapter). In some situations, home studies could increase costs, delay confirmatory laboratory testing, encourage treatment of patients with false-positive results, or allow development of medical morbidity from undiagnosed and therefore untreated OSA.

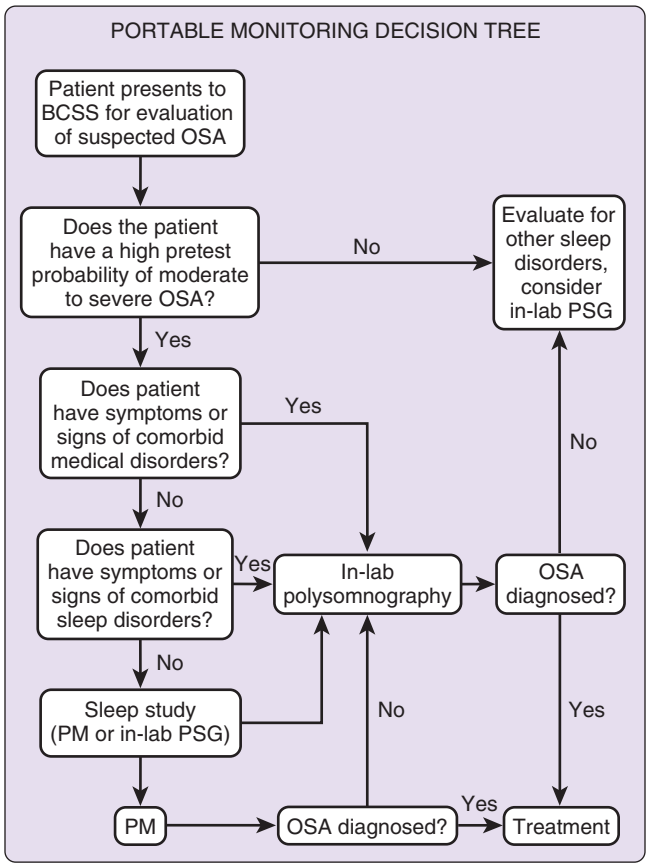

Figure 60-2 Recommended use of home studies. BCSS, Board-certified sleep specialist; OSA, obstructive sleep apnea; PM, portable monitoring; PSG, polysomnography. (From Collop NA, Anderson WM, Boehlecke B, et al. Clinical guidelines for the use of unattended portable monitors in the diagnosis of obstructive sleep apnea in adult patients. Portable Monitoring Task Force of the American Academy of Sleep Medicine. *J Clin Sleep Med* 2007;3:737–47, with permission.)

Studies of Airway Morphology

Although imaging of the upper airway for research purposes has led to a better understanding of OSA pathophysiology, such studies are not routinely performed in diagnostic evaluations of patients, in part because findings that predict OSA or its severity with sufficient accuracy to allow use in management of individual patients have not been identified. However, cephalometric radiography and pharyngoscopy may be useful in preoperative identification of sites of obstruction and in selection of appropriate surgical procedures. The diagnostic value of cephalometrics may be limited in part because only sagittal plane dimensions are provided while coronal plane dimensions or volume may be more pertinent to OSA.[49] Pharyngoscopy allows three-dimensional anatomic characterization, but whether airway collapse with Müller's maneuver predicts response to uvulopalatopharyngoplasty is debated. Pharyngoscopy may be particularly valuable if it is performed during supine sleep.[50] Techniques for quantitative computer-assisted video endoscopic airway analysis are also being developed and have shown, for example, correlation between the

extent of anatomic change after uvulopalatopharyngoplasty and improvement in the AHI.[51]

Computed tomography and magnetic resonance imaging (MRI) studies can show upper airway morphology,[49] and some authors suggest the potential for clinical usefulness.[52] Specifically, MRI evaluates the upper airway in multiple planes and can be used during sleep.[53-55] Dynamic sleep MRI protocols may characterize upper airway obstruction better than single-plane images during wakefulness.[53-55] However, the value of these techniques in the clinical setting is not well defined.

EVALUATION OF HYPERSOMNOLENCE

History and Questionnaires

The history provides important clues to the severity of hypersomnolence. Direct inquiry about sleepiness can be supplemented by questions about sleepiness in sedentary situations, such as driving, desk work, reading, or watching television. However, patients may report little of the excessive daytime sleepiness suggested by family members, clinical signs, or objective tests. Words other than *sleepiness* are often used by patients with sleep disorders to describe the chief complaint. Among 190 apneic subjects in one study, preferred terms included *lack of energy* (40%), *tiredness* (20%), *fatigue* (18%), and *sleepiness* (22%).[56] Furthermore, each of these symptoms tends to resolve after use of continuous positive airway pressure. Patients' opinions about their own sleepiness sometimes show no significant association with results of the Multiple Sleep Latency Test (MSLT).[57]

Questionnaires such as the Epworth Sleepiness Scale[58] and the Stanford Sleepiness Scale[59] (see Chapter 169) provide a more formal and perhaps reliable measure of excessive daytime sleepiness. The impact of sleepiness on activities of daily living can be assessed with the Functional Outcomes of Sleep Questionnaire.[60] Epworth results correlate reasonably well with patients' self-ratings for overall sleepiness but not well with MSLT results.[61] Although the Epworth Sleepiness Scale and the Stanford Sleepiness Scale can have clinical utility, for example, in monitoring response to treatment over time, they do not substitute for well-validated objective measures of sleepiness. Unfortunately, the ability of subjective tests of sleepiness to predict future health outcomes remains largely unknown.

In addition to the severity of EDS, it is critical to assess napping patterns and other symptoms associated with hypersomnolence to determine its etiology. For example, cataplexy is the essential feature that distinguishes narcolepsy type 1 from narcolepsy type 2 and other disorders of sleepiness.[6] Cataplexy must be derived from patient report because it is rarely observed during the clinical evaluation for hypersomnolence. Sleep paralysis and hypnagogic and hypnopompic hallucinations are reported in about 50% of patients with narcolepsy; however, these symptoms are often present in individuals without the disease and thus are not specific.[62] Inquiry about nap duration and quality is also useful because patients with narcolepsy, in contrast to other sleep disorders, may experience a greater (although transient) alerting affect from short naps.[63] In contrast, more than two thirds of patients with idiopathic hypersomnia report that naps are nonrestorative.[64-66]

Physical Examination

Although the alerting effect of an examination obscures physical signs of sleepiness in most patients, overt signs of sleepiness—such as the inability to stay awake or to keep eyes open in the examination room—have high PPV and may obviate the need for additional tests. The examination may also help distinguish severe sleepiness from stupor due to neurologic impairment or drugs.

Sleep Logs and Actigraphy

The evaluation of hypersomnolence includes assessment of sleep duration and timing to rule out insufficient sleep syndrome or circadian rhythm sleep-wake disorders. The clinician should ask about sleep schedules at the time of clinical evaluation. Unfortunately, singular point estimates of sleep duration and timing demonstrate poor agreement with longitudinal measures.[67-69] Therefore tools such as sleep logs and actigraphy are valuable to track sleep patterns over days to weeks. Historically, sleep logs have been used to ensure adequate sleep duration before objective assessment of hypersomnolence with MSLT despite the absence of data supporting this use.[70]

An actigram is a device worn on the nondominant wrist that uses accelerometry to detect movement to estimate sleep and wake. Agreement between actigraphy and PSG in the detection of sleep is approximately 90%, and this device is accepted as a valid method to evaluate sleep patterns.[71-73] Actigraphy and sleep logs recorded for 2 weeks before MSLT were compared in a group of patients who underwent evaluation for hypersomnolence. Sleep logs were found to overestimate average nightly sleep duration by 1.43 hours (±1.31 hours) compared with actigraphy.[67] In the subgroup of patients whose MSLT results objectively confirmed excessive daytime sleepiness, average nightly sleep duration was 4.53 ± 1.37 hours by actigraphy, which was 2.55 ± 1.41 hours shorter than that recorded on sleep logs.[67] This study may be difficult to generalize because it was conducted in a military population. However, in a subsequent study at a large academic institution, poor agreement was seen between actigraphy and sleep logs typically owing to increased total sleep time reported on sleep logs compared with actigraphy.[74] Actigraphy is highly sensitive but not specific for EEG-defined sleep and may overestimate true sleep. Therefore the finding that sleep duration reported on sleep logs exceeds sleep duration derived by actigraphy is troublesome when determining whether sleep duration is adequate before MSLT. The ICSD-3 recommends documentation of sleep duration for 7 days on a sleep log and, whenever possible, actigraphy in conjunction with the sleep log, before the MSLT.[6]

Nocturnal Polysomnography

Many patients referred to sleep centers for excessive daytime sleepiness have nocturnal sleep disorders, and PSG is often more notable for the manifestations of such disorders than for signs of excessive daytime sleepiness. The single polysomnographic variable that best reflects sleepiness, as measured by the mean sleep latency on the MSLT, is nocturnal sleep latency.[75] Polysomnographic measures of sleep pathology, such as the AHI and minimum oxygen saturation, show only low magnitudes of correlation with MSLT results.[76] However, a short latency to REM sleep on overnight PSG can provide a valuable clue to the presence of narcolepsy. Among patients referred to a sleep laboratory, REM onset latency less than 15 minutes on nocturnal PSG had poor sensitivity (approximately 40%) but excellent specificity (99.6%) for type 1 narcolepsy.[77] The ICSD-3 now allows a sleep-onset REM period,

on overnight PSG, to account for one of the two REM periods necessary to diagnose narcolepsy with an MSLT.[6]

Multiple Sleep Latency Test

The mean sleep latency on the MSLT is the most commonly used objective measure in the assessment of daytime sleepiness.[78] The MSLT may contribute to diagnosis but is usually not sufficient, alone, to establish a diagnosis. The mean sleep latency is most useful when it is clearly abnormally low. A patient with a mean sleep latency of 2 minutes on a properly performed MSLT is unlikely to be exaggerating a complaint of excessive daytime sleepiness, to suffer from fatigue rather than sleepiness, or to be free of any sleep disorder. The MSLT can help determine the clinical significance of a sleep disorder or assess response to treatment.

As a general guideline, mean sleep latencies shorter than 8 minutes on a properly conducted MSLT are considered abnormal,[78] and latencies shorter than 5 minutes often indicate severe excessive daytime sleepiness. However, proper interpretation of MSLT results requires integration of other factors and especially knowledge of the limitations of this test. Results may be misleading if they are affected by youth (different criteria apply for children), noise, anxiety, or atypical sleep on the previous night. Use of medications such as stimulants or antidepressants, their recent discontinuance, or inability to be weaned off them at least 10 days before testing can complicate interpretation of an MSLT. Sleep apnea and other sleep disorders may make sleep onset more difficult and thereby interfere with the test. In general, the NPV of a long mean sleep latency is less than the PPV of a particularly short mean sleep latency. When an MSLT is normal, clinicians must carefully consider other possible explanations before telling a subjectively sleepy patient that there is no objective evidence of excessive daytime sleepiness. Formal prospective studies of "real-life" outcomes associated with different mean sleep latencies are still needed, but until such data are available, clinicians should realize that MSLT results form a continuum without strictly interpretable cutoffs. Community-based samples of adults show mean sleep latencies of 8 minutes or less in well more than 20% of subjects.[79] High test-retest reliability among normal subjects[80] does not necessarily generalize to patients.[81] In fact, 40% of central hypersomnia patients had mean sleep latencies that crossed to the other side of the 8-minute threshold when MSLTs conducted about 4 years apart were compared.[82] Interrater reliability can be excellent but adds another source of potential variation in test results.[83]

Nocturnal Polysomnography and MSLT in the Diagnosis of Narcolepsy

The diagnostic criteria for narcolepsy—two or more sleep-onset REM periods (SOREMPs) and short mean sleep latency—were once thought to have high sensitivity and specificity. Original case series suggested that all narcoleptic subjects and virtually no normal controls had two or more SOREMPs[84]; the PPV of two or more SOREMPs for the diagnosis of narcolepsy was 98%, and the NPV was 89%.[85] Subsequent studies did not find the SOREMP criteria to provide such diagnostic accuracy, partly because the most common reasons for sleep laboratory referral evolved. Two or more SOREMPs were found in 25% of 187 sleep apneic subjects,[86] 17% of 139 normal subjects,[87] and 83% of 200 narcoleptic subjects who had cataplexy.[88] Among 2083 patients evaluated with MSLTs at one sleep center, the PPV of two or more SOREMPs was 57% and the NPV was 98%.[89] Thus the presence of SOREMPs must be interpreted in conjunction with other clinical and polysomnographic findings. The criterion of two or more SOREMPs cannot be used to diagnose narcolepsy when the patient has untreated OSA. Furthermore, the number of SOREMPs can change enough to alter the diagnosis (idiopathic hypersomnia versus narcolepsy without cataplexy) in up to 30% of patients on repeated MSLT.[82] As an alternative to the MSLT, cerebrospinal fluid hypocretin-1 levels can be used to confirm type 1 narcolepsy. These levels are low (≤110 pg/mL or <one third of the mean for controls) in more than 90% of affected patients but almost never among patients without this diagnosis.[6]

Variations of the Multiple Sleep Latency Test and Other Physiologic Tests

Results of the Maintenance of Wakefulness Test (MWT) can differ markedly from those of the MSLT,[90] but whether the MWT results are more predictive of adverse effects of sleepiness in daily life remains unknown. Results of both the MWT and MSLT can be influenced by the patient's motivation.[91] The MWT results correlate with measures of sleep apnea severity to about the same extent as MSLT results do[92] but may better reflect improvement with treatment.[90] Shorter sleep latencies on MWTs correlate with increased errors on driving simulation tests.[93,94] However, until MWT and MSLT results are shown to differ in a clinically meaningful way, the MSLT continues to offer advantages of more published experience, familiarity among clinicians, and relevance to the diagnosis of narcolepsy. The Federal Aviation Administration and other agencies may at times request or require an MWT, but given the dearth of proven real-life predictive value, the role of this test or the MSLT in predicting workplace safety remains controversial.[95,96]

MSLT modifications, for which limited validity data exist, include addition of performance tasks[97,98]; analysis of sleep stages during naps[99]; focus on the percentage of time spent awake[100]; definition of sleep onset by failure to respond to a repeated signal[101]; and use of survival analysis to better account for failure to sleep on some naps.[102] In the clinical setting, none of these modifications have been adopted; neither have a range of other physiologic tests, including pupillometry and brainstem auditory evoked potentials. A variety of performance-based tests are used, usually in research settings, to assess variables related to sleepiness. Examples are the Psychomotor Vigilance Task[103] and the Steer Clear driving simulation test.[104]

Another available method to assess hypersomnia is the 24-hour PSG. About 40% of patients with idiopathic hypersomnia demonstrate mean sleep latencies greater than 8 minutes on the MSLT despite severe subjective sleepiness.[65,105,106] This finding is more common in patients with long nocturnal sleep durations. In these individuals, prolonged PSG reveals a total sleep duration near 700 minutes over 24 hours.[105] Therefore a 24-hour PSG that documents total sleep time of at least 660 minutes can be used to diagnose idiopathic hypersomnia in patients with symptoms consistent with the disorder but mean sleep latency greater than 8 minutes.[6] The ICSD-3 also allows actigraphy for this purpose; however, it has not been validated in this particular setting.[6]

EVALUATION OF INSOMNIA

History and Questionnaires

Like excessive daytime sleepiness, the complaint of inadequate, insufficient, or nonrestorative sleep can have many different causes. However, causes of insomnia are often diagnosed by history alone.[107,108] In part because the gold standard is not a physiologic test, few data are available with which to assess the relative value of individual symptoms. Predictive values for some symptoms are likely to be high because symptoms define the disorders. When a history does not reveal a cause of the insomnia, PSG may be useful (discussed under Nocturnal Polysomnography in this section). Psychometric tests can reveal cognitive differences between insomniac subjects and normal controls,[109] but these tests are not commonly used for diagnostic purposes in the clinical sleep medicine setting.

The Insomnia Severity Index is a seven-item self-report instrument that is typically used in insomnia research.[110] However, this tool may also be beneficial in the clinical setting. A score of 10 or higher on the Insomnia Severity Index identified insomnia with a sensitivity of 86% and a specificity of 88% in a community sample.[111]

Sleep Logs and Actigraphy

Sleep logs are an important tool in the evaluation of insomnia.[112] Patients record sleep-onset latency (SOL) and wake after sleep onset (WASO) on sleep logs, and investigators have tested the ability of different cutoffs of these quantitative parameters to predict insomnia. In one study, SOL or WASO of 31 minutes or longer identified insomnia with a sensitivity of 64% and specificity of 77% in subjects with insomnia at least 3 times per week for 6 months.[113] A subsequent investigation that also used sleep logs found that SOL or WASO of 20 minutes or more alone identified insomnia with a sensitivity of 94% and specificity of 80%.[114] Logs are not necessary to establish the presence of insomnia but can help define severity and facilitate identification of causes such as inadequate sleep hygiene or circadian rhythm sleep-wake disorders.

Actigraphy should be used with caution in patients with insomnia. The ability of actigraphy to measure sleep parameters (e.g., total sleep time or WASO) deteriorates as sleep efficiency decreases, which limits utility in patients with insomnia. Among patients with insomnia, in an epoch-by-epoch analysis that compared actigraphy with PSG, the accuracy, sensitivity, and specificity of actigraphy were 0.83, 0.95, and 0.35, respectively.[73] SOL is consistently underestimated by actigraphy in patients with insomnia.[115] Actigraphy is an effective tool to assess sleep-wake patterns when insomnia symptoms are thought to be secondary to a circadian rhythm sleep-wake disorder. However, because of the limitations described previously, actigraphy is not used routinely to confirm a diagnosis of insomnia.[108]

Nocturnal Polysomnography

PSG is not indicated for routine evaluation of insomnia; although when a patient's history and physical examination suggest that insomnia may be due to sleep-disordered breathing, periodic limb movement disorder, paradoxical insomnia, or uncertain causes, it can be an important aid to diagnosis.[116] Additionally, PSG may be indicated if insomnia fails to respond to treatment or in patients who have precipitous arousals with violent or injurious behavior.[108] Of note, injudicious use of PSG can sometimes enhance patient's conviction that insomnia is due to physical rather than behavioral causes or lead to diagnoses that eventually prove irrelevant to the main complaint.

EVALUATION OF SUSPECTED CIRCADIAN RHYTHM SLEEP-WAKE DISORDERS

History and Questionnaires

Discrepancies between the desired time for sleep and wake and the circadian propensity for sleep and wake may present as insomnia or hypersomnolence. Approximately 7% to 16% of patients who present to sleep disorders clinics with symptoms of insomnia are ultimately diagnosed with delayed sleep-wake phase disorder.[117,118] To distinguish circadian rhythm sleep-wake disorders from other causes of insomnia and hypersomnolence, examples of useful questions may include, "What time of day do you feel most alert?" and "When do you perform the best?" Comparison of regular sleep schedules to schedules on days free from work or school can reveal discrepancies that help to identify a circadian rhythm disorder.

Questionnaires such as the Horne-Ostberg Morningness-Eveningness Questionnaire (MEQ) and the Munich Chronotype Questionnaire (MCTQ) evaluate circadian preference, also known as chronotype.[119,120] The MEQ is the most widely used instrument to assess chronotype. It is a 19-item self-assessment tool that evaluates personal preference for the timing of sleep and other behaviors.[119] The MCTQ is also self-completed but assesses the actual (opposed to preferred) timing of sleep on work or school days versus free days.[120] The midpoint of sleep on free days and self-rated chronotype derived from the MCTQ both correlate highly with chronotype based on MEQ score (r = –0.7 and –0.8, respectively).[120,121] In addition to correlating with each other, the MEQ and MCTQ correlate with objective markers of circadian phase. The MEQ scores correlate with salivary dim-light melatonin onset (DLMO) (r = –0.4 to –0.5) and peak serum melatonin (r = –0.4).[122-124] The midpoint of sleep on free days derived from the MCTQ correlates with DLMO (r = 0.5).[124] The MEQ has also been validated against core body temperature and cortisol secretion.[119,125,126]

Sleep Logs and Actigraphy

The AASM recommends the use of sleep logs and, whenever possible, actigraphy for 7 to 14 days to evaluate suspected circadian rhythm sleep-wake disorders. Actigraphy has been validated in patients with circadian rhythm sleep-wake disorders.[72] Inclusion of ad libitum sleep-wake times (e.g., days off from school or work) is essential when sleep is tracked with actigraphy or sleep logs and will provide a more accurate estimate of true, endogenous circadian phase.[122,127,128] Vacation times may be particularly revealing; in fact sleep-wake times of individuals on an unrestricted sleep-wake schedule demonstrate higher correlation (r = 0.77) with DLMO than sleep-wake times of those on a fixed schedule (r = 0.40).[127]

Nocturnal Polysomnography

PSG is not necessary to diagnose circadian rhythm sleep-wake disorders, although it may be performed to rule out other comorbid sleep conditions. A PSG conducted at conventional times may demonstrate a delay of sleep onset or

early morning awakening in patients with delayed or advanced sleep-wake phase disorders, respectively.[129-131]

Multiple Sleep Latency Test

The MSLT is not used to diagnose circadian rhythm sleep-wake disorders; however, if obtained, mean sleep latency may be reduced in circadian rhythm sleep-wake disorders in the setting of sleep loss and excessive daytime sleepiness. Notably, in a large epidemiologic study, shift workers (night or rotating) were almost eight times more likely to have a mean sleep latency of less than 8 minutes combined with at least two SOREMPs on MSLT.[132] Additionally, adolescents with a delay in circadian phase can demonstrate SOREMPs during the MSLT (particularly during the first nap) when they wake according to their school schedule.[133]

Objective Markers of Circadian Phase

The *International Classification of Sleep Disorders*, third edition notes that endogenous markers of circadian phase can confirm the diagnosis of certain circadian rhythm sleep-wake disorders.[6] The salivary (DLMO) or urinary (6-sulfatoxymelatonin, aMT6s) melatonin assays are the most commonly used objective markers of circadian phase. These measures objectively document a stable advance, stable delay, or progressive delay of circadian phase in advanced sleep-wake phase disorder, delayed sleep-wake phase disorder, and non–24-hour sleep-wake rhythm disorder, respectively.[6] Although melatonin assays are infrequently used in clinical practice, at-home DLMO assays correlate well with in-lab DLMO assessments (r = 0.85 when a fixed threshold of 3 pg/mL is used).[134] Salivary melatonin assays can capture the onset of melatonin secretion but are not practical to determine the secretion profile overnight in the ambulatory setting. Alternatively, urinary aMT6s can be collected at 8-hour intervals; therefore the first morning void allows for calculation of overnight aMT6s secretion in the home setting.[135] Further investigation is required to determine whether ambulatory measurement of circadian phase markers is reliable and feasible.

EVALUATION OF RESTLESS LEGS SYNDROME

History and Questionnaires

The diagnosis of RLS is made by a clinical history of an urge to move the limbs that is worse at rest, improved with movement, and worse in the evening or night.[6] These four criteria have a PPV of 76% when expert interview is used as a gold standard.[136] Differentiating RLS carefully from leg cramps or positional discomfort improves the specificity of the four criteria from 84% to 94%.[6,136]

Several instruments exist to assist in the evaluation of RLS or its severity, including the International Restless Legs Scale (IRLS), RLS-6, and Johns Hopkins Severity Scale. The IRLS scale is a 10-item questionnaire that assesses the severity of RLS symptoms.[137] This scale has good internal consistency, interexaminer reliability, and test-retest reliability,[137] and a 6-point decrease is considered to be a clinically relevant improvement.[138] Although these scales are used mostly in research, they may be beneficial in the clinic setting to quantify symptom severity; determine the impact of RLS symptoms on patient quality of life, mood, and sleep; measure the progression of RLS symptoms; and evaluate therapeutic response.[139]

Physical Examination

A full neurologic examination is indicated to evaluate for RLS because this condition may arise in the context of other neurologic diseases, such as neuropathy, multiple sclerosis, or Parkinson disease. Assessment of affect and mood to help identify psychiatric disorders is important because mental health morbidity frequently coexists with RLS.

Laboratory Tests

Evaluation of a patient with RLS should include serum iron and ferritin levels. More than one third of individuals with RLS have low serum iron levels, and greater than two thirds have ferritin values of 50 ng/mL or less. Depression, fatigue, and increased severity of symptoms are associated with low serum iron levels in RLS patients.[140] Ferritin levels are inversely related to RLS severity.[141,142] Iron supplementation may reduce symptoms in RLS, although findings are inconsistent.[143] Therefore evaluation of serum iron and ferritin is an integral part of the evaluation of RLS for both diagnosis and treatment.

Nocturnal Polysomnography

PSG is not routinely indicated in the evaluation of RLS and should be performed only if the clinician suspects a comorbid sleep disorder such as OSA. Periodic limb movements during sleep are found in up to 90% of patients with RLS. However, periodic limb movements during sleep are nonspecific because they also occur in approximately 25% of individuals without RLS.[144,145]

EVALUATION FOR SUSPECTED PARASOMNIAS

History and Questionnaires

With the notable exception of REM sleep behavior disorder (RBD), parasomnias often can be diagnosed by history alone.[6] Information obtained from a bed partner may contribute more than that obtained from the patient.

Physical Examination

The physical examination of patients evaluated for parasomnias can be useful, but its value is not well quantified. Some signs may suggest sleep apnea as an underlying trigger for confusional arousals, sleepwalking, sleep terrors, RBD, or nocturnal enuresis. Worn occlusive surfaces of molars can provide key evidence of sleep bruxism. The urogenital examination is important in patients thought to have sleep enuresis. A neurologic examination may suggest a primary cause of sleep enuresis or RBD. Similarly, appropriate laboratory findings may be helpful in some cases; for example, a urinalysis may reveal the cause of sleep enuresis.

Nocturnal Polysomnography

Few studies have examined the predictive value of PSG for parasomnia diagnoses. When the behavior in question occurs during the PSG, the diagnostic value of the test is likely to be high, especially if appropriate additional recording devices, such as extra EEG leads, extra surface electromyogram (EMG) leads, or video monitoring, are used.[146] Additional EEG leads used during PSG, combined with clinical history, may effectively differentiate sleep-related epilepsy from parasomnias.

However, EEG does not reliably diagnose nocturnal frontal lobe epilepsy (NFLE) because more than 60% of patients with

NFLE fail to demonstrate a definite ictal rhythm.[147] Therefore semiology of the events is the key to diagnosis. Derry and colleagues created a rigorous decision tree algorithm based on 120 nocturnal events recorded on video PSG to distinguish NREM disorders of arousal from NFLE.[147] The algorithm included the following characteristics suggestive of NFLE as opposed to parasomnia: complete arousal after the ictus, discrete offset of the behavior, presence of versive head turning or posturing, and persistence of recumbent posture. This decision tree algorithm classified 94% of events correctly. Unfortunately, PSG often fails to document the behavior—especially in cases of suspected RBD, sleepwalking, night terrors, and epilepsy—either because the behavior does not occur on most nights or perhaps because the sleep laboratory is not an environment familiar to the patient. For evaluation of parasomnias, the NPV of a completely normal study is less clear than the PPV of an abnormal study. In one series of 122 patients with suspected parasomnias, one or two nights of PSG with video monitoring contributed useful diagnostic information in more than 50% of cases.[146]

Even in the absence of abnormal behaviors on the night of the PSG, other findings can be valuable. Examples include excessive limb twitching during REM sleep characteristic of RBD and interictal spike and wave complexes that may represent an interictal expression of epilepsy. REM sleep without atonia (RSWA) is the PSG hallmark of RBD and is required to confirm the diagnosis.[6] RSWA may be quantified manually by the eye or by automated computer programs. When scored manually, RSWA is defined by the AASM manual for the scoring of sleep and associated events as either excessive phasic or tonic elevation in EMG tone.[28] Multiple computer algorithms exist to automatically score RSWA, including the REM atonia index and supra-threshold REM EMG activity metric.[148] A supra-threshold REM EMG activity metric cutoff of 15 or higher is able to detect RBD with 100% sensitivity and 71% specificity.[149]

At this time, manual scoring remains the gold standard to detect RSWA.[148] However, the AASM manual does not specify a minimum number or proportion of epochs that must contain RSWA to meet the PSG criteria to confirm suspected RBD.[28] To address this, different cut points have been investigated. When using the submentalis muscle alone, the presence of RSWA (phasic) in 15% of 2-second REM mini-epochs will correctly classify 84% of patients.[150] The Sleep Innsbrook Barcelona group has extensively tested different methods to quantify EMG tone in stage REM sleep and recommends recording EMG in both the submentalis muscle and the bilateral flexor digitorum superficialis muscles to score RSWA.[151] Use of this montage with specificity set at 100% (no false-positive RBD diagnoses permitted) yields a cut point of 32% of 3-second REM mini-epochs to diagnose RBD (area under the receiving operator characteristic curve = 0.998).[151] Upper limb as opposed to lower limb EMG more reliably distinguishes patients with RBD from those without RBD.[148]

BEYOND SENSITIVITY, SPECIFICITY, AND PREDICTIVE VALUE: DECISION AND COST-EFFECTIVENESS ANALYSES

Data on sensitivity, specificity, pretest probability, and utility of outcomes can be used to construct a decision analysis. A clinical decision analysis typically models a choice between diagnostic and therapeutic alternatives. Logical rules are used to weigh information and to make the best decision for an individual patient.[152] Decision analysis may be useful, for example, when one procedure has a high probability of a small benefit but an alternative has a low probability of a large benefit.

Beyond utility, economic data on a procedure can include cost studies, cost-effectiveness analyses that compare different methods to achieve the same end, cost-utility analyses that compare costs per common unit of utility (often quality-adjusted life years), and cost-benefit analyses that compare monetary costs with monetary gains.[153] Such studies require quantitative information on costs and outcomes, data that are not abundant for sleep disorders.[95,96] Despite uncertainty of some important data points, cost-utility models have focused on the decision of whether to diagnose OSA with the aid of a full-night PSG, split-night PSG, portable cardiorespiratory monitoring, or no ancillary test.[47,48] The full-night PSG costs less and results in more quality-adjusted life-years than split-night PSG or unattended portable monitoring over the course of an individual's lifetime.[48] Despite the increased upfront cost of full-night PSG, these results reflect the high utility of an accurate OSA diagnosis and the expense of diagnostic mistakes. These findings highlight the importance of performing decision and cost-utility analyses before conclusions are made about relative values of diagnostic tests.

CLINICAL PEARL

Evaluation of common sleep complaints is based on symptoms, signs, and test results, combined with an understanding of the diagnostic value that each type of data contributes.

SUMMARY

Clinical tools and tests must be used carefully in the evaluation of suspected sleep disorders. All patients with sleep-related complaints should undergo a history and physical examination. Evaluations for obstructive sleep-disordered breathing start with a history and physical examination, which generate valuable information. Symptom-based questionnaires alone usually show inadequate specificity. Laboratory-based nocturnal polysomnography is a gold standard but not infallible. Final diagnostic decisions should be based on integration of multiple clinical and objective data points rather than on any specific cutoff for one specific variable, such as the apnea-hypopnea index. Evaluation for hypersomnolence also relies on historical symptoms collected during an interview or by use of a questionnaire. Objective testing with an MSLT is particularly useful when a shortened mean sleep latency confirms excessive daytime sleepiness or a shortened latency in addition to sleep-onset REM periods confirm narcolepsy. Results must be interpreted carefully, especially when they are normal, because of potential confounds. Evaluation for insomnia often relies solely on historical information. Sleep logs can be helpful, but polysomnography is indicated only when other occult sleep disorders may underlie the insomnia. Questionnaires to determine chronotype and actigraphy are valuable tools when symptoms suggest a circadian rhythm sleep-wake disorder. RLS is a diagnosis based on

clinical history, but serum iron studies provide valuable information with repercussions for treatment. Evaluation for a parasomnia starts with a thorough history, obtained whenever possible from a bed partner in addition to the patient. Polysomnography may confirm a diagnosis or distinguish between several possibilities.

Classification of Sleep Disorders

Michael J. Sateia; Michael J. Thorpy

Chapter Highlights

- The classification of sleep disorders is necessary to discriminate among disorders and to facilitate an understanding of symptoms, etiology, pathophysiology, and treatment.
- The *International Classification of Sleep Disorders*, third edition (ICSD3),[1] published in 2014, combines a symptomatic presentation (e.g., insomnia) with one organized in part on pathophysiology (e.g., circadian rhythms) and in part on organ systems (e.g., breathing disorders).
- Major sections of the ICSD3 include insomnia, sleep-related breathing disorders, central disorders of hypersomnolence, circadian rhythm sleep-wake disorders, parasomnias, and sleep-related movement disorders.
- The ICSD3 is not only a listing of sleep disorders but also a compendium of major diagnostic features, associated conditions, course, prognosis, developmental features, epidemiology, and pathophysiology.

The classification of sleep disorders has been of particular interest to clinicians since sleep disorders were first recognized. The first major classification, the *Diagnostic Classification of Sleep and Arousal Disorders*,[2] published in 1979, organized the sleep disorders into categories that formed the basis of the current classification systems. The initial *International Classification of Sleep Disorders* (ICSD) was produced in 1990 and revised in 1997. In 2005, the ICSD second edition (ICSD2) was published and included a significant reorganization of the nosology, an approach that has been maintained in the most recent (ICSD3) manual, released in 2014. The *International Classification of Sleep Disorders* is published by the American Academy of Sleep Medicine, with consultation and review by panels of international experts and sleep societies worldwide. The ICSD system, developed primarily for diagnostic, epidemiologic, and research purposes, has been widely used by clinicians and has allowed better international communication in sleep disorder research.

The ICSD3 classification (Table 61-1) lists 59 sleep disorders, each presented in detail and with a descriptive diagnostic text that includes specific diagnostic criteria and coding recommendations. The ICSD3 has seven major sections: (1) insomnia, (2) sleep-related breathing disorders, (3) central disorders of hypersomnolence, (4) circadian rhythm sleep-wake disorders, (5) parasomnias, (6) sleep-related movement disorders, and (7) other sleep disorders.

Two additional sleep disorders classification systems are also in current use. The *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition (DSM-5)[3] of the American Psychiatric Association includes a sleep disorders section that was designed for mental health and general medical clinicians who are not experts in sleep medicine. Efforts to achieve consistency between DSM-5 and ICSD3 were largely successful during the parallel development of these two approaches, although some discrepancies in diagnostic criteria do exist. Notably, the ICSD system is significantly more detailed, as expected in light of the differing target audience. The U.S. clinical modification (CM) of the *International Classification of Diseases,* 9th and 10th revisions (ICD-9-CM and ICD-10-CM),[4] includes a classification and coding for sleep disorders primarily for statistical and epidemiologic purposes, which was substantially revised with the publication of ICSD2. Nevertheless, the crosswalk between ICSD and the ICD system is complex in light of the significant differences that exist between these systems. ICSD3 includes several features not found in ICSD2. All definitions of polysomnography (PSG) findings (e.g., apnea/hypopnea, periodic limb movement, rapid eye movement [REM] without atonia) refer to the most recent version of the *American Academy of Sleep Medicine (AASM) Manual for the Scoring of Sleep and Associated Events.*[5] A separate Developmental Issues section has been added to the text to more effectively address variations in presentation and findings across age ranges, especially in children and adolescents. ICD-9-CM and ICD-10-CM code recommendations are included for each diagnosis. Conditions that were previously included in a separate chapter of ICSD2 (Isolated Symptoms and Normal Variants) have now been assigned to the major chapters to which they are most closely related (e.g., short sleep to insomnia and snoring to sleep-related breathing disorders).

INSOMNIA

Historically, insomnia has been characterized as either primary or secondary (comorbid).[6] The latter was intended to describe insomnia resulting from a medical or psychiatric illness, another sleep disorder, or substance abuse. However, current conceptualization of chronic insomnia has resulted in elimination of this dichotomy. ICSD3 employs a diagnosis of chronic insomnia disorder,[7,8] which includes all insomnias of at least 3 months' duration, regardless of presumed etiology. Insomnia of less than 3 months' duration is classified as short-term insomnia. A

Table 61-1 Sleep Disorder Diagnoses and Codes

Proposed ICSD3 Diagnoses	Proposed ICD-9CM Diagnosis and Codes	Proposed ICD-10CM Diagnosis and Codes
Insomnia Disorders		
Chronic insomnia disorder	307.42 Persistent insomnia—nonorganic origin	F51.01 Other insomnia not due to physiologic or substance
Short-term insomnia disorder	307.41 Transient insomnia	F51.02
Sleep-Related Breathing Disorders		
Obstructive Sleep Apnea		
Obstructive sleep apnea (adult and pediatric)	327.23	G47.33
Central Sleep Apnea		
Central sleep apnea with Cheyne-Stokes breathing	786.04 Cheyne-Stokes respiration	R06.3
Central sleep apnea due to a medical disorder without Cheyne-Stokes breathing	327.27	G47.37
Central sleep apnea due to high-altitude periodic breathing	327.22 High-altitude periodic breathing	G47.32
Central sleep apnea due to drug or a substance	327.29 Other organic sleep apnea	G47.39
Primary central sleep apnea	327.21	G47.31
Primary central sleep apnea of infancy	770.81 Primary apnea of newborn	P28.3
Primary central sleep apnea of prematurity	770.82 Other apnea of newborn	P28.4
Treatment emergent central sleep apnea	327.29 Other organic sleep apnea	G47.39
Hypoventilation/Hypoxemia		
Obesity hypoventilation syndrome	278.03 Morbid obesity with alveolar hypoventilation	E66.2
Congenital central alveolar hypoventilation syndrome	327.25 Congenital central alveolar hypoventilation syndrome	G47.35
Late-onset central hypoventilation with hypothalamic abnormalities	327.26 Sleep-related hypoventilation/hypoxemia in conditions classifiable elsewhere	G47.36
Idiopathic central alveolar hypoventilation	327.24	G47.34
Sleep-related hypoventilation due to drug or substance	327.26 Sleep-related hypoventilation/hypoxemia in conditions classifiable elsewhere	G47.36
Sleep related hypoventilation due to medical or neurologic condition	327.26 Sleep-related hypoventilation/hypoxemia in conditions classifiable elsewhere	G47.36
Sleep-related hypoxemia	327.26 Sleep-related hypoventilation/hypoxemia in conditions classifiable elsewhere	G47.36

diagnosis of other insomnia may be employed when a patient presents with insomnia complaints but does not meet full criteria for either chronic or short-term insomnia.

In ICSD3, insomnia is defined as persistent sleep difficulty despite adequate opportunity and circumstances for sleep, which is accompanied by daytime consequences that are attributable to the sleep disturbance. Complaints may include difficulty with sleep initiation, sleep maintenance, or early awakening. In addition, resistance to going to bed on an appropriate schedule or difficulty sleeping without the intervention of a parent or caregiver constitutes an insomnia complaint (see Chapters 80 to 88). The disturbance may be reported by the patient or by the patient's parent or caregiver. Although any one of these complaints meets the first criterion for an insomnia diagnosis, it is not uncommon for patients to present with two or more of these symptoms (e.g., difficulty initiating and maintaining sleep). In the case of children or cognitively impaired adults, it is often the parent or caregiver who reports the problem. Symptoms of bedtime resistance or requirement of parent or caregiver intervention applies primarily to these groups. An ICSD3 insomnia diagnosis also requires associated daytime consequences (e.g., fatigue, impaired concentration, mood disturbance, or other occupational, social, or academic impairment) and adequate opportunity and environmental circumstances for sleep. A duration of at least 3 months and the presence of symptoms at least three times per week are necessary to establish a diagnosis of chronic insomnia. When the symptoms have been present for less than 3 months, a diagnosis of short-term insomnia disorder is applied. Insomnia symptoms occur frequently in conjunction with many medical and psychiatric disorders. A diagnosis of chronic insomnia disorder should be invoked only when the insomnia component is the focus of independent clinical assessment and treatment.

ICSD3 discusses previously identified subtypes within the context of chronic insomnia disorder. Although these clinical subtypes are no longer considered independent diagnoses, there may be characteristics of these subtypes that are clinically relevant. Major subtypes of what was previously termed *primary insomnia* include (1) psychophysiologic insomnia, characterized by a heightened level of arousal with learned sleep-preventing associations and an excessive concern with the inability to sleep; (2) paradoxical insomnia (formerly known as *sleep state misperception*), which is a complaint of severe insomnia that occurs without evidence of objective sleep disturbance and without daytime impairment to the extent that would be suggested by the amount of sleep disturbance reported; (3) idiopathic insomnia, a long-standing form of insomnia that appears to date from childhood and has an insidious onset; and (4) behavioral insomnia of childhood,[9] including limit-setting sleep disorder and sleep-onset association disorder. The former is a resistance or refusal to go to sleep, which is the result of insufficient limit-setting on the part of care providers. Sleep-onset association disorder occurs when there is reliance on inappropriate sleep associations, such as rocking, watching television, holding a bottle or other object, or specific environmental conditions such as a lighted room or an alternative place to sleep. Previously identified secondary, or comorbid, insomnias include (1) insomnia due to medical condition, which has been applied when a medical or neurologic disorder is believed to give rise to the insomnia; (2) insomnia due to drug or substance, when excessive use, dependence on, or withdrawal from a substance such as alcohol, a recreational drug, or caffeine is causative; and (3) insomnia due to mental disorder, which is employed when an underlying mental disorder is the major etiologic factor.

Patients often present with multiple comorbidities that may contribute to an insomnia complaint. It is often difficult

to ascertain the cause-and-effect relationship between comorbidities and the insomnia. When an ICSD3 diagnosis of chronic insomnia is employed, clinicians are encouraged to list all pertinent comorbidities along with the diagnosis.

Short sleep and excessive time in bed are listed as normal variants within the insomnia section. A short sleeper is a person with a routine pattern of obtaining 6 hours or less of sleep in a 24-hour day without sleep complaints or identifiable daytime consequences. In children, this sleep length can be 3 hours or less than the norm for the age group.

SLEEP-RELATED BREATHING DISORDERS

The disorders in this group are characterized by disordered respiration during sleep (see Chapters 107 to 122). ICSD3 includes four major categories of sleep-related breathing disorders: (1) obstructive sleep apneas (OSAs), (2) central sleep apnea (CSA) syndromes, (3) sleep-related hypoventilation disorders, and (4) sleep-related hypoxemia disorder.

The OSAs are disorders in which obstruction of the airway during sleep results in reduced or absent airflow despite adequate respiratory effort. OSA, adult,[10,11] is characterized by repetitive episodes of cessation of breathing (apneas), reduced breathing (hypopneas), or arousal associated with increased airway resistance and respiratory effort (respiratory effort related arousal). The term *upper airway resistance syndrome* is no longer employed because the underlying pathophysiology and potential consequences are essentially those of OSA. Heavy snoring is reported in most of these patients. Apneic and hypopneic events are often associated with reduced blood oxygen saturation. Diagnosis requires the presence of five or more events (apnea, hypopneas, or respiratory effort related arousals) coupled with at least one sign or symptom (e.g., snoring, observed pauses, excessive sleepiness, insomnia) or medical or psychiatric complications. A predominantly obstructive event frequency of greater than 15/hour meets diagnostic criteria regardless of the presence or absence of symptoms.

OSA, pediatric,[12] is characterized by features similar to those seen in the adult, but cortical arousals may not occur, possibly because of a higher arousal threshold. This may give rise to a pattern of obstructive hypoventilation, which may require CO_2 monitoring for detection. Signs or symptoms are required for a diagnosis of pediatric OSA. These must be coupled with at least one obstructive event per hour of sleep or a pattern of hypoventilation, as evidenced by $Paco_2$ greater than 50 mm Hg for more than 25% of sleep time.

CSA syndromes[13,14] include those in which airflow is diminished or absent in an intermittent or cyclical fashion as a result of reduced or absent respiratory effort. ICSD3 includes nine CSA syndromes. All of the adult forms of these disorders, with the exception of high-altitude periodic breathing, require PSG demonstration of a central apnea or hypopnea index greater than 5/hour. Adult presentations also require associated signs or symptoms (e.g., sleepiness, sleep disturbance, awakening short of breath, snoring, or witnessed apnea), although presence of a medical condition such as congestive heart failure, stroke, or renal failure precludes this requirement in CSA with Cheyne-Stokes breathing. CSA with Cheyne Stokes breathing[15] is characterized by recurrent central apneas or hypopneas alternating with a respiratory phase in which tidal volume waxes and wanes in a crescendo-decrescendo pattern. This pattern is characteristically seen in non–rapid eye movement (NREM) sleep. CSA due to a medical condition without Cheyne-Stokes breathing is generally a result of brainstem lesions of varying etiologies. CSA due to high-altitude periodic breathing[16,17] is seen following recent ascent to altitude, typically greater than 2500 meters, although some individuals may experience the symptoms at lower altitudes. The condition may be diagnosed on the basis of ascent to altitude and symptoms alone, although PSG, if performed, shows a central index greater than 5/hour. CSA due to drug or substance[18] is most commonly associated with long-term opioid use. The substance causes a respiratory depression by acting on the μ receptors of the ventral medulla. Primary CSA is a disorder of unknown cause characterized by recurrent episodes of cessation of breathing during sleep without associated ventilatory effort. A complaint of excessive daytime sleepiness, insomnia, or difficulty breathing during sleep is reported. The patient must not be hypercapnic (Pco_2 >45 mm Hg).

Primary sleep apnea of infancy (if conceptional age of the child is 37 weeks or greater) or prematurity (when conceptional age is less than 37 weeks) is a disorder of respiratory control caused by developmental issues (immaturity of brainstem respiratory centers) or other medical disorders. Diagnosis requires observation of an episode of apnea or cyanosis or detection of apnea or desaturations by monitoring. Recurrent, prolonged (>20 seconds) central apnea or periodic breathing for more than 5% of total sleep time must be demonstrated.

ICSD3 includes a new CSA diagnosis: treatment emergent central sleep apnea.[19] This disorder, which has been referred to in the literature as complex sleep apnea, is characterized by predominantly obstructive apnea on baseline PSG, with resolution of obstruction and emergence or persistence of predominantly central apnea during administration of positive airway pressure without backup rate. The term *complex sleep apnea* has also been used to describe emergence of CSA with Cheyne-Stokes breathing or due to drug or substance in the context of treated OSA. However, a diagnosis of treatment emergent CSA should not be applied when another etiology for the CSA is established. In such cases, clinicians should diagnose both OSA and CSA due to Cheyne-Stokes breathing or substance.

Sleep-related hypoventilation disorders[20] and sleep-related hypoxemia disorder, previously subsumed under a single heading, are now distinct diagnoses. The hypoventilation disorders comprise six disorders associated with hypoventilation during sleep. Hypoventilation must be established by demonstration of elevated Pco_2 (as defined in the most recent version of the AASM scoring manual) by blood gas or, more commonly, by proxy measures such as end-tidal or transcutaneous CO_2.

Obesity hypoventilation[21,22] requires demonstration of daytime hypercapnia, whereas other sleep-related hypoventilation disorders require only sleep-related hypoventilation and may or not be associated with daytime hypercapnia. Congenital central alveolar hypoventilation syndrome[23] is a failure of automatic central control of breathing associated with mutation of the *PHOX2B* gene. The hypoventilation begins in infancy and worsens during sleep. Idiopathic central alveolar hypoventilation refers to sleep-related hypoventilation that is not attributable to another disorder. Late-onset central hypoventilation with hypothalamic dysfunction[24] is newly added to ICSD3. It is characterized by onset of symptoms

after the first several years of life. In addition to hypoventilation, symptoms may include obesity, endocrine abnormalities of hypothalamic origin, emotional and behavioral disturbances, and neural tumors. Sleep-related hypoventilation due to a medical condition[25] may result from pulmonary airway or parenchymal disease, extrinsic factors such as chest wall disorder, or neuromuscular disease. Sleep-related hypoventilation may also be caused by substances such as opioid or other respiratory depressants.

Sustained declines in Po_2 (Sao_2 <88% [90% for children] for ≥5 minutes), in the absence of demonstrated elevation of Pco_2, is diagnosed as sleep-related hypoxemia disorder.

Snoring is an isolated symptom included in this section and is identified when a respiratory sound, typically associated with inspiration, is disturbing to the patient, a bed partner, or others. This term applies when the snoring occurs without evidence of upper airway obstructive events or sleep-wake complaint such as insomnia or excessive sleepiness. Not only can snoring lead to impaired health, but it may also be a cause of social embarrassment and can disturb the sleep of a bed partner.

CENTRAL DISORDERS OF HYPERSOMNOLENCE

Central disorders of hypersomnolence are characterized by a primary complaint of daytime sleepiness that is not attributable to another sleep disorder[26,27] (see Chapters 89 to 91 and 100). Most of these conditions are caused by central nervous system abnormalities or the effects of substances or other disorders on the central nervous system. One exception to this is insufficient sleep syndrome, which results from behaviorally induced sleep deprivation. Daytime sleepiness is defined as the inability to stay alert and awake during the major waking episodes of the day, typically resulting in unintended lapses into sleep. Other sleep disorders may be present, and they must first be effectively treated to establish a diagnosis of a hypersomnia disorder. The disorders previously named narcolepsy with cataplexy and narcolepsy without cataplexy[28-32] are now termed *narcolepsy type 1* and *type 2*. Narcolepsy type 1 is diagnosed on the basis of complaint of excessive sleepiness and the presence of definite cataplexy plus multiple sleep latency test (MSLT) findings (mean sleep latency ≤8 minutes and evidence of two or more sleep-onset REM periods [SOREMPs]. More recent evidence suggests that a SOREMP on the PSG before the MSLT is highly specific for narcolepsy type 1.[33] Therefore a nocturnal PSG SOREMP (within 15 minutes of sleep onset) may substitute for one of the MSLT SOREMPs in making the diagnosis. Alternatively, narcolepsy type 1 can be diagnosed when subjective sleepiness and hypocretin deficiency are present, even in the absence of cataplexy. Some patients with hypocretin deficiency may not manifest cataplexy, at least at the time of initial diagnosis. It is for this is reason that the term *narcolepsy with cataplexy* has been rendered obsolete. Narcolepsy type 2 criteria include subjective sleepiness and the MSLT findings described previously for narcolepsy type 1. Cataplexy is absent, and hypocretin levels, if obtained, must not meet type 1 criteria.

Idiopathic hypersomnia[34] is the diagnosis given to those with subjective sleepiness complaints that are not explained by other sleep disorders, medical illness, or psychiatric illness. An MSLT latency of 8 minutes or less is required with fewer than two SOREMPs (including a SOREMP on the preceding night's PSG, if present) for diagnosis. It is recognized that some patients with legitimate sleepiness problems may not demonstrate mean latencies of 8 minutes or less. Clinical judgment is required in such cases. Particular care must be exercised to exclude insufficient sleep as a cause or contributing factor before a diagnosis of idiopathic hypersomnia is established.

Kleine-Levin syndrome[35,36] is a form of recurrent hypersomnia that persists for days to several weeks and is associated with one or more of the following: eating disorder (most commonly hyperphagia), cognitive dysfunction, perceptual disturbance, or uninhibited behavior, often sexual. In some women, recurrent hypersomnia may manifest as a menses-related phenomenon and is now termed *menstrual-related Kleine-Levin syndrome*.

Insufficient sleep syndrome occurs in patients who maintain a habitually short sleep episode relative to age-appropriate norms. These patients typically sleep significantly longer when schedules allow (i.e., weekends or vacation). Extended sleep resolves the sleepiness. Consideration must be given to the possibility of long sleep requirement in patients presenting with otherwise unexplained sleepiness and ostensibly normal sleep times.

Hypersomnia due to medical condition is excessive sleepiness that is caused by a medical or neurologic disorder.[37,38] Cataplexy or other diagnostic features of narcolepsy are not present. Hypersomnia due to drug or substance is diagnosed when the complaint is believed to be secondary to current or past use of drugs. Hypersomnia associated with a psychiatric disorder is excessive sleepiness that is temporally associated with a psychiatric diagnosis, although, as the name implies, cause-and-effect relationships between true hypersomnolence and psychiatric disorders are not well established.

Long sleeper, a normal variant within the hypersomnolence conditions, applies when a person sleeps more in the 24-hour day than the typical person. Sleep is normal in architecture and quality. Usually, sleep lengths of 10 hours or greater qualify for this diagnosis. Symptoms of excessive sleepiness occur if the person does not get that amount of sleep.

CIRCADIAN RHYTHM SLEEP-WAKE DISORDERS

The circadian rhythm sleep-wake disorders[39,40] share a common underlying chronophysiologic basis. The major feature of these disorders is an alteration of the circadian clock or a persistent or recurrent misalignment between the patient's sleep pattern and the pattern that is desired or required by societal demands or the environment (see Chapters 32 to 40 and 75). Because of the misalignment between circadian sleep-wake propensity and behavioral schedules, these individuals often experience symptoms of both insomnia and excessive sleepiness.

Delayed sleep-wake phase type,[41-44] which is more commonly seen in adolescents and young adults, is characterized by a delay in the phase of the major sleep period in relation to the desired sleep time and wake time, whereas advanced sleep phase type,[44] which is more commonly seen in older adults, is characterized by an advance in the phase of the major sleep period in relation to the desired sleep time and wake-up time. In both of these disorders, sleep, when allowed to occur with the circadian sleep propensity, is normal in quality and duration, but at a later (delayed sleep phase) or earlier (advanced sleep phase) time of day than desired. The irregular sleep-wake type, a disorder that involves the lack of a clearly defined circadian rhythm of sleep and wakefulness, is most

often seen in institutionalized older adults or chronically mentally ill patients and is associated with a lack of synchronizing agents such as light, physical activity, and social schedules. The non-24-hour type or free-running sleep-wake rhythm[44] is a result of lack of entrainment to the 24-hour light-dark cycle. The most common case of this condition is total blindness, although in some individuals an unusually long circadian period (which lies outside the range of entertainment) or an abnormal response to light may be causative. These patients generally exhibit cycles of poor sleep alternating with better sleep as their clock moves in and out of phase with the light-dark cycle.

Jet lag disorder[45,46] is related to an abrupt desynchronization between circadian sleep-wake propensity and the environmental day-night cycle as a result of transmeridian travel across two or more time zones. The severity of the disorder is influenced by the number of time zones crossed and the direction of travel, with eastward travel usually being more disruptive. Shift work type[45,47,48] is characterized by complaints of insomnia or excessive sleepiness that occur as a result of work hours that overlap the usual sleep period.

In addition to the subjective reports of insomnia or sleepiness that are attributable to the circadian disturbance, sleep logs that demonstrate the sleep-wake schedule alteration are required for most of these disorders. Although objective measures are not required, increasing emphasis is placed on the use of actigraphy and biomarkers such as dim-light melatonin onset to provide more accurate diagnosis and treatment guidance. Other sleep disorders (e.g., chronic insomnia disorder) may mimic or overlap with circadian rhythm sleep-wake disorders and must be identified and addressed as part of the overall therapeutic approach.

PARASOMNIAS

The parasomnias[49-51] are undesirable behaviors or experiences that accompany sleep (see Chapters 101 to 105). The motor activity of parasomnias is typically more complex than that observed with the sleep-related movement disorders. Experiences may be cognitive-emotional (as in nightmares or sleep terrors) or sensory (e.g., sleep-related hallucinations or exploding head syndrome). The parasomnias can arise during NREM sleep, REM sleep, or sleep-wake transitions. Many parasomnias represent a sleep-wake state disassociation between either NREM and wake (disorders of arousal from NREM) or REM and wake (REM sleep behavior disorder and recurrent sleep paralysis). The parasomnias often occur in conjunction with other sleep disorders such as OSA. It is not uncommon for several parasomnias to occur in one patient. NREM parasomnias[52,53] include the disorders of arousal from slow wave NREM sleep (confusional arousal, sleepwalking, and sleep terrors) and the closely related sleep-related eating disorder. Confusional arousals are characterized by mental confusion or confusional behavior that occurs during or after arousal from sleep. These arousals are common in children and can occur not only from nocturnal sleep but also from daytime naps. Sleepwalking[54-56] is a series of complex behaviors that arise from sudden arousals from slow wave sleep and result in locomotion during a state of impaired consciousness. Sleep terrors[57,58] also occur from slow wave sleep and are associated with a cry or piercing scream accompanied by autonomic system activation and behavioral manifestation of intense fear. Individuals may be difficult to arouse from the episode and when aroused can be confused and subsequently amnestic for the episode. These two disorders, sleepwalking and sleep terrors, often coexist and may result in a potentially dangerous state of terror and walking or running. Sleep-related eating disorder[59-61] involves recurrent eating and drinking episodes during partial arousals from sleep. The eating behavior is uncontrollable, typically involves ingestion of unusual or inedible substances, and may be associated with potential injury (e.g., from cooking) or other adverse health consequences. Often the patient has limited or no awareness during the episode and impaired recall of the behavior.

Several parasomnias are typically associated with the REM sleep stage. Pathophysiologic mechanisms related to REM sleep may underlie these disorders. REM sleep behavior disorder (RBD)[62-66] involves dream enactment behaviors that occur in REM sleep and may result in injury or sleep disruption. The behaviors are often violent with dream enactment that is action filled. The disorder can occur in narcolepsy and in many patients with Parkinson disease. The delayed emergence of neurodegenerative disorders, primarily synucleinopathies, occurs in a significant percentage of patients with idiopathic RBD, especially in men older than 50 years. Recurrent isolated sleep paralysis can occur at sleep onset or on awakening and is characterized by a frightening inability to perform voluntary movements. Ventilation is usually unaffected. Hallucinatory experiences often accompany the paralysis. Nightmare disorder[67-69] is characterized by recurrent anxiety-laden, often terrifying dreams that occur most commonly in REM sleep and result in an awakening with intense anxiety, fear, or other negative feelings. The disorder is most commonly encountered in the clinical setting in conjunction with posttraumatic stress disorder. The diagnosis should be invoked in this context only when the nightmare component is the focus of independent clinical assessment and treatment.

Sleep enuresis[70-72] is recurrent involuntary voiding that occurs during sleep. Enuresis is considered primary in a child who has never been dry for 6 months or longer; otherwise, it is called secondary. Exploding head syndrome is characterized by a loud imagined noise or sense of a violent explosion that occurs in the head as the patient is falling asleep or during waking in the night.

Sleep-related hallucinations are hallucinatory experiences that occur at sleep onset or on awakening. They may be difficult to distinguish from vivid dreams or nightmares but usually are complex images that occur when the patient is clearly awake. Sleeptalking, an isolated symptom, may arise during NREM or REM sleep and can be idiopathic or associated with other disorders such as REM sleep behavior disorder or sleep-related eating disorder.

SLEEP-RELATED MOVEMENT DISORDERS

The sleep-related movement disorders[73-77] are characterized by relatively simple, usually stereotyped movements that disturb sleep (see Chapter 106). Disorders such as periodic limb movement disorder and restless legs syndrome (RLS) are classified in this section.

RLS[78-83] consists of a complaint of a strong, nearly irresistible urge to move the legs, often accompanied by uncomfortable or painful symptoms. The sensations are worse at rest and

occur more frequently in the evening or during the night. Walking or moving the legs relieves the sensation temporarily. The disorder is commonly associated with repetitive limb movements during sleep, but a separate diagnosis of periodic limb movement disorder is not used when the movement occurs in the context of RLS, narcolepsy, untreated OSA, or RBD.

Periodic limb movement disorder[84,85] is an independent disorder of repetitive, highly stereotyped limb movements that occur during sleep. The movements must give rise to sleep disturbance or daytime sleepiness to meet criteria. Sleep-related leg cramps[86,87] are painful sensations associated with sudden intense muscle contractions, usually of the calves or small muscles of the feet, which occur during the sleep period and can lead to disrupted sleep. Relief is usually obtained by stretching the affected muscle.

Sleep-related bruxism[88,89] is characterized by clenching of the teeth during any stage of sleep and can result in arousals. Often the activity is severe or frequent enough to result in symptoms of temporomandibular joint pain or wearing down of the teeth. Sleep-related rhythmic movement disorder[90] is a stereotyped, repetitive rhythmic motor behavior that occurs during drowsiness or light sleep and results in large movements of the head, body, or limbs. Typically seen in children, the disorder can also be seen in adults. Head and limb injuries can result from violent movements. Rhythmic movement disorder can also occur during full wakefulness and alertness, particularly in individuals who are mentally retarded. Benign sleep myoclonus of infancy[91] is a disorder of myoclonic jerks that occur during sleep in infants. It typically occurs from birth to age 6 months, is not associated with known adverse consequences, and resolves spontaneously. Propriospinal myoclonus at sleep onset[92] is a disorder of recurrent sudden muscular jerks in the transition from wakefulness to sleep. The disorder may be associated with severe sleep-onset insomnia.

Isolated symptoms and normal variants within this section include sleep starts, excessive fragmentary myoclonus, and hypnagogic foot tremor and alternating leg muscle activation. Sleep starts (hypnic jerks) are sudden brief contractions of the body that occur at sleep onset. These movements are often associated with a sensation of falling, a sensory flash, or a sleep-onset dream. Hypnagogic foot tremor and alternating leg muscle activation occur at the transition between wake and sleep or during light NREM sleep. These conditions are listed together because they may represent somewhat different manifestations of a single disturbance. Hypnagogic foot tremor consists of rhythmic movement of the feet or toes, whereas alternating leg muscle activation consists of a PSG pattern of repetitive, transient activation of one anterior tibialis muscle group, alternating with activation of the contralateral tibialis. Excessive fragmentary myoclonus is manifest as small muscle twitches in the fingers, toes, or the corner of the mouth that do not cause actual movements across a joint. The myoclonus is often a finding during PSG that may be asymptomatic or associated with daytime sleepiness or fatigue.

OTHER SLEEP DISORDERS

The diagnosis of other sleep disorder is employed when a sleep disorder cannot be classified elsewhere. Disorders that demonstrate clear features of other, more specific categories (e.g., circadian, parasomnia, or movement disorder), but do not meet criteria for a specific diagnosis, should be classified within those respective categories as "unspecified."

ICSD2 included a diagnosis of environmental sleep disorder within this section. Significant controversy exists regarding this condition. Sleep disturbance that is purely a function of environmental disturbance such as a physical stimulus (e.g., noise or light) or environmental danger does not technically meet criteria for insomnia. When a complaint such as this is encountered in the clinical setting and is accompanied by adverse consequences, a diagnosis of other sleep disorder may be employed.

SLEEP-RELATED MEDICAL AND NEUROLOGIC DISORDERS

The ICSD3 lists six disorders that, although not sleep disorders, per se, are commonly encountered in association with sleep or may have unique presentations during sleep.

Fatal familial insomnia[93-95] is a progressive disorder characterized by difficulty in falling asleep and maintaining sleep that develops into enacted dreams or stupor. Autonomic hyperactivity with pyrexia, excessive salivation, and hyperhidrosis leads to cardiac and respiratory failure. The disease is caused by a prion, and it leads eventually to death. Sleep-related epilepsy[96-98] is the diagnosis employed when epilepsy occurs during sleep. Several epilepsy types are associated with sleep, including nocturnal frontal lobe epilepsy, benign epilepsy of childhood with centrotemporal spikes, benign epilepsy with occipital paroxysms, and juvenile myoclonic epilepsy. Sleep-related headaches[99,100] are cephalgias that occur during sleep or on awakening from sleep. Some are uniquely associated with sleep. Migraine headaches, chronic paroxysmal hemicrania, hypnic headaches, and cluster headaches can all occur during sleep. Sleep-related laryngospasm[101,102] is a disorder in which patients report choking and difficulty breathing at night typically associated with pronounced fear or panic. Its etiology is not well established, although it is encountered in multisystem atrophy and may be associated with OSA or gastroesophageal reflux. Sleep-related gastroesophageal reflux[103,104] is characterized by regurgitation of stomach contents into the esophagus during sleep. Shortness of breath or heartburn can result, but occasionally the disorder is asymptomatic. Sleep-related myocardial ischemia is due to reduction of blood flow to the myocardium during the sleep period.

