Symptoms of jet lag occur because immediately after eastward jet travel, the traveler attempts sleep in the new time zone before his or her internal biologic night. Sleep in the new time zone is thus disturbed, and such sleep disruption contributes to subsequent daytime sleepiness and reports of fatigue. Daytime sleepiness and fatigue also occur because the traveler must stay awake during his or her internal biologic night. Individual differences in the ability to sleep during the biologic day (vulnerability to insomnia) and to maintain alert wakefulness during the biologic night also may contribute to jet lag symptoms. The cognitive impairments associated with jet lag can have serious consequences, resulting in drowsy driving or flying accidents, impaired decision making for the business traveler, and impaired athletic performance. In other cases, jet lag can be an inconvenience leading to difficulty staying awake during sightseeing, attending the theater, or having a meal. Sleepiness and fatigue also increase the performance-impairing effects of alcohol.[145-147] Jet lag often is reported to be worse after eastward than westward travel. Westward travel may be easier because the average period of the circadian clock in humans is longer than 24 hours, so the biologic tendency is for later bedtime and wake time. From 20% to 25% of people, however, have a shorter than 24-hour clock,[148] and such persons may find it easier to adapt to eastward travel.

Treatment

Successful treatment requires a detailed history and knowledge of circadian physiology and of countermeasures to improve sleep, wakefulness, and circadian adaptation. Most evidence for jet lag treatments comes from laboratory studies. Currently, no medications are approved by the U.S. Food and Drug Administration (FDA) for the treatment of jet lag disorder.

Promoting Sleep during Flight and in the New Time Zone

The traveler should be educated on environmental factors that can be controlled to promote sleep[149] (see Chapter 85). Most flights eastward from the United States to Europe are scheduled at night. Eyeshades and earplugs or noise-canceling headphones may help promote sleep during the flight. Alcohol consumption should be avoided during the flight. Although alcohol shortens sleep latency, it disrupts sleep continuity.[130] Direct overnight flights provide more opportunity to sleep during travel than do itineraries with multiple stops. On arrival, it often is recommended to immediately adapt to the new bedtime and awakening times of the new time zone. Exogenous melatonin can shorten sleep latency and increase sleep duration in a dose-dependent manner when taken during the biologic daytime.[112,118,119] Thus, if sleep is attempted during the biologic daytime while in flight and/or in the new time zone, melatonin may be used to improve sleep quality and duration. Melatonin should be tried in the home time zone before use during travel to determine the response to the chosen dose. Prescription melatonin receptor agonists, such as ramelteon[113] and tasimelteon,[110] are reported to improve sleep during the biologic daytime, so they may be useful in the treatment of jet lag. In a clinical trial, ramelteon (1 mg) was reported to shorten the latency to sleep compared with placebo after eastward air travel across five time zones (from Hawaii to the East Coast of the United States). In addition, 4 mg decreased some daytime symptoms of jet lag.[150] Neither ramelteon nor tasimelteon has been FDA-approved for treatment of jet lag.

Over-the-counter sleep aids have not been tested to determine their effectiveness in treating jet lag. Several prescription benzodiazepine receptor agonists approved for insomnia have been tested in simulated and actual jet lag trials. Findings from these studies indicate that sleep is improved during jet

Table 75-2 Clinical Guidelines for Assessment and Management of Shift Work Disorder

Assessment

I. Determine circadian misalignment (sleep diaries and actigraphy with concurrent light exposure).
II. Assess sleep disturbance.
  A. Determine difficulty falling asleep, staying asleep, or having nonrestorative sleep (both during daytime and nighttime sleeps).
  B. Measure degree of alertness.
  C. Assess falling asleep during inappropriate circumstances or times (using Epworth Sleepiness Scale [ESS]), with special attention to drowsy driving.
  D. Determine important job-related factors: duration of commute after shift, number of consecutive shifts, type of shift, time between shifts.
III. Determine impact on social and domestic responsibilities.[165]

Management[93]

I. Shift workers should have regular physical examinations with attention to psychological (e.g., depression), gastrointestinal, cardiovascular, and potential cancer risks associated with shift work.[93]
  A. Sleep-related comorbidity: Determine risk of sleep-disordered breathing, restless legs syndrome, or other potential sleep disorder.
  B. Other comorbidity: Identify medical or psychiatric disorders that may contribute to the symptoms of insomnia or excessive sleepiness.
II. Determine if removal from shift work is appropriate or practically feasible. If patient meets criteria for a diagnosis of shift work disorder, cessation of the shift work schedule should be the first option discussed with the patient.
III. Determine patient-specific therapeutic approach.
  A. Circadian adaptation
    1. Consider individual difference factors (e.g., age, phase preference).
    2. Consider compromise phase position (e.g., partial phase delay using bright light during first half of night and increased darkness during daytime).
    3. *Night workers*: On days off, adopt a late sleep schedule (i.e., bedtime of 3 to 4 AM).
  B. Symptom management
    1. Insomnia
      a. Good sleep behaviors
        i. Target inappropriate sleep behaviors and encourage use of eye mask, ear plugs, and light-blocking shades during daytime sleep.
      b. Sleep maintenance a primary concern
        i. Consider intermediate-acting hypnotic (half-life of 5 to 8 hours).
        ii. Consider melatonin treatment for daytime sleep (~3 mg).
      c. Sleep initiation problems
        i. Consider short-acting hypnotic.
      d. Sleep problems on days off
        i. Consider fixed sleep-wake schedule and consider anchor sleep.
    2. Excessive sleepiness (i.e., ESS score <10)
      a. Address sleep disturbance if present.
      b. Consider wake-enhancing medication before shift (e.g., modafinil, armodafinil) or off-label stimulants (e.g., amphetamine, methylphenidate).
      c. Prophylactic nap before work shift is recommended.
      d. Judicious use of brief to moderate-length naps (30 to 60 minutes), with recognition of risk of sleep inertia (consider prenap caffeine to reduce sleep inertia).
      e. Consider combined treatment strategies during the work shift (alerting medications, bright light, anchor sleep and naps).
IV. Address additional work, social, and domestic factors.
  A. Social/family/psychological: Improve balance between family/social, work, and sleep time and treat psychosocial stress, depression, or marital discord if present,[165] educate patient's family regarding shift workers need of protected time for sleep.
  B. Health and safety: Promote improved healthy eating habits with respect to regularity and timing relative to the major sleep period (not within 2 to 4 hours of bedtime), reduce inappropriate substance use, increase exercise at appropriate times (not within 2 to 4 hours of bedtime), educate on risks of drowsy driving and critical times of performance vulnerability.
  C. Work-related: Reduce number of consecutive shifts (<4),[165] reduce shift duration (<12 hours), use clockwise rotation,[166] ensure adequate time between shifts (>11 hours),[165] move heavy workload outside circadian nadir (4 to 7 AM), address commute time (longer = greater accident risk), move to day or evening shift,[8] consider incorporation of a shift work awareness program.[167]

travel,[151,152] but there is little evidence that subsequent wakefulness is improved by these or other sleep medications. In addition, the side effects of both over-the-counter and prescription sleep-inducing agents must be considered (e.g., cognitive and balance impairments).

Promoting Wakefulness during Flight and in the New Time Zone

Most flights westward from Europe to the United States are scheduled during the daytime. Staying awake until bedtime in the new time zone should promote sleep. Naps when in flight during westward travel and in the new time zone after eastward or westward travel are likely to be effective in promoting subsequent wakefulness.[153,154] Caffeine is perhaps the most commonly used self-selected countermeasure to promote wakefulness during jet travel. As indicated by sleep deprivation and simulated jet travel studies, caffeine can help to promote wakefulness during the biologic night.[133,135,155]

Modafinil has been shown to improve several, but not all, aspects of cognitive function during sleep deprivation combined with circadian misalignment[156]—which are factors common to jet travel. In a clinical trial of patients with jet lag disorder, armodafinil (150 mg) was reported to increase sleep latency on the MSLT and reduce patient ratings of jet lag severity compared with placebo after eastward air travel across six time zones (from the East Coast of the United States to France).[157] However, wakefulness after sleep onset also was higher during the sleep episode in the armodafinil versus placebo condition, and several subjects reported insomnia as a side effect. Thus patients should be monitored for sleep disturbance if armodafinil is used to combat jet lag disorder; alternatively, the shorter-acting compound modafinil may be preferable. Other side effects of armodafinil included headaches, nausea, and heart palpitations.

Circadian Adaptation

Adjustment of the circadian system to a new time zone often takes days. It has been estimated that complete circadian adjustment may require a day or more for each time zone crossed. Proper timing of bright light exposure and dim light or darkness can quicken adaptation of the internal circadian clock to the new time zone (see Figure 75-1). Exogenous melatonin also may help to shift the circadian clock during jet travel. The timing of melatonin administration to induce phase shifts is opposite to that of light (see Figure 75-1). For example, if a westward phase delay is desired, exposure to dim light-darkness and melatonin in the morning is likely to facilitate a delay induced by exposure to bright light at night (Figures 75-2 and 75-3). Inappropriate timing of light and darkness during and immediately after jet travel can shift the circadian clock in the wrong direction, thereby increasing the duration of jet lag symptoms from days to more than a week.

Partial Preflight Circadian Adaptation

Partial preadaptation of the jet traveler's circadian clock before travel[158,159] may shorten the duration of jet lag symptoms. Partial preadaptation involves going to bed and waking up earlier for 1 or 2 days before eastward flight or going to bed and waking up later before westward flight, combined with properly timed exposure to light (see Figure 75-3). Earlier awakening before eastward flight should be combined with exposure to bright light (e.g., a sunrise walk or turning up the lights in the house) and exposure to dim light at night. Later bedtimes and wake times before westward flight should be combined with exposure to bright light in the evening and exposure to dim light in the morning. For a full case presentation of successful assessment and treatment using this approach, the reader is referred to the description by Wright[160]; clinical management recommendations have been summarized by Sack.[161]

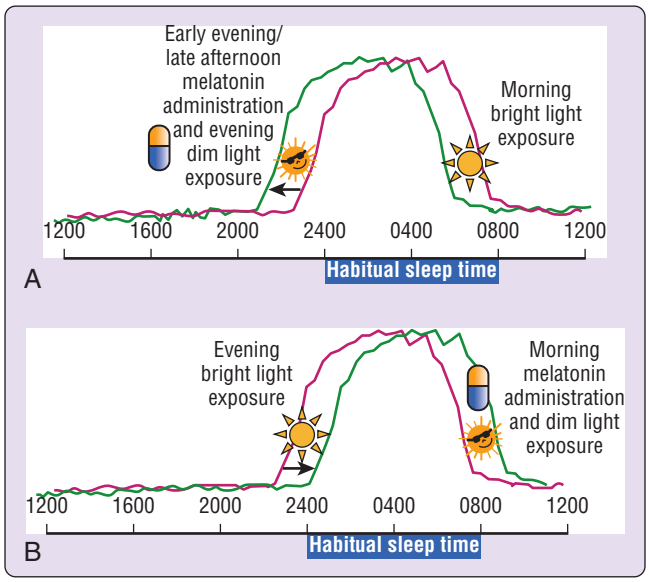

Figure 75-2 Using light and melatonin to phase shift the internal biologic time. **A,** When the traveler is entrained to local time, light exposure during the morning and melatonin ingestion in the afternoon will induce an eastward phase advance shift of the internal circadian clock. *Red line* shows initial melatonin rhythm and *green line* shows advanced melatonin rhythm after treatment. **B,** Light exposure during the evening and melatonin administration in the morning will induce a westward phase delay shift of the internal circadian clock. *Red line* shows initial melatonin rhythm and *green line* shows delayed melatonin rhythm after treatment. Adjustment to eastward travel should include exposure to dim light or darkness in the evening. This can be achieved by wearing sunglasses if the sun has not set and by turning down the lights in the house. Adjustment to westward travel should include exposure to dim light or darkness in the morning. Administration of melatonin when the jet traveler is required to be awake (e.g., for work or driving) should be avoided, because melatonin has been reported to impair performance.

CONCLUSIONS

Shift work can have debilitating consequences from chronic sleep disruption, social isolation, and circadian misalignment.[162] The negative effects of shift work may involve the gastrointestinal, cardiovascular, and other physiologic systems.[163] Although the direct relation between disruptions of the sleep and circadian systems and corresponding morbidity needs further study, circadian and sleep adaptation to shift work can be improved using interventions that target these systems. Impaired alertness may require management strategies beyond circadian and sleep-related interventions. In people with SWD, treatment should be directed at circadian adjustment to the shift work schedule and, if necessary, treatment of excessive sleepiness and/or sleep disruption symptoms. Although data on patients diagnosed with SWD are limited, successful treatment approaches have included wake-promoting medications, prophylactic naps, appropriately

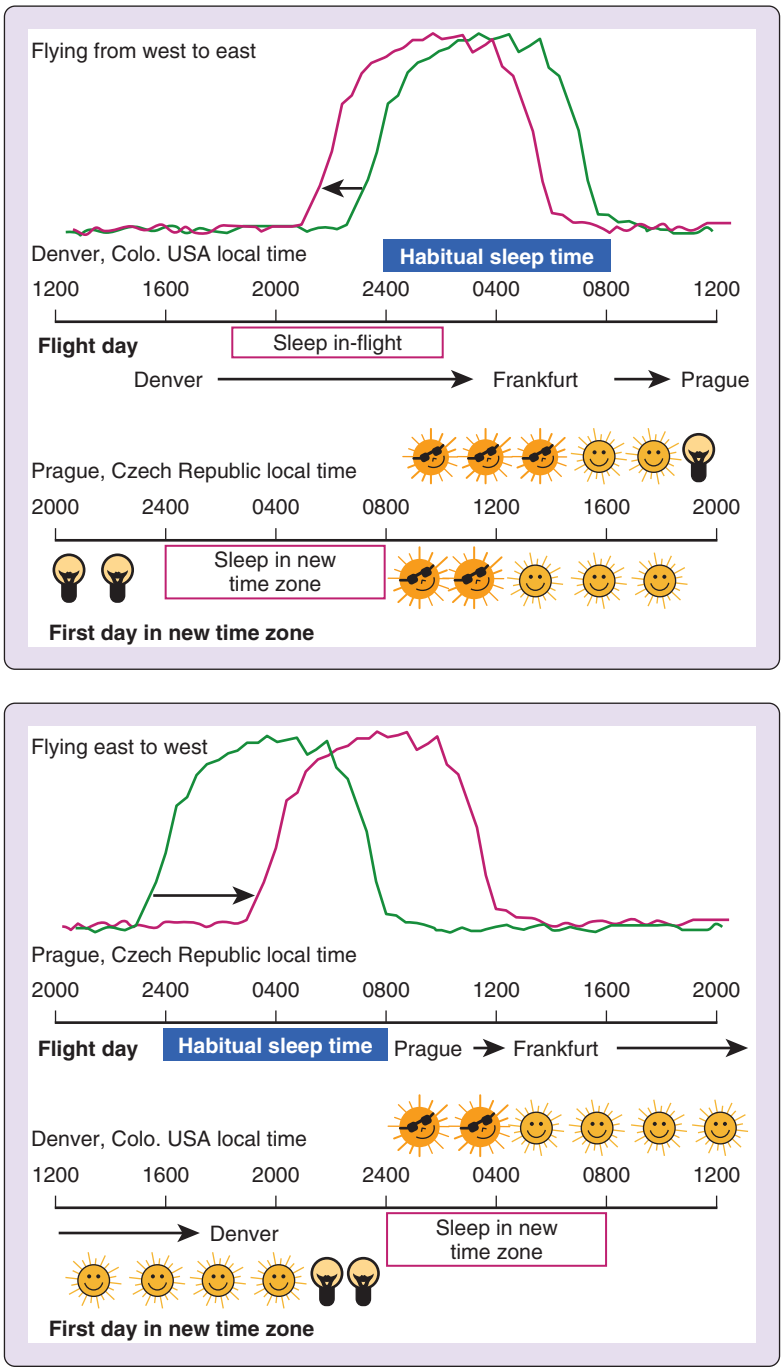

Figure 75-3 Circadian adaptation during jet travel. *Top:* When traveling eastward, the jet traveler needs to advance the timing of his or her sleep schedule as well as the phase of the internal circadian clock so that both occur earlier. In the current example of a trip from Denver, Colorado, to Prague, Czech Republic, the primary plane flight to Frankfurt (*long black arrows*) occurs during the beginning of the biologic night, when endogenous melatonin levels are high (*green line; top panel*). The traveler should sleep as much as possible on the plane flight to reduce the negative impact of sleep deprivation during jet travel. Exogenous melatonin taken shortly after boarding the plane may help the traveler fall asleep earlier than normal when endogenous melatonin levels are low. In this example, the traveler spends several hours in Frankfurt before the flight connection to Prague. Light exposure during most of the biologic night will induce a westward phase delay, opposite to what is needed for an eastward shift; accordingly, the traveler should avoid exposure to bright light (*sun with sunglasses*) and wear an eye mask or sunglasses until after the habitual time of awakening in the home time zone. Subsequent exposure to bright light (*sun without sunglasses and light bulb*) will facilitate the eastward phase advance of the traveler's circadian clock (*red line; top panel*). Sleep timing should be consistent with the local time zone in Prague, and melatonin may again help phase shift the clock and promote sleep onset if taken when endogenous melatonin levels are low. The next day, the traveler should at first continue to avoid exposure to bright light. Each day, the time of exposure to bright light can be moved earlier by 1 to 2 hours per day. *Bottom:* When traveling westward, the jet traveler needs to delay the timing of his or her sleep schedule as well as the phase of the internal circadian clock (*green line; bottom panel*) so that both occur later. In the example of a trip from Prague to Denver, plane flights occur across the biologic day when endogenous melatonin levels are low, and the traveler should remain awake for much of the trip, assuming that sleep was adequate before travel. Caffeine and/or a nap can help to support subsequent wakefulness. Exposure to bright light should occur across the entire plane flight and until just before bedtime in the new time zone, to facilitate a westward phase delay (*red line; bottom panel*).

timed exposure to bright light exposure and darkness, and combined countermeasures (when appropriate). Sleep disturbance, short sleep duration, and circadian misalignment can have a negative impact on productivity, performance, and safety during and immediately after jet travel. Sleep and circadian science principles indicate that appropriately timed exposure to light and darkness before and during the flight and on arrival can hasten adjustment to the new time zone, whereas inappropriately timed exposure to light and darkness during and immediately after jet travel can shift the circadian clock in the wrong direction, thereby increasing the duration of jet lag symptoms.

CLINICAL PEARLS

Shift Work

Shift work disrupts sleep and circadian rhythms and is associated with increased risk for cardiovascular disease, gastrointestinal disorders, and cancer. Careful application of circadian principles (appropriate timed bright light-darkness exposure and melatonin) can improve adjustment to shift work. Melatonin and prescription hypnotic medications may provide additional benefit in some people. Treatment with FDA-approved alerting medication often is useful in patients with SWD.

Jet Lag

Rapid eastward or westward travel across multiple time zones induces circadian misalignment, which produces insomnia and daytime sleepiness with impaired driving performance and cognition. Circadian adaptation to the new time zone requires appropriately timed exposure to light and darkness. Inappropriately timed exposure to light can shift the circadian clock in the wrong direction, prolonging jet lag symptoms. Wakefulness- and sleep-promoting countermeasures can be used to address symptoms of daytime sleepiness and sleep disruption, respectively, during travel and in the new time zone.

SUMMARY

Shift work and travel across time zones are commonplace. These factors pose circadian challenges because they require abrupt and often large shifts in the timing of sleep-wake schedules. Individual differences exist in the ability to adapt to this mismatch between circadian physiology and sleep-wake behavior that in turn impact sleep-wake, cardiovascular, and gastrointestinal system functioning. Insomnia and excessive sleepiness, which contribute to other morbidity (e.g., accidents), are the defining symptoms of SWD. Effective treatments for symptoms of SWD include use of nocturnal bright light and daytime darkness, maintenance of anchor sleep with naps to increase 24-hour sleep time, and sleep- and wake-enhancing medications. Jet lag symptoms include gastrointestinal disturbance, daytime fatigue, sleepiness, and insomnia. Cognitive impairments can have serious consequences, including impaired driving and impaired decision making. Interventions such as appropriately timed bright light and darkness can improve circadian adaptation to time zone changes; sleep-promoting agents and melatonin and its agonists (during the biologic daytime) may promote sleep but may not improve wakefulness in the new time zone. Preadaptation of the circadian clock and use of caffeine and brief naps in the new time zone are useful countermeasures to promote wakefulness.

ACKNOWLEDGMENTS

We thank Drs. Gregory Belenky, Karen Roy, and Thomas Roth for their helpful comments on the manuscript.

Sleep Problems in First Responders and in Deployed Military Personnel

Bryan Vila; Charles Samuels; Nancy J. Wesensten

Chapter Highlights

- Fatigue associated with inadequate sleep and prolonged work shifts is one of the most common health and safety hazards faced by police officers and other first responders and deployed military personnel. Whether caused by extended-duty hours, night work, or circadian disruption, fatigue contributes to morbidity (and possibly mortality) in these occupational groups.
- The impact of insufficient sleep on first responders can extend to bystanders and noncombatants because this deficit tends to degrade cognitive performance, including the ability to make sound judgments, decide on appropriate courses of action, and exercise restraint in the face of threat and provocation. This impairment is particularly problematic in civilian police work, used in this chapter as an exemplar for other classes of first responders.
- The social, organizational, and individual causes of insufficient sleep within these occupational groups are inextricably linked, and the interactions of these various factors must be considered to address the problem of insufficient sleep (and sleep disorders) in these populations.
- By working with operational agencies, physicians and other health care providers can improve individual patient treatment and public health outcomes.

Police officers in the United States, Canada, and other industrialized nations often are exposed to long and erratic work hours, shift work, and insufficient sleep. These factors are likely to contribute to the elevated morbidity observed among police officers. Fatigue-related impairments in officer performance and decision making generate unique social and economic costs, because an error on the part of a police officer (e.g., in distinguishing between an innocent bystander and an aggressor) can result in injury or death.[1]

Managing fatigue in a police force requires balancing the biologic and social needs of officers against the requirements of the organizations that employ them and the safety of the communities they serve. Communities must have sufficient officers on duty at any moment to respond to emergencies, prevent crime, and arrest offenders, but not so many that public resources are wasted. To complicate matters, the need for police services fluctuates across the day, week, and season.

Officers impaired by insufficient sleep are less alert, their cognitive and physical abilities decline, and their mood worsens—all of which translate into degraded ability to effectively cope with stressors. This detriment in turn reduces both public and officer safety because risks of job-related accidents, injuries, errors, and misconduct increase. Over the long term, chronic insufficient sleep may make officers more vulnerable to physical and psychiatric illness and may corrode the quality of family and social interactions that buffer the impact of a stressful work environment. Preventive measures and treatment require consideration of the processes that lead to insufficient sleep and interfere with recovery from exposure to stressors.

PREVALENCE OF SLEEP LOSS, MORTALITY, AND MORBIDITY AMONG POLICE OFFICERS

Compared with workers in the general population, officers whose sleep is chronically disrupted, as a consequence of either personal factors such as medical disorders, intolerance to shift work and schedule changes, or involvement in off-duty activities or because of employer scheduling and work-hour practices, suffer from disproportionately high levels of cardiovascular, gastrointestinal, and metabolic diseases; chronic insomnia, sleep apnea, and other sleep disorders; and psychological disorders including depression, suicide, and family dysfunction.[2-16] Research linking long and erratic work hours to these sorts of disorders is substantial and the findings are compelling.[1,12] Shorter-term links between sleep loss and the sorts of on-the-job accidents and injuries that most frequently kill or seriously harm police officers also are well documented.[1,12,13]

Figures 76-1 and 76-2 show the sources of on-the-job injury and death for police officers. As is evident in Figure 76-1, felonious killings of police officers declined steadily from 1980 to 2013. This decline probably was a consequence of improvements in training, tactics, and soft body armor. Over the same period, accidents declined to a lesser extent despite major improvements in vehicle safety such as crash-resistant designs, air bags, shoulder harnesses, radial tires, antilock braking systems, and disk brakes. Since 1997, accidents have accounted for an average of 57% of all officer deaths, versus 43% for felonies. Reported suicide rates from 1984 to 1998 (the only period for which these official data were available nationally[17]) also declined—and, up to 1998, suicides

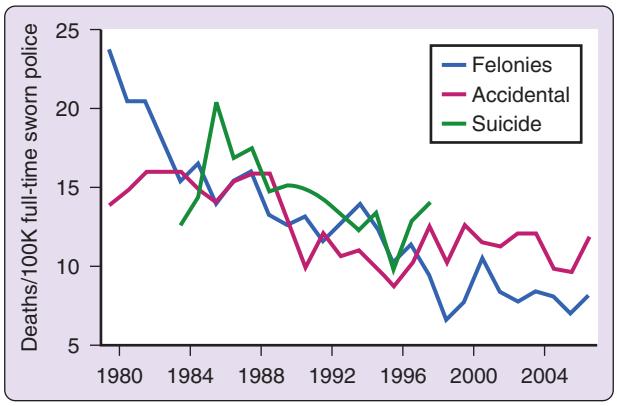

Figure 76-1 Police officers killed per capita in the United States, by cause. (*Felonies and accidents:* Data from Federal Bureau of Investigation. *Law enforcement officers killed and assaulted* [LEOKA]. Uniform Crime Reports. <https://www.fbi.gov/about-us/cjis/ucr/ucr-publications>; 1980–2013. *Suicides*: Data from Centers for Disease Control and Prevention, National Institute for Occupational Safety and Health. National occupational mortality surveillance [NOMS] data 1984 to 1998; and Web surveillance data for 2008 to 2012 [see text].)

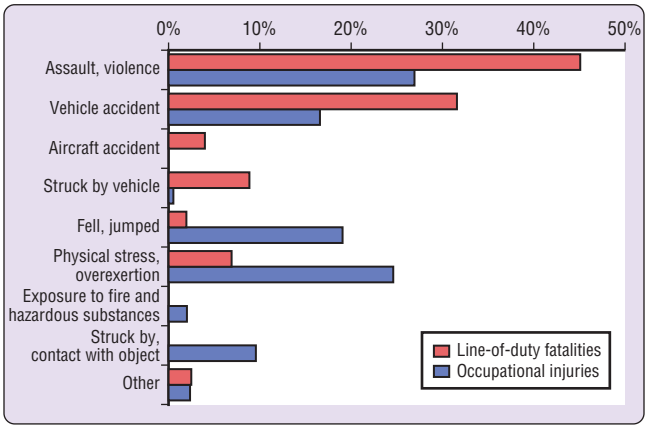

Figure 76-2 Causes of police injuries and fatalities in which work time was lost. (Data from National Law Enforcement Officer Memorial Fund website, 1995 to 2002.)

accounted for slightly more officer deaths annually than either felonious killings or accidents. More recent surveillance data using extensive Web-based reviews of news reports showed average officer suicide rates for 2008 to 2012 that were 28% higher.[18,19] Another recent analysis, using occupational and mortality data from 23 states during 1999, 2003 to 2004, and 2007 to calculate proportionate mortality ratios, found a 69% greater risk of suicide for police officers than for other adult workers in the United States.[15]

Figure 76-2 illustrates common causes of police occupational injuries that were sufficiently serious to result in lost work time and police on-the-job fatalities. It is worth noting that of the various causes, (1) nonfelonious vehicular accidents are the second most common cause of both fatalities and serious injuries (second only to assault and violence); and (2) operational deaths within both police and military forces tend to be split roughly evenly between deadly encounters and operational accidents, especially vehicle collisions.[20] Because the probability of vehicular accidents is significantly increased by sleep loss and disruption[21-23] as well as circadian factors,[14,24] it is highly likely that these two factors increase the likelihood of nonfelonious vehicular accidents in police officers.[24a,24b] These problems are compounded by the substantial amounts of overtime worked by police officers in the United States and Canada.[25-29] Officers assigned to patrol and detective assignments may work 16 or more consecutive hours—and sometimes more than 24 hours straight. As with most occupations, a small proportion of the officers in most departments work a large proportion of the overtime. Extreme examples of officers working more than 3000 hours of overtime per year have been reported regularly during the past decade.[30] On top of these practices, many officers also work second jobs, about which almost no national data are available.

Shift work, overtime, and long work hours interfere with the social and domestic lives of officers, increasing logistical and scheduling problems that affect nearly every aspect of their lives. The burden borne by officers and their families as a consequence of work hour practices is similar to that for other occupational groups.[1] However, unlike occupations in which shift work and long, erratic work hours tend to be limited to the first few years after initial training (e.g., physician, public defender), many police and first responders (e.g., firefighters, emergency medical technicians) are exposed to these types of work schedules throughout their careers. Moreover, they do so in unstructured and unpredictable situations that require expert judgment, decision making, and self-restraint. Dr. William Dement summarized this issue as follows[31]:

> Police work is the one profession in which we would want all practitioners to have adequate and healthful sleep to perform their duties at peak alertness levels. Not only is fatigue associated with individual misery, but it can also lead to counterproductive behavior. It is well known that impulsiveness, aggression, irritability and angry outbursts are associated with sleep deprivation.[31]

SLEEP PROBLEMS IN MILITARY PERSONNEL

Military personnel deployed to theaters of operation (to include both combat missions such as Operation Desert Storm and humanitarian missions such as Operation Restore Hope) are exposed to stressors that preclude sufficient sleep (e.g., night operations) or are thought to cause sleep disturbances (e.g., witnessing the injury or death of a "battle buddy"). In-theater surveys of military personnel serve as the main source of data regarding sleep problems associated with military operations. Since 2003, the U.S. Army's Mental Health Advisory Teams (MHATs) have conducted approximately yearly in-theater surveys of deployed United States military personnel (in active duty, reserve, or National Guard units) to assess personnel behavioral health. Although early MHAT reports did not include survey items pertaining to sleep, such items have been included in more recent years. For the MHAT-5 to -9 surveys (conducted in 2007, 2009, 2010, 2012, and 2013, respectively), personnel were asked how many hours of sleep they obtained per day. In a separate item, they were asked how many hours of sleep per day they needed in order to feel well rested. Possible responses for both items were 4 or fewer, 5, 6, 7, and 8 or more hours. For the MHAT-V (as originally designated) survey, soldiers reported obtaining an average of 5.6 hours of sleep per day and needing 6.4 hours

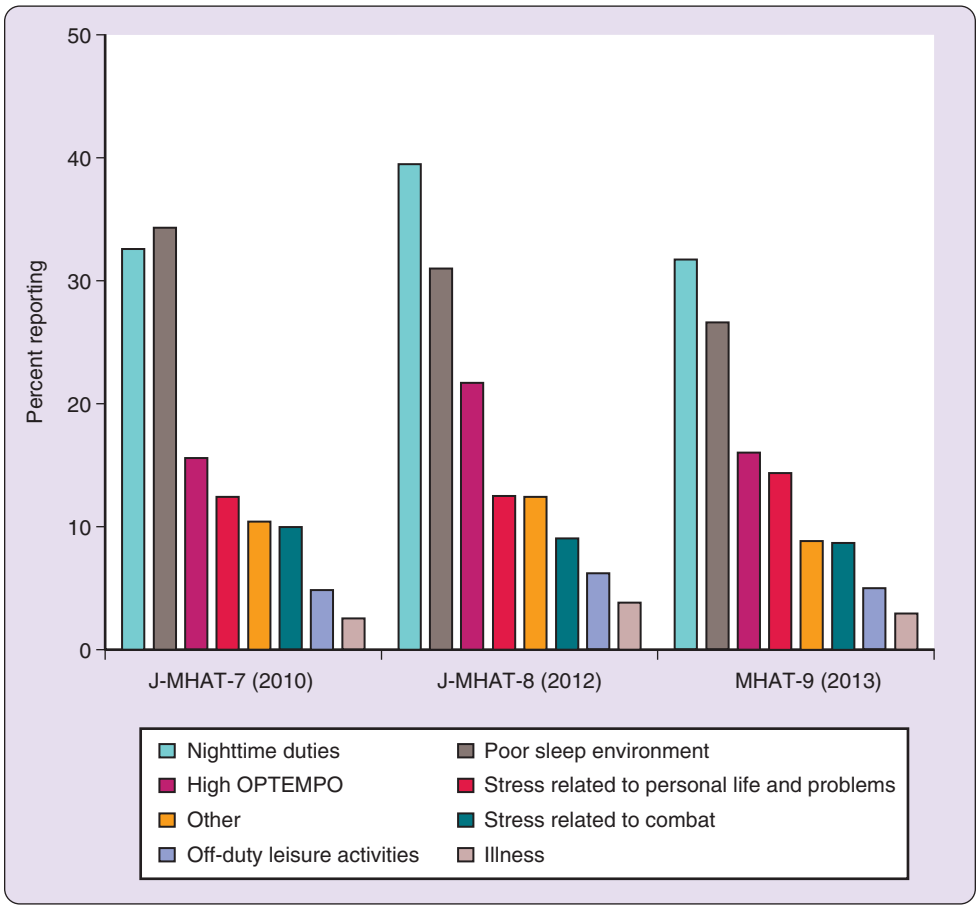

Figure 76-3 Percentage of respondents reporting that a particular factor interfered with their sleep on "more than half the nights" or "nearly every night over the past 30 nights." (Modified from U.S. Department of the Army, Mental Health Advisory Team 9 [MHAT 9]. *Operation Enduring Freedom [OEF] 2013 Afghanistan: report,* Table 5.6.1. Office of The Surgeon General United States Army Medical Command, and Office of the Command Surgeon Headquarters, US Army Central Command [USCENTCOM], and Office of the Command Surgeon US Forces Afghanistan [USFOR-A]. <http://armymedicine.mil/Documents/MHAT_9_OEF_Report.pdf>; 2013.)

sleep to feel well rested (results for these two items were not provided in subsequent MHAT reports).[32] Another item that was included in MHAT surveys conducted in 2010, 2012, and 2013 pertained to the frequency with which various factors interfered with sleep over the past month. Possible responses were "not at all," "few or several nights," "more than half the nights," and "nearly every night." The percentages of personnel responding "more than half the nights" or "nearly every night" are shown in Figure 76-3.[33] Consistently across MHAT reports, the two most frequently reported factors interfering with sleep were nighttime duties and poor sleep environment.

Several MHAT surveys also included an item in which personnel were asked to report how often (during the current deployment) that they had fallen asleep on a convoy, on guard duty, or during a briefing. Possible responses were "never," "seldom," "sometimes," and "often." Figure 76-4 illustrates results for those responding "sometimes" or "often."[33] Response rates were highest for falling asleep on a convoy, with almost 50% reporting that they had fallen asleep on a convoy in 2013. Rates for reporting falling asleep on guard duty and during a briefing were 20% or less. MHAT surveys conducted in 2009, 2010, 2012, and 2013 also contained an item in which personnel were asked to think about their experiences on the current deployment and rank how much trouble or concern had been caused by several factors, one of which was not getting enough sleep. Results for personnel responding that they had medium, high, or very high concern about not getting enough sleep are shown in Figure 76-5.[33] For all years except 2013, greater than 50% of personnel indicated medium, high, or very high concern about not getting enough sleep.

The U.S. Navy also has conducted behavioral health needs assessments. One such assessment consisted of Navy active duty and reservists (n = 3175) serving in a ground combat zone (Operation Enduring Freedom, Afghanistan).[34] The Navy survey was modeled after the Army's MHAT survey and included similar sleep items. Results from the Navy survey indicated that personnel reported obtaining 5.9 ± 1.1 hours of sleep per day, on average, as well as requiring 6.8 ± 1.0 hours of sleep per day in order to feel well rested. Personnel also were asked to rate their difficulty falling asleep and difficulty staying asleep in the past 2 weeks, using a 5-point scale ranging from 1 = "none" to 5 = "very severe." Mean difficulty falling asleep was rated as "mild" (2.1 ± 1.0), as was mean difficulty staying asleep (2.1 ± 1.1).

Results of other analyses from both the Army and Navy assessments revealed relationships between sleep and behavioral health. For example, in the Navy survey, sleep duration

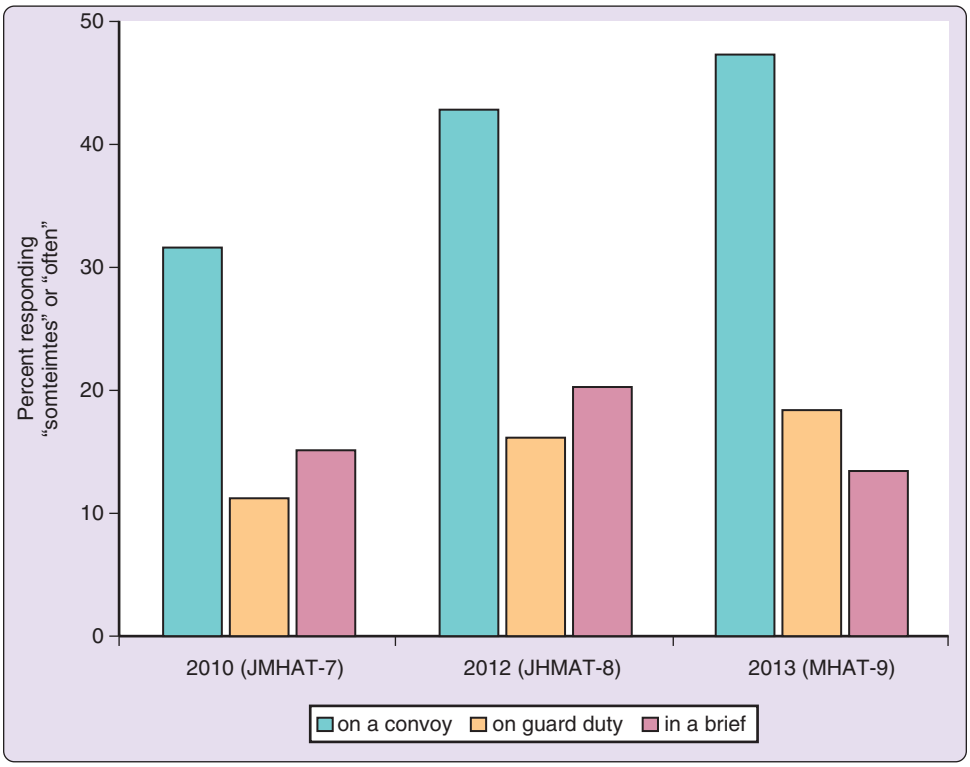

Figure 76-4 Percentage of respondents reporting that they had "sometimes" or "often fallen asleep (even briefly)" during a particular activity throughout the current deployment. (Modified from U.S. Department of the Army, Mental Health Advisory Team 9 [MHAT 9]. *Operation Enduring Freedom [OEF] 2013 Afghanistan: report,* Figure 5.6b. Office of The Surgeon General United States Army Medical Command, and Office of the Command Surgeon Headquarters, US Army Central Command [USCENTCOM], and Office of the Command Surgeon US Forces Afghanistan [USFOR-A]. <http://armymedicine.mil/Documents/MHAT_9_OEF_Report.pdf>; 2013.)

of 6 hours or less, difficulty falling asleep, and difficulty staying asleep were associated with significantly higher likelihood of experiencing symptoms associated with generalized anxiety disorder, major depressive disorder, and posttraumatic stress disorder. For MHAT-V, a sleep debt index was calculated by subtracting reported hours of sleep obtained (e.g., 4) from reported hours of sleep needed to feel well rested (e.g., 6 hours). This sleep debt index was then compared against responses for items pertaining to behavioral health problems. A positive (and approximately linear) relationship was found between amount of sleep debt and percentage of soldiers screening positive for depression, anxiety, or acute stress: Whereas less than 15% of soldiers with zero hours of nightly sleep debt screened positive for a mental health problem, just over 40% of soldiers with 4 hours of nightly sleep debt scored positive for a mental health problem. In addition, a higher percentage of soldiers whose nightly sleep debt score was 1 hour reported that stress or emotional problems over the past month had limited their ability to do their job, caused them to perform their work less carefully, or caused their supervisor to be concerned about their performance, compared with soldiers whose nightly sleep debt score was zero hours.

The MHAT-6 to -9 surveys also included an item regarding use of medications for a sleep problem—specifically, "Have you taken any medication for a sleep problem during this deployment?" Across the MHAT-6 to -9 reports, 9.6%, 11.3%, 6.4%, and 11.4% of respondents, respectively, indicated that they had taken medication for a sleep problem during that particular deployment. Whether using a medication for a sleep problem was associated with hours of sleep (or other sleep-related survey items) was not reported. For example, it might be expected that people working night operations would be more likely to use a medication for daytime sleep problems. Some MHAT assessments also included surveys of health care providers. For the MHAT-4 and -5 surveys, 30% and 52% of primary care providers, respectively, reported prescribing medications for sleep problems on a weekly basis.