CURRENT AND FUTURE CLASSIFICATION CONSIDERATIONS

Insomnia

From the outset of modern-day sleep disorder classification systems, insomnia has been compartmentalized into primary insomnia and insomnia due to a medical disorder, mental illness, or substance use, with several additional subtypes of primary insomnia identified. The consolidation of insomnia diagnoses in ICSD3 is not intended to suggest that there may not be important differences among certain subtypes of insomnia. However, from a clinical perspective, differentiation among a number of these subtypes has proved rather unreliable,[105,106] and after treatment of comorbidities is accounted for, therapeutic approaches do not differ significantly among the various subtypes. Additional research is necessary to determine whether significant, identifiable

differences among insomnias do exist and to what extent these differences might alter therapeutic approaches.

Previous classification systems such as ICSD2 included a complaint of "nonrestorative sleep"[107,108] in the list of possible insomnia symptoms. However, the nature of this complaint is ambiguous. Although many insomnia patients describe their sleep as "nonrestorative," majority of these patients have a presenting complaint of sleep initiation or maintenance resulting in extended periods of nocturnal wakefulness. Although a small percentage of patients have an isolated complaint of nonrestorative sleep, it is not clear that this complaint should be categorized as insomnia. Many other disturbances of sleep (e.g., sleep apnea) result in sleep that can fairly be categorized as "nonrestorative." The limited studies of isolated nonrestorative sleep suggest that, although sufferers share many symptoms in common with insomnia patients, they differ in certain respects. Therefore the evaluation and classification of patients with this complaint are left to the judgment of the clinician.

Sleep-Related Breathing Disorders

Treatment emergent central sleep apnea is a new diagnosis in ICSD3. Some controversy has existed regarding the validity of this diagnosis as well as the conditions under which it should be applied.[19] The diagnosis is established on the basis of PSG performed during positive airway pressure titration for obstructive sleep apnea. However, it has been recognized that some central sleep apnea that is observed during PAP titration resolves spontaneously over time. This may create the potential for unnecessary application of more complex and expensive treatment modalities such as auto servo ventilation. Further long-term follow-up is necessary to address these issues.

The criteria for pediatric obstructive sleep apnea have remain unchanged. However, limited information exists about the appropriate thresholds for treatment intervention in this population.

Central Disorders of Hypersomnolence

Destruction of hypocretin neurons, possibly on an autoimmune basis, is the presumptive etiology of narcolepsy type 1.[31] However, 5% to 10% of patients with narcolepsy and cataplexy (type 1) have normal hypocretin levels suggesting either a downstream problem with hypocretin (e.g., at the receptor level) or an alternative pathophysiologic mechanism. It is unclear whether narcolepsy type 2 shares some common pathophysiologic aspects with narcolepsy type 1 or is a disorder based on an entirely different pathophysiology. Idiopathic hypersomnia is still poorly understood because there is no clear pathophysiologic mechanism identified. Diagnosis can be challenging in that some patients may present with a convincing history of debilitating sleepiness, yet fail to meet the MSLT requirement for the diagnosis. Further work is needed to define the pathophysiology of narcolepsy type 2 and idiopathic hypersomnia as well as the genetic basis of these disorders.

Circadian Rhythm Sleep-Wake Disorders

Much has been learned regarding the biologic basis for circadian sleep-wake disorders. However, use of biologic markers that will enhance diagnostic precision is still quite limited, in part owing to issues of availability and reimbursement. ICSD3 encourages greater use of these markers for diagnosis in the hope that they will become a diagnostic standard and more widely available.

Parasomnia

Definitions of REM sleep without atonia, necessary to establish the diagnosis of RBD, have been somewhat complex and variable in recent years. Users should consult the AASM scoring manual for the most recent definitions. Substantial numbers of patients present with dream enactment behaviors in the context of OSA or antidepressant use. It remains unclear whether these patients carry the same unfavorable prognosis with respect to development of synucleinopathies as those with idiopathic RBD.

CLINICAL PEARLS

- ICSD3 incorporates all chronic insomnia within a single diagnosis of chronic insomnia disorder.
- Treatment emergent central sleep apnea, previously referred to as complex sleep apnea, has been added to ICSD3. This excludes central apneas of known etiology, such as substance-induced central apnea and Cheyne-Stokes breathing.
- Narcolepsy is now classified as type 1 and type 2. This allows more accurate description of hypocretin-deficient cases (type 1) without cataplexy.

SUMMARY

The classification of sleep disorders allows accurate diagnosis, improved communication among physicians, and the standardization of data for research purposes. The ICSD3 identifies six major groups of disorders, including insomnia, sleep-related breathing disorders, hypersomnolence disorders, circadian rhythm sleep-wake disorders, parasomnias, and sleep-related movement disorders. New sleep disorders have been recognized and previous sleep disorders have been clarified with a better understanding of their diagnostic and epidemiologic features. The ICSD3 increases the refinement of sleep disorder diagnoses because of recent advances in sleep research. Referral to the ICSD3 will help clinicians establish a rational differential diagnosis when evaluating patients.

Chapter 62

Epidemiology of Sleep Medicine

Amy W. Amara; Mary Halsey Maddox

Chapter Highlights

- Sleep medicine is a young field of medicine, and as such, the epidemiology of sleep medicine is in the early stages of study. Because of this relatively short history and the evolving classifications of disorders within the field, there is still much to be learned about the epidemiology of sleep medicine.
- Sleep disorders are common and include sleep-disordered breathing, hypersomnia, circadian rhythm disorders, insomnia, restless legs syndrome, and parasomnias, all of which have documented adverse outcomes for patients and many of which have adverse societal outcomes.
- Sleep-disordered breathing causes significant health and economic burdens and affects all ages and ethnicities, although it is most common in older men.
- Parasomnias are divided into rapid eye movement and non–rapid eye movement parasomnias. The non–rapid eye movement parasomnias are more common in children, but lifetime prevalence is high for both.
- Insomnia is common, adversely affects quality of life, and is associated with other health conditions. It is important to exclude other sleep disorders, such as circadian rhythm disorders and restless legs syndrome, when examining the epidemiology of insomnia.

Hippocrates said, "It is far more important to know what person the disease has than what disease the person has." Epidemiology includes not only the number of new and existing cases of certain illnesses and diseases occurring within a population (incidence and prevalence) but also the impact and burden those illnesses and diseases have on society and the people who live in it. The epidemiology of sleep medicine is in its youth and is challenging to define because of the evolution of diagnostic criteria over time, as well as differences in study methodologies.[1] As such, this chapter highlights the larger epidemiologic studies and attempts to summarize the data available, recognizing that, within the study of epidemiology of sleep medicine, there are gaps in knowledge, particularly in the areas of impact and economic burden.

This chapter is divided into sections (Sleep-Disordered Breathing, Hypersomnia, Circadian Rhythm Disorders, Insomnia, Restless Legs Syndrome, and Parasomnias) and generally follows the *International Classification of Sleep Disorders*, third edition (ICSD3) for inclusion criteria of each. The epidemiology of each seeks to focus on the people of the disease rather than the disease itself, as Hippocrates so eloquently stated.

SLEEP-DISORDERED BREATHING

Although disruptions of breathing in sleep had been reported previously (and attributed to hypercapnea),[2] airway obstruction was first recognized as the cause of sleep apnea between 1964 and 1965. At that time, Jung and Kuhlo, who are credited with performing the first tracheostomy as treatment for this disorder, and Gastant and colleagues simultaneously described sleep-related airway obstruction.[3-5] In the 1970s, recognition of obstructive sleep apnea (OSA) expanded in conjunction with enhancement of polysomnography (PSG) techniques and development of diagnostic parameters.[3] Before the 1980s, tracheostomy and weight loss were the only treatments for OSA. In 1981, continuous positive airway pressure was introduced[6] and revolutionized the treatment of OSA. With expansion of the field of sleep medicine, health care providers increasingly recognize sleep-disordered breathing and the adverse health effects and comorbidities of untreated OSA.

Snoring

Although the definition varies somewhat from study to study, habitual snoring in adults is most commonly defined as snoring for three or more nights per week.[7] Most of the studies evaluating snoring prevalence rely on self-report by the subject or spouse based on questionnaires, although some use a two-stage evaluation of questionnaire followed by portable or center-based PSG. In most cases, reports of snoring prevalence do not distinguish between snorers with apnea and those without apnea. The prevalence of habitual snoring ranges from 14% to 84%,[8,9] depending on the population studied. One large questionnaire-based study evaluated 22,389 blood donors in New Zealand and found self-reported snoring in 33%.[10] In the Sleep Heart Health Study (SHHS), snoring prevalence among 13,194 participants ranged from 32% to

52% in men and from 19% to 29% in women, depending on race and ethnicity.[11] Snoring prevalence is consistently higher in males than females and is influenced by body mass index (BMI), age, smoking status, ethnicity, and the presence or absence of a bed partner.

Obstructive Sleep Apnea

The prevalence of OSA varies by study based on how OSA is defined and the population in which it is measured. The ICSD3[12] defines OSA as either (1) 5 or more predominantly obstructive respiratory events per hour measured by PSG or out-of-center sleep testing (OCST) plus a comorbid medical condition, sleep complaint (sleepiness, insomnia, nonrestorative sleep), or witnessed apnea; or (2) 15 or more predominantly obstructive respiratory events per hour by PSG or OCST in the absence of other symptoms or comorbid conditions. This current definition has not been applied to most of the previously performed epidemiologic studies, and the challenges in interpreting prevalence in the setting of such different methodologies is discussed by Davies and Stradling.[13] Despite these challenges, large population-based studies provide very useful information about OSA epidemiology.[14] In the Wisconsin Sleep Cohort Study, the obstructive sleep apnea syndrome (OSAS) (defined in this study as an apnea hypopnea index [AHI] of 5 or greater in combination with the presence of excessive daytime sleepiness [EDS]) was estimated to affect 2% of women and 4% of men between the ages of 30 and 60 years.[15] The estimation of sleep-disordered breathing (SDB) (AHI ≥ 5 with or without EDS) was 9% in women and 24% in men.[15] In the SHHS,[16] 5615 subjects between 40 and 98 years of age were evaluated with questionnaires and OCST. In this sample, 18% had an AHI of 15 or greater (25% of men and 11% of women), and 29% of participants had an AHI between 5 and 14 (33% of men and 26% of women). In addition to sex, age and race also influenced the results.[16] Duran and colleagues evaluated a large cohort of 2148 subjects in Spain in two stages with questionnaire and home-based nocturnal oxygen monitoring in the first phase followed by PSG in a subset of the group. In the first phase, 35% were habitual snorers (46% of men and 25% of women). PSG monitoring showed an AHI of 10 or greater in 19% of men and 14.9% of women.[17] Mehra and colleagues investigated the prevalence of sleep-disordered breathing among 2911 men older than 65 years, finding that 26.4% of these older male participants had a respiratory disturbance index (RDI) of 15 or greater. Age and BMI influenced these outcomes.[18] Using home-based single-channel nasal airflow monitoring in a subset of the Australian Busselton Health Study cohort, Simpson and colleagues reported that 9.1% of 793 subjects had an RDI of 15 or greater (12.4% of men and 5.7% of women).[19] In addition to these prevalence studies, OSA incidence was documented in the Cleveland Family study, which demonstrated a 5-year incidence of 16% for mild to moderate OSA (AHI ≥ 10) and an incidence of 7.5% for moderately severe OSA (AHI ≥ 15) within 5 years following a normal PSG (AHI < 5).[20] The incidence was influenced by body habitus, sex, age, and cholesterol concentration.[20]

In summary, mild OSA with more than 5 events per hour likely affects approximately 1 in 5 adults, with moderate to severe OSA affecting at least 1 in 15 adults.[13,21,22] These may be an underestimation because most of the epidemiologic studies evaluate only those with symptoms, and many groups, including those with diabetes,[23] heart failure,[24,25] Parkinson disease,[26] and others, are less likely to have the typical symptoms of snoring and daytime sleepiness.

Sleep-Disordered Breathing and Sex

A consistent finding among epidemiologic studies investigating snoring and sleep apnea is the increased prevalence among men compared with women. In the SHHS, which reported snoring frequency based on ethnicity among 13,194 individuals older than 40 years, habitual snoring was reported by 32% to 52% of the men evaluated, but only by 19% to 29% of the women.[11] In a study of the Bussleton cohort, which followed 967 nonsnoring subjects from 1981 to 1994, 21% of men and 8% of women reported development of habitual snoring by the conclusion of the study.[27] The Cardiovascular Health Study evaluated participants at baseline for sleep complaints. Of the 5888 subjects, 34% of men and 20% of women self-reported snoring.[28] In a study of 4648 subjects between 20 and 69 years of age in Northern Sweden, 14.6% of men and 6.7% of women reported problematic snoring.[29] This higher prevalence among men than women is also reported in investigations of sleep apnea risk. Wheaton and colleagues evaluated data collected from 2005 to 2008 in the National Health and Nutrition Examination Survey (NHANES). In this population, 6% of men and 3.1% of women had a prior diagnosis of sleep apnea, and habitual snoring (five or more nights per week) was reported by 37.2% of men and 22.4% of women.[30] Bixler and colleagues performed a two-phase study in which they interviewed 12,291 women and 4364 men in Pennsylvania for sleep apnea risk and then randomly selected 1000 women and 741 men for PSG, with oversampling of those with more risk factors. In this sample, 7.2% of men and 2.2% of women had an AHI of 10 or greater, and 3.9% of men and 1.2% of women had an AHI of 10 or greater plus daytime symptoms. The prevalence was lower in premenopausal women and postmenopausal women on hormone replacement therapy compared with the prevalence in postmenopausal women not on hormone replacement therapy.[31] In a subset of the SHHS in which 5615 subjects underwent OCST, men had 2.7 times higher odds of having an AHI of 15 or greater compared with women.[16] These differences between men and women were also evident in the Wisconsin Sleep Cohort and the Busselton Health Study as described earlier in this paragraph.[15,19] Although the cause of these differences in prevalence is not completely defined, male gender appears to be a risk factor for development of OSA compared with premenopausal women.[31] However, because women with OSA tend to have fewer of the symptoms typically associated with sleep-disordered breathing, prevalence among women is likely underestimated.[32,33]

Sleep-Disordered Breathing and Race and Ethnicity

Race and ethnicity may also influence the prevalence of SDB. Many of the earlier epidemiologic studies on sleep apnea focused on Western populations, but in more recent years, more prevalence information is available for other groups. In the SHHS, O'Connor and colleagues evaluated snoring prevalence based on ethnicity.[11] After adjustment for age, BMI, and presence of a bed partner, the odds of frequent snoring were 2.25 times higher among Hispanic women and 1.55 times higher among black women compared with white women. Hispanic men had 2.3 times the odds of frequent

snoring than white men.[11] Redline and colleagues performed OCST in 14,440 Hispanic or Latino participants who live in the United States. In this population, the age-adjusted prevalence of sleep apnea was 25.8% for AHI of 5 or greater, 9.8% for AHI of 15 or greater, and 3.9% for AHI of 30 or greater.[34] The odds of having SDB were higher among persons who were male, obese, and older.[34] In the Northern Manhattan Study, Hispanic subjects had a 3.6 times higher odds of frequent snoring compared with white subjects, and there was no significant difference in self-reported snoring between black and white subjects.[35] However, a PSG-based study comparing severity of SDB among white and black subjects showed a higher AHI in African American males younger than 39 years or between 50 and 59 years when compared to white males.[36] Similarly, Redline and colleagues found that African American subjects 25 years or younger had 1.88 times higher odds of having SDB compared with whites.[37] Ancoli-Israel and colleagues showed no difference in prevalence of SDB (RDI ≥ 15) between whites and African Americans older than 65 years, but African Americans were more likely to have more severe sleep apnea (RDI ≥ 30).[38] Among studies performed in Asian populations, there is a broad range of suspected sleep apnea prevalence as discussed in a meta-analysis by Mirrakhimov and colleagues.[39] This large disparate prevalence is related to differences in study population based on sample size, sex, age, body habitus, and study design.[39] In a comparison of prevalence of OSA (AHI ≥ 5) among individuals based on OCST, Leong and colleagues found that obese South Asians had higher prevalence of OSA (85%) compared with obese white Europeans (66%).[40] Among Chinese men and women evaluated in two studies with questionnaires followed by PSG in a subset of subjects, 23% of men and 14.8% of women reported habitual snoring. The estimated prevalence of sleep apnea was 8.8% of Chinese men and 3.7% of Chinese women with an AHI of 5 or greater and 4.1% of men and 2.1% of women with an AHI of 5 or greater plus EDS.[41,42] In India, estimated population prevalence of OSA (AHI ≥ 5) is 9.3% to 13.7% and of OSAS (AHI ≥ 5 plus EDS) is 2.8% to 3.57%.[43,44] Yamagishi and colleagues reported higher prevalence of OSA in Americans and Hispanics than in Japanese, but this difference was attenuated after controlling for BMI.[45] In Thailand, the estimated prevalence of OSA and OSAS is 11.4% and 4.4%, respectively.[46] Two studies reported the prevalence of habitual snoring in Nigeria ranging from 14% to 18.5%.[8,47] The differences in prevalence of sleep apnea based on ethnicity or race may be in part related to body habitus[40,45] and differences in craniofacial features,[48] but there are differences independent of these factors.[38] Based on available data, the most consistent findings seem to be that Hispanics have higher prevalence of SDB than whites, and African Americans have more severe SDB that is present at a younger age than among whites. The prevalence among Asians varies based on the ethnicity within this group.

Sleep-Disordered Breathing and Age

Studies evaluating epidemiology of sleep apnea have documented a clear effect of age on prevalence of SDB. In the study by Duran and colleagues, which included white men and women between the ages of 30 and 70 years, there was a 2.2 times higher odds of having an AHI of 5 or greater for each 10-year increase in age.[17] Enright and colleagues assessed habitual snoring in subjects older than 65 years and showed that snoring actually decreased with aging, with 41% of men and 20% of women between the ages of 65 and 69 years reporting loud snoring, and only 17% of men and 10% of women older than 80 years reporting loud snoring.[49] A pattern that might reconcile these two observations was noted in the San Marino study, in which snoring was reported to increase with age until between 60 and 65 years, but then plateaued at older ages.[50] Bixler and colleagues studied 4364 men by telephone survey followed by PSG in a subset (741 subjects) and found that OSA increased with age until age 60 years but then decreased with older age.[51] A similar pattern was noted among women.[31] These studies together indicate that sleep apnea prevalence increases with age into the 60s but then plateaus.

Central Sleep Apnea

Central sleep apnea is the absence of airflow for at least 10 seconds with concomitant absence of respiratory effort. According the ICSD3, central sleep apnea can be classified as due to Cheyne-Stokes breathing; due to a medical condition without Cheyne-Stokes breathing; due to high-altitude periodic breathing; due to a medication or substance; or within a category of primary central sleep apnea.[12] Cheyne-Stokes breathing is most common in subjects older than 60 years and is most often associated with heart failure or stroke.[12] In heart failure patients, prevalence of SDB (AHI ≥ 5) is estimated to affect 70% to 80% of patients,[52] with moderate to severe central sleep apnea (AHI ≥ 15) in 21% to 40%.[53-56] The prevalence of central sleep apnea due to other conditions or due to opioids is not known, although healthy persons commonly develop central sleep apnea due to high altitude.[12]

Health and Economic Impact of Sleep-Disordered Breathing

Among adults, SDB results in increased health care use and increased economic burden. A retrospective evaluation of 1,867,876 veterans showed that those with a diagnosis of OSA had more hospitalizations and more emergency department visits than those without a diagnosis of OSA. Additionally, those with OSA had higher odds of having heart failure, hypertension, lung disease, obesity, stroke, depression, diabetes, and other health problems.[57] Similarly, Smith and colleagues found that patients diagnosed with OSA used 23% to 50% more healthcare resources in the 5 years prior to diagnosis compared to age-matched control subjects.[58] The OSA patients were also at higher risk for development of heart disease, lung disease, and depression.[58] These health consequences and other associated symptoms of sleep apnea result in decreased work performance and increased risk for work- and leisure-related injuries, further increasing the economic impact of this common disorder.[59] In the year 2000, the estimated cost of sleep apnea–related motor vehicle collisions was $15.9 billion and 1400 lives.[60] Treatment of sleep apnea can reduce some of this burden.[59,60] In a study of 22,275 Union Pacific Railroad employees, treatment of sleep apnea resulted in a $4.9 billion differential cost savings compared with untreated sleep apnea.[61] The effects and dependence of SDB on other health conditions, such as hypertension, cardiovascular disease, heart failure, cognition, lung disease, obesity, neurologic disorders, and metabolic dysfunction, are explored in more extensive detail in other chapters in this book (see Chapters 93, 94, 96, 97, 117–118, and 126–129).

Pediatric Sleep-Disordered Breathing

Osler described pediatric SDB in reference to pediatric neurocognitive impairment in 1892 in *The Principles and Practice of Medicine,* but it was not identified as clinically important in pediatrics until 1976 when Guilleminault and colleagues described "Sleep Apnea in Eight Children."[62,63] Consequently, the primary base of information about SDB in children stems from the past 35 to 40 years, suggesting that there is much still to be discovered. Over the past 3 to 4 decades, however, SDB in pediatrics has changed from a disorder observed in a small case series to a disease with a significant mental, physical, social, and economic impact.

Pediatric Obstructive Sleep Apnea and Primary Snoring

Most of the epidemiologic data for SDB in children report a prevalence of 4% to 11%, with the prevalence of OSA ranging from 1.2% to 5.7%.[64-66] Most studies evaluating prevalence are based on questionnaires, although two large studies have performed more objective evaluation with PSG in combination with questionnaires. Li and colleagues administered questionnaires and then performed PSG in Chinese school-aged children. The prevalence of symptomatic OSA (defined as AHI > 5) was 4.8% for the entire sample, 5.7% in boys and 3.8% in girls; the prevalence of asymptomatic OSA (AHI > 5) was 9.1% and 5.7% in boys and girls, respectively.[67] In the United States, Bixler and colleagues had a similar protocol with healthy school-aged children that showed a prevalence of 1.2% for an AHI of greater than 5, 25% for an AHI between 1 and 5, and 15.5% for primary snoring.[65] In a meta-analysis of pediatric SDB, Lumeng and Chervin, in their meta-analysis of pediatric SDB reported a prevalence of 4% to 11%, with a breakdown of percentages based on how individual studies framed the questions about primary snoring and apnea. Primary snoring makes up the higher end of the former percentages, ranging from 2.5% in Turkey to 6.2% in Sweden for those who snore "always."[66,68,69] For those who snore "often," the prevalence is 3.2% in Iceland, 14.8% in Spain, and 34.5% in Italy.[66,70-72] OSA makes up the lower end of the spectrum, but prevalence depends on the criteria used for diagnosis. Overall, however, the prevalence of OSA based on PSG ranges from 0.1% in Singapore for an AHI of greater than 1 to 13% in Italy for an oxygen desaturation index of 5 or greater.[66,72,73] Parent reported apnea ranges from 0.2% to 18.6%.[66,72,74] Certainly there is room for more standardized trials involving consistent definitions of OSA, primary snoring, and SDB with larger numbers of subjects to identify the true prevalence of pediatric SDB. Based on available studies, the prevalence of primary snoring appears to range from 1.5% to 27.6% and the range for OSA is 1% to 5%.[75]

Pediatric Sleep-Disordered Breathing and Age

Over time the distribution of SDB by age has changed within the pediatric population as well. In the 1990s, the prevalence of primary snoring was cited at 6% to 12%.[69,76-78] These older studies reported the overall prevalence of primary snoring at 10% of children 2 to 8 years of age with a decreasing prevalence at about 9 years of age.[79] More recent studies suggest a bimodal distribution of sleep apnea with a second peak in adolescence. Although the prevalence of SDB in adolescence is not definitive, it is clear that SDB increases with obesity in this age group. Kohler and colleagues found a 3.5-fold increase in AHI relative to increase in BMI Z-score in pediatric patients older than 12 years.[80] The Childhood Adenotonsillectomy Study (CHAT) found that children younger than 9 years with OSA had better resolution of symptoms if they were not overweight or obese regardless of treatment group (adenotonsillectomy or watchful waiting).[81] Of course, obesity is a problem worldwide and has increased in the pediatric population over the past 30 years, which certainly contributes to the increasing prevalence of SDB and the bimodal peak. Furthermore, studies have begun to investigate racial, social, and health differences among pediatric patients with SDB. These reports suggest that African American ethnicity, prematurity, and low socioeconomic status result in worse SDB in pediatric patients.[37,82-85]

Health and Economic Burden of Pediatric Sleep-Disordered Breathing

In the pediatric population, health and societal implications of SDB are reported with increasing frequency. Perhaps one of the greatest concerns is the neurocognitive impairment seen in children with SDB. Beebe (2006) and Owens (2009) both provide excellent reviews of the association between neurocognitive impairment and pediatric SDB.[86,87] SDB, inclusive of primary snoring and OSA, clearly results in varying degrees of neurocognitive impairment in children. The more recent Childhood Adenotonsillectomy Study study demonstrated that children who were treated for their SDB had more improvement in secondary behavioral scores and quality of life than those in the "watchful waiting" arm, although treatment of SDB did not result in any improvement in executive function and attention scores on neuropsychological testing.[81] Similar to other studies, Bourke and colleagues found cognitive and academic impairment in Australian children, but this did not correlate with the degree of SDB.[88] Landau and colleagues observed a small cohort of Israeli preschoolers in whom treatment of SDB resulted in resolution of the neurocognitive problems and "catch-up" to controls after 1 year.[89] On the other hand, Perfect and colleagues found as part of the Tucson Children's Assessment of Sleep Apnea Study that there is concern for lifetime impairment in those with history of SDB versus controls who have never had SDB.[90] Most studies, however, suggest that treatment of SDB does improve neurocognitive performance.[75] For an extensive review of the studies of neurocognitive function and SDB, please see the Technical Report of the American Academy of Pediatrics Recommendation on the Diagnosis and Management of Childhood Obstructive Sleep Apnea Syndrome.[75]

In addition to neurocognitive impairment, pediatric SDB also results in physical health problems. Historically, when SDB was underrecognized or when diagnosis was delayed, toddlers had failure to thrive, and some pediatric patients presented with cor pulmonale. With earlier recognition of the medical complications of pediatric SDB, these outcomes are now rarely seen, but there is mounting evidence for cardiac, inflammatory, and endocrine effects of SDB. The prevalence of such complications is not yet known, but cardiovascular complications include right and left ventricular changes, blood pressure changes, changes in brain natriuretic peptide, changes in cerebral blood flow, and autonomic dysregulation.[75] Inflammatory consequences and endocrine and growth changes need to be more systematically studied, but early research suggests

that there is an association between SDB in pediatric patients and changes in C-reactive protein and insulin levels.[75] For a thorough review of the studies that have delved into these medical complications of pediatric SDB, please see the Technical Report of the American Academy of Pediatrics Recommendation on the Diagnosis and Management of Childhood Obstructive Sleep Apnea Syndrome.[75] Certainly more longitudinal studies are needed to further characterize and delineate the prevalence and long-term consequences of these metabolic, cardiovascular, and inflammatory complications of SDB in children.

Economically, there have been few studies that have addressed the burden of cost of SDB in pediatrics. Tarasiuk and colleagues looked at a cohort in Israel and found that pediatric patients with SDB used health care resources 215% more than healthy matched controls.[91] Other studies have documented the increased cost in pediatric patients with sleep problems or specific cohorts with other medical problems such as sickle cell disease, but the increased cost has not been delineated for SDB.[92,93] More research is needed, but it stands to reason that children with decreased neurocognitive capabilities and increased medical problems not only will use more health care and social resources but also will not achieve their full potential, a cost that cannot be truly measured.

Other Sleep-Disordered Breathing in Pediatrics

Other SDB in children includes apnea of infancy, congenital central hypoventilation syndrome, central apnea related to obesity, SDB related to neuromuscular disease, and central sleep apnea related to Chiari malformation, but there are no large studies evaluating the prevalence and cost of these types of SDB.[12]

HYPERSOMNIA

The definition of hypersomnia has not been consistent in population-based studies. Some studies define it as perceived insufficient sleep, whereas others define it as too many or too few hours slept compared with the "ideal" number of hours. Still others define hypersomnia as the feeling of "sleepiness" or the ability and urge to sleep during the day. The previous edition of this book reviewed these difficulties defining hypersomnia and includes extensive tables and references, which estimate a prevalence between 0.3% and more than 30%, depending on how hypersomnia is defined.[14] Ohayon and colleagues also reviewed the literature and found that there was little consistency in study methods reporting either excess of sleep or increased propensity to sleep during wakefulness.[94] As such, hypersomnia is acknowledged as a worldwide problem, but one that needs more exploration. For the purposes of this review, prevalence data are divided by diagnosis, limited to the central disorders of hypersomnia as defined by the ICSD3, excluding hypersomnia due to a medical problem, because that topic is too broad for this context and depends on the specific medical problem.[12]

Narcolepsy

At the time of the last edition of this book, there were approximately 30 studies evaluating the prevalence of narcolepsy in the general population. Clear ethnic differences were seen in a handful of studies, but overall, the prevalence seemed to range from 0.025% to 0.05%, with Japan as an outlier, having the highest prevalence at 0.16%. These studies had significant differences in methodology, including patient questionnaires, population reviews, chart review, physician interview, self-report, and HLA typing.[14] More recently, Wijnans and colleagues combined seven patient databases in six European nations and compared the incidence of narcolepsy with or without cataplexy before, during, and after the H1N1 pandemic and reported pooled incidence of about 1 per 100,000 person-years.[95] These results suggested a higher incidence than the 0.6 per 100,000 reported by Longstreth and colleagues in the United States based on multistage screening of patients.[96] Similar findings were reported by Silber and associates from Olmstead County in Minnesota at an incidence of 1.37 per 100,000 person-years for narcolepsy with or without cataplexy and an incidence of 0.74 per 100,000 person-years for narcolepsy with cataplexy.[97] To date, there have been no published epidemiologic studies using the ICSD3 definitions of narcolepsy type 1 and type 2.[12]

After the 2009 H1N1 pandemic in China and the introduction of the ASO3 adjuvant H1N1 vaccine (Pandemrix) in Europe, narcolepsy with cataplexy appeared to have an escalating incidence in certain European countries and parts of China in which H1N1 influenza was epidemic, starting in Sweden and Finland.[98,99] China also noted a sharp increased incidence of narcolepsy after the H1N1 pandemic.[100] This acute increase in diagnoses of narcolepsy in 2009 prompted larger studies of national patient registries across Europe to examine the incidence of narcolepsy and what was previously defined as narcolepsy with cataplexy. In Sweden, the incidence in those who received the Pandemrix vaccine was found to be increased three-fold in those younger than 20 years, two-fold in those 21 to 30 years, and unchanged in those older than 40 years.[101] A small increase in narcolepsy among unvaccinated individuals was also seen; however, it is unknown whether that is due to population bias, increased recognition, or perhaps a true increase related to H1N1 infection.[100,101]

Studies show conflicting results regarding whether narcolepsy preferentially affects men or women, suggesting that more research is needed in this area. There are clear increases in the incidence of narcolepsy in people 10 to 30 years of age compared with other age groups, even excluding those affected by the H1N1-related increase reported previously.[96,97,102] It is thought that there is an autoimmune component because there is a known genetic association with HLA DQB1*0602 as well as an increased relative risk in first-degree relatives.[103]

The burden of narcolepsy is significant in terms of morbidity, health care costs, and societal costs. A higher rate of motor vehicle crashes is reported in narcolepsy, and drowsy driving is a known risk factor for increased collisions. Furthermore, the Burden of Narcolepsy Disease (BOND) study suggested narcoleptic patiens have two to three times the health care use and costs compared with age-matched controls in the United States, higher rates of short-term disability, and more missed work days, suggesting implications for long-term productivity.[104] A Danish study by Jennum and colleagues reported increased morbidity from endocrine, other sleep-related, neurologic, musculoskeletal, ophthalmic, and respiratory disorders in persons with narcolepsy.[105] Ohayon and associates also reported a mortality rate increase of 1.5 in narcoleptic patients across age groups.[106]

Idiopathic Hypersomnia

The prevalence of idiopathic hypersomnia is not known, although it is estimated to be less than that of narcolepsy based on referrals to sleep centers.[12,94,107,108] Further research is needed in this area to determine its prevalence.

Kleine-Levin Syndrome

Kleine-Levin syndrome is known to most commonly present in the second decade, although there are outliers, and it is far more common in males.[109,110] Prevalence is estimated at 1 to 2 per million based on retrospective studies. Additionally, there may be increased risk within families with an affected member.[12,109]

Behaviorally Induced Insufficient Sleep

Behaviorally induced insufficient sleep has been the focus in only two studies estimating prevalence. Komada and colleagues estimated prevalence at 7.1% with a 7:3 male preponderance and Pallesen and associates reported a prevalence of 10.4% of behaviorally induced insufficient sleep in Norwegian high school students, although 22.3% of all the students reported excessive sleepiness.[111,112] However, more studies are needed because cultural pressures and norms most likely play a role in incidence and prevalence.[12]

Other Hypersomnia

Hypersomnia due to a medication or substance depends on the substance used and whether the patient is intoxicated or withdrawing. Prevalence data also depend on which substance is used. However, hypersomnia from stimulant withdrawal occurs most frequently in teens and young adults.[12] Similarly, hypersomnia associated with a psychiatric disorder also depends on the disorder being considered and medications used, but it is known to occur in more than 50% of people with seasonal affective disorder.[12]

Clearly more studies are warranted in determining the epidemiology of hypersomnia, particularly because most of those affected present in the second and third decades, making hypersomnia a lifelong disease and one that affects quality of life significantly.[104,105,113]

CIRCADIAN RHYTHM DISORDERS

Circadian rhythm disorders (CRDs) encompass several disorders as defined by the ICSD3. Epidemiologic data are divided according to each disorder; however, true prevalence is not known for most disorders or for CRD as a whole.

Delayed Sleep Phase

Delayed sleep phase (DSP) is probably the most common of the CRDs and may account for 5% to 10% of patients referred to sleep clinics.[12,114] The true prevalence of DSP is not known; however, it has been estimated to be as high as 7% to 16% in adolescents[12] and as low as 0.1% to 0.2% in the general population.[114,115] Adolescence is the peak age for DSP, with the circadian clock "lateness" peaking at 20 years for most people.[116] Several studies examining prevalence among teenagers have reported rates ranging from 1.1% in Australia to 3.3% in Norway to 8.4% in a different Norwegian study.[117-119] A study out of San Diego found a prevalence of less than 1% in adults ages 40 to 64 years.[120] Two studies have shown that male gender predisposes to eveningness, but one additional study suggested females are predisposed to eveningness.[121-123] No studies have been done to examine racial and ethnic differences among those with DSP.[12] More studies are needed to determine the true prevalence and effect of race and ethnicity in DSP.[124] DSP has a familial pattern in up to 40% of patients, and there is some evidence that DSP is associated with human *hPer3,* arylalkylamine *N*-acetyltransferase, human leukocyte antigen, and *CLOCK* polymorphisms, although it has not been validated in all studies.[12,125,126]

The clinical significance of DSP has primarily been identified as a problem in teens and young adults. Saxvig and colleagues found that grades were negatively affected and that smoking, alcohol use, anxiety, and depression were increased with DSP.[117] Also in teens, DSP is a risk for hypersomnia because of early school start times and, as such, is a risk for the consequences of hypersomnia.[127] Please see the Hypersomnia section of this chapter for further description of the consequences of hypersomnia.

Advanced Sleep Phase

Advanced sleep phase (ASP) is rare and is thought to be found in 1% of the population, although this may be an underestimation because patients may not be sufficiently distressed to seek help. With the exception of familial cases, there are only four reported cases in the literature, and there is not a known gender predilection.[12] Indeed, a study of 10,000 people in Norway found no cases of ASP by strict ICSD criteria.[128] Older age and neurodevelopmental disorders seem to predispose people to ASP.[12,124]

Irregular Sleep-Wake Rhythm Disorder

Irregular sleep-wake rhythm disorder is also quite rare, and there are a paucity of data to support prevalence numbers. However, neurologic disease, mental disability, and dementia all are risk factors, and the prevalence increases with age.[129] There is not enough information to comment on gender or ethnic influences.[12,124]

Non-24-Hour Sleep-Wake Rhythm Disorder

Non-24-hour sleep-wake rhythm disorder is found in more than half of completely blind individuals, and the disorder is demonstrated in 5% to 15% of other types of blindness.[12,114] In blind individuals, onset can be at any age, and there are no data to suggest increased risk based on sex. In sighted individuals, non-24-hour sleep-wake rhythm disorder is rare and associated with psychiatric disorders (25%), traumatic brain injury, and male gender, although it is unclear whether male gender is truly a risk.[12,124]

Shift Work Disorder

Shift work disorder has garnered more interest over the past few years with the recognition that increased morbidity is associated with shift work in general. The prevalence in the general population is estimated to be 1% to 4% and 10% to 33% in shift workers.[12,130-132] Shift work disorder results in accidents, decreased alertness, decreased quality of life, and morbidity.[133] The specific societal and personal consequences are addressed in the chapter in this text about shift work disorder.

Jet lag disorder and circadian sleep-wake disorder not otherwise specified do not have sufficient studies documenting epidemiologic data to comment.

INSOMNIA

The ICSD3 has reclassified insomnia, abandoning previous insomnia categories of primary and secondary insomnia for a broader classification, including chronic insomnia disorder, short-term insomnia disorder, and other insomnia disorder.[12] The criteria for diagnosis of insomnia disorders include a difficulty initiating or maintaining sleep or undesired early awakening despite adequate opportunity for sleep that results in daytime, functional, or social impairment or distress.[12] The prevalence estimates of insomnia vary based on the diagnostic criteria used. In fact, the America Insomnia Survey evaluated 10,094 participants by different diagnostic criteria and found a range of insomnia prevalence within that group from 3.9% based on International Classification of Diseases, 10th revision (ICD-10) criteria to 22.1% based on *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (DSM-IV) criteria.[134] The prevalence range also varies depending on whether subjects are evaluated for dissatisfaction with their sleep, any symptoms of insomnia (sometimes restricted to a certain frequency or severity of these symptoms), or actually qualifying for an insomnia diagnosis.[135] For example, in two separate Canadian cohorts evaluated by telephone survey, 19.8% to 25.3% reported sleep dissatisfaction, 29.9% to 40.2% reported at least one insomnia symptom, and 9.5% to 13.4% met criteria for insomnia based on a combination of DSM-IV and ICD-10 diagnostic criteria.[136,137] This difference is also reflected in a study of 12,778 French individuals, which reported at least one sleep problem more than three times weekly in 29% of subjects, but a prevalence of 19% for those with daytime consequences of the sleep complaint.[138] Bixler and colleagues studied a group of 1741 subjects in Central Pennsylvania with PSG and questions about insomnia and poor sleep. This study showed a prevalence of sleep difficulty in 22.4% and chronic insomnia (symptoms longer than 1 year) in 7.5%.[139] The subjects who did not have chronic insomnia at baseline were evaluated 7.5 years later with the same questions about insomnia and poor sleep. Incidence of chronic insomnia in this group was 9.3% (12.9% in women and 6.2% in men).[140] Within this cohort, incident poor sleep in those with baseline normal sleep was 18.4%. Those who had poor sleep at baseline had a remission rate of 44%, whereas 39% remained poor sleepers and 17% transitioned to chronic insomnia.[141] Regarding acute or short-term insomnia, Ellis and colleagues reported prevalence of 9.5% in the United States and 7.9% in the United Kingdom.[142] Based on these studies and others, the prevalence range of insomnia diagnosis is likely 4% to 22%, with some symptoms of insomnia affecting 20% to 45% of adults.[134,135,143-146]

The prevalence of insomnia appears to be increasing over time. A study performed in England assessing insomnia prevalence over 15 years reported prevalence of 3.1% in 1993 and 5.8% in 2007.[147] Based on the National Health and Nutrition Examination Survey 1999–2010, use of prescription medications for insomnia have also increased over time, with 2% of studied individuals using such medications in the 1999–2000 period and 3.5% in the 2009–2010 period.[148] Notably, the estimated prevalence of insomnia may be underestimated in certain populations because many of those with symptoms do not seek help from a physician.[136,149]

Pediatric Insomnia

Similar to adults, insomnia prevalence rates among adolescents vary based on study design and definitions of insomnia. Pediatric insomnia includes behavioral insomnia of childhood, psychophysiologic insomnia, and sleep-onset association disorder, and all can have overlap with other sleep disorders. As such, prevalence ranges vary. If simply insomnia symptoms are reported, prevalence ranges from 25% to 35%, whereas the prevalence rates are lower when defined by insomnia diagnostic criteria (DSM-IV or ICSD22), ranging from 4% to 14%.[150-154] In a study of 10,220 adolescents in Norway, prevalence of insomnia was 23.8% based on DSM-IV criteria, 18.5% based on DSM-5 criteria, and 13.6% based on the quantitative criteria for insomnia, which requires a 6-month duration of symptoms.[155] The presence of insomnia among adolescents can have significant influence on safety, cognition, and mood and may predict future sleep habits.[156-158] Studies consistently show a higher prevalence of insomnia among adolescent girls than boys, but this difference appears to emerge only after onset of menses.[150,155,156]

Insomnia is also common among children and preadolescents, affecting up to 41% of those aged 2 to 14 years.[159] Most reports, however, place pediatric insomnia prevalence at 10% to 20%. An evaluation of 5- to 12-year-olds by Calhoun and colleagues found a prevalence of insomnia symptoms in 19.3%, with the highest prevalence among preteen girls (age 11 to 12 years).[158] Similar prevalence was found in a study of 4989 Australian preschoolers (age 4 to 5 years), among whom 19.8% had mild sleep problems and 13.8% had moderate to severe sleep problems. Those who reported difficulty falling asleep were more likely to have worse health-related quality of life and diagnosis of attention deficit disorder.[160] The Sleep in America poll of 2004 surveyed parents of children from infancy to 10 years of age, and sleep problems were reported among 6.3% of infants, 10.5% of toddlers, 10.2% of preschoolers, and 10.8% of school-aged children. Those with reported sleep problems were more likely to have a later bedtime and to have a parent present at sleep onset.[161] An important consideration in evaluation of childhood sleep complaints is that there can be considerable impact of parental perception of sleep problems based on cultural and ethnic differences.[162,163]

During infancy, the prevalence of sleep problems is approximately 10%, with most concerns being related to nocturnal awakenings and short sleep duration.[164] Interestingly, sleep difficulty at this age appears to predict sleep problems during the early childhood years. For example, infants who do not self-soothe are more likely to have difficulty with sleep onset at age 2 years.[165] Other longitudinal studies show that sleep problems at 6 to 12 months of age predict sleep trouble at 3 to 4 years of age.[164,166,167] These changes may not persist to older ages because another longitudinal study showed no predictive value of infant sleep problems on sleep outcomes at age 6 years.[168] Regardless, insomnia is common in the pediatric population and can have a significant effect on health, cognition, and safety among patients and their parents.

Insomnia Demographics

The prevalence of insomnia is consistently reported to be higher in women than men.[135,139,169,170] A meta-analysis performed by Zhang and colleagues found a risk ratio of 1.4 for men versus women. The higher prevalence among female adults is present at all age groups but increases with age, with a 1.28 higher risk in women aged 15 to 30 years and a 1.73 risk ratio among those older than 65 years.[171] Aging is often identified as a risk factor for insomnia, but some studies actually show higher rates of incident and persistent insomnia in middle age or in younger age groups.[135,141,172,173] Insomnia in older adults may be associated with more nocturnal awakenings and early morning awakening than in younger adults.[170] The association of age with insomnia varies based on the population studied and may depend on the presence of associated health conditions (which could increase with aging) and the increased use of technology among younger age groups.[173] Race and ethnicity, education, and socioeconomic status may also influence the prevalence of insomnia.[135,170] The influence of these demographic features and health comorbidities on insomnia is further explored in Chapters 81 and 84.

One key thing to remember about insomnia is that it must result in daytime, functional, or social impairment or distress. As such, the effect on quality of life and the cost and burden of insomnia are difficult to quantify, but it stands to reason that there is a societal cost to insomnia related to all the problems related to sleep deprivation, as well as the known medical morbidities related to sleep disorders.

RESTLESS LEGS SYNDROME

Restless legs syndrome (RLS) is characterized by an urge to move the legs, often associated with an uncomfortable sensation, which occurs during periods of rest, is relieved by movement, occurs predominantly in the evening, and causes distress.[12] RLS can be divided into primary and secondary RLS, which is RLS due to precipitating factors, such as iron deficiency, pregnancy, renal failure, neuropathy, and use of certain medications. Primary RLS tends to have younger onset of symptoms, and those with primary RLS are more likely to have an affected family member. Comparatively, secondary RLS usually develops at an older age.[174] Studies addressing the prevalence of RLS may differ in the diagnostic criteria employed and as to whether diagnosis was based on questionnaire report of symptoms, physician diagnosis of RLS, or frequency and severity criteria.[175] For example, Allen and colleagues studied a cohort of subjects in Western Europe, where prevalence of RLS symptoms among 10,564 respondents was 7.6%, but the prevalence decreased to 3.5% when patients underwent physician interview for diagnosis.[176] Similarly, in the United States the prevalence, based on the four diagnostic criteria of RLS by questionnaire screening, was 7.3%.[177] Further, more detailed evaluation to exclude secondary RLS resulted in an adjusted prevalence of primary RLS of 2.4%. The prevalence of moderately to severely distressing symptoms at least twice per week decreased further to 1.5%.[177] Using International Restless Legs Syndrome Study Group criteria, prevalence rates range from approximately 5% to 15%.[174,175,178-181] The prevalence of distressing symptoms occurring at least twice weekly is lower, from approximately 1% to 10%.[174-177,182] Regardless of which criteria are used to establish prevalence, RLS is common and is likely underdiagnosed.[174]

RLS is consistently reported to be approximately twice as high in women as in men.[175,181] There is a higher prevalence of RLS with increasing age.[183] Regarding ethnicity, the prevalence of RLS has been reported to be lower in Asian populations in some studies, but other studies in Asian populations show comparable prevalence rates.[184,185]

The health and societal effect of RLS are significant. RLS can lead to insomnia,[186] daytime sleepiness,[187] increased health care costs, and increased indirect cost related to lost productivity.[188] Additionally, RLS has been associated in some studies with hypertension, cardiovascular disease,[186,189,190] gastrointestinal disease,[191] mood disorders,[182,186] stroke,[190] migraine,[192] multiple sclerosis,[193] and, in men, increased mortality.[194] More studies are needed to determine whether these medical comorbidities are a result of RLS or may actually predict incident RLS.[190,195] RLS has a clear relationship with periodic limb movements of sleep, which are present in 85% to 95% of patients with RLS.[183]

RLS prevalence in school-aged children is estimated to be 2% to 4%.[196] RLS can also be present in young children and infants, although its prevalence in this age group is not known.[197] Prevalence of RLS in adolescents ranges from 1% to 2.8%.[198] Pediatric RLS is associated with attention deficit hyperactivity disorder, depression, anxiety, insomnia, and daytime sleepiness.[197,199-201] As with adults, iron deficiency can be a cause of secondary RLS in the pediatric population.[196,197]

PARASOMNIAS

Parasomnias are divided in the ICSD3 into non–rapid eye movement (NREM) parasomnias, rapid eye movement (REM)-related parasomnias, other parasomnias, and normal variants.[12] Although some observations can be made about parasomnias in general, it is more pertinent to define the epidemiology by specific disorders. Epidemiologic studies of parasomnias must be, in large part, acknowledged as rough estimates because most studies are population based, involve varying methodologies, and may involve recall bias because many of the NREM parasomnias are more prevalent in childhood. Furthermore, parasomnias may be underestimated in cases in which there is no bed partner or self-report is required. Overall prevalence of parasomnias has been reported as high as 88% in preschoolers and 73% in children aged 3 to 13 years, with lifetime prevalence ranging from 4% to 67% in adults.[202-204] Prevalence data are summarized in Table 62-1.

NREM Parasomnias

NREM parasomnias, according to the ICSD3, include somnambulism (sleepwalking), confusional arousals, sleep terrors, and sleep-related eating disorder.[12] Confusional arousals, somnambulism, and sleep terrors tend to initially present in childhood and adolescence; however, somnambulism and confusional arousals may present at any age. All three disorders may persist throughout life, although the incidence of all three decreases with age.[205] These arousal disorders can be triggered by other sleep disorders (e.g., OSA, RLS) or environmental stimuli, and sleep deprivation and stress are known primers for the occurrence of arousal parasomnias.[12]

Table 62-1 Prevalence of Parasomnias

	Adult (%)	Pediatric (%)	Lifetime (%)
NREM Parasomnias			
Confusional arousals	1.8–6.9	ID	18.50
Sleep terrors	2.2–2.7	1–14.7	10
Somnambulism	0.6–3.9	3.5–14.5	22–30
Sleep-related eating	0.4–2.2	ID	4.50
REM Parasomnias			
REM sleep behavior disorder	0.38–2.1	ID	ID
Nightmare disorder	2–8	65–80.5	66.20
Recurrent isolated sleep paralysis	4.7–41	ID	6.20
Other Parasomnias			
Sleep-related hallucinations	23	ID	ID
Enuresis	2–3	Age dependent	ID
Normal Variants			
Somniloquy	6.3–17.7	Age dependent	66.80

ID, Insufficient data.

Confusional Arousals

Even though confusional arousals have been described for years, both in literature as well as in cultural viewpoints and behaviors, very few epidemiologic studies have evaluated this parasomnia.[206] Ohayon and colleagues performed a telephone-based study on 13,057 subjects older than 15 years in the United Kingdom, Germany, and Italy and found a prevalence of 2.9%, with 1.9% of subjects having confusional arousals at least once a month.[206] In the United Kingdom alone, Ohayon and colleagues reported a prevalence of 4.2% in the almost 5000 people evaluated with the Sleep-EVAL system.[205] Bjorvatn and colleagues also performed a telephone based study on 1000 adults in Norway and found a lifetime prevalence of 18.5%, current prevalence (at least once in the last 3 months) of 6.9%, and current prevalence (and occurring at least once a week) of 1.8%.[204] Although no gender difference has been reported, confusional arousals have been reported more by night and shift workers.[206] In pediatric patients, confusional arousals are sometimes confused with somniloquy by the parents, and prevalence data are not well documented.

Sleep Terrors

The prevalence of sleep terrors varies by age, ranging from 2.2% to 2.7% in adults, with a lifetime prevalence of 10% and a much higher prevalence in pediatric populations.[12,204,205] Pediatric epidemiologic reports differ based on the age of subjects studied but range from 1% to 14.7% in children aged 3 to 13 years and older to 36.9% in 18-month-olds.[12,203,207] Night terrors generally abate by age 65 years and occur in less than 1% of subjects older than 65 years.[12]

Somnambulism

Somnambulism also has varying prevalence data. Lifetime prevalence based on a telephone survey by Bjorvatn and colleagues was 22.4%, current (in the last 3 months) was 1.7%, and current (at least once a week) was 0.6%.[204] Within a European population, Ohayon and colleagues reported the prevalence of somnambulism, defined as occurring frequently and being perceived as problematic by the patient, as 2%.[205] Bixler and colleagues reported a prevalence of 2.5% in the United States in the late 1970s.[208] More recently, Ohayon and colleagues reported a lifetime prevalence of nocturnal wandering of almost 30%.[209] Hublin and colleagues reported similar prevalence data in the Finnish twin cohort of 3.9% of male adults and 3% of female adults.[210] Lifetime data for "never" was similar to other studies at 73% to 74%.[210] Compiling these larger studies of somnambulism reveals a lifetime prevalence of 25% to 30% of sleepwalking or nocturnal wandering and a current prevalence of 0.6% to 3.9%, depending on the definition of "current." In pediatrics, the prevalence rates are higher at 3.5% to 14.5%.[202,203,211] There is a clear genetic predisposition, and the same things that can precipitate and prime for confusional arousals can precipitate and prime for somnambulism. Additionally, Z-drugs (nonbenzodiazepine hypnotics) may also precipitate events.[12,210]

Sleep-Related Eating Disorder

Few epidemiologic studies have been performed on sleep-related eating disorder, although a telephone survey by Bjorvatn and colleagues reported a lifetime prevalence of 4.5%, current prevalence (in the last 3 months) of 2.2%, and current prevalence (at least once per week) of 0.4%.[204] In a self-report questionnaire, prevalence in college students was 4.6%, 8.7% in outpatients with an eating disorder, and 16.7% in inpatients with an eating disorder.[212] More studies are needed, but sleep-related eating disorder generally presents in the third decade, tends to be more common in women, and can be associated with sedative-hypnotic use.[12]

REM Parasomnias

REM parasomnias include REM sleep behavior disorder (RBD), nightmare disorder, and recurrent isolated sleep paralysis (RISP). Because REM behavior disorder and nightmares

arise from REM sleep, they most often occur in early morning hours and are associated with recall of dream content. As with other sleep disorders, the diagnostic criteria include the presence of distress related to the condition.

REM Behavior Disorder

RBD is diagnosed by the presence of repeated vocalizations or complex movements that occur during REM sleep, with documented REM sleep without atonia (RWA) on PSG.[12,213] The prevalence of RBD in the general population is estimated to be 0.38% to 2.1%.[214-216] Kang and colleagues additionally reported that the prevalence of subclinical RBD (RWA without history of sleep-related injury) is 4.95%. There is a male predominance of RBD, and it is more common in older individuals, typically with an onset older than 50 years.[217,218] The recognition of RBD is important because it can be associated with injury to the patient or bed partner.[217,218] Patients with RBD tend to have increased muscle twitches and periodic limb movements as well.[217]

There is a significant association between RBD and neurodegenerative diseases, such as Parkinson disease, dementia with Lewy bodies, multiple systems atrophy, and mild cognitive impairment.[218-222] In fact, up to 81% to 90% of those with RBD ultimately develop neurodegenerative disease, with risk increasing over time: 33.1% at 5 years, 75.7% at 10 years, and 90.9% at 14 years.[222,223] Additionally, in those who have synucleinopathy (Parkinson disease, dementia with Lewy bodies, multiple systems atrophy), there is an increased prevalence of RBD compared with the general population and those with other neurodegenerative diseases, such as tauopathies (Alzheimer disease, progressive supranuclear palsy, corticobasal degeneration).[220] In multiple systems atrophy, the prevalence of RBD is particularly high, affecting 90% to 100% of patients.[224-226] This strong association calls into question whether *idiopathic* RBD truly exists. In younger patients with onset of RBD symptoms before age 50 years, RBD is often associated with narcolepsy, and about one third of patients with narcolepsy with cataplexy have RBD.[227-230] There may be a genetic predisposition to RBD because Dauvilliers and colleagues found increased odds of having dream enactment behavior in family members of patients with confirmed idiopathic RBD.[231] In addition to chronic RBD, there can also be acute episodes that are related to medications, such as selective serotonin reuptake inhibitors, alcohol withdrawal, or drug abuse.[12] RBD has been described in the pediatric population as well, with one study reporting RBD in 32.3% of narcoleptic patients younger than 19 years.[230] Additionally, Lloyd and colleagues performed a chart review within their sleep center and found 15 children (age range, 3 to 17 years) with RBD or RWA.[232]

Nightmare Disorder

Nightmare disorder diagnosis requires repeated episodes of dysphoric, often threatening dreams that cause significant functional impairment and from which a person awakens with rapid orientation, dream content recall, and a feeling of distress.[12] The prevalence studies of nightmares are difficult to compare because some studies query "bad dreams" rather than establishing a diagnosis of nightmare disorder. Frequent nightmares that cause distress have been reported to affect 2% to 8% of the general population, although lifetime prevalence is higher.[12,153,204,233-237] In a cross-sectional study of 1000 randomly selected adults, Bjorvatn and colleagues reported the lifetime prevalence of nightmares as 66.2% (72% in women and 61% in men) and the prevalence of nightmares in the preceding 3 months as 19.4%. In addition, 2.8% of subjects reported current nightmares occurring at least once per week.[204] Most epidemiologic studies of nightmares in adults show a higher prevalence among women than men, although this gender difference does not seem apparent in children and older adults.[204,235,238] Nightmare disorder is more common among patients with psychiatric diagnoses and those who have undergone traumatic events.[235,239-241] In fact, a study by Swart and colleagues showed that 29.9% of subjects undergoing outpatient psychiatric treatment reported nightmares at least once per week that resulted in distress.[240] Nightmares can also be associated with insomnia, with a prevalence of approximately 18%.[233,242,243]

The prevalence of occasional nightmares in the pediatric population is likely higher than that among adults. In young children, a longitudinal study (with parental report at 29, 41, and 50 months of age and at 5 and 6 years of age) showed a 65% to 69% prevalence of nightmares "sometimes," whereas there was only a 1.3% to 3.9% prevalence of nightmares "often."[244] Other studies have reported prevalence up to 80.5% in children between the ages of 4 and 12 years.[245] Frequent nightmares in children can be associated with insomnia, hyperactivity, poor academic performance, and mood disturbances.[246] At the opposite end of the age spectrum, nightmares seem to decrease in frequency and prevalence with aging.[241]

Recurrent Isolated Sleep Paralysis

RISP has been described by many names within many cultural contexts, making a true epidemiologic study difficult. Most studies have evaluated small, specific populations, reporting varying prevalence estimates of 4.7% to 41%.[247,248] Ohayon and colleagues performed a larger telephone survey with the Sleep-EVAL system of 8085 subjects in Germany and Italy and reported a lifetime prevalence of 6.2%.[247] Several studies have documented the association of RISP with anxiety and panic disorder, and the association of sleep paralysis with narcolepsy is also well documented.[12,247,249] Bell and colleagues have also reported an increase in the prevalence of RISP in the African American population compared with reports of the population as a whole.[248] RISP usually presents in the second decade and is thought to affect men and women equally.[12]

Other Parasomnias

Other parasomnias include exploding head syndrome, sleep-related hallucinations, sleep enuresis, parasomnia due to a medical disorder, parasomnia due to a medication or substance, and parasomnia, unspecified. There are insufficient epidemiologic data to comment on any of these other than sleep-related hallucinations and sleep enuresis.

Sleep-Related Hallucinations

Sleep-related hallucinations are divided into hypnagogic and hypnopompic hallucinations. Using a telephone survey with the Sleep-EVAL system in the United Kingdom, Germany, and Italy, Ohayon and colleagues reported an overall prevalence of any type of hallucination at 38.7%, but when divided into subgroups, prevalence was 18% for hypnagogic and 4.9%

for hypnopompic hallucinations.[250] In this population, hallucinations were found more commonly in women and in the younger age groups.[250] In a smaller study of medical students in Spain, sleep-related hallucinations occurred with greater frequency in those with insomnia.[170] There is, of course, a well-documented higher prevalence of sleep-related hallucinations in narcolepsy.[12] More studies are needed to determine the frequency of sleep-related hallucinations in the general populations outside of Western Europe.

Sleep Enuresis

Sleep enuresis has not been extensively studied in adults, but existing data suggest a prevalence between 2% and 3%. However, nocturnal enuresis has been reported to be as low as 0.2% in a military population and as high as 6% in the United Kingdom.[251-253] It occurs with much higher frequency in pediatric patients, with prevalence estimates of 15% to 25% of 5-year-olds and decreasing with age until adulthood.[202,203] Enuresis has a strong familial component and is associated with SDB in adults and children. This disorder can result in significant psychosocial ramifications and expense.[12]

Normal Variants

Somniloquy

Somniloquy (sleeptalking) is considered a normal variant and occurs in children and adults. In a cross-sectional study in adults, Bjorvatn and colleagues reported a lifetime prevalence of 66.8%, current (occurring once in the last 3 months) of 17.7%, and current (occurring at least once a week) of 6.3%.[204] In children, the prevalence numbers are higher; for example, Laberge and colleagues report a prevalence of 55.5% in 3- to 13-year-olds.[203]

Despite the work already completed on the epidemiology of parasomnias, more is needed. Most of the previously mentioned studies have primarily been done in the Western European population or in the United States. Additionally, recall bias continues to affect epidemiology of parasomnias. Nonetheless, the presence of parasomnias is significant; in the cross-sectional study by Bjorvatn, only 9.8% of subjects did not have a parasomnia, making parasomnias prevalent indeed.

CLINICAL PEARLS

- The epidemiology of sleep medicine depends on the population studied and methodologies used.
- Sleep disorders have significant health, economic, and safety implications.
- Most people have at least one sleep disorder over their lifetime.

SUMMARY

The epidemiology of sleep medicine is a complex topic, and although many excellent studies have been published, more work is needed to define the true prevalence and incidence of each of the sleep disorders, as well as their health and societal implications. The epidemiologic outcomes differ depending on the population studied, the research methodologies employed, and the diagnostic criteria used. As the definitions of sleep disorders evolve (e.g., with the recent publication of the ICSD3), we hope that study methodology will be standardized and the burdens of the diseases of sleep medicine will be better identified, allowing for targeted treatments. This chapter summarizes the available data on this broad topic.

Chapter
63

Sleep Medicine, Public Policy, and Public Health

Raghu Pishka Upender

Chapter Highlights

- This chapter emphasizes the growing interface between sleep medicine and public health by surveying the various dimensions of sleep known to affect health outcomes. These dimensions include sleep duration, sleep timing, sleep efficiency, sleep quality, alertness, and performance.
- This chapter also surveys how the evolving knowledge of sleep physiology and sleep disorders is shaping public policy in various safety-sensitive occupations, such as the transportation and the health care industries. Brief historical backgrounds behind many of the regulations are also discussed.
- The chapter ends by discussing how the sleep medicine community can shape public policy and improve sleep health and safety by partnering with governmental regulatory agencies and industry stakeholders.

SLEEP MEDICINE AND PUBLIC HEALTH

Sleep is an essential biologic function that is thought to have evolved to help organisms cope with light and dark cycles that occur naturally on Earth. The physiologic importance of sleep is underscored by the fact that humans spend nearly one third of their lives sleeping. Although the function of sleep remains to be fully elucidated, current evidence suggests key roles in development, neurocognitive performance, mood regulation, and metabolic homeostasis. Accumulating evidence suggests that even partial sleep deprivation has far-reaching consequences on health and well-being. *Sleep health*, a term often encountered in the media, is an apt term emphasizing the strong connection between sleep and health.

Public health interest in sleep has been steadily increasing over the past two decades. This interest is driven not only by the growing knowledge of the physiologic importance of sleep but also by the recognition that sleep deprivation and sleep disorders are pervasive among the general population. In a health survey conducted by the Centers for Disease Control and Prevention in the United States, approximately 29% of U.S. adults reported sleeping less than 7 hours per night.[1] The American Institute of Medicine estimates that 50 to 70 million people have chronic sleep and wakefulness disorders.[2]

Poor sleep in its various manifestations is associated with adverse health outcomes and a huge economic burden at both the individual and societal levels. The costs of sleep loss and sleep disorders are estimated to be billions of dollars. For example, the economic burden of obstructive sleep apnea alone is estimated to be between $65 and $165 million in both direct and indirect costs related to comorbid medical conditions, hospitalization, accidents, and productivity loss.[3]

Initiatives to increase public awareness of sleep health are underway in many countries. In the United States, for example, the government-sponsored public health initiative, *Healthy People 2020,* now includes a dedicated section on sleep health to promote public awareness of the ill effects of sleep loss and sleep disorders.[4] The U.S. Army has adopted a program called *Performance Triad* that includes sleep as one of the three pillars of health and performance alongside nutrition and physical activity.[5] Through efforts like this, sleep health literacy is improving, but the chasm between knowledge and health behavior remains formidable. To fully realize the benefits of sleep, public health initiatives will need to spotlight the various dimensions of sleep—sleep duration, sleep timing, sleep efficiency, subjective sleep satisfaction, and daytime alertness—that have been associated with health outcomes.[6]

Sleep Duration

The amount of sleep required for optimal physiologic function varies across age and individuals. For example, newborns spend 16 hours or more sleeping, much of it in rapid eye movement (REM) sleep. By age 2 years, sleep duration declines to about 11 to 12 hours. School-aged children sleep about 10 hours, whereas adolescents sleep 9 to 10 hours each night.[7] Adults sleep about 8 hours per night when unfettered by lifestyle demands. Total sleep time declines with age at a rate of 10 minutes per decade, and sleep efficiency declines at a rate of 3% per decade. Components of sleep such as slow wave and REM sleep also decrease, but at different rates.[8]

Modern lifestyles with long working and commuting hours are increasingly encroaching on traditional sleep time and creating a society that is chronically sleep deprived. By some reports, average sleep duration in America has declined by 20% over the past century.[9] The advent of the electric light bulb and cheap artificial light has had dramatic effects on the 24-hour sleep-wake patterns of humans. Light exposure activates brainstem arousal systems and attenuates sleep signal by suppressing melatonin. As a result, the peak circadian wake signal that normally occurs at the end of the day is delayed and allows individuals to remain awake well into the night.[10] Early start times at school and work prevent compensatory sleep in the morning. Thus sleep duration is squeezed at both

ends. A 2010 National Health Survey found that 30% of all employed U.S. adults (40.6 million workers) reported averaging less than 6 hours sleep per night.[11] Even more alarming is the declining sleep duration of school-aged children, adolescents, and young adults. More than one fourth of high school and college students were found to be sleep deprived.[12] The 2006 *Sleep in America Poll* by the National Sleep Foundation found that sleep duration declined from 8.4 to 6.9 hours per night among 6th and 12th graders, even though physiologic sleep need does not decline significantly across this age span.[13] The problem is global as indicated by a recent systematic review, which found that sleep duration declined by 0.75 minute nightly per year and 1 hour per night over the study period of 1905 to 2008.[14]

It should be noted that not all studies have shown declining sleep duration. For example, a 2003 face-to-face interview of nearly 2000 British subjects aged 16 to 93 years found that self-reported sleep duration was not significantly different compared with sleep surveys conducted in 1969.[15,16] Another study using time use diaries from eight surveys across a 31-year period from 1975 to 2006 indicated that the odds of short sleep had not changed for part-time workers, retired workers, homemakers, or the unemployed and that the odds actually decreased for students, who represented less than 5% of the participants. Full-time workers were the only group that showed an increase in the odds ratio of short sleep of 1.19 (95% confidence interval, 1.00, 1.42; $P = .05$) over 31 years. Long work hours were much more common in those sleeping less than 6 hours, suggesting a possible cause-and-effect relationship.[17] Another study examining data from 15 countries over a period spanning between the 1960s and 2000s found that the average sleep duration of adults actually increased in seven countries: Bulgaria, Poland, Canada, France, Britain, Korea, and the Netherlands (range, 0.1 to 1.7 minutes per night each year) and had decreased in six countries: Japan, Russia, Finland, Germany, Belgium, and Austria (range, 0.1 to 0.6 minute per night each year). The findings were inconsistent in the United States and Sweden.[18,19] Some of the conflicting findings noted in these studies could be related to methodologic factors. It is important to note that most epidemiologic studies evaluating sleep duration employ subjective measures and are susceptible to recall and response bias. Subjects may confuse sleep time with time in bed. Therefore future public health surveillance of sleep practices should include more objective measures of sleep duration. Low-cost activity monitors and social networking platforms may enable collection of more objective measurement of sleep duration.

A large body of literature has linked sleep duration with health outcomes. One of the earliest associations between sleep duration and mortality risk was found in a prospective study of more than 1 million subjects who were followed for more than 2 years. Those who reported sleeping 7 hours per night had a lower death rate than those who reported either more or less sleep than this.[20] These findings were corroborated in a study of 7000 subjects in Alameda County, California who were followed for 9 years.[21] The analysis indicated that those sleeping less than 6 hours or more than 9 hours per night had 1.6 times the total age-adjusted death rate of those sleeping 7 to 8 hours per night. This U-shaped relationship between mortality rates and sleep duration has also been found in a number of studies around the world and holds true across the adult life span.[22] Studies have suggested that short sleep can lead to higher mortality rates even after controlling for comorbidities.[23] Sleep loss is likely to cause higher mortality rates through various adverse effects on physiology. Studies have found higher likelihood of hypertension,[24,25] atherosclerosis,[26] dyslipidemia,[27] and diabetes[28] in short sleepers. A number of studies in both adult and pediatric populations have shown strong associations between obesity and sleep duration, potentially mediated through alterations in hormones regulating appetite.[29] The rising rates of childhood obesity and diabetes are considered to be partly related to chronic partial sleep loss.

Sleep Timing

Traditional sleep-wake schedules are changing to meet the needs of 24/7 modern global economy. About 20 million U.S. workers (17.7% of the workforce) are estimated to work in shifts that at least partly fall outside the traditional 6 AM to 6 PM schdule.[30] As many as 4.3% of workers work primarily during the night. This trend has increased over the past 50 years with globalization of the economy. The rates of nontraditional work hours vary across industry and are the highest among protective service, food service, transportation, and health care industries. Nontraditional schedules can have significant effects on circadian processes that originated to cope with light-dark phases of the environment. The human circadian system is responsible for providing alerting signal during the light phase and sleep signal (melatonin) during the dark phase, thus optimizing sleep-wake functions. Sleep occurring during the light phase is often fragmented and short in duration because the sleep-promoting signal is absent or suboptimal. Studies have shown that night shift workers average about 30 to 60 minutes less sleep on average then daytime workers. Conversely, maintenance of alertness during the dark phase is extremely difficult for most people, especially in early morning hours when the circadian alerting signal reaches its nadir.

Adverse effects of altering the timing of sleep are readily apparent to most people traveling across time zones and are responsible for the phenomenon known as *jet lag*. Rapid travel across multiple time zones leaves circadian rhythms out of sync with the destination's light-dark cycles because circadian rhythms are slower to adapt and can only do so on an average rate of 1 hour per day. As a result, circadian signals conflict with environmental and social cues in the new location and lead to an unpleasant symptom complex that includes daytime fatigue, irritability, poor concentration, digestive problems, and excessive sleepiness and nocturnal insomnia. Less intense symptoms may be experienced by people who delay bed and wake-up time by 1 to 2 hours on weekends. The "social jet lag" could partially explain "Monday morning blues."

Circadian misalignment is a perpetual problem for shift workers because it is practically impossible for people to maintain consistent sleep-wake schedules that are out of phase with environmental light-dark cycles. Even small amounts of ambient light can drive circadian phase to shift toward the light or active phase of the rhythm. Sociologic factors force most shift workers to revert to a more traditional sleep-wake schedule on days off in order to spend time with family and friends and attend to business affairs. This creates a situation in which shift workers are always functioning and sleeping during adverse circadian phases. Ability to cope with

the physiologic challenges created by circadian misalignment varies across individuals and may be inheritable. Approximately 20% to 30% of shift workers experience what has come to be known as shift work disorder.[31] Symptoms are persistent and not dissimilar to jet lag and include fatigue, insomnia, impaired concentration, low mood, and memory. Workers experiencing shift worker disorder have higher rates of depression and anxiety and are more prone to accidents. Higher prevalence of gastric ulcers, heart disease, ischemic stroke, obesity, and metabolic syndrome has been noted in the literature. There has been recent interest in the connection between shift work and increased risk for cancers, especially breast cancer.[32] Melatonin is thought to play a role in tumor surveillance, and its suppression by nocturnal light exposure has been hypothesized as a potential mechanism of tumorigenesis in shift workers. Some recent studies have questioned whether the increased risk for cancer is real.[33,34]

Sleep Efficiency and Sleep Quality

Sleep efficiency is defined as total sleep time divided by time spent in bed trying to sleep and tends to decline with age. Although some of the decline is related to loss of gamma-aminobutyric acid-ergic neurons in the ventral preoptic area, multiple factors—medical, psychological, and sociologic—converge to compromise sleep efficiency with advancing age. It is important to recognize these factors because some are amenable to treatment.

One of the most prevalent sleep problems is insomnia, a condition characterized by difficulty with sleep onset and sleep maintenance. Chronic insomnia affects approximately 30 million Americans and causes much distress to its sufferers. A number of studies have indicated a striking association between insomnia and depression. Some postulate that insomnia may be an early marker for the onset of depression. Although the pathophysiologic relationship remains to be clarified, there may be overlap of neural pathways for anxiety, arousal, and circadian disturbance.[35] The close association of insomnia and depression also raises the tantalizing possibility that treating insomnia may prevent some cases of depression, but limited data are available.[36]

Sleep-disordered breathing is another common sleep disorder that is associated with poor sleep efficiency. The prevalence of obstructive sleep apnea (OSA), as defined by an apnea-hypopnea index greater than 5 and excessive sleepiness, is 9% in women and 24% in men in the adult population.[37] The prevalence of OSA is rising owing to the obesity epidemic and aging demography. Multiple factors are likely to be responsible for the increasing prevalence of sleep apnea in older individuals. These include age-related weight gain, reduced pharyngeal dilator tone, and decline in the sensorimotor responsiveness to hypoxia, hypercapnia, and respiratory load. The cessation of apneic and hypopneic events is often contingent on somatic or cortical arousal, and therefore sleep fragmentation is intrinsic to the pathophysiology of sleep apnea. Sleep fragmentation is very responsive to positive airway pressure therapy, which provides an opportunity to markedly improve sleep efficiency and quality.

Sleep efficiency is also reduced in patients suffering from restless legs syndrome, a neurologic condition characterized by an irresistible urge to move the legs and nocturnal limb movements that affects approximately 5% of the general population.[38]

A number of studies have shown an association between sleep efficiency, subjective sleep quality, and various health outcomes.[6] For example, a Japanese population-based cohort study of self-reported sleep parameters found that woman who reported poor awakening state experienced a higher mortality rate (relative risk, 1.97) compared with those who awakened normally.[39]

Alertness and Performance

The value of sleep for most individuals is its ability to restore alertness and improve performance during the waking period. When sleep is suboptimal, people feel non-restored and experience a number of neurocognitive deficits that include poor memory, decreased concentration, slowed reaction times, and impaired judgment. Elegant studies using psychomotor vigilance tests have shown dose-dependent slowing of response times with increasing sleep restriction.[40] Mean number of lapses on psychomotor vigilance tests increased with increasing sleep restriction. Performance precipitously dropped with sleep durations of less than 5 hours per night. Several nights of recovery sleep were required for performance to be restored to baseline levels.

Beyond their effects on daytime performance, decreased levels of alertness during the day have been linked to poor health. In a study of 5888 individuals, daytime sleepiness was the only sleep disturbance symptom that was associated with mortality, cardiovascular disease, and congestive heart failure.[41] These associations persisted in women after adjustment for age and other factors. In another study of community dwelling older adults (>65 years old), mortality rate was accelerated by 1.73 times in those who napped most of the time and made two or more errors on cognitive tests.[42]

The importance of alertness and performance is nowhere more relevant than it is in occupational safety. The next section describes the interconnectedness of alertness and performance with fatigue and the evolving public policies that aim to mitigate fatigue risk in safety-sensitive industries.

SLEEP MEDICINE AND PUBLIC POLICY

Fatigue related to work demands has long been recognized as a factor contributing to accidents, especially in industries that operate 24/7. With globalization of the economy in the past century, the number of industries and workers operating around the clock has increased. Commensurately, fatigue-related accidents have become more common and have created a greater threat to the environment and public safety. For example, the Three Mile Island nuclear reactor disaster of 1979 resulted from coalescence of human error and mechanical factors that allowed a large amount of nuclear reactor coolant to escape into the environment. Fatigue was implicated in the accident, not surprisingly because the accident occurred at 4 AM. Another fatigue-related accident occurred in 1989 when the oil tanker Exxon Valdez struck a reef off the coast of Alaska and spilled 11 to 32 million gallons of crude oil. It was at the time the largest and most devastating human-caused environmental disaster. Although multiple factors played a role in the accident, crew fatigue was identified as a major factor. Investigators found the crew to be understaffed and overworked. Fatigue has also been implicated in the Chernobyl nuclear and Challenger space shuttle disasters. Other examples of preventable fatigue-related accidents abound in the transportation,

health care, and emergency response industries. In response to these accidents, a variety of governmental regulations have been established in the interest of promoting public safety. Brief histories of these regulations in the transportation and health care industries are discussed next.

Transportation Industry

Railroad

At the end of nineteenth century after a period of dramatic expansion of railroads in America, it became apparent that train accidents, including those related to worker fatigue, were resulting in unacceptable loss of life and economic damages. Railroad workers were permitted and in many cases required to work extremely long hours, especially during harvest time. There was a public outcry for more regulatory oversight, which led to the first public policy attempting to address fatigue-related accidents, the "Hours of Service Act of 1907" (45 USC Sect. 61; 1907). The law as originally adopted prevented workers from working more than 16 consecutive hours in a 24-hour period. The act also established a minimum of 10 consecutive hours of rest after a 16-hour shift, and a minimum of 8 hours of rest after an aggregate of 16 hours of work in a 24-hour period. Although it is difficult to assess the direct impact of the law owing to poor reporting standards, the available data indicate reductions in injuries and fatalities during the 10 years following the enactment of the law despite a rise in passenger and freight traffic.[43] The law was subsequently changed to allow only 14 hours in 1969, and 12 hours in 1971. In response to several fatal rail accidents in 2002 and 2008, Congress passed the Rail Safety Improvement Act of 2008, which enabled the Federal Railroad Administration (FRA), a member of the U.S. Department of Transportation (USDOT), to promulgate new safety regulations governing different areas related to railroad safety, including hours of service requirements. This law provides statutory limits on the total on-duty and "limbo" time (time spent traveling to duty assignment) for rail and signal employees to 276 hours per month; limits total allowable shift time for employees to 12 consecutive hours; increases uninterrupted off-duty hours from 8 to 10 hours in a 24-hour period; requires 2 consecutive days off after 6 consecutive days worked and 3 consecutive days off after 7 consecutive days worked; and reduces allowable limbo time to 30 hours per month.[44] It is important to note that of all transport modes regulated by USDOT, railroad hours-of-service standards are the only ones locked into statute rather than being adjustable by administrative regulations.

Aviation

Pilot fatigue has long been recognized as a factor contributing to pilot error that could exacerbate the dangers inherent to flying an aircraft. In 1931, the U.S. Commerce Department set a monthly flight-time limit of 110 hours as a compromise between the 140 hours wanted by airline operators and the 85 hours advocated by the Airline Pilot Association. In 1938, the Civil Aeronautic Board issued domestic flight-time rules, limiting flight time to 8 hours in a 24-hour period.[45] These flight-time and duty hour regulations have evolved over the years, driven by public safety concerns, widely publicized airplane crashes, and evolving understanding of human fatigue in operational environment. The Federal Aviation Administration (FAA), the U.S. regulatory body overseeing aviation safety, completed a major overhaul of regulations in 2011. Key components of the 2011 rules include varying flight and duty requirements based on what time the pilot's day begins. Flight duty period limits range from 9 to 14 hours for a pilot depending on when the pilot's day begins and the number of flight segments he or she is expected to fly. Flight time is limited to 8 to 9 hours depending on the start time of pilot's entire flight duty period. Pilots are required to have a 10-hour minimum rest period that includes 8 hours of uninterrupted sleep opportunity before the flight duty period, an increase of 2 hours of rest over the previous rules. To address cumulative fatigue, the 2011 rule includes weekly, monthly, and annual limits of flight and duty hours. For example, pilots are required to have 30 consecutive hours off every week. Pilots and airlines are expected to take joint responsibility when considering a pilot's fitness for duty, including fatigue resulting from preduty activities such as commuting. Pilots are required to affirmatively state their fitness for duty, and the airlines are required to remove a pilot from duty when he or she is fatigued or unfit to fly.[46] Airlines are also required to implement a comprehensive fatigue risk management plan. The 2011 rules only apply to passenger pilots and exclude pilots who fly only cargo, even though they fly the same types of aircrafts on the same routes and are susceptible to the same levels of fatigue.

Trucking

As in other transportation modalities, concerns about unsafe commercial driver scheduling practices led to governmental regulations in the United States in the mid-1930s. The first scientific study addressing driver fatigue was conducted in 1938 by the U.S. Public Health Service and supported the need for regulatory limits on hours of service (HOS) to ensure highway safety.

In 1989, the USDOT sponsored a field study, the Driver Fatigue and Alertness Study, to determine the relationships among HOS regulations, driver fatigue, and frequency of serious accidents involving commercial motor vehicles. The study was completed in 1996 and found that time of day was the strongest and most consistent factor influencing driver fatigue and alertness. Drowsiness as determined by video recording of drivers' faces was markedly greater during night driving than during daytime driving. Time of day was a much better predictor of decreased driving performance than hours of driving (*time on task*) or the cumulative number of trips made. The study also found that drivers spent an average of 5.2 hours in bed, which is about 2 hours less time than their reported "ideal" daily amount of sleep. Drivers with night start time spent the least time in bed, about 4.4 hours. Not surprisingly, there was a negative correlation between the length of the principal sleep period and amount of drowsiness during the next driving trip; that is, more sleep was associated with less drowsiness. There was a tendency for drivers to rate themselves as more alert than the performance tests indicated.[47]

Analysis of crash data has revealed that crash risk is statistically similar for the first 6 hours of driving and then increases nonlinearly after 6 hours. The 11th hour has a crash risk more than three times greater than the first hour. Multiday driving schedules are also associated with statistically significant increases in crash risk, comparable in magnitude to driving time.[48]

The previously referenced study and other similar studies have led to modern hours of service regulations that at least

attempt to consider for human circadian physiology. The 2011 Federal Motor Carrier Safety Administration (FMCA) regulations, for example, incorporate a rest period of at least 34 consecutive hours that include two periods between 1 AM and 5 AM, the window of circadian trough. This provision gives drivers who routinely work nights and put in very long workweeks an opportunity to overcome the chronic fatigue that can build up when working nights. In addition, the regulations reduced the maximal workweek from 82 to 70 hours. Previous HOS rules that include an 11-hour driving limit with a mandatory 30-minute break in a 14-hour driving window every 24 hours were maintained.

Marine

Fatigue is a major concern in the marine transport industry, and its operational challenges are unlike those found in other modes of transportation. Crewmembers spend extended time away from home, often working as many as 3 to 6 months at a time in the open seas. They often work under harsh conditions on moving vessels that are subject to unpredictable weather. The absence of clear separation between work and recreation contributes to increased levels of stress, especially when working with shipmates from different countries. Cramped quarters, environmental noise, vibration, heat, and bad weather compromise sleep quality.[49] Twenty-four-hour operations constrain sleep duration and require some crew members to sleep during the adverse phase of their circadian rhythm. These factors contribute to levels of fatigue that are much greater than those seen in other industries.[50] A study relating fatigue to marine casualties found that 33% of personnel injuries and 16% of critical vessel casualties had crew fatigue as a causal or contributing factor.[51]

The first set of international standards for minimum competence and safety for seafarers was drafted in 1978 by the International Marine Organization, an agency of the United Nations. The resulting Standards of Training, Certification, and Watchkeeping for Seafarers (STCW) included a weekly rest hour minimum that was subsequently increased to the current 77 hours of rest per week. In the United States, the Coast Guard regulates inland ("brown water") and coastal ("blue water") waterway operations and sets minimal hours of rest regulations based on STCW. Currently, a minimum of 10 hours per 24-hour period and 77 hours per 7-day period of rest are required. Rest hours can be divided into no more than two periods in any 24-hour period, and one of the periods must be at least 6 hours in length.[52] The inland waterway industry has adopted a square watch consisting of a 6-hour watch period alternating with 6-hour rest period such that each crew member observes two watch and two rest periods per 24 hours. Although this arrangement limits shift length and thus mitigates time-on-task related fatigue risk, it necessitates some crewmembers to work and sleep in the adverse circadian phase. For example, crews working the second watch typically work from midnight to 6 AM and then again from noon to 6 PM. Both of these work periods include circadian temperature minimums that can be associated with increased sleepiness, especially in sedentary work environments such as the wheelhouse. The U.S. Coast Guard has developed the Crews Endurance Management Systems (CEMS), a set of tools and practices to help maritime operators manage their productivity and safety levels in their work environment.[53] CEMS outlines a number of strategies to mitigate fatigue risk, including the use of artificial light to shift the circadian temperature trough into off-duty period. Sleep quarter improvements (noise and light abatement), sleep hygiene, exercise, nutrition, and stress management are also emphasized in the CEMS manual. Although the strategies outlined in CEMS are laudable because they address fatigue risks in a more comprehensive manner than duty and rest hour regulations, the true effect of such efforts on sleep health and operational safety remains to be determined.

Other fatigue risk management systems employ mathematical models that attempt to predict the risk for fatigue-related accidents based on factors known to influence alertness and performance[54] (see also Chapter 73). These factors include homeostatic sleep drive, circadian variations in alertness, wake inertia, task type, and time on task. These models have the potential to identify at-risk individuals so that corrective measures can be undertaken. Although these novel approaches improve current duty hour limitations, caution must be exercised when implementing them in the operational environment. For fatigue models to be applicable, the fatigue scores derived from such modeling must have sufficient positive and negative predictive values for a given operational setting. In other words, the fatigue score must be accurate enough to help management decide which individual should or should not work. Low accuracy models that falsely indicate high fatigue have the potential to disrupt operations and infringe on labor's income and are unlikely to be successfully implemented. Furthermore, many of the available models do not yet incorporate individual differences in susceptibility to fatigue.

Health Care

The care of the sick necessitates around-the-clock operations whereby continuity of care is paramount. Work shifts tend to be long and thus increase the risk for fatigue-related accidents. This problem is in no place more acute than in the training of physicians and surgeons. In the early year of modern medicine, physician education included brief periods of intense training during which "resident" physicians cared for patients 24 hours a day, 7 days a week. By the latter half of twentieth century, "residencies" became multiyear experiences that incorporated new learning modalities.[55] Duty hours remained long and were thought to be critical to physician training. By the 1970s, congruent with accumulating evidence on the effects of sleep deprivation, it became apparent that postcall residents made more errors.[56] As early as the 1980s, some internal medicine and pediatric training programs attempted to balance service and educational needs with personal needs of the residents. The 1984 medication error by residents working 36 hours under insufficient supervision caused the death of Libby Zion in New York and sparked a national debate that continues to this day. It took nearly three decades to arrive at current resident duty hours as promulgated by the Accreditation Council for Graduate Medical Education. The 2011 standards eliminate overnight call responsibilities for first-year residents by limiting the maximal duty period to 16 hours per 24-hour period and 80 hours per 7-day period. One off-duty day per 7 days is also stipulated in the new standards.

A number of studies have looked at error rates before and after implementation of changes in resident duty hours. A 2004 study compared the traditional resident work schedules (>24-hour shifts and long workweeks) with newer schedules

(shorter, <24-hour shifts and fewer weekly work hours). Interns made 35.9% more serious medical errors during the traditional schedule than during the modified schedule (136.0 vs. 100.1 per 1000 patient-days; $P < .001$), including 56.6% more non-intercepted serious errors ($P < .001$). Interns also made 5.6 times more serious diagnostic errors during the traditional schedule as during the intervention schedule (18.6 vs. 3.3 per 1000 patient-days; $P < .001$).[57]

Resident duty hour limits are not without unintended adverse effects. Some studies have argued that the increased number of handoffs necessitated by duty hour limits disrupts continuity of care and leads to delayed diagnoses, lengthier hospital stays, and increased number of preventable complications.[58] Training programs remain concerned that trainees may not gain adequate exposure to case mix and leave the already protracted years of postgraduate training with insufficient experience. Ultimately, new training models will have to address these concerns while balancing the educational, health, and safety needs of residents.

Hazardous Workplace

In addition to the industries discussed earlier, there are a large number of occupations that operate around the clock and have the potential to affect public safety and health. Workers in these occupations include firefighters, paramedics, police, disaster recovery workers, military personnel, utilities operators, and operators of plants producing hazardous or toxic chemicals. Examples of fatigue-related accidents leading to loss of life, environmental disaster, and economic damages are abundant. The 1986 Space Shuttle Challenger disaster occurred partly because of a sequence of ill-fated decisions made by sleep-deprived individuals. The legacy of the environmental damage caused by the grounding of Exxon Valdez in 1989 by overworked and understaffed crew can still be felt today in Prince William Sound, Alaska.

ROLE OF SLEEP MEDICINE COMMUNITY

Progress in recognizing fatigue as an important factor for health and safety is evident in a number of industries, as described previously. However, much work remains to be done. Sleep clinicians, scientists, and advocates play an important role in socializing the evolving fund of knowledge in sleep medicine and science. In addition to raising awareness and educating the public about sleep's role in health and safety, sleep professionals need to play an active role in developing and promoting industry-specific regulations and best practices that mitigate fatigue-related accidents. These fatigue countermeasures have to be practical and must address operational and economic needs of the stakeholders while promoting health and safety.

Before advocating a policy that has the potential for disrupting an industry, sleep professionals must gain reasonable understanding of the operational constraints of a given industry. For example, the inland waterway industry has long adopted a split sleep schedule whereby work and rest periods alternate every 6 hours in what has become known as *square shift*. On the front watch, a pilot operates the boat from 6 AM to noon and then again from 6 PM to midnight. On the back watch, another pilot operates the boat from noon to 6 PM and again from midnight to 6 AM. This schedule allows two pilots to operate a towboat around the clock with neither of them enduring fatigue-inducing 12-hour shifts. The downside to this schedule is that it limits sleep opportunities to short intervals and requires some crewmembers to sleep during the adverse phase of the circadian rhythms. Based on what is currently known about human sleep physiology, this type of work and rest schedule is expected to cause chronic sleep deprivation, performance deficits, and greater risk for accidents. A policy that argues for a longer rest periods without understanding the economic forces that shape the current square-shift practice will bring strong resistance from the industry stakeholders, especially when unequivocal evidence linking the current work-rest schedule with operational safety risk is lacking. Profit margins in the transportation industry are often thin, and employing an additional pilot to expand the rest periods can render the barge industry unable to compete with other modes of transportation.

Sleep professionals are more likely to be successful in bringing about meaningful changes within an industry when they partner with industry advocates. American Waterways Organization and industry leaders have supported fatigue research to clarify the effect of square shift on crew members' sleep quality and duration.[59] Preliminary findings indicate that both front watch and back wheelhouse crew report similar time in bed and sleep duration. One of the sleep periods is longer and is described as anchor sleep, whereas the second shorter sleep period is described as a nap. When the sleep periods are combined, the total sleep duration is same on the boat as at home. Pilots slept on average 6.6 hours even though they were in bed for about 8.1 hours (sleep efficiency, 81.4%). Sleep quality on the other hand is worse for back watch crew, possibly because their sleep periods (6 AM to noon and 6 PM to midnight) occur during adverse circadian phases. Policies that aim to improve sleep efficiency and sleep quality are more likely to be accepted by waterway operators and ultimately reduce fatigue risk in the industry than policies that mandate changes to long observed scheduling practices.

Sleep advocates can also help shape policies that affect public health and workplace safety by engaging governmental regulatory agencies. Familiarity with these agencies and the industries they administer is required to effectively navigate a complex regulatory ecosystem that has various stakeholders vying to promote their own interests. In the United States, the National Transport Safety Board (NTSB) is responsible for investigating major accidents in all modes of transportation and making safety recommendations; however, it lacks the authority to enforce them. The USDOT and its member agencies (i.e., the FAA, FRA, FMCA, and Pipeline and Hazardous Materials Safety Administration) are responsible for creating and enforcing regulations that govern their respective industries.

The regulatory agencies must consider economic impact, cost-benefit analysis, and industry input when formulating new regulations or policy changes. They are often subject to political pressures. To give an example, in late 2013, the FAA decided to modify rules governing untreated OSA, a disqualifying condition for airmen and traffic controllers when untreated. The proposed modification further mandated that all airmen with a body mass index greater than 40 be evaluated by a board-certified sleep specialist and treated for OSA in order to be medically certified. The policy modification also indicated that the body mass index threshold will be gradually lowered until every airman with OSA is treated."[60] Reaction

from industry was swift. In a letter to the FAA, the Aircraft Owners and Pilots Association argued that the "policy inappropriately bypasses the rulemaking process; overlooks potentially more effective and efficient solutions; provides no clear safety benefit; and imposes unjustified costs on the user community.… In 2011 the FAA identified 124,973 airmen who are considered obese, making them potential candidates for testing under an expanded policy … the potential cost to pilots is between $99 million and $374 million for testing alone."[61] As a result of effective lobbying efforts, Congress took action within a matter of days of learning of the FAA's intent and released legislation that would require the FAA to go through the rulemaking process before making policy changes on sleep apnea. The rulemaking process is a public forum through which industry can influence policymaking. The revised guidelines related to OSA require "aviation medical examiners to consider all of the OSA risk factors and make a recommendation regarding an OSA evaluation." Airmen are allowed to see any physician whether or not they are qualified to diagnose and treat OSA. "Evaluations do not require a laboratory sleep study or even a home study if the certifying physician does not feel the pilot requires it."[62] This modification clearly dilutes the intent of the initial policy modification. Without formal sleep testing and clearly defined screening criteria, at-risk pilots may go undiagnosed and untreated by inadequately qualified physicians. Furthermore, financial burden and regulatory scrutiny combine to disincentivize patients and nonsleep specialists to underestimate symptoms, signs, and the full impact of sleep disorders. This example is typical of how a well-intended policy that promotes sleep health and safety becomes less effective because of socioeconomic factors. It is difficult to create policies that may be perceived as an undue burden on individuals when it affects their right to earn their livelihood, especially in an industry like aviation, for which the safety record is strong.

Sleep advocates can help empower industry stakeholders to implement sleep science–based fatigue risk management programs. Even profit-motivated corporations will embrace health and safety promoting measures when those measures make economic sense. Berger and colleagues, with the support of Schneider National Incorporated (SNI), created a sleep apnea diagnosis and treatment program that eliminated or lowered many of the barriers to treating sleep apnea.[63] Education about sleep apnea was provided through multiple channels to increase awareness and reduce driver anxiety and misconceptions about the condition. Occupational health professionals, safety officers, and training engineers were trained to monitor for symptoms of sleep apnea. Drivers referred to the program incurred no out-of-pocket expenses, thus eliminating one of the major financial obstacles. Evaluations were performed at locations near major SNI operating centers and allowed for a 2-day turnaround from diagnosis to treatment of apnea, thus minimizing scheduling constraints and time away from work. SNI also explicitly identified what documentation is required of their contracted USDOT physicians to ensure uniform high-standard reporting. Among 348 drivers diagnosed with sleep-disordered breathing and who were treated, medical costs and accident rates declined by 57.8% and 73%, respectively. The driver retention rate of continuous positive airway pressure (CPAP)-treated individuals was 2.29 times greater than the total company driver population.[63]

Success of the SNI sleep apnea program has encouraged other transportation companies to pursue similar programs. To realize the full health and safety benefits, however, programs need to go beyond screening and treating sleep apnea in order to ensure long-term patient engagement and CPAP adherence. A major challenge to the development of such comprehensive sleep apnea monitoring programs is providing care to a geographically distributed workforce. A small study involving towboat wheelhouse crew members showed that centralized care coordination, remote adherence monitoring, and telemedicine tools can provide sleep apnea care that is acceptable to patients and achieves high CPAP adherence rates.[64]

The most important aspect of any fatigue management program is the presence of a corporate safety culture that puts the safety of the employee and the public ahead of corporate profits. Sleep professionals can play an important role in promoting such culture by engaging and educating industry leaders, governmental agencies, and the public at large. They can draw inspiration from past successful public health campaigns that brought about meaningful behavioral changes and societal benefits. Efforts of Ignaz Semmelweiss and those that followed helped establish hand washing practices that have saved countless number of lives and much suffering over the past 150 years. The many lives saved by reductions in cigarette smoking and widespread use of seatbelts would not have occurred were it not for the efforts of pulmonologists and emergency medicine physicians. Similarly, sleep medicine has an immense potential to improve public health and safety, especially because sleepiness and sleep disorders have far-reaching influences on health and safety.

CLINICAL PEARL

Sleep medicine has the potential to have an immense positive influence on the public because of the many ways in which sleep and sleep loss affect public health and safety. The promise of sleep medicine will only be realized when there is greater awareness of the importance of sleep. Sleep professionals are in a unique position to increase this awareness through education and advocacy. Sleep professionals have many opportunities to help transform sleep science knowledge to practical solutions that improve public health and safety through partnership with industry and governmental agencies.

SUMMARY

Sleep is an essential biologic function whose physiologic importance has become clear only in the past several decades. Despite this growing knowledge and awareness of sleep's role in health, insufficient sleep is all too common in the modern world. The American Institute of Medicine estimates that 50 to 70 million people suffer from chronic sleep loss. Many factors are driving this worrisome trend toward short sleep. Economic forces that drive long work hours, long commute times, and ever-expanding 24/7 operations commingle with modern lifestyles that overconsume digital entertainment and social media to create a culture that champions "work hard and play hard" and leaves little room for sleep. The availability of inexpensive artificial light has had a dramatic effect on the

natural 24-hour sleep-wake patterns in humans. Light exposure interferes with circadian rhythms by delaying the normally occurring peak alertness and allows people to extend wake activities well into the night at the expense of sleep. Early start times common to many occupations necessitate early arousal, and hence the sleep duration is squeezed at both ends of the sleep period. It is estimated that 30% of all employed U.S. adults (40.6 million workers) average less than 6 hours sleep per night. The sleep deficiency is not unique to employed adults. Sleep trends in school-aged children and adolescents indicate a decrease in sleep time of more than 1 hour over the past 100 years. Insufficient sleep has been associated with a number of chronic medical conditions, such as hypertension, diabetes, and cardiovascular disease, as well as all-cause mortality. When sleep disorders are weighed in, the resulting sleep loss is probably the single most important public health issue of our time. This chapter describes current trends in sleep practices across the age spectrum; their potential effect on health, performance, and public safety; and the role sleep professionals can play in promoting sleep health and public safety.

Chapter
64

Sleep and Athletic Performance

Scott J. Kutscher

Chapter Highlights

- Sleep is increasingly being recognized as part of the foundation of optimal athletic performance. Sleep influences on athletic performance include circadian and homeostatic factors.
- Sleep disorders may affect the performance and health of athletes. Although specialized populations of athletes may be at increased risk for certain sleep disorders, exercise itself may be therapeutic for a variety of sleep disorders.
- Rest is a vital component of recovery from training and competition, whereas improper rest may hasten fatigue and predispose to injury.
- Properly managing sleep and identifying problem sleepers and potential sleep disorders requires cooperation of a multidisciplinary team of athletes, coaches, trainers, and physicians. Scheduling of multiple factors, including travel and practice, need to be addressed for optimizing sleep in the athlete.

SLEEP AND ATHLETIC PERFORMANCE

Sleep is increasingly regarded as a major contributor in variation of athletic performance, with emerging evidence suggesting a strong and often intertwined influence of both circadian and homeostatic factors, outlined in Figure 64-1.

Circadian Variations in Performance

Twenty-four-hour variation has been demonstrated in a wide array of athletic performance measures. Peak performance correlates well to variations in core body temperature, with highest results occurring close to the maximal body temperature (Tmax), and poorer performance near the body temperature trough (Tmin). Physiologic studies have confirmed a time of day effect, with peak output typically occurring in the evening (16:00 to 18:00) for isometric power output of leg and back muscles.[1-4] Similar evening preference has been substantiated in elbow flexor muscles.[5,6] There is an evening increase in VO_2max during aerobic energy production,[7] as well as during anaerobic exercises such as stair running and broad jump.[8]

Of course, demonstrating clinical significance of these effects is important if one is to consider a therapeutic intervention. For athletic performance, the most obvious place to look is the place athletes and fans turn to in order to measure results: the scoreboard. To this effect, multiple attempts have been made to establish clinical significance of circadian performance variations.

Major League Baseball (MLB) has been closely studied in this regard, perhaps owing to the frequency and set-up of games. With the same teams typically playing a series of consecutive games, each team serves as its own control. In an evaluation of matchups between teams on the East and West coasts, home teams were found to be at an advantage after cross-country eastward flights and during day games,[9] suggesting effect of both travel and time of day. Another study evaluating 10 years of MLB games demonstrated that the team with a circadian advantage (i.e., the team that did not have to travel across one or more time zones) had a higher winning percentage (52%); and at a 3-hour time zone difference, this actually outperformed winning percentage based on home field advantage alone (60.6% vs. 53.7%)[10]—indicating a team can be at a disadvantage playing at their own stadium, if they had to travel across the country to be there.

The same effect seems to appear in professional football, despite the fact that teams only play one game per week, indicating that circadian effect over effects of fatigue and travel are at play. Through 40 years' worth of games between teams on the East and West coasts, a distinct pattern emerges, with even winning percentages when compared against the point spread in games starting before 8 PM (49% winning percentage for West Coast teams vs. East Coast teams). However, after 8 PM, West Coast teams have a distinct advantage, outperforming the point spread in a significant majority (66%) of games.[11] These findings suggest a circadian advantage for these teams, aligned with their peaks in circadian performance, and bring the obligatory disclaimer that gambling on professional sports is illegal in most places, including the location of this author's residence.

Sleep Deprivation

Another aspect to consider is the effect of sleep deprivation on performance. Studies of acute total sleep deprivation have shown mixed results—with little change in muscle strength and endurance noted even after 60 hours of total sleep deprivation.[12] Sleep deprivation of 24 hours did not demonstrate a significant difference in performance of weight lifters, despite an increase in subjective sleepiness and mood symptoms.[13] Other efforts contradict these studies, demonstrating decrease in maximal bench press,[14] distance covered on self-paced treadmill run,[15] and time to exhaustion on stationary cycling test,[16] after periods of acute sleep deprivation. These tests are

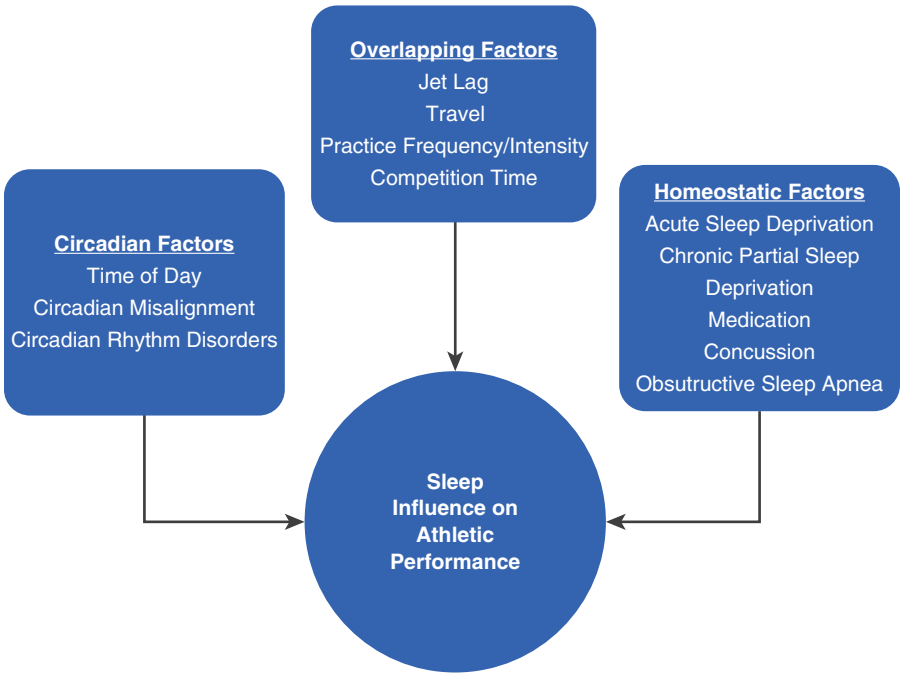

Figure 64-1 The interplay of circadian, homeostatic, and overlapping factors influencing athletic performance.

routinely limited by small sample sizes, and differences in results may simply be attributable to a high rate of individual variability in sensitivity to sleep deprivation.[17]

Of greater clinical concern—assuming athletes are not intentionally sleep depriving themselves for 60 hours—is the role of chronic partial sleep deprivation. Athletes with demanding schedules that include travel, practice, and variable game times may be particularly susceptible to a state of chronic partial sleep deprivation, to say nothing of amateur athletes who may have additional obligations of work or school. This state of insufficient sleep has been confirmed in elite swimmers, who demonstrated significantly less time in bed and time asleep on nights before training days than nights before rest days.[18] As mentioned later in the chapter and also elsewhere in this text, insufficient sleep has its own set of sequelae on health and daytime functioning (see Chapter 5).

Studies that evaluate strength and stamina in a controlled setting are, by definition, removing some of the aspects of athletics, such as judgment, reaction time, and sustained vigilance, that may be particularly susceptible to the effects of chronic sleep deprivation. Batters in MLB, for whom attention and reaction time are vital to success, have been shown to have steadily declining plate discipline during the course of a season. This is despite of potential improvement because of practice and repetition, and this erosion of the ability to tell balls from strikes may indicate a fatigue effect.[19] A study of men's professional basketball further supports this idea, demonstrating significant improvement in team performance with increasing number of rest days between games, with peak performance occurring with 3 days off between games.[20]

Another way of considering sleep deprivation is to measure the effects of sleep extension. One study of male collegiate basketball players examined performance on metrics such as sprint time and shooting accuracy and found a significant improvement after a 5- to 7-week period of sleep extension to 10 hours, compared with each athlete's own baseline sleep.[21]

Finding time for such sleep extension over so many weeks can be difficult for *any* individual. When taken as a whole, studies to date suggest sleep deprivation may have an insidious effect on performance that can be difficult to overcome without clear planning.

SLEEP DISORDERS

Having established a relationship between performance and sleep, it is also important to remember that athletic performance may be acutely sensitive to sleep disorders. Although some athletes, as summarized in Table 64-1, may be considered at higher risk for certain disorders, exercise itself may be therapeutic for others.

Obstructive Sleep Apnea

This author has had a patient—a former professional wrestler—relate anecdotally that he found larger wrestlers would lose consciousness faster when subjected to a chokehold, that is, external pressure to constrict the airway. Although our Independent Review Board might raise some concerns if we tried to confirm his theory with a controlled trial, it certainly is in line with much of what we know about the risk factors contributing to airway narrowing and upper airway collapse.

With elevated body mass index (BMI) and enlarged neck circumference each contributing to obstructive sleep apnea (OSA), it stands to reason that athletes for whom largeness is a performance advantage may be at higher risk for developing OSA. This cohort would include athletes such as linemen in football, weight lifters, sumo wrestlers, and, yes, professional wrestlers.

Unfortunately, population studies in these specialized groups are largely lacking. One study of active professional football players found OSA (apnea-hypopnea index [AHI] ≥10) in 14 of 52 subjects tested by polysomnography. Most

Table 64-1 Suggested Risks of Sleep Disorders Specific to Athlete Populations

Insomnia and Poor Sleep Quality
- Elevated scores on the Pittsburgh Sleep Quality Index
- Excessive worry preceding competition
- Injuries, pain, medications
- Acute concussion, postconcussive syndrome

Hypersomnia and Excessive Daytime Sleepiness
- Insufficient sleep due to schedule demands
- Injuries, pain, medications
- Acute concussion, postconcussive syndrome

Obstructive Sleep Apnea
- Elevated body mass index ≥40 in specialized sport populations
  - Sustained or increased concern in retired athletes
- Concussion

Restless Legs Syndrome
- Training or competition in long distance running
  - Should be carefully differentiated from cramping or other mimics of restless legs syndrome

Circadian Rhythm Disorders
- Advanced sleep phase suggested by early morning preference on Morningness-Eveningness Questionnaire
- Shift work characterized by early, late, or variable competition start times

of these positive cases were offensive and defensive linemen, with elevated BMI higher than 40 being the most significant driver of risk.[22] A larger study of 137 active National Football League (NFL) players using only unattended nasal pressure transducer found that 19% had a respiratory disturbance index of 5 or higher, but only 4.4% had a respiratory disturbance index of 15 or higher.[23]

The seeming driver for the focus on sleep apnea in football players is a 1994 study by the Centers for Disease Control and Prevention that found retired NFL linemen had a 52% higher rate of cardiovascular mortality than the general population and were three times more likely than other position players to die of heart disease.[24] Indeed, the only study of OSA in retired NFL players confirmed this discrepancy, with linemen being more likely to have an AHI of 10 or greater (61% vs. 46%) and obesity (83% vs. 52%) than other position players.[25]

Besides the obvious long-term health risks, there remains the question of whether OSA has an influence on performance. One study attempting to answer this question found that amateur golfers with a diagnosis of OSA (AHI ≥15) could improve their handicaps after continuous positive airway pressure therapy,[26] a finding that may do more to motivate excellent continuous positive airway pressure compliance than any other single intervention. There is also the question of whether exercise itself has an effect on OSA. To this end, a randomized control trial of sedentary adults found that a 12-week exercise regimen significantly lowered AHI compared with stretching, without a similar significant change in BMI to otherwise explain this reduction.[27]

Despite the potential for higher incidences of OSA and cardiovascular disease among certain populations of active and retired athletes, as well as theoretical limitations to performance, outreach and awareness remain barriers to care. Although attempts have been made to provide educational resources for the NFL,[28] no such global outreach has been attempted for other sports, either amateur or professional. Overall diagnosis and treatment rates remain unknown, a fact that larger epidemiologic studies could ameliorate.

Circadian Rhythm Disorders

Given the circadian variation of athletic performance, it is possible that one can be at an advantage or disadvantage depending on how one's own circadian rhythms align with practice and competition time. This is especially true in the major professional leagues, where the financial incentives of television often dictate game times. Given the potential for high variability of game times in some sports, one may reasonably classify some athletes as shift workers.

Few studies address individual circadian variability, which remains largely theoretical. Some effect has been demonstrated in MLB players. Those who scored as advanced on a Morningness-Eveningness Questionnaire (MEQ) had higher batting averages during day games before 2 PM (0.267 vs. 0.259), but the higher average shifted to players with a delayed-type circadian rhythm during evening games (0.261 vs. 0.252).[29] Somewhat counterintuitively, one survey of elite adolescent athletes revealed a preponderance of morning-type circadian rhythms,[30] although it is unclear whether these athletes are truly phase advanced or whether they simply grow accustomed to the early wake-up and practice times often required of elite athletes and adjust their answers accordingly.

Although jet lag is not always directly mentioned, it should be considered a potential confounder of performance in any athlete who has to travel across multiple time zones to compete. Training performance can be affected by eastward or westward travel, and effects can be seen after traveling across as few as two time zones.[31] Performance decrement may be worse after westward travel; however, it has been found to recover to baseline before full reentrainment after flights crossing up to 8 hours.[32]

It is unclear whether studies of travel on, for example, Australian netball players, are generalizable to a population other than Australian netball players. There may be little to no effect in performance demonstrated, even after 4 to 6 hours of transmeridian travel.[33,34] Although circadian studies of performance often site travel, true circadian effect directly attributable to jet lag can be difficult to isolate from confounders like perception of jet lag symptoms, decrements in cortisol level, distance traveled, sleep deprivation, and mood.[35]

On the other hand, with the chronobiotic effect of exercise, typically manifesting as a phase delay when administered in the early evening,[36] it may be considered therapeutic for jet lag. Although these studies, in general, are limited by numerous confounding variables, exercise has been shown to accelerate reentrainment to an advanced circadian rhythm after forced desynchronization under isolation and constant dim light.[37]

Restless Legs Syndrome

Despite the fact that restless legs syndrome (RLS) is a disorder of movement, there is precious little knowledge on its relationship to athletic performance. The suspected pathway

of dopamine dysfunction may implicate motor systems under control of the basal ganglia, such as in Parkinson disease. However, RLS subjects did no worse than controls on multiple tests of motor function.[38]

The fact that RLS is improved by rest suggests a possible role for exercise in therapy. A positive effect was confirmed by a small randomized trial of RLS patients, with a significant decline in RLS severity scale after 12 weeks of aerobic exercise,[39] as well as by one randomized trial in hemodialysis patients with uremia showing improvement in International Restless Legs Syndrome Rating Study Group severity scores after 6 months of graduated resistance training.[40] However, another small study surveying marathon runners actually showed a higher prevalence of RLS than in the general population.[41]

Insomnia and Poor Sleep Quality

It should not be surprising that athletes would have a high prevalence of insomnia. If using the Spielman model of insomnia, it is rather easy to identify predisposing (e.g., hyperawareness), precipitating (e.g., competition time), and perpetuating (e.g., irregular training times, travel, medications) factors. One survey found that 64% of elite athletes questioned admitted to worse sleep on the nights before competition in the preceding 12 months. Most (82%) of these complaints were of sleep-onset insomnia, with preoccupying thoughts (83.5%) and nervousness (43.8%) the most common reasons cited.[42] Incidence of chronic insomnia is unknown, although multiple factors could contribute, including psychosocial factors, travel and jet lag, variable sleep times, and medications.

The mechanism underlying the relationship between exercise and sleep quality is unclear, but there have been well-established positive effects in a number of populations. Exercise has been shown to improve sleep latency and sleep efficiency in patients with chronic primary insomnia.[43,44] Adolescents with increased physical activity report fewer symptoms of insomnia and better sleep quality, along with objectively measured improvements in total sleep time and wake after sleep onset.[45] Subjective sleep latency and total sleep times were improved with moderate-intensity exercise in sedentary older adults.[46] In middle-aged women, greater recent exercise was associated with improved sleep efficiency and sleep quality.[47] Exercise is a proposed modality to improve sleep quality and quality of life in people with diabetes,[48] heart failure,[49] breast cancer,[50] pregnancy,[51] and menopause,[52] among others.

Results of the 2013 National Sleep Foundation Sleep in America Poll—focused on sleep and exercise, surveying 1000 U.S. adults aged 23 to 60 years—support findings in the scientific literature. Despite similar sleep habits, respondents who exercise were more likely to report a good night's sleep (83%, 77%, 76%, and 56% for vigorous exercisers, moderate exercisers, light exercisers, and nonexercisers, respectively) and to feel their overall sleep needs were being met. Nonexercisers were also significantly more likely to report being in poor health, although the assumptions from this correlation are clearly bidirectional (perhaps they cannot exercise *because of* their poor health).

Surprisingly, the results of the survey did not demonstrate significant difference in sleep quality based on timing of exercise, with those performing vigorous or moderate exercise within 4 hours of bedtime reporting similar overall sleep quality to those whose exercise was more than 4 hours before sleep.[53] This runs contrary to the long-held belief that exercise close to bedtime can decrease sleep quality and suggests that if future studies are confirmatory of these survey results, a transition away from this recommendation—and focus on encouragement of exercise at any time—may be in order.

INJURIES

Injury prevention and management are as important as any goal in the practice and preparation athletes undergo before competition. Just as sleep is an integral part of athletic performance, it should be considered integral to maintenance of that performance.

Fatigue-Related Injuries

The concept of fatigue can have several definitions in regard to athletics. At its most precise, fatigue is the decline in force over sustained muscle activity. However, more generally and more frequently, fatigue refers to physical and mental exhaustion due to prolonged exertion.[54] Fatigue-related injuries are common, seen in up to 10% of athletes surveyed. Moreover, in one study, these injuries were significantly associated with both subjective perception of inadequate rest before injury, as well as self-reported sleep times of 6 hours or less.[55] In another study, sleep was consistently listed as the single most important modality for recovery in a survey of 890 male and female elite team athletes, regardless of gender, sport, or level of competition.[56]

Despite the subjective support of the role of sleep in fatigue-related injuries, there are no objective data on the mechanism linking sleep to athletic injuries. Nonetheless, the link between sleep and fatigue-related errors or accidents is so well established—both under laboratory conditions such as seen with psychomotor vigilance testing, as well as safety-conscious fields like military and transportation—that the conditions in athletes are largely extrapolated under the assumption of similar effects.

Sport-Related Concussion

Consensus definition of concussion is a biomechanically induced alteration of brain function, with primary pathophysiology involving a functional, rather than anatomic, disruption. This is distinguished from traumatic brain injury (TBI), which may have evidence of both. Indeed, some argue that concussion represents a distinct subset of mild TBI (mTBI), whereas others use the terms interchangeably.[57] This new working definition of concussion in sport should be noted for what it lacks: requirements for loss of consciousness or even direct contact with the head. Epidemiologic studies demonstrate variable rates of concussions dependent on sport, although there is evidence that incidence is increasing across all sports, to a large degree likely related to increasing awareness.[58]

The consensus statement on concussion in sport, updated in 2012, includes sleep among the modifying factors for concussion.[59] Despite this designation, the relationship between sleep and sport-related concussion (SRC) remains poorly understood.

Increasingly, diagnosis of SRC, as well as decisions for return to play, have incorporated neurocognitive screening

tools. These tools are useful for comparison of multiple domains of cognitive performance, as well as subjective symptoms, in the postconcussion state to personal or group-averaged baselines. Sleep may play an important role in interpretation of these tests. High school and collegiate athletes with sleep times of 7 hours or less on the night before testing have lower scores and higher total symptoms on baseline, preconcussion testing.[60] Lower subjective sleep quality is also correlated to higher number of symptomatic complaints on baseline neurocognitive screening.[61] These findings are consistent with effects of sleep deprivation seen with other neurocognitive tests, such as the psychomotor vigilance test, and suggest that sleep time and sleep quality need to be considered when interpreting concussion screening tools.

As symptoms of SRC, sleep disturbances are among the most common complaints and can include symptoms of hyperarousal, hypersomnia, or both, with sleep symptoms present in up to 30% to 70% of cases.[62] These symptoms may persist as part of the postconcussion syndrome.[63] However, fatigue at the time of injury was not considered predictive of a protracted recovery in one study of high school athletes.[64] Another study examining polysomnography of concussed athletes and controls found no difference in sleep parameters, despite an increase in subjective sleep complaints in the SRC group. This same study did find significant difference in waking electroencephalogram patterns, with the SRC group displaying increased delta and decreased alpha activity.[65]

It should be noted that these findings differ from overall mTBI research, which has shown increased sleep latency, shorter rapid eye movement (REM) latencies, increased N1, and decreased REM sleep.[66,67] In addition to frequent symptoms of insomnia, symptoms of excessive daytime sleepiness may be the result of comorbid sleep disorders such as OSA, periodic limb movement disorder, and narcolepsy.[68,69]

This discrepancy may be partly explained by differing mechanisms of injury. However, this field of research in general is limited to date by small sample sizes and long lead times between injury and study. Furthermore, survey questions following concussion are often vague, including only general terms like *fatigue*, which may be interpreted in multiple ways. Given that cognitive rest encompasses the definitive protocol for management of SRC, it would seem at least somewhat probable for sleep to play a part. Of particular interest is the possible role of sleep disorders in chronic traumatic encephalopathy, a neuropathologically distinct degenerative disorder attributable to repetitive head trauma.[70] Given the significant burden of disease, a better understanding of sleep in SRC is vital.

MANAGING SLEEP IN ATHLETICS

Along with exercise and nutrition, sleep should be considered a pillar of any training regimen, with goals to improve performance and aid in recovery and injury prevention. Managing sleep in the athlete can take on many forms. Summarized in Figure 64-2, this should include broad oversight of scheduling, including practice and travel, to optimize sleep time and circadian alignment, as well as understanding of individual variability, including consideration of adequate sleep satisfaction, mood and stress, and screening for sleep disorders. One should always be cognizant that outside constraints—particularly time and financial pressure on travel, training, and competition times—may require secondary solutions (e.g., if

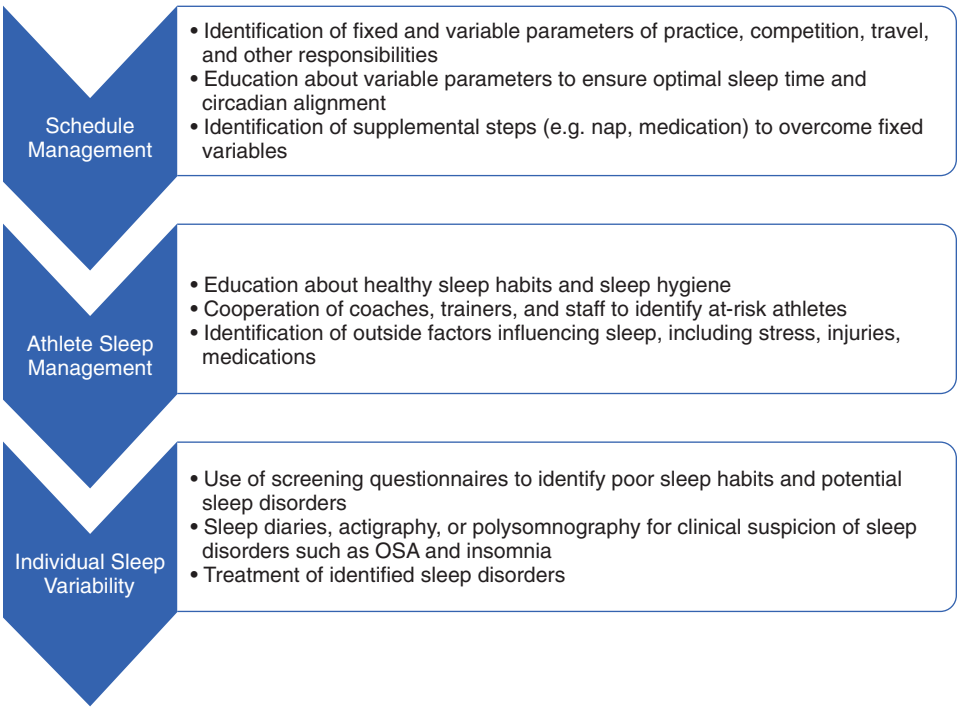

Figure 64-2 Sleep management in athletics includes broad goals generalizable to all athletes as well as highly individualized treatment plans. OSA, Obstructive sleep apnea.

a competition starts at 6 AM, one cannot simply demand a later start time).

Training in Elite Athletes

One concern about sleep management in elite athletes is whether their specific sleep requirements are different than those of the general population, for whom sleep advice is both widely available and well established. Elite Olympic athletes do report poorer sleep quality than controls when measured by Pittsburgh Sleep Quality Index (PSQI),[71] whereas a survey of college athletes showed elevated PSQI and Epworth Sleepiness Scale scores, although these could have been attributed to environmental and social factors.[72] The data are limited, but given the intensity of training often required, it is reasonable to consider the standard to at least be elite performers in other fields such as military, transportation, medicine, and business.

Sport-Specific Considerations

Understanding of sport-specific requirements is vital for adequate sleep opportunity. Each sport represents a unique combination of variables to address for sleep management. Factors to consider include level of competition; seasonal versus year-round sports; intensity of training regimen during off-season, preseason, competition, and postseason times; frequency of competition; frequency of travel and rest days; and time of competition. Athletes who train in the early morning or have late evening competitions may be at increased risk for insufficient sleep and more reliant on supplemental naps. Amateur athletes may have work or school requirements in addition to competition and training, further compromising sleep habits.

Screening for Sleep Disturbance

A required formal sleep evaluation for all athletes would be both costly and impractical. Awareness and education are key; the coaching, training, and ancillary support staffs should be enlisted to identify athletes at risk. Off-season routine physical examinations may be appropriate times to administer sleep screening questionnaires, such as the PSQI or Epworth Sleepiness Scale, the latter of which has been inversely correlated with service time in MLB.[73]

Actigraphy, either alone or in combination with sleep diaries, may be particularly useful in tracking sleep and ensuring adequate time in bed, especially during periods of travel or high-intensity training, when there is high risk for insufficient sleep. Polysomnography is useful for athletes who screen at high risk for OSA. Although less useful as a screening test itself, primarily because of low incidence of findings in this typically healthy population, a treatable sleep disorder should not be missed or ignored.

Managing Sleep Deprivation

Much of the theory behind mitigating sleep deprivation in athletes is derived from our understanding of fatigue, particularly the physical and neurocognitive consequences of chronic partial sleep deprivation, in other specialized patient populations and from laboratory studies of healthy adults.

With the small margins of error inherent in elite athletics, limiting effects of sleep deprivation is vital. A major contributor to sleep deprivation in this population is overscheduling. One should view the goals as similar to legally mandated requirements in medical and transportation fields, with proper time for rest and recovery allotted between practices and competitions. Naps can be useful adjuncts to an anchor sleep period, particularly during times of heavy travel or training.

Making time for sleep is of major importance but is only useful insomuch as an athlete is able to actually sleep during that time. It would be unreasonable to expect an athlete to fall asleep mere minutes after competition or at times at odds with their circadian rhythms. Symptoms of insomnia should be routinely addressed, with behavioral interventions considered first-line therapy.

Managing Circadian Effects

Although it is important to understand time-of-day variability in performance, the consequences remain vague. There is no evidence to date demonstrating that training at one specific time of day (i.e., close to Tmax) actually improves results compared with other times. Certainly, given the predominance and health consequences of a sedentary lifestyle, for many people *any* activity, regardless of relationship to circadian time, should be encouraged, so long as it does not predispose to an insufficient sleep pattern.

For more seasoned athletes, either amateur or professional, training is encouraged at or near time of competition. Although high-output training (i.e., muscle and endurance exercise) should be scheduled to coincide with peak circadian times, it does not preclude less intense activity such as stretching at off times.

Travel and Jet Lag

Fatigue from travel and jet lag should be properly differentiated; the latter consists mostly of a constellation of symptoms resulting from acute circadian disruption, whereas the former can result in cumulative fatigue over time.[74] Travel should be scheduled to allow for continued adequate sleep durations whenever possible. Transmeridian travel across three or more time zones may require circadian adjustment before departure, at the rate of one time zone per day. However, athletes may be better served by simply staying on their home time throughout shorter trips of less than 3 days.[75] Again, complex scheduling may limit the practice of pretravel time zone adjustment.

Medication and Supportive Therapy

Medication effects are largely unstudied in athletes, and principles are derived from general patient populations. Supplemental melatonin may be useful as a sedative or chronobiotic, particularly in the reentrainment period during or after transmeridian travel. Nonbenzodiazepine hypnotics may likewise serve as temporary aides to improve sleep onset and maintenance, with a consistent goal of limited, short-term therapy. Effect of long-term use of these medications in this population is unknown, although anecdotal concern for overuse is present.

Bright-light therapy can be considered for circadian entrainment and may be beneficial both during periods of travel and for athletes who must train at times at odds with their own circadian clocks. Caffeine is a safe supplement whose stimulant properties, mediated by antagonism of andesine receptors, can be useful in addressing fatigue. Prescription stimulants are almost universally banned in elite competition and should not be started without justifiable cause.

CLINICAL PEARL

Peak athletic performance generally occurs in the late afternoon, concomitant with maximal core body temperature. Performance is degraded by chronic partial sleep deprivation, although foundation for this belief is largely based on research in nonathlete populations. Inadequate rest may hinder recovery and exacerbate injury. Sleep disorders should be considered in specific athlete populations. Concussion may also influence sleep, and sleep complaints are common following concussion in athletes. Properly addressing the sleep needs of athletes requires understanding the complexity of variables influencing circadian and homeostatic factors and cooperation of a multidisciplinary team of trainers, coaches, and physicians.