In sum, results from surveys of personnel deployed to military theaters of operation indicate that chronic, insufficient sleep is common—and is associated with symptoms of degraded behavioral health. Some evidence suggests that deployed personnel use medications to help with sleep problems. Finally, the two most commonly reported factors leading to disrupted sleep are night operations and poor sleep environment.

OPERATIONAL PERFORMANCE CHALLENGES RESULTING FROM INSUFFICIENT SLEEP

Police and personnel deployed to combat zones may be seen as model occupational groups for (1) identifying factors that may be driving insufficient sleep and (2) recognizing those capabilities that could be negatively affected by insufficient sleep in other first responders such as firefighters and field emergency medical personnel.[35,36] As in police work and small-unit military operations, the tactical and strategic

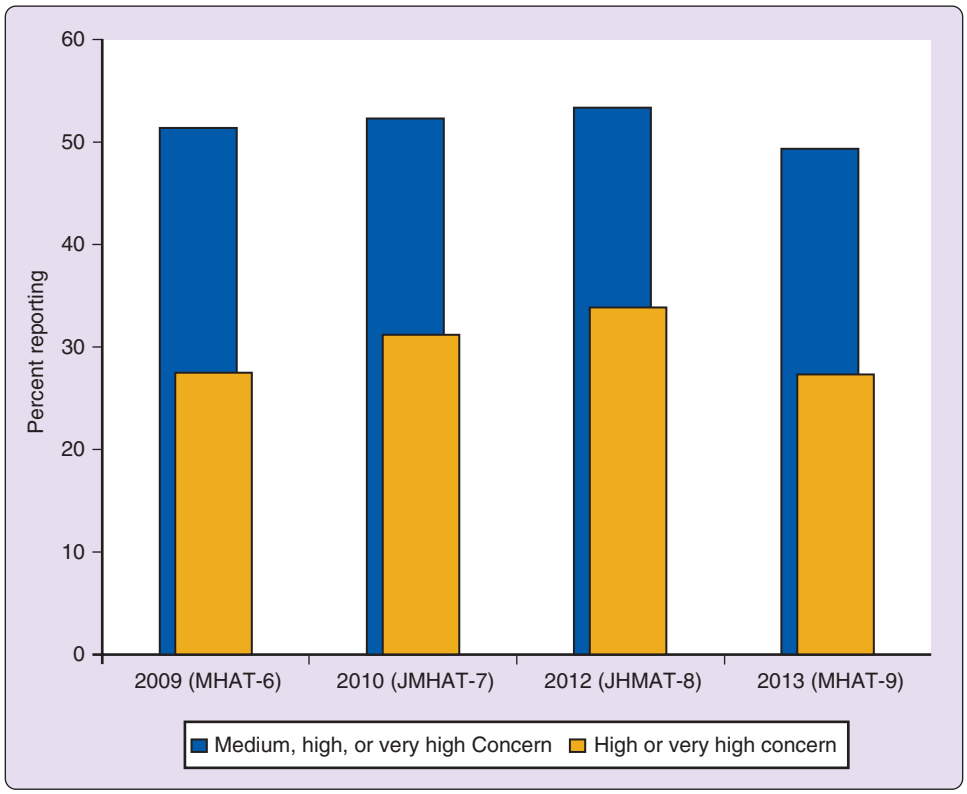

Figure 76-5 Percentage of soldiers reporting "medium" or "high"/"very high" concerns about not getting enough sleep during current deployment. (Modified from U.S. Department of the Army, Mental Health Advisory Team 9 [MHAT 9]. *Operation Enduring Freedom [OEF] 2013 Afghanistan: report,* Figure 5.6a. Office of The Surgeon General United States Army Medical Command, and Office of the Command Surgeon Headquarters, US Army Central Command [USCENTCOM], and Office of the Command Surgeon US Forces Afghanistan [USFOR-A]. <http://armymedicine.mil/Documents/MHAT_9_OEF_Report.pdf>; 2013.)

success of these endeavors requires a balance between the use of aggression and restraint.[30,31,37,38] Success often hinges on the performance of low-ranking infantry and security personnel operating in small, relatively autonomous units. Failure to strike an effective balance between aggression and restraint can lead to serious tactical, operational, and strategic setbacks.

Most of what is known about the effects of insufficient sleep on mental abilities is based on controlled laboratory-based studies (see further on). The most basic (and universal) effect is slowed response time—which on the job translates into impaired decision making, particularly under conditions of time pressure. Extrapolating from such results, it can be anticipated that the most proximal impact of insufficient sleep–related performance decrements in police, deployed military personnel, and other first responders is increased risk of injury (or death) in operators, their peers, and bystanders.

Sleep loss reduces the ability to think clearly, handle complex cognitive tasks, and solve problems.[13,39] Basic skills (e.g., marksmanship, emergency driving, routine enforcement or public safety activities) that are acquired through rote training or repetition or require choosing from only a small number of learned alternative courses of action also are degraded by sleep loss, but to a lesser extent.[40-42] Thus the impact of sleep loss in police and first responders is most likely to manifest in stressful, rapidly evolving, and complex situations characterized by ambiguity, high risk, and personal threat.

SYSTEMATICALLY MANAGING, PREVENTING, AND TREATING SLEEP DISORDERS AND SLEEP DEPRIVATION IN POLICE OFFICERS

Because the frequency, types, and locations of events that drive police judgments, decisions, and actions tend to differ with the daily, weekly, and seasonal rhythms of society, demands for service must be matched with efficient staffing and scheduling patterns that, in turn, limit officer opportunities for sleep and determine how much circadian disruption they must endure. This system of relationships must be taken into account to effectively manage, prevent, and treat police officers' sleep deprivation and sleep disorders.

Shift Work: Interaction Between the Organization and the Individual

The quality of fit between police scheduling and staffing and the moving target of demand for services directly impacts sleep: Poorer fit increases disruption of work schedules, generates more overtime work, and increases instances in which officers work longer shifts or multiple shifts or lose days off. All of these effects increase sleep loss, promote circadian disruption, generate additional stress in daily life, and reduce opportunities for sleep and recuperation. They also contribute to unexpected staff vacancies associated with illness, accidents, injuries, burnout, and early retirement. (Some police agencies in the United States report average daily absenteeism rates that range from 30% to 45%, attributed to sick

call-ins, occupational injuries, and similar causes.) Filling these vacancies generates more overtime and circadian disruption, creating a vicious circle in which long and erratic work hours reduce the number of staff available for work, which in turn increases the prevalence of long and erratic work hours.

Until relatively recently, this sort of human resource management problem could be solved by hiring more officers whenever the costs associated with overtime premium pay exceeded the overhead associated with recruiting and training new officers.[43] Now, however, demographic shifts and increasing demands for police involvement in solving a wider array of community problems have left managers "fishing" for more qualified recruits than are available within the human resource pool.[30,44,45]

Researchers are engaged with police agencies in an attempt to elucidate the health and human performance consequences of long and erratic work shifts in police work. A major goal of this research is to provide evidence-based policy guidance on deployment strategies and standards of practice.[31,46] Until now, demand for services and staffing levels generally were the only variables considered in assessing how efficiently an organization was deploying its personnel. Increasingly, however, managers and policy makers are recognizing that officer performance, health, and safety also are critical for community protection and safety. The essential insight here is that tired cops tend to be less able to serve their community than those who are adequately rested. This correlation puts officer sleep loss and disruption front and center as a research and policy issue. At the heart of this investigative endeavor is the need to explore the complex interaction among the community, police agencies, and police officers.

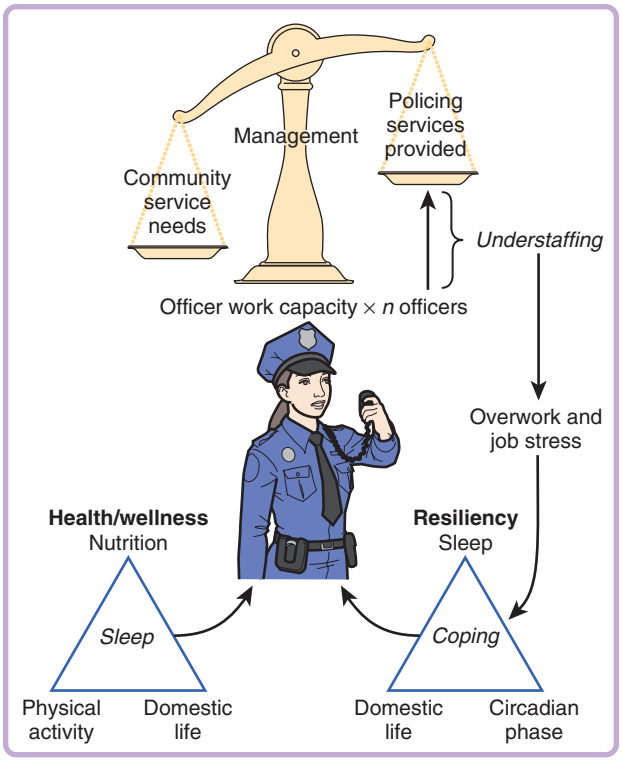

Figure 76-6 Conceptual model of interactions among needs of officers, police organizations, and communities.

Figure 76-6 provides a heuristic for understanding the relationship between individual police officer needs and management needs. As can be seen, the ability of management to provide sufficient police services to the community is a function of both the number of officers assigned to work at a particular time and the work capacity of those officers. Understaffing results in more work load and longer work hours—that is, greater stress to the individual officer. In turn, an officer's ability to cope with the demands of shift work and long work hours is affected by sleep, circadian, and domestic factors.[47] Shift work, long work hours, overwork, and job stress also tend to undermine overall health and well-being because they interfere with good nutrition, physical activity, and a connected social life:[16,48] Late-night shift workers often have difficulty obtaining nutritious food; shift work and long or erratic work hours make it difficult to find sufficient time to sleep, recover, exercise, and interact with others. The combined effects of these various stressors reduce work capacity by diminishing overall health and wellness (Box 76-1). Repeated exposure to the sleep- or circadian rhythm–related stress of shift work and long, erratic work hours throughout an officer's career may affect his or her longevity in the profession, in addition to health, safety, and survival.[11] When treating sleep

Box 76-1 KEY POINTS

- Research evidence to date identifies three key factors associated with negative health and human performance outcomes in shift work: (1) extended hours of service, (2) limited recovery time, and (3) time on task.
- The social, organizational, and individual causes of sleep loss among police and similar occupational groups are systematically linked, so they should be dealt with by striking a careful balance between the needs of society and the impact of shift work and long work hours on officers' health and performance.
- Shift length and rotation policies should be developed to fit the unique needs of each community and its police officers. There is no one ideal system for shift work.
- The development of shift scheduling strategies and staff deployment models in police agencies requires both operational expertise and human factors expertise. Sleep medicine physicians should participate in the scheduling/deployment process both as advocates for police officers and as experts on health and human performance issues. Their input can be crucial to the prevention of health problems and the optimization of wellness, with consequent improvement in officer performance.
- For diagnosing and treating sleep disorders in police officers, an understanding of how occupational factors affect resilience, health, and wellness is essential. Excessive overtime, frequent shift changes, and secondary employment are especially problematic issues in conjunction with sleep disorders.
- Determination of "fitness for duty" requires the expertise of occupational medicine physicians and is their responsibility. Sleep specialists should provide occupational medicine physicians with appropriate fitness-to-work recommendations regarding shift work–related sleep disorders.
- Appropriate management of sleep factors, circadian factors, and sleep disorders can mitigate the need for occupational accommodation and leaves of absence.

problems in police officers, sleep medicine physicians typically focus on sleep and circadian factors. To better address sleep problems in this group and similar first responders, it may be necessary for the clinician to broaden the scope of management to include a discussion with the police officer regarding his or her domestic demands, work scheduling, and similar critical factors.

Increased awareness on the part of sleep medicine physicians is only part of the overall solution. Similarly, incomplete approaches that ignore prevention and treatment issues associated with sleep disorders and related health problems ignore critical opportunities for managing risks and human resources more effectively. Comprehensive models (such as that shown in Figure 76-6) that consider demand for services, staffing, and human factors can improve individual health care, public health, and the management of scarce public resources. As Figure 76-6 emphasizes, adequately rested officers multiply the effective strength of a police force—just as adequate sleep can drastically improve the quality of officers' lives.[49,50]

The comprehensive approach that we advocate suggests measurable, objective outcomes that clinicians, practitioners, and policy makers can use to manage shift work and scheduling in a way that maximizes health, safety, and performance. For example, interventions in a comprehensive fatigue management program could be assessed by measuring independent variables such as timing and duration of sleep (using wrist actigraphy), hours worked (using timekeeping data), and regularity of work hours (using overtime and absenteeism data). Dependent variables such as overwork and job stress, resilience, nutrition, and physical activity all can be measured using standard assessment instruments. This comprehensive approach also supports a systematic attempt to optimize community well-being, organizational efficiency, and worker health and wellness. From a practical standpoint, this approach makes it easier to manage the competing interests of community, management, labor organizations, and individual officers because it provides all involved with a common ground for negotiating changes that help mitigate or minimize the unhealthy effects of shift work. For example, police agencies that take a comprehensive approach to staffing that manages sleep and work-hour issues effectively can conserve human capital by improving retention and reducing lost work days, disability claims, and requests for accommodation. They also may improve recruitment—often from agencies with less desirable work-hour practices.

Shift Work: The Individual Officer

In accordance with the proposed model, an officer's resilience to repeated exposure to sleep restriction, circadian dysrhythmia, and domestic disturbance resulting from shift work and erratic work hours can be enhanced by addressing (1) intrinsic sleep disturbance in the form of primary sleep disorders and (2) extrinsic factors related to the maintenance of general health. The relationships among sleep and shift work, cardiovascular disease, diabetes mellitus, and obesity have been described[51,52,53] in the sleep medicine, occupational medicine, and general medical literature.[54,55] Figure 76-7 conceptualizes how these factors may be causally related.[7]

The high prevalence of cardiovascular and metabolic disease among police officers is currently the focus of three major studies: the Buffalo Cardio-Metabolic Occupational Police Stress (BCOPS) study, the Calgary Police Service Health and Human Performance Research Initiative (CPS/HHPRI), and the Harvard Work Hours and Safety Group Police Study (HWHSGPS). Results from these studies highlight the prevalence of cardiovascular and metabolic diseases and sleep-disordered breathing in this population.[6,7,9,47] HWHSGPS researchers have established a high prevalence of primary sleep disorders (38.4%) and, in particular, sleep-disordered breathing (35.1%) on the basis of a survey conducted in 4471 police officers in the United States and Canada.[9] This result has been corroborated in a smaller pilot study in the Calgary Police Service[56] and in the BCOPS study.[6,7] Table 76-1 demonstrates the strong relationship between standard measures of obesity and sleep disordered breathing in police officers, while Table 76-2 demonstrates that night shift workers tend to snore more and controlling for BMI did not alter this relationship appreciably.

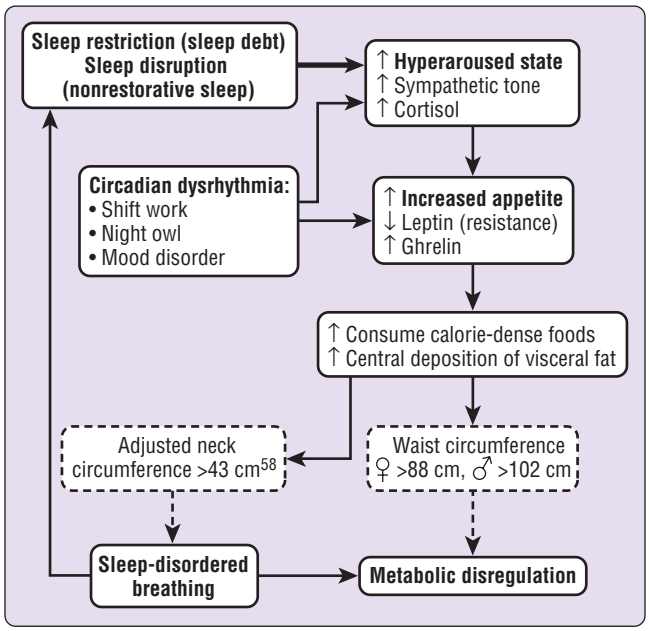

Figure 76-7 Conceptual model of relationship of sleep restriction and disruption to metabolic dysregulation, obesity, and sleep-disordered breathing. (From Samuels CH. Sleep and weight control: a wake-up call. *Can J Diagn* 2005;June:75–9.)

Officers working night shifts also have been shown to obtain less sleep per day (44% higher prevalence of less than 7 hours per day than among day shift officers) and to have a higher prevalence of snoring, a risk factor for sleep-disordered breathing (16% higher prevalence than among day shift officers), both of which are associated with increased risks of vascular disease.[6,7] Primary care, occupational medicine, and sleep medicine physicians can help minimize and mitigate the negative effects of shift work and erratic work hours in police by implementing the following measures:

- Screening clinically for primary sleep disorders
- Screening specifically for sleep-disordered breathing
- Educating officers about the importance of managing chronic cumulative sleep debt
- Educating officers about the relationships among weight control, obesity, metabolic syndrome, cardiovascular disease, and sleep or circadian factors

Table 76-1 Adjusted Mean Values of Anthropometric Obesity Measurements among Police Officers (Models 1 and 2) Stratified According to Symptoms of Sleep-Disordered Breathing

- Motivating officers to optimize behaviors over which they have at least partial control (i.e., physical activity, nutrition, rest/sleep)

Police agencies also can contribute to this effort by conducting educational programs that reinforce the importance of getting adequate sleep. This combination of physician and agency interventions can help officers focus on critical factors that will improve their ability to withstand the rigors of shift work in a challenging work environment.

Shift Work: The Organization

Sleep physicians should be aware that both management and labor share responsibility for mitigating the impact of shift work and erratic work hours. Policy makers, police executives, and officers and their families need to understand the implications of empiric evidence to make good decisions about work-hour issues. Efforts to translate knowledge into practice should emphasize the impact of shift work and erratic work hours on human performance and health. Moreover, they

Table 76-2 Association of Sleep Quality and Quantity* in Police Officers Who Work Night Shifts Compared with Those Who Work Day/Afternoon Shifts

should provide practical solutions that help strike a balance between the sometimes competing needs of officers and the communities they serve.

Shift-work management strategies must go beyond the current focus on identifying an "ideal shift." Wellness and health promotion programs need to broaden their focus to include sleep and circadian factors as well as nutrition, activity, and stress reduction. As Figure 76-7 illustrates, the rigors of shift work in police work require a broad-based and comprehensive approach to be effective.

Exemplary Unified Approach

An example of the unified approach we advocate is the Calgary Police Service (CPS) Health and Human Performance Research Initiative. This effort, which grew out of the 2001 CPS Patrol Officers Shift Schedule Review (POSSR),[49,50] is a long-term research and knowledge transfer project. One of the key POSSR recommendations was for enlistment of a sleep specialist and a knowledge transfer expert to help the service develop and evaluate new shift schedules that were sensitive to officer health and human performance issues. Perhaps the most unique aspect of this initiative is the knowledge transfer component, which uses new scientific evidence as it emerges to develop educational programs. These educational programs guide CPS efforts to change how police officers, labor leaders, and managers view shift-work management and related health and human performance issues.

The CPS Health and Human Performance Research Initiative is a comprehensive, collaborative effort by all stakeholders that recognizes that each has a stake in developing strategies for managing shift work and that cooperation is vital for long-term success. Another important aspect of this initiative is that it has support from high-ranking labor and management leaders, who have been instrumental in maintaining its momentum. The success of this approach has drawn the attention of other police agencies, several of which are developing fatigue management strategies that fit their own resources, needs, and organizational cultures. In each of these efforts, sleep and occupational medicine specialists, along with knowledge transfer professionals, can provide critical expertise and advice.

CLINICAL PEARLS

A comprehensive program of fatigue risk management for police officers and other first responders should include:

- Screening all officers for primary sleep disorders, and specifically for sleep-disordered breathing, owing to its high prevalence in this population
- Emphasizing the importance of managing day and night sleep environments, cumulative sleep debt, early signs of chronic sleep deprivation, and symptoms of shift-work sleep disorder
- Providing educational material for officers and their families for the purpose of preventing and mitigating the health and human performance consequences of shift work.

SUMMARY

Fatigue associated with sleep loss, circadian disruption, and night operations is one of the most common health and safety hazards faced by police officers and other first responders and by deployed military personnel. Sleep-related fatigue contributes to morbidity (and possibly mortality) in these occupational groups. It also degrades cognitive performance, affecting judgment and decision making as well as emotional responses to situational challenges. Because the social, organizational, and individual causes of insufficient sleep within these occupational groups are inextricably linked, the various individual, social, organizational, and environmental processes, as reviewed in this chapter, should be considered in addressing sleep-related problems in these populations.

Physicians and other health care providers can improve individual and public health outcomes by using comprehensive approaches that systematically consider all of these issues. From a practical standpoint, this approach makes it easier to

manage the competing interests of individual police officers/first responders/military personnel and their families, their organizations, and the larger communities they serve. Expert advice from appropriate health care and other professionals will help these competing stakeholders find a common ground for negotiating changes that help mitigate or minimize the unhealthy effects of shift work.

Sleep, Occupational Stress, and Burnout

Torbjörn Åkerstedt; Aleksander Perski; Göran Kecklund

Chapter Highlights

- Results from prospective epidemiologic studies show that work demands are associated with sleep disturbances.
- Results from polysomnography studies show reduced sleep continuity or reduced slow wave sleep in relation to bedtime stress.
- Long-term exposure to occupational stress is related to substantial reductions in sleep continuity and slow wave sleep.
- Rumination, to include worry regarding next-day events, seems to be a key factor related to sleep disturbances.

Disturbed sleep usually is attributed to daily life stress.[1] Among people with insomnia, stress (and depression) is a correlate of disturbed sleep[2] and increased levels of arousal.[3] Before examining work stress and sleep, it is necessary to define stress and work life.

STRESS

Stress generally refers to the observation that repeated exposure to some event without sufficient recovery between exposures leads to physiologic activation that causes wear and tear.[4] Although both the duration and type of rest between bouts of stress may be important factors, sleep is one of the major physiologic means of recovering from stressors. The amount of available data on stress and sleep is relatively modest; however, some of the findings are summarized here.

From a general perspective, *psychosocial* stress refers to the rate of wear and tear in the organism, and *biologic* stress refers to the nonspecific response to any demand[5] that increases the chances of successful handling of a threatening situation. Contemporary physiologic stress models derive from the pioneering work of Cannon[6] and of Selye.[5] Cannon[6] developed the concept of the "fight-or-flight" response, which linked the emotional, central nervous system perception of a threat to physiologic changes in the peripheral nervous system. Selye proposed the *general adaptation syndrome* model of stress, which was composed of three stages—alarm, resistance, and exhaustion—that corresponded to the physiologic nonspecific response to a challenge. The resistance stage of the general adaptation syndrome has extreme physiologic energy requirements, which if persistent over time deplete available resources and lead to exhaustion.

Markers of the fight-or-flight response are the catecholamines epinephrine and norepinephrine and other physiologic indicators associated with the autonomic nervous system.[4] The hypothalamic-pituitary-adrenocortical (HPA) axis is fundamental to the stress response. When the hypothalamus is activated, neuropeptides such as corticotropin-releasing hormone (CRH) and vasopressin are released. They in turn stimulate the pituitary to release adrenocorticotropic hormone (ACTH) into the general blood circulation. ACTH further stimulates adrenal cortex to release hormones including the glucocorticoid cortisol. Cortisol in turn activates mobilization of energy resources.

The ability of the body to increase or decrease the activation level of vital functions to new steady states, dependent on the characteristics of the challenge and the person's emotions and appraisal of the event, is referred to as *allostasis*.[4] *Allostatic load* refers to the cumulative cost to the body of responding to stressful events. It is suggested that serious pathophysiology can occur if allostatic load is not relieved in some way.[4] One of the outcomes may be insomnia.

With respect to *working life,* nonphysiologically based, systematic theories have emerged, and one leading theory in work stress research is the so-called *demand-control model* (Figure 77-1, *top*).[7] This model is based on empiric evidence, such as the finding that high work demands and low decision latitude are predictive of cardiovascular and other types of stress-related diseases.[8] Another work stress model is the *effort–reward model* (Figure 77-1, *bottom*), which focuses on the contrast between demands and resources.[9] Resources include salary, career opportunity, and other rewards. In this model, *immersion* plays an important role and represents major commitment of effort. Immersion (or commitment) involves experiences such as not being able to stop thinking of work in the evening or starting to think of work immediately on awakening. Another important work-related factor may be the amount of social support received at work. Results from several studies indicate that lack of social support is associated with development of cardiovascular disease, depression, and other negative health outcomes.[4]

THE CONNECTION BETWEEN STRESS AND SLEEP: EVIDENCE FROM CROSS-SECTIONAL STUDIES

Considering the physiologic activation involved in the stress response, it seems logical to expect a connection with sleep disturbances. In fact, stress is considered the primary cause of persistent psychophysiologic (primary) insomnia.[3] The evidence supporting a relationship between stress and insomnia is, however, surprisingly modest. No longitudinal systematic studies of causal relationships between stress and sleep have

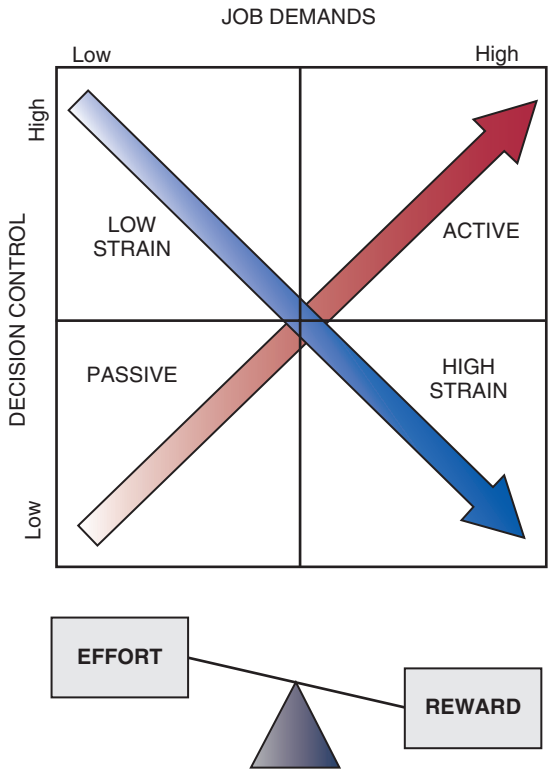

Figure 77-1 Schematics of the demand-control-support model (*top*)[7] and the effort-reward model (*bottom*).[9] In the four-component box at top, degree of decision control and perceived job demands interact to determine the worker's job situation. The ideal situation is "active," where high job demands coupled with high decision control result in active engagement—which in turn is associated with positive health outcomes. By contrast, high job demands with low decision control are associated with poor health outcomes. In the simple balance scale depicted at bottom, the direct relationship between effort (e.g., responsibilities, time pressure) and reward (e.g., salary, career opportunity) affects health and well-being. High commitment of effort is referred to as "immersion," which is associated with rumination (a feature of insomnia).

been conducted. Cross-sectional epidemiologic studies are readily available, however, and survey results indicate a strong link between self-ratings of stress and sleep (as reported by Kompier and colleagues,[10] for example).

Studies of stress and sleep in which sleep was objectively quantified using polysomnography (PSG) are far more limited. Shaver and associates[11] studied women with insomnia and found that stress ratings in the insomniac women did not differ from those in good sleepers. Women with insomnia did show evidence of neuroendocrine activation (and similar measures) suggestive of increased stress. By contrast, Akerstedt and associates found a positive relationship between ratings of daily stress and increased levels of polysomnographically recorded stage 1 sleep.[12] Using actigraphy, Mezick and associates showed that high reported stress level was associated with more variability in sleep duration and increased sleep fragmentation.[13]

WORK DEMANDS

The demand component of the demand-control model of stressful work conditions also has been shown to be associated with reported sleep impairment: Early findings by Urponen and coworkers[14] showed that men rated work-related pressure as a critical factor that impaired the ability to fall asleep and quality of sleep. Åkerstedt and associates[15] found that the strongest item of the demand index was "having to exert a lot of effort at work"; the latter was distinct from simply "having too much to do." The distinction suggests that amount of work per se is not the key factor; rather, the response to the work situation is more important. Also, when the item "not being able to stop thinking about work in the evening" was added to the regression, this variable became the most important predictor of disturbed sleep. Again, it is the response to the work situation that predicts sleep impairment. Imbalance between effort and reward also has been related to disturbed sleep.[16]

Socioeconomic Status

With regard to socioeconomic group, sleep complaints are more frequent in blue-collar workers: Partinen and coworkers[17] investigated several occupational groups and found disturbed sleep to be most common among manual workers and much less so among physicians or managing directors. In a retrospective study in older people (older than 75 years), Geroldi and associates[18] found that former white-collar workers reported better sleep than former blue-collar workers. On the whole, blue-collar workers report higher levels of stress than do white-collar workers, but the source of the stress appears to be related more to living conditions in general (e.g., economy, social situation, neighborhood) than to work stress in particular.

Social Support

In demand-control models, social support is viewed as a countervailing force pushing back against the effects of high demands.[7] Lack of social support may thus function as a risk factor for disturbed sleep. Alfredsson and associates[19] demonstrated an interactive effect on sleep between social support, high demands at work, and lack of control. Poor social support also has been associated with sleep complaints in Vietnam War veterans.[20]

THE CONNECTION BETWEEN STRESS AND SLEEP: EVIDENCE FROM LONGITUDINAL STUDIES

The question of whether stress actually *causes* impaired sleep can be resolved only by implementing longitudinal studies. In one of the first studies of this type, Ribet and colleagues[21] interviewed more than 21,000 subjects in France on two occasions separated by 5 years. They used a five-item sleep disturbance index and provided a variety of occupational questions. Results from the logistic regression analysis indicated that reporting "having to hurry" during the first interview predicted sleep disturbances during the second interview. In another field study approach, Dahlgren and colleagues[22] assessed white-collar workers before and during a period of intense work stress as well as a period without intense work stress. Reported sleep duration, sleep quality (assessed by sleep diary), and evening alertness were reduced during the period of intense work stress, and reported restlessness at bedtime was increased. In addition, the daily cortisol pattern was flattened during intense work stress. In another study of college students, Sadeh and associates[23] found reduced amounts of sleep

(assessed by actigraphy and diary ratings) during a period of examination stress. In both the Dahlgren et al. and Sadeh et al. studies, it is not clear whether reduced sleep was partly due to simply trading sleep time for more work[22] or study[23] time, rather than stress directly impairing the ability to sleep.

Linton[24] studied employees with no reported initial sleeping problems and found that 14.3% developed a sleeping problem during the ensuing year. Even with institution of controls for possible confounding factors, stress in the form of a poor psychosocial work environment doubled the risk of developing a sleep problem. Similarly, Jansson and Linton[25] showed that among people with no insomnia at baseline, high work demands increased the risk of developing insomnia 1 year later. Among participants with insomnia at baseline, high leader support decreased the risk of still reporting insomnia at follow-up. Finally, low (weak) influence over decisions and high work demands were related to the maintenance of insomnia. Results from several large prospective epidemiologic studies also have linked high work demands with subsequent poor sleep.[26-29] Results from a recent systematic review confirmed that both high job demand and low job control are associated with poor sleep quality.[30]

Using a 5-year longitudinal study that included participants with and without sleep problems at baseline, Vahtera and colleagues showed that a self-rated tendency to respond strongly to stress (which they referred to as "liability to anxiety") predicted later sleep disturbances.[31] These results point to a consistent pattern of disturbed sleep in response to stress. Similarly, Drake and coworkers utilized the known "first-night effect" on sleep as a naturalistic stressor—that is, sleep generally is disturbed on the first night that subjects spend in the sleep laboratory. These workers showed that subjectse who reported a higher habitual sleep vulnerability to stress also displayed longer sleep latency and lower sleep efficiency on the first night in the sleep laboratory.[32] These findings suggest that sleep vulnerability to stress is a definitive trait. In the earlier-mentioned study by Sadeh and associates,[23] a stronger sleep duration response to examination stress was seen in those subjects who showed a high emotion-focused coping strategy.

Åkerstedt and colleagues[33] assessed self-rated daytime stress and polysomnographically recorded sleep at home in 50 participants (thereby precluding the first-night effect) on four occasions spaced across several weeks. These investigators showed that nighttime ratings of stress and worries at bedtime were associated with reduced sleep efficiency, increased wake time after sleep onset, and increased latency to slow wave sleep. Self-ratings of "stress" (which the participants recorded every 3 hours) were increased both on the day before and the day after impaired nighttime sleep. Also, interindividual vulnerability was evident: Those participants who showed an increase in stress ratings scored a significantly higher level of depression on the Hospital Depression and Anxiety Scale. In a polysomnographic study of teachers, Petersen and colleagues[34] showed a decrease in sleep continuity and sleep efficiency during high stress periods in persons who reported that their sleep was vulnerable to stress (as determined by the Ford Insomnia Response to Stress questionnaire). In another study, 50 volunteers completed a daily sleep-wake diary and responded to daily questions on sleep and stress for 42 days.[35] Results showed that day-to-day variability in sleep quality was related to the level of stress and worries in the evening.

In other studies, sleep was polysomnographically recorded the night before an important examination[36] and also before a day of skydiving.[37] The results indicated a slightly negative effect on sleep efficiency and the amount of deep sleep. In addition, a number of laboratory studies of stress and sleep have been performed, but the stressors were artificial (e.g., viewing an unpleasant movie). Perhaps not surprisingly, the results from such studies are mixed, suggesting that the stressor must be of some direct significance to the subject to have any effect on objective (PSG-based) measures of sleep. However, results from other laboratory-based studies have demonstrated that anticipatory stress (see further on) can have rather pronounced effects on sleep.[38,39]

Rumination and Anticipation

Results from of the studies just described suggest that it is not the stress experience itself that impairs sleep but rather that the *anticipation* of untoward events and worries about the immediate future was the critical factor. Examinations, high work demands, and external threats are likely to cause this type of negative anticipation. For example, Cropley and colleagues[40] showed that the relationship between strain and poor sleep in teachers was moderated by rumination (i.e., compulsively thinking about a situation, usually a negative situation). Results from the aforementioned cross-sectional study by Åkerstedt and associates[41] showed that not being able to turn off thoughts of work in the evening was significantly associated with subjectively disturbed sleep. Inability to turn off work-related thoughts is a form of rumination, and rumination is seen as a major cause of disturbed sleep.[42] In a cross-sectional study, Hall and coworkers[2] showed that intrusive thoughts at bedtime are related to increased alpha and beta power in the subsequent sleep electroencephalogram (EEG). Similarly, increased cognitive arousal at bedtime is related to increased sleep latency.[43]

Another form of rumination is worrying before sleep about having to awaken early before an early-morning shift. In one study, Akerstedt and colleagues showed that such rumination was associated with less slow wave sleep during subsequent sleep.[44] Their findings support the notion that anticipation of future difficulties also evokes a stress reaction. A similar study was carried out with machine officers on container ships.[45] Sleep EEGs recorded during a night on call (but without any call occurring) showed reduced slow wave sleep and increased stage 2 sleep. Also, heart rate was increased. These results were interpreted as stress activation associated with the possibility that the alarm would sound, which happened on average every second night on call. On the other hand, increased mental activity has been shown to increase sleep intensity.[46] Thus *acute* stress (with associated increased brain activity) could *improve* subsequent sleep so long as there is no lingering negative anticipation or rumination. This hypothesis has yet to be explored.

SLEEP AND LONG-TERM EXPOSURE TO OCCUPATIONAL STRESS

The foregoing studies dealt with relatively acute and modest levels of stress. Assessing the impact of severe stress on sleep in a longitudinal or repeated-measures study (pre- and then poststressor) is difficult because intentionally exposing subjects to severe stressors is considered unethical. Nonetheless,

a critical question is how long-term exposure to stress affects sleep. Little work on this topic has been published. An increasing number of reports of stress-related sickness among otherwise healthy and high-performing persons have emerged, however.[47] Symptoms include profound fatigue, problems with memory and concentration, aches, irritability, anxiety, and a feeling of being emotionally drained—all attributed to long-term exposure to stress. The overall effect, which is relatively long-lasting, is associated with difficulties living up to job expectations. People who are prone to developing symptoms seem to be those who accept high workloads and increasing overtime work to handle increased work demands, and they view work as a positive challenge. The phenomenon also is sometimes referred to as "occupational burnout."[48] Many such patients are diagnosed with depression. A more appropriate diagnosis, however, may be "reaction to severe stress and adjustment disorder" according to the *International Classification of Diseases* (ICD10) (F43), with "work-related" as a further criterion.

The physiologic mechanism underlying the fatigue associated with occupational burnout has not been identified, but the HPA axis is likely to be involved. Results of several studies revealed a blunted cortisol response in the dexamethasone suppression test, suggesting impairments in the feedback loop.[47] Reduced hippocampal size also was observed. The latter finding is interesting in view of the relationship between circulating cortisol levels and impaired cognitive function (a characteristic symptom of occupational burnout). The other consistent finding is an exaggerated cortisol awakening response, suggesting increased anticipation of stress. This exaggerated cortisol awakening response has been mainly observed among female patients with exhaustion syndrome.[49] Results from other studies have shown (1) a functional disconnect between the amygdala and the anterior cingulate cortex/medial prefrontal cortex, (2) reduced 5-hydroxytryptamine HT_{1A} receptor binding potential in the anterior cingulate, the insula, and the hippocampus,[50] and (3) gray matter shrinkage in the anterior cingulate cortex and the dorsolateral prefrontal cortex, caudate, and putamen. Volumes of the caudate and putamen also correlated inversely with the degree of perceived stress.[51]

Although some physiologic (endocrine and brain structural) links between chronic stress exposure and occupational burnout have been established, the results do not necessarily "explain" or indicate direct causation of the symptoms.[52] A mediating factor could be disturbed sleep. To date, only a few PSG studies of sleep have been performed in persons with long-term exposure to stress. In one investigation of young people in the information technology industry with high burnout scores,[53] an increased level of sleep fragmentation was found; subjective sleep problems also were markedly increased. In addition, sleepiness ratings (taken every 3 hours during waking) were increased during the working week (compared with those in subjects who did not exhibit high burnout scores), and sleepiness during days off fell only marginally. In subjects without high burnout scores, dramatic decreases in sleepiness were observed on days off. In the same company, referral for treatment for stress-related disorders was predicted by fatigue and burnout scores at 1 year before referral but even more so by reported "insufficient sleep."[54]

In a study of workers on long-term sick leave because of long-term work stress, a similar increase in sleep fragmentation was seen, as well as lower sleep efficiency, more wake time after sleep onset, a doubled sleep latency, and reduced amounts of stage 3 and stage 4 sleep.[55] The degree of fragmentation of sleep was positively correlated with morning levels of cortisol, lipids, and other stress-related variables.[56] In interviews with a subsample of these patients, they described long periods of stress before becoming sick-listed; they identified the use of self-imposed sleep reduction to obtain more time to carry out work tasks; and they reported suddenly stopping sleeping.[57] The poor sleep was followed by extreme fatigue (the symptom that brought them to medical attention), resulting in a diagnosis of occupational burnout. Follow-up evaluation was performed at an average of 1.5 years after the first investigation; by that time, most PSG measures (as subjective ratings) had improved, as had stress, sleep, and fatigue ratings. Of interest, the PSG variable that best predicted fatigue 1.5 years later was reduction in sleep fragmentation. The group of patients who showed greatest reduction in sleep fragmentation also was the group that had returned to work.[55]

If a causal link exists between occupational burnout and sleep, the latter should predict the former in longitudinal studies. In one study, such a relationship was demonstrated.[58] Those persons who benefited poorly from sleep at baseline exhibited higher exhaustion levels at follow-up evaluation compared with those who benefited from sleep. Trouble falling asleep and less refreshing sleep at baseline were associated with inability to resume work. Armon and colleagues[59] further showed that occupational burnout and insomnia recursively predict each other's development and intensification over time, suggesting that either might be a risk factor for the other. Of note, however, the latter study was conducted with previously healthy workers and persons with occupational burnout.