SUMMARY

Athletes, coaches, and trainers are increasingly looking to sleep in an effort to achieve and maintain peak athletic performance. There exists circadian variation in a number of performance variables, correlated to variations in core body temperature, as well as homeostatic drivers of performance, with athletic schedules often predisposing to risk for chronic partial sleep deprivation. Although certain populations of athletes may be at increased risk for sleep disorders such as insomnia and OSA, exercise itself has demonstrable efficacy in treatment of a number of sleep disorders. Poor sleep may inhibit recovery from training and predispose to injury, and sleep symptoms are a common complaint in SRC. Athletes of all levels should consider sleep as a core component of training and recovery, and for some, a comprehensive analysis of sleep habits, training, competition, and travel schedules, as well as medication and supplement use, may be indicated to promote optimal sleep patterns.

Legal Topics in Sleep Medicine

Chapter 65

Sleep Forensics: Criminal Culpability for Sleep-Related Violence

Michel A. Cramer-Bornemann; Mark W. Mahowald

Chapter Highlights

- Sleep forensics is the application of neuroscience to somnology and sleep medicine to investigate unusual, irrational, or bizarre human sleep-related behavior associated with alleged criminal activity. This investigation is typically used to form the basis of an expert opinion for use in a criminal trial regarding a defendant's state of mind.
- Consciousness is not an all-or-none state but occurs on a spectrum. In addition, sleep and wakefulness are not mutually exclusive states of consciousness. Wakefulness, NREM sleep, and REM sleep may occur simultaneously or oscillate rapidly. This phenomenon is key to understanding the forensic implications of violent parasomnias.
- Consciousness can be dissociated from behavior. Neurophysiologic mechanisms can account for violent or other asocial behaviors associated with sleep.
- In a criminal proceeding, the offer of a clinical diagnosis alone is often insufficient to secure a conviction. Sleep medicine specialists have a role in legal proceedings to describe and address aspects of a defendant's consciousness and culpability.

To blame a person is to express moral criticism, and if the person's action does not deserve criticism, blaming him is a kind of falsehood, and is, to the extent the person is injured by being blamed, unjust to him.

Sanford Kadish, 2000[1]

Philosophers from time immemorial have grappled with the mind–body dilemma. Recent advances in neuroscience put us now on the verge of solving how our brains affect our minds and behavior.

THE DEVELOPMENT OF SLEEP FORENSICS

Sleep forensics is formally defined as the application of the principles and tools of neuroscience as applied to somnology and sleep medicine. These principles and tools have been widely accepted under international peer review as means for investigating unusual, irrational, or bizarre sleep-related behavior associated with alleged criminal activity. The investigation undergoes further examination in a courtroom pursuant to rules of criminal law.

The best application of sleep forensics involves an adaptable conceptual approach. An adaptable approach applies current neuroscientific concepts of consciousness and sleep-wake state dissociation to sleep medicine. This dynamic method is preferred to the approach set forth in the U.S. Model Penal Code (MPC), which uses static definitions and clinical disorder markers from which criminal behavior might be extrapolated.

Therefore a medical expert called on to investigate criminal allegations will need to do more than just evaluate for a possible sleep disorder. Ultimately the expert's determination of

the defendant's state of consciousness will prove pivotal. This requires an understanding of the neuroscience of consciousness, an awareness of relevant neuroscientific models for types of potential behaviors that may arise from sleep, as well as a determination concerning the appropriate application of consensus-driven clinical guidelines to assist in determining purported acts of violence arising from sleep.

The medical expert should also recognize the sleep specialist's primary role when interfacing with lawyers, judges, and law enforcement. The sleep specialist can help facilitate the discourse concerning advances in cognitive neuroscience and help develop the framework for further research, particularly in parasomnias.

EVOLUTION OF LEGAL THOUGHT ON CRIMINAL MENTAL STATES

General

Influenced by Sir Edward Coke, Chief Justice of the King's Bench (1613), Anglo-American law defines criminal offenses whereby a person must be in a certain mental state, called the *mens rea* (guilty mind), necessary to have committed a crime. Persons possessed of *mens rea* cannot be convicted absent a corresponding criminal act, called the *actus reus* (guilty act). Traditionally, intention is found within *mens rea,* and the physical part of the offense resides within *actus reus*. Proof of both is essential to secure a conviction.

Recognition that an impaired mental state might mitigate criminal punishment appears to date back to at least 1772 BC as recorded in the Code of Hammurabi. The Roman Empire also appeared to recognize a person's altered mental status to find defendants not guilty due to *non-compos mentis*, meaning without mastery of mind.[2]

In 1843 Sir Nicolas Tindal established what has become known as the *M'Naghten Rule*. These rules still provide the conceptual legal framework for excusing a person's criminal act committed while the defendant was suffering from a defect of reason or disease of the mind. For the defense to operate, the actor must be shown to be in a state of mind such that he did "not to know the nature and quality of the act he was doing; or, if he did know it, that he did not know he was doing what was wrong."[3,4]

From a neuroscientific perspective, the criminal act or *actus reus* component of the crime is of less interest than the essential *mens rea* element. Implementation of the M'Naghten Rule thereby becomes a watershed moment concerning the influence of neuroscience on criminal law because it is the state of the mind—or perhaps, more accurately, the brain—to which inquiry is focused.

Sleep

With respect to criminal culpability, the inquiry surrounding sleep is whether a person in a sleep state possesses sufficient *mens rea* to support a conviction for the actor's behavior. The first appearance of the "sleepwalking defense" in an American court of law came in *Massachusetts v Tirrell*[5] in 1846. In this landmark case, Rufus Choate, a skilled orator and U.S. senator, successfully employed the "insanity of sleep" defense in the murder trial of Albert Tirrell. The evidence in that case proved that Tirrell brutally killed the victim with a razor, almost severing her head from her body, set the horrifically bloody crime scene ablaze, and then attempted to flee the country.[6] Choate, an innovative legal tactician influenced by the advent of the M'Naghten Rule in the United Kingdom, argued in part that Tirrell, a sleepwalker, murdered the victim in an unconscious sleepwalking state and was able to convince the jury to acquit the Tirrell on this basis.

Later, in the mid to late 1800s there were no plausible medical explanations to account for sleepwalking, let alone account for complex violent actions that apparently arose during sleep. Still, courts were willing to adopt and apply defenses to deadly crimes committed by persons in a sleep state by pleas of a temporary "defect of reason" or "disease of mind." See, for example, *HMS Advocate v Fraser* (1878)[7] and *Fain v Commonwealth* (1879).[8]

Until physiologic aspects of sleep could be objectively measured and verified using validated neuroscientific instruments, defending criminal behavior arising from sleep often meant associating such behavior with other, better-understood medical or psychiatric conditions such as insanity or automatism. For example, courts apply the insanity defense to excuse criminal actions resulting from a diseased mind incapable of knowing right from wrong. Where indicated, courts might also withhold criminal punishment for acts caused by a defendant's involuntary bodily movements exhibited even while in a conscious or sane state. Thus a defense of automatism may be appropriate for acts arising from epileptic seizures, fugue states, and limbic psychotic trigger reactions, whereas an insanity plea would be appropriate if the defendant acted in the throes of fulminant delusional paranoid schizophrenia.

The legal community's perspective toward sleep began to shift in 1968 with Roger Broughton's seminal publication characterizing the relationship among somnambulism, nightmares, confusional states of arousal, and rapid eye movement (REM) sleep.[9] By creating a clear demarcation between sleep disorders and other medical or psychiatric conditions, this appears to be the first scientific sleep-related publication with direct legal implications, as demonstrated by the 1992 Canadian criminal case of *Regina v Parks* (1992)[10] in which Broughton served as an expert witness on behalf of the defense.

The defendant in the *Parks* case claimed that while sleepwalking in the early morning hours he drove to the house of his wife's parents and, provoked to attack by his in-laws' physical contact, killed his mother-in-law with a kitchen knife and left his father-in-law seriously injured.[11] The defendant defended his actions on the basis of automatistic sleepwalking rather than insanity. Expert witnesses for the defense testified that sleepwalking is not a neurologic, psychiatric, or other illness but rather is a sleep disorder very common in children and also found in adults.

The jury acquitted the defendant on the basis of automatism, which is a complete acquittal, as opposed to finding the defendant not guilty by reason of insanity, which typically leads to some institutional incarceration. The Canadian Supreme Court took up the case to decide the single legal issue of whether sleepwalking should be classified as noninsane automatism or insane automatism arising from a "disease of the mind," giving rise to a special verdict of not guilty by reason of insanity. Based on the unchallenged expert testimony that sleepwalking is a sleep disorder rather than a mental defect, the court rejected the characterization of sleepwalking as a mental health disorder.

EVOLUTION OF CONSCIOUSNESS THOUGHT

Criminal law presumes that most human behavior is voluntary and that individuals are consciously aware of their acts. All criminal liability is based on a voluntary act, or an omission to engage in a voluntary act that the defendant would otherwise have been capable of performing. Voluntariness is the first step in establishing *mens rea.* If the state proves *mens rea*, then the state will assess liability according to four levels of culpability: purpose, knowledge, recklessness, and negligence. In criminal law, the level of culpability determines the category of homicide (murder, manslaughter, or negligent homicide), and the category directly influences the severity of punishment.

Because voluntariness is absolutely fundamental to *mens rea,* it is surprising that the MPC offers examples of involuntary acts in lieu of explicitly defining the term *voluntary acts*. One example of an involuntary act is bodily movement during unconsciousness or sleep. Thus the MPC equates sleep with unconsciousness and deems bodily movements performed in a sleep state to be involuntary and presumably excused from criminal punishment. The other three examples of involuntary acts in the MPC include reflex convulsion; bodily movement that is not otherwise a product of the effort or determination of the actor, either conscious or habitual; and conduct during hypnosis or hypnotic suggestion.[12,13]

Waking Consciousness

A comprehensive review of the neuroscience of consciousness is well beyond the scope of this chapter. However, consciousness involves awareness of our environment, awareness of our bodies, and introspection (self-awareness), and it can only fully occur when we are awake.

To neuroscientists, *consciousness* is a term that has varied meanings, although its definition in the legal realm has held steadfast. In science, for example, consciousness may be used to indicate whether an individual is in a conscious state, as in whether it has been altered, reduced, or even lost. On the other hand, consciousness may be a trait or an attribute of a psychological process, as in the ability to think, see, and feel consciously. With trait consciousness, further distinctions may be made between conscious representations, which are usually phenomenal, and required conscious access.

Unfortunately a direct objective marker for the neural basis of state and trait consciousness that is independent of a person's external expressions or behavior has yet to be determined. Nevertheless it is believed that the neuronal processes that mediate access to consciousness take place in a network of frontoparietal cortical regions of the brain. These networks play an important role in attentional and behavioral selection of incoming and stored information. Because the frontoparietal cortical regions govern behavioral selection, it is not surprising that this region becomes active when patients in a vegetative state recover or becomes further activated when healthy subjects perform demanding perceptual tasks.

Sleep is regularly and actively induced by a shift in neuronal activity and neurotransmitter balance in brainstem nuclei. Functional neuroimaging studies performed on sleeping subjects reveal that during both REM and non–rapid eye movement (NREM) sleep the prefrontal and parietal cortical regions become deactivated in comparison to the resting wakeful state.[14-16] The most active regions during the resting wakeful state include the left dorsolateral and medial prefrontal areas, the inferior parietal cortex, and the posterior cingulate and precuneus.[15] In REM sleep, despite overall increases in cerebral blood flow and energy demands, relatively low regional cerebral blood flow persists in prefrontal and parietal cortex.[17] Because consciousness can only fully occur when we are awake, the frontal cortex would appear to be indispensable to consciousness.

Another important region is the dorsal thalamus, the "gateway to the cortex," and its accompanying "guardian of the gateway," the reticular complex (part of which is often called the *perigeniculate nucleus*).[18-21] Francis Crick believed that the input and output gating of the reticular complex were topographically arranged to approximate a map of the entire cortex. In his searchlight hypothesis, the reticular complex thereby was able to heat up the warmer parts of the thalamus and cool down the cooler parts so that "attention" would remain focused on the most active thalamocortical regions.[22] Although the function of the thalamic reticular complex remains incompletely understood, it is essential for consciousness, whereas cerebellar circuits, in contrast, are not.

Consciousness as a Continuum

The modern concept of consciousness was perhaps first established by influential American scientific psychologist and pragmatist William James (1842–1910). Consciousness has been subdivided into nine distinct components (Table 65-1), all of which are seamlessly integrated into our own personal conscious experience.

From the notion that consciousness is graded and not dichotomous, J. Alan Hobson developed the AIM concept. This concept creates a four-dimensional "mind space" in time that is transformed by three variables: activation (A), input-output gating (I), and neuromodulation ratio (M) (as measured by the aminergic-to-cholinergic ratio). All of these determine changes in the state of consciousness, which in turn govern the oscillation from wake to sleep.

These variables account for the physiologic properties within each state.[23] The interaction of these variables can cause temporary nonhomeostatic conditions that, in turn, might trigger or cause undesirable behavior without consciousness or memory. Such behaviors might include violent outbursts related to REM sleep behavior disorder.[24]

The recurrent pattern of state-determining parameters is amazingly consistent. However, there are numerous clinical

Table 65-1 The Nine Components of Consciousness

Component	Function
Perception	Representation of input data
Attention	Selection of input data
Memory	Retrieval of stored representations
Orientation	Representation of time, place, and person
Thought	Reflection on representations
Narrative	Linguistic symbolization of representations
Instinct	Innate propensities to act
Intention	Representation of goals
Volition	Decisions to act

and experimental examples of dissociation of state components. Such dissociation can be explained as simultaneous mixtures of clinical and neurophysiologic elements of the three states of being—wake, NREM sleep, and REM sleep. These fall into three categories, as reviewed by Mahowald and Schenck,[25] and include neuroanatomic lesions or stimulation, pharmacologic mechanisms, and sleep deprivation. Neuroanatomic lesions or stimulation include hypothalamic, thalamic, and brainstem manipulation or stimulation inducing state dissociation. Pharmacologic mechanisms include manipulation of the cholinergic or glutamate neurotransmitter systems resulting in a variety of state dissociations. A consequence of general anesthesia is "cognitive unbinding," which further explains state dissociation.[26] As for sleep deprivation, recent studies by Montplaisir and colleagues suggest that sleepwalking results from a dysfunction of the mechanism responsible for sustaining stable slow-wave sleep and that sleepwalkers are particularly at risk when exposed to increased homeostatic sleep pressure.[27,28]

State dissociations are the consequence of timing or switching errors in the normal process of the dynamic reorganization of the central nervous system as it moves from one state (or mode) to another. Elements of one state persist or are recruited erroneously into another state, often with fascinating and dramatic consequences.

Objective support for state dissociation is provided by depth electrode electroencephalographic studies demonstrating areas of wakefulness and sleep occurring simultaneously in humans.[29-32] This concept helps to explain such phenomena as sleep inertia, waking hallucinations, narcolepsy, REM sleep behavior disorder, lucid dreaming, out-of-body experiences, near-death experiences, repressed or recovered memories of childhood sexual abuse, alien abductions, and disorders of arousal (Figure 65-1).[33-39] The concept of state dissociation supports the notion that consciousness occurs on a continuum.

Fixed Action Patterns and Central Pattern Generators: A Neuroethologic Approach to Behavior

Ethology is the study of whole patterns of animal behavior under natural conditions in a manner that highlights the functions and the evolutionary process of those patterns. With an ever-increasing physiologic approach through the application of refined and elegant laboratory research techniques to animal behavior, neurobiology and ethology have coalesced to develop neuroethology.[40]

An important behavior type in ethology is the fixed action pattern (FAP). This is an instinctive indivisible behavioral sequence that when initiated will run to full completion. FAPs are invariant and are produced by a neural network known as the *innate releasing mechanism* in response to an external stimulus known as a *sign stimulus*.

FAPs are ubiquitous in the animal kingdom and are seen from invertebrates to higher primates. Movements resulting in FAPs may be initiated by central pattern generators (CPGs): "Movements are generated by dedicated network of nerve cells that contain the information that is necessary to activate the different motor neurons in the appropriate sequence and intensity to generate motor patterns. Such networks are referred to as *Central Pattern Generators*."[41]

Tassinari and coworkers recognized that motor events related to certain epileptic seizures and parasomnias share very similar features. This suggests a stereotyped inborn FAP, perhaps initiated by CPGs.[42] Tassinari recognized CPGs as genetically determined neuronal aggregates in the mesencephalon, pons, and spinal cord that, from an evolutionary perspective, were linked with innate primal behavior essential for survival (e.g., feeding, locomotion, reproduction).

In higher primates, CPGs are inhibited by the influence of neocortical control. Many of the CPGs are located in the brainstem and in close proximity to processes that govern the wake, NREM sleep, and REM sleep transitions. Despite diurnal neocortical inhibition, Tassinari provides a neuroethologic model whereby both epilepsy and sleep can lead to a temporary loss of control of the neomammalian cortex that is provided a pathway through a common arousal platform initiated by CPGs, which in turn triggers these FAPs (Figure 65-2), resulting in the abrupt onset of bizarre motor or

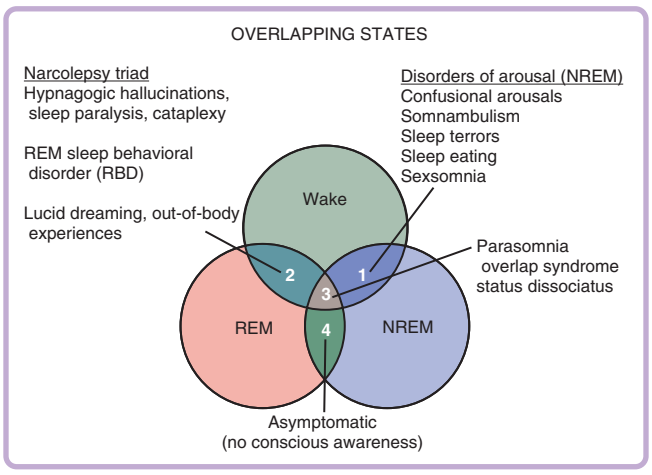

Figure 65-1 Areas of overlap among states of being. (Modified from Mahowald MW, Schenck CH. Dissociated states of wakefulness and sleep. *Neurology* 1992;42:44–52).

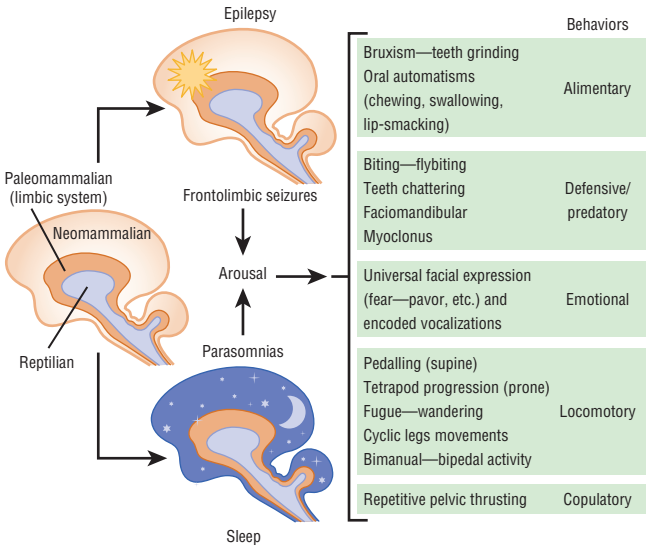

Figure 65-2 The emergence of innate primal behavior facilitated through central pattern generators from the arousal platform. (Modified from Tassinari CA, Rubboli G, Gardella E, et al. Central pattern generators for a common semiology in fronto-limbic seizures and in parasomnias: a neuroethologic approach. *Neurol Sci* 2005;26:S225–32).

emotional expressions that are uncharacteristic of awake neocortical-mediated diurnal behavior.

Tassinari's concept of the role of CPGs and FAPs provides a physiologic explanation for parasomnias. This concept is particularly useful in sleep forensics because parasomnias and epileptic seizures tend to have patterned stereotyped actions without conscious awareness. When addressing criminal allegations and their potential association with sleep-related conditions, the sleep medicine specialist can use behavior pattern recognition, applying neuroethologic concepts that indicate process fractionation, and neurobehavioral investigative techniques. Such an approach could be particularly beneficial and would be consistent with the direction of current mainstream neuroscience.

Dreaming Consciousness

It is obvious with sleep onset that sensory input is largely lost and our ability to interact with the external environment is curtailed. The conscious state paradigm outlined by J. Alan Hobson recognizes that all nine components of consciousness change to varying degrees as the brain changes state and does so in a repetitive and stereotyped manner over the sleep-wake cycle. Furthermore, consciousness is graded, and the state changes appear to be of such dramatic magnitude that strong inferences can be made about the major physiologic underpinnings of consciousness.[23] Sleep physicians on a daily basis appreciate, by interpreting polysomnographic studies, the state-determined uniformity of physiologic events that are consistent from patient to patient. To analyze the transitions in process, from wake to sleep or from NREM to REM, and isolate its individual components in order to deduce its underlying state, including its associated degree of consciousness, is a method called *process fractionation* (Figure 65-3). The application of the conscious state paradigm has led Hobson to declare three important principles.

First, consciousness rides on the crest of the brain activation process. Therefore, even a small perturbation in activation level leads to lapses in waking vigilance. Second, the brain remains highly active and capable of processing information even though consciousness may be largely deactivated. Functional imaging studies reveal that the brain remains about 80% active even when consciousness has largely subsided. Lastly,

	Wake	NREM	REM	Causal Hypothesis
Sensation & Perception	Vivid, externally generated	Dull or absent	Vivid, internally generated	Presynaptic inhibition, Blockade of sensory input
Thought	Logical and progressive	Logical and perseverative	Non-logical and bizarre	Loss of attention memory and volition leads to failure of sequencing and rule inconstancy; analogy replaces analysis
Attention	Intact, vigilant	Lost	Lost	Decreased aminergic modulation causes a decrease in signal to noise ratio
Orientation	Intact	Unstable	Unstable	Internally inconsistent orienting signals are generated by cholinergic system
Emotion	Inhibited	Weak	Episodically Strong	Cholinergic hyperstimulation of amygdala and related temporal lobe structures
Instinct	Inhibited	Weak	Episodically Strong	Cholinergic hyperstimulation of hypothalamus and limbic forebrain triggers CPG/FAP axis
Aminergic Inhibition (-)				Aminergic Inhibition (-)
Cholinergic Excitation (+)				Cholinergic Excitation (+)

Figure 65-3 Process fractionation: contrasts in components of consciousness between states. CPG, Central pattern generator; FAP, fixed action pattern. (Modified from Hobson JA. States of consciousness: normal and abnormal variation. In: Zelazo PD, Moscovitch M, Thompson V, editors. *The Cambridge handbook of consciousness*. New York: Cambridge University Press; 2007. p. 69.)

most brain activity is *not* associated with consciousness. In relation to its evanescence, consciousness "is a very poor judge of its own causation and of information processing by the brain."[23]

There have been seismic shifts in cognitive neuroscience that the legal system has yet to appreciate and incorporate into the legal arena. Rather confusingly, the terms *conscious* and *unconscious* are still used in the lexicon of neuroscience, but the ideas and principles behind these terms have been substantially altered and continue to be refined, with one such example being Tononi's information integration theory of consciousness.[43,44]

Advances in neuroscience since the 1980s support the existence of a continuum of conscious and unconscious processes, and neuroscience has largely dispensed with Freudian-influenced psychoanalytic concepts and theories. The boundaries between conscious and unconscious, as between wake and sleep, are permeable, dynamic, and interactive. As such, there is no valid scientific support for the sharp dichotomy between consciousness and unconsciousness currently held by the MPC and the legal community. It is this model of state dissociation that assists in the explanation of unusual, irrational, or bizarre human behavior in sleep forensics.

COMPLEX BEHAVIOR ARISING FROM SLEEP

Increasingly, experts in sleep medicine are being called on by attorneys to assist in reviewing legal cases, most of which involve allegations of criminal behavior. The conventional path is to make an evaluation for parasomnias to explain a wide variety of sleep-related violent behavior. The typical defense strategy is to clothe the behavior as a parasomnia symptom and thus completely exonerate the perpetrator's actions. Case requests to review bizarre nocturnal activities as mere rage reactions attributed to pharmaceutical agents such as benzodiazepines and, particularly, nonbenzodiazepine drugs are not uncommon.

Incidents of violent sleep-related behavior have been reviewed in the context of automatic behavior in general, with many well-documented cases resulting from a wide variety of disorders. Conditions associated with violence during the sleep period fall into two major categories: neurologic and psychiatric (Box 65-1). Those actions arising from a primary neurologic condition can be explained by applying conceptual approaches based on models of evanescent consciousness, the overlapping physiology of clinical disorders, and the platform of CPGs supported by semiotic neuroethology.

CLINICAL GUIDELINES TO ASSIST IN DETERMINING PURPORTED VIOLENCE ARISING FROM SLEEP

Legal implications of automatic behavior have been discussed and debated in the medical and legal literature.[45-49] The identification of a specific underlying organic or psychiatric sleep and violence condition does not establish causality for any given deed.

To assist in determining the existence of an underlying sleep disorder in a specific violent act, practitioners should follow guidelines based on peer-reviewed international clinical experience. Several clinical guidelines have been proposed[50-53] that identify certain features occurring as a result of a sleep disorder:

- There should be reason by history to suspect a bona fide sleep disorder. Similar episodes, with benign or morbid outcome, should have occurred previously.
- There has to be some degree of interaction with the environment. This behavior cannot be entirely passive in nature.
- The duration of the action is usually brief (seconds), although action of longer duration (minutes) does not necessarily exclude a sleep disorder or a sleep-related behavior. The action is usually abrupt, immediate, impulsive, and senseless—without apparent motivation. Although ostensibly purposeful, it is completely inappropriate to the total situation, out of (waking) character for the individual, and without evidence of premeditation.
- The victim is someone who merely happened to be present, usually in close proximity, and who may have been the stimulus for the arousal. Sleepwalkers rarely, if ever, seek out victims.[53,54]
- Immediately following return of consciousness, there is perplexity or horror, and there is no attempt to escape, conceal, or cover up the action. There is evidence of lack of awareness on the part of the sleepwalker during the event. There is usually some degree of amnesia for the event, but this amnesia need not be complete.
- In the case of sleep terrors, sleepwalking, or sleep inertia, the act may occur on awakening (rarely immediately on falling asleep) and usually at least 1 hour after sleep onset. It occurs on attempts to awaken the subject. The action has been potentiated by sedative-hypnotics or by prior sleep deprivation.
- Lastly, the violent behavior cannot be better explained by another mental disorder, medical condition, medication, or substance use. Ultimately, to attribute a violent behavior with criminal implications to parasomnia is a diagnosis of exclusion with the explicit understanding that other conditions are often more statistically likely. Note that this final guideline is also in accord with the diagnostic criteria for parasomnias in the *International Classification of Sleep Disorders*, 3rd edition.

Box 65-1 CONDITIONS ASSOCIATED WITH AUTOMATIC BEHAVIOR ARISING FROM THE SLEEP PERIOD

Primary Sleep Disorders (Neurologic Conditions)

Disorders of arousal
- Confusional arousal
- Sleep-related abnormal sexual behavior (sexsomnia)
- Sleep terror
- Somnambulism

REM sleep behavior disorder
Nocturnal seizures
Compelling hypnagogic hallucinations
Somniloquy

Psychiatric Conditions

Dissociative states (may arise exclusively from sleep)
Posttraumatic stress disorder
Malingering
Munchausen syndrome by proxy
Psychopathy

The guidelines for determining the role of a sleep disorder in violence are not meant to be perceived as a rigid rule nor as a set of necessary criteria. They merely provide direction to gauge whether an argument in favor of a sleep disorder could be sustained in the formulation of a possible criminal defense. The strength of the argument should consider current neuroscientific models of consciousness and behavior as supported by the medical expert's specialized clinical experience.

THE ROLE OF THE SLEEP MEDICINE SPECIALIST

To address the problem of junk science in the courtroom, some professional societies have developed guidelines for expert witness qualifications and testimony. The American Academy of Sleep Medicine's stance on expert witness testimony is to accept opinions held by the American Medical Association in its 2004 Report of the Council on Ethical and Judicial Affairs.[55] Similarly, influenced by both the American Academy of Neurology and the AMA, the following guidelines should serve as a compass.

Expert Witness Qualifications

Expert witnesses should have a current, valid, unrestricted medical license. Expert witnesses testifying about sleep medicine should be diplomats of the American Board of Sleep Medicine or should have passed the American Board of Internal Medicine specialty examination in sleep medicine. Membership in the Sleep Research Society is strongly encouraged. An expert witness in sleep medicine must be a recognized resource within the sleep medicine community and should have been actively involved in clinical practice in a manner consistent with the requirement of the criminal case at the time of the event. Given the essential position of *mens rea* in criminal law and the pivotal role of levels of consciousness, an expert witness should have significant direct experience in either neurology or neuroscience.

Guidelines for Expert Testimony

Expert testimony must be impartial. The ultimate test for accuracy and impartiality is a willingness to prepare testimony that could be presented unchanged for use by either the plaintiff or the defendant. Fees should relate to time and effort and should not be contingent on the outcome of the claim. Fees should not exceed 20% of the practitioner's annual income. The practitioner should be willing to submit such testimony for peer review. To establish consistency, the expert witness should make records from his or her previous expert witness testimony available to the attorneys and expert witnesses of both parties. The expert witness must not become a partisan or advocate in the legal proceeding.

It is not the role of the medical expert to win the case for a client, although it is not uncommon to use irrelevant disingenuous technicalities in an attempt to deceive so as to attain an advantage to secure the decision. Instead, the salient ethical decision for those who assume this mantle of medical expert witness is to recognize and value the privileged position given within our society as an educator inside the legal system by promoting current published peer-reviewed science and minimizing bias while rendering an opinion. The goal of the expert witness is not to simply ascertain or promote an argument addressing "reasonable doubt" in any given case because this is best deferred to legal parlance most often provided during counsel's closing statements. Instead, the role of the expert witness is therefore to attempt to succinctly and clearly communicate scientifically valid information without bias within the context of the case to the jury, who in turn determines culpability based on this information. The weight of the decisions of either guilt or innocence should never rest in the hands of medical experts, whose task is to contribute to the due process of an efficient and functional legal system by ensuring that the jury is educated and well informed.[56]

CLINICAL PEARLS

In a court of law, the undisciplined use of scientific technical data is a real concern, especially given the public misperception that science is a field that deals with absolute certainties when in actuality it is a field that reflects probabilities of occurrence. In many ways, the legal community has misrepresented the nature of science for many years and continues to attempt to do to so in an admittedly adversarial environment.

One problem with presenting results of scientific research is a condition called *brain overclaim syndrome*.[57] In general, the public has an overfascination with new developments in science and often assumes statements of scientific evidence are true, even when the statements cannot be conceptually or empirically sustained. Studies have shown, for example, that the results of a simple experiment in cognitive psychology are more positively evaluated and considered important if a brain scan is included in the report of the results.[58] The limitations of neuroscience data in the courtroom must be appreciated.[59]

In a sleep-related example, a review has clearly established that polysomnography performed after the fact is of absolutely no value in determining whether the accused was sleepwalking at the time of the criminal activity. On very infrequent occasions, polysomnography may be considered to assess potential mitigating influences, such as obstructive sleep apnea. Even sleepwalking during a formal sleep study would only indicate that the person was a sleepwalker, not that sleepwalking was involved at the time of the crime.[60]

SUMMARY

Advances in neuroscience are increasing our understanding of how the brain enables action, including everything from simple movement, to thought, to the diurnal and nocturnal variability of sleep-wake processing.

The societal and cultural implications of these scientific advances have yet to be understood or even conceived.[61] However, the legal community is aware of the implications of this new neuroscience because science directly challenges the law's currently held constructs of consciousness as defined by *mens rea* and the voluntary act requirements. To study these problems, the John D. and Catherine T. MacArthur Foundation has established the Law and Neuroscience Project in 2007 (www.lawandneuroscienceproject.org) comprising 40 neuroscientists, legal specialists, and philosophers.[62] Two important concepts to be incorporated into the legal community are that consciousness is not all-or-none but occurs on a spectrum and that consciousness can be dissociated from behavior.

Sleep forensics does more than provide medical expert testimony in individual legal cases. The growth of cognitive neuroscience will continue to change our understanding of what it means to be human, and as a result the law will have to change in conformity with it.

The conceptual approach to sleep forensics encourages further research to define and characterize mixed states of wake and sleep and the parasomnias. Understanding all of these is beneficial in understanding the spectrum of complex human behavior. Close collaboration among basic neuroscientists, sleep medicine clinicians, and the legal community will facilitate the development of a commonly shared concept of consciousness and culpability.

Legal Obligations of Persons Who Have Sleep Disorders or Who Treat or Hire Them

Chapter 66

Daniel B. Brown

Chapter Highlights

- Patients have a right to refuse treatment for sleep-related breathing disorders, but they may be liable if the foreseeable results of their sleep-disordered actions cause injury to others.
- Drivers who experience a "sudden blackout" while behind the wheel are excused from liability for damages arising from crashes caused as a result of their unexpected unconsciousness or seizure. However, this legal defense fails if the driver knew that his or her "blackout" or sleep episode was imminent or otherwise foreseeable.
- At least two states, New Jersey and Arkansas, factor fatigue into a criminal finding of reckless driving by drowsy drivers.
- Employers will be found liable for the negligence of their employees if the accident causing the injury occurred during the course of the employee's employment. Thus a trucking company will likely be found liable for injuries caused by an employee truck driver who falls asleep at the wheel while on the job.
- Employers are not likely to be found liable for injuries caused by their employees' sleep-induced actions that occur outside the scope of the employee's employment, even if the employee's fatigue is caused directly by the employer's overscheduling the employee's work hours.
- Whether a sleep disorder is a "disability" for purposes of the Americans with Disabilities Act (ADA) depends in large part on whether the discriminatory actions taken by an employer against a sleep-disordered individual occurred before or after passage of the ADA Amendments Act of 2008 (ADAAA). Sleep disorders are much more likely to be considered disabilities eligible for ADA protection after the effective date of the ADAAA.

Sleep disorders such as obstructive sleep apnea (OSA) have been shown to fragment sleep and deprive the sufferer from restful and regenerative slumber.[1] In addition to comorbidities such as cardiopulmonary diseases, untreated OSA can lead to daytime hypersomnolence, which, in turn, can directly and adversely affect an OSA sufferer's overall daytime performance on the job or on the road.[2]

Legal systems examine a person's adherence to reasonable or statutorily defined standards of conduct and whether variance from such standards causes injury to others. Civil legal remedies generally award monetary penalties to injured parties as compensation for their damages incurred at the hands of a negligent party.[3] Criminal law metes out fines, imprisonment, or other punishments for conduct determined by state or federal statute to be injurious against the public at large.[3]

Legal proceedings under civil law focus on whether the wrongdoer had a duty of care to the injured party and whether the actor's breach of that duty caused the injured party's damages.[3] Criminal court actions focus on whether the actor's conduct violated each element of an activity that a particular statute considers to be criminal.[4]

Because there exists a causal connection between a person's sleep-disordered fatigue and such person's impaired daytime activity, the law will examine whether the sleep-disordered patient or those treating or employing the patient owe any special duty of care. That duty might arise to protect the patient or those with whom the patient may come into contact. This chapter briefly discusses the legal duties owed by sleep-disordered patients, the health care professionals who diagnose and treat them, and those persons or entities who employ potentially fatigue-prone persons under current U.S. law.

SURVEY OF SLEEP APNEA IN THE LAW

What ultimately was called *sleep apnea* was described by several European groups in the 1960s, and the first description in a major journal appeared in 1973[5] (see Chapter 1). It was not until the 1980 Social Security benefits case of *Parks v. Harris* that the disorder was first seen in a reported decision in the United States.[6] Parks, who had recently been diagnosed with sleep apnea, sued to overturn his benefits denial based on a vocational expert's testimony that Parks suffered from uncontrolled somnolence due to a sleep disorder.[6] This early case did not consider disease treatment as a factor to defeat the disability claim because continuous positive airway pressure (CPAP) treatment for OSA was not available until 1981, or a year after the *Parks* decision.[7]

Legal notice of OSA was slow to develop following *Parks*. For example, in the 9 years after the *Parks* case, references to sleep apnea in all reported U.S. appellate decisions appeared in only 17 cases. However, recognition of OSA in U.S. jurisprudence grew quickly after 1980 and fairly exploded after 2005. References to OSA in reported U.S. cases grew more than 4000% in the 25 years from 1980 to 2005, with 772 cases making some reference to OSA during this period. The references to OSA in U.S. case law grew an astounding 5196 additional cases in the 8-year period between January 1, 2006 and July 1, 2014, mostly in cases associated with patient disability. To be clear, most of the combined 5985 cases since *Parks* contain only passing references to OSA. For example, OSA often appears only as one of many conditions that make up a defendant's general health profile and has no bearing on the outcome of the case. For example, only 215 of these cases include any mention of malpractice, and hardly any those address a health care practitioner's malpractice with regard to a sleep disorder.

Legal Obligations of Persons with Obstructive Sleep Apnea

A long-established general rule states that patients may choose to ignore their medical conditions and refuse treatment without facing legal consequences.[8] That right of refusal does not give those patients the right to ignore the risks to public safety caused by their decisions.[8] In California, for example, there is a statute requiring those with certain infectious diseases to take precautions to avoid the willful spread of their diseases through public contact.[9] Similarly, although an OSA patient may choose not to treat his or her condition with CPAP, oral therapy, or surgery, there can still be legal consequences to driving on the road while fatigued or performing other safety-sensitive activities.

A 1925 Connecticut Supreme Court case addressed the then novel question of a driver's legal duty when possessed by sleep or other unconscious episode. In *Bushnell v. Bushnell,*[10] Mr. and Mrs. Bushnell drove from Connecticut to Rhode Island to drop their son off at college. On the return trip, Mr. Bushnell dozed off at the wheel and crashed into a tree in a single-car accident. Mrs. Bushnell, who had been sleeping while Mr. Bushnell drove, was injured in the accident.

Mrs. Bushnell sued her husband in negligence for failing to operate the car in a reasonable manner. Mr. Bushnell demurred, arguing in essence that he was to be excused from his duty to maintain control of the car while asleep because sleep, like any other unforeseeable blackout condition, comes about without warning. In essence, Mr. Bushnell argued that he had no duty to adjust his driving conduct that day because the instant of sleep onset cannot be determined in advance.

The Court challenged Mr. Bushnell's assertion that he had no warning of sleep onset. The court received medical evidence indicating that unlike a sudden blackout, sleep displays routine and recognizable precursor conditions. Based on early twentieth century medical knowledge, these conditions include sensations of well-being, fatigue, and dulling of the senses. On the basis of this medical evidence, the Court ruled that Mr. Bushnell knew, or should have known, that sleep was overtaking his driving and that he should have pulled off the road. Because his sleep episode was foreseeable, the Court found Mr. Bushnell liable for the cost of his wife's injuries. This ruling sets out the rule that an unforeseeable loss of consciousness, such as a suddenly unexpected seizure or blackout, would excuse the driver's duty to exercise due care in driving.

The "sudden blackout" rule is an important legal protection for drivers who suffer from a sudden and unforeseen onset of sleep or seizure disorder. This awareness may exist as a result of disease or past experience of a tendency to either fall asleep or lose consciousness while driving. If a patient knew that he or she suffered from frequent seizures or narcoleptic episodes several times a day, it would be negligent for that individual to get behind the wheel of a car even if the seizure events were unexpected.

An example of the endurance of the sudden blackout rule is seen in a 2006 Vermont case, *State v. Valyou*.[11] In *Valyou,* the defendant dozed off multiple times on the way to work yet continued his drive, eventually colliding with another vehicle after falling asleep.[11] The Vermont Supreme Court recited the Bushnell rule that falling asleep at the wheel does not, in and of itself, constitute gross negligence.[11] "On the other hand, when a driver is on sufficient notice as to the danger of falling asleep but nevertheless continues to drive, the driver's subsequent failure to stay awake may be grossly negligent."[11] The Vermont Supreme Court held the defendant liable because he remained at the wheel despite his knowledge that he was at high risk for falling asleep and injuring others.

CRIMINAL LIABILITY FOR DROWSY DRIVING

Some states have reviewed their negligent homicide or reckless driving laws and amended these to recognize erratic driving behavior caused by sleep deprivation. The first state to do so was New Jersey through enactment of Maggie's Law in 2003.[12] This law arose following the death of college student Margaret "Maggie" McConnell. McConnell was struck by a driver who had not slept for 30 hours leading up to the crash and had smoked crack cocaine hours before the accident.[13] Unlike drunkenness, no New Jersey statute required the State to consider drowsy driving as a condition or factor in the driver's reckless operation of the car. The judge refused to admit evidence of the driver's sleep deprivation to establish reckless behavior, and the driver received only a $200 penalty for causing the accident.[13]

Maggie's Law is an evidentiary rule establishing that proof of driving after 24 hours of sleeplessness "*shall* give rise to an inference that the defendant was driving recklessly" in order to convict a defendant for vehicular homicide[12] (*emphasis added*). The law also establishes that falling asleep while driving may infer recklessness without regard to sleeplessness.[12]

As finally adopted, Maggie's Law does not criminalize drowsy driving. Fatigued driving provides only inferential evidence that a defendant was driving recklessly. This is to be contrasted with intoxication, the presence of which under Maggie's Law "*shall* give rise to an inference that the defendant was driving recklessly."[12] Thus, unlike proof of intoxication, evidence of drowsy driving in New Jersey will not, by itself, automatically lead to a conviction of reckless driving.

Unlike inebriation, proof of reckless fatigue under Maggie's Law is itself difficult under the law's definition of sleeplessness. Conviction under Maggie's Law requires proof that the defendant was driving "after having been without sleep for a period in excess of 24 consecutive hours." Under this language, evidence that the driver took a 10-minute nap during the

relevant 24-hour period can defeat a prosecutor's offer of the inference of reckless driving due to sleeplessness. Despite its shortcomings, Maggie's Law does open a path for states to consider drowsy driving as a factor in proving reckless driving in vehicular homicide cases.

In 2013, Arkansas became the second state to expand its negligent homicide statute to recognize fatigue as a factor in proving criminal vehicular homicide. The Arkansas law provides that a defendant shall be guilty of a class B felony for negligently causing the death of another person as a result of operating a vehicle, aircraft, or watercraft in a state of intoxication, while passing a stopped school bus, or while fatigued.[14] Fatigue is defined as "having been without sleep for a period of twenty-four consecutive hours," or "having been without sleep for a period of twenty-four consecutive hours and in the state of being asleep."[14] Unlike New Jersey's statute, Arkansas creates no distinction between driving fatigued and driving while intoxicated for purposes of proving negligent homicide.

Several states are now considering drowsy driving statutes similar to those found in New Jersey and Arkansas. High-profile events, such as the sleep-deprived Wal-Mart truck driver who crashed into comedian Tracy Morgan's limousine in 2014, frequently raise public awareness of the issue and draw significant attention of lawmakers.

DUTIES OF PHYSICIANS TO SLEEP DISORDERED PATIENTS

On establishment of the physician-patient relationship, the physician owes the patient the duty of reasonable care present in the community when treating the patient.[15] Very few reported cases can be found that specifically hold a health care provider liable for malpractice surrounding diagnosis or treatment of sleep disorders. A rare example is the 1993 Louisiana case of *Cornett v. State, W.O. Moss Hospital,*[16] which stands for the principle that a physician owes a the duty of reasonable care to treat the patient's conditions and warn the patient of potentially fatal risks that may be associated with untreated sleep disorders such as OSA.

In the Cornett case, the hospital treating Mr. Cornett was found liable for his death after he suffered from cardiopulmonary arrest. Mr. Cornett had complained to the hospital's physicians of sleep apnea symptoms, including his falling asleep at the wheel on three separate occasions. Nonetheless, the hospital physicians focused for months on Mr. Cornett's other medical conditions, ordering endocrinology tests for diabetes and acromaly.

Although the hospital physicians knew that OSA is a potentially fatal condition, Mr. Cornett was never tested or treated for OSA or warned of the risks posed by untreated sleep apnea. At trial, expert witnesses testified that Mr. Cornett's death was likely caused by his untreated sleep apnea. The hospital's own medical expert testified that OSA is an emergency condition. On these facts, the hospital and its physicians were unable to avoid liability for malpractice following the patient's death.[16]

Within the duty of care that a physician owes to patients is the duty to obtain all pertinent information that may be relevant to a patient's health care. In *Feitzinger v. Simon,*[17] the patient, Mr. Feitzinger, was brought in for a routine hernia operation. The anesthesiologist neglected to inquire about Mr. Feitzinger's sleep apnea, and he did not learn about his history of OSA and his current use of CPAP. As a result, CPAP was not recommended for use during the surgery or during recuperation.

Mr. Feitzinger developed pneumonia and died of cardiac arrest 3 days after the hernia operation. His estate sued for malpractice, claiming that if the anesthesiologist had taken Mr. Feitzinger's complete medical history, the anesthesiologist would have known of the patient's OSA and would have recommended CPAP as part of the patient's procedure and recovery. According to expert testimony, CPAP use could have prevented the patient's pneumonia and eventual death. The court determined that the anesthesiologist's failure to check for a sleep-related breathing disorder established sufficient cause to take the trial to a jury.[17]

The principle of informed consent requires a physician who orders surgical treatment for OSA to inform the patient of surgical risks and treatment alternatives such as CPAP.[18] Thus, in *Russell v. Brown,*[18] the plaintiff visited an otolaryngologist complaining of snoring and recurrent tonsillitis. The physician recommended a tonsillectomy for the tonsillitis and the surgical uvulopharyngoplasty procedure for snoring after diagnosing the patient with mild sleep apnea.

The patient suffered complications from the surgery and brought suit against the physician, claiming that the physician never informed the patient of the risks of surgery or the availability of nonsurgical alternatives to his sleep apnea such as CPAP or laser surgery. The jury nonetheless found in favor of the physician.[18] Medical experts testified at trial that the physician's actions reasonably fell within the accepted standard of care. In addition, the patient had signed a broad consent form that undercut his claim of invalid consent. Although the testimony supported the jury verdict in this case, the judge noted the established rule in informed consent cases that patients must be informed of alternative methods of treatment and the risks and benefits of such treatment.[18]

PHYSICIAN'S DUTIES WITH REGARD TO THIRD PARTIES

In the usual case, a physician is not liable for damages to third parties caused by the negligent or criminal acts of his or her patient.[19] In legal terms, it is atypical for a physician to owe a legal duty to unknown third parties.[19] Whether liability for the acts of a physician's sleep-disordered patient redounds to the sleep physician depends on the facts of the case and the physician's documented warning to patients of the potential adverse effects of failure to adhere to disease treatment.

Under a seminal California case, if a physician knew or should have known that his or her patient was likely to cause serious bodily harm to others, such as a psychiatric patient who tells his psychologist of his plans to kill a woman he was stalking, then a duty arises for the physician to take reasonable steps to prevent the patient causing injury to others.[20] However, this duty rarely attaches in circumstances in which the physician merely dispenses medication or diagnoses a potentially debilitating condition.[21] Although some contrary law exists,[22] courts usually reason that it is beyond a physician's control whether a patient takes the medication prescribed for the patient's condition[23] or, in the case of sleep apnea, whether the patient complies or fails to comply with the patient's CPAP therapy.

If a physician prescribes treatment whose use or nonuse could cause an impaired condition, then the physician has a duty to warn the patient of the risks stemming from use or misuse of the treatment.[24] In *Gooden v. Tips*,[25] a physician prescribed Quaalude tablets for his patient but neglected to warn her of the dangers of driving under the influence of the medication. After taking the pills, the patient injured third parties while driving. The injured third parties sued the physician for damages.

The court ruled that the physician was liable to the injured third parties not because the physician had a duty to prevent his patient from driving but because the physician had the duty to warn the patient not to drive, which he failed to do.[25] A physician treating a patient for OSA or another sleep disorder would have a similar duty to warn the patient about the risks of driving while drowsy or under the influence of medication that impairs performance.

The duty to warn applies only when the physician knows or should have known of the patient's condition that could give rise to injuries. In the case of *Calwell v. Hassan*,[26] the defendant physician examined his patient, Sharon Rylant, who complained of disordered sleep and fatigue. The physician ruled out narcolepsy and prescribed Elavil for Ms. Rylant's excessive daytime sleepiness. Ms. Rylant visited the physician for the next 3 years, but she never complained of drowsy driving during the years following her first visit. Ms. Rylant fell asleep while driving sometime later and ran into Calwell, who was bicycling along the street. Calwell sued the physician for failing to warn Rylant not to drive.

The court determined that the physician was not liable for Calwell's injuries.[26] The court focused on the years-long gap period during which Rylant continued to visit the defendant physician but during which she never complained of hypersomnolence. On these facts, the court determined that the defendant did not breach a duty of care by neglecting to warn Rylant of the dangers that hypersomnolence posed to her driving.[26]

A physician may discharge his or her duty to warn by complying with state public safety disclosure laws. These laws, which are discussed in more detail in Chapter 67, either require or recommend physicians to inform governmental public health or motor vehicle officials of the identity of patients who present a danger to the public by continuing to drive.

EMPLOYER'S DUTIES WITH REGARD TO EMPLOYEES WITH SLEEP DISORDER

In the United States, the legal doctrine of *respondeat superior* provides that an employer may be held vicariously liable for the acts of an employee that are performed as part of the employee's duties.[27] Because many employers, such as trucking companies, taxi cab companies, or mail delivery services, employ drivers, those employers will be vicariously liable if the driver falls asleep at the wheel and injures a third party in a crash while performing his or her job.[28]

If the accident occurs within the scope of employment, then the trucking company will often try to defend by denying that their driver acted negligently. Thus, when Norman Munnal fell asleep at the wheel of a tractor-trailer and killed a woman when he drifted into oncoming traffic, his employer invoked Ohio's version of the "sudden blackout" doctrine by blaming the accident on Munnal's "sudden unconsciousness."[29]

As discussed, the sudden blackout defense fails if the defendant knew that loss of consciousness was likely to occur and thus was foreseeable.[29] In the *Munnal* case, Munnal testified that he had a propensity to fall asleep at unpredictable times and that he had fallen asleep at the wheel at least once before.[29] Munnal's fiancé testified that he slept poorly and only slept an average of 3 hours a night despite Munnal's testimony that he slept 8 hours. Munnal was also diagnosed with severe OSA following a sleep test ordered after the accident.[29]

Although there was no evidence that Munnal was aware he had sleep apnea before the test, or that his fiancé had shared her concerns about the quality of his sleep, the court found sufficient evidence that Munnal was aware of his excessive sleepiness. As a result of this knowledge and an expert's testimony that Munnal probably fell asleep rather than suffering from a sudden blackout, the court found Munnal negligent for failing to operate the truck in a safe manner. Munnal's employer was held vicariously liable because Munnal had been operating the rig within the scope of his employment.

EMPLOYER'S OVERSCHEDULING LIABILITY

Some employees who fall asleep at the wheel after the end of an overly long work day have sought to hold their employers liable for scheduling excessive work time. Courts generally refuse to hold employers liable for the postwork actions of their employees, even if the employer contributed to the employee's alleged fatigue.[30]

The case of *Black v. William Insulation Co.*[31] is representative. In that case Black fell asleep while driving and crossed over into oncoming traffic. The resulting collision killed Black. Black's widow sued her husband's employer, alleging that the trucking company negligently required Black to commute long distances and work long hours and that the employer had failed to provide proper training or safeguards to prevent such an accident from occurring.[31]

The court determined that the employer owed no duty to Black and that it was Black's personal responsibility to ensure that he was capable of safely driving to work.[31] Some of Black's personal decisions, such as working a second job and completing long commutes, were considered more significant contributions to his sleepiness than his working conditions.[31]

In *Barclay v. Briscoe*,[32] Sgt. Barclay suffered catastrophic injuries after a head-on collision with Richardson, who had fallen asleep on his way home following a 22-hour work shift. Barclay sued Richardson's estate and his employer. The court stated that it was the employee's responsibility to get to or from work and that absent special circumstances, an employer was not liable for the actions of employees traveling to and from work.[32] The court did not determine the 22-hour shift to be a special circumstance, especially because Richardson elected to complete such a long shift rather than having it forced on him by the company.[32]

EMPLOYER'S DUTY TO ACCOMMODATE AN EMPLOYEE'S SLEEP DISORDER UNDER THE AMERICAN WITH DISABILITIES ACT

The federal Americans with Disabilities Act (ADA) works in conjunction with various state job protection statutes to protect

employees with disabilities from discrimination by their employer.[33] The ADA prohibits employers from firing, failing to promote, or failing to provide "reasonable accommodations" to employees who suffer from a protected disability.[33]

A protected disability is one that limits one or more "major life activities" as defined by the court system.[34] The court seldom adds new major life activities, but it has long held that sleeping and breathing are major life activities.[35] As discussed later, few cases of OSA or other sleep disorders rose to the level of a qualified disability under the law before adoption of the ADA amendments in 2008.

To establish an ADA violation, an employee must show that (1) he or she is disabled; (2) he or she is otherwise qualified to perform the essential functions of the job with or without reasonable accommodation; and (3) the employer took an adverse job action against the employee because of the disability or failed to make a reasonable accommodation.[36]

Before passing of the American with Disabilities Act Amendments Act (ADAAA) in 2008,[37] few courts found that a diagnosis of OSA affected either sleep or breathing sufficiently to trigger ADA protections. By passing the ADAAA, Congress lowered the plaintiff's burden so that he or she needs only to show a "degree of functional limitation," which is a lower standard than the "substantially limits" standard applied before the ADAAA. The ADAAA applies to fact patterns occurring on or after January 1, 2009.

Before the ADAAA, allegations of OSA or sleeping difficulties without proof of an impairment to a major life activity were found insufficient to establish a substantial limitation in the major life activity of sleeping.[37] One court concluded that an individual's inability to get to sleep did not adversely affect the activity of sleep because difficulty sleeping was deemed extremely widespread and because the plaintiff in question did not provide evidence that his difficulties were any worse than difficulties suffered by a large number of other adults.[38] Successful use of oral appliances or positive airway pressure therapy to treat symptoms would also remove OSA as a disability for ADA purposes altogether because the courts found that successful treatment negated disability symptoms.[39]

There were rare circumstances when a court would find OSA severe enough to trigger pre-ADAAA protections,[40] particularly in situations in which therapy such as CPAP failed to relieve fatigue caused by severe sleep apnea.[41] The 2009 Pennsylvania case, *Peter v. Lincoln Technical Institute, Inc.*, is illustrative.[41] There, the plaintiff testified to waking up five to six times a night and falling asleep during the day, even while working and driving to work. The patient's disorder was unresponsive to a variety of therapies, including CPAP, tonsil surgery, oral medication, and pure oxygen therapy. The extreme and untreatable aspects of this particular patient's sleep apnea led to a disability determination.

The ADAAA was designed to refocus ADA cases on determining whether employers are discriminating against their employees, rather than extensively analyzing whether the patient is truly disabled under the legal definition. The plaintiff still possesses a burden of proof to show that he or she is disabled compared with the general population, yet the burden may be met by merely providing physician testimony of a sleeping disorder that interferes with sleep and leads to falling asleep on the job. In addition, successful CPAP treatment no longer acts as a mitigating measure to prevent OSA suffers from claiming a disability under the ADA.

The 2013 case of *Orne v. Christie*[42] showcases several of the changes seen in ADA decisions since the ADAAA was passed. While working as Primary Counsel to the Virginia State Corporation Commission's Bureau of Financial Institutions, Orne was informed he had been sleeping on the job, which he attributed to having difficulty sleeping at night. Orne went to a sleep disorders specialist, was diagnosed with OSA, and was prescribed CPAP. This treatment proved effective in treating Orne's symptoms.

Orne made his employer aware of the diagnosis and treatment plan, yet, after a few months, he was told that he would have to accept a demotion with a pay cut or face termination. The court found that Orne's sleep apnea, and the corresponding sleepiness he experienced during the day, was sufficient to qualify him as disabled under the new ADAAA standards. In addition, the successful CPAP treatment had no impact on the presence of a disability.[42]

SUMMARY

OSA and other types of sleep-related breathing disorders may impair an individual's ability to sleep. This can result in drowsiness during the day and can impair one's ability to work or drive. Although patients have a right to refuse treatment for sleep-related breathing disorders, they may be liable if that decision harms others. For instance, new criminal negligence laws in certain states address impaired driving due to fatigue.

Physicians have obligations when treating a patient with a sleep-related breathing disorder. Physicians who have created a physician-patient relationship must inform patients of the risks of driving while suffering from a sleep-related breathing disorder that may result in severe sleepiness. Employers will be liable for the negligence of their employees, but do not owe any duty to employees for actions after they leave work, even if the employer scheduled the employee to work extremely long hours.

Finally, a 2008 update to the ADA has loosened the definition of a disability for purposes of ADA protections. As a result, sleep-related breathing disorders are more likely to qualify as a disability under the ADAAA language.

Chapter 67

Legal Aspects of Fatigue- and Safety-Sensitive Professions

Daniel B. Brown; Jeffrey Masor

Chapter Highlights

- Lack of sleep can cause mistakes in the workplace. These mistakes can have tragic consequences.
- Various industries, including maritime, aerospace, medical, military, nuclear, and shipping, have implemented regulations concerning fatigue and sleep to reduce workplace accidents.
- Drowsy driving regulations have been implemented in some states, potentially resulting in legal liability when driving without adequate sleep.

Lack of sleep can inhibit performance and cause mistakes in the workplace. Over the past few decades, high-profile incidents resulting from a lack of sleep have created a public awareness of the dangers of sleep deprivation. In response, Congress, as well as many administrative agencies and professional groups, have weighed the harmful risks of lack of sleep and have crafted safety regulations to protect its members in the workplace and the community as a whole.

HISTORY

Lack of sleep can cause mistakes in the workplace that have tragic repercussions. Historically, many accidents have been attributed to lack of sleep. A partial list follows:

- In 1979, a nuclear reactor located on Three Mile Island in Pennsylvania experienced a partial meltdown due to human error.[1] Shift workers were suffering from lack of sleep and did not notice that a stuck valve was causing the reactor to lose coolant.[2] Eventually, the core overheated and was damaged.[3]
- In January 1986, Space Shuttle Challenger exploded moments after launch and resulted in the deaths of all astronauts onboard.[4] This incident has been partially attributed to lack of sleep because key managers had had only 2 hours of sleep and had been on duty since 1 AM, which resulted in poor decision making.[5]
- In April 1986, the Chernobyl nuclear plant experienced a serious meltdown.[6] This disaster was a result of human error in conditions where employees were fatigued after working more than 13 hours.[7] The aftermath of this event resulted in the most horrific nuclear accident in human history.[8]
- In 1989, the Exxon Valdez ran aground and spilled 10.8 million gallons of crude oil into the ocean.[9] This disaster occurred after the third mate stayed awake for more than 18 hours and, being greatly fatigued, did not properly account for the ship's position.[10] This oil spill dealt a great deal of damage to the surrounding wildlife, and the area's environment has still not fully recovered.[11]
- In 1999, American Airlines Flight 1420 crashed during a severe thunderstorm.[12] While the main cause was due to the weather, both pilots for the aircraft were near the end of their 14-hour duty shift and displayed poor judgment by trying to land in an area with such dangerous conditions.[13]
- In 2013, an engineer operating a Metro-North train fell asleep at the controls, which resulted in the train derailing from the track.[14] Although the engineer had no previous record of a sleep disorder, later investigation found that he had sleep apnea.[15]

LEGAL OBLIGATIONS REGARDING FATIGUE IN NON-SAFETY-SENSITIVE INDUSTRIES

Businesses engaging in retail, entertainment, lodging, and other activities not generally considered to be safety sensitive typically operate without regulatory limits on employees' hours of service. Employers in these fields are free to schedule their employees for as many hours of service as their employee desires and as the employer is willing to pay. An employer's legal risk in these industries for their employees' impaired job performance due to fatigue is far more limited than the risk faced by employers in safety-sensitive industries such as transportation.

For example, courts routinely find employers who over-schedule their employees to be free from liability for injuries caused by fatigued employees at the end of their lengthy shift. The case of *Barclay v. Briscoe*, 47 A.3d 560, 427 Md. 270 (Md., 2012), is instructive. In Barclay, a longshoreman fell asleep at the wheel while traveling home after working a 22-hour shift at his job site located at the Port of Baltimore. The longshoreman crashed head-on into a morning commuter, causing catastrophic injuries to the commuter and the longshoreman's own death. The commuter brought suit against the longshoreman's employer for primary negligence in failing to protect the motoring public from an employee driving after an unreasonably long shift.

Following rules laid down by most American state courts, the Maryland Court of Appeals denied the injured commuter's request for damages. The Court found that the employer Ports did no more than establish the work schedule for the job. It did nothing to affirmatively control whether Richardson drove home in a fatigued state. As such, the Court held that an employer has no duty to a third party who might be injured by a commuting employee based solely on the fact that an employee's fatigue was a foreseeable consequence of the employment.[16] In that regard the Court flatly refused "to fashion some type of judicially-imposed maximum working hours standard across all industries."

INDUSTRY REGULATIONS

Unlike employers in non-safety-sensitive industries, employers whose workers' tasks have the direct ability to affect public safety are subject to legal obligations for the fatigue-impaired actions of their employees. These legal obligations arise in the form of government and industry regulation addressing hours of service and fatigue management. The remainder of this chapter discusses a variety of these regulatory schemes.

Maritime

U.S. Maritime law, codified in 46 U.S.C. § 8104, has set rules to reduce accidents due to fatigue. These rules set limits on how many hours an individual may work per day, while leaving an exception for emergencies.

As stated in § 8104, for vessels leaving port, an officer in charge of deck watch must have been off duty for at least 6 hours of the previous 12 hours.[17] When serving on certain kinds of vessels under 100 gross tons, mariners may not work for more than 9 of 24 hours when in port and more than 12 of 24 hours when at sea.[18] An exception waives these requirements during an emergency.[19] On certain larger vessels over 100 gross tons, mariners on the boat must be split into at least three separate watches, where each watch rotates duty shifts.[20] This allows those not on duty to rest and recuperate. Those on deck or in the engine department may not be required to work for more than 8 hours a day.[21] Again, exceptions can apply in case of an emergency.[22]

Specific rules may apply to certain kinds of vessels. For instance, on towing vessels, mariners may not work for more than 12 hours per day, except in an emergency.[23] Furthermore, on a tanker, a mariner may work up to 15 hours of every 24-hour period or up to 36 hours of a 72-hour period, except for emergencies.[24]

National Aeronautics and Space Administration

The National Aeronautics and Space Administration (NASA) has internal regulations over employees and subcontractors that limit work hours "to ensure personnel safety, protect high value assets and to maintain the quality of on-the-job performance."[25] For missions involving suborbital and certain orbital projects, personnel may work up to 72 hours per 7-day period, unless they get a waiver.[26] Only the Director of suborbital and special orbital projects may issue waivers.[27] Personnel may also only work up to 13 days consecutively without a break.[28] NASA has also set a minimum time off between work periods, between 8 and 24 hours, depending on the length of the previous work period.[29]

Medical Residents

New York was the first state to implement residency work duration limits.[30] Support for these regulations grew as a result of the death of a patient due to improper medical care, believed to have been a result of overworked physicians and residents.[31] New York's work duration limits on medical residents, codified in 10 CRR-NY § 405.4, states that work hours for medical residents with inpatient care responsibilities must not exceed 80 hours per week over a 4-week period.[32] In addition, residents must not be scheduled to work for more than 24 consecutive hours.[33] On-call duties for surgical residents are exempt from these requirements if (1) such shifts have infrequent interruptions limited to patients that the resident has a continuing responsibility, (2) this responsibility occurs no more than every third night, (3) a continuous assignment that includes a night shift on-call is followed by a nonworking period of at least 16 hours, and (4) additional policies are implemented by the hospital to relieve residents after an unusually active on-call period.[34]

In 2003, after New York implemented these work hour restrictions, the Accreditation Council for Graduate Medical Education (ACGME) created a new accreditation requirement, mirroring New York's law, which applies to medical residents in all accredited institutions.[35] In 2011, ACGME issued a revised rule that further restricts resident work hours.[36] Currently, ACGME requires that duty hours be limited to 80 hours per week, averaged over a 4-week period, inclusive of all in-house call activities and moonlighting.[37] A review committee may grant programs a limited exception, up to a maximum of 88 hours per week.[38] Residents must be scheduled for a minimum of 1 free day a week, averaged over 4 weeks.[39] At-home calling cannot be assigned on these free days.[40] In addition, duty periods of residents are restricted to a certain duration per day, with minimum time off requirements between scheduled duty periods.[41]

United States Military

Unlike many other regulations that mandate compliance, regulations issued by the U.S. Army tend to act more as a guidance; however, that is to be expected given the uncertain day-to-day conditions in the field. The Army's training regulations recommend that each trainee receive 7 hours of sleep per night.[42] The Army's *Combat and Operational Stress Control Manual for Leaders and Soldiers in the Field* describes the factors considered by military personnel when scheduling time for sleep.[43] The Army recommends the best time for sleep as between 11 PM and 7 AM because of the body's natural circadian rhythms.[44] It also recommends 7 to 8 hours of sleep per 24-hour period and cautions that any reduction in this amount will degrade performance.[45] Although continuous sleep is preferred, sleep may be divided between two or more shorter periods to obtain the full 7 to 8 hours of sleep.[46] The manual also prioritizes the need to sleep based on the task being performed.[47] Leaders making critical decisions have a top priority for sleep.[48] Soldiers on guard duty, performing tedious tasks, or analyzing information have second priority for sleep.[49] Finally, soldiers performing duties that require only physical labor have third priority for sleep.[50]

Nuclear Power Plants

In light of several high-profile nuclear incidents that were at least partially caused by operator fatigue, the U.S. Nuclear Regulatory Commission has mandated limits on the work hours of nuclear power plant operators. As codified in 10 C.F.R. § 26.205, employees may work up to 16 hours per 24-hour period, 26 hours per 48-hour period, and 72 hours per 7-day period.[51] Exceptions may be granted in limited circumstances.[52] Employees must also be provided rest breaks after each work period.[53] These rest break lengths vary depending on how long the employee had been working.[54] For instance, employees must receive at least a 10-hour break after working for at least 10 hours.[55]

In addition, employees must receive a minimum number of days off, depending on their work schedule.[56] For example, employees working 10-hour shifts must have, on average, at least 2 days off of work per week.[57] In the event of an unscheduled preparedness drill, the duration of an employee's unscheduled participation in this drill is not calculated into the hours worked that day.[58]

Railroads

With passage of the Rail Safety Improvement Act of 2008, Congress directed certain railroads to develop and implement a railroad safety risk reduction program.[59] By statute, the program must include a fatigue management plan designed to reduce fatigue experienced by railroad employees and to reduce the likelihood of accidents, incidents, injuries, and fatalities caused by fatigue.[60] This fatigue management plan must consider physiologic and human factors that affect fatigue and promote appropriate fatigue countermeasures to address safety concerns, such as scheduling practices, napping policies, and avoidance of abrupt changes in rest cycles for employees.[61]

Existing regulations address hours of service limitations for railroad employees as follows. These regulations, codified in 49 U.S.C. § 21103, provide that employees may spend up to 276 hours per month working for their carrier.[62] In addition, employees are limited to no more than 12 consecutive hours of work.[63] Each employee must receive at least 10 consecutive hours of off-duty time per 24 hours.[64] Employees must not work more than 6 or 7 consecutive days, depending on how much time the employee had off before that work duration.[65] Exceptions may apply in case of emergency; however, even then, employees are limited to 4 additional hours per 24-hour period.[66]

Trucking

Drowsiness among truck drivers is a highly prevalent risk in the trucking industry. For instance, a Federal Motor Carrier Safety Administration–sponsored study found that 45% of U.S. truck drivers sometimes or often had difficulty staying awake while driving.[67] In addition, a number of high-profile accidents have involved truck drivers who fell asleep at the wheel,[68] and a 5-day study found that truck drivers tended to average 4.78 hours of sleep per day with only 5.18 hours in bed per day.[69] As a result, regulations limit the number of hours a truck driver may be on the road.

Trucking regulations cover commercial motor vehicles (CMVs). A CMV vehicle is one that either (1) weighs 10,001 pounds or more; (2) is transporting hazardous materials such that it requires a placard; (3) is designed or used to transport 16 or more passengers, including the driver, not for compensation; or (4) is designed or used to transport 9 or more passengers, including the driver, for compensation.[70]

Solo truck drivers that transport property may drive for a maximum of 11 hours after 10 consecutive hours off duty.[71] At the same time, a driver cannot be on duty for more than 14 consecutive hours.[72] Drivers may not drive more than 60 hours per 7-day period or 70 hours per 8-day period.[73] However, truck drivers who reach this hour limit may rest for 34 consecutive hours that include two nights from 1 AM to 5 AM, and then they may resume driving.[74] This "restart" may be used up to once per 168-hour period.[75] Truck drivers are also required to take a 30-minute break during the first 8 hours of a shift.[76]

The U.S. Department of Transportation (DOT) is also working toward requiring drivers to undergo sleep apnea testing. Although the DOT gained the congressional authority to require this testing in October 2013, a lengthy, formal rule-making proceeding must first be completed before this requirement may take effect.[77] A formal rule-making proceeding is a process whereby the administrative agency researches the costs and benefits of a new rule and allows for public comment from the industry.[78] Some applauded this decision, arguing that testing and treatment of obstructive sleep apnea could cost the industry more than $1 billion; the government should take its time to ensure that proper analysis is completed and that suitable regulation language is chosen.[79] Others see the rule-making process as an unnecessary delay in a much-needed rule.[80] These groups worry that the rule-making process will take several years and that new sleep testing requirements may never be implemented.[81]

Airlines

Airline pilots are restricted from working excessive hours by the Federal Aviation Administration (FAA). Pilots of a one- or two-pilot crew may fly for up to 500 hours per calendar quarter, 800 hours per two consecutive calendar quarters, and 1400 hours per calendar year.[82] For a 24-hour period, work duration limits vary depending on whether it is a one- or two-pilot crew.[83] For a one-pilot crew, the total flight time cannot exceed 8 hours.[84] For a two-pilot crew, the total flight time cannot exceed 10 hours.[85] After a duty period, a varying amount of rest is required depending on whether the destination crosses time zones and whether the flight was extended because of unforeseen factors, such as bad weather.[86] For instance, a multiple–time zone flight that had no unforeseen extensions of flight time would require that the pilot rest for at least 14 hours.[87]

Currently, the FAA requires that all pilots diagnosed with OSA be treated in order to be fit to fly an aircraft.[88] Like the DOT, the FAA is also working toward requiring sleep testing.[89] Although Congress gave the FAA the authority to implement this new testing requirement, Congress also required that the FAA complete a formal rule-making process.[90] The FAA initially planned to limit this requirement to pilots with a body mass index of more than 40.[91] Over time, the FAA intended to reduce the requirements for mandatory sleep testing until all pilots had been tested.[92] However, this rule has undergone several revisions in its quest to become a new mandatory requirement.[93] For instance, on March 28, 2014, the FAA proposed rule had been changed to require

pilots to undergo testing based on a recommendation by an Aviation Medical Examiner who considers all obstructive sleep apnea risk factors.[94]

DROWSY DRIVING

Drowsy driving can greatly increase the risk for a collision. For instance, a study found that the risk for a car crash nearly tripled when drivers had less than 5 hours of sleep in a 24-hour period.[95] Drowsiness has also been compared with alcohol consumption. In one study, individuals who had been awake for 24 hours performed like an individual with a blood alcohol concentration of 0.10%.[96] For comparison, the legal blood alcohol concentration limit in the U.S. is 0.08%.[97]

In addition to regulating professionals' sleep, some states have amended laws to factor sleep deprivation into their definition of criminally reckless driving. The first state to do so was New Jersey, which enacted legislation referred to as "Maggie's Law" as part of the state's criminal code in 1997, following the death of college student Margaret "Maggie" McConnell.[98] A driver, who had not slept for 30 hours before the crash and had smoked crack cocaine hours before the accident, hit McConnell.[99] During litigation, the judge refused to admit evidence of the driver's sleep deprivation to establish reckless behavior, and the driver received only a $200 penalty for causing the accident.[100]

Maggie's Law is an evidentiary rule establishing that proof of driving after 24 hours of sleeplessness "*may* give rise to an inference that the defendant was driving recklessly" *(emphasis added)*.[101] The law also establishes that falling asleep while driving may infer recklessness without regard to sleeplessness.[102] Although it may prove difficult to establish that a driver was asleep at the wheel at the time of the collision, or had been awake for the entirety of the 24-hour statutory period, Maggie's Law establishes that drowsy driving, if proven, can uphold a criminal conviction in the State of New Jersey.

In 2013, Arkansas became the second state to pass a drowsy driving amendment to its negligent homicide statute, making it a class B felony to negligently cause the death of another person as a result of operating a vehicle, aircraft, or watercraft while fatigued.[103] *Fatigued* is defined as "having been without sleep for a period of twenty-four (24) consecutive hours," or "having been without sleep for a period of twenty-four (24) consecutive hours and in the state of being asleep."[104]

Several states, including Massachusetts, Tennessee, New York, and Oregon, have attempted to pass statutes similar to those found in New Jersey and Arkansas that would criminalize drowsy driving.[105] Although these attempts have proved unsuccessful thus far, high-profile events, such as the sleep-deprived Walmart truck driver who crashed into comedian Tracy Morgan's limousine in 2014,[106] frequently raise public awareness of the issue and draw significant attention of lawmakers.

CLINICAL PEARLS

- As a general matter, in situations after work hours, employers do not have a legal duty to protect the motoring public from the drowsy driving of employees whose fatigue may have been caused by the employer overscheduling the employee's work shifts.
- On the other hand, employers are liable under law for the negligent acts of their employees, such as vehicular accidents caused by impaired driving because of fatigue, if the accident occurred during the employee's course of employment.
- To protect the public, the U.S. government imposes hours of service regulations on many safety-sensitive industries, such as commercial trucking, nuclear power, and commercial airlines.

SUMMARY

Lack of sleep can cause mistakes in the workplace and while driving, leading to tragic consequences. Historically, many high-profile accidents have been at least partially attributed to lack of sleep. Various industries, including maritime, aerospace, medical, military, nuclear, and shipping, have implemented regulations concerning fatigue and sleep in order to reduce workplace accidents. For instance, the ACGME requires that medical residents limit their duty hours in order for a medical institution to maintain its accreditation. Some states have also implemented drowsy driving regulations, which result in criminal liability for a driver who causes a collision after remaining conscious for at least 24 hours.

Sleep Medicine Clinical Practice and Compliance—United States

Daniel B. Brown

Chapter Highlights

- The delivery of sleep medicine and the treatment of sleep disorders in the United States are highly fragmented. Government and most commercial insurance payers cover sleep medicine, sleep testing, and sleep therapy under separate reimbursement categories with separate requirements for licensure, accreditation, personnel certification, and coverage conditions. Legal restrictions on patient self-referrals can limit, in certain cases, the ability of treating physicians to dispense continuous positive airway pressure (CPAP) or other items of durable medical equipment to treat their own patients' sleep disease.
- In-laboratory and home sleep testing for obstructive sleep apnea performed by physicians and stand-alone sleep centers are reimbursed by Medicare, Medicaid, TRICARE, and most commercial insurance payers. Polysomnography and home sleep testing (HST) for many other sleep disorders, such as insomnia, restless legs syndrome, and narcolepsy, are not typically covered by government or private insurance.
- The government views polysomnography, HST, and CPAP treatment as an activity ripe for fraud and abuse. Accordingly, government health care programs condition reimbursement for sleep medicine services to a wide array of technical requirements, including, but not limited to, a face-to-face examination by a treating physician whose notes must include certain specified notations, testing by laboratories whose programs are accredited by select agencies and who use only certified sleep technicians, test interpretations by physicians who hold certain board certifications, and CPAP dispensing only by durable medical equipment suppliers who, in the case of home sleep tests, are not affiliated with the provider of the home sleep test.

Like many chronic conditions, detection and treatment of obstructive sleep apnea (OSA) and other sleep disorders triggers a complex range of clinical activity. Patient care plans for sleep-disordered patients include medical examinations, overnight testing, ongoing respiratory or dental appliance treatment with durable medical equipment, monitoring, and follow-up. This collection of care services touches a wide variety of legal, regulatory, and reimbursement rules, few of which operate in concert to promote seamless delivery of clinical sleep medicine.

This chapter addresses some of the legal, regulatory, and reimbursement roadblocks sleep practitioners in the United States face in offering their services to their sleep-disordered patients.

STATE LICENSING OF SLEEP SERVICES

State Licensing for Sleep Laboratories

Many states allocate health care resources within their borders through the Certificate of Need (CON) process.[1] Obtaining a CON for the operation of a health care facility is a lengthy, expensive, and often adversarial process. Fortunately, sleep laboratories will typically fall below the threshold for CON review and escape review requirements in CON states.[2]

Separate from CON review are state laws requiring health care facilities to obtain licensure before operation. Although diagnostic testing performed as part of a hospital or physician practice is almost always exempt from state health care facility licensure, freestanding sleep laboratories may fall within a state's regulatory jurisdiction as a "health care clinic" or other health care facility.[3] Freestanding laboratories are sleep laboratories operated separately from physician practices or hospitals.[4]

At least three states now require freestanding sleep laboratories to obtain health facility licensure before operating. These states are Florida,[5] New Jersey,[6] and Alabama.[7] Licensure requires completing an application and disclosing the laboratory's ownership structure, medical supervision, and affiliations with other health care facilities.[8] Interestingly, these states require facility licensure even if the entity performs only home or portable sleep tests in the absence of any physical health care structure visited by patients. Other states may join in regulating the licensing of freestanding sleep laboratories.

Sleep Physician Certification

Physician certification in the specialty of sleep medicine is a fairly recent phenomenon. The American Board of Sleep Medicine (ABSM) began issuing diplomate status in Sleep Medicine to physicians and PhDs in the late 1970s. After 2007, the American Board of Medical Specialties (ABMS) began issuing subspecialty board certification to physicians in

sleep medicine as part of the boards of internal medicine, family medicine, anesthesiology, otolaryngology, pediatrics, and psychiatry and neurology.[9]

As discussed later, government and commercial payers often require that the physicians who interpret polysomnograms or home sleep tests hold ABSM, ABMS, or certain other credentials as a condition for reimbursement. However, one state—Oklahoma—has adopted legislation that prohibits non–board-certified physicians from interpreting sleep tests without regard to the source of payment for the test.

Believing that public safety requires specific regulation of sleep disorders testing, the Oklahoma legislature in 2009 adopted the Oklahoma Sleep Diagnostic Testing Regulation Act.[10] The act establishes minimum medical standards of care in the field of sleep medicine. It declares that it is illegal in Oklahoma for a licensed physician to interpret a sleep test unless the physician is board-certified in sleep medicine by the ABSM or ABMS. Alternatively, the interpreting physician must have completed a 1-year sleep medicine fellowship accredited by the Accreditation Council for Graduate Medical Education or received a Certification of Special Qualifications or a Certification of Added Qualifications in Sleep Medicine issued by the American Osteopathic Association. Otherwise, it is illegal for a medical doctor in Oklahoma to interpret the results of a diagnostic sleep test performed in Oklahoma.[10]

Oklahoma also establishes minimum requirements for sleep testing facilities and their employees.[10] Under the Act, (1) sleep diagnostic testing facilities in Oklahoma must be fully or provisionally certified or accredited as a sleep laboratory by the American Academy of Sleep Medicine (AASM), the Accreditation Commission for Health Care (ACHC), or The Joint Commission; (2) Oklahoma sleep laboratories must be supervised by board-certified sleep physicians; and (3) home sleep testing must be performed by technicians who are supervised by board-certified sleep physicians.[10] In this regard, the Oklahoma law is the most intrusive in the nation.

State Licensing for Nonphysician Polysomnography Technicians

Nonphysician persons who perform and score sleep tests have specialized skills and training. These individuals have enhanced their professional skills and standing by earning certification through organizations such as the Board of Registered Polysomnographic Technologists[11] and the American Association of Sleep Technologists.[12] These credentialing entities generally recognize three levels of sleep technician expertise: trainee, technician, and technologist.[13]

Sleep laboratories are encouraged to use technicians holding Board of Registered Polysomnographic Technologists or American Association of Sleep Technologists credentials. Some payers require the participation of certified technicians as a condition to payment. For example, Medicare will not consider a sleep test performed by an independent diagnostic testing facility to be medically necessary unless the technician attending the overnight test or handling the home sleep test is properly credentialed.

Quite apart from bodies that credential sleep technicians are a handful of state medical boards that impose licensure requirements on sleep technicians operating in their state. For example, the states of Idaho,[14] Tennessee,[15] New York,[16] and California,[17] among several others, have recognized the allied health profession of polysomnography (PSG) and adopted mandatory licensure requirements for these nonphysician sleep test personnel. In New York, for example, licensure of PSG technologists requires applicants to be at least 18 years old, complete educational requirements that provide knowledge of PSG technology, pass an examination, and prove "good moral character."[18] Sleep laboratories that fail to use licensed sleep technicians, when required, face potential state law criminal or civil penalties.[19]

Because CPAP titration performed during PSG borders on respiratory therapy, some state respiratory therapy boards have brought disciplinary actions against some sleep laboratories for the unlicensed practice of respiratory therapy.[20] States that have adopted PSG technology laws typically exempt licensed PSG technicians from any requirement to hold a respiratory therapy license.[20]

State Licensing for Dispensing Continuous Positive Airway Pressure

Because CPAP is a prescriptive device under the U.S. Food and Drug Administration rules,[21] CPAP is considered a medical device for most state law regulatory purposes. CPAP is also an item of durable medical equipment (DME) for purposes of state law[22] and for insurance reimbursement purposes.[23]

Roughly half of states, including Florida,[24] Tennessee,[25] and Ohio,[26] require persons or entities that dispense DME, like CPAP, to obtain a state license before delivery of DME items. Almost all states that license DME suppliers exempt physicians or other licensed health care practitioners, who dispense devices from their practices to their patients, from licensure.

Notwithstanding licensure of the CPAP supplier, most states consider CPAP titration and education to be the practice of respiratory therapy to be performed only by persons holding respiratory therapy licenses issued by the applicable state.[27] States that have licensed or regulated the activities of PSG technicians have almost universally exempted PSG technicians from also obtaining a respiratory therapy license.[28]

REIMBUREMENT FOR SLEEP MEDICINE SERVICES

Reimbursement drives the delivery of health care services in America. The provision of sleep medicine and the types of testing and treatment depend, in large part, on the coverage conditions that health insurance plans impose on the providers of sleep disorders services.

Medicare Coverage for Sleep Testing

The Medicare Part B Program covers in-laboratory and home sleep testing performed by physicians or stand-alone independent diagnostic testing facilities as "other diagnostic tests" payable under the under Medicare's Physician Fee Schedule.[29] Medicare reimburses hospitals for hospital sleep tests under Medicare's Outpatient Prospective Payment System.[30] Services under this system are classified into groups called ambulatory payment classifications (APCs), with payment rates established for all activities assigned to each classification group.[31] For example, home sleep tests are payable under APC group 213,[32] and attended PSGs are in the APC group 209.[32]

Medicare coverage for all diagnostic tests requires a physician's order and proper physician supervision.[33] The Centers for Medicare and Medicaid Services (CMS) has delegated to

Medicare Administrative Contractors (MACs) the authority to specify special medical necessity coverage conditions for activities in the MAC's jurisdiction.[34] Some MACs, such as are Cahaba Government Benefits Administrators, LLC, have not adopted local coverage determinations (LCDs) describing special conditions for sleep test coverage in Cahaba's oversight area of Alabama, Georgia, and Tennessee. Thus sleep laboratories seeking Medicare reimbursement for sleep tests in those states need not hold any sleep laboratory accreditations or, other than independent diagnostic testing facility sleep laboratories, engage only certified technicians.

On the other hand, the Part B MAC for Florida, First Coast Service Options, Inc., and many other MACs have published LCDs for sleep testing in their jurisdictions. First Coast's LCD, L29949, is quite restrictive.[35] For example, in Florida, a sleep test will be medically necessary and payable by Medicare only if (1) the laboratory is accredited by the AASM, ACHC, or The Joint Commission; (2) the physician interpreting the test is board-certified or meets certain other criteria; and, among other items (3) the technicians performing the test, even the home sleep test, holds certain certifications or evidence of training.[35] First Coast further requires that each patient have a face-to-face examination with a physician before testing.[35]

The notes of the physician visit covered under the First Coast Local Coverage Determination must contain a sleep history and physical examination, an Epworth sleepiness scale, notations of the patient's body mass index and neck circumference, and a focused cardiopulmonary and upper airway evaluation.[35] First Coast takes the position that sleep tests for Medicare patients whose initial examination notes do not show the measurement of neck size circumference, body mass index, or Epworth scores are not medically necessary and are ineligible for Medicare coverage, even if all other indications for OSA are present and made clear in the examination notes.[35]

Medicare Coverage for CPAP Therapy

Because Medicare categorizes CPAP devices, CPAP masks, oral appliances, and items of CPAP resupply as DME, Medicare coverage for such items derives from a Medicare fee schedule and system separate from Medicare coverage available for sleep examinations and sleep testing.[36] This bifurcation means that Medicare reimbursement for OSA treatment devices follows its own separate rules and coverage conditions.

For example, CPAP suppliers who enroll in the Medicare system must adhere to a complex set of 30 or so supplier standards, including minimum space, insurance coverage and hours of operation requirements, possession of accreditation from selected accrediting bodies, and the posting of a $50,000 surety bond to offset losses due to improper practices.[37] Medicare enrollment and payments are governed by regional DME Medicare Administrative Contractors, each of which has published a similar LCD indicating the conditions of coverage for CPAP reimbursement in the contractor's jurisdiction.[38] According to these LCDs, Medicare will reimburse a DME supplier for CPAP to treat OSA only in the following circumstances:

1. The beneficiary has a face-to-face clinical evaluation by the treating physician before the sleep test to assess the beneficiary for OSA.
2. The beneficiary has a sleep test showing minimum criteria for OSA.
3. The sleep test is performed by a test provider who meets Medicare coverage for sleep testing.
4. The sleep test is interpreted by a boarded sleep physician or a physician on staff of a sleep center accredited by the AASM, ACHC, or The Joint Commission.
5. The beneficiary shows continued use of the device and that he or she benefits from the device within 90 days of initiation by subjective and objective evidence.[38]

In 2008, CMS stated that it believes that the sleep test provider has a self-interest in the result of that test if the provider, or its affiliate, also supplies the CPAP device. To CMS, affiliations between the test provider and the CPAP supplier provided an incentive to test more frequently or less frequently than is medically necessary and to interpret a test result with a bias that favors self-interest.[39]

In an effort to curtail these perceived abuses, CMS adopted a special payment prohibition in 2008 that prohibits Medicare from paying a DME supplier for CPAP if the CPAP supplier is directly or indirectly affiliated with the provider of the sleep test from which a diagnosis of OSA is obtained.[40] *Affiliation* means a relationship among parties by compensation arrangement or ownership.[41] This special payment prohibition only applies if the underlying sleep test is a home sleep test. In other words, Medicare will reimburse a DME supplier for CPAP even if the DME supplier is affiliated with the provider of the sleep test, as long as full, in-laboratory PSG was used to diagnose the patient's OSA.[40]

Medicaid Coverage

Medicaid is a state-run health care program subsidized with federal funds but operated under terms and conditions adopted by individual states for their citizens. A comprehensive 50-state survey of Medicaid coverage for sleep testing is beyond the scope of this chapter. However, the coverage conditions for sleep tests under the State of Washington's "Apple Health" Medicaid program are illustrative.

Apple Health will reimburse participating providers only for the performance of full, in-laboratory PSG or a Multiple Sleep Latency Test.[42] Home sleep testing is not a covered service under Apple Health at this time.[42] The PSG and Multiple Sleep Latency Test are covered only if ordered by the client's physician and performed in an agency-designated center of excellence that is an independent diagnostic testing facility, sleep laboratory, or outpatient hospital.[42] Providers obtain eligible center of excellence status if they hold sleep laboratory accreditation from the AASM and at least one staff physician is board-certified in sleep medicine.[43]

Commercial Insurance Coverage of Sleep Testing

Almost all commercial health insurance plans cover testing for OSA. The conditions for coverage vary widely according to the terms of the individual plan. Although commercial payers cover the attended, in-laboratory PSG as the gold standard method of detecting OSA, these payers are now promoting the less expensive home sleep test for their members.[44] Large health plans do this by requiring plan members to obtain prior authorization for the more expensive in-laboratory PSG.[45] Absent a showing that an in-laboratory PSG is medically necessary, the payers will cover only the less expensive home sleep test for purposes of detecting OSA.[45]

FRAUD AND ABUSE LAWS

Health care fraud and abuse laws can be separated into two separate conceptual categories. One category deals with prohibited self-referrals. These laws prohibit physicians from referring their patients to entities in which the physicians or their families have an ownership or other financial interest. On the federal level, the major regulation in this area is the Stark Law.

The other broad category is anti-kickback laws. These prohibit any person (not just doctors) from paying or receiving money, or other items of value, for the referral of a health care service.[46] The federal anti-kickback law extends beyond payments for referrals alone.[46] This law also covers payments, gifts, or other valuable items to anyone who merely recommends or even arranges health care services reimbursed by Medicare, Medicaid, or any other federal health care program.[46]

The Stark Self-Referral Law

Absent an exception, the federal Stark Law prohibits a physician (or an immediate family member of such physician) from making a referral for a designated health service to an entity in which the physician has a direct or indirect ownership or compensation arrangement—if the service is reimbursed by Medicare or Medicaid.[47]

Penalties for violating the Stark Law include denial of payment, refunds of amounts collected in violation of the statute, and a civil money penalty of up to $15,000 for each bill or claim for a service a person knows or should know is for a service for which payment may not be made.[48] If the physician or the entity engages in a circumvention arrangement that the physician or entity knows, or should know, has a principal purpose of indirectly evading the Stark Law, the civil money penalty jumps to $100,000 for each such arrangement or scheme.[49]

Only referrals for designated health services are prohibited. Overnight PSG or home sleep testing, generally characterized as a type of electroencephalogram, does not fall within any of the categories of designated health services.[50] Consequently, a physician's referral of a Medicare or Medicaid sleep test falls *outside* the Stark Law prohibition, unless the sleep test is performed in a hospital setting. Inpatient and outpatient hospital services are designated health services, and a physician's referral of a Medicare or Medicaid sleep test performed as an inpatient or outpatient hospital service would be considered a referral of a designated health service. However, a violation would occur only if the referring physician had an ownership or compensation arrangement with the hospital that did not meet a Stark Law exception.

Self-Referrals for Durable Medical Equipment

Unlike referrals for nonhospital sleep tests, referrals for DME *are* referrals for designated health services under the Stark Law.[51] Because CPAP and oral appliances are items of DME, the entirety of the Stark Law applies to these items of OSA treatment. This means that, absent an exception, a physician may not refer a patient to a DME supplier in which the physician or a member of the physician's family has an investment or compensation interest, if the DME supplier requests payment of the item from a government health care program.

The Stark Law exempts referrals of certain items of DHS that are ancillary to the physician's in-office procedures, such as imaging or prescription drug services. This in-office ancillary services exception permits physicians to refer items of DHS to be furnished by the physician's own practice if certain conditions are met.[52]

Unfortunately, items of DME such as CPAP or oral appliances are not included in the in-office ancillary services exception.[52] This means that a physician may not furnish CPAP to his or her own OSA patient from the physician's office if the patient is a Medicare or Medicaid beneficiary, unless another Stark Law exception exists, such as the rural provider or personally performed exceptions.

State Self-Referral Laws

Many states have their own laws restricting self-referrals. Some states, such as Michigan, adopt language very close to the federal Stark Law.[53] Therefore an exception under the federal law is likely an automatic exception under the state law.[53] Other states, such as Georgia, use their own definitions and exceptions.[54]

Importantly, these states punish self-referrals regardless of the reimbursement of the item or service by a federal or state health care program.[54] Referrals of even private-pay patients to entities owned by the physician or in which the physician has a compensation arrangement not covered by an exception may be unlawful under these laws.

Federal Anti-Kickback Statute

The federal Anti-Kickback Statute makes it unlawful for anyone to knowingly and willfully solicit or receive any payment in return for referring an individual to another person or entity for the furnishing, or arranging for the furnishing, of any item or service that may be paid in whole or in part by any federally funded health care program.[55]

Violations of the law require the solicitation, offer, payment, or acceptance of illegal remuneration.[55] Remuneration includes the transfer of anything of value in cash or in kind (e.g., goods), whether made directly or indirectly, and whether made overtly or covertly.[55,56]

The statute is a two-way street. Soliciting for and accepting payments in return for referrals is as bad as paying the kickback itself. A violation of the Anti-Kickback Statute constitutes a felony punishable by a maximum fine of $25,000, imprisonment for up to 5 years, or both.[55] Conviction will also lead to automatic exclusion from Medicare, Medicaid, and other federally funded health care programs.[57]

Civil monetary penalties may be applied to violations of the Anti-Kickback Statute in the amount of $50,000 for each act that violates the statute, plus three times the amount of remuneration unlawfully transferred.[58] Significantly, the imposition of civil monetary penalties requires proof by only a preponderance of the evidence, not proof beyond a reasonable doubt, which is required for criminal penalties.[59] Consequently, it is easier for the government to establish violations in a civil proceeding than in a criminal proceeding. The addition of civil monetary penalties increases the risk associated with practices that implicate the statute but are not protected by statutory exceptions or regulatory safe harbors, discussed later.

Anti-Kickback Exceptions and Safe Harbors

The Anti-Kickback Statue has the breadth to capture almost every health care transaction in the United States.[55] At risk

are not only envelopes stuffed with cash but also a wide array of negotiated business practices—sales commissions, below-market rent, distributions arising from joint ventures with suppliers, expensive gifts, medical director fees, and certain equipment rental arrangements. It is these arrangements that the government or its contractors may review as part of its audit of sleep test services.[60]

Responding to industry concerns, Congress has included several exceptions in the law and approved the promulgation of specific "safe harbor" payment practices.[61] Examples of safe harbor arrangements common in sleep medicine include joint ventures among referring physicians and sleep test providers, medical director and other personal services agreements, and space lease arrangements. Compliance with all aspects of the applicable safe harbor protects the actor from prosecution under the Anti-Kickback Statute. However, failure to meet each of the elements of the applicable safe harbor does not automatically mean that the activity is illegal. The activity may be acceptable in the eyes of the government, depending on a variety of factors.

State Anti-Kickback Laws

Many states have enacted their own anti-kickback laws. Almost all state physician-licensing boards prohibit paying or sharing fees for referrals. Some, like California and Florida, criminalize payments or in-kind exchanges to refer patients.[62,63]

The Florida Patient Brokering Act makes it illegal for any person, including any health care provider or health care facility, to (1) offer or pay any commission, bonus, rebate, kickback, or bribe, directly or indirectly, in cash or in kind, or engage in any split-fee arrangement, in any form whatsoever, to induce the referral of patients or patronage from a health care provider or health care facility; (2) solicit or receive any commission, bonus, rebate, kickback, or bribe, directly or indirectly, in cash or in kind, or engage in any split-fee arrangement, in any form whatsoever, in return for referring patients or patronage to a health care provider or health care facility; or (3) aid, abet, advise, or otherwise participate in such conduct.[63] The act specifically covers the actions of attorneys and other advisors and participants who counsel persons in the participation of such arrangements.[63]

Federal False Claims Act

Presenting a claim to CMS for payment for an item or service performed in violation of the Stark Law or Anti-Kickback Statute may constitute a false claim under the federal False Claims Act. Enacted during the Civil War to deter war profiteers,[64] the False Claims Act permits private "whistleblowers" to bring actions against health care companies for filing fraudulent claims with the government.[65] Penalties include repayment of the fraudulent claim and a mandatory civil penalty of at least $5500 and no more than $11,000 per claim, which amounts can be tripled.[66] The whistleblower gets to keep a percentage of the damages and penalties, which could be as much as 30% in some circumstances.[66] Because the penalties could reach upward of $30,000 per sleep study performed, potential recoveries under the law add up quickly.

The risk to sleep laboratory operators under false claims whistleblower statutes has increased in recent years. A wave of states have adopted state False Claims Acts that mirror the federal False Claims Act in many respects.[67]

Sleep laboratories and sleep physicians participating in government reimbursement programs are well advised to adopt compliance plans, or take other audit and monitoring actions, to ensure compliance with fraud and abuse laws.

SUMMARY

Although sleep testing and CPAP devices may be reimbursed under Medicare, Medicaid, and private payers, many wide-reaching prohibitions on reimbursement fraud and abuse have been established. On the federal level, the Anti-Kickback Statute prohibits medical practices from offering or receiving any direct or indirect remuneration to encourage the referral of patients. In addition, the Stark Law prohibits physicians from referring designated health services to an entity owned by themselves, an immediate family member, or to someone with whom the physician has a financial relationship, unless an exception applies. Furthermore, the False Claims Act prohibits medical providers from fraudulently billing for medical services from government payers. States may also have their own fraud and abuse legislation. To provide these services, some states require licensing for technologists performing sleep testing. Oklahoma has even more stringent rules that require physicians to possess specialized credentials to interpret sleep tests.

Sleep Medicine Clinical Practice and Compliance—Europe

Thomas Penzel

Chapter 69

Chapter Highlights

- European sleep medicine is coordinated through the European Sleep Research Society (ESRS). The ESRS is composed, in part, of the Assembly of National Sleep Societies with delegates from all European Sleep societies. The levels of sleep medicine and sleep medicine delivery differ in European countries according to the health care systems in the various countries.
- The ESRS has published European guidelines for certification of sleep physicians, psychologists, scientists, and sleep technologists. Examinations for European somnologists started in 2012.
- European sleep center certification guidelines have been published, and a network of research centers has been created. Harmonized guidelines for sleep medicine center accreditation in Europe are being considered by various European national sleep societies with support from the ESRS.

Sleep medicine research in Europe has a long tradition with a strong focus on basic science. A variety of medical and educational institutions across Europe long engaged in sleep research resulted in pioneering insights in the past century. In 1972, a small group of individual sleep researchers and clinicians sought a forum to exchange and advance scientific ideas relating to sleep research and founded the European Sleep Research Society (ESRS or Society) in Switzerland.[1] Since then the Society has become the pre-eminent aggregator and distributor of sleep research in Europe. Its goals are to promote sleep research in Europe, to improve care for patients with sleep disorders, and to disseminate information regarding sleep research. The ESRS is a founding member of the World Federation of Sleep Research Societies. In 1992 the ESRS founded the *Journal of Sleep Research,* and the Society holds biannual conferences in different cities all over Europe.

Unlike sleep research, the development and delivery of sleep medicine for European patients suffering from sleep disorders have evolved independently along national lines. This is because the health care systems in Europe differ much among the countries. In the beginning European sleep medicine was closely related to clinical research, which the ESRS exchanged among pioneering sleep medicine groups in various European countries.

Today there are large national sleep societies with a few thousand members in those European countries that have large populations. Many of these national sleep societies outnumber the membership of the ESRS. However, many European countries with smaller populations do not have reasonably sized national sleep societies and do not have the infrastructure to run professional societies. For these countries the ESRS is of utmost importance to provide support for national sleep medicine needs and services.

In 1994 the ESRS set up a clinical committee to exchange national experiences regarding sleep medicine services in Europe. The committee also sought to coordinate activities among the different insurance and reimbursement schemes across Europe. Additional goals of the committee included the development of standard practice papers and support for the educational exchange of sleep medicine clinicians across Europe.

The Assembly of National Sleep Societies (ANSS or Assembly) grew out of this committee's work. The Assembly is a membership organization comprising approximately 30 national European sleep societies. The association is devoted to the clinical needs of sleep physicians and is made up of national delegates who exchange ideas and concepts to serve sleep-disordered patients and promote sleep medicine in Europe. The ANSS exists under the auspices of the ESRS.

In 2004 the ESRS board met with the national society presidents as representatives of the ANSS for the first time. The Assembly agreed that a number of unifying policies and procedures addressing the delivery of sleep medicine in Europe would be desirable. Acting through task forces, the ANSS and ESRS developed uniform standards for European sleep center accreditation in 2006,[2] certification of sleep professionals in 2009,[3] clinical procedures for adults in accredited sleep centers,[4] and clinical education standards in 2014.[5] Each of these standards and procedures has been published in the *Journal of Sleep Research*.

To address the patchwork standards of European countries that did not adopt ESRS protocols, the ESRS established the Sleep Medicine Committee (SMC) of the ESRS in 2010. The SMC is charged with adopting and promoting (1) standards of practice papers and guidelines for clinical service, (2) certification of sleep medicine professionals (physicians,

psychologists, and other scientists, technicians), and (3) accreditation of sleep medicine centers.

The SMC provides certification and accreditation to sleep professionals and sleep centers in countries that do not have access to national certification and accreditation or that desire to supplement national accreditation with the ESRS emblem. Working with national delegates at the ANSS, the SMC works on educational courses together with other groups of the ESRS to provide educational opportunities. The SMC acts as an educational clearinghouse to help standardize sleep medicine education throughout Europe.

STANDARDS

Sleep Technicians and Technologists

As elsewhere, performance of overnight polysomnography (PSG) in Europe contemplates the participation by nonphysician technicians and technologists to set up and attend the overnight test. The involvement of trained sleep technicians is part of the ESRS sleep center accreditation standards. Several European countries recognize the separate allied health profession of PSG Technician or Technologist. Several European countries have established their own sleep technician societies, and the independent European Society of Sleep technologists (ESST) was formed in 1996. The ESST meets regularly together with the biannual ESRS conferences and works closely together with the ESRS in terms of education and certification.

Sleep Center Accreditation

The ESRS is also working toward an accreditation of European sleep centers. In 2006, the Steering Committee of the ESRS published European Guidelines for the Accreditation of Sleep Medicine Centres in the *Journal of Sleep Research*. Implementation of an accreditation of European sleep centers is still in progress.

The establishment of institutional sleep medicine programs in Europe is less prevalent than in the United States.[6] This is because many sleep centers in Europe are linked to individuals active in the field who, as yet, have not sold or otherwise had their centers incorporated into institutional health care systems or facilities. Some scholars view this as a loss because the implementation of academic sleep centers is needed to cover the increasing challenges brought up by the importance of sleep medicine as part of medical health care.[7,8]

CERTIFICATION OF SLEEP MEDICINE PROFESSIONALS

The ESRS has inaugurated a sleep medicine committee to serve the needs of the various European national sleep societies and to coordinate sleep medicine standards in Europe. The larger national sleep societies have established national certifications for sleep medicine for sleep professionals in their respective countries. Depending on the national medical education system, these examinations are implemented by the national sleep society or by a chamber of physicians, a university, or some other educational institute.

National recognition of these certifications varies largely across Europe. At this time only Germany and Hungary recognize a national subspecialty in sleep medicine. The German Chamber of Physicians has established the subspecialty in sleep medicine under the primary specialties of pneumology (pulmonology), neurology, psychiatry, pediatrics, and ear-nose-throat medicine.

The lack of universal certification for sleep medicine across Europe has led to a European initiative for all countries to harmonize certifications under the authority of the ESRS. A European certification of sleep professionals started in 2012 based guidelines for certification requirements published by an ESRS task force in 2009.[3] In general it is recognized that certification of sleep physicians improves health care in patients with sleep disorders.[9]

The task force guidelines specify four different certifications: one for physicians, one for psychologists, one for scientists, and one for sleep technologists, depending on the previous education of the applicant. All certifications are called *European somnologist* with mention of the specific type as an attribute.

The basic requirement for certification includes a full-time clinical training period in a sleep center for 12 months. During this time the applicant should have evaluated at least 100 patients, with cases of sleep-disordered breathing, insomnia, hypersomnia, movement disorder, and circadian disorder. Certification requires experience in clinical interviewing, use of diagnostic criteria and classification systems, use of sleep diaries, questionnaires and rating scales, psychometric evaluation, and physiological monitoring. Assessment with actigraphy is required.

PSG experience needs to include hook-up, nighttime surveillance, PSG scoring, interpretation, and reporting. Experience with the Multiple Sleep Latency Test and the Maintenance of Wakefulness Test as well as other tests must be proved. In relation to treatment, applicants need to show skills in patient education, treatment delivery, and experience with treatment of patients related to their original professional discipline.

The certification programs require experience in a variety of sleep disorder treatments, such as pharmacotherapy, continuous positive airway pressure (CPAP), cognitive behavioral therapy, and health behavior. Some of these experiences may be obtained at approved sleep medicine courses.

All certifications require applicants to sit for a written examination. The first examinations in 2012 and 2013 were held according to a grandparenting rule. These "grandparents" had to prove at least 10 years of practice and strong engagement in sleep medicine in the past. The first regular examinations for physicians, psychologists, and scientists began in 2014. Sleep technologists had their first grandparenting examination in 2014 and will have their regular technologist examinations in 2016. In addition to taking their examinations, they have to visually score a number of cases.

Somewhat parallel to the ESRS push for commonly recognized European sleep specialty certifications is the contemporaneous effort of the European Respiratory Society (ERS) to create European certifications for respiratory sleep physicians.[10] Although the ESRS focuses on the needs of the national sleep societies to have their sleep expert members show proof of qualifications, the ERS approach has been to create a curriculum, then courses, then certificates to practitioners who successfully completed a final examination after the courses.

The ERS approach is part of a larger framework of certifications for Europeans in respiratory medicine launched in

2009.[11] The framework is a mission to harmonize education in respiratory medicine for European specialists (HERMES) because medical education in Europe is primarily a national duty. To date, European medical associations have been slow to harmonize medical education. The ESRS and the ERS are working together to align their parallel activities in terms of educational content and recognition of educational and examination modules.

ACCREDITATION OF SLEEP MEDICINE CENTERS

Like physician certification, accreditation of sleep centers in Europe is currently a patchwork of rules. The larger national sleep societies in Europe, such as Great Britain and Germany, have established an accreditation procedure for their sleep centers. Depending on the national health care system of these particular European countries, the accreditations are recognized by health insurance, by health care officials, or for quality of care. However, sleep center accreditation standards have not been adopted by most European countries.

Although the ESRS has initiated a European somnologist certification, it is not expected that the ESRS will implement a common European sleep center accreditation. In 2009, the *Journal of Sleep Research* published European guidelines for the accreditation of sleep medicine centers.[2] Currently it is envisaged to check national accreditations that are in place in some countries against the published recommendations and endorse these national accreditations if applicable. For countries in which there are no national accreditations, the ESRS will help the national sleep societies to create a national accreditation system or will organize site visits with sleep center accreditation as preferred by the host country.

It is expected that the current accreditation recommendations[2] will be updated to reflect changes in recording and scoring sleep. In addition to the technical update the revisions will include a reflection on sleep medicine services with varying degrees of specialization ranging from the family physician level through sleep medicine services in university level facilities.[12]

MANAGEMENT OF PATIENTS

The management of patients with sleep disorders differs greatly among European countries. This depends much on the health care systems in place and the activity of the local sleep societies. The management of sleep-related breathing disorders had been investigated across Europe.[13] Home sleep testing is prevalent in several European countries for managing patients with sleep-disordered breathing. Some countries require level III home sleep testing, whereas other countries accept level IV home sleep testing as sufficient to diagnose sleep breathing disease and to initiate treatment. Still other countries require cardiorespiratory PSG for the diagnosis of obstructive sleep apnea and the prescription of CPAP therapy.

EDUCATION

The ESRS supports education for researchers and physicians and specialized education for sleep physicians and sleep scientists. In addition to accreditation and certification, the ESRS sleep medicine committee supports the development of educational material for future somnologists in Europe.

A first step will be establishment of a base set of knowledge and skills. A handful of European universities have implemented master classes in sleep science or sleep medicine for a number of selected students. It is believed that a common curriculum for sleep medicine can be built from these initial experiences.

In 2014 the *Journal of Sleep Research* published the *Catalogue of Knowledge and Skills for Sleep Medicine*.[5] The catalogue is intended to describe a standardized curriculum for sleep medicine education across Europe. The ESRS Board and its SMC compiled the catalogue based on textbooks, standard of practice publications, systematic reviews, and professional experience. The compilation was later validated by an online survey completed by 110 delegates specializing in sleep medicine from different European countries.

The catalogue is intended to be a basis for sleep medicine education, for sleep medicine courses, and for sleep medicine examinations, serving not only physicians with a medical specialty degree but also PhD and MSc health professionals such as clinical psychologists and scientists, technologists, and nurses, all of whom may be involved professionally in sleep medicine. The treatise comprises 10 chapters covering sleep physiology, pathology, diagnostic and treatment procedures, as well as selected societal and organizational aspects of European sleep medicine. A European textbook on sleep medicine was published following this outline of chapters.[15] Required levels of knowledge and skills are defined, as is a proposed workload of 60 points according to the European Credit Transfer System. In the future, the catalogue will be revised in accordance with advances in the field of sleep medicine.

COMPLIANCE WITH REGULATIONS AND REIMBURSEMENT

Government regulations for the delivery and reimbursement of sleep medicine in Europe differ as much as the health care systems in European countries differ. Although many countries recognize the need to diagnose, treat, and follow patients with sleep disorders as a matter of good medicine and—with regard to hypersomnolent drivers—public safety, there is little movement to align the disparate regulatory schemes at this time.

A 2007 study indicates that most European countries recognize the public safety risks presented by drivers with excessive daytime sleepiness caused, in part, by sleep-disordered breathing.[14] However, a review of the licensure requirements of 25 different European countries as part of the study showed that less than half of the countries referenced obstructive sleep apnea in their licensure regulations. Still, at the time, seven countries required a physician's medical certificate indicating treatment compliance to process applications for drivers with sleep breathing disorders, and in two countries it was up to the patient to decide (on the physician's advice) whether to drive again. France required a Maintenance of Wakefulness Test for symptomatic commercial drivers to pass fitness-to-drive standards.[14] Still, driving license regulations are different throughout European countries, and efforts are being made to harmonize regulations. To proceed with this, on July 1st, 2014, an update of the European directive on driving was published, which now mentions obstructive sleep apnea and daytime sleepiness specifically. The directive has to be adopted by national laws in Europe until Dec 15th, 2015, in order to become effective.

HEALTH INSURANCE COVERAGE FOR SLEEP MEDICINE: THE GERMAN EXPERIENCE

The insurance and regulatory aspects of covering and delivering sleep medicine in Germany provide one example of the European experience. Everybody in Germany has health insurance and expects that all medical care is covered by the insurance. In Germany there are a little less than 200 insurances available to citizens. Very few patients are not insured.

There are two types of insurances: a general basic insurance for 85% of the population that is open to anybody and a so-called private insurance for 15% of the population. Although the medical care is the same under each insurance program, small differences exist. Patients with private insurance have a wider choice to select their physician and better chances to obtain single-bed rooms if admitted to a hospital. Physician reimbursement is higher for private patients than for general plan patients for the same service.

German citizens with private insurance pay monthly premiums that vary according to age and risk. Thus premiums are relatively low for younger insured persons and higher for older persons. Therefore a person must earn a high salary to be eligible for private health insurance. The cost of health insurance under the general insurance plan is simply a percentage of the insured person's income.

In general, health insurance in Germany covers all costs for a diagnosis of sleep apnea and the treatment of sleep apnea and all replacement and service items. A patient with complaints of irregular snoring or observed apneas will go to the family physician to get guidance for his or her problem. The patient cannot go to a sleep center directly. Sleep centers are only allowed to admit referred and diagnosed patients.

If the patient's family physician suspects sleep apnea, the physician will send the patient to a pneumologist who has a license for home sleep testing. To receive reimbursement for home sleep testing from the health insurance, the pneumologist has to get a license, which requires attending a 5-day course about basics of sleep medicine with an emphasis on sleep-disordered breathing and passing a 60-minute examination at the end of the course.

If the home sleep test is positive in terms of sleep apnea, the pneumologist will refer the patient to a sleep center for CPAP titration with attended PSG. The sleep center has to be accredited by either the German Sleep Society or by another institution to obtain health insurance reimbursement. The patient then returns after 6 months of treatment to the pneumologist for another home sleep test as a treatment follow-up. Thereafter are no planned follow-ups unless the patient experiences new complaints.

If the health insurance company determines that a diagnosis was wrong or a referral at any step was not justified, the insurance company can ask a control body to review the patient's medical records. These review bodies, called medical service of insurances, typically consist of special physicians employed by the control body. They will check the case and will see whether all diagnostic steps were done according to guidelines. They will review the pneumologist for credentials and licensure as well as the sleep test data to determine the quality of the recording signals and whether the diagnostic and therapeutic decisions are justified.

The criteria used by the reviewing physicians derive from evidence-based literature and are compiled in a reviewers' guide for sleep-disordered breathing for the medical insurance services. If the reviewing body denies reimbursement for the claim, the pneumologist cannot appeal to the patient or to the insurance company, but only to the independent control body. The physician is not prohibited from asking the patient to pay privately for the services provided, but as a cultural matter, German patients do not expect to have to pay privately for health care services. Accordingly, providers almost never ask for patients to cover services from their own pockets. If the prescription was found to be erroneous or a procedure was found to be not necessary, then the physician, not the hospital or institution, is liable and will be charged for the prescription. To cover this, German physicians have a professional insurance. Hospitals may cover this claim, if agreed on in the contract with the employed physician.

CLINICAL PEARLS

- Sleep medicine education in Europe is in the process of being coined in curricula that are based on evidence and worldwide knowledge on sleep physiology, sleep disorders, and treatment.
- Certification of sleep professionals and accreditation of sleep centers is advancing in all countries, and large efforts are taken to achieve the same consensus on patient service and quality of care independent of the health care system and more dependent on the underlying pathologies.
- Management of sleep disorders is developed through academic institutions that are in the process of installing sleep medicine programs and aligning these programs to achieve comparable goals to finally optimize patient care.

SUMMARY

Europe has a long tradition of sleep research. Sleep medicine evolved in parallel with other countries worldwide. The ESRS covers both sleep science and sleep medicine. Sleep medicine is more a national issue because health care systems are very different across the European countries. Some countries have large national sleep societies with sleep center accreditation and sleep expert certification. Other countries lean much on the ESRS. The Society tries to set consensus rules for sleep expert certification, for sleep center accreditation, and provides education for sleep experts and technologists. Publications on these issues are compiled and published in the *Journal of Sleep Research*. The implementation of these steps is coordinated among the European countries and is recently coordinated with similar activities initiated by the ERS. The management of patients with sleep disorders differs much among European countries and is strongly linked to reimbursement schemes.

Section 10

Occupational Sleep Medicine

Chapter 70

Introduction

Gregory Belenky; Torbjörn Åkerstedt; Nancy J. Wesensten

Occupational sleep medicine draws on clinical, experimental, and field research to sustain human performance. Broadly, the goal of occupational sleep medicine is to sustain performance, and attendant productivity, safety, health, and wellbeing, in the workplace and in the operational environment. An operational environment is a workplace in which human performance is critical to system output; if the human fails, the system fails.

Sleep loss (time awake), adverse circadian rhythm phase (time of day), and workload (time on task/task difficulty) interact to degrade performance and increase self-reported fatigue and sleepiness. With increasing fatigue, performance degrades, productivity decreases, and the risk of error, incident, and accident increases. Occupational sleep medicine aims to mitigate these adverse effects.

Occupational sleep medicine applies to all operational environments. Examples of operational environments include military operations, maritime operations, medicine, land transportation, aviation, security work, energy generation, resource extraction, financial markets, industrial production, the information media, and intelligence-gathering operations.

Occupational sleep medicine applies to any system involving human performance and 24/7 operations. Occupational sleep medicine will likely develop as a subset of sleep medicine with ties to occupational medicine and industrial and organizational psychology. Occupational sleep medicine could be the basis for enterprise-wide systems of fatigue risk management.

What follows in this introduction are brief overviews of the chapters making up the section on occupational sleep medicine.

CHAPTER 71: PERFORMANCE DEFICITS DURING SLEEP LOSS AND THEIR OPERATIONAL CONSEQUENCES

Does the pattern of sleep-loss–induced neurobehavioral (alertness, response speed) deficits seen during laboratory studies tell us anything about how workplace performance is likely to be affected by insufficient sleep? Under controlled laboratory conditions, the duration of lapses in sustained attention increase as sleep loss accumulates—an effect that is exacerbated during the circadian alertness trough. As the ability to sustain attention degrades, time on task becomes more salient, and breaks (time off task) restore performance. However, this effect is temporary, and its efficacy (duration and magnitude) decreases with increasing sleep loss.

Under operational conditions, accidents occur when lapses in sustained attention temporally align with the requirement for attention to avoid critical errors. Accident risk is thus a function of duration and frequency of attention lapses (which themselves are a function of sleep-wake and circadian factors) and exposure to critical events. Although the ability to predict a specific individual's risk has yet to be achieved, predicting general risk or likelihood based on sleep-wake history and time of day is possible.

CHAPTER 72: SLEEP AND PERFORMANCE PREDICTION MODELING

Currently available mathematical sleep and performance prediction models are based on a conceptual two-process model of sleep regulation. According to such models, performance

(and in the original conceptual model, sleep) is governed by two processes: a homeostatic process that is determined by sleep-wake amounts and a relatively (but not entirely) static circadian (24-hour) process. Such models can be used to quantify the effect of a given sleep-wake-work schedule on mental effectiveness. Importantly, the *relative* effect of several sleep-wake-work schedules can be quantified. The ability to quantify effectiveness associated with any sleep-wake-work schedule allows for proactive risk management and mitigation in the form of alternative scheduling, shifting the timing of critical events outside the window of reduced effectiveness, and implementation of countermeasures (e.g., naps). Application of predictive models as components of comprehensive fatigue risk management systems (FRMS) is gaining momentum in transportation sectors, most notably commercial aviation.

CHAPTER 73: FATIGUE RISK MANAGEMENT SYSTEMS

Fatigue risk management is an emerging applied arm of occupational sleep medicine. As indicated by its name, fatigue risk management involves actively managing risk (which in turn implies acceptance of some amount of risk in the same way that risk associated with poor weather or other factors would be considered and managed). In contrast, prescriptive hours-of-service rules specify shift duration, between-shift intervals, and within-shift breaks, thus imposing a priori boundaries that are designed to eliminate risk. However, because such hours-of-service (HOS) rules are not based in the physiology that drives performance (i.e., the human circadian rhythm and homeostatic drive for sleep), they are overly restrictive in some aspects (e.g., restricting consecutive hours worked) and potentially unsafe in other aspects (e.g., allowing for 23-hour days and other schedules that are incompatible with circadian physiology).

An FRMS based on sleep-wake and circadian principles affords an alternative to prescriptive HOS. FRMS is adapted to the operational environment and is iteratively reviewed and revised to meet operational demands. Unlike prescriptive HOS rules, in which operators are incentivized to work to HOS limits, FRMS may incentivize operators to sleep (e.g., in-flight napping) to extend duty hours (e.g., ultra–long-range flights). This unexpected consequence of FRMS implementation results from shifting the locus of responsibility for safety away from the regulator and toward employers and employees.

CHAPTER 74: DROWSINESS IN TRANSPORTATION WORKERS

Driving while drowsy places the driver, other motorists, and pedestrians at risk for injury. Professional drivers may be at particular risk (perhaps owing to the previously indicated issues with HOS regulations that allow for long, nighttime driving bouts), and it is likely that the problem of drowsy driving in professional drivers is underestimated. Individuals driving to work during the circadian alertness trough and from work after extended duty hours are also at risk for drowsiness-induced automobile collisions. Depressant drugs, sleep-disordered breathing, and narcolepsy increase these risks. Degree of impairment (and thus risk) can be quantified by objective measures including the Multiple Sleep Latency Test and the Maintenance of Wakefulness Test. Effective treatment of sleep-disordered breathing and other sleep disorders reduces accident risk.

Because drowsy driving in professional drivers poses serious risks, some have suggested that a provision be included to screen for sleep disorders in this population. However, to date no transnational standards for such evaluation exist, nor is there agreement regarding what constitutes effective treatment and corresponding return-to-duty (or remain-on-duty) standards.

In lieu of regulatory requirements, physicians can routinely evaluate patients for risk for drowsy driving by clinical interviews that include queries related to sleep disorder symptoms as well as questions regarding sleep hygiene. Public service campaigns regarding the dangers of driving drowsy, magnification of risk associated with alcohol use, and the value of countermeasures (e.g., avoiding driving during the circadian low, tactical use of napping and caffeine) can be of value.

CHAPTER 75: SHIFT WORK, SHIFT-WORK DISORDER, AND JET LAG

In industrial economies, shift work and travel across time zones are common. Both displace sleep and wake from their usual temporal alignments with the 24-hour alertness rhythm. The circadian alertness rhythm will eventually (over days) resynchronize to a new time zone, but in most shift workers, the circadian alertness rhythm does not resynchronize to night-shift work. The resulting insomnia during the daytime sleep period and excessive sleepiness during the nighttime work period, when sufficiently severe, are diagnosed as shift work sleep disorder (SWSD). In addition to a thorough sleep history, tools including the Epworth Sleepiness Scale, the Insomnia Severity Index, and the Pittsburgh Sleep Quality Index can be used to diagnose SWSD with or without polysomnography. Distinguishing fatigue from sleepiness is critical to differentiate depression from SWSD.

In lieu of organization-level adjustments in shift timing and duration, treatments to mitigate SWSD include environmental manipulations, such as nocturnal bright light and daytime sleep in darkness, and pharmacologic tools, such as stimulants to maintain alertness while on shift at night and sleep-inducing medications to maintain and extend sleep off-shift during the day. Jet lag is characterized by excessive daytime sleepiness and nocturnal insomnia at the new local time. In contrast to SWSD, jet lag is self-limited because the circadian alertness rhythm gradually resynchronizes to new local time as a function of consistent daylight exposure. Thus bright light exposure can facilitate resynchronization if timed properly. Naps and caffeine are safe and effective countermeasures that can be implemented to reduce excessive daytime sleepiness.

CHAPTER 76: SLEEP PROBLEMS IN FIRST RESPONDERS AND THE MILITARY

First responders such as police and firefighters are required to work extended hours and engage in shift work, both of which result in sleep loss and circadian desynchrony. In these occupational groups, impaired judgment may result in more severe and enduring adverse consequences than in other occupational groups. The same is true for deployed military personnel. In police forces, organizational (e.g., direction and speed

of shift rotation, staffing), social (e.g., overtime, second jobs), and individual (e.g., overall health) factors promote fatigue. High prevalence of sleep disorders further increases morbidity and mortality. Primary care physicians may serve as the first line of defense by screening for sleep disorders and educating police officers regarding sleep hygiene, weight management, and other controllable factors.

CHAPTER 77: SLEEP, OCCUPATIONAL STRESS, AND BURNOUT

Occupational stress plays a major role in the etiology of insomnia. Results from both cross-sectional and prospective studies support this connection. The inability to stop thinking about work in the evening and ruminating over anticipated next-day stress appears to be the main factor causing insomnia. High job demands coupled with low job control, lower socioeconomic status, and low social support contribute to work-related insomnia. Long-term exposure to occupational stress may result in extreme fatigue, impaired cognition, and depressed mood; associated sleep disturbance is characterized by sleep fragmentation, increased sleep latency, and reduced slow wave sleep. A blunted cortisol response (dexamethasone suppression test) and an exaggerated cortisol awakening response indicate involvement of the hypothalamic-pituitary-adrenal axis. Neural markers include reduced volume in cortical and subcortical areas. It is tempting to see these effects as the culmination of a chain of events that begin with occupational stress, pass through stress-induced insomnia and sleep disturbance, and eventually lead to extreme fatigue and inability to work, frequently labeled "occupational burnout." Occupational burnout is associated with increased sickness absence and should be considered in patients with unusually high absentee rates. Occupational burnout seems at least partly reversible.

CHAPTER 78: OPTIMIZING SHIFT SCHEDULING

Scheduling of shift timing and duration is a key organization-level factor that determines worker on-duty alertness and off-duty ability to obtain sleep. In principle, a schedule that minimizes circadian misalignment with the sleep-wake schedule, minimizes build-up of sleep loss over a single shift and across a shift cycle, and permits sufficient recovery during days off will best maintain on-duty alertness and off-duty sleep quality. In practice, although evidence indicates that day work is superior to night work, there is little evidence to support rotating over permanent night-shift work or fast-rotating over slow-rotating shifts. In contrast, evidence strongly supports clockwise (progressively later) shift rotation over counterclockwise (progressively earlier) shift rotation. Early-morning starts (e.g., 3:00 AM) and long shifts are associated with reduced sleep amounts, and duration of time off between shift rotations affects amount of time available for sleep recovery. Under conditions in which workers sleep onsite, workers have few (or no) social obligations, and light exposure can be controlled (e.g., oil rig workers), numerous consecutive long-duration (12-hour) shifts can be worked with few problems.

Evidence supports the use of countermeasures, including caffeine, preduty napping, and on-duty napping. Arguments that the possibility for postnap sleep inertia should preclude on-shift napping are largely unsubstantiated.

CHAPTER 79: OBSTRUCTIVE SLEEP APNEA IN THE WORKPLACE

Obstructive sleep apnea (OSA)-induced sleep fragmentation causes excessive daytime sleepiness and impaired mental performance. In addition to workplace safety risks, OSA exacts a toll in terms of absenteeism and lost productivity. Managing OSA in the workplace consists of a tiered approach that starts with screening for both nonmodifiable and modifiable risk factors. Nonmodifiable screening risk factors for OSA include older age, male gender, postmenopausal status in females, and ethnicity. The most significant modifiable screening risk factor is obesity or adiposity, which can be objectively determined by body mass index and neck circumference. Screening also consists of self-report tools aimed at daytime sleepiness and related symptoms and functional performance tests for detecting impairment. Workers exceeding cutoffs are referred to a sleep disorders medicine specialist for diagnosis (ranging from portable monitoring to full polysomnography), treatment (positive airway pressure plus prescription stimulants to treat residual sleepiness; weight loss management), and compliance monitoring. Currently only the U.S. Federal Aviation Administration lists untreated OSA as a disqualifying condition of employment. Requirements that medical examinations for operator licenses (e.g., commercial motor vehicle operator licenses) be obtained from a certified medical examiner (CME), combined with sleep disorders education for CMEs, will serve to increase rates of OSA detection and treatment.

GROWTH IN OCCUPATIONAL SLEEP MEDICINE

Sleep medicine focuses mainly on diagnosis and treatment of specific sleep disorders (e.g., sleep apnea) in the individual patient. Complementing the clinical practice of sleep medicine, occupational sleep medicine is implemented at the group level not only to sustain workplace productivity and safety but also to maintain overall worker health across a career.

Occupational sleep medicine is advancing in several areas, including fatigue risk management, prevention of drowsy driving, mitigation of SWSD, behavioral and pharmacologic interventions in special populations (e.g., first responders), and even genetics. In particular, fatigue risk management efforts have benefited directly from growth in occupational sleep medicine through wider awareness of the effect of sleep-wake and circadian factors on safety. In turn, occupational sleep medicine specialists benefit from increased opportunities to provide consultation to industries and occupational groups on screening, diagnosis, and treatment of sleep disorders and implementation of organizational fatigue risk management.