SLEEP PHYSIOLOGY THAT SEEMS TO LINK SLEEP WITH STRESS

Insights into the connection between sleep and stress also may be obtained by comparing the physiologic changes during sleep versus after sleep loss with those during stress. Reductions in rectal temperature, rate of breathing, heart rate, blood pressure, and so on that occur during non-REM (NREM) sleep are normal aspects of sleep physiology.[60] Also, in adults, the first part of sleep is characterized by increased growth hormone (GH) release (together with increased slow wave sleep and low levels of REM sleep) and suppressed secretion of hormones of the HPA system[61] (i.e., CRH, ACTH, and cortisol are suppressed). Suppressed HPA axis hormone secretion during early portions of sleep is the opposite of that seen after stress. When sleep is prevented, cortisol secretion increases,[62] as it does subsequent to stressor exposure. Thus sleep reduction has effects similar to those of stress (i.e., increased cortisol secretion). Also, secretion of GH is strongly reduced if no sleep occurs.[62] GH promotes protein synthesis, which means that it is essential for growing and for repairing tissue. In other words, insufficient sleep may itself constitute a stressor.

Sleep not only regulates stress hormone secretion but also is affected by it. For example, the rate of sleep fragmentation (manifested as microarousals) increases with increased levels of cortisol.[56] Thus the quality of sleep partly depends on an interaction of GH-releasing hormone and CRH.

Reduced glucose clearance after sleep loss[62] also possibly reflects changes that constitute a stress response. The immune system is strongly suppressed by stress, mediated by, for

example, increased activation of the HPA axis. Similarly, reduced or fragmented sleep is associated with increased levels of proinflammatory cytokines such as interleukin-1β, interleukin-6, and tumor necrosis factor alpha.[63] Essentially, lack of sleep is linked with the metabolic syndrome, as are other stressors—further evidence that lack of sleep itself is a stressor and, moreover, exacerbates the physiologic response to other stressors.[64]

SIMILARITY OF MORBIDITY DUE TO STRESS AND TO SLEEP LOSS

Poor sleep is associated with an increased prospective risk for development of diseases that are considered to be stress-related, including myocardial infarction[65]and hypertension.[66] In women undergoing rehabilitation from a myocardial infarction, the risk of recurrent myocardial events is increased in self-reported poor sleepers.[67]

In addition, type 2 diabetes (also considered to be stress-related) has been shown to correlate with poor sleep.[68] For example, patients with type 2 diabetes report more sleep problems than nondiabetic subjects (although this association could be confounded by obesity or by obstructive sleep apnea). However, in a prospective follow-up study of healthy middle-aged men from Malmö, Sweden, it was shown that the 12-year risk of developing type 2 diabetes was independently predicted by self-reported difficulties with falling asleep and by elevated resting heart rate, after adjusting for obesity, lifestyle factors, and other risk factors.[69] Obstructive sleep apnea was not measured in the Malmö study and presumably could mediate the relationship between type 2 diabetes and sleep. Another possibility is chronic low-grade inflammation, which is linked to both insomnia and risk of type 2 diabetes. Finally, as noted earlier, short sleep duration also is involved in the metabolic syndrome.[64]

MEASURING STRESS

From the discussion so far, it is obvious that "stress" has many meanings. Earlier, stress was defined as an activating response to demands. In many of the aforementioned studies, stress was operationally defined as high levels on the demand-control questionnaire and/or on the basis of commonsense notions that the anticipation of an examination or of sky diving should be stressful. In short, a generally accepted operational definition of stress is lacking. Several attempts to provide one have been made, but these attempts reflected broad approaches that frequently included numerous subjective self-assessments of the consequences of stress. For example, the Perceived Stress Questionnaire[70] contains 20 items such as "tension," "worries," and "joy" in addition to items on pressure and demands. The Perceived Stress Scale[71] contains 14 items such as "upset," "on top of things," and "nervous" in addition to items on demands and stress. The Stress Response Inventory contains 39 items, including scales on depression, frustration, anger, and others.[72] The Calgary Symptoms of Stress Inventory[73] is a similar scale. Because these types of scales combine the cause (e.g., stress, demands, pressure) with the effects (e.g., anger, anxiety), they are not well suited for use in cause-and-effect studies of stress and sleep. Understanding the role of stress in sleep disorders requires the development of unambiguous instruments for quantifying stress.

CONCLUSIONS AND FUTURE DIRECTIONS

It is apparent from the foregoing that more detailed knowledge regarding the development of stress and sleep problems is needed—that is, longitudinal studies with frequent measures of stress and objectively measured sleep. These are labor-intensive and thus difficult studies for both researchers and participants; it is unlikely that many studies of this type will be forthcoming. In addition, longitudinal studies of the amount and duration of stress needed to affect sleep are needed as are longitudinal studies of recovery from stress-related sleep disturbances. Furthermore, information is needed regarding the contribution of both work and private life stressors to sleep and the impact of sleep on stress and work performance.

Although available evidence indicates that stress causes subjectively impaired sleep, little is known about the effects of stress on sleep architecture, at what level or by what type of stress sleep is impaired, and what duration of stress causes insomnia. Also lacking is information on trait factors contributing to vulnerability. Long-duration longitudinal studies are needed.

When meeting a patient who suffers from insomnia that may be stress-related, the clinician may find it useful to conduct a structured interview regarding the patient's work and personal life situations that may be stressful. In our experience, much information is gained from questions that focus on preoccupation with work, ruminations, and worries about the immediate future. Such a question may be phrased more specifically: "Are you often unable to stop thinking about work in the evening?"

Another area of exploration with patients is work pressure. Inquiries may be phrased variously, as follows: "Do you have to exert a lot of effort at work?" "Do you get enough time for sleep?" "Do you reduce sleep duration to make room for work?"

Specific treatment of sleep problems due to stress is covered in Chapter 79, on psychological treatment for sleep disturbances. It might also be useful, however, to refer the patient to a short stress management course (based on cognitive therapy), which often is effective for reducing sleep problems and may be combined with cognitive behavior therapy for sleep disorders. The stress management courses usually involve stress reduction techniques, teaching basic life hygiene, and relaxation techniques to improve bedtime practices. Patients with work-related occupational burnout may benefit from sleep treatment based on cognitive techniques (see Chapter 79).

SUMMARY

Long-term exposure to stress is viewed as a major cause of insomnia. Results from cross-sectional studies consistently support this view and demonstrate close relationships between reported occupational stress and impaired sleep. Prospective studies are rare, however, but results from the few that are available indicate that new cases of insomnia follow increases in previously already high work demands. Polysomnographic findings reveal minor effects, such as slightly increased sleep latency or slightly decreased sleep efficiency, after periods of increased day-to-day stress. The level of stress in these studies usually is rather modest, however. One key factor seems to be

worries (rumination) at bedtime, often related to upcoming difficulties during the subsequent day. In the few PSG-based studies of long-term exposure to work stress, results indicate that sleep is characterized by pronounced sleep fragmentation, increased sleep latency, reduced sleep efficiency, and reduced slow wave sleep. Also, subjective sleep self-assessments indicate major sleep problems. An interesting link between sleep loss and stress is that they exert similar endocrine and metabolic effects. Both involve increased levels of cortisol, lipids, and insulin resistance, for example. Furthermore, typical stress-related diseases such as cardiovascular disease or type 2 diabetes have been linked to previous sleep disturbance. Although correlational evidence that stress affects sleep negatively is substantial, little is known about the direction of the effects (which are likely to be bidirectional), or regarding details such as the critical levels and durations of stress necessary to cause insomnia and the process of the development of stress-related insomnia across time.

CLINICAL PEARL

Insomnia often is a result of long-term exposure to stress. Even modest amounts of day-to-day variation in stress may significantly affect sleep architecture. Patients with complaints of incapacitating fatigue (e.g., occupational burnout) should undergo appropriate investigation for disturbed sleep and long-term exposure to stress. From the standpoint of prevention, as well as treatment, it is important to recognize that impaired sleep results from *anticipatory* stress. Effective stress management techniques, applied to address and correct difficult work and general life issues, may even improve sleep.

Optimizing Shift Scheduling

Göran Kecklund; Mikael Sallinen; John Axelsson

Chapter Highlights

- Sleep loss, transient insomnia, and excessive sleepiness are common consequences of shift work, in particular if the shift system involves night work. Among the organizational remedies, shift scheduling plays a key role. According to sleep-wake regulation theory, a schedule that (1) minimizes circadian disruptions and an accumulation of sleep loss work periods and (2) permits sufficient time for recovery during days off will maintain alertness and sleep quality, which in turn will be beneficial for occupational safety and long-term health.
- Operational requirements of companies and industries differ. The design of a shift schedule includes a number of components that can be adapted to meet different requirements in an optimal manner. The organizational elements of a shift system of greatest importance relative to sleep and sleepiness are (1) the duration and timing of shifts, (2) the number of consecutive shifts, (3) the distribution of days off in the schedule, and (4) the length of off-duty time between two consecutive shifts and shift cycles. An additional important aspect of system design is the choice between a permanent (fixed) and a rotating shift schedule.
- This chapter summarizes the current knowledge on the role of organizational elements—most notably, shift schedule characteristics—in determining the various factors affecting sleep and sleepiness and (when data are available) the work performance of shift workers. On the basis of this knowledge, general recommendations for organizing shifts to optimize sleep and on-the-job alertness are presented.

As discussed in Chapter 75, insomnia and excessive sleepiness are common consequences of shift work, in particular if the shift system involves night work.[1] The primary causes of these symptoms are (1) the mismatch between the internal circadian clock and the usual timing of sleep and wakefulness that is imposed by a shift schedule and (2) an altered ratio between sleep and wakefulness within a 24-hour or longer period. In night work, changes in the usual relationships between circadian and homeostatic processes of sleep and sleepiness are often most dramatic, as the worker is required to stay awake and alert during the biologic night and try to sleep during the biologic day.

Because disturbed sleep and consequent increased sleepiness pose substantial health and safety hazards, numerous attempts have been made to develop effective and feasible remedies for these problems in the context of shift work (Table 78-1). Generally speaking, three levels of remedies are in use: regulatory (e.g., hours of service regulations), organizational (e.g., a fatigue risk management system), and individual (e.g., napping strategies). These remedies constitute important elements of health and safety management in shift work.[2] *Regulatory* remedies are inflexible and not under the control of a given operational entity and are not considered further here. Some aspects of hours of service regulations are discussed in Chapter 73, on fatigue risk management. *Individual* remedies are highly flexible but also not under the direct control of a given operational entity; these are discussed in Chapter 75. *Organizational* remedies can be adapted to meet the unique requirements of a given operational entity and constitute the basic content for this chapter.

Among the organizational remedies, shift scheduling plays a key role. According to Borbely's two-process model of sleep-wake regulation (see Chapter 72), a schedule that (1) minimizes circadian misalignment, (2) limits, to the exent possible, buildup of sleep loss over a single shift and across a shift cycle, and (3) permits sufficient recovery during days off will best maintain alertness and allow for sufficient sleep. In turn, alertness and sleep are necessary for occupational safety and long-term health.

Because the operational requirements of companies and industries often significantly differ from each other, a wide range of shift systems have been devised. The design of a shift schedule includes a number of components that can be adapted to meet specific company/industry requirements in an optimal manner. Adaptable elements of a shift system that are of importance in addressing sleep and sleepiness include (1) the duration and timing of shifts, (2) the number of consecutive shifts, (3) the distribution of days off in the schedule, and (4) the length of off-duty time between two consecutive shifts and shift cycles. In addition, either a permanent (fixed) or a rotating shift schedule can be used. If work shifts rotate between different shift types (e.g., morning, evening, and night shifts) within a certain period of time, a number of additional issues, such as the regularity, speed, and direction

Table 78-1 Remedies Related to Health and Safety Management in Shift Work

Regulatory Remedies	Organizational Remedies	Individual Remedies (Countermeasures)
Hours of service regulations (e.g., limiting maximum work hours, imposing minimum number of off-duty breaks)	Fatigue (health) risk management systems	Napping
Occupational health and safety regulations	Shift scheduling	Bright light therapy
	Education/training programs	Hypnotics (to improve sleep)
		Melatonin

of the shift rotation, also need to be addressed. These issues are discussed next.

PERMANENT VERSUS ROTATING SHIFT SYSTEMS

One of the cornerstones in the design of a shift system is whether the schedule should be based on rotation or on permanent fixed shifts. In a *rotating* shift system, the worker alternates between various work shifts (e.g., morning, evening, and night shifts). An alternative to rotation is *permanent* shifts, in which the workers are divided into groups that work only one type of shift (e.g., permanent morning, permanent evening, and permanent night shifts).

From a theoretical standpoint, a shift system based on permanent shifts should facilitate circadian adaptation (e.g., to the night shift), which manifests as reduced sleep problems, reduced on-the-job sleepiness, and reduced likelihood of poor job performance.[3] The discussion of pros and cons for permanent versus rotating shift systems has focused on night work. Some experts claim that rapidly rotating shift systems (alternating among morning, evening, and night shifts) should be abolished because of the problems they create for sleep, sleepiness, safety, and health stemming from lack of circadian adjustment.[3] A compromise option is to minimize rotation and to alternate only between evening and night work, or between morning and evening work, because these compromises should produce less circadian misalignment between the internal circadian clock and the forced sleep-activity cycle.[3]

To date, few controlled intervention studies have been conducted to investigate how the change from a rotating shift system to a permanent shift system affects sleep and sleepiness.[4] However, results from two intervention studies on police officers showed that removal of rotation reduced self-reported sleep disturbances.[5,6] Turning to studies using an observational (cross-sectional) design, more research is available. Several investigators have compared rotating shift workers with permanent night workers. In a meta-analysis, Pilcher and colleagues estimated that the average (daytime) sleep length of permanent night workers was 6.6 hours, which was slightly longer than that of workers in rapidly rotating shift systems (approximately 6.5 hours).[7] Permanent day and evening workers obtain the most sleep (more than 7 hours). In several studies sleep was measured using objective methods. In one study, actigraphs were used to compare sleep amounts in permanent night workers with their day and evening counterparts.[8] Results showed that permanent night workers obtained the least sleep (4.7 hours, compared with 5.7 and 6.1 hours for the day and evening shifts, respectively) and reported poorer sleep quality than the other shift groups. Studies using polysomnography are rare, but Dahlgren showed that permanent night workers obtained slightly better sleep (less wake time after the onset of sleep) than rotating night shift workers. However, sleep duration in permanent night workers was still quite short (5.5 hours) and only marginally longer (10 to 15 minutes) than that of rotating shift workers.[9] Thus permanent night workers are not likely to obtain more sleep than regular three-shift workers when the entire shift cycle is taken into account (i.e., also morning and evening shifts and days off), as suggested by Folkard.[10]

Table 78-2 Prevalence of Insomnia Symptoms on Each Type of Shift (Day, Evening, Night, and Off-Duty) for Two Different Shift Schedules*

	Symptom Prevalence	
Insomnia by Shift Type	Rotating Three-Shift Group	Permanent Night Group
Day shift insomnia	35.6% (× 7 days = 249.2)	—
Evening shift insomnia	19.8% (× 7 days = 138.6)	—
Night shift insomnia	67.7% (× 7 days = 473.9)	41.7% (× 21 days = 875.7)
Rest-day (off-duty) insomnia	3.6% (× 7 days = 25.2)	11% (× 7 days = 77)
(Sum score/28 days) = Hypothetical mean over shift cycle	(886.9/28) = 31.7%	(952.7/28) = 34.0%

*The hypothetical mean over a 4-week (28-day) shift cycle was calculated. The latter calculation was generated by multiplying means for each shift by 7.
Data from Flo E, Pallesen S, Åkerstedt T, et al. Shift-related sleep problems vary according to work schedule. *Occup Environ Med* 2013;70:238–45.

In several studies, investigators have compared sleep quality between permanent night workers and rotating night workers. Table 78-2 summarizes the prevalence of insomnia-related sleep complaints associated with different shifts among permanent night shift workers versus three-shift workers.[11] Higher rates of insomnia were reported in the rotating three-shift group during night shifts (68%) than in the permanent night shift group (42%).[11] However, a greater percentage of the permanent night shift group reported rest-day (day off) insomnia (11%) compared with the rotating three-shift group (4%). The percentage of three-shift workers reporting insomnia during day shifts was 36%, compared with 20% for evening shifts. We have calculated a hypothetical average insomnia score over the shift cycle for the rotating three-shift group and the permanent night group (see Table 78-2). The "mean over shift cycle" insomnia score for the three-shift group (31.7%) was slightly lower than that calculated for the permanent night shift group (34.0%).

The observation that permanent night shift workers reported more sleep problems during days off (rest-day insomnia; see Table 78-2) has been noted in several studies.[12,13] Most permanent night shift workers revert to day schedules and nocturnal sleep on their days off. It has been shown that readaptation to sleeping at night is difficult and creates sleep problems if the circadian rhythm has adjusted (phase-delayed) to working at night.[14] On the other hand, results from other studies show that permanent night shift workers might be no worse off or even slightly less sleepy during the night than rotating shift night workers.[11,13] However, the levels of on-shift sleepiness reported by permanent night workers were higher than those reported by day and evening workers, suggesting that the circadian rhythm did not adapt to working at night. In the few studies comparing permanent night shft workers with rotating shift night workers with respect to cognitive and psychomotor performance, the results did not show significant group differences.[15,16]

Folkard summarized results from six studies related to circadian adaptation to permanent night work and calculated that only a small percentage of workers (approximately 3%) seem to show complete circadian adaptation (as indexed by the endogenous melatonin rhythm).[17] Partial circadian adaptation in permanent night shift workers is more common and might explain the small increase in daytime sleep (approximately 30 minutes) obtained by that group compared with rotating shift workers. However, longer daytime sleep durations also might be explained by a later circadian phase in permanent night workers. Permanent night shift workers are in many cases a highly self-selected group—that is, persons who have chosen such a shift system because they prefer to work at night and can sleep during the day. It is not likely that self-selection is going to solve the problem with night work, because few people prefer to work only at night because it fits their sleep-wake rhythm. Also, the choice of permanent night work may be based on social factors (e.g., the goal of obtaining more time with children).[18]

In summary, the differences in (1) the duration of daytime sleep, (2) insomnia over the entire shift schedule, and (3) nighttime sleepiness between permanent and rotating shift night workers seems to be small. These results indicate that permanent night shift workers suffer from circadian disruption, as do rotating shift workers during their night shifts. Thus no clear evidence exists showing that permanent night work is more advantageous than the rotating shift system. However, permanent night work may be a good solution for persons who have a late circadian phase and who can maintain a night-oriented rhythm during days off.

SPEED AND DIRECTION OF SHIFT ROTATION—NUMBER OF CONSECUTIVE SHIFTS

The speed and direction of shift rotation vary considerably between shift schedules. The speed of rotation refers to the number of consecutive shifts that are at the same time of day (e.g., morning) before rotating to the next shift. A shift schedule including only one to three consecutive shifts of the same type (e.g., two consecutive morning shifts before the ensuing two evening and night shifts) is considered to be a fast-rotating shift schedule, whereas a schedule including at least five consecutive shifts of the same type is considered to be a slowly rotating schedule.

The direction of shift rotation can be either counterclockwise or clockwise. *Counterclockwise rotation* (also referred to as backward or advancing rotation) means that shift start time advances as the worker changes from one shift type to the next one within a shift cycle (i.e., night to evening to day shift). *Clockwise rotation* (also referred to as forward or delaying rotation) means that shift start time delays as the worker changes to the next shift type within a shift cycle (i.e., day to evening to night shift). An example of counterclockwise rotation is seen in a shift cycle consisting of three night shifts, two days off, three evening shifts, two days off, and three morning shifts, in that order. An example of clockwise rotation is that of a shift cycle starting with morning shifts followed by evening shifts and then night shifts, in that order. Regarding the human circadian system, clockwise rotation can be considered preferable to counterclockwise, because for most adults, it is easier to extend subjective days (i.e., delay bedtime) than to shorten them (i.e., advance bedtime) (see chronobiology chapters, in Section 5).

In principle, both fast- and slow-rotating shift cycles have their advantages and disadvantages. Fast rotation means that early-morning shifts and night shifts (both of which are associated with sleep disruption and increased sleepiness[11,19]) do not occur more than three times in a row, so a significant buildup of sleep loss and sleepiness can be mitigated (which is not the case with slow shift rotation). On the other hand, slowly rotating shift cycles could be considered advantageous, particularly if the circadian rhythm of the worker showed significant adaptation to the work-sleep patterns required by the working hours. In relation to early-morning work, adaptation would mean a circadian phase advance; in relation to night shift, adaptation would mean a circadian phase delay.

Previous findings regarding the effects of the speed of shift rotation on sleep and sleepiness are mixed. Results from a meta-analysis of data from 36 studies showed that slowly rotating shift cycles were preferable to fast-rotating ones with regard to sleep length.[7] The difference between slow- and fast-rotating shift cycles was most pronounced during night shifts: Persons who worked on slowly rotating shift cycles obtained, on average, 1 hour and 18 minutes more self-reported sleep than those who worked on fast-rotating shift cycles. For morning and evening shifts, the differences between fast and slow shift rotations were marginal. Of note, the meta-analysis did not take direction of shift rotation into account.

In a later systematic review including 26 studies on organizational interventions, the findings regarding rotation speed were in disagreement with those in the aforementioned meta-analysis.[4] A change from slowly rotating shift cycles to fast-rotating ones was found to most consistently improve self-assessed sleep quality. Self-assessed sleepiness also was reduced to some extent.

A specific issue associated with the speed of shift rotation is the number of consecutive work nights, because sleep-wake disturbances are known to be most pronounced during night work.[11] Working several consecutive night shifts in a row has been associated with increased risk for occupational accidents and injuries.[20,21] In comparison with the first night shift, risk for occupational injuries and accidents was found to increase by 36% on the fourth night shift in a row.[20] In nurses, having worked one- to two-night shifts in the past 7 days was associated with a 1.26-fold increased risk for occupational injuries, whereas having worked three- to six-night shifts was

associated with a 2.90-fold increased risk.[21] Taken together, these results suggest that the maximum number of consecutive night shifts should be limited to three.

On the other hand, results from other studies do not support the view of limiting the number of consecutive night shifts to fewer than four. Results from a study of rotating shift workers found that those who worked four consecutive night shifts showed levels of cognitive functioning, as measured by tests tapping executive function and automatic and controlled attention processing (e.g., Digit Symbol Substitution Test, Symbol Searching Test, Wisconsin Card Sorting Test), either the same as or better than those in nurses who had worked only two consecutive night shifts.[22] In line with this field study of actual shift workers, results from a laboratory-based study of healthy, non–shift-working males and females showed that subjective sleepiness reached its peak on the first simulated night shift and then gradually diminished during the ensuing four night shifts.[23] A similar trend was observed for some of the performance measures.

Finally, the consequences of working several night shifts in a row also differ according to specific circumstances such as location of operations. The specific situation of working at remote locations (such as off-shore installations and mines) is discussed separately later in the chapter (see Shift Scheduling in Extended, Offshore, and Mining Operations).

With regard to the direction of shift rotation, the current findings are more consistent than those for the speed of rotation. In two published systematic reviews, the investigators concluded that clockwise-rotating shift cycles were preferable over counterclockwise-rotating ones.[4,24] These conclusions were based on studies comparing the results of self- and actigraphy-assessed sleep, subjective sleepiness, and vigilance performance between these two shift cycles.

In practice, improvements due solely to changing from a counterclockwise to clockwise shift rotation are difficult to estimate, because the change in the direction of rotation often is accompanied by changes in other shift characteristics (e.g., speed of rotation, shift length, time-off period).[24,25] In a narrative review of the results of observational and intervention studies regarding the speed and rotation of shift cycles, the investigators reported that especially fast- and clockwise-rotating shift cycles were associated with better sleep and on-the-job alertness than in slow- and counterclockwise-rotating cycles.[25] The reasons for this difference between "fast plus clockwise" versus "slow plus counterclockwise" may lie not only in the speed and direction of rotation themselves but also in time-off periods between two consecutive shifts. "Slow plus counterclockwise" rotating shift cycles often are characterized by short, 7- to 9-hour time-off periods (e.g., in connection with a combination of an evening shift followed by a morning shift), whereas "fast plus clockwise" rotating cycles are always characterized by at least 11 to 12 hours of free time.

To conclude, fast- and clockwise-rotating shift cycles seem to be an optimal choice in terms of sleep between shifts and alertness at work, but supporting evidence is limited. In addition, individual difference factors (such as age, gender, diurnal type, and personality characteristics) contribute to adaptation of the sleep-wake pattern to rotating shift schedules.[26,27] In practice, this means that fast and clockwise rotation would not be optimal for everyone because considerable interindividual differences in response to changes in the speed and direction of shift rotation are likely.

OFF-DUTY TIMES BETWEEN SHIFTS

The off-duty time between shifts varies considerably, ranging from the usual 15 to 16 hours off-duty between consecutive 8-hour shifts to 12 hours off-duty between consecutive 12-hour shifts, to only 8 to 9 hours off-duty between work shifts requiring "quick returns" (e.g., when an evening shift is followed by a morning shift) or in irregular/unpredictable work environment systems. More extreme split shift systems/watch-keeping systems may be characterized by 4, 6, or 8 hours off-duty between shifts.[28] The reasons for reducing off-duty time between shifts are many, ranging from compressing the working period (e.g., finishing a series of night shifts with an afternoon shift) to allowing for continuity between staff and patients (i.e., so that patients have the same staff caring for them in the evening and on the following morning).

A number of aspects affect the sleep duration during off-duty time between work shifts. Besides sleep, the workers must commute to and from work, eat meals, unwind, maintain hygiene, and carry out other household and social responsibilities. As discussed previously regarding night shift work, timing of the off-duty period also is critical because a worker is less likely to obtain sufficient sleep if the off-duty time occurs during the day as opposed to nighttime.

Although results from some studies indicate that 12 hours of off-duty time may be sufficient for many workers,[29,30] other results indicate that 12 hours may be too little and allow for obtaining less than 6 hours of sleep.[31] Accordingly, most authors recommend avoiding off-duty times of less than 12 hours in general, and off-duty times less than 10 hours (quick returns) in particular.[32] The main reasons for the conflicting findings on sleep duration are likely related to different commute/travel times, extent of social obligations, and poor versus optimal sleep conditions. Hence, an employer using schedules with off-duty times of less than 12 hours should arrange for workers to sleep on site or close by in a sleep-conducive environment. Good sleeping conditions, short travel time, and few social obligations may explain why 12-hour shifts allow for sufficient sleep duration among oil rig workers.[30]

Quick returns (less than 11 hours of off-duty time between shifts) are used as a transition between shift types (e.g., as a transition from a series of night shifts to a period of morning shifts). This quick return compresses working hours and therefore results in extra off-duty time at some point. The general finding is that quick returns reduce average sleep durations to between 4 and 6 hours.[25,33] A quick return from a morning shift to a subsequent night shift is most disruptive, resulting in an average sleep duration of 3 hours or less.[34]

Results from several questionnaire studies show that severe sleepiness is more common in schedules incorporating quick returns. Most of these studies were carried out among nurses, for whom a quick return between the afternoon shift and a subsequent morning shift is particularly common.[35,36] By contrast, results from studies in which the investigators have attempted to predict fatigue often failed to find quick returns to be a strong predictor of fatigue.[37] Some evidence indicates that quick returns increase the risk for accidents in steel manufacturing workers.[38]

To conclude, short off-duty times have a negative impact on sleep duration. Off-duty times of fewer than 12 hours typically reduce sleep duration to 4 to 6 hours, with more reductions in sleep duration if the off-duty period occurs

during the day. Many individual and work site–related factors, such as travel times and accommodations for sleeping on site, affect sleep duration. Inasmuch as short sleep duration increases fatigue and impairs cognitive functions, off-duty periods between shifts that are shorter than 12 hours in duration should be avoided.

SHIFT CHANGEOVER TIMES AND START TIME OF THE MORNING SHIFT

One challenge in shift design is to find the optimal changeover time—that is, the time when night shift workers go off-duty and morning shift workers come on-duty. On the one hand, an early changeover time (e.g., at 5:00 AM) might result in less circadian disruption and increased daytime sleep duration for the night shift workers. On the other hand, an early start for morning shift workers is often associated with decreased sleep length, impaired sleep quality, and increased on-shift sleepiness.[39] For example, results from a large epidemiologic study showed that sleep duration was less than 5 hours when the morning shift started between 3:00 AM and 4:30 AM; early-morning shifts were also associated with increased risk for (self-reported and nonspecific) accidents.[40]

The effect of changeover time on sleep and sleepiness in three-shift work was examined in a controlled intervention study carried out by Rosa and coworkers.[41] The intervention involved a 1-hour delay of the shift changeover time: The shift changes occurred at 7:00 AM, 3:00 PM, and 11:00 PM on the new schedule. After the change in shift changeover time, participants extended their (self-reported) sleep by 0.5 hour on morning shifts (6.2 hours before the change). No significant changes in sleep duration occurred on evening shift (7.2 hours) or night shift (5.8 hours) days. Subjective sleep quality improved on morning shift days and worsened to some extent on night and evening shift days. Self-rated sleepiness decreased during the morning shift and increased on the night shift. In a control work site where shift changeover times remained unchanged, no significant changes occurred in sleep or alertness. In all, the results suggest that minor changes in shift start and end times are important factors affecting sleep and sleepiness when such changes occur within a normal night sleep period. Similar results were obtained in another study in which changes in shift changeover times were compared.[42]

The negative effects of early start times for morning shifts have been demonstrated in several studies. Results from studies in which polysomnography was used to objectively document sleep-wake have shown that with early-morning work (defined as start times at 6:30 AM or earlier), sleep duration is only slightly longer than 5 hours.[43,44] Ingre and colleagues carried out an experimental study in train drivers using a within-subject design in which they compared three different start times of the morning shift: 5:49 AM, 7:49 AM, and 9:49 AM).[39] The results demonstrated strong effects of start time on early-morning work in irregular shift systems—on average, drivers obtained only 5.6 hours of sleep before the earliest shift start time (5:49 AM). By contrast, drivers obtained 7.7 hours of sleep before the latest shift start time (9:49 AM). Results also showed that the earliest shift resulted in higher degree of subjective sleepiness, and 82% of the drivers reported at least one period of severe sleepiness (defined as a Karolinska Sleepiness Scale score of 7 or greater) during the work shift.[39] The corresponding value for the latest shift was 53%. The observation that an early start time for the morning shift is associated with increased sleepiness also has been noted in several other studies.[45]

To summarize, the shift changeover time between night and morning shifts affects sleep duration and sleepiness. A later changeover time is beneficial for the morning shift but detrimental for the night shift. This situation illustrates the difficulty in designing a shift system to optimize sleep and alertness for all shifts because there does not seem to be an optimal changeover time between the night and the morning shift that does not negatively affect one or the other.

LONG WORK SHIFTS AND ON-CALL WORK

Long work shifts (defined as shifts longer than 10 hours) are used in a wide range of settings and are common in the medical field (e.g., among nurses and medical interns). Although results from several studies show that 12-hour work shifts reduce opportunities to obtain sufficient sleep between shifts,[31] one report indicated that oil rig workers can manage up to 14 consecutive 12-hour shifts with relatively few problems.[30] In this report, the oil rig workers displayed the worst sleep problems during the sleep period before the first night shift but thereafter were able to achieve an average of 6.5 to 7.0 hours of sleep per off-duty period, with a gradual reduction of sleepiness during the subsequent night shifts. These findings indicate that it is possible to manage 12-hour shifts and that many workers can adapt when conditions are optimal: The oil rig workers slept on site, with few social obligations, and their light exposure allowed for circadian adaptation.

In contrast to findings in oil rig workers, results from studies of 12-hour shifts in other occupations are mixed: Both poorer sleep and better sleep have been observed when 12-hour shift systems were compared with shift systems based on 8-hour shifts.[46] One factor that may explain the inconsistent findings is different starting times.[46] Also, workers may have more free days to recover between work periods in a 12-hour shift system and thus may be more motivated to obtain sufficient sleep before the shifts. A negative aspect of schedules with long work shifts is the difficulty in taking prophylactic daytime naps before the night shift.

According to some evidence, long shifts increase severe sleepiness and fatigue,[47,48] although results of several studies failed to show any differences in sleepiness or fatigue between 8-hour shifts and 12-hour work shifts.[29,46] Results from several studies support the notion that 12-hour shift systems may reduce severe sleepiness, suggesting that a good 12-hour shift system is better than a poor 8-hour shift system.[49] The evidence also indicates that fatigue accumulates over successive long work shifts, particularly when the shifts are as long as 15.5 hours.[48] The study authors argued that a main reason for the accumulation of fatigue was the short off-duty time (8.5 hours) between shifts (allowing workers to obtain only 5.5 hours of sleep) in a schedule with several concomitant long shifts.[48] In a study of 104 railway traffic controllers, the risk for severe sleepiness increased in long shifts, the increase being 15% for every hour on the shift.[37]

On-call work is a scheduling approach used to provide 24-hour coverage of personnel to deal with emergencies in a prompt manner when normal staff resources are not present (e.g., at night). The main reason for this working arrangement is that having employees on call is a more effective (i.e., less

costly) use of staff than maintaining full coverage during off-peak hours. This working arrangement is common in a wide range of occupations including the medical field (e.g., physicians, midwives, medical technologists), utilities (e.g., electrical technicians), and other fields in which full coverage over a 24-hour period would be cost-prohibitive (e.g., ship engineers, tugboat pilots). The characteristics of on-call shifts in these fields vary considerably and particularly with respect to whether the employee must be on site (as in the case for medical residents) or may remain off site (e.g., on-call utility workers).

The limited literature suggests that on-call work is associated with disturbed sleep.[50,51] On-call workers report experiencing difficulties falling asleep and reduced sleep amounts (as reported by 198 locomotive engineers[51]). Few researchers have investigated how on-call affects polysomnographic sleep, but in a small-scale study of ship engineers ($n = 5$), the sleep EEG showed less slow wave sleep and less REM sleep, associated with a higher heart rate, all of which might have been caused by the anticipation of having to wake up and work.[50] Sleep periods during on-call shifts typically are short but even within the same occupation may differ considerably between work sites: Actigraphically recorded sleep durations reported among emergency medical specialties in France averaged 4.75 hours on on-call shifts,[52] whereas medical residents in Chicago averaged 2.8 hours[53] and medical residents in Houston averaged 3.8 hours.[54] A strong inverse relationship has been found between the amount of working hours across a work week with extended shifts and the amount of sleep the residents obtain.[55]

Important evidence shows that long working hours also increase the risk of on-the-job accidents. The authors of a systematic review of work shift duration and accidents concluded that the increased risk is approximately doubled after approximately 12 hours of work, compared with the risk after 8 hours of work.[56] Landrigan and coworkers[57] carried out a randomized intervention study in medical interns working in two intensive care units. One unit kept the traditional schedule (which included several shifts lasting 24 hours or longer), and the other unit was assigned to an intervention schedule that eliminated the extremely long shifts, so that the longest shifts were approximately 16 hours. The objective was to determine whether the intervention schedule increased the interns' opportunities to sleep. Diagnostic error rates were significantly higher for the traditional schedule than for the intervention schedule (24 ± 18.6 versus 3 ± 3.3). Moreover, the rate of serious medical errors was higher for the traditional schedule as well (176 ± 136.0 versus 91 ± 100.1). The intervention schedule still contained several 16-hour shifts and 60 to 63 hours of scheduled work hours per week (plus overtime). Additional evidence suggests that the commute home from work is characterized by an increased risk of falling asleep and for being involved in a vehicle accident on schedules with extended shifts.[58]

In sum, long work shifts and on-call work are associated with increased sleepiness and an increased risk for accidents and errors on shift and during the commute home. Moderately long work shifts (i.e., 12-hour shifts) may not necessarily reduce sleep duration—and the ability to obtain approximately 6.5 to 7 hours of sleep in between successive shifts appears to be the key aspect allowing oil rig workers to manage long work periods with few fatigue problems. Shift timing is crucial for long working shifts, and early start times are to be avoided because the combination of short sleep and long working periods may lead to an accumulation of sleepiness. On-call work among residents disrupts sleep and may cause severe sleep loss if the weekly working hours are extended. Finally, in safety-critical operations, long work shifts are associated with fatigue, serious medical errors, and increased accident risk after approximately 8 to 9 hours on duty.

COUNTERMEASURES AND SHIFT SCHEDULING

On-Shift Napping

A countermeasure for reducing sleepiness in shift work (and especially during night shifts) is to implement rest breaks with an option for sleeping. Results from studies conducted in medical staff,[59] air traffic controllers,[60] and industrial workers[61] show that a nap (even for less than an hour) can reduce sleepiness on night and extended shifts. Results from a systematic review of data from 13 laboratory and field-based studies showed that napping during night shifts consistently reduced sleepiness and improved performance but was not likely to impair post-shift daytime sleep.[62] In these studies, nap start time varied, ranging from midnight to 4:00 AM, with nap break duration of 20 to 120 minutes and nap sleep duration of 17 to 117 minutes. In all, these findings propose that preplanned nap breaks constitute a useful sleepiness countermeasure for addressing sleepiness in shift work. The only putative negative consequence of taking a nap is sleep inertia (which lasts only 15 to 20 minutes). In general, the short-lived impairment of sleep inertia probably is outweighed by the larger, long-term benefit associated with nap sleep; especially in safety-critical occupations (e.g., airline pilot), it is important to schedule enough time for the process of awakening after a nap break to avoid sleepiness-related performance errors.[63]

Prophylactic (Pre-Shift) Napping

Another countermeasure for sleepiness during the night shift is to nap before the shift (and particularly before the first night shift), because otherwise the duration of sustained wakefulness will be approximately 24 hours by the end of the first night shift. Results from a study of policemen working on fast-rotating shift cycles showed that taking a nap before the night shift (which spanned 1:00 AM to 7:00 AM) was associated with a 48% reduction in on-duty car accidents.[64] The length of the nap sleep was approximately 1.5 hours, and the nap occurred either in the afternoon or closer to the beginning of the night shift.

Shift Scheduling in Extended, Offshore, and Mining Operations

The relationship of the shift schedules used at North Sea oil and gas installations to workers' sleep, sleepiness, and performance has been studied extensively. Two widely used shift schedules for a 2-week offshore work period (usually followed by 2 to 4 weeks of free time) are the fixed schedule and the swing shift rotation. With the *fixed schedule*, workers alternate between offshore tours of 14 consecutive night shifts and 14 consecutive day shifts. The *swing shift rotation* is composed of seven 12-hour night shifts followed immediately by seven 12-hour day shifts.

These extended schedules have different effects on circadian disruption, sleep, and sleepiness, during both the offshore period and during the break when workers return home.

Regarding sleep and sleepiness, the fixed schedule has proved to be less disruptive than the swing schedule.[65] This benefit is explained mainly by the fact that workers show significant or even complete adaptation to night shifts during the first work week—a phenomenon that does not occur in on-shore personnel doing comparable work.[66] Significant adaptation to consecutive night shifts in off-shore workers is mostly explained by only low-level exposure to morning light and a good opportunity for daytime sleep during a shift cycle. Adaptation to night shifts is evidenced by changes in cortisol and melatonin production rhythms and improvements in sleep, sleepiness, and performance.[67,68] The amount of sleep obtained per 24-hour period has been reported to be 6 to 7 hours, independent of whether the schedule consists of 14 consecutive day or night shifts.[69] Of note, a relatively large number of oil rig workers still report problems coping with long stretches of consecutive 12-hour shifts—23% have been classified as suffering from shift work sleep disorder[70] (see Chapter 75). The most important disadvantage of the fixed schedule system is that workers must readapt to a diurnal sleep-wake rhythm after 14 consecutive night shifts. The readaptation process takes at least a week.[67] When working the swing shift schedule, workers must adapt to night shifts and then readapt to a diurnal sleep-wake rhythm during each 2-week work period. This readaptation process has been shown to lead to more circadian disruption and sleep loss than with the fixed shift schedule.[65]

As with offshore oil and gas installations, extended periods of consecutive 12-hour shifts are typical of the mining industry. Investigators of one field-based study examined sleep during four types of shift schedules, differing in terms of (1) the number of consecutive night (6:00 PM to 6:00 AM) and day (6:00 AM to 6:00 PM) shifts (4 to 7), (2) the number of consecutive shifts (4 to 14), and (3) the number of days within a shift cycle (15 to 22).[71] The results showed that the shift schedules or shift types (day versus night) did not differ from each other in terms of self-reported sleep duration or quality on workdays. On average, workers obtained 6 hours of sleep per 24-hour period. The workers slept most (7.5 to 9.5 hours) before the first night shift on all schedules, which suggests that they prepared themselves for the upcoming night shifts and also, for some schedules, tried to recover as completely as possible from the preceding sequence of consecutive 12-hour shifts.

Results from another study in miners showed that in contrast with the data for offshore workers, physiologic adaptation to seven consecutive night shifts was limited.[72] This lack of adaptation also was reflected in progressive impairment in psychomotor performance over consecutive shifts. Taken together, the findings indicate that the effects of similar shift schedules on sleep are largely dependent on the prevailing working environment.