Chapter 71

Performance Deficits During Sleep Loss and Their Operational Consequences

Hans P.A. Van Dongen; Thomas J. Balkin; Steven R. Hursh

Chapter Highlights

- Sleep loss induces sleepiness and exerts profound negative effects on cognitive performance, increasing the risk for errors and accidents.
- Three operationally relevant phenomena associated with the impact of sleep loss on performance are presented, including sleep loss-induced performance instability, interaction of sleepiness with time on task, and sleepiness-induced alteration of regional brain activity.
- Current knowledge regarding the impact of sleep loss on performance is summarized, and issues pertaining to the real-world application of this knowledge in operational environments are discussed.

Although difficult to estimate, it is likely that sleep loss-induced performance deficits cost the world economy hundreds of billions of dollars per year in accidents, direct health care costs, and lost operational efficiency and productivity. This can be inferred from the fact that sleep insufficiency is experienced at least occasionally by everyone and is experienced chronically by a considerable proportion of the adult population.

According to the 2004–2006 National Health Interview Survey,[1] approximately 21% of adults in the United States typically obtain 6 or fewer hours of sleep per 24 hours—considerably less than the 7 to 8 hours of sleep that is generally recommended.[2] If those with sleep disorders (e.g., sleep apnea, insomnia) are considered along with those who are chronically sleep-restricted for other reasons (e.g., shift work, lifestyle), it is estimated that as many as 70 million Americans experience chronic sleep loss[2] and are therefore likely to experience correspondingly impaired performance on a daily basis.

In this chapter, current knowledge regarding the impact of sleep loss on performance is summarized, and issues pertaining to the application of this knowledge to real-world, operational environments are discussed.

THE NATURE OF SLEEP LOSS-INDUCED PERFORMANCE DEFICITS

Cognitive performance is not solely a function of (and is therefore not simply a direct reflection of) sleepiness level (drive to sleep). Nonetheless, level of sleepiness, as determined by duration of prior sleep, time since awakening, and circadian timing (see Chapter 37), affects performance on a variety of tasks in a predictable manner. For example, performance on a psychomotor vigilance test (PVT) declines in a dose-dependent fashion with decreasing amounts of nighttime sleep across multiple days of sleep restriction.[3,4] However, sleepiness-induced declines in performance are not the result of a wholesale shift (general slowing) in the entire distribution of reaction times (RTs), but rather reflect increased trial-to-trial variability in RTs,[5,6] with an increasing proportion of relatively long RTs intermixed with "normal" RTs (i.e., RTs within the range typical of the well-rested state).[6,7]

It has been posited that the increased performance variability that characterizes sleep loss is most likely a manifestation of a reduced level of stability in the physiologic processes by which wakefulness is maintained—specifically, that it is caused by intermittent intrusion of sleep into wakefulness.[6,8] An implication of this hypothesis is that performance deficits due to sleep loss should be generic; that is, sleep loss should affect all facets of cognitive performance. However, evidence from cognitive-behavioral and neuroimaging studies does not uniformly support this hypothesis.[9,10] Recent evidence regarding the organization of sleep-wake processes suggests that the effects of sleepiness are greatest in those neuronal pathways most intensively used during task performance. Accordingly, the deleterious effects of sleepiness have been found to be most salient for those specific cognitive processes mediated by these same neural pathways, in a use-dependent manner.[10,11]

Although it would be interesting from a scientific standpoint, and useful as a tool to increase the accuracy with which task performance could be predicted in operational environments, the relative extent to which any two cognitive processes (e.g., information encoding, working memory) are differentially affected by sleep loss cannot be specified, much less quantified. This is because (1) multiple cognitive processes are involved in any given performance task, with each individual (and typically unobservable) cognitive process being affected by sleep loss to an unknown extent,[12] and (2) there is no scale against which different cognitive processes can be commonly measured and thus compared (i.e., the old "apples vs. oranges" conundrum).

Certain cognitive task designs allow for the effects of sleep loss on a specific cognitive process to be assessed by contrasting distinct task conditions (e.g., performance on a working memory task with two, three, or four items to be held in memory),[13] but these require the assumption that the effects of sleep loss on all other relevant cognitive processes remain invariant under each tested condition. Although research in this area is gaining some traction,[9] the experimental and

logical challenges to achieving substantial scientific breakthroughs remain considerable. In part, this is because a test's sensitivity to sleep loss varies not only as a function of the sensitivity to sleep loss of the admixture of cognitive processes involved in the task performance, but also as a function of the parameters of the test itself. For example, manipulation of task duration, time pressure, and amount of feedback provided during testing can affect the sensitivity of a performance measure to sleep loss[14,15] (see Chapter 37).

Likewise, statistics such as effect size are useful for comparing the sensitivity of specific tests administered with a specific set of test parameters, under specific sleep loss conditions,[16,17] but they cannot be used as a basis for comparing the extent to which sleep loss generally affects one cognitive ability versus another. To complicate matters further, large, trait-like individual differences in vulnerability to sleep loss exist.[18,19] These uncertainties also exist in workplace settings, where a job typically involves a wide range of tasks with several individuals performing a given job.

These challenges complicate researchers' efforts to understand the neurocognitive underpinnings of performance deficits due to sleep loss. However, from a practical standpoint, application of the known principles by which circadian and homeostatic processes mediate alertness and performance can nevertheless be usefully applied in operational environments. That is, although the precise degree to which performance on a particular task will be degraded is not currently predictable for a specific individual, the general trends (both timing and extent) of sleep loss-induced performance deficits can be predicted and usefully applied in operational settings.

In this chapter, we discuss three phenomena that characterize sleepiness in operational settings. The first is concerned with the translation of performance instability into errors and accidents in operational settings. The second is the interaction of sleep loss with time-on-task effects. The third is sleepiness-induced change in the brain activation patterns associated with degraded cognitive performance.

PERFORMANCE INSTABILITY: EFFECT ON ERRORS AND ACCIDENTS

In large-scale correlational studies, work schedules that militate against adequate daily sleep (including extended work hours and shift work) have been linked to increased risk for human error and accidents,[20-22] resulting in reduced safety and productivity.[23-25] Yet, sleepy people do not make errors or cause accidents simply by virtue of the fact that they are sleep deprived, just as being fully alert does not guarantee error-free performance. In accident investigations, the unequivocal establishment of sleepiness as a causal factor is often impossible, even when the presence of sleepiness is itself undisputed (unless there is evidence that the accident was caused by frank sleep onset).

There are two reasons for this. First, sleepiness is rarely the sole reason that accidents occur; multiple, diverse factors ranging from personnel shortages to equipment failures and safety check overrides typically combine with human error to result in adverse outcomes. Second, as previously mentioned, human error because of sleepiness occurs against a backdrop of increased performance variability[6] and is therefore at least partly stochastic (i.e., random) in nature. In other words, although the likelihood or frequency of decremented performance increases with sleep loss (and is exacerbated during the descending phases of the circadian rhythm of alertness), actual task performance of a sleepy individual can vary from "impaired" to "normal" on a moment-to-moment basis.

Sleep-wake history and circadian rhythmicity interact to determine sleepiness-alertness and performance capability (see Chapter 37). Sleepiness varies as a function of time awake, with longer wakefulness inducing progressively increasing sleep drive. Sleepiness also varies as a function of time of day, with the biologic clock's alertness output declining during "nighttime," resulting in elevated drive to sleep (sleepiness). As a consequence, alertness level and performance capability are reduced when working extended hours involving sleep loss and when working at night or in the early morning.[26,27] Moreover, chronic sleep loss leads to cumulative degradation of performance across days, weeks,[3,4] and perhaps longer (definitive longer term studies have not yet been performed).

Not surprisingly, it has been determined that the circadian (i.e., time of day) variation in alertness and performance is associated with a circadian rhythm of accident rate and injuries.[20,28] There is less evidence for a relationship between accidents or injuries and changes in performance related specifically to duration of time awake. However, a relationship between duration of time awake and accident risk can be inferred from statistics on road crashes that were attributed to the driver having fallen asleep.[29,30] Although definitive evidence is lacking (and it should be noted that there is a possibility that investigators are more likely to attribute accidents to sleepiness when occurring at certain times of the night), it is reasonable to presume that the same interaction between sleep-wake history and circadian rhythm that increases sleepiness and decreases performance capability also increases the probability of driving errors and resulting traffic accidents.

Many occupationally relevant tasks, ranging from systems monitoring and threat detection to driving, are likely vulnerable to sleep loss, at least in part because these tasks require sustained attention.[31,32] In modern operational settings characterized by extensive automation, such tasks are common. Automation and other technologic innovations have broadly improved safety, but by shifting performance demands to sustained attention tasks, they may have simultaneously increased the likelihood of human error.[33] This is because the ability to sustain attention is negatively affected by sleep loss and time of day (and time on task, discussed later). The paradoxical result is that although serious accidents are increasingly rare, when they do occur such accidents can be especially devastating and costly.[34,35]

Because such catastrophic accidents are rare, and because their occurrence also typically depends on the chance convergence of random factors or events, it remains difficult to predict the risk for sleep loss-induced accidents. Even when considering incidents more broadly by including near-accidents ("near-misses"[36]) and other performance errors, a relationship between sleepiness and accident rate remains difficult to discern. Consideration of the stochastic nature of performance impairment due to sleep loss may shed some light on this issue.

Figure 71-1 illustrates how sleep loss-induced stochastic instability in performance impairment may lead to an accident. The PVT is a validated assay of sustained attention that is particularly sensitive to sleep loss.[16,37] As such, the series of

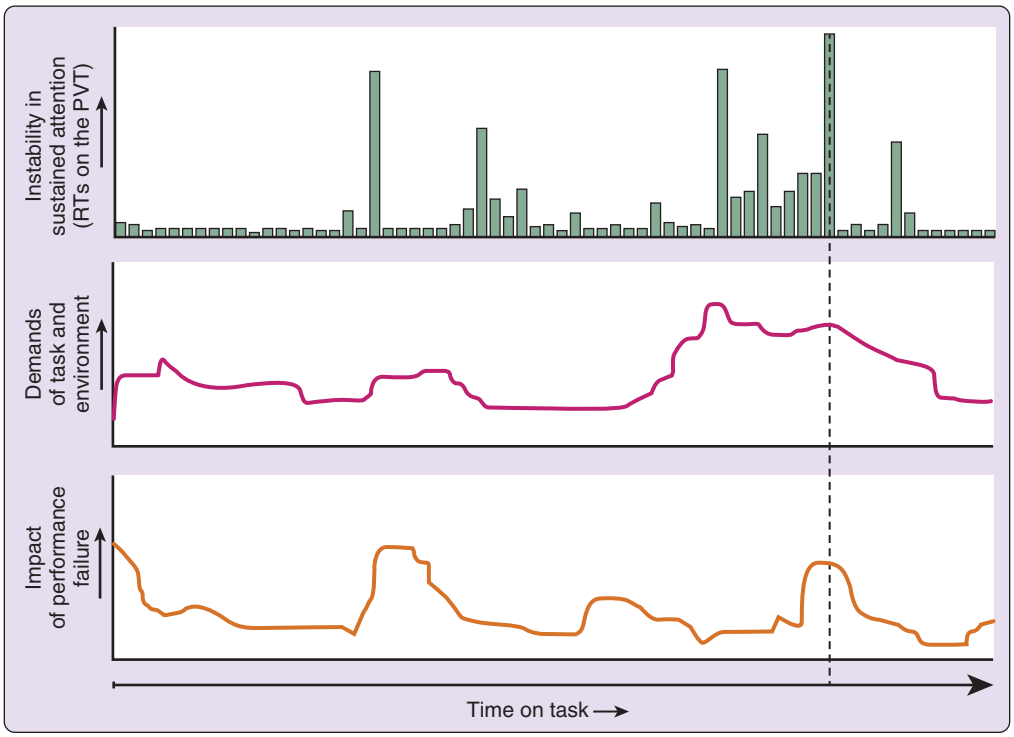

Figure 71-1 Schematic of a proposed mechanism by which sleep loss may contribute to accidents. The *top panel* depicts reaction times (RTs) across a 10-minute span of task performance on a psychomotor vigilance test (PVT) for an individual who continuously maintained wakefulness for 60 hours, as observed during an experiment published by Doran and colleagues.[6] This illustrates stochastic instability in sustained attention over a 10-minute interval. *Longer bars* represent slowed responses indicative of lapses of attention. The *middle panel* shows a hypothetical pattern of changing demands of the task at hand and the environment in which it is performed (*upward* corresponds to greater demands). The *bottom panel* displays a hypothetical level of impact that human error would have over the course of the task. In this view of how sleepiness contributes to accident causation, intervals of inattention when cognitive processing demands are high lead to human error, which in turn—if the impact of error is considerable—results in an accident. Thus, for sleep loss to actually lead to an accident, there must be temporal alignment of attentional lapses, substantial cognitive processing demands, and high impact of human error (in this case represented by the *dotted black line*). (From Doran SM, Van Dongen HPA, Dinges DF. Sustained attention performance during sleep deprivation: evidence of state instability. *Arch Ital Biol* 2001;139:253–67, with permission.)

RTs recorded in a PVT session can be considered a record of task inattentiveness. Assuming for the purpose of illustration that the same admixture of cognitive functions is required for a given task in an operational setting, long RTs on the PVT would reflect intervals of inattentiveness (lapses of attention) during the task at hand. When the demands for cognitive processing are high during such an interval of inattentiveness, human error would be likely. In addition if the negative impact of human error at that specific time is also high, then an accident might result.

For example, if the task is driving a car, and an interval of inattentiveness coincides with the approach to an intersection with a stop sign, then detection and processing of the stop sign might fail and the intersection would be crossed without braking—that is, human error. If at the same time another car enters the intersection, a collision could ensue. Yet, if no other car entered the intersection, or there had been no intersection, or if the interval of inattentiveness had occurred a little earlier or later, then the accident would not have occurred.

From this perspective, it is necessary for a period of inattentiveness and significant effect of error to temporally align in a manner that results in an accident. It follows that accident risk is proportional to both total time of inattentiveness (cumulative lapse time) and density of critical task events (i.e., prior risk or exposure[38]). Given information about the latter, it may be possible to predict accident risk by predicting cumulative lapse time. There is a strong correlation between the number of lapses of attention and their duration,[37] so a mathematical model that predicts PVT lapse counts[39] could potentially serve this purpose (see Chapter 72).

THE TIME-ON-TASK EFFECT

It is ironic that hours-of-service regulations intended to mitigate the effects of sleepiness on performance and risk in operational settings are typically focused exclusively on "time on duty" and fail to account for sleep-wake history and circadian rhythm. However, there are good reasons for this. Dealing effectively with sleep-wake and circadian factors would require regulation of the timing and duration of workers' sleep, which is nearly impossible to enforce from both logistical and socioethical standpoints. In addition, even when individuals are well rested, performance tends to deteriorate as a function of continuous work time[40] and is improved by rest breaks.[41] However, with the passing of work hours, time awake also accrues and the phase of the circadian rhythm of alertness

changes. Depending on whether these changes are toward increasing or reducing alertness, they may offset or amplify the performance-impairing effects of increasing work time. Therefore, prescriptive hours-of-service regulations that do not take all of these factors into account will never be more than partially effective.[42,43]

Performance degradation caused by continuous performance over time is a phenomenon commonly referred to as the time-on-task effect. This effect is especially pronounced for tasks requiring sustained attention, such as the PVT.[44,45] Such tasks are also especially sensitive to sleep loss.[14,45] The time-on-task effect has been conceptualized as arising from cognitive work-related depletion of cognitive resources over time—resources that, unlike those mediating sleepiness, require only rest (time off task) to effect recuperation.[45] Recent insights into the neurobiology of sleep and wakefulness suggest that the underlying mechanism may be use-dependent, local sleep-like states occurring increasingly frequently in neuronal pathways subserving the cognitive processes most intensely used while performing the task at hand.[11]

The time-on-task effect interacts with time awake and time of day. That is, when sleepiness is increased because of time awake or time of day, performance degrades faster during continuous task performance. This is illustrated in Figure 71-2. The figure depicts minute-by-minute mean response speed on the 10-minute PVT, which was administered every 2 hours across 40 hours of continuous wakefulness.[46] Time-on-task effects were evident before significant sleep loss, that is, from 0800 to about 2400 on the first day. Sleep deprivation exacerbated the time-on-task effect, especially during the night and early morning hours. For example, comparison of the performance change across the 10-minute test at 0800 on day 1 versus 0800 on day 2 suggests differences not only in overall performance but also in the rate at which performance declined across the 10 minutes.

Also noteworthy in Figure 71-2 is the extent to which performance on the PVT recovered from minute 10 on one trial to minute 1 on the next, despite the fact that there was no intervening sleep. This was evident even when overall performance was degraded most significantly (at about 0600 to 1000 on the second day). Thus mean speed on the PVT at minute 1 on the 0800 test was greater than mean speed at minute 10 on the 0600 test, despite the fact that average 10-minute performance declined across this time interval. In other words, the time-on-task effect is reversed by rest breaks (time off task), even during sleep deprivation.

One reasonable hypothesis is that time-on-task effects are at least partly motivational, that is, that the decrements across each 10-minute PVT bout represent declining within-bout motivation and that the recovery from the end of one PVT bout to the beginning of the next merely reflects some temporary restoration of motivation. However, it has been found that performance impairment from time on task may carry over to performance of another task performed immediately afterward,[47,48] strongly suggesting that declining motivation does not account for all of the time-on-task variance. That said, the time-on-task effect does not *necessarily* carry over between tasks performed back to back; in certain cases, performing a different task restores performance similarly to a

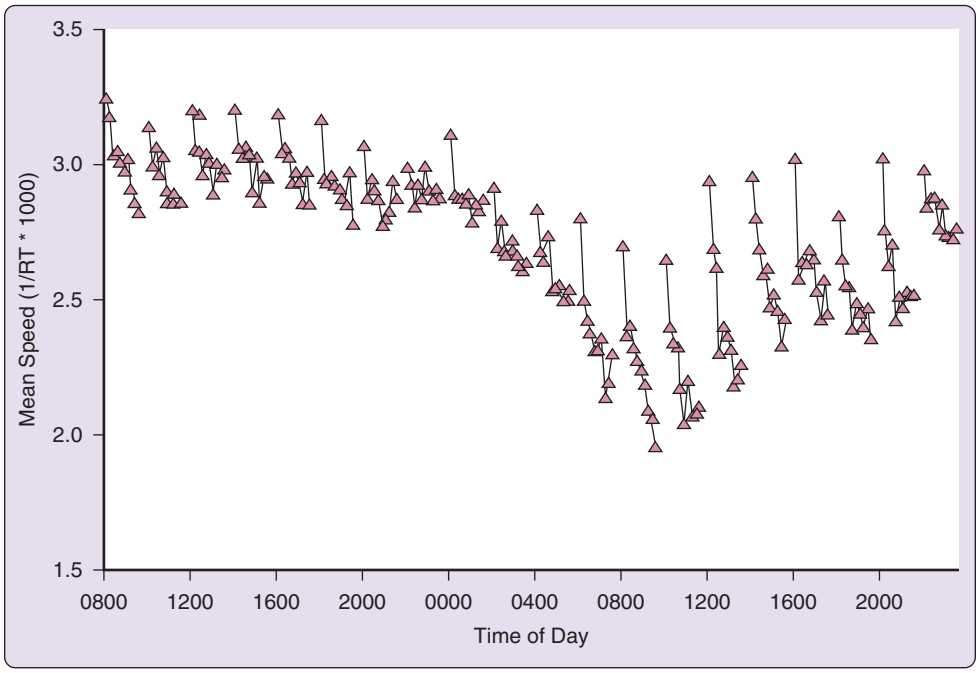

Figure 71-2 Time-on-task effect across a 10-minute psychomotor vigilance test (PVT) during 40 hours of total sleep deprivation. Each set of data points shows average speed (inverse of reaction time [RT]) in consecutive 1-minute bins (not drawn to scale on the time axis) during the 10-minute task duration. Note the changes in overall performance across the 40 hours of sleep deprivation due to the interaction of the effects of time awake and time of day. Furthermore, note the improvement from minute 10 of one PVT bout to minute 1 of the next PVT bout 2 hours later despite the absence of intervening sleep. (From Wesensten NJ, Belenky G, Thorne DR, et al. Modafinil vs. caffeine: effects on fatigue during sleep deprivation. *Aviat Space Environ Med* 2004;75:520–5, with permission.)

rest break. It has been hypothesized that time-on-task carryover effects reflect use of common neuronal pathways for cognitive processes, thus preventing rest-mediated recovery in these pathways and resulting in further degradation of performance (as discussed in the prior section).[45]

From a practical standpoint, the extent to which sleepiness from time awake and time of day interacts with time on task to produce performance deficits is an important issue. Sleep loss often occurs because of externally imposed (e.g., occupational) requirements for individuals to remain awake for extended periods, performing goal-directed tasks. Thus studies in which the effects of sleep loss are measured on tasks performed nearly continuously may best replicate real-world operational conditions. In one such study, subjects performed cognitively demanding work on a nearly continuous basis across 54 hours of sustained wakefulness, with occasional administration of subjective rating scales (including mood, fatigue, and sleepiness scales) and with short breaks for meals and personal hygiene.[49] The study did not include a comparison condition in which work was performed at a slower pace (i.e., with more frequent and/or longer breaks). Nonetheless, by assessing the relative rates of performance decline from this study with those of previously published sleep deprivation studies in which similar performance measures had been administered but for shorter periods of time, it was suggested that sustained cognitive work accelerates the rate at which performance declines during sleep deprivation.

Thus the rate and extent to which performance is impaired varies as a function of both time on task and sleepiness (a joint function of the homeostatic sleep pressure and the circadian rhythm of alertness).[50] The portion of the performance degradation that is due to time on task is reversed by simple rest (time off task), whereas the portion that is due to sleep loss is reversed only by recovery sleep.

FUNCTIONAL BRAIN IMAGING STUDIES OF SLEEP LOSS AND PERFORMANCE

Results from functional brain imaging studies have revealed reduced regional brain activity during sleep deprivation, with greatest reductions manifest in prefrontal cortex, inferior parietal and superior temporal cortex, and thalamus.[51] Based on such findings, specific sleep loss–induced deficits in various aspects of performance have been predicted. For example, noting that sleep deprivation results in reduced metabolic activity in regions of the prefrontal cortex known to mediate specific aspects of cognitive performance and perception, it has been predicted and confirmed that sleep deprivation causes deficits in executive mental functions such as risky decision making,[52] moral reasoning,[53] and humor appreciation[54] and that it results in reduced ability to differentiate odors.[55]

Although such results suggest a relationship between the absolute level of activity in specific brain regions and cognitive performance, the relationship between regional brain activation and performance is not always straightforward. For example, data from functional magnetic resonance imaging (fMRI) studies have revealed not only that sleepiness-related performance deficits are associated with region-specific reductions in activation but also that the ability to maintain performance near baseline levels on specific tasks during sleep deprivation is associated with relative activation of cortical regions that were not significantly activated during performance of the same task in the well-rested state.[56,57] Those individuals whose fMRI images revealed such "new" regional relative activations during sleep deprivation were better able to maintain task performance than those individuals whose fMRI images failed to reveal similar new activations. These findings suggest that individual differences in recruitment of resources from other brain regions may underlie task-specific individual differences in resilience to sleep loss.

However, results from subsequent fMRI studies have painted a more complex picture.[58,59] These results indicate that individuals possess varying degrees of redundant functional neuronal circuitry to process information in a given task context in the well-rested state.[10] The results also indicate that sleep deprivation reduces the number of functional neuronal circuits available.[10,59] These findings suggest an alternative explanation for task-specific individual differences in resilience during sleep loss. Namely, individuals with the greatest baseline redundancy in functional neuronal circuits for the task at hand are the ones who can tolerate the greatest reduction in available circuits during sleep deprivation and are therefore the most resilient to performance impairment from sleep loss.[10,60]

Paradoxically, the relationship between sleepiness and performance may also be investigated during the first several minutes after awakening. This immediate postawakening period is characterized by profound sleepiness and performance deficits, which rapidly dissipate over about 20 minutes of continuous wakefulness.[61,62] This phenomenon is referred to as "sleep inertia." Sleep inertia constitutes a state of sleepiness and performance deficits not necessarily associated with sleep loss. Studies during the immediate postawakening period characterize a sleepy, yet sleep-satiated, brain that is ascending toward alertness.[63]

It is informative to compare regional cerebral blood flow patterns, as measured with positron emission tomography, during sleep deprivation, non–rapid eye movement (NREM) sleep, and sleep inertia. Relative to well-rested wakefulness, sleep-deprived wakefulness is characterized by global reductions in brain activity, with the greatest reductions evident in heteromodal (primarily prefrontal) association cortices and thalamus.[51] A similar pattern is evident when comparing NREM sleep to well-rested wakefulness: global deactivation (albeit of a greater magnitude than during sleep-deprived wakefulness), with the greatest deactivations evident in anterior (prefrontal) cortical regions and centrencephalic regions, including the thalamus.[64] In contrast, the immediate postawakening, sleep inertia period is characterized by bidirectional changes in regional cerebral blood flow, with waxing activity in anterior cortical regions and waning activity in centrencephalic regions across the first 5 to 20 minutes of wakefulness[65] (Figure 71-3).

Because deactivated anterior/prefrontal cortex is the only common finding among these three states (sleep-deprived wakefulness, NREM sleep, and sleep inertia), it has been surmised that activity in the prefrontal cortices is a critical determinant of sleepiness and its attendant performance deficits. Taken together, findings from neuroimaging studies suggest that performance impairment on tasks affected by fluctuations in sleepiness vary as a function of regional brain activity and interregional connectivity patterns, especially those functional connections involving prefrontal cortices.

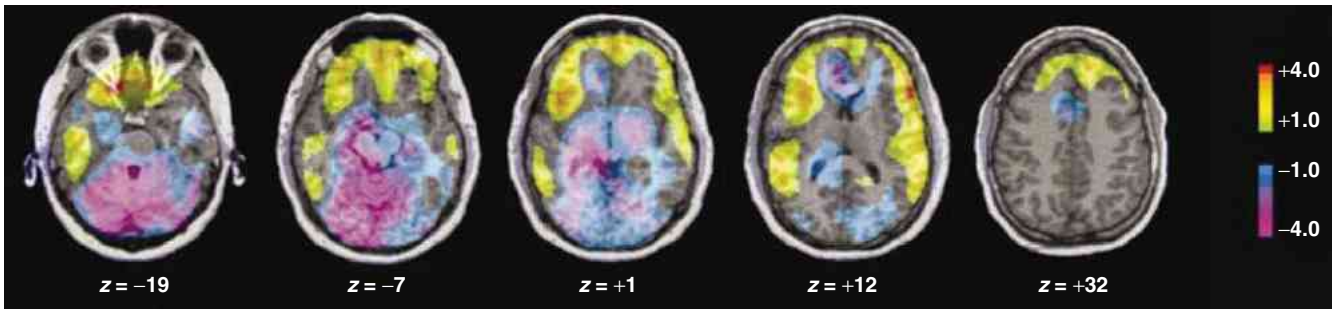

Figure 71-3 Brain map depicting changes in regional cerebral blood flow during the sleep inertia period between 5 and 20 minutes after awakening from stage 2 sleep. Color-coded values are Z-scores representing the significance level of changes in proportionally normalized regional cerebral blood flow in each voxel between scans acquired at 20 versus 5 minutes after awakening. The range of Z-scores is coded in the color table, with *red* designating Z-scores of greater than +4.0 and *purple* designating Z-scores of less than –4.0. Positive scores reflect increases in relative blood flow from 5 to 20 minutes after awakening; negative scores reflect concomitant, relative decreases during this period. (From Balkin TJ, Braun AR, Wesensten NJ, et al. The process of awakening: a PET study of regional brain activity patterns mediating the reestablishment of alertness and consciousness. *Brain* 2002;125:2308–19, with permission.)

CONCLUSION

Sleepiness contributes to hundreds of thousands of road accidents each year[66] and has been cited as a contributing factor in occupational disasters such as the meltdown of the Chernobyl nuclear reactor, the grounding of the Exxon Valdez oil tanker, and the decision to launch the ill-fated Challenger space shuttle. This chapter provides an overview of current thinking regarding the combined effects of sleep loss, the circadian rhythm of alertness, and time on task on performance. To the extent possible, the separate and combined effects of these factors should be considered when determining the risk for errors and accidents in operational environments and should be weighed against the costs and potential consequences of errors and accidents when determining and implementing fatigue management strategies.

Present-day hours-of-service regulations do not adequately account for all of these risk factors and are therefore of limited utility for promoting safety and productivity in operational environments. Recent developments that integrate mathematical performance prediction models into regulatory frameworks for hours of service can be used to address at least some of these issues (see Chapter 72).

In addition, indirect effects of sleep loss on performance and accident risk should be noted. Sleepiness tends to promote impulsivity and risk taking[67,68] and impairs self-monitoring of performance.[69,70] The extent to which these aspects of impaired judgment contribute to errors and accidents is unknown, although risk taking and sleep loss have been noted to be a potentially deadly combination in young male drivers.[71,72]

At the level of individuals, the consequences of sleepiness and the need to intervene remain difficult to gauge. A clinician seeing subjectively sleepy patients should discuss with them the risk for errors and accidents. The clinician may also try to estimate risk level by asking questions about the following:

- Type of job
- Nature of job (e.g., safety sensitive, mission critical)
- Level of exposure
- History of incidents or "near misses"
- Safety measures that could be put in place (e.g., rest breaks, ergonomic tools)
- Habitual sleep-wake-work schedules
- Tasks, hobbies, and circumstances that intrude on time for sleep
- Length of commute to and from work
- Possible consequences of adverse events

It is important to explain that a patient's own subjective evaluation of his or her impairment resulting from sleepiness is likely to be inaccurate, with a tendency to overestimate one's own capabilities.[4,73] Furthermore, because of the stochastic nature of human error, past performance or safety does not guarantee future performance or safety. Bringing these issues to the attention of patients may prompt them to make behavioral changes and thereby helps to reduce their risk for sleep loss-related errors and accidents.

CLINICAL PEARL

Interactions among multiple factors, such as recent and long-term sleep-wake history, circadian rhythm, time-on-task effects, and individual differences in vulnerability to sleep loss, lead to sleepiness-related performance deficits and contribute to errors and accidents. Such factors should be taken into consideration when devising operational work-rest schedules, implementing fatigue management strategies, and assessing patients who complain of sleepiness or fatigue.

SUMMARY

During the past decade, significant progress has been made toward elucidation of the physiologic basis of sleepiness and the neurobiologic and neurobehavioral correlates of sleepiness-induced performance deficits. The deleterious effects of sleep loss on various aspects of performance are well known and well documented. Nonetheless, inadequate sleep remains virtually ubiquitous and exacts an inestimable toll on society through increased errors and (sometimes catastrophic) accidents as well as reduced efficiency and productivity.

Sleepiness manifests as a function of the combined effects of the homeostatic pressure to initiate sleep and the circadian rhythm of alertness, with considerable trait-like individual differences in the ability to maintain performance under sleepiness-inducing conditions. Although it is not possible to compare the relative extent to which specific cognitive abilities or processes are decremented by sleepiness, it is known that

sleepiness is (for example) associated with an increased tendency toward risk taking and overestimation of one's own performance capabilities, deficits in judgment that can clearly contribute to the likelihood of errors and accidents.

Although sleep loss in real-world operational environments is typically characterized by continuous (or near-continuous) work, there is a dearth of studies in which the interaction between sleep loss and cognitive load or time on task has been addressed specifically or adequately. Nevertheless, the evidence that does exist provides compelling evidence that performance under operational conditions is the result of an interaction between sleepiness and cognitive workload. Future progress will be realized with an improved understanding and appreciation of the interactions between sleep loss and task-related variables, an improved ability to measure these effects, and implementation of alertness and performance management strategies that, unlike current hours-of-service regulations, effectively account for these effects.

Sleep and Performance Prediction Modeling

Steven R. Hursh; Thomas J. Balkin; Hans P.A. Van Dongen

Chapter 72

Chapter Highlights

- Sleep loss and circadian misalignment cause neurobehavioral performance impairment and contribute to errors, incidents, and accidents. Biomathematical models may be used to help manage fatigue risk in operational settings.
- Most currently available biomathematical models predict sleepiness or neurobehavioral performance impairment based on three basic components: circadian variation, homeostatic sleep-wake regulation, and sleep inertia.
- Recent advances in biomathematical modeling include accounting for nonlinear interaction between circadian and sleep-wake homeostatic processes, prediction of the cumulative effects of chronic sleep restriction on neurobehavioral performance, and extension of model predictions from group averages to individuals.
- Biomathematical models are gaining acceptance in operational settings as components of fatigue risk management systems.

Alertness and cognitive performance vary as a function of time of day, time awake, and a variety of situational factors. Prescriptive rules for hours of service do not capture these intrinsic temporal influences and therefore do not fully protect against performance deficits. Accordingly, a number of "biomathematical models of fatigue" have been (and continue to be) developed for anticipating and avoiding performance impairment; targeting optimal timing and dosing of countermeasures; improving work schedules, productivity, and safety; and informing accident investigations.

Most biomathematical performance prediction models are based on quantification of two primary and one secondary neurobiologic processes underlying variation in alertness and performance over time: the circadian process and the homeostatic process (see Chapter 37) as well as the sleep inertia process.[1-7] A variety of other factors affecting alertness and performance, including stimulant use, light exposure, distractions, and motivation, are currently not accounted for in most models. Instead, these factors are generally considered to effect transient deviations from the general trend that temporarily mask but do not alter the circadian or homeostatic processes that drive those trends. As such, current biomathematical models are useful for predicting normative performance for specific times of day, durations of time awake, and recent sleep history, with the understanding that actual, moment-to-moment alertness and performance of individuals may vary as a function of a broad array of factors.

One of the primary processes on which physiology-based, biomathematical models are built is the circadian process, which influences both performance and sleep regulation. This process is presumed to reflect physiologic activation apparent in measurements of body core temperature and certain hormones (such as melatonin). Performance increases (improves) with circadian activation, whereas propensity to sleep decreases (and vice versa).

The other primary process tracks the brain's level of sleep debt (level of physiologic need for sleep), which in turn affects alertness and performance capacity such that it is depleted while awake and replenished while asleep. This sleep-wake homeostatic process is dependent on the number of hours of recent sleep obtained (prior day), the number of hours of wakefulness (time since awakening), and current overall sleep debt (which is dependent on the amount of sleep loss that has accumulated over days, weeks, or perhaps longer). Performance capacity decreases (degrades) with homeostatic depletion, and propensity to sleep increases. The circadian and homeostatic processes continuously interact to influence observed performance and propensity to sleep.

A third process, called sleep inertia, reflects the temporary degradation in performance that is seen immediately after awakening. The magnitude of this effect depends primarily on depth of sleep at the time of awakening (which is itself affected by both the circadian and homeostatic processes). Sleep inertia dissipates with time since awakening, and recovery of performance is typically essentially complete within about 20 minutes of awakening. [8]

Recent advances have refined the mathematical representations of these three components, have added interaction terms among the components, and have added factors to account for chronic sleep restriction and dynamic variations in circadian phase (including the influence of light exposure). Additionally, methods have been developed to estimate patterns of sleep under specific work schedules.[5,9-13]

COMPONENTS OF THREE-PROCESS BIOMATHEMATICAL MODELS

To illustrate the modeling approach shared in general form by several three-process models,[2-5] the Sleep, Activity, Fatigue, and Task Effectiveness (SAFTE) model will be used in this

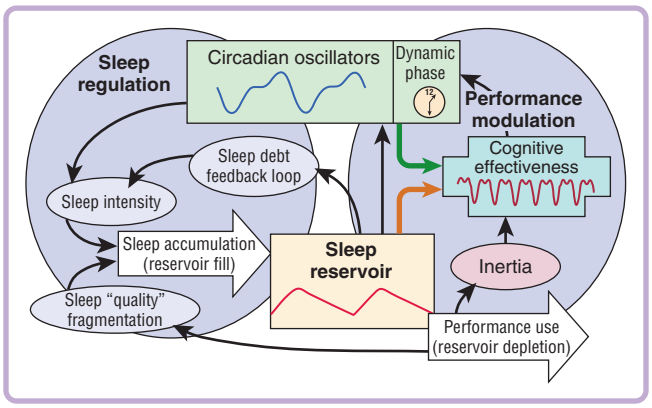

Figure 72-1 Schematic of the Sleep, Activity, Fatigue and Task Effectiveness (SAFTE) model.[5,9]

chapter. The components of this model are diagrammed in Figure 72-1.

Circadian Oscillator

Performance while awake and the drive to sleep are both controlled, in part, by a circadian process.[3,14,15] For a person entrained to a sleep period of 11 PM to 7 AM, performance reaches a peak in the early evening at approximately 7 PM and—if it could be measured during sleep—would fall to a minimum at approximately 4 AM. There is a secondary peak of performance in the morning at about 10 AM, and a secondary minimum (dip) in the early afternoon at about 2 PM. Negatively correlated with this alertness pattern is a tendency to fall asleep, which reaches a peak at about the same time performance and alertness reach a trough.

The existence of both a major and a minor peak in performance with corresponding troughs between them is often modeled as the result of two linked harmonic oscillations (cosine functions), one with a period of 24 hours and the other with a period of 12 hours. This results in a combined function of the form shown in Figure 72-2.[16] More dynamic models of the circadian process use a limit cycle or Van der Pol oscillator that yields a function of similar form.[17]

A simplifying assumption of most biomathematical models is that the same underlying arousal oscillator drives the variations in both cognitive performance and sleep propensity. The amplitude of the circadian process is dependent on the level of sleep debt modeled by the sleep-wake homeostatic process.[6,18,19] The phase (timing) of the circadian process is driven largely by environmental factors, most notably the timing of sunlight exposure,[12,20] but also has an individual trait component expressed as morningness and eveningness.[21]

Sleep-Wake Homeostatic Regulation

The control of sleep and its influence on cognitive capacity is usually modeled as a homeostatic process.[15,22-24] One way to conceptualize this process is through a sleep reservoir (see Figure 72-1). A fully rested person has a certain performance capacity (represented by the sleep reservoir capacity). During wakefulness, units are subtracted from the sleep reservoir according to a use function. During sleep, units are added to the sleep reservoir and the capacity to perform and be alert is restored.

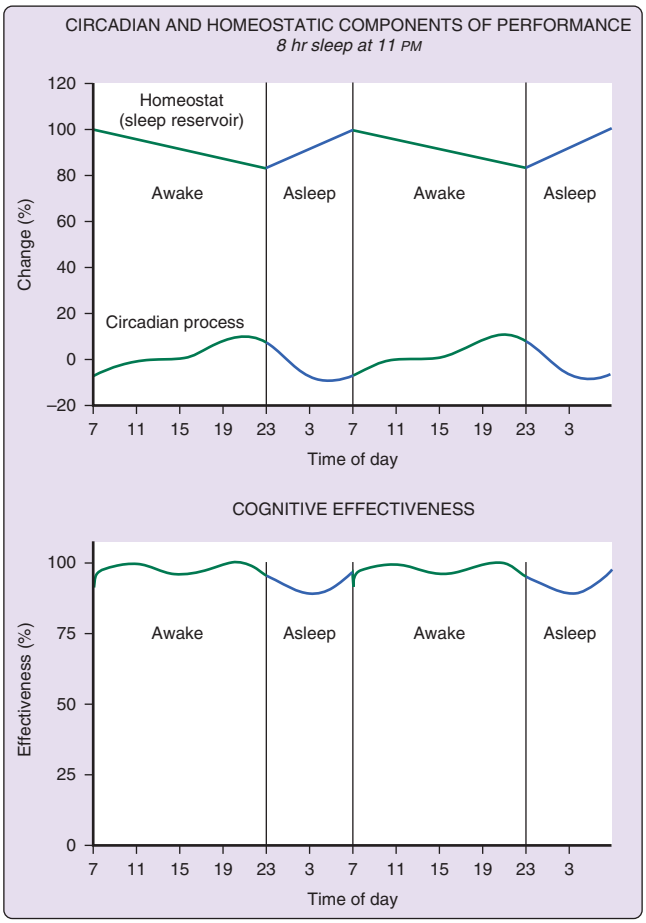

Figure 72-2 The sleep-wake homeostatic (*top*) and circadian (*middle*) processes affecting performance (cognitive effectiveness, *bottom*). Graphs are based on SAFTE model simulations of a 16-hour wake/8 hour sleep schedule, with sleep starting at 11 PM. (Performance predictions during sleep are suppositional because they cannot actually be observed during the sleep state.)

The rate of unit accumulation during sleep is driven by two factors: circadian variation and current overall sleep deficit, which is the shortage in the current level of the reservoir. Because the rate of unit accumulation is in part regulated by the current level of the reservoir, the process is homeostatic. The top panel of Figure 72-2 shows the decrease in performance units during wakefulness and the increase during sleep.

Results from laboratory studies have revealed that chronic sleep restriction (anything less than approximately 8 hours per 24 hours) leads to cumulative alertness and performance deficits.[25-27] For sleep durations of more than 4 hours per night, performance declines across days but eventually reaches a suboptimal plateau or equilibrium level.[13,26] The achievement of this suboptimal equilibrium state implies a feedback-modulated control system. Modeling this phenomenon has led to much new activity in model development.[5,11,13,28,29] In the SAFTE model, this phenomenon is implemented by reducing the reservoir capacity each time sleep restriction occurs (see later).

Accumulation of performance units does not start immediately on falling asleep. There is a 5-minute delay from sleep onset until performance units begin to accumulate. This delay

accounts for the approximate time required to return to restorative sleep following a brief arousal and results in a penalty during recuperation (see Figure 72-1) in an environment that leads to frequent interruptions (sleep fragmentation).

Sleep Inertia

A third factor diagrammed in Figure 72-1 is the transient performance impairment that often occurs immediately following awakening (i.e., sleep inertia).[8,22] It is typically modeled as an exponentially decreasing performance deficit.[5,30,31] Because of the relatively short duration of sleep inertia, it is relevant mainly in operational contexts in which individuals may be required to perform immediately on awakening (e.g., first responders), and therefore it is not included in some biomathematical models.[6,10,32]

COMBINED EFFECTS: PREDICTED PERFORMANCE

Alertness and performance are modeled as the combined effect (in most models calculated as the sum) of the mathematical functions for the circadian oscillator, the sleep-wake homeostatic reservoir, and sleep inertia immediately following awakening. The sum of the homeostatic process with the circadian process produces a performance function with two nadirs, one in the late night to early morning and a smaller one in the early afternoon. These two processes are shown in the top panel of Figure 72-2. Their combined effects on performance are shown in the bottom panel of Figure 72-2.

During the first part of a daytime waking period, the circadian process increases (growing activation) and the homeostatic process decreases (reservoir depletion). When summed, the changes in these two processes are approximately offsetting each other, leading to relatively constant daytime performance. After the 7 PM (approximately) evening peak in the circadian process, both the circadian process and homeostatic process decline, leading to a precipitous loss of alertness and performance at approximately 11 PM that facilitates sleep onset.

During nighttime sleep, the circadian process continues to decrease (declining activation, which facilitates sleep maintenance) and the homeostatic process increases (restoration of reservoir level). After the early morning nadir in the circadian process, both the circadian and homeostatic processes rise, culminating in spontaneous awakening at approximately 7 AM.[1] Combined (summated), the two processes produce the performance profile depicted in the bottom panel of Figure 72-2.

QUANTIFYING RECUPERATION DURING SLEEP

During sleep, the sleep reservoir is replenished. In the SAFTE model, the rate at which the reservoir is filled depends on the prior long-term sleep debt (as reflected in the current level of the reservoir). A large reservoir deficit leads to an increased rate of replenishment; a small deficit leads to a reduced rate of replenishment. The rate of replenishment also appears to be modulated by the circadian variation in sleep propensity[33] and may follow the circadian pattern of sleep propensity[34,35] (the inverse of the circadian pattern of activation in the top panel of Figure 72-2). The net effect is a near-linear homeostatic reservoir accumulation through a normal night (see top panel of Figure 72-2), which is in line with results that show an approximately linear relationship between sleep duration and performance recuperation.[25,36]

The homeostatic regulation of sleep[37] leads to equilibrium states under certain conditions of chronic sleep restriction.[8] If a subject is scheduled to take less than an optimal amount of sleep each night (defined here as approximately 8 hours) and instead obtains, for example, 5 hours per day, the reservoir initially loses more units during the waking period than are made up during the sleep period. This results in a sleep debt at the end of the sleep period that accumulates over days.[24,25] However, because the rate of accumulation during sleep increases with sleep debt, eventually the rate of accumulation increases so that 5 hours of sleep makes up for 19 hours of wakefulness. At this point, the reservoir reaches an equilibrium state over days, and no further debt is accumulated. However, the reservoir remains at less than 100% replenished as long as the person remains on this reduced sleep schedule.

The sleep-wake homeostatic process is not infinitely elastic, and results show that there is a limit to the rate of accumulation and thus to whether a given sleep-wake schedule permits equilibrium. In the SAFTE model, any schedule that provides less than 4 hours of sleep per day will not reach an equilibrium state, and performance capacity will gradually deplete entirely. Results of biomathematical model analyses have provided further evidence that there is such a bifurcation (i.e., qualitative change in behavior) for the homeostatic process when sleep is reduced to below approximately 4 hours.[8]

The long-lasting effects of chronic sleep restriction on performance impairment and reduced capacity to recuperate[24,25] suggest that some aspect of sleep-wake homeostasis undergoes a gradual change that is slow to recover.[2,27] This phenomenon has prompted modelers to revise the sleep-wake homeostatic process by adding a long-term process.[2,8,27,28,38,39] Within the context of the SAFTE model, this process is instantiated as a gradual downregulation of the sleep reservoir capacity during chronic sleep restriction. When sleep durations return to the nominal value of approximately 8 hours per day, the downregulation of the reservoir capacity is gradually reversed.

The implication is that after a period of chronic sleep restriction, it takes multiple days of recovery sleep to restore performance to baseline levels.[8,24] Laboratory evidence has shown that extending sleep to more than 8 hours per day for an extended period of time provides some resilience to the effects of subsequent sleep restriction.[33] This recent finding implies that it should also be possible to moderately increase the capacity of the sleep reservoir.[6] In the SAFTE model, more than 8 hours of sleep per day will hasten the recovery of the reservoir set point to the full value but will not increase capacity beyond the nominal limit for a person consistently sleeping 8 hours per day, so the findings that sleep extension confers performance benefits during subsequent sleep restriction may require further model refinement (as has already been pursued in another model[6]).

The time of day also affects the recuperative potential of a sleep period. For an individual given 8 hours of sleep per day from 11 AM until 7 PM, waking performance reaches a peak about 4 hours after awakening (9 PM). It then rapidly declines during the late night and early morning hours to a

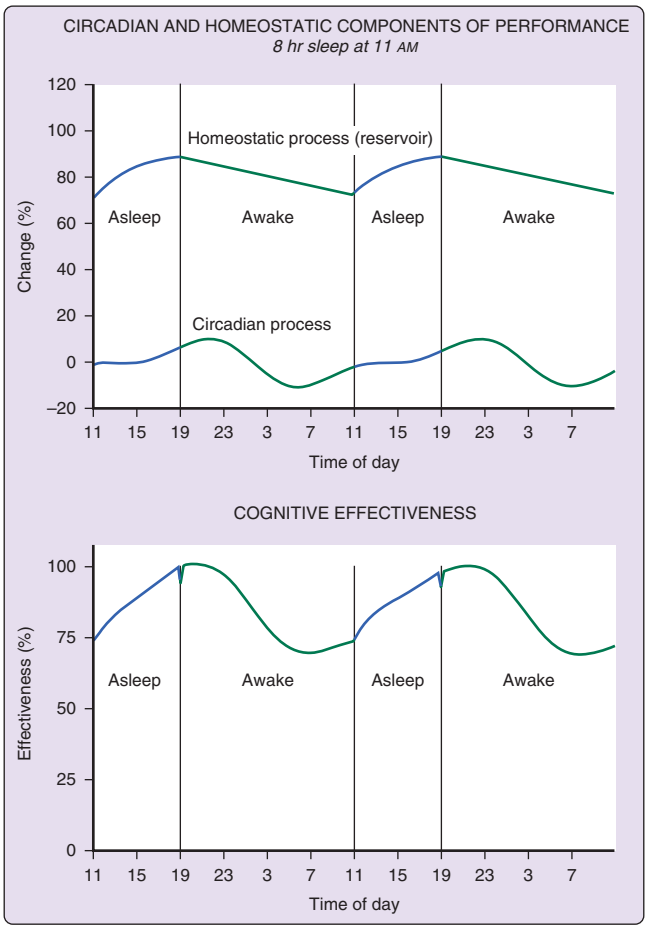

Figure 72-3 The sleep-wake homeostatic (*top*) and circadian (*middle*) processes affecting performance (cognitive effectiveness, *bottom*) when 8 hours of sleep occurs during the day starting at 11 AM. Graphs are based on SAFTE model simulations.

deep minimum at about 5 AM, as illustrated in the bottom panel of Figure 72-3. This pattern is substantially different from the performance pattern seen after nighttime sleep (see Figure 72-2) for two reasons. First, owing to the circadian rhythm in sleep propensity, daytime sleep periods exhibit less physiologic sleep and therefore less homeostatic reservoir replenishment, that is, the reservoir level does not return to 100% (see Figure 72-3, top panel). Second, circadian activation reaches its minimum in the early morning hours, at the same time that the sleep-wake homeostatic reservoir is increasingly depleted.

This pattern has negative implications for performance under shift schedules that require daytime sleep. It is well documented that most mistakes on the night shift occur during the early morning hours,[34,35] and biomathematical models predict this outcome. Note also that the pattern illustrated in Figure 72-3 is likely to be a "best case scenario" in that it was presumed that 8 hours of sleep was achieved during the 8-hour daytime sleep period. However, results indicate that shift workers seldom achieve 8 hours of sleep during the daytime hours even if they are sleep deprived. That is, sleep propensity (debt) tends to be insufficient to completely overcome countervailing circadian wake drive and environmental factors such as daylight and social activities.[36,37]

SLEEP ESTIMATION

The accuracy of biomathematical model predictions is dependent on accurate measurement or prediction of sleep times and durations. Sleep timing and duration can be estimated mathematically using the two-process model of sleep regulation[38] (see Chapter 36) and detailed models of sleep neurobiology.[40,41] However, these models do not account for social and other nonbiologic constraints on sleep.[42] For this reason, in situations in which biomathematical models are applied to work schedules, it may be necessary to make use of an alternative method for estimating potential sleep given the available sleep opportunities.

One approach to developing a sleep estimation algorithm involves modeling the observed likelihood of sleep from results of field studies in the operational environment in which sleep was recorded by means of diaries or actigraphy.[43] In the SAFTE model, it is assumed that the occurrence of major sleep episodes is largely the result of a decision to go to bed, conditioned by the person's typical need for sleep and opportunities to sleep, reflective of social, cultural, and professional factors. A sleep estimation algorithm simulates the decision process that governs when a person chooses to sleep. Sleep is assumed not to occur during work or commuting to work because these periods limit sleep opportunities.

Within sleep opportunities, further decisions about when to sleep are made based on sleep habits. These habits might include such factors as the preferred bedtime, the normal duration of sleep on work and rest days, the minimum duration of a nap, and any time during the day that a person normally uses for personal activities and not sleep. The sleep estimation algorithm combines these parameters with circadian factors (described earlier) to generate estimates of the timing and duration of sleep during opportunities afforded by the work schedule.[11,42]

In recent studies with airline pilots (36 domestic and 15 international) and shift workers (147 workers with fixed and rotating shift patterns with irregular shift extensions and overtime), the algorithm was trained on actigraphically recorded sleep-wake to achieve 85% to 87% accuracy for predicting sleep and wakefulness for individual subjects. The algorithm estimated average total sleep per 24 hours to within 1 minute of the actual group average.[44] Although there remained considerable individual differences in sleep patterns, from an aggregate risk assessment perspective, the SAFTE model predictions based on such data were as good as inputting actual wrist actigraphy data. The optimal settings of the algorithm were nearly identical for these two very different work populations, a function of the fact that the sleep-wake behaviors of all humans are governed by essentially the same physiologic and environmental factors.

CIRCADIAN PHASE SHIFTING

When people move to another time zone or alter work patterns so that sleep and wake consistently occur systematically at new times of day, the internal circadian oscillator that modulates alertness and performance shifts to this new schedule. During this period, individuals experience performance degradation, disrupted mood, and feelings of dysphoria, collectively termed jet lag (see Chapters 35 and 37).[45-48] Several models simulate this process and adjust the phase of the

circadian rhythm to coincide with the new activity pattern. This feature is critical for the accurate prediction of the effects of moving to a new time zone or changing to a new and regular work schedule, such as changing from the day shift to the night shift.[37]

The factors that mediate phase shifts vary across models. Research suggests that a major driver of circadian phase is exposure to sunlight or bright light[49]—especially the blue part of the spectrum[50] (see Chapter 35). In some models, direct measurements of light exposure are required as input and are used to predict changes in circadian phase.[3] Other models use a surrogate for sunlight measurement.[5,9,11,51]

In the SAFTE model, it is assumed that the probability of bright light exposure is proportional to the time spent awake during daytime hours. Hence, the model adjusts the rate of phase change based on the proportion of waking time that occurs during daytime hours. This simplification eliminates the need to take continuous measurements of light to drive the circadian process, but it also means that there is no mechanism to input light exposure as a deliberate countermeasure.[52-54] Given that the interaction between the circadian oscillator and the sleep-wake homeostatic process appears to be bidirectional,[18] the timing of the sleep period may in and of itself also contribute to circadian adjustment.[11,55]

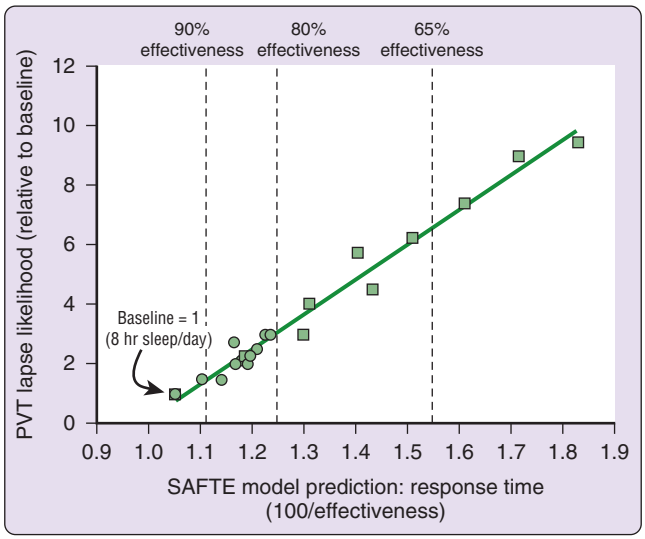

Figure 72-4 Linear relationship of lapse likelihood on a psychomotor vigilance test (PVT) to predicted response time (100/effectiveness) from the SAFTE model. PVT data were recorded during days of chronic sleep restriction to 3 hours per day (○) or 5 hours per day (■).[26]

PERFORMANCE PREDICTION

As illustrated in Figures 72-2 and 72-3, biomathematical performance prediction models simulate the dynamic interplay of circadian variation in alertness and sleep propensity, homeostatic sleep-wake regulation supporting performance capacity, and short-term sleep inertia following awakening. Specific models differ in the manner in which these three factors are represented and mathematically combined. The predictions of such models also depend on the metrics (units) of the models. For example, the units expressed by the SAFTE model are percent changes in cognitive speed from baseline performance when fully rested (i.e., 8 hours of sleep per 24 hours) and diurnally oriented (i.e., sleep from 11 PM to 7 AM). Cognitive speed corresponds to speed of response on a psychomotor vigilance test (PVT).[56] Studies that have included other cognitive tests along with the PVT have shown them to be highly correlated, with the PVT showing the greatest sensitivity to daily sleep amounts.[57]

When predicting group averages (but not individual performance[41]), translation functions can be used to calculate other performance metrics such as lapse likelihood, reaction time, and mean cognitive throughput (correct responses per unit of time) on other cognitive tests, such as serial addition-subtraction, choice reaction time, logical reasoning, and code substitution. Figure 72-4 shows output from a translation function that expresses performance as PVT lapse likelihood, which increases with time awake and mirrors response speed.

To illustrate the potential of these models to accurately predict performance under a variety of sleep-wake-work schedules, two examples are offered. The first example concerns performance changes on a variety of cognitive tasks during a period of total sleep deprivation in a laboratory.[58] As depicted in Figure 72-5, these measures were compared with model predictions and found to conform to the group means of the performance observations with 98% of the variance explained.

The second example deals with chronic sleep restriction as encountered in demanding schedules that allow for less than optimal nightly sleep durations over extended periods of time. Figure 72-6 shows performance observations (daytime averages) obtained during a laboratory dose-response study involving 7 days of sleep restricted to 3, 5, 7, or 9 hours per day, preceded by 3 baseline days and followed by 3 recovery days, each with 8 hours of time in bed per night.[26] As shown in the figure, the group means of the objective performance measures were compared with the predictions of the model and found to explain 94% of the variance.

Biomathematical models may predict performance on a selected, standardized performance task, such as the PVT, or on an abstract performance metric, such as a sleepiness scale from, say, 0 to 100. Mathematical modeling may be applied to make absolute predictions, which are compared against a threshold (e.g., that distinguishes acceptable from unacceptable performance[59]). In these applications, the specific performance metric used and the value of the threshold are crucially important.

More commonly, biomathematical modeling is used to make relative comparisons of predicted performance during two or more alternative sleep-wake or work scheduling options. In such cases, modeling enables selection of the scheduling alternative that is less fatiguing, or less fatiguing as well as more productive or cost-effective.[60] In this application, the specific performance metric used is not critical. However, there is debate about whether "better versus worse" should be quantified based on maximum or minimum level of the metric (i.e., highest risk) or on some other calculation such as a combination of both level and duration of performance impairment (i.e., risk exposure).[61]

Ongoing mathematical modeling efforts are aimed toward predicting, in greater detail, the effects of sleep loss on performance on a diverse range of tasks.[62,63]

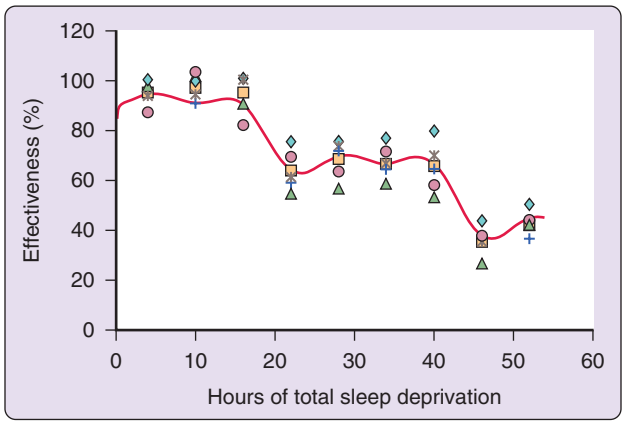

Figure 72-5 Fatigue model predictions for group-average (n = 12) cognitive performance during 54 hours of total sleep deprivation (beginning at 7 AM) compared with actual observations[58] for several cognitive measures (different symbols) and mean cognitive performance (*squares*) expressed relative to baseline. Model predictions were made with the SAFTE model (*solid line*) with a reservoir depletion rate of 1.1% per hour.[5] ◆, Serial reaction time; +, decoding problem performance; ж, encoding problem performance; ●, auditory vigilance; ▲, logical reasoning.

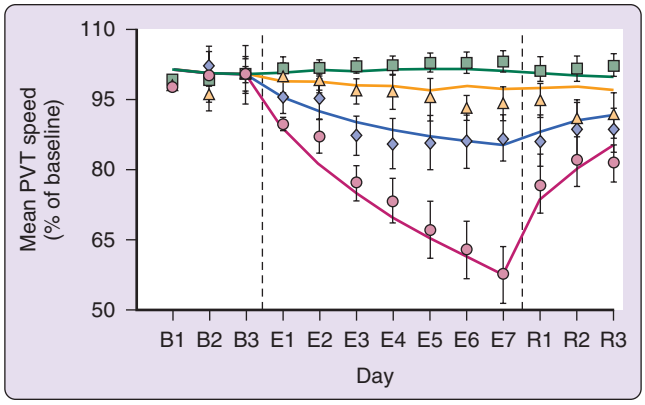

Figure 72-6 Fatigue model predictions for group-average psychomotor vigilance test (PVT) performance (averaged within each day) across 3 baseline days (B1–B3) with 8 hours time for sleep; 7 experimental days (E1–E7) with daily sleep restricted to 3 hours (●, n = 13), 5 hours (◆, n = 13), 7 hours (▲, n = 14), or 9 hours (■, n = 16); and 3 recovery days (R1–R3) with 8 hours time for sleep.[26] Model predictions were made with the SAFTE model (*solid line*).[5]

MODELING APPLIED TO OPERATIONAL SETTINGS

Most biomathematical performance prediction models are optimized to predict changes in cognitive performance as measured by standard laboratory tests performed under controlled laboratory conditions. It is assumed that these tests measure changes in the fundamental capacity to perform a variety of tasks that rely, more or less, on the cognitive skills of attention, detection, discrimination, reaction time, mental processing, reasoning, or decision making. However, the extent to which any specific operational task relies on these cognitive skills is generally not known. Thus deficits in cognitive capacity seen in the laboratory may not always predict deficits in the capacity to perform different operational tasks.

It is reasonable to assume, however, that changes in task performance will be correlated with changes in underlying

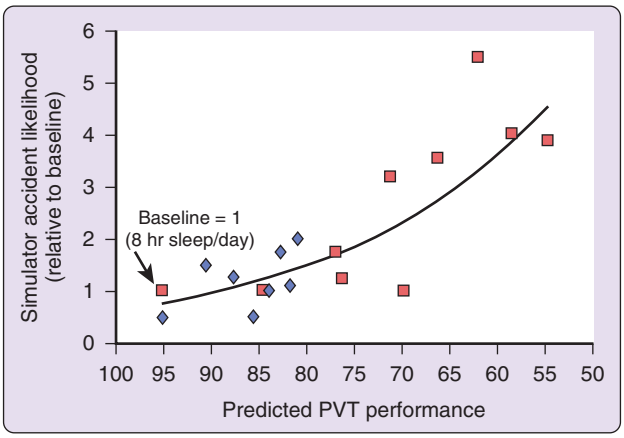

Figure 72-7 Systematic relationship (*solid line*) between model predictions optimized to predict psychomotor vigilance test (PVT) performance and group-average accidents observed in a driving simulator.[64] Model predictions were made with the SAFTE model.[5] ■, 3 hours sleep per day (n = 13); ◆, 5 hours sleep per day (n = 13).

cognitive capacity and therefore that changes in one task will be correlated with changes in another task if both tasks tap the same underlying capacity. The validity of this assumption has been demonstrated in job task simulator experiments. For example, Figure 72-7 illustrates that there is a systematic relationship between predicted performance for the PVT (generated from SAFTE) and driving simulator accident data from subjects given varying amounts of daily sleep for a week.[64]

Biomathematical modeling (prediction) of operational task performance could be used to design better work schedules, alter the timing of critical tasks to coincide with periods of predicted optimal performance, or time the application of countermeasures to prevent errors and accidents. Unlike prescriptive hours-of-service regulations, these models provide physiology-based, flexible, and quantifiable ways to optimize safety and performance in operational environments.

Current uses of biomathematical modeling alone or as a component of fatigue risk management systems in operational settings include the following:

- Prediction of risk for impairment associated with a given work-rest or wake-sleep schedule, allowing for selection of optimal duty scheduling
- Guidance for effective implementation of countermeasures
- To inform, supplement, or substitute hours-of-service policies and regulations
- As an aid in post hoc incident or accident investigations to determine the extent to which fatigue may have been a contributing factor
- As an educational tool for understanding the operational consequences of insufficient sleep and circadian misalignment

A relatively new application of biomathematical modeling involves the use of model predictions as a surrogate for performance measurements in settings where sleep can be measured (e.g., with actigraphy) but measuring performance would interfere with performance of critical tasks.

Biomathematical modeling plays a key role in the approval of exceptions to flight and duty time limitations under the fatigue risk management system approval process of the U.S. Federal Aviation Administration (FAA) as implemented in

2014.[65] Using a multistep approval process, the FAA accepts applications for exceptions to prescriptive flight and duty time limitations that combine longer duties with offsetting rest and time-of-day limitations. To obtain final approval, the aviation certificate holder must collect data to verify that sleep and performance under the alternative means of compliance (AMOC) are equivalent to what might be observed under the prescriptive rules.

To gain temporary approval to conduct operations to collect the necessary data, the aviation certificate holder is allowed to provide biomathematical modeling results or actual sleep and performance data (when available) to the FAA in order to establish a safety case for the AMOC. The FAA bases its final approval for the AMOC on statistical equivalence[66,67] of actual sleep and performance findings compared with a control condition (i.e., one that meets the prescriptive limitations). The integration of biomathematical modeling into a regulatory framework that allows for AMOC reflects the demonstrated utility of modeling for simultaneously enhancing both fatigue risk management or operational safety and efficiency of flight operations.

INDIVIDUAL DIFFERENCES

Individual differences in responses to sleep loss and circadian timing (e.g., in shift work)[68] represent a substantial source of error variance in most biomathematical models, which were developed first and foremost to predict group-average performance. Individual differences can be accounted for broadly by reflecting the expected distribution of performance outcomes in the model predictions, based on the individual variability of performance changes observed in laboratory studies.[11,69] This approach provides information on the range of effects to be expected under a specific sleep-wake-work schedule, but it does not provide information about where any specific individual would fall within that range.

Individual differences in vulnerability to sleep loss have been demonstrated to be traitlike[70] and thus predictable on a subject-specific basis.[71] Two complementary strategies could be implemented to enhance individual-level prediction.[41] The first is to incorporate predictors of performance vulnerability, such as morningness-eveningness,[72] basal sleep need,[73] or specific genetic polymorphisms,[74-76] into the model equations.[77] To date, none of these predictors has been demonstrated to account for a substantial portion of interindividual variability, but research efforts are ongoing[76,78] and novel candidate predictors continue to be identified.

The second strategy is to tailor the parameters of the model to the individual based on real-time or near-real-time performance observations obtained from the individual. Algorithms for this have been developed,[41,79,80] with confidence intervals indicating the statistical certainty level of the predictions.[79]

LIMITATIONS OF BIOMATHEMATICAL MODELS

Biomathematical modeling has become a valuable tool for fatigue risk management (see Chapter 71). However, it is also based on evolving science, and thus there are limitations that should be noted.[77,81,82] Some limitations to consider when evaluating a model include the following:

- Accuracy of model predictions relative to observations obtained from laboratory versus field studies
- Generalizability, that is, to what extent the model is applicable to sleep-wake-work scenarios not used in its development
- Balance between sensitivity and specificity, that is, the extent to which predictions are liberal or conservative with regard to identifying periods with meaningfully increased or decreased performance

These and other modeling issues were discussed at the international Fatigue and Performance Modeling Workshop (June 13 to 14, 2002, Seattle, Wash.) and were documented in the proceedings of that meeting.[83] Since then, biomathematical models have undergone further development, rendering some of the information in the proceedings outdated. Nevertheless, the volume continues to provide valuable documentation of biomathematical modeling as a developing science.

The accuracy of a model depends on the accuracy of the major inputs to that model. A key input is the pattern of sleep-wake under a given work schedule. In laboratory studies, precise polysomnographic quantification of sleep-wake is possible. Such data are seldom available in operational settings, but a variety of other techniques can be used to obtain sleep data, such as wrist actigraphy (see Chapter 73), sleep diaries, or an algorithmic sleep estimator (discussed previously). Although algorithmic sleep estimation can be useful for prediction of elevated accident risk,[84] the accuracy of such predictions depends on the accuracy of the sleep estimates that serve as input to the model. Such estimates may suffice when the goal is prediction of the average performance of large groups of workers, but they may be problematic when the goal is prediction of individual performance.

Similarly, as noted previously, measures of circadian rhythm are rarely available in the operational environment, and thus estimates of the phase and amplitude of the circadian process must be generated from the timing of sleep, light exposure, or other environmental drivers of biologic rhythms. Again, such estimates may suffice for large groups but are likely to be less useful for predicting the performance of individuals who may, for example, be extreme morning or evening types.[72] Additional information (e.g., recent sleep-wake history) would be required to reduce this source of error.

Another major input to performance prediction models is "initial state." This refers to the sleep debt (reservoir level), circadian phase, and (depending on the specific model) other relevant variables that provide the starting point from which predictions are made. If the initial states are unknown, assumptions regarding the likely sleep-wake history and circadian phase need to be made. The accuracy of these assumptions initially determines the accuracy of the model predictions. However, the influence of the initial state estimates diminishes over time,[85] and the accuracy of the model improves as actual daily sleep measures (e.g., actigraphic sleep measurements) or work schedule–based sleep estimates accrue and are used as input to the model.

CONCLUSION

Biomathematical models predict physiology-based cognitive capacity as a function of sleep-wake history, circadian rhythm, and sleep inertia. Cognitive capacity affects the ability to perform specific tasks and thereby affects the risk for making an error or the probability of rare events like accidents.[84]

It is important to understand assumptions underlying biomathematical models. In most three-process models, it is assumed that the rate and magnitude of cognitive performance impairment are independent of the nature of activities performed while awake (e.g., task load, work pace). However, it is known that performance decreases as a function of time on task,[86,87] the number of flight segments during an aircrew duty period,[88] successive duty periods in shift work,[89] and other factors. Conversely, performance is temporarily restored by rest breaks and sustained by days off.[39,90] Current performance prediction models do not account for these factors, nor do they account for the effects of pharmacologic countermeasures (e.g., caffeine, although model development to address caffeine is underway[91]).

As a rule of thumb, biomathematical model predictions should be interpreted as representing the fundamental cognitive capacity of a group or person unaided by pharmacologic countermeasures, that is, a cap on performance as determined by underlying brain physiology. However, actual performance will depend on additional factors, such as the nature of the tasks being performed and the circumstances at hand,[92] which are not accounted for in the model prediction.

CLINICAL PEARL

Sleep loss and circadian misalignment produce deficits in cognitive performance. Biomathematical models that predict performance based on these factors are valuable tools that are increasingly being applied in both operational and nonoperational settings. For personal use, these models can be applied to determine the effects of sleep-wake duration and timing on performance and alertness and thus serve to guide clinical, professional, and personal decision making regarding sleep habits and use of countermeasures. For employers, regulatory agencies, and practitioners in occupational medicine, these models are useful to guide the design of better work schedules, reduce performance errors and accidents, improve the health and well-being of employees, and advance public safety.

SUMMARY

Because insufficient sleep (which is prevalent in modern society) leads to lapses of attention, slowed reaction time, and impaired reasoning and decision making, it is a major proximate cause of errors and accidents in both industrial and military operational settings. Biomathematical models have been developed to predict sleep- and alertness-mediated performance in laboratory and field environments. Such models are already being incorporated into scheduling tools to anticipate and avoid performance impairment in operational settings. Most available models predict performance based on three basic components: circadian variation in alertness and sleep propensity, homeostatic sleep-wake regulation, and sleep inertia. These processes vary over time as a function of sleep-wake patterns and combine to produce changes in subjective alertness and cognitive performance capacity. Current models provide accurate predictions of average performance of groups under variations in sleep opportunities or work schedules. Efforts are underway to further refine these biomathematical models to enhance accuracy of prediction for individuals.

Chapter 73

Fatigue Risk Management Systems

Philippa H. Gander; Lora J. Wu; Margo van den Berg; Amanda Lamp; Laura Hoeg; Gregory Belenky

Chapter Highlights

- Fatigue-related performance impairment is widely recognized as a workplace hazard. The traditional approach to managing fatigue risk has been to limit work hours and set minimum rest breaks in government regulations or industrial agreements. This chapter introduces a flexible alternative approach—fatigue risk management systems (FRMSs), which are based on scientific understanding of the dynamic effects of sleep loss and recovery on performance, and of the modulating influence of the circadian system on performance capacity.
- The core of an FRMS is a closed-loop process consisting of (1) ongoing monitoring of fatigue levels, (2) identification of situations in which fatigue may constitute a hazard, (3) risk assessment, and (4) introduction of risk mitigations and strategies when needed. Multiple defensive strategies can be incorporated, tailored to the workplace, the level of operator fatigue, and the associated safety risk. This enables more robust safety management than the single defensive layer of one-size-fits-all prescriptive regulations on work hours and rest breaks.
- Implementation of FRMSs is expanding, particularly in the transport sector. Their effectiveness depends on dialogue between scientists and people with operational expertise in the workplaces(s) where these systems are implemented. This is an exciting new area of application of sleep and circadian science that highlights issues for which better scientific understanding is needed.

Limits on maximum working hours and minimum breaks (hours-of-service regulations) are the traditional approach to managing workplace fatigue, with a history dating back to the industrial revolution in Britain and the first Factory Acts in the early 19th century.[1] This chapter describes a new approach: fatigue risk management systems (FRMSs). FRMSs have evolved from advances in sleep and behavioral science and in safety science, leading to better understanding of the causes of human error and its role in the etiology of accidents, and to improvements in the practice of risk assessment and management. Central concepts in FRMS are as follows:

- Human functional capacity is variable (both between individuals and in the same person across time).
- Some of this variability is predictable from previous sleep history and the phase of the circadian pacemaker.
- To maintain safety, systems are needed to monitor and mitigate both the level of fatigue-related impairment and its potential consequences.

The FRMS approach is developing rapidly in the transportation sector in response to several converging trends. The complexity and scope of operations and vehicles continues to increase in all modes of transportation. As an example, pilot fatigue was historically managed through prescriptive regulatory limits on flight and duty times, including a 16-hour flight time limit for non-stop flights in commercial aviation.[2] However, advances in aircraft technology now allow flights much longer than 16 hours, which not only enables different route structures and duty schedules but also requires new approaches for managing pilot fatigue. With the accelerating evolution of transport operations, it is not surprising that the effectiveness of prescriptive hours-of-service regulations is being questioned. The United States introduced prescriptive limits for rail in 1907, for trucking in 1937, and for aviation in 1938. Nevertheless, in 2011, addressing human fatigue was ranked second on the U.S. National Transportation Safety Board's most wanted list of safety improvements across all modes of transportation. In parallel, increasing scientific understanding of the causes and consequences of fatigue-related impairment has provided an evidence base for more sophisticated fatigue risk management approaches.

In this chapter, the focus is on fatigue risk management in the aviation industry, where implementation of FRMSs is rapidly expanding. As a foundation, a comprehensive definition of fatigue is presented that identifies the key physiologic causes of fatigue-related impairment and its potential safety consequences.[3] The essential elements and processes of FRMSs are then described. This highlights the importance of being able to measure operator fatigue and its consequences

for safety in a given work context. Examples of what to measure and how to measure it are considered.

Measures have been proposed as safety performance indicators (SPIs) for FRMSs in commercial aviation, based on their demonstrated sensitivity to sleep history and circadian phase in laboratory protocols. An evaluation is presented of how reliably the proposed SPIs reflect these key determinants of performance capacity in the complex environment of very long commercial flights crossing multiple time zones.[4,5] In these operations, pilots have only one flight per duty period and have the opportunity for in-flight sleep. As more data become available, this evaluation can be expanded to other types of commercial aviation operations that involve different causes of pilot fatigue—for example, short-haul operations that involve multiple flights during long duty days with no opportunity for in-flight sleep. Short-haul operations may include night flying but typically cross only one or two time zones.

The chapter also introduces scientific and safety management principles for FRMSs, which can be adapted to other environments. In addition to these more generic principles, FRMSs require operational knowledge and expertise that are specific to each work situation, so they are not "one-size-fits-all." With increasing scientific knowledge and more widespread FRMS implementation, FRMSs will continue to evolve. The chapter concludes with a discussion of ways to improve the effectiveness of FRMSs.

DEFINING FATIGUE

The definition of fatigue has been the subject of academic debate,[6] although the term is commonly used in occupational safety. For example, in New Zealand, the Health and Safety in Employment Amendment Act (2002) specifically identifies workplace fatigue as a hazard, which means that it is a potential source of harm to employees that must be managed by all employers. The International Civil Aviation Organization (ICAO) is the United Nations agency responsible for regulating the global aviation industry. In 2011, the ICAO released a regulatory framework for FRMSs based on the following comprehensive definition.[3]

> Fatigue is a physiological state of reduced mental or physical performance capability resulting from sleep loss or extended wakefulness, circadian phase, or workload (mental and/or physical activity) that can impair a crew member's alertness and ability to safely operate an aircraft or perform safety-related duties.

In this definition, fatigue is recognized as a physiologic state. The main factors affecting performance capability are identified, as well as the potential consequences of fatigue-related impairment for operational safety (for pilots, their ability to safety operate an aircraft; for cabin crew, their ability to perform safety-related duties).

A feature of fatigue that differentiates it from most other workplace hazards (such as noise, vibration, or toxic substances) is that exposure is not limited to the workplace. Fatigue also is affected by activities and choices made outside of work, sometimes described as a "whole of life issue." Thus effective fatigue management must be a shared responsibility between employers and employees. In analyzing fatigue-related safety incidents, consideration needs to be given to the actions (or inactions) of the individual(s) involved, work demands leading up to the event, and the safety systems present in the workplace. This approach is consistent with the principle that human error should be the starting point for analysis of safety incidents and accidents, rather than the end point.[7]

INTERACTING CAUSES OF FATIGUE-RELATED IMPAIRMENT

Evidence from laboratory studies shows that sleep loss and circadian phase have interactive effects on performance. For example, a study using 28-hour forced internal desynchrony protocols with either a 9.33-hour sleep opportunity or a 4.67-hour sleep opportunity found that the adverse effect of sleep restriction on psychomotor vigilance task (PVT) response speed was greatest during "biological night" (the part of the circadian cycle when sleep normally would be occurring).[8]

Some evidence from field studies supports interactions between circadian phase and time on duty and/or time awake. For example, an early German study recorded failures of locomotive engineers to interact with an on-board vigilance system which required them to extinguish a light within 2.5 seconds of its appearing on the console; otherwise, an acoustic warning sounded.[9] Data were gathered from 10 trains tracked for at least 30 days each (a total of 6304 work hours accumulated by approximately 1000 drivers). Figure 73-1 shows the hourly mean frequency of the acoustic warning sounding across the 24-hour day, comparing hours 1 to 3 of shifts with hours 4 to 6 of shifts. Clear peaks in signals missed were evident at the expected circadian times (early morning and early afternoon) only when engineers had been on duty for more than 3 hours. In a large field study of fatigue ratings self-reported by air traffic controllers at the end of each period of active controlling (interspersed with breaks) across duty periods, the following factors were independently associated with the level of fatigue: time of day, self-rated workload, time since coming on duty, duration of continuous wakefulness, and duration of the active operational duty period.[10] The effects of time on duty and time of day appeared to be additive, with highest fatigue ratings at the end of long duty periods that finished around 6 A.M.

The ICAO definition of fatigue includes workload as a potential cause of fatigue-related impairment; however, no clear operational definition of workload has emerged. In principle, it could include both factors relating to the nature of the work (e.g., time on task, task difficulty and complexity, and work intensity and whether this is paced by task demands or by the individual worker) and factors relating to the performance capacity of the individual worker (e.g., experience and skill level, sleep history, and circadian phase). Few studies have attempted to investigate the influence of workload on fatigue or potential interactive effects between workload and other causes of fatigue-related impairment. In the field study of fatigue ratings by air traffic controllers,[11] some evidence pointed to interactive effects of self-rated workload and time-on-task on fatigue. When self-rated workload was low, fatigue ratings remained relatively stable for continuous work periods up to 4 hours. However, when workload was high, rapid increase in fatigue was seen after 2 hours of continuous work. These effects of workload became more evident after controllers had been awake for at least 12 hours. The time-of-day

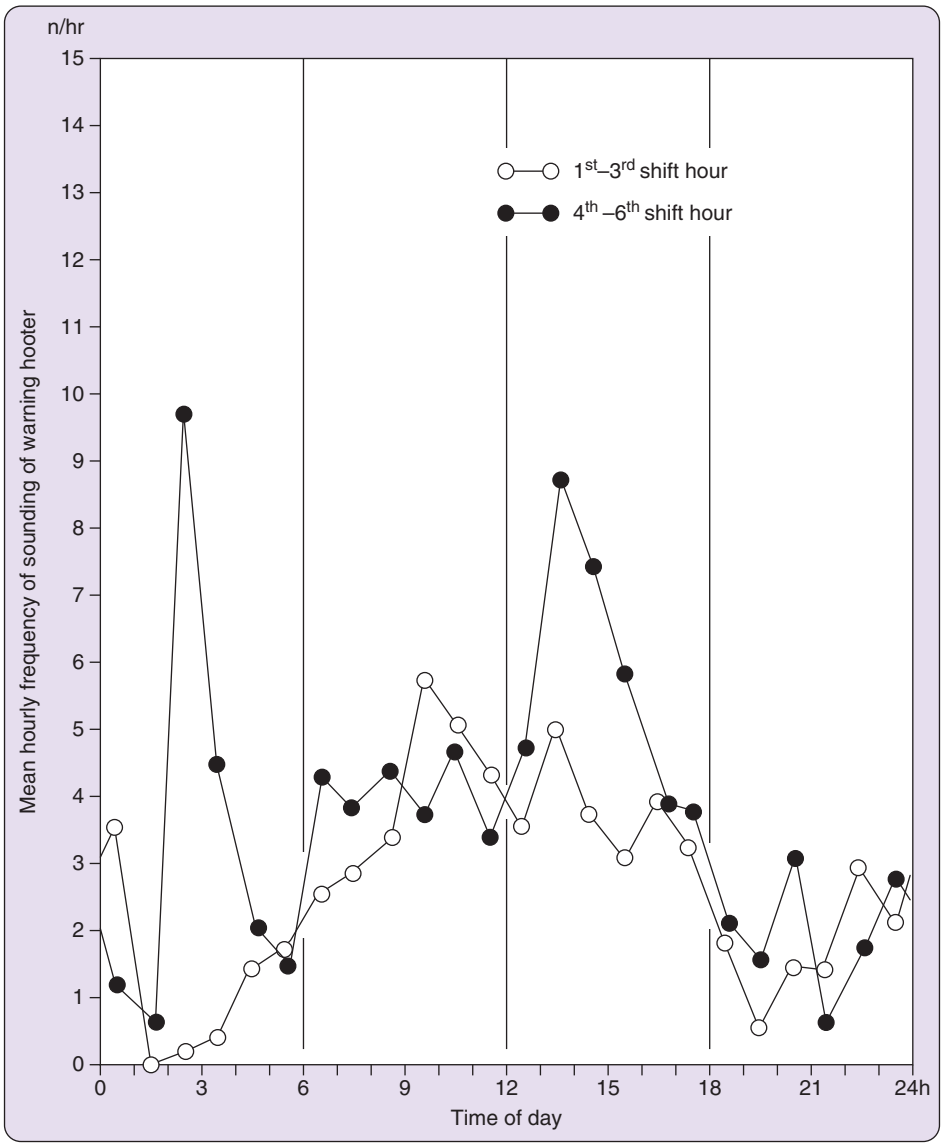

Figure 73-1 Locomotive engineers' failures to interact with a vigilance device across the 24-hour day, comparing hours 1 to 3 of shifts with hours 4 to 6 of shifts. (From Hildebrandt G, Rohmert W, Rutenfranz J. 12 and 24 h rhythms in error frequency of locomotive drivers and the influence of tiredness. *Int J Chronobiol* 1974;2:175–80, with permission.)

variation in fatigue ratings also was influenced by workload, being more marked at low and high levels of workload than at intermediate levels. To manage fatigue-related risk, it is difficult (if not impossible) to design prescriptive rules that address the interacting effects of duty history, sleep history, circadian phase, and workload.

The interactions of factors causing fatigue can have major effects at the population level. A robust, case-controlled study has estimated that motor vehicle crashes resulting in injury could be reduced by 19% on the Auckland metropolitan road network if drivers did not drive when they felt sleepy, or when they had slept 5 hours or less in the last 24 hours, or between 02:00 and 05:00.[12] This degree of improvement in road safety is not expected to be achieved by separate campaigns to reduce speed, enforce seat belt use, or eliminate drunk driving.

TYPES OF FATIGUE-RELATED IMPAIRMENT

Many aspects of performance are subject to fatigue-related impairment, and the consequences in a workplace can be complex.[13] For example, very little research has addressed the effects of individual team member fatigue on team performance. A flight simulation study with 67 Boeing B747-400 crews demonstrated that sleep loss increased the number of errors made by these two-pilot crews.[14] Paradoxically, however, when crew position was considered, greater sleep loss and higher subjective fatigue ratings among first officers were associated with improved rate of error detection, whereas greater sleep loss among captains led to a higher likelihood of failure to resolve detected errors. Greater sleep loss and higher subjective fatigue ratings also were associated with slower

decision making and a tendency toward choosing lower-risk options.[15]

These findings are consistent with evidence from laboratory studies indicating that more complex cognitive tasks, particularly those involving executive functions dependent on the prefrontal cortex, are more severely affected by sleep loss than are simpler tasks.[15-17] Other support derives from brain imaging studies suggesting that the regions involved in higher-order complex cognitive performance are most affected by sleep deprivation and have the greatest need for sleep-mediated recuperation.[18-21]

A compelling illustration of the possible safety consequences of fatigue-related impairment comes from debriefings after friendly fire incidents during Operation Desert Storm.[22] Sleep deprivation was identified as contributing to Bradley fighting vehicle and M1 tank crews becoming misoriented to the battlefield (a complex mental task involving situational awareness enabled by working memory), who then mistook friend for foe. They were, however, able to shoot straight (a simple task involving putting cross-hairs on the target and squeezing the trigger). This combination of degradation in complex task performance coupled with relative preservation of simple task performance led to their firing upon and destroying friendly vehicles.

PROCESS AND COMPONENTS IN A FATIGUE RISK MANAGEMENT SYSTEM

Rather than relying on a priori decisions about the factors most likely to be causing fatigue (the basis of prescriptive rules), FRMS is based on real-time monitoring and management of actual fatigue levels and their associated safety risk in an operation. The processes underlying FRMSs are summarized in Figure 73-2, which highlights that these processes are intended to be data-driven.[3]

Data for Fatigue Risk Management Systems

In ultrasafe systems such as commercial aviation operations, safety-critical errors and incidents are unpredictable, rare events. In FRMSs, they must be analyzed to identify whether operator fatigue was a contributing factor. Because they are rare, however, safety-critical errors and incidents cannot be used in FRMSs for routine tracking of fatigue levels and identification of potential hazards. A variety of additional sources of data are needed, from which a set of SPIs can be identified, together with acceptable values or ranges for each SPI. The use of multiple SPIs is recommended for robust safety management.[23] For commercial aviation, two different types of SPIs have been proposed: operational SPIs, which monitor the duty-related causes of fatigue, and SPIs based on monitoring actual levels of crew member fatigue.[3]

Operational SPIs can be derived from routinely collected data—for example, by comparing planned versus actual schedules. In commercial aviation, potential fatigue hazards may be identifiable from data such as how often flight duty periods end at least 30 minutes later than scheduled; how often flight duty periods start or end within the window of circadian low; or how often reserve crew members are called out on particular flights at a particular crew base. Acceptable limits might consist of the following: If report time is earlier than 05:00, then the actual flight duty period will not exceed the scheduled flight duty period on more than 10% of days in any 28-day period; or for crew members who do not have the opportunity for in-flight sleep, no duty period longer than 9 hours will be scheduled to end in the window of circadian low. Operational SPIs and their acceptable limits need to reflect the specific causes of fatigue risk in different operations, such as early starts and multiple flights during long duty days in domestic short-haul operations versus single flights during long duty days that cross multiple time zones with resulting circadian desynchrony in international long-haul operations.[23,24]

Monitoring operator fatigue as a source of data for FRMSs is relatively resource-intensive and time-consuming compared with using routinely collected operational data. In view of the fact that fatigue affects diverse aspects of waking function, it is considered inadvisable to make operational decisions based on any single measure of functional status (or based only on thresholds applied to biomathematical model predictions of functional status).[3,4] Measures of crew member fatigue are considered in more detail later in this chapter.

An essential source of fatigue monitoring data in FRMSs is voluntary fatigue reporting (hazard identification) by staff. In the ICAO FRMS approach, crew members must be able to voluntarily report potential fatigue hazards without fear of retribution, in addition to the mandatory reporting required for more serious safety events.[3]

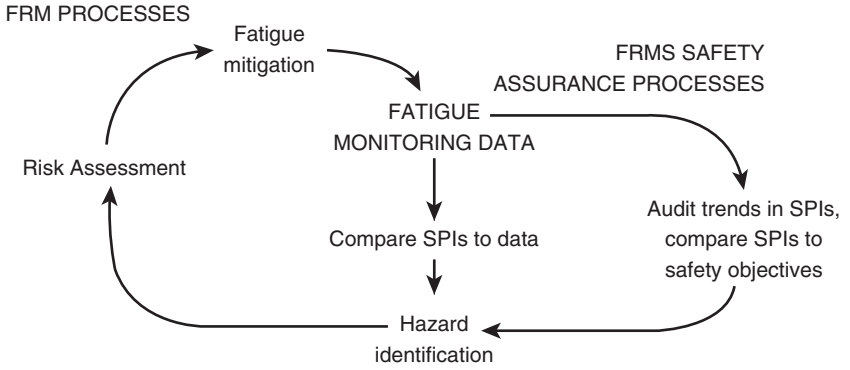

Figure 73-2 Summary of the core activities in fatigue risk management systems (FRMSs), as defined by the International Civil Aviation Organization (ICAO).[3] The left-hand loop (fatigue risk management [FRM] processes) deals with day-to-day management of fatigue in an organization. The right-hand loop (FRMS safety assurance processes) ensures that the FRM processes are delivering an acceptable level of fatigue risk and provides input for continuous improvement of the FRM processes. SPIs, Safety performance indicators.

Hazard Identification, Risk Assessment, and Mitigation

When data of any type suggest that fatigue is a potential hazard, the safety risk associated with that hazard needs to be evaluated (the fatigue risk management processes loop on the left in Figure 73-2). In airlines, risk assessment often is carried out by a specialized safety team that evaluates risk across all types of hazards, including crew member fatigue. As appropriate, additional fatigue mitigations may need to be implemented. Although a very common response is to change work patterns (rosters) to reduce fatigue hazards, other mitigations usually are possible and in some instances are preferable. For example, the main pilot fatigue mitigation on long flights is to have additional pilots and provide on-board crew rest facilities with horizontal bunks. This enables each pilot to take one or more rest breaks away from the flight deck, with the opportunity and environment for sleep. In the ICAO approach to fatigue risk management, the effectiveness of fatigue mitigations is continuously monitored by tracking the fatigue SPIs, so the fatigue risk management processes in Figure 73-2 constitute a closed loop.

Safety Assurance and Continuous Improvement

The FRMS safety assurance loop on the right hand side of Figure 73-2 represents another layer of organizational defenses against fatigue risk. This loop is designed to check whether the fatigue risk management processes are delivering an acceptable level of fatigue risk that meets internal and external standards set by company policy and/or by regulations. Data-derived SPIs inform decision making in the FRMS safety assurance loop. This loop also monitors external changes that could affect fatigue risk in the organization. In aviation, examples of such external changes might be the introduction of a new route or aircraft type, or changes made to flight schedules by the marketing department in response to a new competitor entering the market. The feedback provided by the FRMS safety assurance processes drives continuous improvement of the fatigue risk management processes.

Other Components of the Fatigue Risk Management System

The two loops in Figure 73-2 are considered the core operational activities of the FRMS.[3] In the ICAO regulatory framework, they are supported by additional required elements—namely, an FRMS policy (which includes an identified manager responsible for the resourcing and effectiveness of the FRMS), documentation of all FRMS activities, fatigue management education for crew members and other relevant personnel (schedulers, managers, and so on), and a communications plan.

MONITORING OPERATOR FATIGUE

Monitoring operator sleep history and waking function will sometimes be necessary in an FRMS, for example, when more in-depth information is needed about a particular fatigue hazard, or as an additional defensive layer when a new type of operation is being introduced. As a general rule, the type of monitoring undertaken should be commensurate with the anticipated level of fatigue and safety risk. Options range from retrospective surveys to full-scale studies monitoring sleep history before, during, and after a roster, with performance testing and subjective assessments during work periods. Resources for data collection (financial, logistical, and human) usually are limited. It also is important to consider the burden on staff asked to participate in data collection from time to time, particularly because sleep and performance monitoring often occur outside the workplace as well as at work. Ongoing commitment and cooperation of staff are critical not only for study participation but for all aspects of an effective FRMS.

The study design and measures used need to be adequate to provide scientifically defensible answers to the operational questions being asked about fatigue and safety. In the aviation context, recommended criteria for selecting measures include the following: They have been validated, to confirm that they measure what they purport to measure; they do not jeopardize a crew member's ability to perform operational duties; and they have been widely used in aviation, allowing data to be compared between different types of operations.[3]

Measuring Sleep

Sleep-wake history arguably provides the most valuable information about fatigue status, because insufficient sleep has a negative impact on diverse aspects of waking function, only some of which are captured by subjective ratings or objective performance tests.[5] Polysomnography, the laboratory gold standard, has been used to monitor sleep for short periods of time in field studies.[25-31] However, with current recording equipment and analytical procedures, this procedure is intrusive for participants as well as time-consuming and costly to analyze.

Actigraphy is a widely used alternative to polysomnography for objective sleep monitoring in field studies.[2,4,5,29,30,32–35] It can reliably measure total sleep time but cannot identify sleep stages.[34,36] An actigraph is an unobtrusive wristwatch-size device, worn on the nondominant wrist, that sums movements across a specified time period (usually a 1-minute epoch).[36] An algorithm (validated against polysomnography) is used to determine whether the wearer is asleep or awake in each epoch across the record. The actigraph can record sleep-wake history reliably[34,36] for weeks to months with minimal inconvenience to the wearer, and data analysis is much less complex and time-consuming than for polysomnography. Figure 73-3 shows an example of an actigraphy record from a commercial airline pilot.

Sleep diaries can be used to gather subjective data prospectively on sleep timing and quality and have the advantages that they are easy to implement (in paper form or electronically) and inexpensive. They typically are used to aid interpretation of actigraphy records and can be used to gather other relevant information such as duty-rest times. Subjective estimates of sleep duration in flight and on the ground were shown to be correlated with polysomnographic measurement in a group of 25 pilots.[34] However, there was wide variability among pilots in the accuracy of their subjective estimates, particularly for in-flight sleep duration.

Measuring Subjective Sleepiness and Fatigue

Two validated subjective rating scales have been recommended for use in airline FRMSs.[3] On the Karolinska Sleepiness Scale (KSS), participants rate their current level of sleepiness from 1 to 9, where 1 = "extremely alert;" 3 = "alert;" 5 = "neither

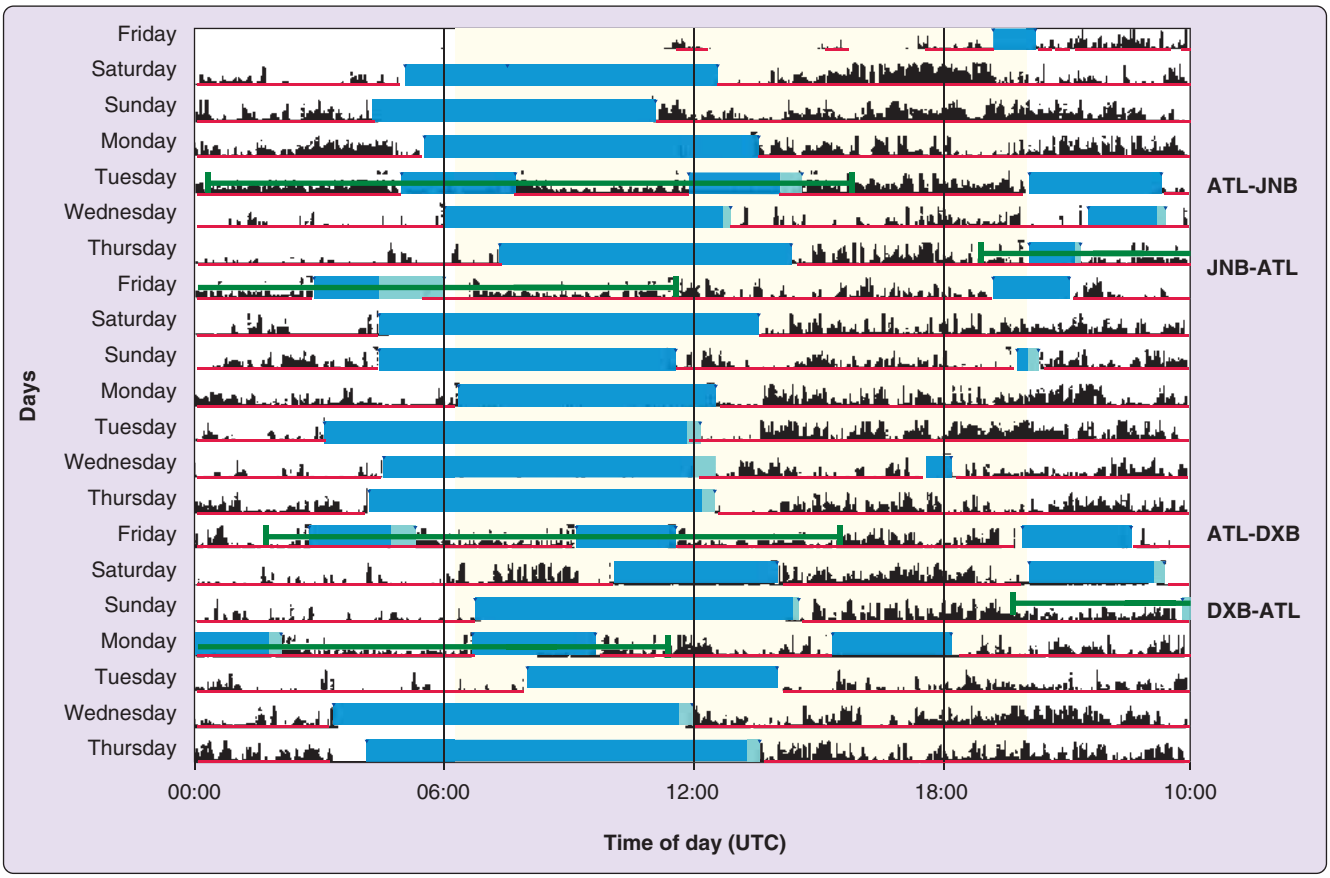

Figure 73-3 Actigraphy record from an airline pilot over a 3-week period during which he flew a return trip between Atlanta (ATL) and Johannesburg (JNB) (crossing six time zones) and a return trip between Atlanta (ATL) and Dubai (DXB) (crossing eight time zones). *Black vertical bars* are minute-by-minute activity counts. *Blue horizontal bars* indicate sleep as identified by actigraphy. *Turquoise horizontal bars* indicate times attempting to sleep but not asleep by actigraphy. *Red horizontal bars* indicate times awake as identified by actigraphy. *Green horizontal lines* are times on duty. Note *blue horizontal bars* for in-flight sleep periods during the flights. UTC, Coordinated universal time.

sleepy nor alert;" 7 = "sleepy, but no difficulty remaining awake;" and 9 = "extremely sleepy, fighting sleep."[37] The KSS was developed and validated in a laboratory context[38–40] and has been used in a variety of operational settings. Ratings of 7 to 9 have been associated with the onset of polysomnographically recorded microsleeps.[37] In a 28-hour forced desynchrony protocol with sleep restriction (4.7-hour sleep opportunity, 23.3 hours awake), KSS ratings were found to increase across wakefulness and to have significant circadian variation, being highest during biological night.[40]

On the Samn-Perelli Crew Status Check (also known as the Samn-Perelli Fatigue Scale), participants rate their current fatigue level from 1 to 7, where 1 = "fully alert, wide awake;" 2 = "very lively, responsive, but not at peak;" 3 = "okay, somewhat fresh;" 4 = "a little tired, less than fresh;" 5 = "moderately tired, let down;" 6 = "extremely tired, very difficult to concentrate;" and 7 = "completely exhausted, unable to function effectively."[41] The scale was developed for military airlift operations and has been widely used in aviation studies.[31,42] The original scale explicitly linked ratings to the likelihood of performance impairment.[41] At scores of 1 to 3, no fatigue-related performance impairment is expected. For a score of 4, "performance impairment is possible but not a significant factor." A score of 5 is equated with "moderate fatigue, performance impairment possible, flying duty permissible but not recommended unless urgent." A score of 6 is equated with "severe fatigue, performance impairment probable, flying duty not recommended." A score of 7 is equated with "severe fatigue, performance definitely impaired, flying duty not recommended, safety of flight in jeopardy." These proposed relationships between scores and performance impairment do not appear to have been systematically validated against objective measures of performance or quantified in other operational settings. The B747-400 simulator study mentioned earlier suggests the possibility of complex relationships between the Samn-Perelli fatigue scores of individual pilots and the flight deck performance of two-pilot crews. Higher Samn-Perelli fatigue ratings were associated with improved rates of error detection among first officers,[14] but with slower decision making by the crew and a tendency toward choosing lower-risk options.[15] A laboratory study using 28-hour forced desynchony protocols has demonstrated circadian variation in presleep and postsleep Samn-Perelli ratings, as well as cumulative effects of sleep restriction on postsleep Samn-Perelli ratings.[43]

Factors influencing KSS and Samn-Perelli ratings at top of descent (TOD) on very long flights have been analyzed using combined data from four airlines (237 pilots in four-pilot crews, monitored on 730 out-and-back flights between 13 city pairs, with 1- to 3-day layovers).[5] Mixed model

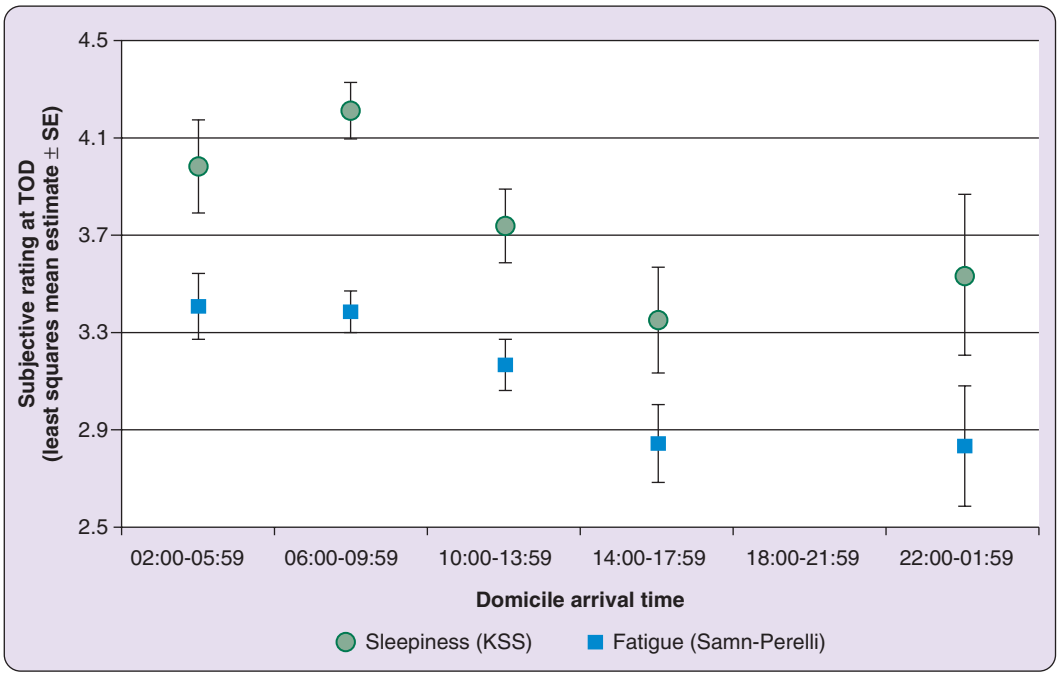

Figure 73-4 Subjective sleepiness (KSS) and fatigue (Samn-Perelli scale) ratings at TOD on flights arriving at different domicile times. Only eight flights arrived between 18:00 and 21:59, so this time bin was excluded from the analyses. KSS, Karolinska Sleepiness Scale; TOD, top of descent. (From Gander PH, Mulrine HM, van den Berg MJ, et al. Effects of sleep/wake history and circadian phase on proposed pilot fatigue safety performance indicators. *J Sleep Res* 2015;24:110–9, with permission.)

analysis of variance was used to examine relationships between ratings at TOD, sleep-wake history, and circadian phase, after controlling for within- and between-subjects variability and operational factors (flight direction and duration). Circadian phase was approximated by local (domicile) time in the city where each trip began and ended.

For every 1-hour increase in continuous time awake by TOD, KSS ratings increased by an estimated 0.2 point and Samn-Perelli fatigue ratings increased by an estimated 0.1 point. For every 1-hour increase in total in-flight sleep, KSS ratings decreased by an estimated 0.3 point and Samn-Perelli fatigue ratings decreased by an estimated 0.2 point. Neither subjective rating was significantly associated with total sleep in the 24 hours before TOD. The independent effect on TOD ratings of the (domicile) time of arrival is illustrated in Figure 73-4. The pattern of variation is consistent with the circadian variation in these measures observed in 28-hour forced desynchrony protocols.[40,43]

Measuring Performance

A variety of approaches have been developed for measuring performance in field studies, each with strengths and weaknesses. Well-validated laboratory tasks such as the psychomotor vigilance task (PVT)[44,45] can easily be implemented on smartphones for field studies.[3-5,13,46,47] These added performance measures, however, interrupt the normal flow of work and could therefore be considered intrusive.[48] In addition, little is known about how an individual's performance on the PVT relates to performance on more complex tasks, or to that person's contribution to the performance of a workplace team. The flight simulator study with 67 B747-400 crews found no relationship between individual pilots' PVT performance before the 70-minute simulator session and the two-pilot crew's ability to detect threats or manage them effectively, or the number of errors made by the crew members and their ability to detect and manage those errors.[14]

Embedded measures, defined as measures taken unobtrusively as a part of the normal course of operations (e.g., aircraft-handling parameters), have the potential to monitor individual and crew performance during work. They have high ecologic validity and do not interrupt the normal flow of work. However, this approach can encounter participant resistance if it is seen as an assessment for clandestine purposes other than safety. In addition, well-established causal links between fatigue-related impairment of individuals and changes in embedded measures of workplace performance are needed if they are to be used as a source of data in FRMSs. Despite considerable effort, to date no embedded measures have been identified that are consistently related to available fatigue SPIs.

Simulator studies offer a middle ground, with greater ecologic validity than laboratory tests and greater experimental control than embedded measures in the workplace. They can be expensive, however, and even high-fidelity simulators are open to the criticism that participants' knowledge that they are in a simulator may alter their behavior. For example, deciding to divert to a different destination in a flight simulator has very different consequences from those associated with deciding to divert to a different destination with an airplane full of passengers.[15]

The PVT performance test has been recommended for use in FRMSs in aviation.[3] A 5-minute version of the task can be administered on a smartphone.[46,47] Participants are instructed to respond by button press when the stimulus appears (e.g., a bull's eye) on the screen. The time from presentation of the

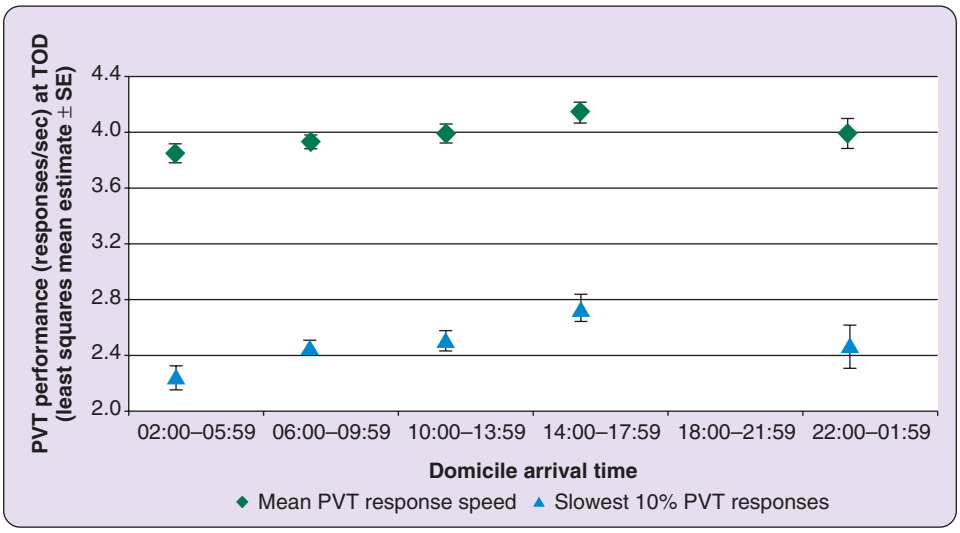

Figure 73-5 PVT performance at TOD on flights arriving at different domicile times. Only eight flights arrived in the period 18:00 to 21:59, so this time bin was excluded from the analyses. PVT, Psychomotor vigilance task; TOD, top of descent. (From Gander PH, Mulrine HM, van den Berg MJ, et al. Effects of sleep/wake history and circadian phase on proposed pilot fatigue safety performance indicators. *J Sleep Res* 2015;24:110–9, with permission.)

stimulus to button response is recorded as reaction time. The stimulus reappears at random intervals across the duration of the task, so vigilance is required to maintain reaction times. Laboratory studies using forced internal desynchrony protocols have shown that PVT performance reaches its circadian nadir shortly after the circadian temperature minimum and degrades with increasing time awake.[8,49–53] Laboratory sleep restriction studies have shown cumulative sleep-dose–dependent slowing in PVT responses.[8,54,55]

Factors influencing PVT performance at TOD on very long flights were analyzed using the combined data from four airlines, as described previously.[5] Mixed model analysis of variance was used to examine relationships between performance at TOD, sleep-wake history, and circadian phase, after controlling for within- and between-subjects variability and operational factors (flight direction and duration). Circadian phase was approximated by local (domicile) time in the city where each trip began and ended. No significant relationships were found between PVT performance speed and time awake at TOD, total sleep in the 24 hours before TOD, or total in-flight sleep.

Compared with laboratory studies using a 10-minute version of the PVT,[54,56] 5-minute PVT response speeds of these pilots at TOD were relatively fast (median = 4.0 responses/second; in one of the four studies, pilots undertook a 10-minute PVT). This is noteworthy, considering that participants in the laboratory studies had 7 to 8 hours of time in bed for sleep at night, whereas most pilots had multiple sleep episodes in the 24 hours before TOD and median total sleep was 4.75 hours (range, 0.23 to 11.50 hours). Possible explanations for the lack of association between PVT response speed at TOD and previous sleep history might be that the levels of fatigue at TOD are relatively modest on these flights, owing to in-flight sleep (median time awake from last in-flight sleep period to TOD = 2.33 hours; range, 0.00 to 11.68 hours) and/or that these pilots represent a highly selected group with unusually fast PVT performance. The findings raise the question of whether PVT performance is a discriminating measure of fatigue-related impairment in pilots, supporting the need for additional objective performance measures to be developed and validated for use in airline FRMSs.

The independent effect of the domicile time of arrival on PVT performance at TOD is illustrated in Figure 73-5. The pattern of variation is consistent with the circadian variation observed in 28-hour forced desynchrony protocols.[8,49–51,53]

Routine Operator Monitoring and Biomathematical Modeling

In some contexts, particularly military operations or other high-risk environments, it may be appropriate to continuously record sleep-wake patterns in the field using actigraphy. These data could potentially be used to predict performance minute by minute, using biomathematical models that integrate the effects of sleep-wake history and circadian phase and, in the future, workload.[13] Ideally, models also would be tailored to reflect individual differences in chronotype ("morningness"/"eveningness") and resilience to sleep loss.[57–60] On the other hand, in scheduled commercial operations, routine operator monitoring may be unnecessary, and people may well be resistant to being monitored 24/7, including while off-duty, to improve their performance at work.

In the ICAO model of FRMS, biomathematical models are an optional tool for predicting potentially hazardous levels of fatigue in schedules or rosters. They also could be seen as a fatigue mitigation strategy if they aid the design of less fatiguing rosters. Current biomathematical models, however, aim to predict measures of operator fatigue (performance and/or subjective ratings), not the safety consequences of that fatigue in specific operational environments. This fact highlights why "bright lines"—model output values above which an individual worker is proposed to be "safe" and below which the person jeopardizes operational safety—are too simplistic for fatigue risk assessment in FRMSs. Biomathematical models are not a stand-alone substitute for the processes outlined in Figure 73-2. If models are used within the fatigue risk management process loop, then their effectiveness (along

with all other fatigue mitigations) is monitored by the SPIs. In this context, models are only one defensive strategy, and their limitations are less likely to inadvertently increase fatigue-related safety risk.

IMPROVING FATIGUE RISK MANAGEMENT

Scientific Challenges

Fatigue risk management aims to minimize fatigue-related impairment in the workplace *and* its operational consequences. Strategies to minimize fatigue-related impairment focus primarily on minimizing sleep loss (or its effects) and improving recovery sleep. Addressing important research questions in these areas can be expected to lead to improved FRMSs.

Sleep restriction is the most common sleep disturbance associated with 24/7 operations and is associated with both short-term consequences for productivity and safety[61-63] and long-term consequences for health.[64-70] Whether or not an individual is sleep-restricted, their performance capacity fluctuates across the circadian body clock cycle. There are stable trait-like differences between people in the extent to which their performance is impaired by sleep restriction and at suboptimal times in the circadian cycle.[58-60] Better understanding of the basis of this differential sensitivity may provide insights into the neurophysiologic mechanisms underlying the effects of fatigue on waking function. In very-high-risk occupations, it also may be appropriate to screen for people with high resilience to fatigue-related impairment. This approach does not have widespread applicability as a fatigue mitigation strategy, however, because it would probably exclude too many people from working in 24/7 operations.

Additional research is needed to be able to provide robust scientific advice on the amount of sleep needed to recover from chronic sleep restriction, in terms of both the duration of recovery sleep episodes and the number of consecutive nights of sleep required.[54,55,71] The recovery value of split sleep versus a single consolidated sleep also is an important question for fatigue risk management. Laboratory studies suggest that having a restricted sleep period at night plus a daytime nap has equivalent recovery value to the same total amount of sleep taken in one consolidated block at night.[72-75] However, these are short-term studies that take place in a quiet laboratory sleep environment with no distractions, and nighttime sleep is not always an option in 24/7 working environments.

A recent field study with junior doctors demonstrated that a split sleep schedule with napping during the night shift resulted in the same amount of total sleep per 24 hours (7 hours) as was obtained when working the day shift. Measures of vigilance, verbal and spatial learning, and memory were also comparable on the night shift and the day shift.[76]

For pilots on long commercial flights, in-flight sleep results in split sleep patterns. Split sleep also is typical on layovers between transmeridian flights. Figure 73-3 shows an example in which the participant was part of a four-pilot crew and had two opportunities per flight for horizontal sleep in an onboard crew rest facility. For two-pilot crews, planned 40-minute nap opportunities in the flight deck seat have been shown to provide an average of 23 minutes of sleep (confirmed by polysomnography) and improved alertness (by polysomnography) and PVT performance at TOD, with no apparent effect on subsequent layover sleep (as measured by actigraphy).[77,78] Controlled flight deck napping has been recommended by the ICAO as a fatigue mitigation strategy[3] and has been incorporated into aviation regulations in a number of countries. Although the Federal Aviation Administration (FAA) in the United States funded this research and the drafting of an advisory circular on how to implement controlled flight deck napping, it has not yet approved its use as a fatigue countermeasure for U.S. airlines.

The safety hazards associated with fatigued employees in different workplaces remain poorly understood. The relationship between individual fatigue and system safety is likely to be complex in ultrasafe systems[79] such as commercial aviation, where multiple layers of operational defenses (e.g., automation, teamwork, standardized procedures) reduce the probability of having an accident attributable uniquely to an error made by a fatigued individual. A comprehensive research approach is needed that integrates (1) experimental studies focusing on the effects of sleep restriction on different types of performance and on communication; (2) simulation studies to address the impact of fatigued individuals on the performance of workplace teams; (3) studies identifying causal links between fatigue-related impairment of individuals and teams and changes in embedded measures of workplace performance; and (4) careful investigation and analysis of fatigue-related incidents and accidents. Over time, this research should identify and validate better objective performance measures for use as safety performance indicators in FRMSs.

In field studies, the interacting causes of fatigue-related impairment—sleep loss, circadian modulation of performance capacity, and workload—are affected by a range of operational factors.[3] In long-haul aviation, for example, these include departure times, flight direction and duration, number of time zones crossed, crew complement, and layover timing and length.[80] Field studies usually are targeted to address a particular set of operational issues, so typically they include only limited combinations of operational factors. In addition, the number of participants is restricted because fatigue-monitoring studies in the field are expensive and time-consuming. These constraints can be overcome by combining data from multiple studies to evaluate the independent contributions of the different operational factors that influence fatigue.[4,5,80] This is possible only when studies use a standard set of core measures.[3] Meaningful data merging also requires detailed contextual knowledge about each data set, and issues of data ownership and confidentiality need to be addressed.

In addition to sleeping and working at inappropriate times in the daily cycle of the circadian pacemaker in the hypothalamus, people working in 24/7 operations are likely to be eating at inappropriate times in the cycle of the circadian master clock in the hypothalamus. Increasing evidence suggests that this mistiming can lead to desynchrony between rhythms in the circadian clock genes in the liver, fat, pancreas, and muscle, and those in the hypothalamic master clock. Better understanding is needed of the consequences of mistimed eating, both for short-term digestive complaints and for longer-term health consequences, including increased risk of obesity and type 2 diabetes[64,81-83] In the context of FRMSs, these may be exacerbating factors that affect an operator's functional capacity, and dietary advice may be an important part of fatigue education for some workforce groups. Advances in biomedical monitoring techniques hold promise for noninvasive field monitoring of circadian rhythms and sleep-wake patterns over long time periods.[13] For FRMSs in aviation, this will increase

understanding of the effects of rosters and combinations of transmeridian flights on the circadian system.[32,80]

Implementation Challenges

The legislative and regulatory context is a key factor in the implementation of FRMSs, and differs among countries and industries.[84–86] The FRMS approach is consistent with performance-based occupational health and safety legislation (required outcomes are specified, but not the means for achieving them) and with shared responsibility of employers and employees for occupational health and safety. In addition to the general health and safety legislation, in public transportation an additional expectation is that governments have a duty to regulate the activities of companies to limit the societal risk posed by fatigue-impaired workers.

Prescriptive hours-of-service regulations require regulators to clearly define the limits of acceptable performance, or the levels of fatigue that cause performance to become unacceptable, in every context across a broad range of operations.[11,85,86] These regulations can be difficult to defend from a scientific perspective.[87] From a regulatory perspective, however, hours-of-service regulations provide clear standards for judging violations and deciding culpability in legal contexts, whether or not the prescribed limits are scientifically defensible. FRMSs need to convince both governments and the public that the level of protection they offer is at least equivalent to that provided by hours-of-service regulations. Statistical testing for equivalence has significant potential as an adjunct to traditional testing for differences when comparing safety performance indicators in FRMSs versus prescriptive hours-of-service regulations.[88]

Regulatory frameworks permitting FRMSs as an alternative means of managing operator fatigue are spreading across the transport sector. Because they are relatively new, FRMSs remain relatively untested compared with prescriptive hours-of-service limits. However, FRMSs are designed with multiple defensive strategies to manage uncertainties, along with processes for continuous improvement. These characteristics enable them to respond to changes in rapidly evolving industries such as transportation. By contrast, traditional hours-of-service regulations offer only a single rigid, brittle defensive layer against fatigue-related risk, and regulatory change often is too slow to keep up with changes in industry practice.

In commercial aviation, there has traditionally been provision for airlines to be able to apply to the regulator for exemptions to exceed the prescriptive limits in specific situations. This provision can lead to ad hoc changes with potentially compounding effects that are difficult to evaluate. In 2014, the FAA introduced a new set of prescriptive flight and duty time limits and an FRMS regulatory framework for managing pilot fatigue.[86] To exceed the prescriptive limits, an airline regulated by the FAA now must have an approved FRMS and present a specific safety case for the exemption sought, to demonstrate that it can deliver an equivalent level of safety to flights compliant with the prescriptive limits.

FRMSs shift the locus of responsibility for safety away from the regulator and toward employers and employees. This approach is consistent with the philosophy that permitting industry to self-regulate fosters greater ownership of safety by industry and that those who create the risk are best placed to manage it.[89] An important subtext is that safety considerations should be separated from industrial bargaining and remuneration, because cooperation is necessary to manage fatigue as a "whole of life issue." Voluntary fatigue reporting (hazard identification) by staff is an essential source of fatigue monitoring data in FRMSs. An effective safety reporting culture requires a clear understanding by all parties of the delineation between intentional violation of policies or procedures (disciplinary matters dealt with outside the FRMS) and fatigue-related impairment and errors (a normal subset of human behavior).[3]

To meet their responsibilities, all parties involved in FRMS implementation need to have adequate understanding of the scientific principles on which it is based, of the specific causes and consequences of fatigue in their particular operational context, and of their role in the FRMS. Accredited, competency-based education and training programs are needed, and some regulators are providing detailed advice on training content.[90] Evaluation of the effectiveness of training also is a neglected area, with conflicting findings that may be linked to the type of training and the presence or absence of other ongoing strategies to maintain awareness of fatigue risk in an organization.[91,92]

The costs of implementing and running an FRMS may be disproportionately heavy for smaller operators, which could be seen as inequitable if an FRMS gives larger companies a competitive edge. In principle, the complexity and cost of an FRMS should be commensurate with the complexity of the operations that it covers and the level of fatigue-related risk. However, there are few detailed examples of how FRMSs can be scaled to the needs of smaller organizations.[93] Maritime New Zealand has introduced a fatigue management program for vessels as part of the safe ship management system. The program has three levels: for crew and the skipper, for vessel owners and managers, and for safe ship management companies and maritime safety inspectors who are involved in implementing the program. Tailored guidance material is available for different roles and types of operations.[94]

As awareness of the importance of sleep in the management of fatigue risk increases, transport regulators are increasingly turning their attention to regulatory requirements for managing people with clinical sleep disorders. Clinical sleep services clearly have a role in FRMSs, in the diagnosis, treatment, and return to work (when possible) of employees whose sleep disorders put them at elevated risk for fatigue-related impairment.[95] On the other hand, long waiting lists and high costs can be a significant disincentive for disclosure by an employee who is experiencing chronic sleep problems. Employees also may be facing loss of their livelihood if they fail to meet medical standards for fitness to work (e.g., in commercial driving and aviation).[96] The sleep medicine community needs to engage in active dialogue with regulators about these issues to ensure that any regulatory requirements imposed are appropriate and workable.

CONCLUSIONS AND FUTURE DIRECTIONS

FRMSs represent a new approach that seeks to integrate advances in sleep science, circadian science, and safety science to reduce the occupational hazard of workplace fatigue. As implementation and development of FRMSs expand, there will be increasing opportunities for scientists with expertise in sleep science and chronobiology to contribute. Such participation requires a willingness to enter into respectful

transdisciplinary collaborations with operational experts to find workable solutions for managing different fatigue hazards. Scientists also have a role in developing best practice standards for data collection and analysis in FRMSs, including when and how independent ethical approval should be obtained for data collection, and advocating for publication of findings in the open peer-reviewed literature whenever possible. Combining data from multiple studies enables evaluation of the independent contributions to fatigue-related impairment of the different operational and physiologic factors and has exciting potential for increasing scientific understanding and improving FRMSs.

CLINICAL PEARL

Fatigue risk management systems (FRMSs) are a new approach that integrates advances in sleep science and safety science to reduce the occupational hazard of fatigue-related performance impairment in the workplace. The core of an FRMS is a closed-process loop comprising (1) ongoing monitoring of fatigue levels, (2) identification of situations where fatigue may constitute a hazard, (3) risk assessment, and (4) when needed, introduction of risk mitigation measures whose effectiveness is monitored by step 1. This is an exciting new area of application of sleep and circadian science that highlights areas where better scientific understanding is needed.

SUMMARY

The traditional approach to managing workplace fatigue risk has been to impose regulatory limits on maximum work hours and minimum breaks within and between work periods (hours-of-service regulations). This approach, however, does not address all of the known causes of fatigue-related performance impairment and represents a single-layer defensive strategy. FRMSs are a flexible alternative approach based on scientific understanding of the dynamic effects of sleep loss and recovery on performance and of the modulating influence of the circadian system on performance capacity. The core of an FRMS is a closed-loop process that includes (1) ongoing monitoring of fatigue levels, (2) identification of situations where fatigue may constitute a hazard, (3) risk assessment, and (4) introduction of risk mitigations when needed. The effectiveness of mitigation strategies is in turn tracked by the ongoing monitoring of fatigue levels. This closes the FRMS process loop, which relies on measuring or estimating operator fatigue. Multiple defensive strategies can be incorporated, tailored to the operational environment, the level of operator fatigue, and the associated safety risk. Improving FRMSs requires dialogue between scientists and people with operational expertise in the environment(s) where these systems are implemented. FRMSs will improve as scientific knowledge grows and implementation expands.

ACKNOWLEDGMENTS

The ideas and constructs presented in this chapter have been developed through collaborative projects and discussions with many academic colleagues, industry partners, and regulatory agencies over a number of years. Responsibility for the content of the chapter rests with us alone.

Drowsiness in Transportation Workers

Pierre Philip; Patricia Sagaspe; Jacques Taillard

Chapter Highlights

- For years, fatigue has been associated with increased risk of accidents, but the causes of fatigue were unclear. More recently (over the past 20 years), drowsiness and falling asleep at the wheel have been identified as causes of some fatal crashes and traffic accidents.
- Sleep physicians tend not to pay sufficient attention to the problem of drowsy driving in their clinical evaluation of nonprofessional drivers, and better awareness in the health community will help in reducing the risk of accidents.
- Objective measures of sleepiness such as the Maintenance of Wakefulness Test (MWT) seem to be the most suitable tools to assess fitness to drive, compared with subjective self-assessments.
- Public campaigns integrating information on sleep hygiene and countermeasures as well as promotion of sleep awareness within the medical community to combat drowsy driving will significantly improve driving safety.

Traffic accidents are an increasing cause of death and injury around the world, and several countries have launched road safety campaigns in recent decades to decrease mortality and morbidity on their roads.[1] Alcohol and excessive speed have been highlighted in past years as major threats, but quite surprisingly, the sleep health status of drivers has received little attention.

For many years, fatigue has been associated with an increased risk of accidents, but the causes were unclear. Extended or nocturnal work or driving was correlated with accidents, but few reports differentiated fatigue (which usually is seen as due to driving time) from sleepiness (which is due to reduced sleep),[2] extended time awake, and/or being awake at the circadian trough,[3] alone or in combination with the influence of drugs.

Results from epidemiologic studies from the 1990s showed that sleep-related accidents represent up to 20% of all traffic accidents in industrial societies.[4-6] Although drowsiness[7-9] has been identified as the reason behind fatal road crashes and many industrial accidents,[10] many people drive when alertness is at its lowest level. Results from one case-control study[6] has shown that driving between 2 and 5 o'clock in the morning multiplies 5.6-fold the risk of traffic accidents and that being sleepy at the wheel multiplies eightfold the risk of accidents. These statistics provide clear measures of the risk associated with drowsy driving.