WHAT IS THE OPTIMAL SHIFT SYSTEM DESIGN FOR REDUCING SLEEP-WAKE PROBLEMS?

The recommendations for shift schedule designs that are beneficial for sleep and on-the job alertness are listed in Table 78-3. A shift schedule that (1) is fast and clockwise-rotating, (2) limits consecutive working days in a row, (3) eliminates extremely long (16 hours or longer) shifts, and (4) spreads out days off across the schedule decreases the risk of accumulated sleep loss and fatigue and minimizes circadian disruption.[73] If work is safety-critical, long shifts (lasting more than 10 hours should be avoided. Nevertheless, occurrence of acute sleepiness (e.g., toward the end of the night shift) is highly likely, because no circadian adaptation occurs on a fast rotation. Use of sleepiness countermeasures (e.g., on-shift or pre-shift napping) is therefore important to avoid severe work-related sleepiness. Of note, permanent night work rarely results in complete circadian adaptation, and the partial adjustment observed in some field studies seems to be due to sleep problems during days off.

Also of note, the scientific evidence supporting several of the shift design recommendations is insufficient, so definitive recommendations on how a shift system should be designed universally are few.[24] The lack of definitive shift scheduling recommendations is partly because of the difficulties of introducing a randomized controlled study designs in shift work settings. In addition, the shift workers themselves often participate in the development of the new shift system, so the results from some of the intervention studies might be related more to the shift workers' expectations and attitudes about the new schedule, rather than to the specific components of the shift system. Moreover, sleep and sleepiness are influenced by factors other than working hours; the internal validity of field studies, therefore, usually is lower in comparison with laboratory-based experimental research (on the other hand, laboratory studies often possess low ecologic validity and are not optimal for drawing conclusions regarding shift scheduling). Most field studies use subjective self-reported metrics, and relatively few studies have applied objective methods for measuring sleep and alertness. Furthermore, many of the intervention studies are based on small samples, and follow-up times are short (less than 12 months). These limitations require that the recommendations for shift scheduling be interpreted with some caution. Of note, the recommendations are based on the "one-size-fits-all" assumption. Individual differences in sleep need, circadian phase, and sleep flexibility probably are substantial among shift workers. As a consequence, some workers will encounter problems tolerating fast-rotating shift systems and might prefer a more regular (and fixed) shift system. Also of note, various domains and occupational settings differ significantly in terms of operational requirements and working conditions, which makes it difficult to apply exactly the same shift scheduling recommendations to all cases.

CLINICAL PEARLS

- Sleepiness and impaired sleep associated with shift work are due to (1) failures in circadian adaptation and (2) an accumulated sleep debt. Tolerance to shift work is therefore determined by the design of the shift schedule: A shift schedule that minimizes both circadian disruption and the buildup of sleep loss is easier to tolerate and may improve long-term health and safety.
- An optimal shift schedule should feature fast and clockwise rotation, few consecutive night shifts, at least 11 hours of off-duty time between shifts, no extremely long-duration (16 hours or longer) shifts, and avoidance of early (before 6:00 AM) starting times for the morning shift. Even with an optimal shift system, however, workers are likely to have a high level of sleepiness at the end of the night shift. It is therefore important to incorporate alertness-enhancing countermeasures (e.g., pre-shift or on-shift naps), to avoid sleepiness-related incidents at the job site as well as accidents during the commute home from work.

Table 78-3 Recommendations for Shift Scheduling

Shift Schedule Characteristic	Recommendation	Expected Result
Permanent or rotating shifts	Rotating shift system	Limits repeated circadian disruption and reduces the risk of accumulated sleep loss and build-up of severe sleepiness Less sleep and wake problems during days off
Speed and direction of rotation	Fast (maximum three similar shifts in a row) and clockwise (e.g., morning-evening-night) rotation	Limits circadian disruption and reduces the risk of accumulated sleep loss and buildup of severe sleepiness
Number of consecutive work days	Maximum 6 days in a row, but should be reduced if the length of work shift is >8 hours, the off-duty time between shifts is <11 hours, and if the work shifts include early morning work and night work	Reduces the risk of accumulated sleep loss and buildup of severe sleepiness
Duration of off-duty time between shifts	Minimum off-duty time between shifts is 11 hours	Reduces the risk of accumulated sleep loss and build-up of severe sleepiness
Duration of work shift	Very long (>16 hours) shifts should be eliminated. Shifts longer than 10 hours should be avoided if the work task requires sustained attention, is safety-critical, and does not contain breaks during work	Reduces the risk of accumulated sleepiness within the work shift May also reduce accident risk
Starting time of the shift	The start time of the morning shift should be later than 6:00 AM and preferably around 7:00 AM	Reduces severe sleep loss, insomnia, and sleepiness during the morning shift May cause more disturbed sleep related to the night shift
Distribution of off-duty days within the shift schedule	Days off should be spread out in the shift schedule to avoid compressed work hours	Decreases the risk of developing accumulated sleep loss and buildup of severe sleepiness

Modified from Knauth P, Hornberger S. Preventive and compensatory measures for shift workers. *Occup Med (Lond)* 2003;53:109–16.

SUMMARY

Sleep loss, disturbed sleep, and excessive sleepiness are common consequences of shift work, in particular if the shift system involves night work. Although misalignment between the internal circadian clock and the sleep-work pattern determined by the shift system is a key factor, certain shift scheduling factors also play an important role. According to sleep-wake regulation theory, a schedule that minimizes circadian disruptions and buildup of sleep loss over a single shift and a shift cycle, and permits sufficient recovery during days off, will optimize on-shift alertness and off-duty sleep quality, which in turn benefits occupational safety and long-term health. The recommendations for shift schedule design are to use fast and clockwise-rotating shift system with few consecutive working days in a row, to eliminate very long (16 hours and longer) shifts, and to spread out days off across the schedule. Such a schedule decreases the risk of developing accumulated sleep loss and fatigue and minimizes circadian disruption. One of the most well-studied and effective interventions is to eliminate extremely long (more than 16 hours) work shifts—and if work is safety-critical, long (more than 10 hours) shifts should be avoided. Nevertheless, the occurrence of acute sleepiness (e.g., toward the end of the night shift) is highly likely, because no circadian adaptation occurs on a fast rotation. It is therefore important to use sleepiness countermeasures (e.g., pre-shift and on-the-job napping) to avoid severe work-related sleepiness and consequent errors and accidents.

Chapter 79

Obstructive Sleep Apnea in the Workplace

Chunbai Zhang; Mark B. Berger; Albert Rielly; Atul Malhotra; Stefanos N. Kales

Chapter Highlights

- Obstructive sleep apnea (OSA) is highly prevalent among workers and a common cause of excessive daytime sleepiness at work.
- Untreated OSA negatively affects occupational health, safety, and productivity.
- Untreated OSA increases the risk of transportation accidents.
- Clinicians are likely to encounter employees in several situations for evaluation for possible OSA.
- In the occupational setting, subjective symptom reports are unreliable for screening and diagnosis of OSA.

OVERVIEW AND BACKGROUND

Obstructive sleep apnea (OSA) is characterized by repetitive cessations of or decrements in airflow through the upper airway during sleep, resulting in a variety of physiologic and metabolic disturbances, including frequent arousals from sleep.[1] Untreated OSA has been linked to excessive health, safety, and lost productivity costs in the range of $65 billion to $165 billion per year in the United States alone.[2] Motor vehicle accidents and other workplace injuries in safety-sensitive occupations are increased owing to the resulting excessive daytime sleepiness and decreased vigilance/attention associated with OSA.[3-6] In addition to lost productivity and increased absenteeism, individual and public health costs attributable to the cardiovascular and metabolic comorbidity associated with OSA have been well documented.[7,8]

OSA remains underdiagnosed and often goes untreated. Accordingly, sleep specialists and occupational physicians can expect to encounter several typical workplace referral scenarios in which patients or employees with potential OSA will require evaluation. One of the most common scenarios is that in which an employee is observed to be sleeping at work (as with an employee in an unsupervised position that requires close attention to the assigned task) or falling asleep repeatedly during group meetings. Supervisors may mistake such behavior for laziness or may recognize the possibility of a medical problem. In such cases, the employee may agree to be medically assessed or may be in denial regarding his or her impairment. A more urgent referral scenario is that in which the employee is required to present to the sleep clinic after falling asleep and causing an accident during performance of a safety-sensitive job (e.g., professional driver, airline pilot, health care worker, nuclear plant employee, public safety officer). In keeping with the increased public awareness of transportation accident risk associated with OSA, sleep professionals can expect to see occupational medicine professionals and employers refer transportation operator-employees who deny all symptoms of OSA yet are found to have objective risk factors (e.g., obesity, increased neck circumference and/or hypertension). These employees may be referred for evaluation to rule out OSA as a condition of employment or to medically qualify for an operating license. In all of these scenarios, the determination of a diagnosis of OSA and reports of treatment compliance data will have medicolegal relevance for the clinician and potential job security implications for the referred employee.

CONSEQUENCES OF OBSTRUCTIVE SLEEP APNEA IN TRANSPORTATION WORKERS

Experts estimate that between 7%[9] and 20%[10] of all large truck crashes are due to drowsy or fatigued driving.[11] As reported over the past decade (2003-2012), between 3454 and 9528 deaths and between 84,000 and 224,000 serious injuries (mostly among the traveling public) are likely attributable to sleep-related impairment in commercial motor vehicle (CMV) drivers in the United States alone.[9,10,12] OSA is the most common medical cause of excessive daytime sleepiness.[13] Not surprisingly, therefore, several high-profile transportation accidents related to insufficient sleep and OSA have been reported.[14] In one such accident, a pilot of an oil tankship collided with a general cargo vessel, which led to a spill of crude oil. The volume of the spill was estimated at 1000 to 11,000 barrels. The official investigation concluded that contributing to the accident was the pilot's fatigue caused by his untreated obstructive sleep apnea and his work schedule.[15] In 2008, a tour bus carrying passengers returning from a weekend ski trip crashed and killed nine people and injured 43 others. The driver was found to be suffering from OSA that was inadequately treated in the days before the accident. In 2009, two airline pilots on a flight in Hawaii dozed for at least 18 minutes during a midmorning flight, initially overshooting the specified destination. The captain subsequently was diagnosed with OSA. In December 2013, a southbound New York Metro-North Railroad train derailed as a consequence of excessive speed, killing four passengers and injuring 59 others. A diagnostic evaluation of the train's engineer as part of the accident investigation revealed that he was suffering from untreated severe OSA.[16]

PRINCIPLES OF OBSTRUCTIVE SLEEP APNEA MANAGEMENT IN THE WORKPLACE

Occupational medical programs that address OSA screening, diagnosis, and management should be accompanied by administrative controls related to hours of service, shift work, and other factors that affect worker fatigue. Taken together, these factors are referred to as fatigue risk management systems (FRMSs). In 2012, the American College of Occupational and Environmental Medicine (ACOEM) Presidential Task Force on fatigue risk management published a guidance statement to assist in the design and implementation of FRMSs.[17] A successful FRMS should be science-based, data-driven (with decisions based on collection and objective analysis of data), cooperative (designed together by all stakeholders), fully implemented (systemwide use of tools, systems, policies, and procedures), integrated (built into existing corporate safety and health management systems), continuously improved (for progressive reduction of risk using feedback, evaluation, and modification), adequately budgeted (justified by an accurate return-on-investment business model), and "owned" (responsibility accepted by senior corporate leadership).[17] For an FRMS to function efficiently, a senior manager must be assigned accountability for the program. Active engagement from everyone employed will make the program more successful, as will a culture of mutual trust between management and employees. Gander and colleagues provide an in-depth discussion of FRMSs in Chapter 73.

Sleep Disorder Management

The principles of fatigue management apply to OSA management and require a proactive approach rather than a reactive approach. In safety-sensitive positions, minimizing fatigue by actively screening, diagnosing, and managing OSA in advance, with implementation of corrective actions when necessary to address noncompliance with prescribed treatment, is expected to be more cost-effective than responding to a fatigue-related incident after it occurs. For most workplaces, the sleep disorder management program need not be extensive. A screening questionnaire that encourages follow-up evaluation with personal physicians for response profiles suggestive of sleep disorders may be adequate. In safety-sensitive occupations, however, objective physical assessments may be required because they are much more sensitive and reliable screening tools than most self-report questionnaires (as discussed further on).

Screening and Risk Factors

Nonmodifiable risk factors for OSA include older age, male gender, postmenopausal status in females, and ethnicity (Asian American or African American descent). Obesity/adiposity is the most significant risk factor and is modifiable.[18-21] Results from studies have shown that OSA is closely associated with higher body mass index (BMI) and larger neck and waist circumference.[21-24] These findings make the foregoing parameters key objective elements for OSA screening in an occupational setting. Visceral fat is significantly correlated with increasing OSA severity.[23,25-27] Higher waist-to-hip ratio also has been shown in some studies to be more predictive of OSA than is obesity in general. Among morbidly obese patients with a BMI of 40 kg/m^2 or higher, OSA is nearly universal. Among men with BMI of 32 kg/m^2 or higher, the prevalence of OSA is approximately 75%.[28] Persons with large neck circumferences (in men, greater than 17 inches; in women, greater than 16 inches) should raise clinical suspicion for presence of OSA.[29]

Women with OSA tend to report fewer "classic" daytime symptoms of OSA—for example, instead of reporting daytime sleepiness, they may report fatigue and lack of energy. In addition, women have different anatomic and functional upper airway properties and differences in control of breathing compared with men.[30,31] These diagnostic and biologic differences between men and women contribute to lower rates of sleep apnea diagnosis in women.

Among different races, obesity plays a variable degree of importance. For example, adult African Americans younger than 25 years or older than 65 years have higher prevalence of OSA than others.[20,32] In the East Asian population, although the prevalence of obesity is lower, the prevalence of OSA is similar to that for Western populations.[33,34] Ethnic differences in adipose tissue distribution (i.e., peripheral versus visceral) and predisposing craniofacial profiles such as crowded posterior oropharynx, shorter cranial base, and more acute cranial base flexure may be important in explaining the pathogenesis of OSA among certain nonobese populations.[18,30,35]

Finally, smoking and use of alcohol and other sedatives are important modifiable risk factors.

OBSTRUCTIVE SLEEP APNEA SCREENING METHODS IN THE WORKPLACE

Screening is defined in this chapter as risk assessment or stratification before referral for a diagnostic test. Employer screening refers to the use of questionnaires (such as the STOP-Bang questionnaire; for further information, see www.stopbang.ca), anthropometric measures, and other subjective and objective criteria applied to all employees to identify those who should be referred to a sleep disorders specialist, who will then confirm or exclude the diagnosis of OSA. "Diagnosis" and "diagnostic procedures" for OSA refer to sleep studies that measure or estimate the presence of sleep apnea (see later on). OSA screening modalities include (1) subjective/self-identified reports of perceived sleep disorders, daytime sleepiness, and sleep-related symptoms; (2) objective measures such as BMI and neck circumference, with cutoff values, and blood pressure; (3) guidelines that combine subjective and objective criteria; and (4) functional performance screens designed to detect impairment related to fatigue or sleepiness. Table 79-1 summarizes a number of these screening methods regarding characteristics of workplace performance (in this case, transportation operators) and effectiveness in detecting OSA.

Subjective Measures

Subjective screening modalities depend on the individual employee's self-report of previous OSA or daytime sleepiness. However, this approach to OSA screening in an occupational setting creates multiple challenges.[36-39] Unlike in a sleep clinic, where patients with undiagnosed OSA typically are actively seeking diagnosis and treatment for inadequate sleep, snoring, and/or excessive daytime sleepiness, employees in safety-sensitive positions (e.g., truck drivers, pilots, mariners) wish to avoid incurring an OSA diagnosis because of its potential

Table 79-1 Comparison of Various Obstructive Sleep Apnea (OSA) Screening Strategies in a Typical Population of Transportation Operators

	Estimated Performance during Occupational Medical Examinations of Transportation Operators				
Screening Criterion	Prevalence of Positive Screens (%)	OSA Case Yield* (%)	Sensitivity (%)	Positive Predictive Value (%)	Mean AHI in Cases Detected
U.S. Federal Commercial Drivers' License Exam Driver Sleep Question	0-3	0-2	0-7	—	—
ESS score >10	3.4	1.4	4	—	37± 28
SomniSage Questionnaire	30	21	75	68	40 ± 28
BMI ≥30 kg/m^2	50	19	68-70	38	41 ± 29
Joint Task Force Guidelines	12-13	10-12	36-46	79-≥95	42-49
BMI ≥ 40 kg/m^2	6-7	6-7	23	>95	51 ± 32

*Percent of commercial drivers who will screen positive and then be diagnosed with OSA (defined as AHI >10) by polysomnography.
AHI, Apnea-hypopnea index; BMI, body mass index; ESS, Epworth Sleepiness Scale.
Modified from Kales SN, Straubel MG. Obstructive sleep apnea in North American commercial drivers. *Ind Health* 2014;52:13-24.

negative economic and occupational consequences.[40] In fact, data from diverse sources confirm that commercial drivers generally do not report their symptoms and diagnoses because of the negative economic and occupational consequences (perceived or real) of an OSA diagnosis. These concerns range from the inconvenience of having to submit to a diagnostic workup after a positive screening result, to the negative impact on employee pay resulting from being pulled out of service during a medical evaluation, to potential loss of a job and/or medical certification for employment.[9,14,41] In view of this reluctance of employees to self-report symptoms of OSA, it is especially important that occupational medicine physicians take the time to implement objective measures (described further on) as well as to ask supplementary questions in evaluating high-risk drivers.

In the United States, commercial vehicle drivers are required to complete a federal medical form that contains the single yes-or-no question "Do you have sleep disorders, pauses in breathing while asleep, daytime sleepiness, loud snoring?" Among those drivers identified as being at high risk for OSA, as many as 85% answered "No" to this question.[38]

The Epworth Sleepiness Scale (ESS) is a widely used questionnaire designed to identify persons with excessive daytime sleepiness due to either lifestyle circumstances (e.g., chronic sleep deprivation stemming from demanding work or social schedules) or a sleep disorder.[42] Unfortunately, among commercial drivers, the ESS questionnaire may produce a high rate of false-negative results. Most commercial vehicle operators report very low ESS scores at driver certification examinations (ESS scores in the range of 2 to 4 indicate a low likelihood of abnormal sleepiness), lower than ESS scores from the general community.[40] Similarly, results from an anonymous survey of transportation operators conducted by the National Sleep Foundation revealed a mean ESS score of 5.2 among professional truck drivers assessed.[43] By contrast, in another anonymous survey of U.S. truck drivers, more than 20% reported falling asleep at traffic lights.[39]

Somni-Sage is a questionnaire that incorporates weighted values for BMI, neck circumference, hypertension, and other medical comorbid conditions, as well as heavy snoring, witnessed apneic episodes, and other manifestations of excessive daytime sleepiness, and calculates categories of relative OSA risk.[44] Results from a retrospective assessment of Somni-Sage Questionnaire validity in more than 19,000 drivers showed that almost 6000 of the respondents (30%) were at higher risk for OSA. Of more than 2000 higher-risk drivers who underwent PSG, 68% were diagnosed with definite OSA (AHI greater than 10) and 80% had at least probable OSA (AHI of 5 or greater). A conservative prevalence estimate for definite OSA (AHI greater than 10) was 21% among commercial drivers in the population studied.[44]

Although evidence-based data are lacking, our own clinical experience supports the practice of a more probing interview of higher-risk commercial drivers by an experienced physician to obtain critical information. Drivers who deny symptoms and diagnoses on questionnaires and self-report forms often divulge more information when skilled physicians ask repetitive and additional questions regarding sleep hygiene, symptoms of daytime sleepiness, comorbid conditions, and findings on previous evaluations.[40]

Objective Measures

Objective screening tools have the advantage over questionnaires that they are less subject to manipulation, deception, and underreporting by drivers. Therefore application of such tools to obtain objective physical findings (e.g., BMI cutoff values) should be the screening modality of choice for OSA evaluation of employees who are in safety-sensitive positions.

At least four groups have generated recommendations for objectively screening CMV operators: (1) Dagan and colleagues,[45] (2) the U.S. Department of Transportation's Federal Motor Carrier Safety Administration (FMCSA) Medical Review Board (MRB),[46] (3) the FMCSA Medical Expert Panel (MEP),[47] and (4) the Joint Task Force (JTF) of the American College of Chest Physicians, the ACOEM, and the National Sleep Foundation.[48,49] Dagan's group showed that 78% of commercial drivers with a BMI of

32 kg/m^2 or greater had polysomnography (PSG)-confirmed OSA, and almost 50% also had objectively confirmed excessive daytime sleepiness as measured by a Multiple Sleep Latency Test. Confirming our review finding (see earlier) that subjective measures may yield a high number of false negatives, Dagan and colleagues also found that 100% of these affected drivers denied symptoms of OSA or excessive daytime sleepiness.[45]

The FMCSA MEP consisted of experienced clinicians and researchers knowledgeable in evidence-based medicine. In its 2008 report, the panel recommended referral of all CMV operators with BMI of 33 kg/m^2 or greater for a sleep study.[47] The MEP took feasibility of implementation into consideration by aiming to identify those CMV operators who were most likely to have severe OSA. After reviewing all of the negative long-term medical outcomes from untreated OSA, the FMCSA MRB recommended that a lower BMI criterion (BMI of 30 kg/m^2 or higher) be used for referral.[46] Neither set of recommendations from the MEP and the MRB have been implemented by the FMCSA as requirements. Barriers to a federal mandate include political, financial, liability, and legal concerns.[36,38]

The 2006 JTF issued recommendations for OSA screening of commercial drivers at certification examinations performed by commercial driver medical examiners (CDMEs).[48,49] Their screening recommendations include self-reported historical findings and the ESS, but they emphasized objective physical examination findings such as BMI, neck circumference, and hypertension criteria. The JTF guidelines recommended a higher BMI threshold (BMI of 35 km/m^2 or higher) for sleep study referral compared with that issued by either the MEP or the MRB of the FMCSA. This threshold was designed to have a high positive predictive value and to identify more severe OSA cases while not removing too many drivers from service. In the absence of a clear federal mandate for OSA screening of commercial drivers, the JTF guidelines are viewed by many occupational medicine professionals as representing a minimum standard for OSA screening to be implemented by the occupational medicine community.

Functional Screening

Functional or performance-based screening is an emerging approach for OSA screening at work sites using techniques such as psychomotor vigilance testing (PVT) and driving simulation. PVT is attractive as an adjunct to screen for OSA[50]: This testing modality has been shown to detect decrements in performance due to sleep deprivation, and it requires only a few minutes to administer. However, PVT performance cutoff criteria and correlation with accident or safety risks associated with OSA have not yet been established. Likewise, results from studies of driving simulation consistently demonstrate decrements in performance among subjects with OSA and other sleep disorders, as well as in subjects who have been sleep-deprived. At present, however, robust evidence associating simulator performance with on-road driving performance is lacking.[48] Additionally, performance criteria for identifying operators with OSA have not been established, and testing generally takes at least 30 minutes to complete. The latter characteristic makes use of simulators less attractive as an addition to occupational medical examinations.[40]

DIAGNOSIS OF OBSTRUCTIVE SLEEP APNEA IN OCCUPATIONAL SETTINGS

A "diagnosis" of OSA incorporates the results obtained from different types of sleep studies. Sleep studies may be performed using portable monitors (PMs) or full-channel PSG to measure (or estimate) the subject's sleep-disordered breathing (if present) via the AHI, respiratory disturbance index (RDI), or other means.[1] Although the current gold standard for diagnosing OSA is a laboratory-based PSG study, in-laboratory PSG is more expensive, time-consuming, and frequently of limited availability. The high prevalence of obesity means that more employees will have a positive result on screening and require follow-up sleep studies; consequently, the up-front costs of performing sleep studies has become a challenge to more widespread OSA screening and detection.[51-56] Using laboratory-based PSG as the diagnostic standard is less feasible because U.S. health insurers have placed increasing restrictions on reimbursement for the use of such studies. For all of these reasons, there has been an increasing interest in and push for use of PMs for diagnosing OSA in occupational settings, and this topic recently has been reviewed in depth.[51] To date, comparative effectiveness studies in safety-sensitive occupations (e.g., truck drivers, pilots) are lacking.

In the occupational setting, the major concern regarding the use of PMs is that transportation operators may actively avoid incurring an OSA diagnosis because of its economic and occupational implications (as discussed previously).[51] It is therefore imperative that clinicians be aware of scenarios whereby employees could alter PM results. They may stay awake to avoid sleep-disordered breathing events, which would go undetected if the PM does not record or estimate sleep stages, or the device may be placed on a healthier family member to avoid diagnosis. Accordingly, occupational medicine experts advocate using PM devices with a so-called chain-of-custody feature (such as a bracelet or other identifier placed on the driver by a professional technician), which deactivates the PM if it is removed. The best diagnostic use of PMs in an occupational context is to confirm the presence of OSA in an employee who already has been deemed to be at high risk for the disorder on the basis of symptoms or other screening techniques. When OSA is confirmed using the PM, treatment can be recommended and implemented without further testing. On the other hand, a negative or indeterminate result from a PM should not be considered sufficient evidence to exclude OSA, particularly in a high-risk employee working in a safety-sensitive position (e.g., transportation).[51]

Other unique considerations have emerged as important in interpreting diagnostic sleep tests in the occupational setting. Unlike in the nonoccupational setting (where the presence of symptoms can be used to make the diagnosis or decide on the necessity of treatment in cases in which the AHI or RDI is relatively low), the absence of symptoms should not be used to rule out OSA or accident risk.[38,40,45] Second, no clear thresholds of OSA severity (i.e., based on AHI/RDI, oxygen desaturation, or other measures) below which OSA-affected employees are *not* at an increased risk for accidents have been established.[4] Accordingly, in cases of mild OSA, the bias should be toward treating the OSA in affected employees who work in safety-sensitive positions (e.g., transportation operators).

TREATMENT OPTIONS AND COMPLIANCE MONITORING

As in the nonoccupational setting, continuous positive airway pressure (CPAP) is the first-line and best treatment for OSA in an occupational context. For employees in non–safety-sensitive positions, other OSA treatments may be considered. For transportation operators, however, CPAP is the only nonsurgical therapy for which the effectiveness of treatment and compliance can be objectively monitored. All employees in safety-sensitive positions (including transportation operators who receive surgical treatment) should undergo follow-up PSG to document improvement.

For safety-sensitive workers, once CPAP is instituted, compliance should be documented for at least 2 to 4 weeks and then reassessed at least yearly. Compliance is based on objective measures using data downloads or printouts from the CPAP device. Most practitioners regard minimum adequate compliance to consist of at least 4 hours of CPAP use per sleep period (or nightly) on at least 70% of nights.[48]

Adjunctive treatment with prescription stimulants for residual excessive daytime sleepiness in safety-sensitive workers should be undertaken only after consultation with the company medical director and after review of applicable federal rules. Failure to successfully respond to CPAP therapy should be a red flag regarding overall fitness for duty (particularly among transportation operators). Furthermore, some federal agencies may prohibit stimulant use or advise caution (see further on).

FEDERAL REGULATIONS AND RECOMMENDATIONS

Transportation operators with known diagnoses of OSA generally should be disqualified when their condition is untreated. However, despite various calls from the National Transportation Safety Board (NTSB), expert panels, and other bodies, regulating agencies under the Department of Transportation do not contain explicit objective requirements for OSA screening. Selected relevant regulations and recommendations are summarized in Table 79-2.

In April 2012, the FMCSA published a request for public comments on its proposed recommendations on regulatory guidance for diagnosis and management of obstructive sleep apnea.[57] The proposed guidance was based on MRB recommendations, as reviewed previously. A final ruling is still pending—and subsequent legislation forbids the FMCSA from using guidance alone to mandate sleep apnea screening for drivers before formal federal rulemaking.[58] On the other hand, since May 2014, medical examiners (i.e., CDMEs) providing screening examinations must belong to a Federal Registry of Certified Medical Examiners, which requires meeting certain licensing, continuing education, and testing requirements. Previously, such screening could be conducted by almost any health care practitioner, and these assessments often were performed by providers with little knowledge of occupational medicine, sleep disorders, and fitness for driving.[59] It is now expected that more drivers will be subject to examinations conducted in a stringent manner by persons with training in objective OSA screening as part of their practice standards.

The Federal Aviation Administration (FAA) regulates pilots and air traffic controllers. Pilots who are identified by an aviation medical examiner as being at risk for OSA are granted a medical certificate but are then required to undergo OSA evaluation within 90 days.[60] Examiners may reissue an airman medical certificate under the provisions of an Authorization, if the applicant provides the following: a current report (performed within the last 90 days) from the treating physician that references the present treatment, whether the treatment has eliminated any symptoms—with specific comments regarding daytime sleepiness. If any question arises regarding response to or compliance with treatment or if the applicant has developed some associated illness (e.g., right-sided heart failure), then examiners must defer to the Aerospace Medical Certification Division or the Regional Flight Surgeon.[61]

For the U.S. Coast Guard, the Mariner Medical Standards apply for OSA screening. No objective screening criteria are required or recommended, but the mariner is asked to disclose voluntarily an OSA diagnosis, if present.[62] To be considered for a waiver for sleep disorders, the mariner must demonstrate compliance with and efficacy of OSA treatment. In the case of OSA treatment with dental devices or positional therapy, the mariner must undergo PSG while using a dental device or positional therapy to demonstrate efficacy. If the condition was treated with surgery, then a postoperative sleep study is requested to document resolution of the condition. Once the initial information has been reviewed and a determination made that a mariner qualifies for a sleep disorder waiver, then the mariner is required to submit to periodic evaluations that include compliance information.[62]

The Federal Railroad Administration does not have any specific regulations regarding OSA; however, it has issued a safety advisory, which is summarized in Table 79-2.[63]

The FAA disqualifies pilots using prescription stimulants.[64] The FMCSA does not disqualify drivers using modafinil but advises monitoring and other precautions.[65] The U.S. Coast Guard Mariner Medical Standards do not routinely allow use of stimulants for OSA treatment, and waivers are granted on a case-by case-basis.[62]

RISK FACTOR REDUCTION

Beyond screening, diagnosis, and treatment of OSA in the workplace, other risk factor reduction measures can further mitigate OSA-related sleepiness and its consequences (see also the earlier discussion of FRMSs).

Because obesity is a primary risk factor for OSA, effective employee fitness and wellness programs can produce a return on investment for the transportation industry. Such programs fall within the realm of productivity and health management, where employee health and employer costs are viewed from a holistic perspective—with the ultimate goal of reducing costs by improving health.

Shift work is another risk factor for accidents (see Chapter 75), and shift work is likely to produce synergistic impairment with OSA. Therefore we do not recommend rotating shifts or night shift driving or night operations for OSA-affected employees even when they are compliant with CPAP treatment. This is particularly true for OSA-affected transportation operators.[40]

When possible, the work environment can be modified to allow for short but frequent breaks and strategically timed

Table 79-2 Summary of Selected Federal Regulations* or Recommendations for Medical Examiners Regarding Obstructive Sleep Apnea (OSA)

Federal Agency	Regulation/Recommendation	Required/Recommended Reporting Specifically Related to OSA	BMI Threshold for PSG Referral
FMCSA	*Regulation(s)*: No established medical history or clinical diagnosis of respiratory or neurologic dysfunction likely to interfere with the ability to control and drive a commercial motor vehicle safely[a]	*Required*: "Do you have sleep disorders, pauses in breathing while asleep, daytime sleepiness, loud snoring?"[b]	*Required*: None
FRA	*Regulation(s)*: With the exception of examinations and minimum standards for vision and hearing, U.S. commercial railroad companies have discretion as to the content, frequency and extent of their medical screening programs.[c] *Recommended*: That railroads and representatives of employees working together, develop and implement policies such that, "when a railroad becomes aware that an employee in a safety sensitive position has an incapacitating or performance-impairing medical condition related to sleep, the railroad prohibits that employee from performing any safety-sensitive duties until that medical condition appropriately responds to treatment."[d]	*Required*: None *Recommended*: That "employees' medical examinations include assessment and screening for possible sleep disorders and other associated medical conditions"[d]	*Required*: None
FAA	*Regulation(s)*: Untreated OSA is a disqualifying medical condition. "If a pilot is diagnosed with OSA, an AME must submit all pertinent medical information and a current status report, a sleep study with a polysomnogram, and use of medications and titration study results to the FAA. The FAA will then decide if a special issuance medial certificate is appropriate."[f]	*Required*: None	*Recommended*: BMI >40 (high BMI not disqualifying by itself)[e]
U.S. Coast Guard	*Regulation(s)*: "Are of sound health; have no physical limitations that would hinder or prevent performance of duties; and are free from any medical conditions that pose a risk of sudden incapacitation, which would affect operating, or working on vessels."[g]	*Required*: None— relies on self-disclosure of a sleep apnea diagnosis[h]	*Required*: None
NTSB	*Recommended*: Elicit preexisting diagnoses of OSA; screen for OSA risk factors; and ensure operators with sleep apnea are effectively treated before granting unrestricted medical certification.[i]	*Recommended*: Develop standard medical examination forms to elicit diagnoses of sleep disorders and to screen for sleep disorders; require use of these forms[j]	*Recommended*: Not specified

naps. As reviewed in Chapter 75, naps decrease subjective fatigue and improve objective alertness and performance.

CLINICAL PEARLS

- Employees in safety-sensitive positions (e.g., truck drivers, pilots, mariners) may specifically deny or underreport symptoms to avoid incurring an OSA diagnosis because of its potential negative economic and occupational consequences.
- Screening for OSA should include BMI, neck circumference, and other easily obtained objective criteria. Negative subjective symptom reports should be considered unreliable. A more probing interview performed by an experienced physician to obtain critical information often is required.
- Monitoring with portable devices can be used to confirm the presence of OSA so that appropriate treatment can be initiated. Negative or inconclusive PM-based findings warrant a follow-up evaluation with full in-laboratory PSG, particularly for high-risk employees working in safety-sensitive positions.
- CPAP remains the first-line treatment for OSA, and minimum adequate compliance consists of at least 4 hours of CPAP use per sleep period on at least 70% of nights.

SUMMARY

OSA is common in the workplace and often goes undiagnosed and thus untreated, with negative consequences for health, safety, and productivity. Transportation accidents constitute a particular concern. Sleep and occupational medicine professionals are likely to encounter a number of patients in several workplace referral scenarios that trigger evaluation for possible OSA, including falling asleep at work, on-the-job accidents, and screening or diagnostic assessment for safety-sensitive positions (especially in transportation). Because employees may be reluctant to disclose OSA-related symptoms, clinicians cannot depend on symptom reports for screening or diagnosis and must rely primarily on objective measures, tests, and demonstration of treatment compliance. Screening can be accomplished objectively through use of BMI and neck circumference, for which thresholds can be set for referring employees to a sleep medicine specialist.

Insomnia

Chapter 80

Insomnia: Recent Developments and Future Directions

Daniel J. Buysse; Allison G. Harvey

Chapter Highlights

- Recent revisions of widely used classification systems now include one broad insomnia diagnosis category to cover most adult and child insomnias. In the *International Classification of Sleep Disorder,* third edition, this is termed chronic insomnia disorder, and in the *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition, it is insomnia disorder.
- Both classification systems include the specification of 3 months as the duration criterion for insomnia disorder and the specification of 3 times per week as a minimum frequency.
- There is now strong evidence supporting the relationship between insomnia and subsequent development of depression.
- The "insomnia with short sleep" phenotype is associated with hypertension, diabetes, neurobehavioral performance impairments, and mortality risk.
- Cognitive behavior therapy for insomnia and related techniques may be useful for a broader range of patients, including those with comorbid psychiatric conditions such as depression, bipolar disorder, posttraumatic stress disorder, and schizophrenia.

Insomnia is the most common sleep disorder, but not the most commonly addressed in research studies or in the development of clinical practice models. Although the manifestations and immediate consequences of insomnia are perhaps less dramatic than those of several other sleep disorders, accumulating evidence demonstrates the adverse effects of insomnia on long-term health, functioning, and productivity, as well as their associated health care costs. Important developments have occurred in the diagnosis and assessment of insomnia, understanding its long-term clinical consequences, identification of important physiologic features, and strategies for both psychological-behavioral and pharmacologic management. These new developments are addressed in each of the chapters in this section. Here, we highlight some of the most important new developments in insomnia research and clinical practice and outline several areas for future investigation.

DIAGNOSIS AND ASSESSMENT

Two new classifications for sleep disorders have been published, the *International Classification of Sleep Disorders*, third edition (ICSD3),[1] and the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5).[2] As discussed in Chapter 83, both classifications have changed not only the specific diagnostic criteria for insomnia but also its very conceptualization. Fortunately for clinicians, the two systems are consistent with each other, which will enhance the clinical utility and clarity of each system. The most important change embraced in each classification is the specification of one broad insomnia diagnosis category to cover most adult and child insomnias. In ICSD3 this is termed chronic insomnia disorder, and in DSM-5, insomnia disorder. ICSD3 also includes a specific category of short-term insomnia disorder, which is included as a subtype of insomnia disorder in DSM-5. These categories replace the previous distinction between "primary" insomnia and "secondary" insomnia diagnoses, recognizing the fact that it is often impossible to reliably determine directionality or causality between insomnia and comorbid conditions.[3,4] Previous editions of the ICSD included subtypes of "primary" insomnia," such as psychophysiological, idiopathic, and paradoxical insomnia; ICSD3 collapses these subtypes into a single diagnosis, given poor reliability and discriminant validity of these subtypes.[5,6] Importantly, the insomnia diagnoses in ICSD3 and DSM-5 apply to both children and adults, which has advantages for billing and coding of pediatric insomnia in clinical practice. Other important changes in ICSD3 and DSM-5 include the specification of 3 months as the duration criterion for insomnia disorder, the specification of 3 times per week as a minimum frequency, and the elimination of nonrestorative sleep as a sufficient symptom for the diagnosis of insomnia. Nonrestorative sleep, although a common symptom in patients with insomnia, infrequently occurs without sleep initiation or sleep maintenance difficulties, and it also occurs in many other sleep disorders.[7] Taken together, these changes may enhance the reliability of insomnia diagnoses and make it easier to diagnose insomnia across a wide range of medical and health care settings. The shift to a single broad diagnosis need not stifle research into potential phenotypes or subtypes, but it does prevent the promulgation of subtypes with inadequate reliability and validity.

CONSEQUENCES OF INSOMNIA

New epidemiologic studies have provided additional evidence for adverse health and functional consequences of insomnia. Numerous individual studies and an influential meta-analysis have demonstrated the relationship between insomnia and subsequent development of depression.[8] In addition, longitudinal studies have demonstrated a relationship between insomnia and incident cardiovascular disease and even mortality.[9] As discussed by Hall, Vgontzas, and colleagues, several studies have also demonstrated that the adverse health correlates of insomnia may interact with those of short objective sleep duration. This "insomnia with short sleep" phenotype is associated with hypertension,[10] diabetes,[11] neurobehavioral performance impairments,[12] and mortality risk.[13] These studies need to be replicated in independent samples and with other measures of sleep duration than overnight polysomnography to maximize their utility. However, the identification of a novel insomnia phenotype will surely open the door to further studies of insomnia mechanisms and treatment impact. In a larger sense, studies documenting the health correlates and consequences of insomnia provide support for assessment, diagnosis, and treatment of insomnia across the full range of health care settings.

ETIOLOGY AND PATHOPHYSIOLOGY

Perlis and colleagues provide a scholarly overview of various models of the etiology and pathophysiology of insomnia. Several psychological, behavioral, and cognitive models of insomnia have reached maturity, and their influence on research and clinical practice are evident. However, additional work on the etiology and pathophysiology of insomnia has also addressed other levels of analysis, ranging from genes[14] and specific neurotransmitter molecules[15] to brain morphology,[16,17] functional connectivity,[18] and functional responses to cognitive and affect tasks.[19,20] These studies have been the subject of several recent reviews.[21,21-23] Although published studies have provided tantalizing leads into the neurobiology of insomnia, they often suffer from low power, varying diagnostic criteria and imaging techniques, and lack of replication. Genetic studies have failed to identify specific genes associated with human insomnia, although findings from experimental studies in *Drosophila* species suggest a relationship among insomnia phenotypes, metabolism, and mortality.[24] Epigenetic mechanisms have also been discussed as a mechanism through which genes and environment may interact to produce sleep problems.[23] Current neuroimaging evidence implicates dysfunction in the hippocampus, anterior cingulate cortex, default mode network, and primary sensory networks.[21] These findings may help to explain the relationship between insomnia and affective and cognitive difficulties, as well as subjective-objective sleep discrepancies in insomnia. However, much more work is needed to identify consistent patterns of dysfunction in neural structures and circuits associated with insomnia or vulnerability to insomnia, as well as how such patterns may change with treatment. Such studies could help to develop and refine future treatments and potentially usher in the era of personalized insomnia medicine.