Results from an Internet-based survey[11] showed that inappropriate line crossings related to drowsy driving was a good predictor of future sleep-related accidents. Similarly, a Swedish epidemiologic study showed that more than 40% of the reported incidents involved crossing the far right line (on the passenger side of the automobile) before awaking and 16% involved crossing the center line.[12]

Although both the European Union and the United States have launched public campaigns to make their citizens aware of the risk of drowsy driving (e.g., the U.S. National Sleep Foundation "Drive Alert–Arrive Alive" campaign, the European Sleep Research Society's "Wake Up Bus" campaign), major problems remain in (1) the identification of patients who are at risk (or behaviors that put individuals at risk) for traffic accidents and (2) the best way to reduce these risks by appropriate countermeasures.

This chapter presents an update on (1) the relationships among extrinsic or intrinsic sleep disorders, drug intake, and traffic accidents; (2) the present state of knowledge; and (3) studies needed to improve safety.

PREVALENCE AND ASSOCIATED RISKS

Impact of Rest-Activity Patterns on Driving

Behavioral changes affecting the sleep-wake pattern can lead to sleepiness-related accidents. Studying large populations of drivers,[13,14] we demonstrated that long-distance driving frequently was associated with sleep curtailment (advanced wake-up time). Results from several experimental studies conducted by our group showed that sleep restriction[15] or nocturnal driving[16] impaired driving performance; the number of inappropriate highway line crossings was significantly increased by both.

Sleep deprivation affects not only the general population of automobile drivers but also many professional (commercial motor vehicle) drivers all over the world. Results from a study of professional truck drivers[17] revealed a mean duration of sleep of 4.78 hours/day in a 5-day period. Within that period, 56% of drivers displayed at least 6 noncontinuous minutes of sleep as recorded on the electroencephalogram while driving. The vast majority of these "micro" sleep episodes occurred during the late night and early morning.

Health care workers also are affected by sleep loss and frequently must drive home after a night on call. Results from

a prospective survey[18] in 2737 medical residents provided detailed information about work hours, work shifts of an extended duration, and documented motor vehicle accidents. The odds ratio (OR) for reporting a privately owned motor vehicle accident and for reporting a near-miss driving incident after an extended work shift was 2.3 (95% confidence interval [CI], 1.6 to 3.3), compared with an OR of 5.9 (95% CI, 5.4 to 6.3) for a shift that was not of extended duration.

Results of another study showed that extensive nocturnal driving worsens driving performance.[19] Eight hours of nocturnal driving from 9 P.M. to 5 A.M. increased six-fold the number of inappropriate highway line crossings over that for a 2-hour nocturnal driving session (3 to 5 A.M.). These results suggest that the fatigue caused by extended driving duration is amplified at night (implying that maximal driving duration should be shorter for nighttime driving than for daytime driving). The effects of driving duration on lane-tracking can be appreciated by comparing them with impairments in lane-tracking caused by (higher) blood alcohol concentration (BAC) levels. For example, 2 hours of continuous nocturnal driving were sufficient to produce driving impairment comparable to a BAC of 0.05%; after 3 hours of continuous nocturnal driving, impairment corresponded to a BAC of 0.08%.[20]

Impact of Sleep Disorders on Driving

Sleep Apnea

Of all sleep disorders, obstructive sleep apnea syndrome is possibly the most-studied pathologic process with regard to traffic accidents. Indeed, results from several studies performed in the past 20 years showed a clear positive relationship between sleep disorders and traffic accidents.[21-27,27a]

In a study to evaluate the additional accident risk related to sleep-disordered breathing,[28] patients with an apnea-hypopnea index (AHI) of 10 or higher had an OR of 6.3 (95% CI, 2.4 to 16.2) for having a traffic accident as compared with those without sleep apnea. Researchers in another study[29] found increased accident risk in 460 apneic patients, although only the most severely affected patients (AHI ≥30) presented an accident risk factor higher than that of the control subjects. In a third study,[30] the investigators performed an integrated analysis of recordings of sleep-related breathing disorders and self-reported automotive and company-recorded automotive accidents in 90 commercial long-haul truck drivers. In this study, truck drivers with sleep-disordered breathing had a twofold higher accident rate per mile than drivers without sleep-disordered breathing. In contrast with the study cited earlier,[29] accident frequency was not dependent on the severity of the sleep-related breathing disorder.[31] In another study on professional drivers,[8] more than 20% of long-haul drivers reported having dozed off at least twice while driving. Near-misses due to dozing off occurred in 17% of these drivers.

Debate is ongoing regarding the best predictive symptom for risk of sleep-related accidents. Surprisingly, in one study, excessive daytime sleepiness as measured by the Epworth Sleepiness Scale (ESS) was not associated with increased accident risk in apneic patients.[28] This finding could be explained by a low percentage of chronically sleepy drivers in the studied population (only 9% scored above 10 [i.e., borderline or higher sleepiness] on the ESS). In a case-control study[32] of a series of 189 consecutive patients and a control group of 40 hospital staff workers, the best predictors of traffic accidents were self-reported sleepiness while driving (OR, 5; 95% CI, 2.3 to 10.9), having quit driving because of sleepiness (OR, 3; 95% CI, 1.1 to 8.6), and being currently working (OR, 2.8; 95% CI, 1.1 to 7.7). Similarly, a sample of 4002 randomly selected drivers[33] were interviewed to define the prevalence of habitual sleepiness among drivers. The habitually sleepy drivers reported a significantly higher frequency of vehicular accidents than control subjects (adjusted OR, 13.3; CI, 4.1 to 43.0) and a significantly higher prevalence of respiratory sleep disorders than in control subjects. The authors concluded that habitually sleepy drivers are a large group (1 in 30 drivers) who are involved in several-fold more vehicular accidents than control subjects. More recently, in a meta-analysis[34] of sleep apnea and driving risk, it was found that results from 23 of 27 studies and 18 of 19 studies with control groups revealed a statistically significant increased risk of having a driving accident associated with sleep apnea, with results from many of the studies indicating a two-fold to three-fold increased risk.

Narcolepsy and Other Hypersomnias

Narcolepsy also is associated with excessive daytime sleepiness, and it also has been studied as a risk factor for traffic accidents. Narcoleptic patients are at higher risk for sleep-related accidents than those with sleep apnea.[22] The proportion of persons with sleep-related accidents is 1.5- to 4-fold greater in hypersomnolent patients than in control subjects. Apneic and narcoleptic persons account for 71% of all drivers involved in sleep-related accidents. Surprisingly, results of Multiple Sleep Latency Tests (MSLTs) did not correlate with the rate of accidents among sleepy patients. However, the number of patients in the study who underwent sleep latency testing was limited (46 apneics, 22 narcoleptics, 17 other patients diagnosed with various causes of excessive daytime sleepiness), suggesting a lack of statistical power. It is worth noting that regardless of diagnosis, sleep-disordered victims of accidents presented with sleep latencies shorter than those of control subjects.

Elevated risks for motor vehicle accidents due to sleepiness and cataplexy have been reported for persons with untreated narcolepsy.[35] In one study,[36] researchers compared performance on a simulated driving task (the Divided-Attention Driving Test) for 21 male patients with obstructive sleep apnea, 21 sex-matched control subjects, and 16 narcoleptic patients. Narcoleptic patients were younger and sleepier than the patients with obstructive sleep apnea. Tracking error (measured as distance in centimeters from the center of the driving lane) was greater in both patient groups than in control subjects (228 ± 145 cm for obstructive sleep apnea vs. 196 ± 146 for narcolepsy versus 71 ± 31 for control subjects; $P < .001$). Under actual driving conditions,[37] driving performance (measured as inappropriate line crossings and standard deviation of lateral position of the vehicle) of narcoleptics and patients with idiopathic hypersomnia was worse than performance of control subjects. Results from this study confirm that patients with untreated hypersomnia (regardless of etiology) are at higher risk for sleepiness-related driving accidents than persons without hypersomnia.

Insomnia and Attention Deficit–Hyperactivity Disorder

Although not always associated with excessive daytime sleepiness, insomnia also has been evaluated as a risk factor for

driving accidents. Results from a cross-sectional study conducted in 10 different countries showed high rates of car accidents related to sleep disturbances among patients with insomnnia; this association was independent of any adverse effects associated with hypnotic treatment.[38] As expected, reduced total sleep time was one factor explaining the high risk of car accidents for people who complain of insomnia.

Results from a recent study of patients with attention deficit–hyperactivity disorder[39] showed that a significant number of these patients exhibited altered levels of alertness in addition to attention problems. Patients in this study were drug-free. Results from driving simulator measurements combined with electrophysiologic measures showed that subjects with sleep latencies shorter than 19 minutes had significantly worse driving performance than the other patients and control subjects.

Impact of Hypnotics and Other Drugs on Driving Risk

Although results from numerous publications[40-44] have shown an association between central nervous system drugs and risk of accidents, very few results show a direct link between sleep-related accidents and drug intake. According to the French medication classification system, an increased risk of being responsible for a road traffic crash for users of prescribed medicines is defined as a level 2 ("be very careful") or level 3 ("danger: do not drive") risk of driving impairment. The percentage of road traffic crashes attributable to level 2 and level 3 medicine use was 3.3% (2.7% to 3.9%).[45] Results from a study conducted under actual driving conditions demonstrated that a single lorazepam dose (2 mg given by mouth) caused higher standard deviation of lateral position increases than a BAC above 0.05%.[46] Antiepileptics[47] and antidepressants themselves were not associated with risk of a road traffic crash, but this risk increased on *initiation* of antidepressant treatment (OR, 1.49; 95% CI, 1.24 to 1.79) and after a *change in* antidepressant treatment (OR, 1.32; 95% CI, 1.09 to 1.60).[48] Hypnotics with long half-lives (i.e., medium- and long-acting benzodiazepines and antihistamines) carry an increased risk of accidents when subjects drive in the morning.[49] The types of drugs associated with traffic accidents (i.e., hypnotics and benzodiazepines) suggest that insomnia-related sleepiness could be a major underlying cause of drug-related accidents, but further evidence is needed. Users of methadone and buprenorphine were more likely to be responsible for injurious road traffic crashes. This increased risk could be explained by the combined effect of drug addiction, risky behaviors, and its treatment.[50]

EVALUATION OF DRIVING RISK IN PATIENTS WITH SLEEPINESS

As noted earlier, some debate remains regarding the best predictor of risk of a sleep-related accident. Results of two studies[32,33] showed that simply asking a patient specifically about excessive sleepiness while driving may better predict which patients with sleep-disordered breathing are at risk for accidents (as opposed to asking about overall sleepiness). Thus a thorough clinical interview can serve to evaluate a patient's driving risk in most cases. Nevertheless, this strategy requires a truthful subjective self-assessment by the patient. Patients who are drivers dependent on their driving license for their job may be less willing to be truthful if they believe that their commercial driving license may be revoked.

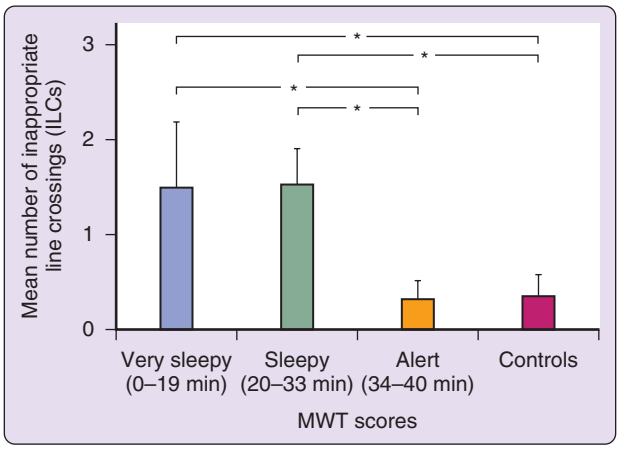

Figure 74-1 Mean number of inappropriate line crossings (ILCs) during real driving (mean ± SE) in the three sleep latency groups on the Maintenance of Wakefulness Test (MWT) and in healthy control subjects. *$P \leq .05$. (From Philip P, Sagaspe P, Taillard J, et al. Maintenance of Wakefulness test, obstructive sleep apnea syndrome, and driving risk. *Ann Neurol* 2008;64:410–6.)

Few studies have investigated the relationship between objective measurement of sleepiness (or Maintenance of Wakefulness Test [MWT] scores) and driving performance. In a study[51] of the Wisconsin Sleep Cohort, the investigators found a correlation between MSLT scores and driving accidents in male apneic drivers: Lower MSLT scores (indicating greater sleepiness) were associated with higher number of reported driving accidents. In another study,[52] comparing MWT scores with performance on a driving simulator in healthy sleep-deprived volunteers, the authors reported the first evidence of the predictive value of the MWT for driving performance. When additional studies were performed in a driving simulator and under actual driving conditions, the authors confirmed that lower MWT scores (indicating greater sleepiness) are significantly associated with impaired driving (i.e., number of inappropriate highway line crossings)[53,54] (Figure 74-1). This study showed that the MWT (administered four times per day using a 40-minute protocol) is a suitable clinical tool to assess fitness to drive in patients with hypersomnias of central origin (narcolepsy or idiopathic hypersomnia) as well as in patients with obstructive sleep apnea.[55] It seems reasonable to consider that patients with MWT sleep latency times under 19 minutes are "unsafe" to drive. Physicians should consider both objective measures (MWT scores) and clinical evaluation (self-reports of sleepiness at the wheel) when providing recommendations about fitness to drive in these clinical populations. Further data are needed to confirm the predictive value of the MWT for accident risk in larger cohorts of apneic and narcoleptic patients.

IMPACT OF TREATMENT AND COUNTERMEASURES ON ACCIDENT RISK

In view of the established sleepiness-related risk of a driving accident, a critical question is how accidents involving these patients can be reduced.

Uvulopalatopharyngoplasty has been evaluated as a therapeutic strategy to treat obstructive sleep apnea and thereby

reduce risk of a driving accident.[56] In one study, the investigators compared the rate of car accidents in 56 apneic patients for 5 years after surgery versus 5 years immediately before surgery. Risk in apneic patients was compared with that in a control group of subjects followed for nasal surgery. Eighty-seven percent ($P \leq .001$) of apneic patients who had reported habitual sleepiness while driving preoperatively reported no sleepiness while driving postoperatively. Accident risk reduction (corrected for mileage) in apnea patients was almost four times greater than the reduction in control subjects ($P \leq .001$) after surgery.

Results from several studies investigating the impact of continuous positive airway pressure (CPAP) on traffic accidents[57-59] confirmed that this therapy is associated with reduced risk of motor vehicle accidents due to obstructive sleep apnea.

For the first time, results from a study conducted under actual driving conditions demonstrated that modafinil (400 mg) improved on-road driving ability (mean number of inappropriate line crossings and standard deviation of lateral position of the vehicle) in narcoleptic and idiopathic hypersomnia patients although lane-tracking was not improved to the level seen in healthy control drivers.[37] This important finding confirms the usefulness of alerting drugs for improving driving safety. The results also indicate that systematic driving evaluations are useful for measuring the efficacy of sleep disorders treatments.

Although cold air or listening to the radio has not demonstrated any efficacy,[60] coffee and naps are effective for combating sleepiness at the wheel.[16,57-59] We have shown that the efficacy of specific countermeasures varies according to age and individual physiology.[61] Indeed, a cup of coffee containing 200 mg of caffeine significantly improved performance in both young (20 to 25 years) and middle-aged participants (40 to 50 years) on nighttime highway driving performance, whereas a 30-minute nap was more effective in younger than in middle-aged drivers. Recently, we showed that in-car continuous nocturnal blue light exposure could be used to mitigate nocturnal sleepiness at the wheel in blue light–tolerant drivers, regardless of age.[62] Critically, nighttime coffee intake or blue light exposure did not modify the quality, quantity, and timing of three subsequent nocturnal sleep episodes. During daytime driving, conversation with a passenger also was shown to contribute to safer lane-keeping in a driver in whom sleepiness was induced by benzodiazepine ingestion.[63] Whether cell phones and other electronic devices that enable social contact while driving may actually improve driving safety (as opposed to serving as a distractor) under some conditions (e.g., in solitary drivers) has yet to be confirmed.

DRIVER'S LICENSE REGULATIONS

Excessive daytime sleepiness and several sleep disorders have been targeted by experts as medical conditions impairing driving skills. As part of the European Cooperation in Science and Technology Action B-26 (the main objectives of which are to assess the role of obstructive sleep apnea syndrome as a possible cause of increased cardiovascular risk and coordinate studies on pathogenetic mechanisms of increased cardiovascular risk associated with several diseases—see http://www.cost.eu/domains_actions/bmbs/Actions/B26)—a review paper[64] was generated in which driving license regulations in 25 European countries was assessed. Excessive daytime sleepiness was mentioned as a medical handicap for driving in 9 countries (Belgium, Finland, France, Germany, Hungary, the Netherlands, Spain, Sweden, and the United Kingdom), whereas sleep apnea syndrome was mentioned in 10 countries (Belgium, Finland, France, Germany, Hungary, the Netherlands, Spain, Sweden, the United Kingdom, and Poland). In all these European countries, a patient with untreated obstructive sleep apnea syndrome is considered unfit to drive. Recently, the Commission Directive 2014/85/EU (amending Directive 2006/126/EC on driving licenses) was adopted. Introducing obstructive sleep apnea syndrome in the Annex for fitness to drive, this directive represents a major step forward in the official recognition of sleep disorders as a major factor in driving safety.

Implications for patients and physicians differ in each country. In the vast majority of European Union countries, once a diagnosis of sleep disorder is made it is the physician's responsibility to inform the administrative authorities issuing driving licenses of the driver's condition. This is not the case in four countries (Belgium, France, Germany, and The Netherlands), where the physician is expected to inform the patient, but not the authorities, that he or she is unfit to drive. Medicolegal authorizations for driving once a patient is diagnosed with a sleep disorder require a certificate delivered by a general practitioner or specialist (pulmonologist or neurologist) in eight countries (Belgium, Finland, France, Germany, Hungary, Spain, the United Kingdom, and Poland). This certificate is based on the patient's clinical improvement and therapeutic compliance, but in two countries the final decision for fitness to drive is determined by the patient's self-evaluation.

Despite available scientific evidence,[34] many countries in Europe do not yet include sleep apnea and excessive daytime sleepiness as risk factors for traffic accidents. A unified European directive seems desirable and should include several sleep disorders and excessive daytime sleepiness in the list of medical conditions adversely affecting driving skills.[65,66]

Several states within the United States require physicians to report to the Motor Vehicle Administration if a professional driver is diagnosed with a sleep disorder. Such a reporting requirement can have dramatic negative consequences for the driver's continued employment. A 2014 conference on Neurological Disorders and Commercial Drivers recommended that a person with a diagnosis of hypersomnia and/or restless legs syndrome should be disqualified from driving commercially.[67] In addition, narcoleptic patients and those with untreated apnea should be disqualified from commercial interstate driving.

This restrictive attitude regarding clinical conditions and driving fitness is not followed in Europe.

Owing to the potentially devastating consequences of disqualifying a professional driver, it is critical that a driver suspected of having sleep apnea be diagnosed by a physician specializing in sleep medicine based on polysomnography, preferably in an accredited sleep laboratory. A full-night study should be conducted unless a split-night study is indicated (severe obstructive sleep apnea identified after at least 2 hours of sleep). Treatment (e.g., CPAP) should be started as soon as possible (i.e., within 2 weeks of the sleep study). After a minimum of 2 weeks after initiating therapy (and preferably within 4 weeks), the driver should be reevaluated by the sleep specialist and compliance (as well as resolution of sleepiness)

assessed. If the driver is compliant, the driver can return to work but should be initially certified for no longer than 3 months, at which time continued compliance and resolution of sleepiness are assessed. Such an approach has been shown to reduce health care and disability costs.[59]

In Europe, driving regulations are similar to U.S. recommendations for apneic commercial drivers, with minor changes in terms of period of evaluation (e.g., 1 year in France).

Finally, whereas in some countries sleepiness while driving is considered the major problem regarding driver safety, only France requires an objective quantification of alertness (the MWT) to evaluate fitness to drive. A mean sleep latency score under 19 minutes associated with severe episodes of sleepiness at the wheel should disqualify patients from driving.[37] This specific requirement thus addresses the frequent combination of sleep disorders and poor sleep hygiene in truck drivers—that is, the requirement specifies the required outcome (objectively demonstrated alertness) rather than identifying the specific cause of sleepiness. To ensure legal protection for drivers and physicians, French experts determined that it was mandatory to demonstrate objectively that patients respond to treatment before allowing them to drive again. In case of a sleep-related accident in treated drivers, physicians could not be sued for insufficient efficacy of treatment and patients should not be prosecuted for misreporting the beneficial effects of treatments.

Based on recent data[37,54,55] collected for treated and untreated patients suffering from nocturnal breathing disorders and also hypersomnia, it seems reasonable to consider that patients presenting with mean sleep latencies under 19 minutes on the MWT are at major risk for sleep-related traffic accidents.

FUTURE CONSIDERATIONS

Although much has already been done in this field, many issues remain. First, at the diagnostic level, no simple objective measure to quantify sleepiness is available, as are available for other accident risk factors (e.g., using a breathalyzer for alcohol testing). Ideally, a "somnotest" is needed to quantify sleepiness-related driving risk, but driving simulators and electroencephalogram measures provide indirect and variable estimation of driving risk and have not been adapted for field use.

Second, treatments other than CPAP (or uvulopalatopharyngoplasty), such as mandibular advancement devices, could provide alternatives to treat sleepiness in lower-risk (less-impaired) patients. The efficacy of oral appliances has not yet been studied specifically regarding driving risk, but they have been shown to reduce sleepiness in patients with mild sleep apnea.[68]

Evaluating the impact of driving durations (and at different times of day) in treated and untreated patients is also important because of the high prevalence of sleep-disordered breathing in professional drivers. These studies are needed not only to define the phenotype of apneic persons involved in traffic accidents but also to determine when these drivers are at greatest risk for a sleepiness-related accident. Even though only 1 patient in 30 with sleep-disordered breathing is involved in a sleepiness-related accident, tracking these persons over time may better inform driving recommendations (e.g., no nocturnal driving) in this population.

Prescription stimulants may have some utility as adjunct treatments for sleepiness due to sleep-disordered breathing,[69] but their impact on driving risk is not known. Pharmacologic countermeasures should be tested and dosing recommendations developed. In addition, guidelines and recommendations regarding fitness to drive in patients with other disorders in which sleepiness is a symptom are needed.[70] Finally, public campaigns on the risks of drowsy driving and the effectiveness of naps and coffee as countermeasures need to be mounted in every country.

CLINICAL PEARLS

- Sleepiness at the wheel is now identified as a cause of many fatal traffic accidents.
- Sleep restriction and/or sleep disorders have been identified in up to 20% of traffic accidents. Use of sedative drugs affecting the central nervous system also has been associated with increased risk of driving accidents.
- Caffeine and naps have demonstrated efficacy for decreasing driving impairment in sleepy drivers.
- Medical treatments such as CPAP are efficacious in drivers with sleep apnea.
- Prescription stimulants may prove to be useful adjuncts for decreasing accident risk in sleepy patients.
- In many countries, it is a legal requirement to systematically evaluate medical disorders among professional drivers, but criteria are variable; an effort toward standardization would be beneficial. Objective measurements of sleepiness such as the MWT can be used to determine fitness to drive. Useful information also can be obtained directly from the patient by specific inquiries regarding subjective sleepiness while driving.
- Finally, public awareness of the danger of drowsy driving needs to be reinforced. Physicians can and should play a key role in educating their patients on risks associated with driving while sleepy.

SUMMARY

Extended work hours and nocturnal driving have been associated with driving accidents—falling asleep at the wheel associated with insufficient sleep and nocturnal driving have been identified as causal factors in up to 20% of traffic accidents. Drugs affecting the central nervous system (i.e., benzodiazepines, antidepressants, narcotic analgesics, and antihistamines), insomnia, nocturnal breathing disorders, and narcolepsy also have been associated with an increased risk of driving accidents. Self-reported drowsy driving is associated with increased risk of accidents. Objective measures of sleepiness such as the MWT can predict accident rates and deteriorated driving performance. Even if not easy to implement in daily clinical practice, the MWT remains the more suitable tool to assess fitness to drive. An MWT sleep latency under 19 minutes combined with self-reported sleepiness at the wheel characterizes status of a patient who is not capable of safe driving. Results from a recent study of actual driving showed that modafinil significantly reduces driving impairment in diagnosed narcoleptic and hypersomniac patients. Further studies of objective and subjective sleepiness before and after treatment are required in patients with periodic leg movement syndrome, insomnia, and circadian rhythm disorders (and other disorders associated with sleepiness) to determine cutoff criteria that can be used to determine safe driving. Treatments

improving daytime vigilance (e.g., CPAP in obstructive sleep apnea) or drugs that promote alertness significantly reduce the risk of traffic accidents for a reasonable cost. Many countries systematically evaluate medical disorders in professional drivers, but the criteria are variable. Efforts to achieve standardization would be beneficial, especially in Europe and in the United States, where sleepy drivers cross several countries or states, each of which may maintain different driving regulations. Regardless of cause, sleepiness at the wheel—a key factor associated with increased risk for motorvehicle accidents—remains underdiagnosed.

Chapter 75

Shift Work, Shift-Work Disorder, and Jet Lag

Christopher L. Drake; Kenneth P. Wright, Jr.

Chapter Highlights

- Circadian misalignment during shift work and jet lag negatively affects sleep, cognition, and work productivity and increases the risk of accidents on the job and during the commute to and from work.
- Shift work negatively affects mood and cardiovascular and gastrointestional health and is associated with an increased risk for developing cancer; jet lag is associated with gastrointestinal distress.
- Clear individual differences (genetic and behavioral) are recognized in the ability to adapt to shift work and time zone travel.
- This chapter emphasizes circadian science principles and pharmacologic strategies for the treatment of shift work disorder and jet lag.

The increased use of technologies such as artificial light and increased air travel have increased exposure to sleep-wake schedules that oppose internal circadian physiology. The ensuing circadian rhythm–mediated disruptions in sleep-wake and other physiologic processes are associated with significant morbidity and mortality. Other chapters in this book address the physiologic basis for conditions such as jet lag and shift work disorder (SWD) in terms of biologic regulation of the circadian system. The discussion in this chapter bridges basic science and laboratory studies and describes the impact of the underlying physiology on health. A summary is provided of results from available laboratory and field-based occupational health studies that can inform the clinician and the patient about clinical issues central to SWD and travel across time zones (jet lag).

SHIFT WORK

Prevalence

The current total working population of the United States is approximately 146 million.[1] Estimates regarding prevalence of shift work vary depending on the definition employed and the region studied, but U.S.-based estimates indicate that nearly 20% of employed adults are shift workers. The proportion is higher if workers engaged in early-morning shifts and infrequent or irregular shifts are included. In the United States today, 17.7% to 25.9% of the total workforce start their shifts between 2 PM and 6:30 AM.[2] These data suggest that between 25.8 and 37.8 million U.S. adults engage in shift work on a regular or rotating basis. Data from other countries also indicate that a high prevalence of the population is engaged in shift work: In Slovenia, the estimated prevalence is 32%; in the United Kingdom, 22%; in Australia, 16%; in Greece, 25%; and in Finland, 25%.[3,4]

Not all persons who engage in shift work develop SWD. Factors including scheduling differences, shift frequency, shift duration, family and social responsibilities, and differences in sleep and circadian physiology affect an individual's response to shift work and hence the development of SWD. These same factors also are important influences on development of jet lag and its impact on work performance and health.

Types

Although the literature is not always precise in defining shift work in terms of start times, the following classifications are based not only on statistics from the U.S. Department of Labor but also on differences in circadian physiology.

Night Shift Workers

Night shift workers with regular start times between 6 PM and 4 AM make up an estimated 4.3% of the total U.S. workforce.[5] This is a conservative estimate, however, because it does not include workers on variable shift schedules. Some have speculated that permanent night work may have benefits in terms of circadian adjustment (compared with variable shift schedules) and accordingly have advised shift workers to stay on a night shift schedule on days off. Little support for this contention can be mustered, however.[6] Indeed, results from both objective and subjective metrics show that night shifts result in greater loss of total sleep time than evening and slow-rotating shift schedules.[7-9] Sleep loss accumulates over successive night shifts, resulting in a buildup of homeostatic sleep debt. The latter, combined with the effects of circadian misalignment, negatively affects productivity and safety in shift workers. Sleep loss alone has been shown to impair alertness and performance (including driving ability), with impairment comparable to that associated with up to 0.19% breath ethanol concentration.[10] Not surprisingly, the night shift produces the greatest degree of sleepiness relative to daytime work, evening shifts, and even rotating shifts, with the sleepiness greatest during the early morning hours close to commute times.[11,12]

Early-Morning Shift Workers

The *International Classification of Sleep Disorders* (ICSD3) classifies early-morning shifts as those starting between 4 AM and 7 AM.[13] This is the most common alternate work shift,

with at least 18.1 million U.S. workers (12.4% of the workforce) falling into this category.[5] Given these start times, many early-morning shift workers awaken before 5 AM. As a consequence, these workers are on the road during the circadian trough and may be partially sleep-deprived because of their early time of rising.[14] These consequences are consistent with the high rate of excessive sleepiness reported in this population.[15] Objective measures of sleep show that early-morning shift workers accrue significantly less sleep than day workers; stage 2 and rapid eye movement (REM) sleep were particularly reduced.[15] Indeed, sleep disturbance is close to that in permanent night workers.[16] These factors, coupled with severe sleep inertia at that hour,[17] suggest that early-morning shift workers are at highest risk of all workers for motor vehicle accidents. Further examination of the prevalence of excessive sleepiness and accidents in this specific population is needed.

Evening/Afternoon Shift Workers

Evening shift workers with regular start times between 2 and 6 PM make up 4.3% of all U.S. workers.[5] This category of workers is at risk for social isolation and consequent reduced quality of life.[18] Unlike early-morning shift workers (who obtain less total sleep time), the average evening-shift worker sleeps 7.6 hours/night,[8] which is more than most day workers obtain (6.8 to 7.0 hours/night).[12] Because the human circadian pacemaker has an intrinsic period that is on average slightly longer than 24 hours,[19] the resulting tendency to delay internal rhythms combined with schedules that allow later morning wakeup times may account for the increased total sleep time observed in evening-shift workers. However, some evening shift workers may have shortened sleep times owing to family obligations that require earlier wakeup times on days off; such reduced sleep time could result in significant impairment over time.

Rotating Shift Workers

The U.S. population is estimated to include 4 million rotating shift workers (2.7% of the total workforce),[2] but nearly all shift workers could be considered to have rotating schedules, because most revert to daytime wakefulness and nocturnal sleep on days off. Nonetheless, even on their days off, rotating shift workers remain sleepier than daytime workers.[20] In a meta-analysis of sleep patterns, the amount of sleep reduction in rotating shift workers was almost as much as in permanent night workers, relative to day workers.[8]

Workers with regular rotating shift schedules face additional challenges related to the speed and direction of shift rotations. Rapid shift rotations (e.g., multiple rotations within a week) are associated with reduced total sleep duration compared with slower rotations (e.g., at least 3 weeks per shift schedule).[8] With respect to direction, both rapid clockwise and counterclockwise rotations negatively reduce total sleep duration and increase circadian misalignment.[21] These effects are thought to be less severe for clockwise rotation, because of the natural tendency of the circadian clock to delay to a later time,[19] and the increased time between shifts with such scheduling. Shift direction and duration may interact, however; findings from one controlled study showed that rapid clockwise and counterclockwise rotations were not significantly different in terms of total sleep duration or degree of excessive sleepiness.[22] The latter finding may have been due to napping; before a counterclockwise rotation to the midnight shift, 80% to 90% of workers nap. By contrast, before a clockwise rotation to the midnight shift, only 40% to 60% of workers nap. In short, napping before a counterclockwise shift to midnights may help to ameliorate some of the impairments in sleep and sleepiness that otherwise would be expected. This interpretation also is consistent with numerous studies demonstrating the beneficial effects of napping among shift workers.[23,24]

Circadian Misalignment and Effects of Light Exposure

The internal circadian clock promotes sleep and related functions during the biologic night and wakefulness and related functions during the biologic day.[25] The circadian clock in humans must be reset on a daily basis to remain entrained to the 24-hour day.[26] Light is the dominant environmental time cue that entrains the human circadian clock to the 24-hour day,[27] and the timing of light exposure will determine whether the internal clock is phase-delayed or phase-advanced[28] (Figure 75-1). Circadian misalignment can be caused by shift work and time zone travel—both of these rapidly alter the temporal relationship between the internal circadian clock and environmental time cues. That is, both shift work and time zone travel require wakefulness during the biologic night and sleep during the biologic day. The resulting circadian misalignment can produce significant morbidity in the form of disturbed sleep, impaired alertness, gastrointestinal disturbances, and so on.

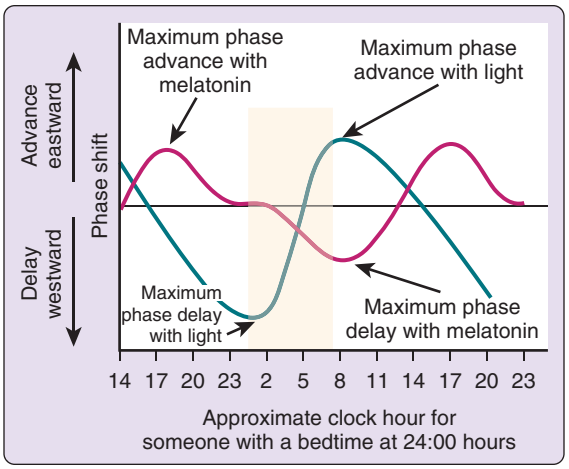

Figure 75-1 Schematic representation of the phase response curves to 1 day of light exposure (6.7 hours) (*blue line*) and 3 days of 3 to 5 mg of exogenous melatonin administration (*red line*) when the circadian system is entrained to local environmental time. The circadian phase resetting response to light and melatonin depends on the internal biologic time of exposure. Generally, bright light exposure before habitual bedtime and several hours thereafter will induce the largest westward phase delays, whereas bright light exposure just before the habitual time of awakening and several hours thereafter will induce the largest eastward phase advances. The time at which phase delays cross over to phase advances is, on average, approximately 2.5 hours before the habitual time of awakening in young adults and 2 hours in older adults.[164] Therefore bright light exposure close to the crossover point may shift the circadian phase in a direction opposite to what is desired. Opposite to the effects of light, ingestion of exogenous melatonin in the late afternoon will induce the largest eastward phase advances, whereas melatonin ingestion shortly after the habitual time of awakening and several hours thereafter will induce the largest westward phase delays. The time at which melatonin-induced phase delays change to phase advances is, on average, in the early afternoon.[106,107]

Morbidity Associated with Shift Work

Sleepiness and Insomnia

Among the most common problems experienced by shift workers are excessive sleepiness and insomnia.[29,30] For example, measures of sleepiness in anesthesia residents show impaired alertness after a single night shift; sleepiness levels were similar to levels observed in patients with diagnosed sleep disorders.[31] Shift workers may further exacerbate the problem by spending less time in bed during the day[32] to attend to everyday domestic activities. These latter issues are in addition to difficulties maintaining daytime sleep (i.e., when the circadian clock is promoting wakefulness).[29,30] Shift workers also may remain awake longer when changing from one shift schedule to another, producing a further accumulation of sleep debt. The known slow rate at which the circadian clock shifts (requiring days or even weeks) combined with erratic exposure to light in shift workers[33] results in impaired adaptation of biologic rhythms to shift work schedules. Thus, in some workers, both sleep disturbance and sleepiness continue even after months or years of shift work or even after discontinuation of long-term shift work.[34]

Reduced Alertness and Accidents

A high proportion of shift workers are involved in safety-sensitive operations, such as transportation, and one of the most well-documented and long-established effects of night shift work is an increased rate of motor vehicle accidents. Converging evidence from controlled laboratory settings, large epidemiologic studies, and clinical samples has established an incontrovertible link between shift work and accidents.[35,36] In a classic study, Smith and colleagues demonstrated that working a night shift increased the frequency of on-road accidents by 50%.[37] In a study of a large sample of nurses, 79.5% of those working the night shift reported at least one drowsy driving incident, equal to an increased odds ratio (OR) of 3.96 (95% confidence limit [CI], 3.24 to 4.84) relative to data for nurses working a day shift.[38] Residents who have frequent on-call schedules are involved in 6.7 times more motor vehicle accidents than those experienced by those working less-demanding call schedules.[39] Other studies have shown that risk increases nearly 10% for every extended shift worked in a month.[40] Driving home from the night shift is a time of particularly high risk, consistent with its proximity to the circadian nadir in alertness.[41,42] Increased rate of accidents after a night shift also is likely to be related to accumulated sleep loss. One study of night and rotating shift nurses showed that the odds for a hazardous driving event was eight times greater during the commute home from a night shift than during the pre-shift commute.[41]

Sleepiness-related impairment is not confined to motor vehicle accidents; for example, among medical personnel, an increased number of accidental injuries with sharp instruments (percutaneous injuries),[43] medication administration and diagnostic errors,[44] and increased patient death rates has been documented in those working extended and unconventional shift schedules.[45] These findings are not surprising, because driving impairment in residents on heavy call rotations in the hospital is similar to that in residents on light call rotations whose blood alcohol concentration is 0.05%.[46] In industrial settings, accidents and injuries increase on the night shift, and over successive night shifts, and with successive hours on a shift.[35]

Major catastrophes such as the event at Three Mile Island, the American Airlines flight 1420 crash, and the Chernobyl disaster occurred during the night shift, drawing increased attention to both the risks and costs associated with shift work schedules.[47,48] Cost of sleepiness-related accidents in the United States is estimated at up to $40 billion per year, representing 24% of the total cost of traffic accidents in the United States.[49] These data suggest that the economic savings associated with shift work for specific industries should be carefully weighed against the overall cost to society.

Work Productivity and Quality of Life

The negative impact of shift work is not limited to major adverse events and catastrophes. It also affects productivity. An association has been demonstrated between shift work and reduced dexterity and efficiency,[50] impaired threat detection,[51] and lower productivity.[52] Thus worker performance is significantly reduced at night in a broad range of occupational settings.[47] Additional evidence shows increased absenteeism in night workers compared with day workers, particularly among those experiencing insomnia and/or excessive sleepiness.[12]

Shift work negatively affects the worker's family as well as the worker's quality of life,[53] as evidenced by 57% higher divorce rates,[54] reduced job satisfaction,[55] and limitations on family and social interaction.[12] After controlling for a number of demographic variables, findings from a 5-year longitudinal study demonstrated a relationship between parental shift work and poor school performance and behavioral problems in children 5 to 12 years of age.[56]

Health Effects of Shift Work

A wealth of information documents the negative health effects associated with shift work. Notable are results from large prospective studies showing a 36% to 60% increased risk of breast cancer.[57,58] The latter effect is particularly evident with increasing years of night shift exposure. Additional findings include a fourfold increased risk of duodenal ulcers (verified by endoscopy)[59] and increased cardiovascular morbidity and mortality,[60-62] with specific disorders including atherosclerosis and myocardial infarction.[60] Poor eating habits[63] and other adverse health behaviors among shift workers may account for some of the increased morbidity.

Genetic Contributions to Shift Work Tolerance

People on the same shift schedule differ dramatically with regard to two of the most common consequences, excessive sleepiness and insomnia.[12,64] This large interindividual variability may be related in part to findings that most night workers' internal circadian rhythms (as indexed by endogenous melatonin levels) do not adapt to their adjusted sleep-wake schedule.[65,66,67] The subgroup of nonadapted workers show reduced daytime sleep relative to that in persons whose melatonin profiles showed rapid adaptation in response to night work.[68] Such individual differences in the circadian system itself (i.e., period, amplitude, response to light) may account for the adverse response (insomnia, excessive sleepiness) to shift work.

Several lines of research suggest that the aforementioned individual differences in adaptation to shift work are at least

partially genetically determined. Results from one study suggest approximately 50% genetic heritability for vulnerability to insomnia[69] (which can be elicited by a circadian misalignment[70]). Likewise, vulnerability to sleep loss during nocturnal hours is associated with a variable number tandem repeat (VNTR) polymorphism in the circadian clock gene *PER3*.[71] People possessing the *PER3*$^{5/5}$ genotype were shown to be more vulnerable than those possessing the *PER3*$^{4/4}$ genotype. It recently was shown that night shift workers who are carriers of the 5-repeat allele (*PER3*$^{5/5}$) experience a high degree of excessive sleepiness during the night shift, whereas *PER3*$^{4/4}$ homozygotes do not.[72] One predictor of shift work tolerance is circadian preference (i.e., "morningness" versus "eveningness"),[73] a heritable trait also linked to the VNTR polymorphism in the *PER3* gene[74] and the intrinsic period of the circadian clock.[75] Morning-type people tend to have a reduced tolerance for night shift work compared with evening-type people.[76] Morningness also has been associated with the *PER3*$^{5/5}$ genotype.

SHIFT WORK DISORDER

As described earlier, large individual differences in circadian and sleep-wake system responses to shift work have been observed.[77] In some cases, inability to adapt to shift work is extreme and constitutes shift work disorder (SWD). Diagnostic criteria for SWD are listed in Table 75-1.[13] People who are unable to tolerate the effects of a shift work schedule present with symptoms of excessive sleepiness or insomnia despite adequate time in bed (i.e., 7–8 hrs) and an absence of other sleep disorders. Although few studies have polysomnographically documented the insomnia associated with SWD, the sleep of patients with SWD is likely to be characterized by sleep fragmentation and early final awakenings. Such persons are unable to remain awake during the early-morning work/commute hours.[78] These deficits can adversely affect job performance, driving safety, quality of life, work satisfaction, and health.[12,64] In addition to better documentation of the sleep and alertness of persons with SWD, a major challenge will be to determine which specific forms of morbidity are associated with insomnia, excessive sleepiness, or circadian misalignment, or some combination of these three factors.

Prevalence

Clinical evaluation of insomnia and excessive sleepiness in shift workers is necessary to determine the actual prevalence of SWD, but few population-based studies are available. In one representative sample, the prevalence of the disorder has been conservatively estimated at 14% to 32% among night shift workers and 8% to 26% among rotating shift workers.[12] Findings from other studies provide similar estimates, with approximately 23% of a sample of oil rig workers in the North Sea,[79] approximately 38% of a sample of 5400 nurses working more than half-time,[80] and approximately 32% of night workers from a random population sample affected.[81]

Table 75-1 Diagnostic Criteria for Shift Work Disorder

***International Classification of Sleep Disorders* (ICSD3) Criteria: General Criteria for Any Circadian Rhythm Sleep-Wake Disorder**

A. A chronic or recurrent pattern of sleep-wake rhythm disruption due primarily to alteration of the endogenous circadian timing system or misalignment between the endogenous circadian rhythm and the sleep-wake schedule desired or required by the person's physical environment or social/work schedules.
B. The circadian rhythm disruption leads to insomnia symptoms, excessive sleepiness, or both.
C. The sleep and wake disturbances cause clinically significant distress or impairment in mental, physical, social, occupational, educational, or other important areas of functioning.

Specific Criteria for Circadian Rhythm Sleep-Wake Disorder, Shift Work Disorder (ICD-9-CM code: 327.36)*

A. There is a report of insomnia and/or excessive sleepiness, accompanied by a reduction of total sleep time, which is associated with a recurring work schedule that overlaps the usual time for sleep.
B. The symptoms have been present and associated with the shift work schedule for at least three months.
C. Sleep log and actigraphy monitoring (whenever possible and preferably with concurrent light exposure measurement) for at least 14 days (work and free days) demonstrate a disturbed sleep and wake pattern.
D. The sleep and/or wake disturbance are not better explained by another current sleep disorder, medical or neurologic disorder, mental disorder, medication use, poor sleep hygiene, or substance use disorder.

Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition: DSM-5*: Diagnostic Criteria for Circadian Rhythm Sleep Disorder (307.45)

A. A persistent or recurrent pattern of sleep disruption that is due primarily to an alteration of the circadian system or to a misalignment between the endogenous circadian rhythm and the sleep-wake schedule required by the person's physical environment or social or professional schedule.
B. The sleep disruption leads to excessive sleepiness or insomnia, or both.
C. The sleep disturbance causes clinically significant distress or impairment in social, occupational, and other important areas of functioning.

Specify Type:

Shift work type: insomnia during the major sleep period and/or excessive sleepiness (including inadvertent sleep) during the major awake period associated with a shift work schedule (i.e., recurring unconventional work hours).

*ICD-10-CM code: G47.26 circadian rhythm sleep-wake disorder, shift work type.

Morbidity

In addition to sleep-wake disturbances, persons with SWD show significant impairments in neurophysiologic measures of attention and memory compared with night shift workers without SWD.[82] In comparisons of shift workers with and without SWD, those with SWD also show a higher prevalence of ulcers, absenteeism, and difficulties with family and social activities and higher rates of major depression and mood problems.[12,83] A relationship also has been found between reduced satisfaction with the work schedule and excessive sleepiness on the night shift.[64] Not surprisingly, persons with SWD report higher rates of sleepiness-related accidents[84] than shift workers without SWD or day workers. Although increased rates of heart disease have been found in shift workers, it is not clear whether this morbidity is directly related to the excessive sleepiness or sleep disturbance characteristic of SWD.[12] Additional studies with patients meeting SWD diagnostic criteria are needed before definitive conclusions regarding unique morbidity in SWD (as opposed to shift work per se) can be determined.

Clinical Evaluation

SWD can be diagnosed by a thorough sleep history without polysomnography (PSG), although PSG may be indicated if there is a high level of suspicion for presence of another sleep disorder (e.g., obstructive sleep apnea).[85] The clinical evaluation for SWD is similar to that for other sleep disorders, particularly the other circadian rhythm sleep-wake disorders covered in Chapter 40. Evaluation of the shift worker, however, also requires careful attention to effects of the work-sleep schedule on cognitive, social, and health-related functioning. Ability to maintain wakefulness, particularly during sedentary activities (e.g., commute home from work), should be carefully assessed, because patients with SWD still have a twofold increase in sleepiness-related accidents compared with shift workers who do not meet diagnostic criteria.[12] The use of a sleep diary and actigraphy monitoring (when feasible and preferably with concurrent light exposure measurement) with a focus on regularity, duration, and timing of sleep periods for at least 2 weeks are helpful for determining the degree and pattern of sleep disturbance and circadian disruption.[86] This information should be collected for both days off and days on the work schedule that produces the symptom complex.

Fatigue often is confused with sleepiness and is a common presenting complaint.[87] If fatigue is present, an important consideration in the differential diagnosis in the shift worker is major depressive disorder.[12] Patients complaining of mental or muscle fatigue (as opposed to sleepiness) may find that sedentary activity or rest without sleeping leads to symptomatic improvement. On the other hand, patients with excessive sleepiness often state that sedentary activities or "rest" periods exacerbate their sleepiness. This is an important distinction to make because patients frequently do not recognize that dozing off in such situations is abnormal. Brief, well-validated tools can be used for assessing sleepiness.[86] The Epworth Sleepiness Scale (ESS) is particularly useful in this regard and can be easily administered in most clinical settings. An ESS score of greater than 10 is considered clinically important. With excessive sleepiness defined by the ESS cutoff score of greater than 10, prevalence rates of this symptom of up to 44% have been reported in shift workers,[12] compared with 24% to 33% in representative samples of daytime workers.[12,88,89]

Assessment tools such as the Insomnia Severity Index and the Pittsburgh Sleep Quality Index are useful for determining the extent and relative impact of sleep disturbance.[90] Practical issues regarding their implementation are discussed in detail in Chapter 83. Extensive clinical guidelines for the general evaluation of insomnia, including its relation to functioning, have been published and should be considered in evaluating a shift worker.[91] Whether the patient reports difficulty initiating sleep, maintaining sleep, or both is important to ascertain before considering appropriate treatment strategies. A thorough history of the patient's recent work schedule is essential to diagnosis, because many types of shift schedules (particularly rapidly backward-rotating schedules) cause significant sleep disturbance and excessive sleepiness.[92] If an evening shift worker presents with excessive sleepiness or insomnia, causes other than the effects of circadian misalignment due to shift work should be considered, because evening shifts are unlikely to lead to SWD (however, SWD might occur in evening workers with a strong morning circadian phase preference or high social or domestic demands).

The clinician also must be aware of potential mental health (e.g., depression), gastrointestinal, cardiovascular, and other health risks associated with shift work, and workers should be encouraged to undergo regular physical examinations to rule out these conditions.[93] In addition, health risks related to use/abuse of substances to relieve insomnia (e.g., illicit drugs and alcohol), poor diet, and nicotine use, which are common in shift workers, also should be addressed during the clinical evaluation. Finally, educating the shift worker on appropriate sleep behaviors (sleep hygiene), with an emphasis on adequate sleep opportunity, is beneficial.

Treatment

A cardinal feature of SWD is that symptoms are directly linked to the shift work schedule and thus are likely to remit after returning to daytime work.[13] Observation of such improvement indicates that circadian misalignment is the underlying pathophysiologic mechanism. Short of going off the night shift, occupational adjustments such as slower rotations (with weeks spent on a particular shift), moving to an evening shift, changing from backward to forward shift rotation, and incorporating increased worker control by allowing "self-scheduling" of shifts may be of some benefit.[94] In most cases, however, clinical intervention is needed, because occupational constraints generally prevent scheduling adjustments or a return to a diurnal schedule that would correct the circadian misalignment. Accordingly, treatment is necessarily targeted at the two symptoms of SWD: reducing excessive sleepiness and/or improving sleep.

Even before the diagnosis of SWD is made, the clinician must first address all potential safety concerns—and the threshold for immediate treatment intervention should be lower in a shift worker presenting with excessive sleepiness while driving and for occupations in which performance is critical for individual or public safety.[13] Shift workers typically have a chaotic sleep-wake schedule and may drastically curtail their time in bed in an attempt to meet their social, occupational, and daily obligations. Potential contributing factors include a short shift transition, long overtime hours to keep up with work demands, a second job, or staying awake to

engage in normal social activities during the day. All of these factors can make it difficult for the shift worker to get enough sleep. The clinician needs to address these issues with each patient.

Circadian Interventions

Appropriately timed bright light exposure to shift endogenous rhythms has been extensively studied in shift workers. Exposure to bright light in the evening near habitual bedtime and for several hours thereafter will induce a phase delay of internal biologic time, whereas exposure to bright light in the morning from approximately 2 hours before habitual wake time and thereafter will induce a phase advance (see Figure 75-1). In general, for every hour of properly timed exposure to bright light, there is a 0.5-hour shift in internal biologic time.

Using these principles, interventions aimed at producing phase delays of the circadian pacemaker (i.e., bright light during the first half of the night shift followed by daytime darkness) have been shown to improve daytime sleep and nocturnal functioning.[95,96] In a landmark study, Czeisler and colleagues treated circadian misalignment due to shift work with exposure to 7.5 hours of bright light (7,000 to 12,000 lux) on 4 consecutive nights in the laboratory and scheduled sleep in darkness between 9 AM and 5 PM at home.[95] In comparison with a control group exposed to room light (150 lux) and unscheduled sleep, those treated exhibited a 9.6-hour delay (i.e., to a later hour) of their circadian rhythms (i.e., temperature, cortisol, alertness). They also averaged 2 hours more sleep during the day and showed improved nocturnal alertness and cognitive performance. Additional details of circadian interventions are available in an American Academy of Sleep Medicine review.[97]

Despite the ability to achieve large phase shifts in controlled laboratory environments, investigators have been less successful in producing complete circadian adaptation in shift workers under field conditions.[98-102] Phase shifting requires near-complete control over the timing of exposure to light and darkness (which requires bright light and light-blocking glasses, respectively), which may not be practical in most real-world settings. Furthermore, complete circadian phase reversals could be maladaptive in that patients could not participate in family and social obligations (i.e., revert to a diurnal schedule) on their days off.

Recognition of practical limitations regarding continuous bright light exposure (e.g., 6 to 8 hours at 10,000 lux) and the limitations of complete phase shifts has led some investigators to study the sleep and performance effects of using brief intermittent light exposure to induce a "compromise" circadian phase (i.e., moderate but stable delays) compatible with permanent night work and common day schedules on days off. In a study by Smith and Eastman,[103] subjects engaged in three simulated night shifts (11 PM to 7 AM) followed by two "weekend" days off, with a final four additional night shifts, closely simulating the variable sleep-wake schedule of shift workers that often occurs in the real world. Subjects were exposed to brief light pulses during the night (15 minutes each hour), with total light exposure duration of 1.25 hours per shift, and wore sunglasses while outside, with the goal of achieving a moderately delayed or "compromise" circadian phase position in which the lowest point of alertness would occur just a few hours after their shift work ended (10 AM). The intervention produced a larger delay in onset of melatonin secretion (from 9 PM to 4:30 AM—a 7.5-hour delay) than that in the control group (3.5-hour delay). Sleep duration (determined by actigraphy and sleep logs) improved in the delayed group participants relative to the control subjects. Treatment also resulted in better and more consistent psychomotor performance. Importantly, delayed circadian phase was positively correlated with improved sleep even in the control group ($r = 0.65$), suggesting that some persons benefit from even small delays in circadian phase. These findings emphasize potentially important individual differences in the response to large and abrupt circadian shifts of the sleep-wake cycle. The effectiveness of this intervention for SWD needs to be studied. Not surprisingly, the benefits of light-induced phase shifts to improve sleep and wakefulness in shift workers appear to be particularly strong for people who commonly experience sleep-wake difficulties when exposed to night shift work schedules.[104]

Compounds with phase-shifting properties (e.g., chronobiotics) also may be beneficial for shift workers. Exogenous melatonin is perhaps the strongest nonphotic time cue agent in humans. Normally, endogenous melatonin levels rise approximately 2 hours before habitual bedtime,[105] remain high across the night, and decline again near the habitual time of awakening. Use of exogenous melatonin to shift circadian rhythms generally follows the reciprocal of the phase response curve for light (see Figure 75-1). Thus melatonin ingested during the biologic day can be used to phase advance or phase delay the circadian clock.[106,107] Properly timed exogenous melatonin administration for 3 days can lead to an approximate 1.5-hour shift in internal biologic time.[106] However, for melatonin to be an effective phase-resetting agent, control over light exposure appears to be necessary, because bright light can counter the phase shift produced by melatonin. Properly timed combinations of melatonin and bright light also can be used to induce larger phase shifts than either alone.[108]

Four days of treatment with 1, 2, or 4 mg of the prescription melatonin agonist ramelteon[109] or 3 days of treatment with 100 mg of the prescription melatonin agonist tasimelteon[110] had significant phase-advancing effects (80 to 120 minutes) when normal sleep-wake schedules were abruptly shifted earlier by 5 hours. Although these effects may have more practical applications for circadian rhythm disorders such as delayed sleep phase syndrome and jet lag,[111] in which modest shifts in the circadian pacemaker may improve symptoms, melatonin or melatonin agonists may still provide benefits in patients with SWD through the sleep-promoting and phase-shifting properties of these compounds.[112,113,110] In studies of shift work, melatonin (0.5 to 3 mg) improved circadian adaptation through phase delays or advances, depending on the time of administration.[96,112] Of note, however, although chronobiotic compounds may benefit shift workers, these benefits will be counteracted by inappropriate exposure to the more powerful zeitgeber—that is, daylight during the early morning hours. Melatonin has been shown to cause performance impairment at doses as low as 5 mg, suggesting caution if wakefulness is intended to be maintained for more than 30 minutes after administration.[112] Finally, no large-scale clinical trials have been conducted to evaluate the effectiveness or safety of melatonin use. Therefore melatonin use should be discussed with the patient's physician. In addition to prescription-only melatonin agonists, in the United States,

melatonin also is available over the counter as a dietary supplement. Some melatonin preparations are certified for purity and dosage level, and such preparations are recommended. Use of melatonin to induce and maintain sleep as opposed to phase-shifting is reviewed later.

Findings from studies have also demonstrated that exercise interventions delay circadian rhythms.[114] Without adequate control over daytime light exposure, however, the usefulness of such interventions alone may be limited owing to the extensive time required for significant phase-shifting effects.

Improving Diurnal (and Nocturnal) Sleep

Shift workers should be encouraged to attempt sleep immediately after the night shift and to maintain a sleep-conducive environment during their sleep time by using light-blocking shades, ear plugs, and a comfortable eye mask. If near-complete circadian alignment to the night shift is achieved, improvements in daytime sleep occur.[95,115] However, the practical limitations of circadian interventions often prevent complete alignment (e.g., diurnal light exposure), thus necessitating interventions directly targeting sleep improvement. This lack of circadian adjustment in shift workers manifests as sleep disturbance during the latter half of daytime sleep.[115] Use of two sleep periods—(1) an "anchor" sleep period of approximately 4 to 5 hours that represents a time of day (e.g., 8 AM to noon when the shift worker is instructed to "always sleep" regardless of its being a workday or day off and (2) another 3- to 4-hour period of sleep taken at irregular times, depending on the work schedule—may help to stabilize circadian rhythms and increase sleep duration for a given 24-hour period.[116] Results from one study showed that splitting sleep into two phases provided more daytime sleep than that obtained with an equal daytime duration of consecutive time in bed.[117]

Although melatonin is less likely to produce circadian phase shifts when light exposure is not controlled or when endogenous melatonin is present,[112] exogenous melatonin (and melatonin agonists), administered during the biologic day when endogenous melatonin levels are low, increases total sleep time even at doses as low as 0.3 mg.[113,110,118,119] In shift workers, some improvements in sleep have been shown with melatonin doses between 5 and 10 mg.[120,121] By contrast, with use of subjective measures of sleep[122,123] or lower doses (2 mg), soporific effects have not been found.[124] Studies in patients diagnosed with SWD are needed, because some subjects in previous studies may not have had significant sleep disturbance.

Benzodiazepine receptor agonists have been shown to improve daytime sleep in simulated shift work environments,[125,126] yet these medications do not normalize nocturnal alertness.[125,127,128] Use of the benzodiazepine triazolam was shown to improve sleep during the daytime hours (by 30 to 60 minutes/day) under conditions of simulated night shift work; however, these effects did not translate into substantially improved alertness during the night.[125,126] Use of newer benzodiazepine receptor agonists have produced similar results in subjective reports of daytime sleep[129] and slight improvements in nocturnal performance; however, evidence for worsened mood also has been reported.[127] Patients diagnosed with SWD may show greater benefits from benzodiazepine receptor agonists, but this has yet to be demonstrated. In contrast with medium-acting compounds (half-life of 5 to 12 hours), short-acting hypnotics (i.e., half-life of 1.5 hours) may be of little benefit in shift workers with isolated sleep maintenance problems (i.e., difficulty staying asleep with no problems falling asleep). However, the possibility of residual sedation should be considered with use of longer-acting hypnotic medications, because shift workers frequently have shorter sleep periods than those for day workers. Behavioral treatment of insomnia in shift workers may be helpful, but specific approaches (e.g., relaxation therapy, stimulus control techniques) have not been systematically evaluated.

Despite its sedative properties, the use of alcohol as a hypnotic in SWD should be strongly discouraged owing to fragmentation of sleep in the second half of the night after alcohol consumption (a time when sleep is particularly vulnerable to disruption in this population).[130]

Napping during the day before the night shift and for brief episodes during the night has been effective for improving alertness and performance.[23,24,131] In two recent studies, the combination of an evening nap and caffeine (250 to 350 mg) 30 minutes before the night shift was particularly beneficial for improving alertness and performance for up to 3 nights.[132] Findings from one study in shift workers who were professional drivers demonstrated that a clinically feasible combination of brief naps (two at 20 minutes each) and a short light exposure period (10 minutes at 5000 lux) reduced polysomnographically measured number of episodes of falling asleep while driving.[24]

Pharmacologically Enhancing Alertness

Many people who experience sleepiness use caffeine to combat the problem. Caffeine can be used to improve wakefulness and performance during the biologic night.[132,133] Although prenap caffeine may be beneficial in reducing the performance-impairing effects of sleep inertia,[134] this approach has yet to be tested in patients with SWD. In a study by Wyatt and colleagues, low-dose caffeine (0.3 mg/kg/hour) administered over periods of extended wakefulness (29 hours) and circadian misalignment helped subjects remain awake and improved memory and psychomotor performance.[135] Overall, evidence supports a role for the use of caffeine to enhance alertness in shift workers.[136] Although other alerting agents have been used, Schedule II stimulant medications such as amphetamines and methylphenidate have several disadvantages, including high abuse potential, that offset their ability to enhance alertness in the context of shift work.[137,138]

Medications indicated for enhancing alertness in SWD have been used to promote nocturnal wakefulness in patients.[85] A study on the use of modafinil for treatment of SWD provides evidence for its therapeutic benefit in occupationally related outcomes, including sleepiness while driving. In that study, 204 patients who met the criteria for SWD were given either 200 mg of modafinil or a placebo for 3 months during the clinical field trial.[139] The group taking modafinil showed significant improvement over those taking the placebo in psychomotor vigilance and drowsy driving on the commute home, among other end points. Patients also exhibited significant reductions in objectively defined sleepiness on the Multiple Sleep Latency Test during the night shift, although alertness levels did not normalize to those seen during typical daytime assessments. Importantly, modafinil did not have detrimental effects on subsequent daytime sleep when taken at the beginning of the night.[139] Armodafinil, the longer-lasting isomer of modafinil, also has been shown to be effective for the treatment of excessive sleepiness in SWD and has reduced

the level of sleepiness during the commute home.[140] In a placebo-controlled driving simulator study in patients with SWD, armodafinil improved driving performance including reduced standard deviation of lateral position and reduced off-road deviations during the night shift up to 9 AM.[141] It has been FDA-approved for use in SWD and has been shown to significantly reduce excessive sleepiness and to improve overall clinical condition and performance in this patient population.[140] Additional studies regarding pharmacologic treatment of circadian desynchrony are reviewed in Chapter 40.

Enhancing Alertness with Combined Treatments

Several investigations have examined the efficacy of combined treatments for promoting wakefulness during the biologic night in normal, healthy volunteers. Combined treatments studied include caffeine and bright light,[133] caffeine and naps,[132] and naps and modafinil.[142] Such wakefulness-promoting treatment combinations have been reported to be of greater benefit than the use of either treatment alone (Video 75-1). With respect to efficacy, these nonprescription alternatives have not been compared with prescription agents (such as modafinil) for treatment of SWD.

Management Guidelines for Shift Work Sleep Disorder

In light of the paucity of clinical tools for assessing and treating SWD, we have proposed a brief set of clinical guidelines, presented in Table 75-2. These guidelines are based on established circadian principles, the literature on morbidity associated with shift work, and data from the few currently available studies on the assessment and treatment of SWD and tolerance to shift work. Several useful clinical case reviews from initial evaluation through treatment follow-up are presented in Chapter 76, with specific reference to high-risk occupations.

Jet Lag

Many millions of people travel by jet plane each year. Jet lag results from a mismatch between internal biologic time and environmental time caused by rapid eastward or westward travel across multiple time zones. Disturbed and/or shortened sleep duration before and during travel also may contribute to jet lag symptoms.

Severity and duration of symptoms (i.e., tolerance to travel) are dependent on (1) the direction and number of time zones traveled, (2) the ability to obtain sufficient sleep while traveling, and (3) exposure to environmental circadian time cues in the new time zone. Symptoms include daytime fatigue and sleepiness and insomnia in the new time zone. Gastrointestinal disturbance is common and may be related to intake of food at a biologic time when the body is not prepared to undertake this function.[143,144] Although the circadian principles used in the management of jet lag are similar to those of shift work, environmental cues (e.g., daytime light exposure) often support adaptation after travel to a different time zone. Thus jet lag symptoms typically subside in a few days (although in some cases symptoms can last for weeks).