PSYCHOLOGICAL-BEHAVIORAL TREATMENTS

Psychological-behavioral interventions for insomnia have seen the development of new approaches and more aggressive efforts at dissemination of evidence-based treatments, as reviewed by Edinger and colleagues. Morin and colleagues draw our attention to the newer approaches that include the use of mindfulness-based techniques, either singly or in combination with cognitive-behavioral approaches,[25] and the investigation of cognitive therapy as a stand-alone intervention for insomnia.[26] Initial evidence suggests that each of these approaches may be efficacious, although further work is needed to identify which patients respond best to which approach.

Major efforts have been applied to the dissemination of evidence-based treatments for insomnia, mainly cognitive behavior therapy for insomnia (CBT-I). This is a great need and a major challenge given the substantial gap between

treatment development and upscaling for use in routine practice.[27] A national training effort was carried out in the Veterans Administration health system to teach CBT-I to behavioral health providers.[28-30] The impact of this education effort, as well as studies that it might engender, will be investigated for many years. Dissemination may also involve alternate modes of administration, including self-guided Internet-based approaches.[31,32] Several research groups have independently developed online CBT-I programs, which have been evaluated in empiric research studies and made available to the public. Although initial studies demonstrate the efficacy of these approaches, implementation of online CBT-I in actual practice settings may be more challenging and requires further study. For instance, one study identified several groups (e.g., older people, unemployed people) who responded better to a higher intensity therapist-delivered intervention than they did to online CBT-I.[33] Hence research breakthroughs in the anxiety disorders, involving combining computerized delivery of a CBT treatment but assisted by a mental health worker,[34] may be a combination also worth trying for insomnia.

As Edinger and colleagues note, stepped care approaches to the management of insomnia were investigated in early studies in single-payer health systems such as the United Kingdom but require further development and testing in private-public health systems such as those in the United States. Finally, dissemination efforts also include the use of CBT-I and related techniques for a broader range of patients, including those with comorbid psychiatric conditions such as depression, bipolar disorder, posttraumatic stress disorder, and schizophrenia.[35] The results of small initial trials have been promising, and the results of larger studies are now becoming available.

PHARMACOLOGIC TREATMENTS

After a period of intense development efforts by the late 1980s and early 1990s, the development of new pharmacologic agents for the treatment of insomnia has been relatively quiescent. One notable exception, reviewed by Krystal and colleagues, is U.S. Food and Drug Administration (FDA) approval of a first-in-class orexin receptor antagonist, suvorexant.[36] This medication has a novel mechanism of action, antagonizing orexin receptors and inhibiting wake-promoting centers of the hypothalamus and brainstem. Although clinical trials in support of the FDA filing demonstrate the short and long-term efficacy of suvorexant, understanding its role in clinical practice will require further experience. Additional histamine receptor antagonists are also under development, which may provide additional therapeutic options.

The mainstay of pharmacologic treatment remains benzodiazepines and similar drugs that antagonize benzodiazepine receptors. Use of these agents steadily climbed during the 1990s and 2000s. Additional concerns have been raised regarding potential adverse consequences of these agents, ranging from development of dementia[37] to increased mortality risk.[38] As Walsh and colleagues note, epidemiologic studies cannot demonstrate causation, and additional work is needed to understand the mechanism by which benzodiazepines may increase risk, or whether comorbidities and confounders may explain the observed associations.

CLINICAL MANAGEMENT

Additional developments have affected insomnia at the organizational and practice-based level. The American Academy of Sleep Medicine published quality measures for tracking patient care for several sleep disorders, including insomnia, in 2015.[39] The insomnia metrics focus on outcomes of improving sleep quality and satisfaction and daytime functioning and on process measures of assessing sleep quality, daytime function, and treatment-related side effects, as well as the provision of evidence-based treatment. Quality measures serve as a means of promoting appropriate care for patients with insomnia across a wide variety of practice settings. As further evidence accumulates on important outcomes and process measures, the quality metrics can be refined.

Although not directly related to insomnia, the National Sleep Foundation[40] published recommendations for sleep duration across the life span, and the American Academy of Sleep Medicine and the Sleep Research Society are preparing to publish recommendations for the adequate amount of sleep to promote health in adults. These guidelines are an important step in addressing sleep as a public health need. They set the stage for future recommendations that could focus on other aspects of sleep, including sleep timing, regularity, and quality—attributes that are critical to consideration of insomnia.

CHALLENGES AND FUTURE DIRECTIONS

The brief summaries provided previously note some of the challenges confronting future efforts in the research and clinical management of insomnia. Although genetic and imaging studies hold great promise for understanding the etiology and pathogenesis of insomnia, more investigators and research studies are needed, using consistent and convergent approaches. Techniques such as epigenetic and proteomic studies, magnetic resonance spectroscopy, and both resting state and event related functional magnetic resonance imaging will undoubtedly play a role. In addition, studies using high-density electroencephalography and magnetoencephalography may be useful for understanding both regional and temporal sources of dysregulation. In addition to defining broad categories of alterations in insomnia patients, these techniques may also be useful for developing and validating specific phenotypes, such as insomnia with short sleep duration.

Psychological and behavioral treatments are clearly efficacious for insomnia. However, further clarity is needed to define which patients are most likely to benefit from which type of treatment. Treatments of younger age groups and more "real life" patient populations, such as those with multiple medical problems and serious mental illness, are also needed. Cognitive behavioral interventions for insomnia are ready to be incorporated into dissemination, implementation, and patient-centered outcomes research studies. However, few insomnia studies of this sort have been supported by federal research agencies to date. Further effort is needed to understand the role of online treatment modalities and to develop methods to mount and train a workforce, including a variety of practitioners, to act as first-line insomnia therapists. As one successful example of the latter, the Improving Access to Psychological Therapies (IAPT) program trained 3600 new therapists to deliver CBT treatments for anxiety and

depression across the United Kingdom between 2008 and 2011.[41] By 2013 IAPT was treating approximately 400,000 patients each year, nearly half of whom had recovered by the end of treatment and many more of whom benefited.[42] In other words, rapidly mounting and training the required workforce can be achieved with the appropriate funding resources. The funding for IAPT was provided by the United Kingdom government on the basis of an economic analysis that concluded that the costs of providing these treatments would be fully covered by the savings from fewer people with anxiety and depression being unemployed.[43]

Finally, insomnia may benefit from being placed in a broader health context. Healthy People 2020[44] for the first time has sleep-related public health goals, and sleep organizations are actively partnering with the Centers for Disease Control and Prevention on these efforts. The expertise and techniques of insomnia researchers and clinicians may aid such efforts. For instance, addressing issues such as insufficient sleep at the population level would benefit from the accumulated expertise of insomnia researchers and clinicians who have been addressing insomnia from a behavioral health perspective. Using the techniques of behavioral sleep medicine to promote population health provides an exciting and meaningful challenge to the field.

CLINICAL PEARL

Insomnia is comorbid with several important psychiatric disorders. CBT-I and related techniques may be useful for a broader range of patients, including those with comorbid psychiatric conditions such as depression, bipolar disorder, posttraumatic stress disorder, and schizophrenia.

Insomnia: Epidemiology and Risk Factors

Chapter 81

Kenneth L. Lichstein; Daniel J. Taylor; Christina S. McCrae; Megan E. Petrov

Chapter Highlights

- The prevalence of chronic, clinically significant insomnia is about10%, but diagnostic and methodologic inconsistences render a definitive estimate difficult. Moderately frequent insomnia symptoms appear in a much larger percentage of persons. Advancing age, female gender, and low socioeconomic status are strong insomnia correlates.
- Some variant of hyperarousal and psychiatric or medical comorbidity are often associated with insomnia and are therefore deemed risk factors. Precise mechanisms and causal paths with respect to insomnia correlates and risk factors are poorly understood. Transient insomnia and genetic factors may also emerge as important risk factors.
- Insomnia is itself a risk factor for a wide variety of psychological, psychiatric, and medical disorders, including depression, substance abuse, and hypertension.
- The highest priorities for future research are establishing a widely accepted, consistent definition of insomnia, performing longitudinal studies, and cultivating a more comprehensive understanding of insomnia by expanded monitoring of psychological, psychiatric, and medical comorbidity, race, and genetic variables.

Insomnia is the most common sleep disorder and is among the most prevalent of all mental health disorders. However, at the core of the challenge in evaluating the epidemiology of insomnia is demarcating the border between insomnia complaints and clinical insomnia.

Twenty-six percent of people complain of difficulty falling asleep, and 42% complain of difficulty staying asleep at least a few nights a week.[1] These survey results illuminate the potential magnitude of insomnia, but they also serve to caution us that a sleep complaint alone does not necessarily meet formal diagnostic criteria for insomnia.

Numerous factors predict insomnia, and insomnia creates heightened risk for declining health. Although the identification of causal mechanisms remains elusive at this point, there is a robust insomnia risk literature. It should be immediately apparent that complexities impede efforts at clarifying the epidemiology of insomnia and associated risks. This chapter enumerates such obstacles and presents a summary of current knowledge on the epidemiology and risk factors of insomnia.

EPIDEMIOLOGY

Definition of Insomnia

Defining insomnia is a complex task for several reasons. First, insomnia can occur as a symptom, a disorder, or both. Second, insomnia that begins as a symptom of another disorder often evolves over time into an independent disorder. Third, as a disorder, insomnia is heterogeneous, with varying durations, types, and etiologies. Fourth, insomnia severity fluctuates over time. Epidemiology studies of insomnia have too often been secondary analyses of epidemiologic studies in which sleep or insomnia was assessed only with as few as one question, which could be current, past month, or even lifetime history of a sleep complaint. However, the most recent revisions of the *International Classifications of Sleep Disorders*, third edition (ICSD3)[2] and the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5)[3] both specify a sleep complaint that occurs at least three times per week for at least 3 months and is associated with daytime impairment to diagnose insomnia.

Given this complexity, it is not surprising that the literature contains numerous definitions of insomnia, ranging from the broad and inclusive to the narrow and exclusive. For example, some epidemiologic studies have relied on respondents to provide their own definitions by simply asking whether or not they have trouble sleeping,[4] whereas other studies have defined insomnia more narrowly using quantitative severity threshold criteria, such as greater than 30 minutes of sleep-onset latency or wake time after sleep onset.[5] Unfortunately, the study of insomnia has been hampered by such varied definitions of insomnia as evidenced by a review of epidemiologic studies in which prevalence rates in the general population ranged from 4% to 48% depending on the definition used.[6] Efforts to standardize insomnia criteria[7] might prove helpful in the future.

Evaluation

Epidemiologic surveys have traditionally relied on self-report data because large-scale data collection using objective methods (polysomnography [PSG] or actigraphy) is expensive and cumbersome. It may be relevant to note that in most clinical practice settings, routine insomnia assessment does not include PSG or actigraphy. Further, self-report

instruments better capture sleep perception (but are vulnerable to missing other confounding sleep disorders such as sleep apnea) than objective methods, and the subjective view may have greater import for insomnia than objective assessment.[7] A consensus sleep diary is now available,[8] and this should make an important contribution to elevating the quality of self-report sleep data and promoting consistency of such data across studies.

Self-reported accounts of one's sleep experiences are necessarily retrospective in nature. However, the time period over which published studies have asked subjects to provide sleep estimates has varied widely—from 1 year to the previous night.[5] Both recency and saliency effects are likely to contribute to inaccuracies in estimating one's average total sleep time, sleep-onset latency, and other sleep variables over a 1-week period, let alone up to a year. The term *prospective* refers to the future, but when used to compare with retrospective sleep data, prospective sleep data refer to sleep diaries collecting information on sleep from the night just completed and for multiple nights thereafter. This distinction is important because sleep diaries allow researchers to capitalize on the immediacy of retrospective recall.

The heavy reliance on retrospective assessment that requires a patient to average across multiple nights is problematic because of the increased risk for recall errors and unreliability when respondents are asked to provide sleep estimates, and averages, over long periods of time. The recall bias introduced by retrospective estimates may produce overestimates of insomnia symptoms. Indeed, retrospective estimates of total sleep time and number of awakenings are poorly correlated with parallel sleep diary estimates,[9] and PSG sleep variables correlate better with daily sleep diaries than with retrospective reports.[10] Additionally, retrospective estimates can introduce unreliability because single-point estimates may be susceptible to situational influences that are temporary. Momentary emotional states (e.g., work-related stress, depressed mood) tend to influence recall more than do routine experiences. Recency bias can also introduce unreliability because participants can exhibit a tendency to respond based on their previous night's sleep. Another problem plaguing some retrospective studies is the absence of a specified time period of assessment. For example, some studies asked respondents to report how they "usually" or "generally" sleep.

Prospective assessment using at least 1 week of sleep diaries, preferably 2 weeks, avoids or reduces many of the limitations inherent in retrospective assessment.[11] It also allows a richer characterization of sleep because sleep diaries provide detailed quantitative descriptions (e.g., sleep-onset latency, wake time after sleep onset, sleep efficiency) and information on type of insomnia (i.e., onset, maintenance, terminal). At the same time, it is also important to note that the time- and resource-intensive nature of obtaining prospective sleep diary data affects the feasibility of routinely collecting such data. Although prospective assessment is ideal for obtaining the most accurate prevalence estimates, examining insomnia-related items in publically available datasets helps to highlight the need for greater clinical and research focus on insomnia. However, such retrospective data should be interpreted with the knowledge of their limitations and the understanding that the estimates provided, although informative, may also overestimate the level of clinically relevant insomnia.

Table 81-1 Insomnia Prevalence Rates by Four Main Definitional Categories and Three Symptom Categories

Category	Prevalence (%)
Definitional Category	
DSM-IV insomnia diagnosis ($n = 5$)	4–6
Dissatisfaction with sleep quantity or quality ($n = 11$)	8–18
Insomnia symptoms plus daytime consequences ($n = 8$)	9–15
Insomnia symptoms* ($n = 21$)	10–48
Symptom Category	
Insomnia symptoms only	30–48
Insomnia symptoms plus frequency criteria (≥3 nights/week or often/always)	16–21
Insomnia symptoms plus severity criteria (moderately to extremely)	10–28

*Insomnia symptoms included difficulty initiating or maintaining sleep. Some studies also included nonrestorative sleep as a symptom.
DSM-IV, *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition, text revision.
Modified from Ohayon MM. Epidemiology of insomnia: what we know and what we still need to learn. *Sleep Med Rev* 2002;6:97–111.

Prevalence

The methodologic inconsistencies in defining and assessing insomnia have resulted in a wide range of insomnia prevalence estimates for the general population. As shown in Table 81-1, Ohayon reviewed more than 50 studies and found large decreases in prevalence as criteria stringency increased, resulting in rates as high as 48% (using a single symptom) to as low as 4% (using *International Classification of Diseases,* tenth revision [ICD-10] criteria for insomnia).[6] The America Insomnia Survey of more than 10,000 managed health care plan subscribers further highlights the effect that differences in several established classification systems criteria can make on these rates.[12] In that survey, insomnia prevalence varied considerably: 22% (based on DSM-IV-TR[13]), 15% (based on Research Diagnostic Criteria[14]), and 4% (based on ICD-10[15]).

European and Scandinavian findings indicate insomnia prevalence is on the rise. A Norwegian study[16] examined the 10-year trend in insomnia in two separate adult samples (1999 to 2000, $n = 2001$; and 2009 to 2010, $n = 2000$). Controlling for gender, age, socioeconomic status, and region, that study found increases in the prevalence of sleep-onset difficulties (13% to 15%), dissatisfaction with sleep (8% to 14%), and DSM-IV diagnoses (12% to 16%). Similarly, a study of middle-aged Swedish women[17] between 1968-1969 and 2004-2005 found that sleep problems almost doubled over that time period. Interestingly, an English study[18] of more than 20,000 adults revealed only modest increases of already high insomnia prevalence rates over a 15-year period from 1993 (35%) to 2007 (38.6%).

Consistent with most of the epidemiologic literature, these studies were all single-point retrospective estimates. Of the more limited number of studies using prospective assessment,

Lichstein and colleagues[5] collected 2 weeks of sleep diaries and multiple daytime impairment measures from at least 50 men and 50 women in each age decade from 20 to 80+ years. Based on standard diagnostic criteria (ICSD) supplemented by empirically derived quantitative criteria,[19] the overall prevalence of insomnia, weighted by gender and age, was 15.9%. This rate is higher than expected based on the rate decreases seen with increasing methodologic rigor in Ohayon's review but is consistent with the higher rates found by Roth and colleagues.[12]

Comorbidities

Comorbid insomnia is an important topic that is increasingly receiving attention in the epidemiology literature. This is attributable to changes in the conceptualization of insomnia that occurred after a 2005 National Institutes of Health State-of-the Science Consensus Panel[20] recommended that the term *comorbid insomnia* replace the term *secondary insomnia* when insomnia occurs in the context of another disorder (medical or psychiatric), indicating that the insomnia is at least a partially independent and separate disorder. This recommendation was based on a review of the evidence and expert consensus that insomnia initially occurring secondary to another condition often becomes an independent problem or a partially independent problem that shares a reciprocal relationship with the original primary disorder.[21] With comorbid insomnia accounting for 70% to 90% of insomnia in the general population,[22-24] increasing focus on comorbid insomnia in the epidemiology literature is a welcome change.

The most common comorbidities associated with insomnia are psychiatric disorders, including anxiety, depression, panic disorder, adjustment disorder, somatoform disorders, and personality disorders. Epidemiologic studies consistently demonstrate high comorbidity rates for anxiety and mood disorders. In the National Comorbidity Survey—Replication,[25] respondents with mood (45.5%), anxiety (45.6%), or comorbid mood and anxiety (62.8%) disorders were more likely to report insomnia symptoms than those with no mood or anxiety disorder (23.3%). In another study, Taylor and colleagues[26] found that 20% percent of people with insomnia displayed clinically significant depression and 19.3% demonstrated clinically significant anxiety. People with insomnia were 10 times more likely to have depression and 17 times more likely to have anxiety than normal sleepers.

Medical conditions that commonly co-occur with insomnia include arthritis, cancer, hypertension, chronic pain, coronary heart disease, and diabetes. In a cross-sectional study of 9000 persons 55 to 84 years of age, Foley and colleagues[27] found an association between history of insomnia and difficulties with activities of daily living, respiratory symptoms, and other health problems, including hypertension, heart disease, cancer, stroke, diabetes, and hip and other fractures. A 3-year follow-up (n = 6800) revealed that heart disease, stroke, hip fracture, and respiratory symptoms were associated with incident insomnia, meaning new cases of insomnia. Heart disease, diabetes, respiratory symptoms, and stroke were also associated with the maintenance of insomnia.[28] Such findings are not limited to older adults, as studies that have examined adults across the lifespan demonstrate. In a survey of 3161 adults[24] 18 to 79 years of age, those who reported insomnia symptoms were more likely to report having two or more health problems than were normal sleepers.

Table 81-2 Prevalence of Medical Problems in People with or Without Insomnia

Taylor and colleagues[29] focused on prevalence of medical problems in persons with insomnia in the general population. Controlling for anxiety, depression, and symptoms of other sleep disorders, they found that persons with insomnia had a higher prevalence of comorbid medical problems than did persons without insomnia (Table 81-2). Additionally, the adjusted odds of having any chronic medical problem were 5.17 times higher in persons with insomnia than in those without insomnia. From a different perspective, the same study calculated insomnia rates in the same medical disorders (Table 81-3). Insomnia prevalence varied between 44% in people with hypertension and 66.7% in people with neurologic disease, with an overall adjusted odds ratio of 5.26. Another study[30] (n = 3282) of the prevalence of insomnia in persons with self-reported medical diseases revealed similar findings. Controlling for age and gender, the investigators found higher prevalence of insomnia in persons reporting 13 different diseases than in those who did not.

Demographics

Gender

Insomnia is more common in women than in men. Lichstein and colleagues[5] reported prevalence for insomnia by gender derived from their review of 42 epidemiology studies (33 of which reported gender comparisons). Overall, insomnia prevalence was 50% greater in women: 18.2% in women and

Modified from Taylor DJ, Mallory LJ, Lichstein KL, et al. Comorbidity of chronic insomnia with medical problems. *Sleep* 2007;30:213–8.

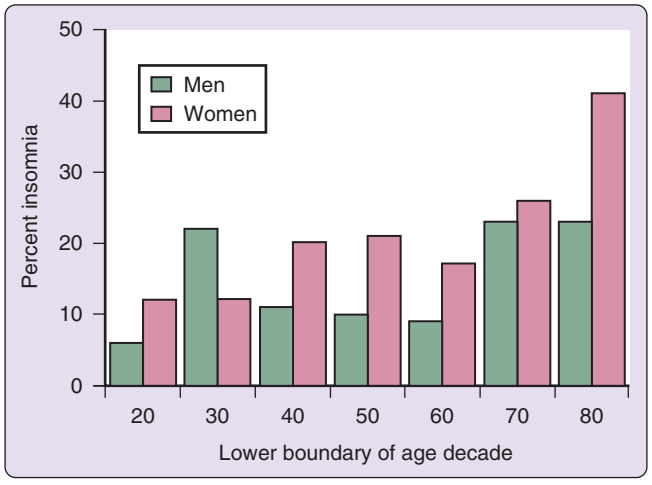

Figure 81-1 Insomnia prevalence by sex and age. Each value on the abscissa represents the beginning of an age decade as in 20 (to 29) and 30 (to 39). (Data from Lichstein KL, Durrence HH, Riedel BW, et al. *Epidemiology of sleep: age, gender, and ethnicity.* Mahwah, NJ: Erlbaum; 2004.)

12.4% in men. Results from the associated prospective epidemiology study further support the overall greater prevalence of insomnia in women (Figure 81-1). There was no reliable difference in the sleep (e.g., sleep-onset latency, total sleep time) of men and women with diagnosed insomnia. This study also provided a decade-by-decade breakdown of insomnia prevalence for women and men. With the exception of the decade 30 to 39 years, women exhibited greater prevalence of insomnia than men across the lifespan. Specifically, insomnia prevalence rates for women ranged from 12% (20 to 29 and 30 to 39 years) to 41% (80+ years). For men, rates ranged from 6% (20 to 29 years) to 23% (70 to 79 and 80+ years). Although prevalence rates are generally higher for women, insomnia may be particularly problematic for men because mortality risk has been associated with insomnia and short sleep duration (<6 hours) in men, but not women.[31]

A meta-analysis[32] examined 29 published epidemiologic studies (n = 1,265,015; female subjects = 718,828, male subjects = 546,187) to estimate sex differences in the risk for insomnia. Women exhibited a higher risk ratio (RR = 1.4) for insomnia than men. Women's risk ratio varied depending on the sample size and strength of methodology of the studies included in the analyses. Specifically, women exhibited a higher risk ratio in larger studies with more rigorous methodology (RR = 1.64) than in smaller, less rigorous studies (RR = 1.32). As in prior results,[5] this female preponderance in the risk for insomnia was evident across elderly (65 years or older), middle-aged (31 to 64 years), and young adult (15 to 30 years) age groups. This risk may begin as young as prepubescence; a study[33] of children (n = 700; 5 to 12 years of age) found that the prevalence of insomnia symptoms (controlling for anxiety and depressive symptoms) was 10% to 14% higher in girls 11 to 12 years compared with boys and younger girls.

Education and Socioeconomic Status

Epidemiologic studies have consistently shown that education and socioeconomic status inversely predict sleep quality.[6] In a study[34] of 159,856 U.S. adults (age 18 years or older), Grandner and colleagues found that the odds of sleep complaints were higher for those who were unemployed compared with those who were employed. Amongst the unemployed, men had a higher likelihood of sleep complaints than women. Gender also affected the education and sleep complaint relationship, such that the association between greater sleep complaints and lower education was stronger in men who did not finish high school.

Another study[35] investigated insomnia and related impairment. Persons with lower individual and household education were significantly more likely to experience insomnia and also reported greater insomnia-related impairment. Importantly, education level was related to insomnia even after controlling for race, gender, and age.

Research on the potential role of childhood economic status on insomnia in adulthood has produced mixed results. Lallukka and colleagues[36] found that economic difficulties in childhood were associated with adult insomnia complaints, but these results failed to replicate in another study[37] by the same research group.

Aging

The prevalence and severity of insomnia increases with advancing age.[5,6,38] Reporting at least one insomnia complaint of varying frequency is common in the United States[27,39] and in other countries,[40,41] with a similar prevalence, about 40%. In studies reporting on separate younger and older samples, average yearly incidence rates of chronic insomnia range from

3.6% to 12.3% in older adults,[41-45] whereas young to middle-aged adults report incidence rates ranging from 2.8% to 4.2%.[46,47] One of the studies was longitudinal[43] and determined that incident insomnia increases with age and nearly doubles in the 75 years and older group. Insomnia also appears to be more persistent with age. The odds ratio of having persistent insomnia increases 1.1-fold each decade of life.[44] Annual persistence rates of insomnia symptoms among older adults range from 15.4% to 22.7%.[41,45]

Researchers and clinicians have debated considerably about whether aging is an independent risk factor for insomnia. Evidence suggests that age, per se, does not inevitably herald the incidence and persistence of insomnia, but rather physical and mental health complications account for the correlation.[48,49] Indeed, consistent predictors of insomnia include mood disorders, poor perceived health, bodily pain, cardiovascular disease, respiratory symptoms, stressful life events, somatic complaints, and memory problems.[41,42,45]

Race

In the last couple of decades, the role of race/ethnicity as an important explanatory factor is a growing topic of interest given that data indicate there are sleep health inequities by ethnic group. For example, one study found that ethnicity may account for 20% of the variance in insomnia among adult women.[50] Most epidemiologic data on race/ethnicity and insomnia have focused on comparing non-Hispanic whites and non-Hispanic blacks. A meta-analysis of 13 studies comparing insomnia symptom prevalence found that whites were more likely to report difficulty maintaining sleep (Hedges g = –0.19; 95% confidence interval [CI] = –0.21, –0.17) and early morning awakenings (Hedges g = –0.07; 95% CI = –0.09, –0.04) than blacks.[51] There was no ethnic difference in difficulty initiating sleep. In the meta-analysis, age and gender were noteworthy moderators. The ethnic differences in insomnia symptoms were attenuated but still significant among samples of older adults. In samples of women, the ethnic difference was reduced for difficulty maintaining sleep, yet larger for early morning awakenings. Studies not included in this meta-analysis suggest that ethnic differences in insomnia symptoms are mixed.[52,53]

These discrepancies in findings may be partly accounted for by study design and insomnia definition differences. It is also possible that the interpretation of questions about sleep varies with ethnicity. Moreover, unexplored moderation by age, gender, and socioeconomic status may also be a factor.[32-35] For example, middle-aged blacks tend to have a higher rate of insomnia symptoms than whites,[17,54] whereas no ethnic differences were found among multiethnic adolescents and young adults.[55,56] Also, black women tend to sleep worse than black men and whites.[27,57]

Available data on ethnic differences in the prevalence of insomnia among other racial/ethnic groups remain minimal. A large, national survey found that blacks, Mexican Americans, and other Hispanic/Latino groups were less likely to report insomnia symptoms than whites.[58] Yet, blacks were more likely to report sleep-onset latencies of longer than 30 minutes. This result indicates that blacks may be at greater risk for insomnia but are likely to deny experiencing symptoms. Asian groups reported comparable likelihood in experiencing insomnia symptoms as whites. Overall, ethnic minority groups appear less likely to report symptoms of insomnia than whites. However, this does not necessarily mean that insomnia is not occurring in these groups, nor does it indicate that these groups are not at increased risk for insomnia, particularly among blacks.

RISK FACTORS

A risk factor is a disorder or characteristic that predicts future poor health status.[59] The behavioral model of insomnia[60] proposes that certain predispositions (i.e., risks) make people more susceptible to developing insomnia. Several studies have also begun to investigate insomnia as a risk factor for the development of other difficulties. Although it is costly and time consuming to collect the data, prospective or longitudinal research designs are the best way to determine risk, assessing presence of a condition or trait of interest (e.g., hyperarousal) before the onset of diseases or events of interest (e.g., insomnia). Cross-sectional and retrospective research designs sometimes purport to assess risk, but these methods are less reliable than the longitudinal studies because of the inability to determine temporal relationships and retrospective bias.[61] One caveat to this statement is where the correlate is a relatively static condition or status (i.e., gender, race, ethnicity, age, genetics).

Next we review primarily prospective studies investigating risk factors for the development of insomnia, as well as the converse, where insomnia serves as a risk factor for the development of other problems and disorders. More static risk factors for insomnia, such as gender and race/ethnicity, were reviewed previously.

Personality

Certain personality characteristics may predispose individuals to insomnia. For instance, cross-sectional studies show that neuroticism, internalization, and perfectionistic traits are associated with insomnia. Unfortunately, very little longitudinal data exist,[62] other than recent studies finding social introversion and low ego strength were predictive of incident insomnia.[63,64]

Hyperarousal

All of the models of insomnia (i.e., physiologic, behavioral, cognitive, and neurocognitive) assume some degree of hyperarousal as a predisposition or risk factor for the onset of insomnia. To date, virtually all of the evidence for this relationship has been cross-sectional.[65] The absence of longitudinal evidence to explicate these associations makes it impossible to delineate causal paths. It is possible that individuals with hyperarousal are predisposed to developing insomnia, but it is also possible that hyperarousal is a downstream effect of having insomnia.

Brief Insomnia Episodes

Although long neglected by researchers, three recent reviews of what is termed *acute* or *transient insomnia* are helping to focus attention on its potential clinical significance as a signal of insomnia predisposition.[66-68] Transient insomnia may be an important risk factor for chronic insomnia as it increasingly becomes independent of precipitating stress triggers and instigates perpetuating factors such as worry about sleep and maladaptive safety behaviors. Methodologic limitations that contaminate the findings on insomnia cited earlier, such as

inconsistent definitions of insomnia and unreliability of retrospective sleep reports, also taint the literature on transient insomnia.

Genetics

Familial Risk

Familial aggregation is a type of statistical analysis in which one determines whether a disorder (i.e., insomnia) occurs more commonly in members of a family than among nonrelated persons. To date, several studies of familial aggregation of insomnia have been reported, using a variety of different methodologies (e.g., adults with insomnia, children with insomnia, no-insomnia controls), definitions of insomnia and insomnia symptoms (e.g., severity scales, DSM-III, DSM-IV), and degree of control for potential confounding factors (e.g., age, gender, work schedules, comorbidities).[69,70] In one of the earliest studies, Hauri and Olmsted[71] found that 55% of adults whose insomnia started in childhood had a family member with insomnia compared with 39% of those whose insomnia started in adulthood, suggesting a stronger genetic predisposition for childhood-onset insomnia. Later studies, using similar methods but with less rigorous definitions of insomnia, have found rates of 20% to 73% of family history,[72-76] with this rate sometimes being higher in mothers than fathers.[72,73,76] In studies in which normal sleeping control groups were used, continued inconsistent results have been found. Rates have varied from 38% to 73% of people with insomnia having a relative with insomnia compared with 23% to 29% of their normal controls.[72,75,77]

Twin Studies

Several twin studies have now reported heritability of a composite insomnia-type syndrome of 28% to 57%.[78-83] A few of these studies also reported results on the frequency of specific insomnia symptoms. The adult studies reported heritability rates of 28% to 32% for sleep-onset difficulties and 33% to 45% for sleep maintenance difficulties.[78,79] The child study was more variable depending on parent (79%) or child (17%) report, both of which were somewhat questionable given the age of the children (8 years old) and the potential biases of parental reporting.[84]

Several research groups have now attempted to take the next step and identify specific genetic mechanisms or polymorphisms that may underlie the risk for developing insomnia or be a perpetuating mechanism. The most commonly studied genes are the period circadian clock gene (i.e., *PER*, *CLOCK*) and serotonin transporter genes (i.e., *5-HTTLPR*).[70] As with other areas of research in the epidemiology and risk domain, results are likely to be contaminated by heterogeneity of diagnostic criteria and insomnia type. Future research would benefit from greater effort to secure subject type purity (e.g., no history of insomnia vs. chronic insomnia).

Psychological and Psychiatric Comorbidities

Examining the risk relationship between insomnia and psychological disorders is complicated. Insomnia is a symptom of many psychological disorders, raising the possibility that these disorders cause insomnia, but there appears to be even more research showing that insomnia is a risk factor for the development of these disorders. This has led some to hypothesize a reciprocal relationship between insomnia and psychological disorders.[85]

Depression

Sleep problems are some of the most prevalent complaints in patients with major depressive disorder, with as many as 84% reporting insomnia versus on average 10% to 30% of the general population.[22,86,87] Several studies have now shown that depression or depressive symptoms increase the risk (odds ratio [OR] = 1.1 to 8.6) of developing insomnia across multiple age groups and populations.[28,44] Interestingly, only 23% to 29% of patients report their insomnia symptoms start after the occurrence of a mood disorder, whereas 41% to 69% report insomnia symptoms started before the depression, and 8% to 29% report they started at the same time.[88,89] A large body of research has established that insomnia is a significant risk factor for depression, as seen in a recent meta-analysis. Insomnia resulted in nearly two times greater risk (OR = 1.10 to 3.51) for developing depression.[90]

Suicide

There is considerable evidence that insomnia is a risk factor for suicide. In a recent meta-analysis, insomnia symptoms were significantly associated with suicidal ideation, attempt, or completion (OR = 1.63 to 2.41) after adjusting for comorbidities.[91] Augmenting the insomnia influence, nightmares[92] and hypnotic use[93] are independent risk factors for suicidality.

Anxiety

Insomnia is also closely associated with anxiety disorders, with as many as 64% of patients with generalized anxiety disorder reporting insomnia symptoms.[94] As many as 44% to 73% of patients report their insomnia symptoms started *after* the occurrence of an anxiety disorder, but only 16% to 18% reported their insomnia started *before* the anxiety.[88,89] Studies indicate that anxiety disorders are a significant risk factor for the development of insomnia in both adults (RR = 1.39 to 4.24) and adolescents (RR = 2.3 to 5.5).[88]

Insomnia is also a risk factor for the development of anxiety disorders. One review of the literature found that people with insomnia are 1.97 to 6.3 times more likely to develop an anxiety disorder than people without insomnia.[85] More recently, Morphy and colleagues[44] found that having insomnia at baseline increased the risk for developing incident anxiety disorders by 1.43 to 3.64 times, after controlling for age, sex, socioeconomic status, and baseline depression and pain.

Posttraumatic Stress Disorder

Approximately 41% to 47% of people with posttraumatic stress disorder (PTSD) report symptoms of insomnia.[95] To date, very few longitudinal studies have examined the relation between insomnia and PTSD. Two recent prospective studies produced similar results. Among Palestinians living amid violent political turmoil[96] and deployed U.S. soldiers,[97] PTSD did not predict insomnia, but insomnia did predict PTSD.

Substance Use and Abuse

One early review found that people with insomnia symptoms at baseline were 2.35 times more likely to develop alcohol abuse or dependence disorders ($d = .02$ to $.05$), and 7.18 times more likely to develop drug abuse or dependence disorders ($d = .07$) than people without insomnia symptoms at baseline.[85] These results were not replicated in a study examining insomnia risk in adolescents for predicting substance use as

young adults, after controlling for the higher report of substance use in adolescents with insomnia than adolescents without insomnia (OR = 1.26 to 2.85).[98] A more recent review found that the insomnia symptom of difficulty falling asleep was a consistent predictor of relapse among persons recovering from alcohol addiction.[99]

Medical Comorbidities

Medical comorbidities are ubiquitous in insomnia. One could argue that even though this is based mostly on cross-sectional data, when insomnia prevalence runs two to four times the population prevalence (see Table 81-3), as is the case in many severe medical conditions, these conditions are likely a risk factor for insomnia. The few longitudinal studies that have investigated medical status have found that medical disorders in general and having greater than one medical disorder are risk factors for the development of insomnia (OR = 1.3 to 3.8).[28,63,64] One study found that baseline kidney/bladder problems and migraines, and to a lesser extent allergy/asthma and anemia, were risk factors for incident insomnia, but these significant results were lost after controlling for baseline mental health.[63] Other prospective studies of cancer patients assessed before curative surgery and 2 to 18 months later showed that 18.6% and 14.4%, respectively, developed new-onset insomnia.[100,101]

Even fewer studies have investigated whether insomnia is a risk factor for the development of medical disorders. This is surprising considering that people with severe insomnia report more medical problems, have more physician office visits, are hospitalized twice as often, and use more medications compared with good sleepers.[102] Also relevant is the experimental demonstration that short sleep increases the risk for catching a cold.[103]

Cardiovascular Disease

Perhaps the most thoroughly researched area of insomnia as a risk factor is cardiovascular disease. Studies of the risk of insomnia on hypertension have been mixed. One study (n = 4913) of subjects stratified by age found that baseline insomnia was predictive of hypertension at follow-up (hazard ratio [HR] = 1.01 to 1.09), and these authors hypothesized that insomnia might mediate the relationship between depression and subsequent hypertension diagnosis.[104] A similar study of 4794 Japanese male workers found that sleep-onset and maintenance insomnia symptoms were significant risk factors for development of hypertension (OR = 1.42 to 2.70 and 1.45 to 2.45, respectively).[105] These results were replicated in an even larger study of 8757 participants without hypertension at baseline, which found that difficulty initiating or maintaining sleep predicted slightly increased risk for hypertension (OR = 1.03 to 1.3).[106] However, another relatively smaller cohort of 1419 older adults (≥64 years old) who were not hypertensive at baseline found that insomnia symptoms did not predict hypertension at follow-up, but instead appeared to be a protective factor in white men.[107]

Studies of cardiovascular disease have more consistently found that insomnia symptoms are risk factors. One study of Taiwanese adults found insomnia frequency, as a proxy for severity, was a significant risk for the development of cardiovascular disease and all-cause death (OR = 1.03 to 3.08 and 1.16 to 2.49, respectively).[108] Another study found that sleep-onset insomnia symptoms were a risk for coronary artery disease death in males (RR = 1.5 to 6.3), but not in females.[109]

In a study of 11,863 participants without cardiovascular disease at baseline, only the combination of three sleep complaints (difficulty initiating and maintaining sleep and awakening fatigue) predicted a slight increase of cardiovascular disease (OR = 1.1 to 2).[106]

The largest study to date followed 52,610 participants over 11.4 years to determine whether insomnia increased the risk for an acute myocardial infarction (AMI) identified at hospitals or by the National Cause of Death Registry. After adjusting for numerous health risk factors, there was a moderately increased risk for AMI for people with difficulties initiating (HR = 1.18 to 1.80) or maintaining (HR = 1.01 to 1.68) sleep almost every night compared with people who never experienced these sleep difficulties.[110]

Stress and Life Events

Models of insomnia commonly assume that high stress is a risk factor for the onset of insomnia, but this area has actually received mixed support. Stressful life events have been shown to be only mildly related to the incidence of insomnia.[111,112] Several studies indicate that reactivity to life events is the more important factor in the development of insomnia.[64,112,113] For example, one study found that baseline arousal predisposition, but not baseline perceived stress, predicted incidence of insomnia at follow-up, after controlling for baseline demographic, psychological, and health factors.[64]

Work

Evidence has been steadily growing on the reciprocal relation between work stress and insomnia. Several studies have now identified work stress as a significant predictor of insomnia. For instance, high work demands increased the risk for developing insomnia.[114] People with insomnia also reported poor self-esteem at work, less job satisfaction, and less efficiency at work compared with good sleepers.[115] In turn, insomnia appears to take a considerable toll on worker quality of life and productivity. Insomnia is a significant risk for absenteeism, lost productivity, and disability.[115-117]

CLINICAL PEARLS

- Methodologic faults, primarily inconsistent definitions of insomnia and single-point sleep assessments, corrupt the epidemiology literature on insomnia.
- Advancing age, female gender, and low socioeconomic status are the strongest correlates of insomnia, although it is premature to infer causal influence. Hyperarousal in its many forms and comorbidity are the most common insomnia risk factors, but the mediator or moderator influences associated with this mechanism are poorly understood, as are causal paths.
- Insomnia is itself a risk factor for medical and psychiatric disorders, including depression, hypertension, and substance abuse.

SUMMARY

The prevalence of chronic, clinically significant insomnia is about 10%, but poor sleep complaints occur in as many as 40% of the population. Attributes such as advanced age, female gender, and low socioeconomic status, as well as hyperarousal and psychiatric or medical comorbidity, are the most frequently observed insomnia risk factors, although causal paths are

poorly understood. Transient insomnia and genetic factors may also emerge as important risk factors. Insomnia is itself a risk factor for a wide variety of psychological, psychiatric, and medical disorders, including depression, substance abuse, and hypertension. The highest priorities for future research are a standard definition of insomnia, longitudinal studies, and more attention to monitoring psychological, psychiatric, and medical comorbidity, race, and genetic variables.

Chapter 82

Etiology and Pathophysiology of Insomnia

Michael Lloyd Perlis; Jason Gordon Ellis; Jacqueline DeMichele Kloss; Dieter Wilhelm Riemann

Chapter Highlights

- Since the 1990s there has been a proliferation of theoretical perspectives on the etiology of insomnia that now includes nine human models. The central concepts for the nine models include the following:
  - Stress-diathesis
  - Stimulus dyscontrol and classical conditioning
  - The interaction of basal arousal and sleep requirement
  - Sleep extension and the mismatch between sleep opportunity and ability
  - Altered sensory and information processing and an attenuation of the normal mesograde amnesia of sleep
  - Appraisal as a determinant of the patient's perception of disease
  - The concept of "the inhibition of sleep-related dearousal" (vs. hyperarousal)
  - The role of attention, intention, and effort
  - The etiologic importance of daytime deficits, selective attending to sleep-related threats, and safety behaviors
  - Chronic insomnia as a hybrid state that occurs in association with local neuronal wakefulness during non–rapid eye movement and rapid eye movement sleep

Until the late 1990s there were only two models regarding the etiology and pathophysiology of insomnia. The relative lack of theoretical perspectives was due to at least three factors. First, the widespread conceptualization of insomnia as owing directly to hyperarousal (levels of physiologic or central nervous system arousal that are sufficiently high as to directly prohibit sleep) may have made it appear that further explanation was not necessary. Second, the long-time characterization of insomnia as a symptom carried with it the clear implication that insomnia was not itself worth modeling as a disorder or disease state. Third, for those inclined toward theory, the acceptance of the behavioral models (i.e., the three-factor model [3P] and the stimulus control model[1,2]) and the treatments that were derived from them might have had the untoward effect of discouraging the development of alternative or elaborative models. Since the 1990s there has been a proliferation of theoretical perspectives on the etiology and pathophysiology of insomnia that includes both human and animal models. In this chapter, nine of the human models are described and critiqued. The models presented span from the classical behavioral perspectives, to the traditionally cognitively focused frameworks, to the more modern cognitive information–processing perspectives, to an interaction paradigm that takes into account basal arousal and sleep requirement, to the neurocognitive and neurobiologic models that essentially frame insomnia, from a functional and neurophysiologic point of view, as a hybrid state (part wake and part non–rapid eye movement [NREM] sleep).

DEFINITION OF INSOMNIA

The *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition (DSM-5)[3] and *International Classification of Sleep Disorders,* third edition (ICSD3[4]) define *insomnia disorder* as difficulty initiating or maintaining sleep on three or more nights per week for at least 3 months. This definition further stipulates that the diagnosis of insomnia must take into account sleep opportunity, level of daytime impairment and distress, whether symptom presentation (in the case of children and elders) varies with caregiver presence, and the possibility that the insomnia is not better explained by (or does not occur exclusively during the course of) other sleep disorders or medical or psychiatric illnesses.

This definition is different from the DSM-IV-TR and the ICSD2 in several important ways. First, the diagnostic terms primary insomnia and secondary insomnia have been replaced to reflect the change that insomnia is now viewed as a disorder, regardless of whether it is comorbid with other disorders. Second, although quantitative values are not given for insomnia severity (i.e., that sleep latencies or wake after sleep onset durations must be greater than some minimum duration to be of clinical significance), insomnia frequency and chronicity are explicitly stated. The frequency criterion is new, and the

chronicity criterion has been changed from 1 month to 3 months. Third, nonrestorative sleep has been removed as a diagnostic criterion for insomnia. Finally, both the DSM-5 and the ICSD3 allow for the identification of insomnia types (different modes of clinical presentation including initial, middle, and late insomnia), but only the ICSD3 specifies insomnia subtypes, including idiopathic, psychophysiologic, and paradoxical insomnia.

MODELS OF INSOMNIA

Nine models of insomnia are critically reviewed in this chapter. Each of the models described and critiqued presents a view of how insomnia develops, becomes chronic, or comes to be self-perpetuating. Basic and experimental models are not reviewed in this chapter. Information about these may be found in the prior edition of this text (fifth edition). The review is organized chronologically. Following the explication of each of the nine models, a discussion is provided regarding the issues that have not been well integrated into existing models, including how dysregulation of normal sleep-wake regulatory processes may contribute to the development, incidence, or severity of chronic insomnia and why it may be that chronic insomnia occurs disproportionately in women and older adults. The final section of the chapter provides an integrative or transtheoretical perspective represented by a parallel process model that attempts to illustrate how all of the models contribute something unique to our understanding of the etiology of insomnia.

Stimulus Control Model (1972)

Basic Description

Stimulus control, as originally described by Bootzin in 1972,[2,5] is based on the behavioral principle that one stimulus may elicit a variety of responses, depending on the conditioning history. A simple conditioning history, wherein a stimulus is always paired with a single behavior, yields a high probability that the stimulus will yield only one response. A complex conditioning history, wherein a stimulus is paired with a variety of behaviors, yields a low probability that the stimulus will elicit only one response. In individuals with insomnia, the normal cues associated with sleep (e.g., bed, bedroom, bedtime) are frequently paired with behaviors other than sleep. For instance, in an effort to cope with insomnia, the patient may spend a large amount of time in the bed and bedroom awake and engaging in behaviors other than sleep. These coping behaviors appear to the patient to be both reasonable (i.e., staying in bed at least permits the patients to get "rest") and reasonably successful (i.e., engaging in alternative behaviors in the bedroom sometimes appears to result in cessation of the insomnia). These practices, however, set the stage for stimulus dyscontrol, that is, reduced probability that sleep-related stimuli will elicit the desired response of sleepiness and sleep. Figure 82-1 provides a schematic representation of stimulus control and stimulus dyscontrol.

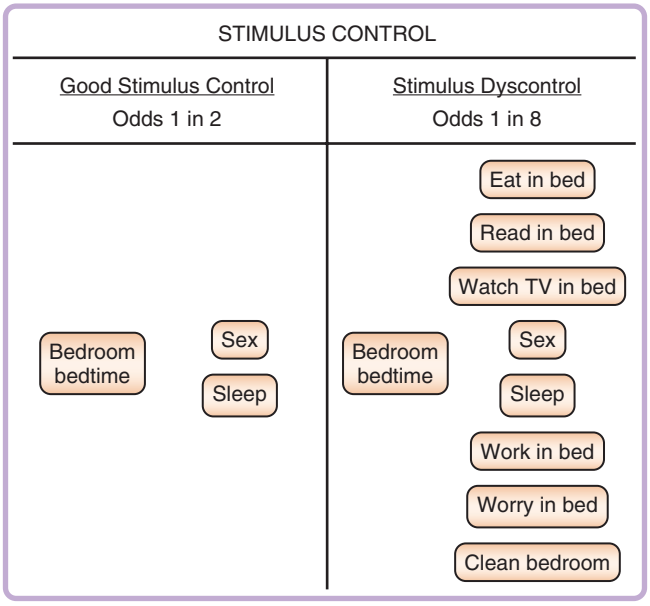

Figure 82-1 The Stimulus Control Model. The schematic represents the instrumental conditioning perspective on stimulus control. In the *left frame* (good stimulus control) the bedroom is tightly coupled with sleep and sex where, given the orthogonality and equal probability of events, the probability of association of bedroom to sleep is 1 in 2. In the right frame (stimulus dyscontrol) the bedroom is no longer a strong associate of sleep and sex where, given the orthogonality and equal probability of events, the probability of association of bedroom to sleep is 1 in 8. The treatment implication of stimulus dyscontrol is that the voluntary elimination (hence instrumental conditioning) of the nonsleep associates except for sex should make it more likely that sleep will occur in the bedroom.

Strengths and Limitations

The treatment derived from stimulus control theory is one of the most widely used behavioral treatments, and its efficacy has been well established.[6-10] The success of the therapy, however, is not sufficient evidence to say that stimulus dyscontrol is responsible for predisposition to, precipitation of, or perpetuation of insomnia.* In fact, one investigation found that the reverse of stimulus control instructions also improved sleep continuity.[11] Another limitation of the stimulus control perspective is that it focuses on instrumental conditioning. That is, there are behaviors that reduce or enhance the probability of the occurrence of sleep. The original model does not explicitly delineate how classical or Pavlovian conditioning may also be an operational factor. Specifically, the regular pairing of the physiology of wakefulness with sleep-related stimuli may lead to sleep-related stimuli becoming conditioned stimuli for wakefulness. This latter possibility, although not part of the classical stimulus control perspective, is clearly consistent with it.

Implications for Current and Future Research and Therapeutics

Given the efficacy of stimulus control therapy, it would be useful to determine how much of the treatment outcomes with cognitive behavior therapy for insomnia (CBT-I) result from the manipulation of this factor. One way to assess the relative importance of stimulus control would be as part of a dismantling study. This alone would not, however, confirm the importance of stimulus dyscontrol as a perpetuating factor. Perhaps what is needed is a dismantling study for stimulus

*The conceptual frame for causality in terms of "predisposition, precipitation, and perpetuation" was first articulated by Spielman as part of the three-factor model. It is used in this context for its general explanatory value.

control itself, given that the treatment contains not only the instruction to limit activities in the bedroom to sleep and sex but also instructions to go to bed only when sleepy, leave the bedroom when awake, get up at the same time every morning irrespective of how much sleep is obtained, and not nap during the day. Any of these components, alone or in combination, may account for the efficacy of stimulus control and may do so through mechanisms other than stimulus dyscontrol, such as sleep homeostasis dysregulation. This is particularly true for the prescription to get up at the same time every morning irrespective of how much sleep is obtained. When patients are compliant with this instruction, it prevents the deleterious effects of excessive time in bed (see Spielman's three-factor model discussed next) and may ensure that sleep loss will prime for better sleep on subsequent nights.[12] In a related vein, the instruction to leave the bedroom when awake may serve as a means of ensuring that patients are fully awake (vs. microsleeping) and thus may also improve sleep through sleep homeostatic or circadian processes.

Three-Factor Model (1987)

Basic Description

This model, alternatively referred to as the Spielman model, 3P model, or behavioral model, delineates how insomnia occurs acutely and how acute insomnia becomes both chronic and self-perpetuating[1] (Figure 82-2). The model is based on the interaction of three factors. The first two factors (predisposing and precipitating factors) represent a stress-diathesis conceptualization of how insomnia comes to be expressed. The third factor (perpetuating factor) represents how behavioral considerations modulate chronicity. Predisposing factors extend across the entire biopsychosocial spectrum. Biologic factors include, for example, the genetic predisposition for insomnia or related etiologic factors, increased basal metabolic rate, hyperreactivity, and fundamental alterations to the neurotransmitter systems associated with sleep and wakefulness. Psychological factors include worry or the tendency to be excessively ruminative. Social factors, although rarely a focus at the theoretical level, include factors such as the bed partner keeping an incompatible sleep schedule or social pressures to sleep according to a nonpreferred sleep schedule (e.g., child rearing). Precipitating factors are acute occurrences that trigger sleep continuity disturbance.[†] The primary "triggers" are thought related to life stress events, including medical and psychiatric illness. Perpetuating factors refer to the behaviors adopted by the individual that are intended to compensate for or cope with sleeplessness, but that actually reinforce the sleep problem. Perpetuating factors include the practice of nonsleep behaviors in the bedroom, staying in bed while awake, and spending excessive amounts of time in bed. Stimulus control speaks to the first two of these (as reviewed earlier). The classic version of the three-factor model focuses primarily on the last of these. Excessive time in bed (or sleep extension) may involve going to bed early, getting out of bed late, and napping as ways of coping with insomnia. Such compensatory behaviors are enacted to increase the opportunity to get more sleep and are likely to be highly self-reinforcing because they allow lost sleep to be "recovered" and the daytime effects of lost sleep to be ameliorated. Extension of sleep opportunity can lead to a mismatch between sleep opportunity and sleep ability.[1,13] The greater the mismatch, the more likely the individual will spend prolonged periods of time awake during the given sleep period, regardless of what factors predisposed to or precipitated the insomnia.

The three-factor model and its graphic representations have periodically been updated by Spielman.[14] As shown in Figure 82-3, one version of the model represents the speed of onset and offset of events in the development of insomnia, and a 4P representation takes into account Pavlovian (classical) conditioning as a perpetuating factor. Classical conditioning refers to the reliable elicitation of specific physiologic responses by what were once neutral stimuli. In the context of insomnia, classical conditioning refers to the elicitation of arousal or wakefulness in response to what were once sleep-related stimuli. This phenomenon corresponds to the common patient report that "it's as if I just walk into the bedroom and I am suddenly wide awake … it's like some switch got flipped from sleepy to wide-awake."

Strengths and Limitations

The three-factor model is conceptually appealing and comports well both with clinical experience and with the two-process model of sleep-wake regulation.[15] The model has good face validity for both patients and clinicians, and the therapy derived from the model (sleep restriction) is efficacious. This said, there have been very few studies evaluating sleep restriction therapy as a monotherapy[16] and no studies evaluating the relative efficacy of sleep restriction therapy as a component of CBT-I (i.e., no dismantling studies). It is therefore difficult to assess the extent to which treatment efficacy supports the model. Further, even if studies could show that sleep restriction therapy accounted for most clinical gains with CBT-I, formal validation of the model would still require a natural history study showing that the transition from acute to chronic insomnia is largely mediated by sleep extension.

Another limitation of the original model is the implication that the predisposition for insomnia varies across individuals

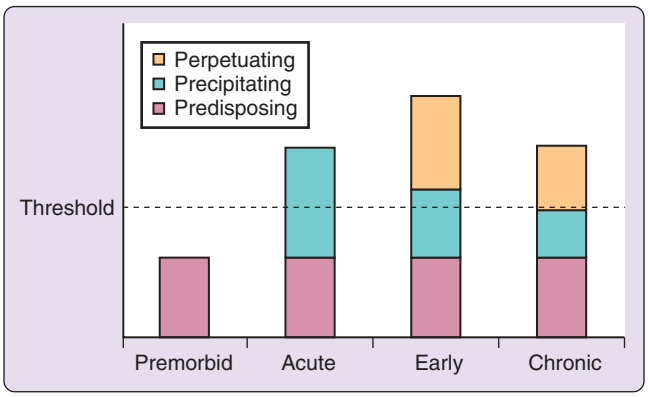

Figure 82-2 The 3P Model. This schematic represents the classic 1987 rendition of the 3P model. There are two more recent representations in Figure 82-3. The reader is encouraged to compare the three versions of the model.

[†]Sleep continuity is meant to denote the class of variables that include sleep latency, number of awakenings, wake after sleep onset, total sleep time, and sleep efficiency (i.e., sleep architecture vs. sleep continuity).

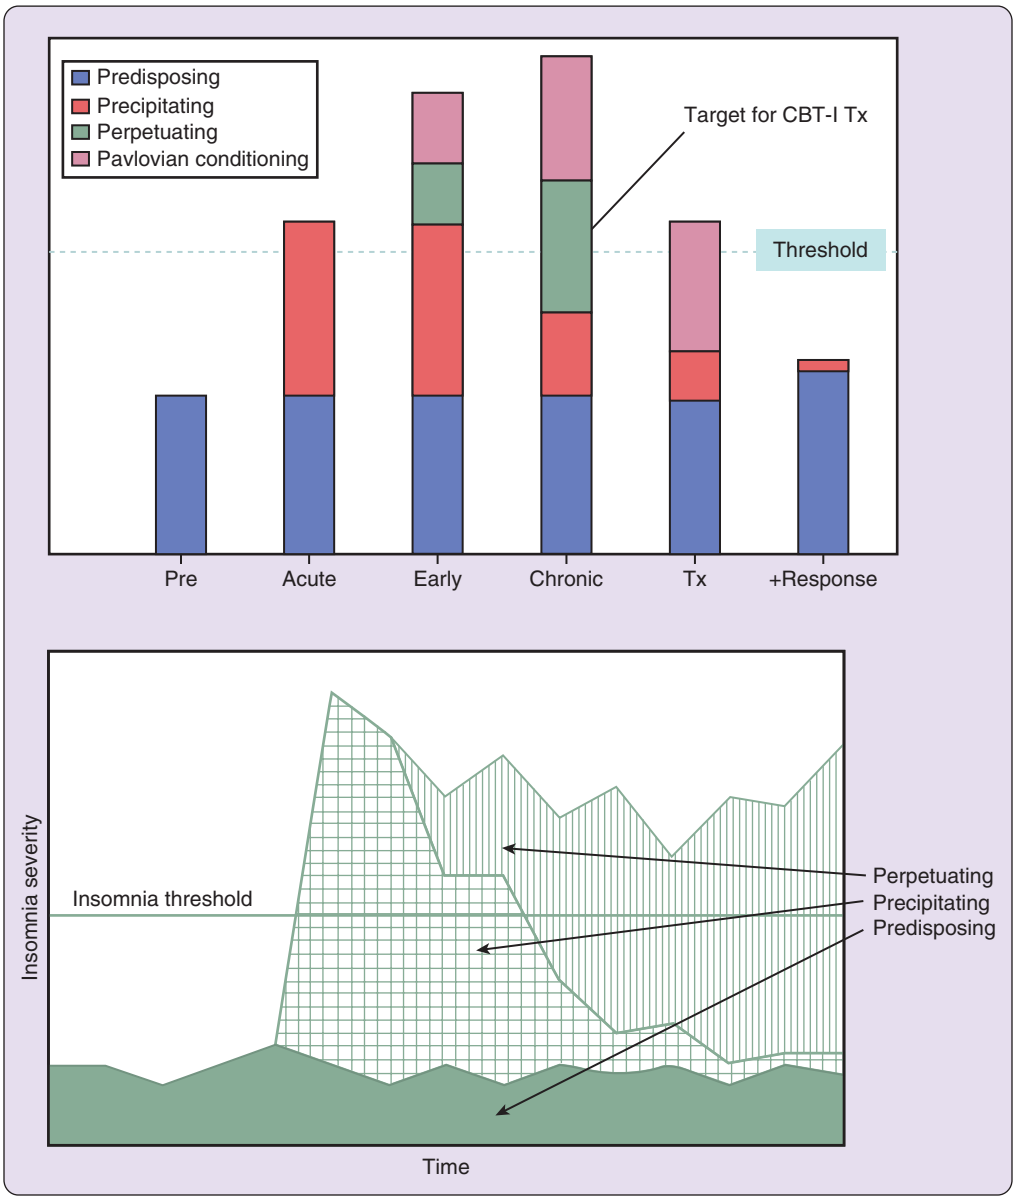

Figure 82-3 The Dynamic 3P and the 4P Models. The dynamic 3P model has the added value (compared with the original model) of illustrating the temporal course of each of the factors. The 4P model has the added value of explicitly incorporating Pavlovian conditioning and how this factor affects the clinical course of insomnia and response to treatment (Tx). CBT-I, Cognitive behavior therapy for insomnia.

but is a trait factor within the individual. With respect to between-subjects variability, presumably this means that some individuals are not prone to insomnia, some are marginally at risk, and still others are at high risk. Although it stands to reason that the vulnerability for insomnia exists on a continuum, it is also plausible that *all individuals* are at risk for insomnia (acute insomnia) and that this may be so to the extent that insomnia represents an adaptive response to stress (i.e., a real or perceived threat, as part of the flight-fight response, triggers a systemic response that overrides the normal homeostatic and circadian imperatives for sleep). Although some predispositions may be indeed be "hard-wired," some predispositions vary over the life span (e.g., new sleep environments or partners, pregnancy or child rearing, altered hormonal status, aging effects, prior insomnia experience). The newer rendition of the Spielman model explicitly allows predisposing factors to vary with time.[14]

Implications for Current and Future Research and Therapeutics

Despite its heuristic and practical value, most tenets of the three-factor model have not been empirically tested. Several avenues for research are possible. Predisposition to insomnia could be, and has recently been, evaluated using molecular and behavioral genetic approaches.[17-20] As a complement to this approach, medical anthropologic studies could be used to assess vulnerability to insomnia at the cultural level (e.g., industrial vs. nonindustrial societies). The precipitation of insomnia, while evaluated with stress induction studies in good sleepers,[21] has not been studied prospectively to

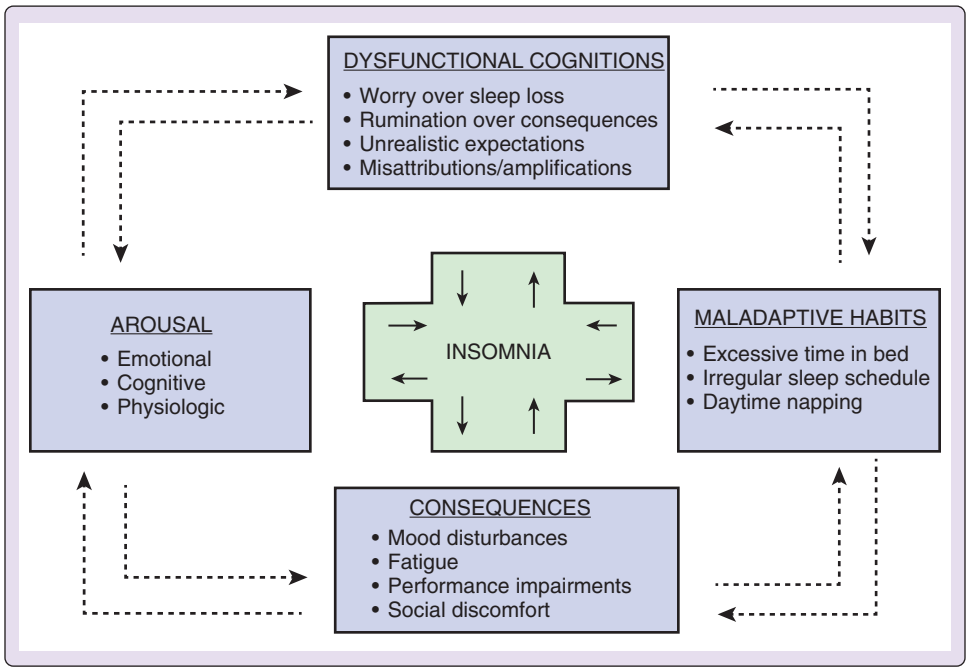

Figure 82-4 The Microanalytic Model. As noted in text, this is primarily a state model that focuses on how insomnia may be self-perpetuating. Note that arousal is arrayed as occurring within three domains: emotional, cognitive, and physiologic.

determine what events reliably trigger acute insomnia. Finally, as noted earlier, natural history studies (with high temporal resolution) are now assessing whether the putative perpetuating factor of sleep extension does indeed mediate the transition from acute to chronic insomnia.

The three-factor model has served as the conceptual basis for one treatment modality in particular: sleep restriction. This therapy, although believed by many to be the single most potent component of CBT-I, was developed to target one particular perpetuating factor, sleep extension. In multicomponent CBT-I, other treatment components may address other perpetuating factors (e.g., stimulus control addresses the engagement of nonsleep behaviors in the bedroom and the tendency to remain in bed when awake; cognitive therapy addresses the problem of catastrophic or dysfunctional thinking about insomnia; sleep hygiene addresses the misuse of counterfatigue measures). The three-factor model may also help to identify alternative treatment targets for insomnia. For instance, this model could help guide the development or adaptation of existing therapies to target predisposing factors. Such treatments could be used to increase treatment response, diminish the risk for recurrence (as an adjuvant to traditional CBT-I), or prophylactically to prevent first episodes of insomnia.

Microanalytic Model (1993)

Basic Description

Morin put forward the microanalytic model in his seminal book, *Insomnia: Psychological Assessment and Management*[22] (Figure 82-4). This model suggests that four bidirectional factors account for the perpetuation of insomnia over time (i.e., how it is that insomnia is self-perpetuating through arousal, dysfunctional cognitions, consequences, and maladaptive habits.) Arousal is conceptualized in terms of emotional, cognitive, and physiologic components. Dysfunctional cognitions are construed in terms of worry, rumination, and unrealistic expectations about sleep and sleep loss. Consequences refer to the negative psychosocial outcomes that occur with insomnia. Maladaptive habits refer to behaviors such as excessive time in bed, irregular sleep-wake schedules, and napping, each of which presumably occurs in relation to the effort to recover lost sleep. Central to this model is the concept that each occurrence of insomnia has consequences, including increased arousal, and results in the engagement of cognitions and behaviors that prolong the index episode or increase the likelihood of additional occurrences of insomnia.

Strengths and Limitations

Major strengths of the microanalytic model are that it posits that insomnia is a self-reinforcing phenomenon that will continue unabated without an adaptive response on the part of the individual or the provision of treatment; construes arousal along multiple dimensions; incorporates the central behavioral concept of excessive time in bed (i.e., the behavioral maladaptation of sleep extension); and implies that adaptive responses or treatment can target any of the four contributory factors. This model, however, is not an etiologic model; that is, it does not delineate how the first episode of acute or chronic insomnia occurs.

Implications for Current and Future Research and Therapeutics

The delineation of the four contributory factors provides a conceptual basis for the assessment of the relative contribution of each to the occurrence and severity of chronic insomnia. To our knowledge, no such study has been conducted on this topic. The clear therapeutic implication of the model is that treatment of insomnia may benefit from adopting a

multicomponent approach. This is appropriate given that the model was introduced as part of a treatment manual (the first of its kind) that delineated a multicomponent treatment approach to insomnia. Given the centrality of dysfunctional cognitions to the model, the form of CBT-I standardized by Morin and colleagues[22] has a cognitive component that is dedicated to the assessment and treatment of dysfunctional beliefs and attitudes about sleep.[23] To date, there is evidence that dysfunctional beliefs and attitudes about sleep vary with treatment outcome with CBT-I[24]; whether monotherapy with this component of CBT-I is effective is not known.

Neurocognitive Model (1997)

Basic Description

The neurocognitive model (Figure 82-5) is based on and is an extension of the 3P and 4P models[25] (see Figure 82-3). The central tenets of neurocognitive model include (1) a pluralistic perspective of hyperarousal (cortical, cognitive, and somatic arousal); (2) the specification that cortical arousal (as opposed to cognitive or somatic arousal) is central to the etiology and pathophysiology of insomnia; (3) the proposition that cortical arousal, in the context of chronic insomnia, occurs as a result of classical conditioning and is permissive of cognitive processes that do not occur with normal sleep; (4) the proposition that sleep initiation and maintenance problems do not occur because of hyperarousal but because of increased sensory and information processing at sleep onset and during NREM sleep; and (5) the suggestion that sleep state misperception derives from increased sensory and information processing during NREM sleep or the attenuation of the normal mesograde amnesia of sleep.

As with the 3P and 4P behavioral models of insomnia, the neurocognitive model posits that acute insomnia occurs in association with predisposing and precipitating factors and that chronic insomnia occurs in association with perpetuating factors. Like the 3P model, chronic insomnia is perpetuated by the instrumental conditioning that occurs with sleep extension. Like the 4P model, the neurocognitive model posits that classical conditioning also serves as a perpetuating factor for chronic insomnia; that is, the repeated pairing of sleep-related stimuli with insomnia-related wakefulness (arousal) ultimately causes sleep-related stimuli to elicit (or maintain) higher than usual levels of cortical arousal at around sleep onset or during the sleep period. This form of arousal is, in the context of chronic insomnia, thought to be independent of somatic arousal; the biological substrate for, and precipitant of, cognitive arousal; and the form of arousal that directly contributes to sleep continuity disturbance and sleep state misperception. In the case of sleep continuity disturbance and sleep state misperception, cortical arousal is not necessarily antithetical to sleep but exerts its deleterious effects through enhanced sensory processing, enhanced information processing, and long-term memory formation.

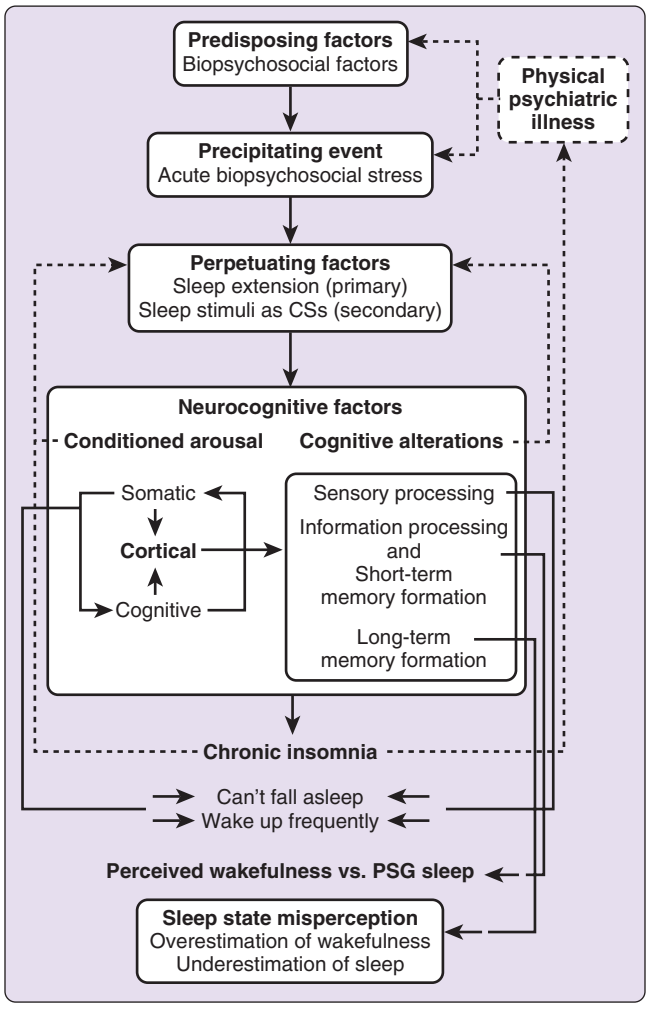

Figure 82-5 The Neurocognitive Model. The schematic is different from prior publications of the neurocognitive model in several ways: (1) *Dotted lines* are provided to highlight feedback loops (*solid lines* represent feed-forward loops). (2) The examples provided for perpetuating factors have been changed. The primary factor is designated as "sleep extension" (previously denoted as increased time in bed and staying awake in bed). The secondary factor is designated as "sleep stimuli as CSs." This is meant to represent when "sleep stimuli" become conditioned stimuli for wakefulness (arousal). The section of the diagram denoted "neurocognitive factors" may well correspond to the "persistence of wakefulness" (when such events occur before sleep onset proper) and the "failure to inhibit wakefulness" (when such events occur during NREM sleep). The latter may correspond to what is characterized by Cano and Saper as a "hybrid state" (not entirely sleep or wakefulness) and may be accounted for by "local neuronal wakefulness" as posited by Buysse and colleagues. PSG, Polysomonography.

Enhanced sensory processing (detection of endogenous or exogenous stimuli and, potentially, the emission of startle or orienting responses) around sleep onset and during NREM sleep is thought to directly interfere with sleep initiation or maintenance.

Enhanced information processing (detection of and discrimination between stimuli and the formation of a short-term memory of the stimulating events) during NREM sleep is thought to blur the perceptual distinction between sleep and wakefulness and thus contribute to sleep state misperception.

Enhanced long-term memory (detection of and discrimination between stimuli and recollection of the stimulating event hours after its occurrence) around sleep onset and during NREM sleep is thought to interfere with the subjective experience of sleep initiation and duration and thus contribute to the discrepancies between subjectively and objectively assessed sleep continuity.

Finally, conditioned cortical arousal is hypothesized to be self-reinforcing and thus, like sleep extension, serves to perpetuate insomnia in the absence of the original precipitants. That is, each time sleep-related stimuli (i.e., the specifics of the sleep environment) elicit cortical arousal, this reinforces the potential of sleep-related stimuli to serve as conditioned stimuli for enhanced sensory and information processing or long-term memory formation.

Strengths and Limitations

In general, the major strengths of the neurocognitive model are that it allows for a pluralistic perspective on the concept of arousal; does not require that hyperarousal be so intense as to directly interfere with sleep initiation and maintenance; delineates a mechanism beyond that of instrumental conditioning (i.e., classical conditioning as a perpetuating factor); specifies how chronic insomnia "takes on a life of its own" (i.e., is self-reinforcing); and is based on hypotheses that are falsifiable.

To date, the evidence for the model derives from observations about patients with insomnia compared with good sleepers exhibiting increased cortical or central nervous system arousal using such measures as quantitative electroencephalography[26-30] and positron emission tomography[31-32]; increased sensory or information processing using such measures as evoked response potentials[33-35]; an attenuation of the normal mesograde amnesia of sleep using such measures as implicit and explicit memory tests for semantic stimuli presented during sleep[36]; and an association between sleep state misperception and objective measures of cortical arousal or evoked response potential abnormalities.[37-39]

The primary limitations of the neurocognitive model are that it does not adequately account for the transition from good sleep to acute insomnia, the importance of circadian and homeostatic influences on sleep, which brain regions or circuits are abnormally activated around sleep onset and during NREM sleep, the likely possibility that abnormal activation may also occur in subcortical regions, and the neurobiologic mechanisms by which insomnia may occur as a hybrid state. Some speculations regarding the functional anatomic substrate of the neurocognitive model have subsequently been published.[40]

Implications for Current and Future Research and Therapeutics

Many of the model's central tenets require further empiric validation. For instance, natural history studies are needed to determine whether the transition from acute insomnia to chronic insomnia is accounted for by sleep extension, and laboratory studies are needed to determine whether neurocognitive processes (sensory and information processing and long-term memory formation) are altered before and during the sleep period in patients with chronic insomnia. Further, it must be shown that altered cognitive processing has clear neurobiologic substrates (e.g., altered metabolic activity in specific brain regions or the occurrence of local neuronal wakefulness) and functional consequences (sleep continuity disturbance and sleep state misperception). In short, novel experimental paradigms need to be developed to test the model's core hypotheses.

The neurocognitive model may provide some insight into the potential mechanisms of action of existing therapies and also some guidance regarding potential targets for new treatments. In the case of existing therapies, pharmacotherapy might be effective to the extent that the various compounds block sensory and information processing or promote amnesia for episodic memories formed during the sleep period. This idea, first espoused by Mendelson,[41-47] seems probable given the effects of benzodiazepines and benzodiazepine receptor agonists on arousal thresholds and memory formation. Sleep restriction therapy might also work through these mechanisms to the extent that this treatment modality serves to deepen sleep, which may augment the endogenous form of sleep-related mesograde amnesia. Potential avenues for new medical treatments include the assessment of compounds that have greater than normal amnestic potential for their efficacy as hypnotics, provided that such effects can be limited to the desired sleep period. Given that this is not possible, potent amnestics may be used experimentally to determine the extent to which amnesia for events occurring during the sleep period influences morning recall about sleep continuity and sleep quality. Alternatively, it may be possible to use stimulants during the day (e.g., modafinil) to promote wake extension and thereby their potential to diminish nocturnal cortical arousal through increased sleep pressure. The latter has been attempted with modafinil alone and in combination with CBT-I. Potential avenues for behavioral treatment include protocols that use more intensive forms of sleep restriction to promote counterconditioning, such as intensive sleep retraining therapy.[48]

Two-Factor Model (1997)

Basic Description

Bonnet and Arand propose a two-factor model to account for the incidence of insomnia and hypersomnia[49] (Figure 82-6). As described by the authors,

> *… each individual has his own sleep requirement determined by his sleep system and each individual has a basal level of arousal determined by his arousal system. Sleep deprivation will eventually override the arousal system, but the arousal system can also mask the sleep system. By thinking of these systems as relatively independent, one can dichotomize their effects. (p. 99)*

High basal arousal and a short sleep requirement are posited to account for idiopathic or psychophysiologic insomnia. Psychophysiologic insomnia occurs when the individual attempts to sleep when sleep is not required and the concurrent high level of basal arousal prohibits the obtention of "optional" sleep. Idiopathic insomnia likely represents the same scenario but as a life-long problem. High basal arousal and a long sleep requirement are posited to account for sleep state misperception (paradoxical insomnia). Presumably, sleep state misperception occurs when individuals sleep "because they can" but the concurrent high level of basal arousal results in shallow sleep, which may be perceived as wakefulness.

Strengths and Limitations

The major strengths of this model are that it has a corresponding program of research that empirically assesses and experimentally models the hyperarousal and sleep continuity disturbance that occurs with insomnia; allows for the distinction between primary insomnia (psychophysiologic insomnia), idiopathic insomnia, and sleep state misperception insomnia

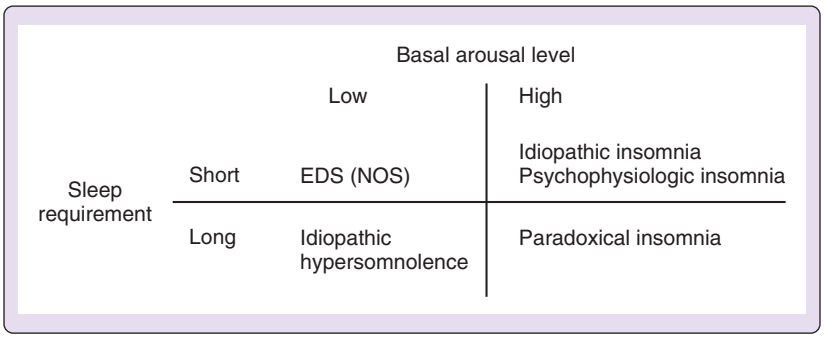

Figure 82-6 The Two-Factor Model. This schematic illustrates how high and low basal arousal and long and short sleep requirement interact to produce six forms of sleep continuity disturbance. EDS, Excessive daytime sleepiness; NOS, not otherwise specified.

(paradoxical insomnia); and takes into account sleep requirement as a moderator of hyperarousal. Programmatic research on this model has included measures of heart rate variability and Vo_2 measures of metabolic rate and experimental studies based on a "yoked insomnia" protocol and a high-dose caffeine paradigm.[50-53] The former provides evidence that patients with primary insomnia do indeed exhibit increased basal metabolic arousal compared with normal controls and patients with sleep state misperception (paradoxical insomnia). The latter provides evidence that many of the symptoms of insomnia can be produced experimentally (i.e., induced hyperarousal or sleep continuity disturbance).

The weaknesses of the model are that it does not directly provide a perspective on the etiology of insomnia (i.e., how basal arousal comes to be or continues to be elevated or how basal arousal varies with time); the concept of sleep requirement appears to combine the concepts of sleep need and sleep ability into a single factor and does not account for the related concept of sleep opportunity (how much sleep individuals attempt to obtain).

Implications for Current and Future Research and Therapeutics

The work related to the definition and measure of arousal has been, and will continue to be, an essential goal for insomnia research. Moving forward, it will be important to determine what type of arousal (e.g., cognitive arousal vs. general metabolic rate vs. global cortical arousal vs. local activation within the central nervous system) and what level of arousal (how much activation) are required to prohibit sleep initiation or maintenance. Further, the delineation of sleep requirement as a potential moderator of insomnia type or subtype will need to be specifically defined, operationalized, and further studied.

The therapeutic implications of the model are clear: arousal and sleep requirement are potential targets for interventions. Currently, basal arousal is targeted pharmacologically with benzodiazepines, benzodiazepine receptor agonists (putatively altering central nervous system arousal through gamma-aminobutyric acid modulation), melatonin agonists (presumably affecting propensity for wakefulness), histamine antagonism (depotentiation of wakefulness), and most recently, with orexin antagonism (depotentiation of wakefulness). Although many directions for research and new therapeutics are possible, one possible direction would be to evaluate the soporific potential of compounds administered at time of bed that attenuate arousal in the periphery (e.g., heart rate) as opposed to within the central nervous system.

Basal arousal is targeted with cognitive behavioral treatments through sleep restriction (diminishes arousal by mild sleep deprivation) and relaxation training. Stimulus control may also serve to diminish basal arousal to the extent that leaving the bedroom and engaging in a nonsleep behavior prevents microsleeps and increases the time awake during the night. This may, in turn, result in mild sleep deprivation and thereby diminish arousal. Newer approaches include the anxiolytic potential of the practice of mindfulness. Currently, there are no therapies that address (modulate) sleep requirement, although CBT-I clearly involves a reset with respect to sleep opportunity and sleep ability.

Sleep Interfering-Interpreting Process Model (2000)

Basic Description

Lundh and Broman propose a two component etiologic model[54] (Figure 82-7). One of the components is identified as sleep interfering and is responsible for arousal and sleep continuity disturbance. The other is identified as sleep interpreting and is responsible for the individual's appraisal of the emergent insomnia (i.e., whether the insomnia is viewed or reported as a problem). The sleep interfering component is represented at two levels of causality.

The first level (distal causation) represents several factors that may lead to or be permissive of hyperarousal. These factors include arousability, stimulus arousal associations, behavioral and cognitive coping strategies, and interpersonal relations. Stimulus arousal associations and behavioral and cognitive strategies are also articulated in other insomnia models, but arousability and interpersonal relations are more novel constructs. Arousability, the magnitude of the individual's tendency to react to and recover from elicited arousal, appears to constitute a predisposing factor for insomnia. Interpersonal relations refer to the potential of social conflict to increase arousal and predispose the individual to insomnia. The second level (proximal causation) is arousal itself, conceptualized in terms of emotional, cognitive, and physiologic activation. These forms of arousal (alone or in combination) are posited to interfere with sleep initiation and maintenance. Finally, the sleep interpreting component is also represented at two levels of causality. The first level includes attributions, perfectionism, and beliefs about sleep and daytime functioning. These factors feed forward and determine the individual's

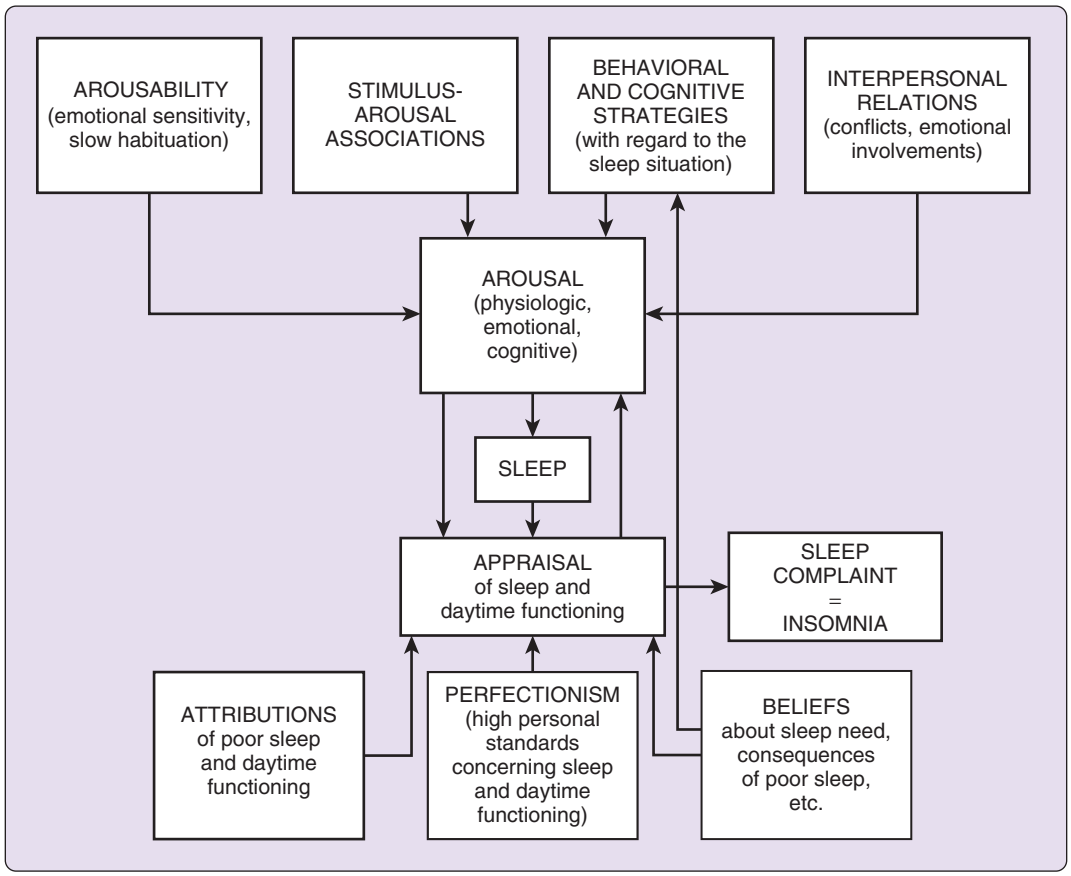

Figure 82-7 Sleep Interfering-Interpreting Process Model. This schematic represents the components of the two factors (sleep interference and sleep interpretation) and how they lead to the physiologic, emotional, and cognitive arousals that impinge on sleep.

appraisal (second level) of whether the insomnia is viewed or reported as a problem.

Strengths and Limitations

The major strengths of the model are that it takes into account the importance of individual factors (arousability and appraisal) and interpersonal relationships as primary triggers for emotional, cognitive, and physiologic arousal. The identification of individual factors appears to be unique to the Lundh and Broman model and is critical because it may explain why, given similar levels of life stress, some develop acute or chronic insomnia, and some do not and why when sleep continuity disturbance occurs, some view the emergent insomnia as a problem whereas others do not. The major limitations of the model are that it does not account for the difference between acute and chronic insomnia and that it assumes that increased arousal necessarily results in sleep continuity disturbance.

Implications for Current and Future Research and Therapeutics

If appraisal and interpretation moderate insomnia severity, these factors may constitute targets for intervention. Morin and colleagues, as part of their formulation of CBT-I, single out at least one aspect of appraisal for assessment and treatment: dysfunctional beliefs and attitudes about sleep.[23] More recently, two additional approaches have been developed to address appraisal and interpretation: behavioral experiments[55] and mindfulness training.[56] Both are likely to influence patients' tolerance of or response to the experience of insomnia or the consequences of insomnia. Empiric studies can evaluate the extent to which each of these approaches produces different outcomes or additive effects when combined with behavioral or pharmacologic interventions.

Psychobiologic Inhibition Model (2002)

Basic Description

The psychobiologic inhibition (PI) model posits that good sleep is ensured by automaticity and plasticity[57,58] (Figure 82-8). Automaticity refers to the involuntary nature of sleep initiation and sleep maintenance, governed by processed such as homeostatic and circadian regulation.[15] Plasticity refers to the ability of the system to accommodate real-world circumstances. Under normal circumstances, sleep occurs passively (without attention, intention, or effort). Within the context of normal sleep, stressful life events precipitate both physiologic and psychological arousal, which can result in inhibition of sleep-related dearousal and the occurrence of selective attending to the life stressors and insomnia symptoms. In acute insomnia, physiologic and psychological arousal interfere with the normal homeostatic and circadian regulation of sleep. Acute insomnia may, in turn, resolve or be perpetuated based on whether the stressor resolves or the individual attends to the insomnia symptoms that occur with the acute insomnia.

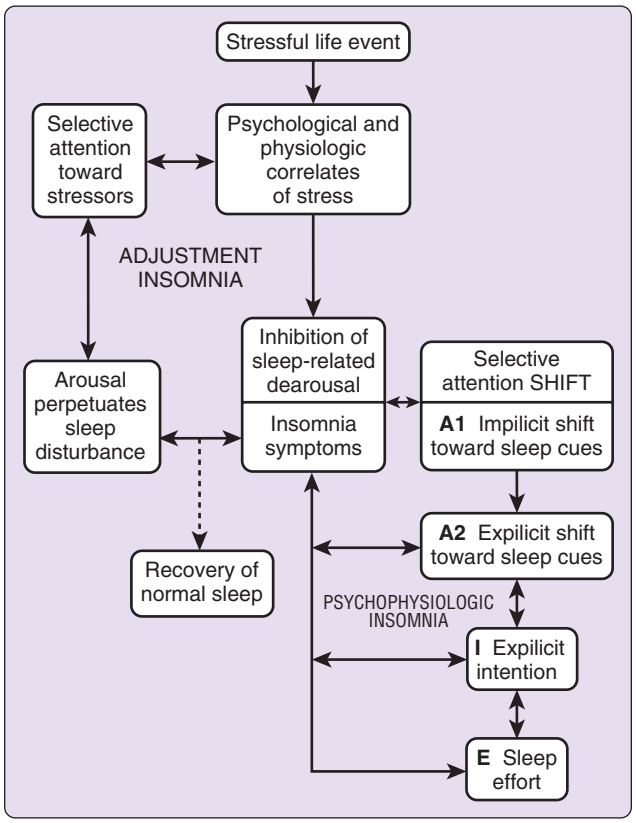

Figure 82-8 The Psychobiologic Inhibition Model. The psychobiologic inhibition model focuses on how insomnia may be perpetuated by (1) the inhibition of sleep-related dearousal and (2) increased sleep-related attention, intention, and effort.

The shift of attention from the life stressor, implicitly or explicitly, to the insomnia symptoms is posited to be the first of three critical events that transition acute insomnia to a form of sleep disturbance that is self-perpetuating. Collectively, the three events (attention, intention, and effort) are referred to as the A-I-E pathway. When individuals are unable to sleep, their attention is drawn to an otherwise automatic process. The very process of attending, in turn, prevents perceptual disengagement and behavioral unresponsiveness (sleep).[59] Because a primary function of attention is to promote action in response to perceived need, an intentional (purposive) process is initiated that acts to further inhibit the normal downregulation of arousal. Finally, the intention to fall asleep triggers sleep effort, and this effort, like enhanced attention and intention, serves only to further inhibit sleep-related dearousal. Ultimately, in chronic insomnia, the inhibition of sleep-related dearousal reflects ongoing or elicited sleep-related attention, intention, and effort.

Strengths and Limitations

Major strengths of the PI model are that it differentiates between acute and chronic insomnia and clearly delineates the mechanisms that are thought to mediate the transition between acute and chronic insomnia. Not only are these mediating variables clearly specified, there is also substantial support for attention bias or selective attention as operational in both in mental illness and insomnia.[60-72] Several studies have assessed the descriptive and predictive utility of the PI model. For instance, sleep-related mental preoccupation appears to be associated with the transition from acute to persistent insomnia in cancer patients.[66] Further, attention bias has been observed in individuals with psychophysiologic insomnia compared with good sleepers and subjects with delayed sleep phase syndrome,[68,69] and sleep-related attentional bias is also associated with self-reported sleep quality and sleepiness.[71] Finally, individuals with psychophysiologic insomnia exhibit effortful preoccupation with sleep.[73]

Another strength of the PI model is that it allows for objective measurement of cognitive processes in insomnia. Insomnia patients commonly complain of mental events interfering with sleep, such as intrusive thoughts, racing thoughts, worry, and inability to disengage from environmental "noise" or bodily sensations. The identification of such mental events relies on self-report. The constructs of the PI model can be operationally defined and tested with objective measures like the computerized emotional Stroop task, the induced-change blindness task, and the dot probe task.

Finally, the PI model poses the novel hypothesis that inhibition of sleep-related dearousal rather than hyperarousal may be responsible for acute and chronic insomnia. In acute insomnia the inhibition of dearousal is engaged by the psychologic and physiologic correlates of stress. In chronic insomnia, the engagement of sleep-related attention, intention, and effort further inhibit dearousal. This shift from hyperarousal as the primary explanatory variable for chronic insomnia to inhibition of sleep-related dearousal represents a potential paradigm shift with regard to the etiology of insomnia.

One limitation of the PI model and the A-I-E pathway is the need for further validation, particularly the intention and effort components. Some conceptual limitations are also present. First, the model focuses on cognitive factors and does account for behavioral mediators or moderators such as sleep extension and stimulus dyscontrol. These factors could be considered forms of sleep effort and thus be accounted for implicitly within the model. This said, explicit inclusion of sleep extension and stimulus dyscontrol would allow the PI model to be more comprehensive and integrative. Second, sleep-related attentional bias tends to be conceptualized as a perpetuating factor, but this factor may also serve as a vulnerability factor for acute or recurrent insomnia.[74] Third, the conceptualization of sleep-related dearousal needs to be explicated in a way that specifically delineates how it is similar to, and different from, the more traditional concept of hyperarousal[75] and the potentially related and alternative concept of the failure to inhibit wakefulness.

Implications for Current and Future Therapeutics and Research

The PI model may help to explain the efficacy of many existing elements of CBT-I and potentially of medical therapies as well. Any behavioral or cognitive intervention that potentiates sleep-related dearousal or promotes the disengagement of attention, intention, and effort should help to restore normal sleep. For example, sleep restriction may help to reinstate sleep automaticity by increasing homeostatic pressure and overcoming the effects of increased attention, intention, or effort. Similarly, stimulus control may strengthen adaptive and automatic bed-sleep dearousal associations. Finally,

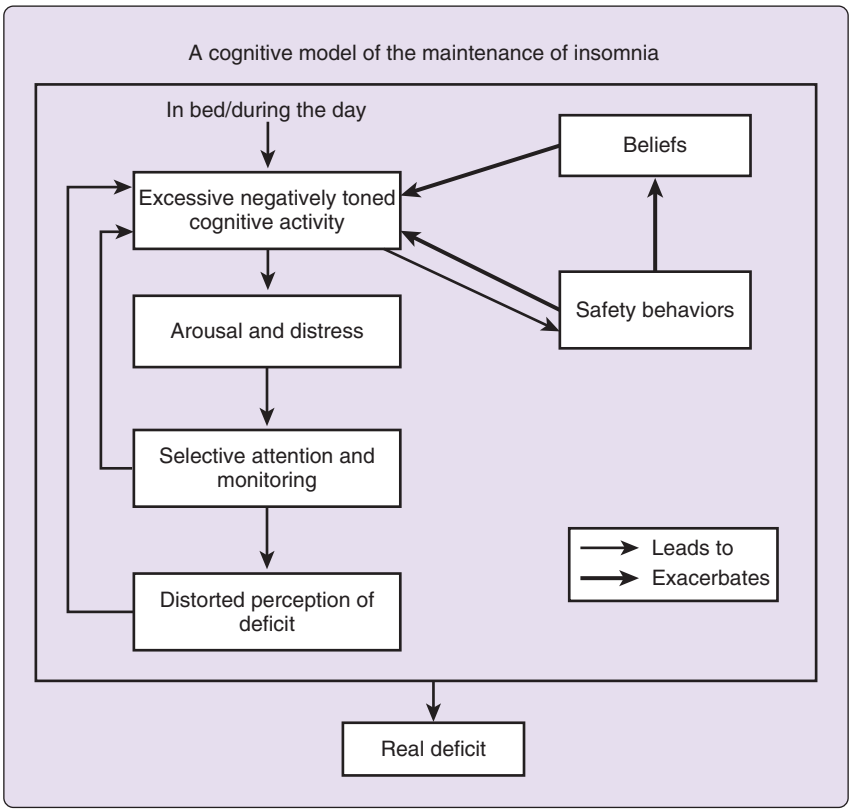

Figure 82-9 **The Cognitive Model.** The cognitive model was originally rendered as a state model that focuses on how insomnia may be perpetuated by (1) selective attention to sleep-related threats and the daytime consequences of insomnia and (2) the engagement of safety behaviors.

relaxation, distraction, and imagery methods may reduce worry about sleep, and paradoxical intention methods may entirely refocus the A-I-E pathway away from sleep preoccupation. The PI model suggests that the mechanisms for existing pharmacotherapies may reside in their capacity to promote relaxation, inhibit exteroception, and reduce sleep-related attention, intention, and effort. Clearly these are features of traditional sedatives (e.g., barbiturates, benzodiazepines, and benzodiazepine receptor agonist therapies). Finally, the model may point to the development of new approaches. For instance, the PI model supports the rationale for sensory gating training and mindfulness therapies. From the pharmacologic point of view, the PI model suggests that it may be productive to antagonize wake-promoting or wake-consolidating systems, for instance, through the modulation of orexin or a histamine.

Cognitive Model (2002)

Basic Description

Harvey's cognitive model adopts a framework that has been applied to anxiety disorders and uses the concepts of selective attention, monitoring, and detection of threat described previously[76] (Figure 82-9). The model posits that in chronic insomnia, sleep-related worry, selective attention and monitoring, and the detection of sleep-related threats perpetuate a level of physiologic arousal that continuously interferes with sleep initiation or sleep maintenance. The transition from acute to chronic occurs when individuals perceive that they have a sleep problem and engage in sleep-related worry, which in turn, prompts them to selectively attend to sleep-related threats and the daytime consequences of insomnia. Enhanced monitoring inevitably results in the increased detection of sleep-related threats and daytime effects of insomnia and the engagement of safety behaviors. Sleep-related worry includes thoughts and ruminations about sleep timing, duration, and quality and the functional and health consequences of sleeplessness. Selective attention to sleep-related threats, including both internal events, such as experiences of alertness or sleepiness, pain or discomfort, and the passage of time, and external events, such as environmental stimuli (e.g., light, sound, temperature) and the passage of time. The detection of sleep-related threats is coupled with the belief that internal sensations or environmental stimuli are interfering with sleep initiation or maintenance. The individual may also detect adverse outcomes during the day (e.g., being late to, missing, or performing badly at work) and attribute them to sleep loss or poor sleep quality. Finally, the engagement of safety behaviors includes both compensatory behaviors (e.g., extending sleep opportunity) and avoidance behaviors (e.g., cancelling social activities) that are intended to mitigate poor sleep and its effects.

Strengths and Limitations

Major strengths of the cognitive model include an explicit focus on the etiologic relevance of the daytime consequences of insomnia, identification of specific factors that perpetuate insomnia (sleep-related worry), and identification of specific mechanisms for how sleep-related worry is perpetuated over

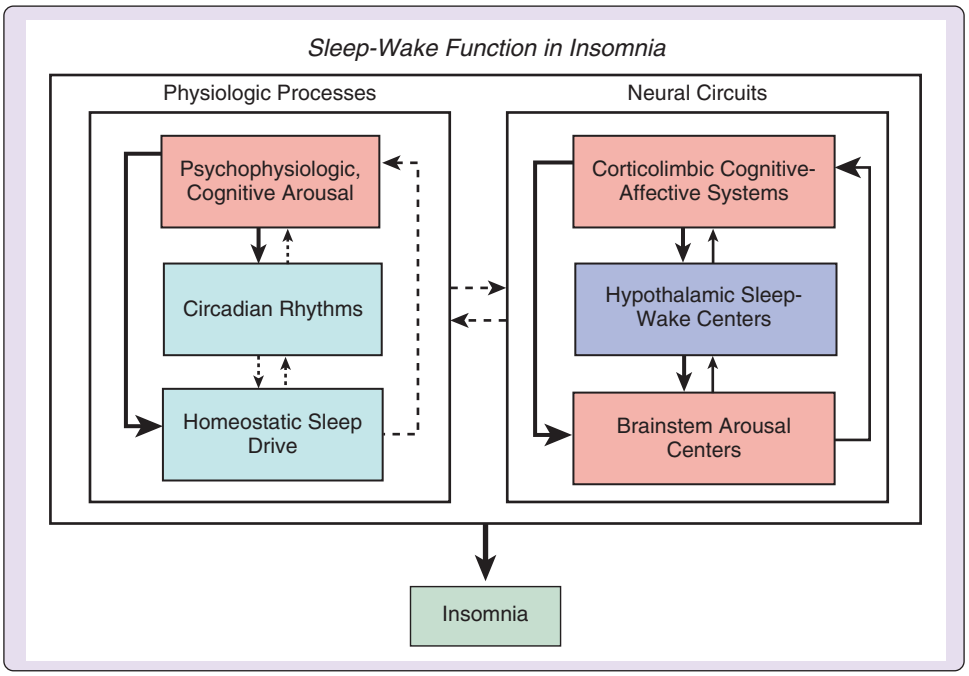

Figure 82-10 The Neurobiologic Model. The neurobiologic model is primarily a state model that focuses on how insomnia may be a hybrid state that has as its neurobiologic substrate "local neuronal wakefulness" during NREM sleep.

time through selective attention and detection of sleep-related threats and consequences. Multiple studies have been conducted on several of the central tenets of the model, including experimental assessments of the relative roles of worry, selective attention, and safety behaviors. For example, experimental manipulations designed to increase worry among good sleepers increase sleep-onset insomnia,[77,78] and experimental manipulations designed to decrease worry in insomnia patients shortened sleep-onset insomnia.[79,80] A range of methodologies, including daily diaries, interviews, questionnaires, and experimental manipulations of monitoring,[81-85] support the prediction that attention to internal and external sleep-related threat is higher among individuals with insomnia relative to good sleepers and contributes to the vicious cycle of insomnia. In addition, one study provided evidence for the predicted association between monitoring and increased negative thoughts and use of safety behaviors at night and during the day. Furthermore, safety behaviors among patients with insomnia have been documented.[86] In addition, one study supported the predicted relationship between unhelpful beliefs about sleep and use of safety behaviors. Specifically, unhelpful beliefs about sleep predicted the use of daily safety behaviors.[86]

Implications for Current and Future Research and Therapeutics

The cognitive model and related empiric work challenge the predominant behavioral perspective on insomnia. The model reasserts the relevance and centrality of cognition as an etiologic factor for insomnia and in so doing suggests that cognitive approaches, long deemphasized in favor of sleep restriction and stimulus control therapies, may deserve further study and clinical use. Several approaches to the management of sleep-related worry have been evaluated, including disputation of dysfunctional beliefs, decatastrophization exercises, mindfulness training to evoke moment-to-moment, nonjudgmental awareness, and behavioral experiments to invalidate worry-related thoughts and beliefs. Dismantling studies could be useful for evaluating the efficacy of cognitive versus behavioral approaches. To date, one such study[87] has been attempted that concluded that, "full CBT is the treatment of choice. Both BT and CT are effective, with a more rapid effect for BT and a delayed action for CT. These different trajectories of changes provide unique insights into the process of behavior change via behavioral versus cognitive routes" (p. 670). Beyond this, the emphasis on centrality of cognition may also provide an insight into the common use of antipsychotics in the management of chronic and severe or treatment-resistant insomnia. Although such treatments may or may not directly alter dysfunctional beliefs, catastrophization, sleep-related worry, or selective attention and monitoring, it remains possible that the sedating effects of these agents (and benzodiazepines and benzodiazepine receptor agonists as well) alter cognition in a manner that contributes to their efficacy.

Neurobiologic Model (2011)

Basic Description

The neurobiologic (NB) model of insomnia primarily focuses on the changes in brain activity and function that may account for insomnia (Figure 82-10). Specifically, Buysse and colleagues[88] posit that insomnia is "a disorder of sleep–wake regulation characterized by persistent wake-like activity in neural structures during NREM sleep, resulting in simultaneous and regionally specific waking and sleeping neuronal activity patterns" (p. 133). Wakelike levels of activity during cortically defined sleep (NREM sleep) are specified as occurring in the prefrontal and parietal cortices, the paralimbic

cortex, the thalamus, and the hypothalamic-brainstem arousal centers. Localized activation within these regions (local wakefulness) during what is otherwise more globally sleep can be expected to be associated with "persistent awareness of the environment" (p. 133). Put differently, coactivation of this sort may directly result in an altered or attenuated capacity to initiate and maintain sleep (hypothalamic-brainstem) but also in abnormal levels of sensory and information processing (thalamus and parietal cortex), emotional processing (paralimbic cortex), and formation of perceptual representations that are evaluated for their appropriateness for action or nonaction (prefrontal cortex) during polysomnographically defined sleep.

Strengths and Limitations

The NB model attempts to be an integrative model that proposes a more specific mechanism for insomnia than provided by the general concept of hyperarousal or the inhibition of "sleep-on" systems. This model defines insomnia as a hybrid state (part sleep and part wakefulness) that occurs with local neuronal variations in sleep depth and may help to explain clinical features of insomnia. The model is informed by the neurocognitive model (described previously), the neuronal transition probability model,[89] the two-process model of normal sleep-wake regulation,[15] and recent findings within neuroscience regarding both the sleep switch[90] and the phenomenon of local neuronal sleep.[91] Further, the NB model echoes the concept of status dissociatus as propounded by Mahowald and Scheck,[92] which suggests that hybrid states of consciousness (coactivations of wake, NREM, and rapid eye movement [REM] sleep) may occur in a variety of the sleep disorders, including narcolepsy, REM sleep behavior disorder, and confusional arousals. The concept of insomnia as a hybrid state was first suggested by Cano and Saper in conceptualizing findings from their rodent model of insomnia.[93]

The proposal that insomnia represents an aberrant state of persistent awareness that occurs as a result of local neuronal wakefulness adds to the existing literature in two ways. First, the model is explicit about what other models only imply: insomnia is, in part, a disorder of persistent wakefulness that may occur globally (objective insomnia) or more locally (subjective insomnia [i.e., sleep state misperception]). Second, the application of the concept of local sleep provides a mechanistic explanation for the proposition that insomnia entails aberrant levels of sensory and information processing or memory formation during the sleep onset period or during sleep. The NB model provides a framework for understanding the phenomena of shallow sleep or sleep state misperception and the paradox that small objective treatment gains are regularly paralleled by larger subjective effects. With respect to paradoxical treatment gains, small treatment-related changes in the polysomnogram may be associated with larger subjective improvements given reduced local waking neural activity in critical regions or circuits, such as the default mode network or the thalamocortical system.

The primary limitation of the NB model is that it is not an etiologic model. It does not focus on how good sleep transitions to insomnia nor on how acute insomnia transitions to the chronic form of the disorder. Like Morin's microanalytic model, the NB model adopts a state perspective. Future elaborations of this model could address how local wakefulness develops and how the functional and physiologic abnormalities that occur with this phenomenon map onto the symptoms of insomnia (difficulties initiating and maintaining sleep).

Implications for Current and Future Research and Therapeutics

Future investigations of the NB model are likely to rely heavily on neuroimaging studies before and during sleep to document regional and circuit-level brain dysregulation in patents with insomnia. Extending such paradigms cross-sectionally and longitudinally could address the transition between acute and chronic insomnia. The therapeutic implications of the NB model are varied and include the exploration of whether present medical and cognitive behavioral approaches minimize or eliminate neuronal local wakefulness. CBT-I may accomplish this by increasing homeostatic pressure for sleep and medical treatment with benzodiazepines, and benzodiazepine receptor agonists may do this through modulation of central nervous system gamma-aminobutyric acid activity. Techniques to increase regional brain activity during wakefulness or to decrease such activity during sleep, such as transcranial magnetic stimulation, may also warrant further study.

LIMITATIONS OF THE EXISTING MODELS

In aggregate, the models presented in this chapter help to explain many of the clinical features and treatment effects commonly observed in chronic insomnia. However, several important aspects of insomnia are not well accounted for.

Most Models Do Not Explicitly Take into Account the Role of Classical Conditioning

Most of the etiologic models do not explicitly address the issue of classical or Pavlovian conditioning, focusing instead on the instrumental side of behavioral processes, that is, on the behaviors that maintain insomnia. Being awake in bed may directly elicit arousal responses or wakefulness through classical conditioning, and such conditioning may contribute to the self-perpetuating nature of insomnia. Classical conditioning as a perpetuating factor can help to explain two reliable findings from the treatment outcome literature. First, CBT-I produces about a 50% reduction in symptoms during the acute treatment phase,[94] which is less than might be expected if only instrumental behavioral factors were responsible for chronic insomnia (see Figure 82-3). Second, patients treated with CBT-I continue to improve over follow-up periods as long as 12 months.[95,96] If only instrumental factors were responsible for chronic insomnia, no additional improvements would be expected beyond the acute treatment phase. From a classical conditioning perspective, successful treatment with CBT-I in the short term may result in counterconditioning over the longer term: Repeated pairing of sleep-related cues with sleep over time may extinguish conditioned arousal.

Most Models Do Not Take into Account Normal Sleep-Wake Sleep Regulation

Although most of the human models of insomnia are compatible with Borbély's two-process model, only the NB and PI models explicitly embrace this perspective on sleep-wake

regulation and how these abnormalities within these systems may serve to predispose, precipitate, or perpetuate insomnia. This is unfortunate because it leaves out the likely possibility that at some point abnormalities within these arenas (process S and process C) contribute to the etiology of insomnia. For example, from the 3P point of view, sleep expansion by retiring to bed earlier likely leads to dysregulation of sleep homeostasis and possibly to a phase advance. Retiring to bed earlier in the evening (while keeping rise time constant or delaying this as well) not only creates a potential mismatch between sleep opportunity and ability but also likely diminishes the homeostatic prime for good sleep continuity and normal sleep architecture and may promote shallow sleep if not local wakefulness. Phase-advancing the sleep period (and the resultant alterations to light exposure and melatonin secretion) may prompt a fundamental shift in all the physiologic parameters that have circadian or ultradian rhythms.

Most Models Do Not Explicitly Differentiate between Acute and Chronic Insomnia

All of the models presented directly or indirectly address how acute insomnia transitions to chronic insomnia or how chronic insomnia is maintained over time. Significantly less attention is paid to what precipitates acute episodes of insomnia, whether acute insomnia is a distinct entity from chronic insomnia, and what may characterize the differences between acute and chronic forms of the disorder.

Within the current nosologies (e.g., the DSM-5[3] and ICSD3[4]), acute and chronic insomnia are defined temporally, with a threshold of 3 months. Individuals who meet all criteria for chronic insomnia except duration are diagnosed with acute insomnia (adjustment insomnia, short-term insomnia disorder, or transient insomnia). It is unclear, however, whether other clinical or physiologic factors distinguish acute and chronic insomnia, such as precipitating and perpetuating factors, symptoms, and polysomnographic features. On a more basic level, it is not clear whether acute insomnia should even be considered a pathologic state. It could be argued that acute insomnia is a normative adaptive phenomenon, part of the fight-or-flight response to threat that overrides the normal homeostatic and circadian imperatives for sleep. Put differently, "it may be the case that we live with insomnia today, because at some point in our evolutionary history insomnia allowed us to live."[97]

Most Models Do Not Account for Gender and Age Differences with Respect to Chronic Insomnia

Women experience insomnia at a rate nearly double that of men,[98-99] and older adults report chronic insomnia at a rate that is approximately three times that of general population,[100] but the reasons for these differences are not well-defined. Although none of the models presented here explicitly address sex or age discrepancies, several of them provide a framework for doing so. For example, within the 3P framework, specific predisposing factors for women may include physiologic and psychosocial concomitants of menstrual cycles, childbirth, and menopause,[101-105] and predisposing factors in older adults may include chronic medical and psychiatric conditions, other sleep disorders, medication effects, and age-related changes in sleep behaviors and physiology (e.g., advanced time to bed, weakened homeostatic sleep drive). Precipitating factors specific to women may again include physiologic and psychosocial aspects of reproductive function, as well as a host of more general interpersonal and social factors; precipitating factors in older adults include acute illnesses, new medications, and psychosocial stressors such as retirement, bereavement, and loss of independence. Finally, although many perpetuating factors may be common across sex and age, worry, rumination, and anxiety are more often exhibited by women,[106,107] which may help explain why acute insomnia occurs with about equal prevalence in men and women[108] but chronic insomnia appears more often in women. Older adults may be particularly vulnerable to increased time in bed as a perpetuating factor.

Most Models Do Not Account for the Types and Subtypes of Insomnia

Most of the models reviewed in this chapter do not account for different clinical presentations such as initial insomnia, middle or late insomnia, or a combination of these symptoms. The models also do not consistently address other phenomena, such as varying degrees of subjective-objective sleep discrepancy or varying age of onset. Finally, most models do not account for differences in clinical presentation that are characterized as idiopathic, psychophysiologic, or paradoxical insomnia. More research is needed to determine whether these states differ with respect to etiology, pathophysiology, or their responsiveness to treatment.

Most Models Posit that Insomnia Occurs in Association with Elevated Arousal or Hyperarousal

At present, no theoretical distinctions have been made (or studies conducted) showing that the hyperarousal of acute insomnia is the same as or different from the hyperarousal that is present with subchronic and chronic insomnia. In the absence of data, it seems reasonable to hypothesize that the arousal (at least somatic hyperarousal) that occurs with the hypothalamic-pituitary axis–related fight-or-flight response far exceeds the arousal that occurs with chronic insomnia. If this is the case, then it follows that the persistent inability to initiate or maintain sleep occurs, in part, as a result of other factors. The NC model focuses on functional changes with respect to perceptual disengagement. The PI focuses on a weakening of the sleep system in terms of the inhibition of sleep-related dearousal. The NB model focuses on the persistent wakelike activity in neural structures during NREM sleep. Taken together, along with basic findings from the Cano-Saper rodent model,[93] this suggests not only that chronic insomnia may be maintained by unique factors but also that chronic insomnia may well be a hybrid state in which there is either a persistence of wakefulness (at sleep onset) or a failure to inhibit wakefulness (following nocturnal awakenings). Moving forward such concepts should be evaluated for how they differ from and interact with the concepts of basal arousal and hyperarousal. Further, these concepts should serve to spur the development of novel interventions.

CONCLUSION

Each of the models presented in this chapter provides a unique perspective, and for the most part, none are mutually exclusive. In recognition of this, we provide in Figure 82-11 an integrative perspective, parallel process model. This model

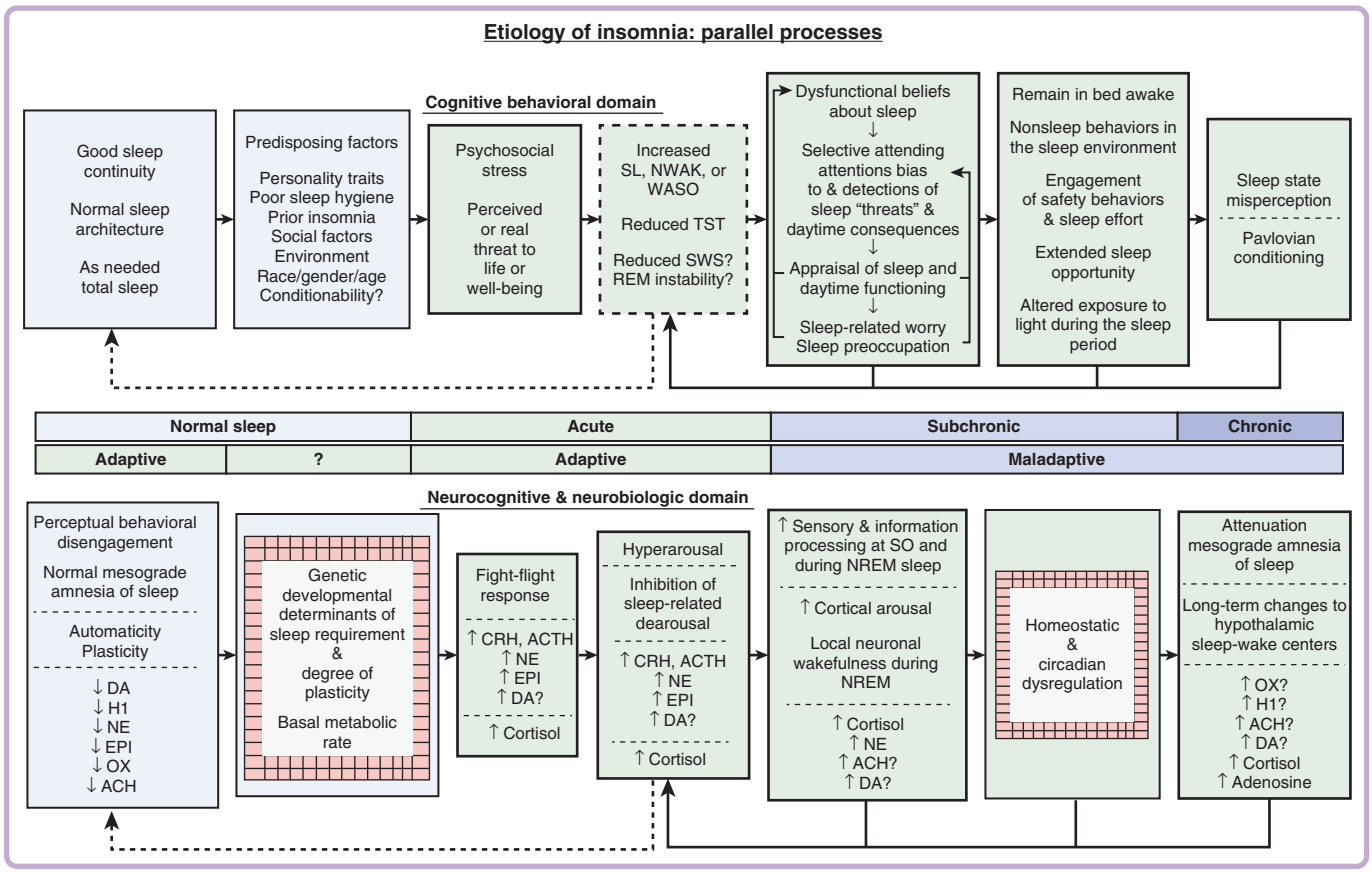

Figure 82-11 The Parallel Process Model. The parallel process model is provided to illustrate how (1) all of the identified factors may be contributory and (2) the cognitive and behavioral domains may be viewed as parallel processes to the neurocognitive and neurobiologic domains. ACH, Acetylcholine; ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; DA, dopamine; EPI, epinephrine; H1, histamine-1 receptor antagonist; NE; norepinephrine; NWAK, number of awakenings; OX, orexin; SL, sleep latency; SO, sleep onset; TST, total sleep time; WASO, wake after sleep onset.

is intended to represent each of the core components from the nine models within one framework, the perspective that the cognitive-behavioral and the neurocognitive-neurobiologic domains represent two sides of the same phenomena, and the possibility that acute insomnia is adaptive. In framing the various factors in this manner we hope to stimulate new ideas for both research and possible interventions.

CLINICAL PEARL

Although many consider theory to be largely an academic enterprise, the models presented in this chapter provide a framework for understanding how insomnia becomes chronic, why the disorder presents as it does, and how or why different treatments may work. Such frameworks, although inevitably imperfect and incomplete, help in the conceptualization of both individual cases and the directions for future research.

SUMMARY

Since the 1990s there has been a proliferation of theoretical perspectives on the etiology of insomnia that now includes nine human models. Each is summarized, reviewed for its strengths and weaknesses, and evaluated for its potential to generate new research and therapeutics. Following the summaries, limitations of the present models are considered and an integrative perspective provided.

Insomnia Diagnosis, Assessment, and Evaluation

Chapter 83

Jason C. Ong; J. Todd Arnedt; Philip R. Gehrman

Chapter Highlights

- This chapter provides an update on the *Diagnostic and Statistical Manual of Mental Disorders (DSM),* fifth edition and *International Classification of Sleep Disorders (ICSD),* third edition diagnostic criteria for insomnia disorders.
- The tools for conducting a clinical assessment of insomnia are described. The essential tools include the clinical interview, sleep diaries, and self-report measures. Optional tools include polysomnography and actigraphy, which are not routinely used but might be indicated to rule out other sleep disorders.
- Considerations for case formulation, assessing treatment progress, and variations in clinical setting are discussed. Also, the potential use of mobile technology is discussed with regard to a need for further research.

This chapter provides an overview of the diagnosis of insomnia disorders and procedures for conducting clinical assessments of insomnia disorders. The first section reviews the diagnosis of insomnia with an update on the current diagnostic criteria. The second section describes the components for conducting a clinical assessment with insomnia patients, including the clinical interview, the use of self-reported measures, and the role of objective measures. The chapter concludes with a discussion on formulating a case conceptualization, assessment of treatment progress, and contextual considerations for conducting the assessment of insomnia.

DIAGNOSIS OF INSOMNIA

At a surface level, the diagnosis of insomnia seems straightforward and can be as simple as self-reported "trouble sleeping." Even if this complaint is expanded to include difficulty falling asleep, difficulty maintaining sleep, or awakening earlier than desired, these symptoms lack specificity and do not sufficiently capture the complexities of the sleep problem or the impact on daytime functioning. The main classification systems of sleep disorders include the *Diagnostic and Statistical Manual of Mental Disorders (DSM)* and the *International Classification of Sleep Disorders (ICSD),* and each iteration of these systems has sought to improve the value of a diagnosis of insomnia based on new research findings. Beyond the sleep-specific symptoms, the first diagnostic consideration is the requirement that an insomnia disorder only exists if there is clinically significant distress or impairment. Each of the diagnostic systems requires some degree of distress or impairment, such as fatigue, irritability, difficulty with concentration or memory, and worry about inadequate sleep that is perceived by the patient to be associated with the sleep disturbance.[1] There are some patients who present with insomnia symptoms but on subsequent clinical interview fail to experience this criterion and thus are not diagnosed with an insomnia disorder.

A second issue in the diagnosis of insomnia that has been more controversial is whether the insomnia is a symptom of another condition or a disorder in its own right.[2] This distinction stems from the fact that a wide range of mental and physical disorders are known to cause insomnia, including chronic pain, depression, and anxiety disorders. Also, approximately 80% of patients with insomnia have one or more comorbidities.[3] Early concepts posited that when insomnia occurs in conjunction with these comorbidities, it is a secondary symptom rather than an independent condition. In the absence of comorbidities the insomnia could be considered to be a primary disorder. This distinction is reflected in the DSM-IV-TR[4] and ICSD2[5] criteria for insomnia. The DSM-IV-TR[4] included diagnoses of Primary Insomnia and several secondary insomnia diagnoses including Insomnia Related to Another Mental Disorder, Substance-Induced Sleep Disorder—Insomnia Type, and Sleep Disorder Due to a General Medical Condition. Similarly, the ICSD2[5] included insomnia subtypes that could be divided between primary (Psychophysiological Insomnia, Paradoxical Insomnia, Idiopathic Insomnia) and secondary (e.g., Insomnia Due to a Mental Disorder, Insomnia Due to a Medical Condition, and Insomnia Due to a Drug or Substance) insomnia diagnoses.

The distinction between primary and secondary insomnia diagnoses has not held up over time. At an empiric level, most of the diagnoses fail to demonstrate adequate validity and reliability.[6] At a conceptual level, secondary insomnia would be expected to resolve with successful treatment of the primary disorder, but this is often not the case. Insomnia tends to persist over time, even with remission of comorbid conditions. As a result, the current versions of the DSM and ICSD dramatically reduced the number of insomnia diagnoses. The DSM-5 abandoned the primary versus secondary distinction and now has a single diagnosis of Insomnia Disorder with specifiers to indicate comorbidities when present.[7] Similarly, the ICSD3 has included two diagnoses, Chronic Insomnia Disorder and Short-Term Insomnia Disorder, that are distinguished by the duration of illness.[8] Also, nonrestorative sleep is no longer included in the diagnostic criteria, and the diagnosis of insomnia disorder can be applied to both children and adults in DSM-5 and ICSD3. The essential elements for an

B. Associated consequence	Clinically significant distress or impairment in social, occupational, educational, academic, behavioral, or other important areas of functioning	One or more of the following related to the nighttime sleep difficulty: 1. Fatigue/malaise 2. Attention, concentration, or memory impairment 3. Impaired social, family, occupational, or academic performance 4. Mood disturbance, irritability 5. Daytime sleepiness 6. Behavioral problems (e.g., hyperactivity, impulsivity, aggression) 7. Reduced motivation, energy, initiative 8. Proneness for errors, accidents 9. Concerns about or dissatisfaction with sleep
C. Frequency	Sleep difficulty and associated consequence occurs at least 3 nights per week	
D. Duration	Sleep difficulty and associated consequence is present for at least 3 months	
E. Adequate opportunity	Sleep difficulty occurs despite adequate opportunity and circumstances for sleep	
F. Relationship to another condition	Sleep-wake problems are not better explained by another sleep disorder, a coexisting mental disorder, or coexisting medical condition and are not attributed to the physiologic effects of a substance	

*American Psychiatric Association (APA). *Diagnostic and Statistical Manual of Mental Disorders.* 5th ed. Arlington, VA: APA; 2013.
† American Academy of Sleep Medicine (AASM). *International Classification of Sleep Disorders.* 3rd ed. Darien, IL: AASM; 2014.
Note: Additional specifiers are made in DSM-5: (1) with non–sleep-disorder mental comorbidity, including substance use disorders; (2) with other medical comorbidity; (3) with other sleep disorder and for *episodic* (symptoms last at least 1 month but less than 3 months), *persistent* (symptoms last 3 months or longer), or *recurrent* (two or more episodes within 1 year).

insomnia disorder that are common between the DSM-5 and ICSD3 are summarized in Box 83-1 and include the following patient-reported criteria:

A. Difficulty initiating sleep, difficulty maintaining sleep, or early morning awakenings
B. Distress or impairment that is caused by the insomnia
C. Frequency of at least three nights per week for at least 3 months' duration
D. Duration of at least 3 months
E. Adequate opportunity for sleep
F. Insomnia that is not better explained by another disorder or a substance

Criterion F retains the option of deciding that the insomnia is secondary to another condition, but in this case no insomnia diagnosis would be given, as opposed to the prior practice of assigning a secondary insomnia diagnosis. Thus, the DSM-5 and ICSD3 took a lumping approach to the diagnosis of insomnia instead of the traditional splitting approach because of the lack of evidence to support multiple diagnoses. As our understanding of the pathophysiology of insomnia advances it may become possible to reintroduce diagnostic subtypes with greater empiric support.

ASSESSMENT OF INSOMNIA

The clinical assessment of insomnia should include, at a minimum, a clinical interview and self-report measures of global insomnia symptoms and sleep diaries. Objective measures, such as polysomnography (PSG) and actigraphy, are not routinely recommended but may be indicated to rule out other sleep disorders as part of the evaluation process. When conducting an insomnia assessment, conceptual models for the development and maintenance of insomnia (see Chapter 82) can provide a useful framework for organizing assessment data from multiple sources. For example, the biobehavioral model, or 3 P model,[9] can be useful when assessing a patient's predisposing factors (e.g., family history of insomnia or trait tendencies toward worry that preceded the onset of insomnia), precipitating events that initially caused the onset of insomnia (e.g., loss of a job or other psychosocial stressors), and perpetuating factors that appear to be maintaining the insomnia (e.g., napping during the day or worry about sleep). Also, etiologic models of hyperarousal[10] and the role of cognitions[11] can be useful to inform the case conceptualization and treatment planning for an individual patient. The following section provides a guide to conducting a clinical assessment for insomnia.

The Clinical Interview

The clinical interview remains the cornerstone of insomnia assessment, and a number of semi-structured[10,12] and structured[13,14] interviews for sleep disorders and insomnia have been developed. A primary advantage of the clinical interview is that it enables the clinician to be flexible in approach,

fostering the clinician-patient relationship and allowing tailoring of questions to collect the most pertinent information. For the experienced sleep practitioner, the clinical interview yields a comprehensive differential diagnosis list and logical treatment plan. Insomnia patients often seek treatment because of the daytime consequences of their nighttime symptoms; thus focusing on the 24-hour impact of insomnia for the patient is critical and provides treatment targets beyond nighttime symptoms. An assessment outline with general category areas and key specific areas of inquiry can be found in Table 83-1.

Characterization of the Nocturnal Insomnia Complaint

The clinical interview often begins by eliciting the patient's chief insomnia complaint. Specific quotes vary widely, but the nature of the complaints falls along a limited number of dimensions: inability to fall asleep, inability to stay asleep, waking too early in the morning (or a combination of these symptoms), poor quality sleep, too little sleep, work or lifestyle interference with sleep, or inability to sleep without medications.[15] As indicated previously, the weekly frequency of the nighttime complaint and its duration are required for the DSM-5 and ICSD3. It is additionally helpful to gauge the perceived severity of the nighttime sleep problem and its effects on next-day functioning, which can be accomplished with a simple Likert scale ranging from 1 (no severity) to 10 (maximum severity). It should be noted that patients commonly report during the clinical interview that the insomnia symptoms occur nightly, but further assessment with a daily sleep diary identifies that the sleep pattern is more variable, with evidence of both good and bad nights. This inconsistency highlights the importance of a multimethod approach to insomnia assessment.

An important line of inquiry involves identifying a precipitant, or precipitating factor, for the initiation of the sleep problem. For many, the onset of insomnia is intimately linked with a specific event, but for others the precipitant is less clear. When an obvious insomnia trigger is identified, the clinician can explore premorbid sleep patterns to identify potential predisposing factors. Commonly, patients will report being "light sleepers" before the onset of a more extended bout of insomnia. Previous episodes of transient insomnia may serve as a precipitant to more chronic insomnia, although few studies have evaluated this empirically. Evidence does suggest that transient episodes of insomnia can be elicited in vulnerable individuals.[16,17]

Daytime Consequences of Nighttime Symptoms

Integral to the ICSD3 and DSM-5 diagnostic criteria is the presence of reported daytime impairments related to the insomnia complaints. Most patients report insomnia-related daytime consequences, most commonly in the domains of daytime fatigue, mood disturbances, cognitive deficits, and physical illness.[10,18,19] Reported daytime consequences can seem excessive relative to the magnitude of the nighttime sleep symptoms, which may reflect the contribution of psychological processes to the perception of daytime impairment.[20] Objective confirmation of daytime deficits among insomnia patients has yielded mixed results,[21] but it is important to maintain the perspective that perceived daytime impairment from insomnia is usually what prompts patients to seek treatment.

Current Sleep Pattern

Information about the patient's typical sleep pattern during a recent week under normal life circumstances should be elicited early in the interview. Patients are often better able to describe a "typical" night than an "average" night. Specific information to collect includes bedtime, rise time, time to fall asleep (sleep latency), number and duration of awakenings during the night, final wake-up time, frequency and duration of daytime naps, estimated total sleep time, perceived sleep quality, and morning restfulness. It is also important to determine how this typical pattern differs on weekdays or workdays versus weekends or nonworkdays, on and off sleep medication, and on good nights versus bad nights. The clinician should additionally inquire about presleep activity, perceived causes for awakenings during the night, the patient's coping response when unable to sleep (e.g., remain in bed, watch television), and factors that improve or exacerbate sleep. A functional analysis examining how patients make various decisions related to sleep can be informative. For example, understanding a patient's responses to insomnia symptoms (e.g., level of distress on awakening during the night) and daytime consequences (e.g., napping due to fatigue or sleepiness) can be helpful for case formulation and for the identification of treatment targets. It is common for many insomnia patients to report their sleep to be invariable, unpredictable, and resistant to environmental circumstances, but the patient should nevertheless be challenged to consider differences between bad and good nights.

History of Insomnia Treatments

The most common form of insomnia treatment is prescription hypnotic medication. However, up to 15% of the population has used alcohol as a sleep aid,[22] and insomnia patients commonly initiate self-help treatments before seeking more formal treatment from a sleep specialist.[23] The evaluation of current and past treatments should therefore include any over-the-counter remedies, nonmedication strategies, and alcohol in addition to any sleep-related prescription medications. Current and past treatments should be assessed for type, dosage, frequency of use, time of administration, typical response, and the conditions surrounding deviations from this pattern. It is important to establish in each case whether the specific treatment was given an adequate trial because past failures can result from suboptimal treatment as well as partial or no response. It is additionally important to gauge patients' attitudes toward pharmacologic and nonpharmacologic therapies because these attitudes will likely influence adherence with treatment recommendations and success with treatment outcome.[24] A thorough evaluation of all treatment efforts should enable the clinician to suggest modifications to previously attempted treatments, while providing plausible reasons for previous failed trials.

Sleep-Incompatible Thoughts and Behaviors

Insomnia patients often engage in patterns of behavior and thinking that precipitate or perpetuate the insomnia episode.[10,25] Moreover, there are many daily activities that interfere with nighttime sleep. A careful assessment of compensatory behavioral strategies used to increase nighttime sleep (e.g., variable bedtimes and rise times, spending excessive amounts of time in bed awake) or to deal with the daytime

Table 83-1 Assessment Outline

Category	Specifics
A. Chief complaint	Difficulty falling asleep, staying asleep, waking up too early, poor quality sleep, too little sleep, work or lifestyle interferes with sleep, inability to sleep without medications Define frequency (weekly, monthly), duration, severity, and course (episodic, seasonal variation)
B. Circumstances surrounding onset	Age of onset, precipitating events, sudden or gradual onset, premorbid sleep pattern and quality, previous insomnia episodes
C. Daytime consequences	Fatigue vs. sleepiness, napping, cognition, performance, and mood
D. Current sleep-wake schedule	Bedtime, wake time, rise time, sleep latency, frequency and duration of nighttime awakenings, estimated total sleep time Define average night and variability (e.g., weekdays vs. weekends, medication vs. nonmedication), identify factors that ameliorate and exacerbate sleep pattern Identify prebedtime activities and environment
E. Current and past treatments, adequacy of trial, efficacy	Type (prescription, over-the-counter, behavioral), dosage, efficacy, adequacy of trial
F. Perpetuating factors	
Behavioral	Practices intended to improve sleep (e.g., going to bed early, staying in bed late, increasing time in bed, falling asleep with TV or radio on, staying in bed during awakenings, delayed rise time on weekends) Practices intended to counter fatigue (e.g., napping vs. dozing vs. resting, increasing caffeine ingestion, decreasing physical activity)
Cognitive	Worry about (1) consequences of insomnia (fatigue, performance deficits, health, appearance), (2) sleeplessness ("I'll never get to sleep tonight"), (3) self-perception ("I'm not together, I can't even sleep like a normal person," "My sleep is out of control—just like my life") *False beliefs:* Misconceptions about sleep ("Everybody sleeps 8 hours," "I can't function on less than 7 hours of sleep"), catastrophizing ("Insomnia is ruining my life"), requirements for sleep ("I cannot sleep without sleeping pills," "I must sleep alone")
Other	Alcohol, noise, pets sleeping in the same bed, clock watching during the night, getting home late without enough time to wind down
G. Work	Stress, work schedule incompatible with sleep schedule or contributing to insomnia
H. Family/social	Childhood habit of staying up late with a parent Family history of sleep and psychiatric disorders Stressful life events (past stressful events may be precipitants and present stressful events may be perpetuators)
I. Medical factors	Pain and other medical conditions that can interfere with sleep
J. Pharmacologic considerations	Activating and sedating drugs that interfere with the sleep-wake cycle (consider type, dosage, frequency, and timing), side effects, history of hypnotic use
K. Psychiatric factors	Key features of depression: • *Mood*: sadness, crying, inability to enjoy oneself, irritability, reduced motivation, diurnal mood variation (worse in the morning) • *Cognitive:* reduced attention and concentration, reduced speed of processing, preoccupations, guilt, hopelessness, helplessness, worthlessness, catastrophic thinking • *Physiologic:* reduced (or increased) appetite, diminished sex drive, poor sleep, early morning awakening, psychomotor agitation or lethargy, increased fatigue • *Other:* social withdrawal, suicidal thoughts, intentions, plans, and attempts Key features of anxiety: • Exaggerated worry, tension and irritability; restlessness, headaches, trembling, sweating, and sleep disturbance Key features of substance use disorders: • Excessive and persistent use of substance with evidence of impaired control, use in risky circumstances, or significant social impairment • Consider relationship with current insomnia complaint and status of treatment
L. Other sleep disorders	Circadian rhythm sleep-wake disorders (mismatch between intrinsic circadian rhythm and external environment), restless legs syndrome (sensory discomfort or restlessness in limbs when sedentary), periodic limb movement disorder (repetitive stereotypical leg movements during sleep), sleep-related breathing disorder (snoring, gasping, witnessed apneas, daytime sleepiness)
M. Significant other report	Obtain collateral information from bed partner when possible about sleep pattern and other sleep disorders

consequences of poor sleep (e.g., napping, increased caffeine intake), as well as a thorough evaluation of all "sleep hygiene" behaviors, will uncover maladaptive behaviors. Insomnia patients may exhibit more adverse sleep hygiene practices relative to good sleepers,[26] but most insomnia patients have already attempted to remedy many of these before seeking formal treatment. However, many patients fail to appreciate that altering only a few of these behaviors is unlikely to benefit sleep over the long-term and that good sleep hygiene practices need to be implemented over an extended period of time to reveal their impact on sleep. It is equally important to understand patients' beliefs and attitudes about sleep in general as well as any cognitive responses and reactions to nighttime and daytime sleep-related symptoms. Recent evidence highlights the importance of modifying unhelpful sleep-related cognitions to produce positive and sustained treatment gains.[27,28]

Work, Family, and Social History

Survey studies suggest that patients with insomnia have a higher incidence of first-degree relatives with sleep disturbances compared with controls, with the mother being the most commonly affected family member.[29-31] Specific inquiry regarding a family history of insomnia and psychiatric disorders can provide insight into potential predisposing factors to the insomnia disorder. Assessing the patient's psychosocial history, including occupational or school performance and typical work hours, perceived quantity and quality of interpersonal support, and presence of psychosocial stressors, can also elicit factors that can be treatment targets. Finally, assessment of work hours and timing (e.g., multiple jobs, night shifts) and caregiver demands can determine whether there is an adequate opportunity to achieve sufficient sleep.

Evaluation of Comorbid Conditions

A significant portion of the clinical interview should focus on the evaluation of medical disorders, psychiatric conditions, other sleep disorders, and substance use that are commonly comorbid with insomnia.[32,33] The general approach to this part of the evaluation is to establish the nature of the relationship between the comorbid condition and the insomnia disorder, including temporal precedence. It should not be assumed that any condition co-occurring with insomnia should be the sole or initial focus of treatment.[34] Insomnia frequently persists despite resolution of other conditions and requires independent treatment.[35,36] Studies indicate that cotreatment of insomnia and cooccurring conditions yields more rapid improvement of both conditions compared with sole treatment of only the cooccurring condition.[37,38]

Evaluation of specific medical conditions can be accomplished during the course of the clinical interview through the use of self-report questionnaires or with physical examinations and laboratory testing. Medical comorbidity is high in insomnia disorders,[39] and accompanying medical conditions can often exacerbate insomnia symptoms, impair the patient's ability to cope with subsequent stressors, and directly interfere with treatment progress. (See Table 83-2 for common medical conditions that are comorbid with insomnia.)

Like medical conditions, insomnia is commonly associated with psychiatric disorders, with rates ranging from 40% to more than 50%.[34] Insomnia is listed as a symptom in several disorders in the DSM-5, the most common of which are indicated in Table 83-2. Thus it is important to assess for undiagnosed or inadequately treated psychiatric conditions that may be causing or contributing to the insomnia complaint. Insomnia symptoms are reported by as many as 80% of outpatients with major depressive disorder and more than 90% of inpatients, and up to 20% of outpatients report suffering from hypersomnia.[40,41] Patients in a hypomanic or manic state may present with complaints of intermittent insomnia, which might arise from a decreased need for sleep during a manic phase. A history of manic episodes should also be considered as part of treatment planning because sleep deprivation resulting from behavioral strategies such as sleep restriction could precipitate a manic episode. Complaints of insomnia are also common in patients with panic disorder, generalized anxiety disorder, and posttraumatic stress disorder; they are less likely to be significant features of social phobia, obsessive compulsive disorder, or simple phobias.[42,43] Differentiating an anxiety disorder from an insomnia disorder can present a diagnostic challenge because patients with insomnia are frequently anxious. However, patients with generalized anxiety disorder will describe worry that encompasses

Table 83-2 Medical and Psychiatric Conditions Commonly Comorbid with Insomnia

Medical Conditions	Psychiatric Conditions
Neurologic (e.g., headache, stroke, seizure disorders, brain injury, dementia, Parkinson disease)	Mood disorders (e.g., major depressive disorder, dysthymic disorder, bipolar disorder, seasonal affective disorder)
Cardiovascular (e.g., angina, congestive heart failure)	Anxiety disorders (e.g., generalized anxiety disorder, posttraumatic stress disorder)
Pulmonary (e.g., chronic obstructive pulmonary disease, asthma)	Psychotic disorders (e.g., schizophrenia)
Digestive (e.g., irritable bowel syndrome, reflux, peptic ulcer)	Eating disorders: bulimia nervosa, anorexia nervosa
Endocrine (e.g., hyperthyroidism, diabetes mellitus)	Attention deficit/ hyperactivity disorder
Musculoskeletal (e.g., rheumatoid arthritis, chronic pain disorders)	Adjustment disorder
Reproductive (e.g., pregnancy, menopause)	Personality disorders (e.g., borderline)
Genitourinary (e.g., incontinence, enuresis, benign prostatic hypertrophy)	
Other sleep disorders (e.g., sleep apnea, restless legs syndrome, periodic limb movement disorder)	

Modified from Schutte-Rodin S, Broch L, Buysse D, et al. Clinical guideline for the evaluation and management of chronic insomnia in adults. *J Clin Sleep Med* 2008;4(5):487–504.

multiple daily events and activities outside of the sleep domain, whereas insomnia patients tend to have sleep-focused worry, such as the ability to fall asleep or the consequences of insufficient sleep. One third to more than three fourths of patients with a substance use disorder complain of insomnia.[44,45] Subjective sleep complaints in alcohol-dependent patients continue for a minimum of several weeks after withdrawal, but sleep abnormalities can persist much longer.[46] Insomnia complaints also predict relapse to alcohol during early abstinence after controlling for other confounding variables.[45,47,48] Consideration should be given to the pattern of substance use to determine whether the substance use is restricted to the sleep period or extends into the daytime with attendant adverse consequences to daily functioning. In addition to alcohol, specific attention should be given to licit prescription substances that may be abused (e.g., methylphenidate) and to illicit stimulants (e.g., cocaine, MDMA or "ecstasy") and depressants (e.g., cannabis, opioids).

Medications and Substances

A wide variety of medications and substances can contribute to insomnia complaints and their daytime consequences. A thorough assessment of prescription and nonprescription medications, herbal remedies, and licit (caffeine, nicotine, and alcohol) substances can determine their role in precipitating and perpetuating the insomnia disorder. The assessment should include type, dosage, frequency, and timing of use. For hypnotics, understanding how and when the patient decides to take the medication can provide important therapeutic material. Medication use can be collected during the course of the clinical interview or with locally developed checklists. Patients can also be asked to have available an updated list of their current medications for the initial evaluation. The clinical evaluation will need to consider the timing of the insomnia disorder relative to the initiation of medications or substances and alterations in sleep as a function of use, extended exposure, and discontinuation.

Other Sleep Disorders

Insomnia symptoms can occur in the context of another sleep disorder, and the assessment should evaluate whether these symptoms are better accounted for by another sleep disorder. Importantly, the current nosology systems allow for diagnosis of an insomnia disorder in addition to the presence of another sleep disorder, as long as the criteria are met for both. Insomnia complaints with daytime sleepiness that involve a misalignment between the patient's endogenous circadian rhythm and the external environment may reflect a circadian rhythm sleep-wake disorder (CRSWD) (see Chapter 40). The distinction between an insomnia disorder and a CRSWD can be informed by asking whether the patient's insomnia complaints are resolved when the patient is able to choose a preferred schedule, such as on weekends or days off work. Those with delayed sleep phase disorder will report difficulty with sleep onset, whereas those with advanced sleep phase disorder will report waking up earlier than their planned times. Furthermore, patterns of sleepiness or alertness (e.g., "second wind") across a 24-hour period can help to distinguish an insomnia disorder from CRSWD, in which the diurnal pattern is related to the timing of the sleep phase. For insomnia related to shift work, the clinician should evaluate the relationship between poor sleep and work hour distribution when making a differential diagnosis. Restless legs syndrome (RLS) is another sleep disorder that could include insomnia symptoms (see Chapter 95). RLS is characterized by a complaint of a strong, irresistible, urge to move the legs, usually accompanied by abnormal sensations. The symptoms are aggravated at rest, relieved with movement or activity, and worse in the evening.[49] RLS patients can present with insomnia complaints because the symptoms become worse in the evening and can disturb a patient's ability to fall asleep or return to sleep after awakening. When these symptoms are reported, laboratory tests to examine blood serum ferritin levels (less than 50 mcg/L) can aid in differential diagnosis. Periodic limb movement disorder is a disorder in which periodic limb movements during sleep are repetitive, highly stereotyped movements of the lower extremities. Approximately 80% to 90% of patients with RLS also have periodic limb movements during sleep,[50] and these movements may occur in up to 15% of insomnia patients. The frequent nighttime limb movements are often disruptive of bed partner's sleep, highlighting the importance of including the significant other in the evaluation. More than 40% of patients with obstructive sleep apnea (OSA) have at least one insomnia symptom,[51] and insomnia symptoms are more likely to be reported by women than men with OSA (see Chapters 113 and 114).[52] Men with OSA are more likely to report snoring, gasping in sleep, and excessive daytime sleepiness. Patients with comorbid OSA and insomnia report sustained awakenings in the night with difficulty returning to sleep. Moreover, the presence of insomnia can affect adherence to positive airway pressure, the first-line treatment of OSA.[53] Therefore assessment of comorbid sleep disorders is important for diagnosis and treatment planning.

Self-Report Measures

To complement the clinical interview, administering self-report measures can provide important additional information or corroborate the symptoms reported during the clinical interview. Depending on the clinical setting and available time for the assessment, these measures might be collected at the time of the assessment or sent to the patient before the assessment for review by the clinician during the initial clinic visit. The selection of these measures should be based on the goals of the assessment, with respondent burden taken into consideration. Table 83-3 provides a summary of the most common self-report measures.

Global Measures of Insomnia Symptoms

Global measures of insomnia can provide an index of the severity of the insomnia symptoms and can also be administered longitudinally to inform response to treatment. A number of these measures have been recommended in the standard assessment of insomnia,[54] and three measures are particularly useful in a clinical setting. The Pittsburgh Sleep Quality Index (PSQI) is one of the most widely used sleep questionnaires.[55] It consists of 10 questions that assess a number of aspects of sleep quality. An advantage of this instrument is its widespread use in a variety of settings and translation into more than 50 languages. The primary disadvantage of its use as an insomnia assessment tool is that it is designed to assess the broader construct of sleep quality and not insomnia per se. As such, an individual can have a high score on the PSQI for reasons other than insomnia. A more specific insomnia questionnaire is the Insomnia Severity

Table 83-3 Summary of Self-Report Measures

Domain	Measure	Utility/Purpose
Global measures of insomnia	Insomnia Severity Index Pittsburgh Sleep Quality Index Patient Reported Outcomes Information System	Assess severity of insomnia symptoms and change in symptoms during follow-up
Sleep-wake patterns	Consensus Sleep Diary	Prospective estimates of sleep parameters, bedtimes, sleep quality ratings, and daytime naps
Other measures	Epworth Sleepiness Scale Fatigue Severity Scale Beck Depression Inventory State-Trait Anxiety Inventory Beliefs and Attitudes about Sleep Pre-Sleep Arousal Scale Glasgow Sleep Effort Scale Morningness-Eveningness Questionnaire	Assess daytime functioning, presence of psychiatric symptoms, or etiologic factors

Index (ISI).[56] The ISI consists of seven items on the nighttime and daytime symptoms of insomnia. The scoring is straightforward and yields a total score with standard cutoffs for clinically significant insomnia. It has been widely used as a screening tool and as an outcome measure in insomnia clinical trials. Lastly, there are the Sleep Disturbance and Sleep-Related Impairment scales from the Patient Reported Outcomes Measurement Information System initiative that measure the nighttime and daytime aspects of sleep disturbance, respectively.[57] Although these scales have not yet been widely used, they are noteworthy in that they were developed using item response theory, a more sophisticated psychometric approach than used in the development of other scales, which allows for computerized adaptive testing. Similar to the PSQI, the items do not pertain just to insomnia, although most items are insomnia specific.

Sleep Diaries

The clinical interview and global measures of insomnia are based on retrospective estimates of sleep, which can be heavily influenced by memory and cognitive biases. Sleep diaries are a prospective form of assessment in which an individual completes a series of questions each morning pertaining to the previous night of sleep. A standard sleep diary is now available[58] that includes items for recording estimated sleep parameters such as bedtime, sleep latency, number of nighttime awakenings, and rise time. Sleep diaries are typically kept for 1 to 2 weeks to capture a representative sample of data, and then the average for each parameter is computed. An advantage of sleep diaries is their prospective nature, which is less subject to bias (e.g., primacy, recency effects). They also yield a series of quantitative values that can more precisely describe an individual's sleep patterns and can be useful in delivering behavioral treatments or measuring treatment-related changes. A disadvantage of sleep diaries is that patient nonadherence to completing diaries as prescribed each morning might result in inaccuracies or missing data. Another disadvantage is that some patients become more anxious or vigilant about sleep when monitoring their sleep patterns. Sleep diaries are an essential ingredient to the assessment of insomnia and are typically kept during treatment as part of cognitive behavioral therapy.

Other Measures

Depending on the particular goals of the assessment process, other measures that assess daytime functioning, psychiatric symptoms, or etiologic factors might be considered to provide a more complete clinical profile.[54] If there is a desire to have a better understanding of daytime functioning, it may be useful to include measures of sleepiness or fatigue, such as the Epworth Sleepiness Scale[59] or the Fatigue Severity Scale.[60] Given the high rates of psychiatric comorbidities in insomnia, self-report measures of depression (e.g., Beck Depression Inventory) and anxiety (e.g., State-Trait Anxiety Inventory) are often included to inform the presence of psychiatric symptoms. A number of questionnaires have been developed to assess various features that are related to etiologic factors. A commonly used measure to assess cognitive features is the Dysfunctional Beliefs and Attitudes about Sleep Scale,[61] which assesses the degree to which an individual endorses particular beliefs about sleep that could contribute to the maintenance of insomnia. Measures also exist to assess pre-sleep arousal (Pre-Sleep Arousal Scale) and sleep effort (Glasgow Sleep Effort Scale[62]), as well as circadian tendencies (e.g., Morningness-Eveningness Questionnaire[63]) and sleep hygiene practices.

Objective Measures

Polysomnography

The use of PSG is not indicated for routine evaluation of a transient or chronic insomnia disorder, which places primacy on the subjective complaint for diagnosis.[64] It is indicated to rule out the presence of a sleep-related breathing disorder (e.g., OSA) or a periodic limb movement disorder, or when the initial insomnia treatment fails.[64] However, emerging evidence suggests that sleep-related breathing disorders in particular may be underrecognized causes of insomnia complaints, even among individuals who deny cardinal sleep-related breathing disorder symptoms on initial presentation.[65] PSG may also be used in patients suspected of paradoxical insomnia, a specific subtype of an insomnia disorder characterized by subjective insomnia complaints without objective evidence of insomnia. Although insomnia patients often complain of daytime sleepiness, the Multiple Sleep Latency Test, the standard assessment tool for objectively measuring daytime sleepiness,[66] is not indicated for the evaluation of sleepiness in insomnia.[67] Patients with insomnia may show longer sleep latencies on the Multiple Sleep Latency Test than normal

controls, which is attributed to their heightened physiologic arousal.[68]

A major limitation of PSG is that 1 to 2 nights of PSG may not adequately capture a representative sleep period for the patient, thus it is less useful for assessing the pattern of sleep that is important in the context of insomnia. Moreover, laboratory-based studies can exaggerate sleep problems (the first-night effect), or paradoxically, some insomnia patients may sleep better in the laboratory than they do typically in the home environment, a phenomenon termed the *reverse first-night effect*.[69]

Actigraphy

Actigraphs are small motion sensor detectors (accelerometers) that are encased in a unit about the size of a wristwatch and can be worn continuously for days to months. Actigraphy does not measure sleep per se, but rather level of activity, which is highly correlated with sleep. Sleep can be reliably inferred when low activity occurs in the presence of other indicators of sleep, such as self-report sleep diaries.[70] Dedicated software provides summary measures of behavioral sleep-wake activity and circadian rhythm parameters. Current practice guidelines suggest that actigraphy is not indicated for the routine diagnosis of insomnia but is a useful adjunct to the sleep history or other sleep assessment, such as a sleep diary, particularly for the evaluation of circadian rhythm sleep disorders or paradoxical insomnia, and in the evaluation of treatment response after insomnia interventions.[71] Compared with PSG, actigraphy is more cost-effective and is capable of measuring sleep-wake patterns across several days in the patient's home environment. However, actigraphy is less accurate at detecting sleep compared with PSG, with the accuracy diminishing with increasing amounts of nighttime wakefulness.[72] Another notable issue with the use of actigraphy is the lack of standardized scoring algorithms for sleep and wakefulness across the different devices and manufacturers. Thus it is difficult to compare results between devices that use different scoring algorithms.

Case Formulation

At the conclusion of the assessment, the clinician should have generated a list of potential differential diagnoses based on a synthesis of the information collected from the clinical interview, self-reported measures, and objective measures, if indicated. These initial diagnostic impressions should be discussed with the patient, emphasizing that they are working hypotheses and subject to change. Preliminary treatment options should be outlined and decided on with patient input, including a discussion of referrals for further assessment or treatment of other identified conditions. It is critically important to emphasize a collaborative approach with the patient as the evaluation continues and treatment strategies are initiated.

Assessment of Treatment Progress

In addition to the diagnostic assessment of insomnia, ongoing assessment should include an evaluation of treatment progress. After initiating treatment, clinicians should continue to assess insomnia symptoms at each follow-up visit. This includes an assessment of changes in nocturnal symptoms, the frequency of insomnia symptoms (e.g., how many times per week), changes in conditioned arousal or perpetuating factors, and changes in daytime functioning. The most common approach to monitoring treatment progress is to have patients complete sleep diaries during treatment. Another approach is to have patients complete an insomnia questionnaire, such as the ISI, at every session to track progress over time. Actigraphy can also be used to monitor treatment progress or adherence to treatment recommendations, if self-report alone is insufficient. In addition to the symptoms of insomnia, evaluation of treatment should include assessment of side effects. For medications, these might include amnestic episodes at night, residual daytime sleepiness, or nighttime falls for older adults. For cognitive-behavioral therapy, side effects are not well defined but might include potential daytime sleepiness associated with sleep restriction therapy.[73] Ongoing evaluation of treatment benefits and side effects can aid the overall clinical management and quality of care.

Other Considerations for Conducting the Assessment of Insomnia

This chapter described the basic tools for conducting an assessment of insomnia. Beyond these nuts and bolts, there are several considerations for conducting the assessment. First, the clinical setting will provide certain parameters for the length of the assessment and the use of self-report or objective measures. For example, if the assessment occurs in a primary care clinic or mental health clinic, the assessment will likely need to be conducted in a short amount of time and thus should focus on making a clear diagnosis of an insomnia disorder and the most appropriate treatment plan or need for further sleep evaluation. If the assessment occurs in the context of a sleep clinic, the focus should be on a comprehensive sleep evaluation for insomnia and differential diagnosis from other sleep disorders, medical conditions, and psychiatric conditions. Second, the clinician's training background and discipline will play a role in the assessment process. Physicians who conduct physical examinations can further inform the need for a PSG as part of the assessment. Evidence of a crowded upper airway, large tonsils, or enlarged turbinates may indicate the presence of sleep-disordered breathing and the need for a PSG. An assessment conducted by a psychologist might focus more on a functional analysis of the sleep schedule or differential diagnoses between insomnia and psychiatric disorders. Ideally, a collaborative care model that includes a sleep physician and a sleep psychologist can cover the entire biopsychosocial spectrum of causes and contributors to insomnia. Third, considerations for specific patient populations are important. For example, assessing children or those who might not be able to provide accurate self-reports (e.g., cognitive impairment) might rely more on objective measures than the clinical interview or questionnaires. For patients who have a bed partner, gathering information from the bed partner's observations is frequently a source of valuable information in the insomnia evaluation and should be included whenever possible. Bed partners can provide collateral information about the nature of the insomnia disorder, including symptom frequency, severity, and duration as well as the nature and degree of daytime impairment. Recent evidence suggests associations between bed partner sleep quality and daytime relationship functioning,[74] and some researchers have proposed models for engaging bed partners of insomnia patients into the treatment plan.[75] Clinical experience suggests that any patient-partner discrepancies in the insomnia

evaluation can be both important and useful therapeutically. The significant other can provide insight into important differential diagnoses, such as the presence of symptoms of sleep-related breathing disorders, periodic limb movements in sleep, or parasomnias.

With the rapid growth in mobile technology, consumer devices for monitoring sleep and daytime activity levels are becoming increasingly popular and could potentially play a role in the assessment of insomnia. These devices typically use accelerometers worn on the wrist, similar to actigraphy, which can connect with a smartphone, computer, or other mobile device and can track sleep-wake patterns. The data are processed through an "app" that the consumer can use to download the data and review progress. Currently, there is scant scientific evaluation of these consumer devices. One study compared the Fitbit device (Fitbit, Inc., San Francisco, Calif.) with actigraphy and PSG on a small sample of healthy adults.[76] Similar to actigraphy, the Fitbit device overestimated total sleep time and sleep efficiency by misidentifying wake as sleep. However, the low cost, accessibility, and convenience of these devices provide an opportunity to gather naturalistic data from patients that could be useful in a clinical assessment. Further scientific research on the use of these devices in clinical populations is needed, and the role of clinicians in interpreting these data should be clarified before these consumer devices can be recommended for the assessment of insomnia.

CLINICAL PEARLS

- The DSM-5 and ICSD3 provide better convergence on the diagnostic criteria for insomnia disorders compared with previous versions by collapsing primary versus secondary distinctions and subtypes of insomnia.
- A comprehensive clinical assessment using a clinical interview, self-report questionnaires, and sleep diaries should be able to characterize the nocturnal sleep disturbance, daytime distress or impairment related to the sleep disturbance, the temporal pattern of these symptoms, and etiologic factors related to the insomnia.

SUMMARY

The current diagnostic criteria in the DSM-5 and ICSD3 include more convergence on the essential elements of an insomnia disorder and less emphasis on distinguishing primary versus secondary insomnia or subtyping insomnia based on presumed etiology. As a result, the clinical assessment of insomnia should aim to evaluate these elements using a comprehensive clinical interview, sleep diaries, and self-report measures. These tools should enable the clinician to characterize the nocturnal sleep disturbance, identify daytime distress or impairment related to the sleep disturbance, and determine the course or temporal pattern of these symptoms. In addition, etiologic factors that predispose, precipitate, or perpetuate insomnia should be assessed, including sleep-related cognitions, circadian preferences, sleep-related arousal, and comorbid medical or psychiatric conditions. PSG and actigraphy are not routinely used in the assessment of insomnia but may be indicated to rule out other sleep disorders. The data gathered from these tools should inform case formulation and treatment planning. Ongoing assessment during treatment should be conducted to monitor progress and potential side effects.

Insomnia and Health

Martica H. Hall; Julio Fernandez-Mendoza; Christopher E. Kline; Alexandros N. Vgontzas

Chapter Highlights

- This chapter is focused on insomnia and three specific health outcomes: cardiovascular disease and diabetes (hereafter referred to as cardiometabolic disease) and all-cause mortality.
- Epidemiologic and experimental studies support an association of insomnia with clinical (e.g., hypertension) and subclinical (e.g., heart rate variability [HRV]) cardiovascular risk factors as well as cardiovascular disease per se. Emerging data suggest that the association of insomnia with cardiovascular morbidity is more pronounced when insomnia is associated with objectively measured short sleep duration or other measures of physiologic arousal, including elevated heart rate, blunted HRV, and longer latencies in MSLT.
- Available evidence—especially epidemiologic research—has linked insomnia to poor metabolic function, ranging from overt metabolic disease (i.e., type 2 diabetes) to subclinical manifestations (e.g., metabolic syndrome, insulin resistance) that are risk factors for future diabetes. These studies also suggest that the metabolic risk is greatest among individuals with insomnia and short sleep duration. However, clinical studies involving small samples of adults diagnosed with chronic insomnia have largely failed to corroborate the epidemiologic findings, and studies that have experimentally induced poor sleep quality may generalize to other sleep disorders (e.g., sleep-disordered breathing) as well as insomnia.
- The association between insomnia and mortality is rather modest based on studies that have used insomnia symptoms not associated with any severity or chronicity criteria. Furthermore, in these studies, the lack of objective polysomnographic measures raises the question of whether this association is confounded by the presence of other sleep pathology, such as sleep apnea. More recent studies that have used more stringent criteria and polysomnographic measures suggest that mortality in insomnia is marked and significant, particularly in men and in those with short sleep duration.
- Candidate pathways through which insomnia adversely affects health include changes in physiology (e.g., increased inflammation, endocrine dysregulation, autonomic imbalance) and poor health behaviors (e.g., physical inactivity and caffeine, alcohol, and nicotine use) observed in association with chronic insomnia. More research is needed to determine whether interventions that reduce symptoms of insomnia are associated with concomitant improvements in physiology (e.g., decreased inflammation, normalization of cortisol and adrenocorticotropic hormone, increased heart failure or HRV) or health behaviors (e.g., increased physical activity, improved diet, decreased alcohol, nicotine, and caffeine use). Also unclear is whether any improvements in physiology and health behaviors associated with improvements in insomnia would attenuate the long-term risk associated with chronic insomnia disorder.

If sleep is essential to health, it stands to reason that sleep disorders may have adverse downstream consequences to health. Mounting evidence suggests that insomnia and sleep apnea, the two most common sleep disorders, are associated with significant morbidity and risk for mortality. The health consequences of sleep apnea are covered elsewhere in this text (see Chapters 14 and 126). This chapter focuses on insomnia and three specific health outcomes: cardiovascular disease and diabetes (hereafter referred to as cardiometabolic disease) and all-cause mortality. Our focus on cardiometabolic disease and mortality is driven by the current state of science. This chapter also presents a discussion of putative mechanisms through which insomnia may influence these outcomes. As research on the health consequences of insomnia becomes more established, the number of insomnia-related health outcomes may grow. Although insomnia has also been linked to mental health, these associations are not covered here because they are covered in other chapters (see Section 17, Psychiatric Disorders). We conclude with a discussion of important next steps needed to advance the state of science linking insomnia

and health, including promising areas of inquiry. This research question is relevant to basic scientific questions about the functions of sleep and definitions of sleep health,[1] as well as public health campaigns to disseminate effective and durable interventions to treat insomnia and reduce its downstream consequences to adverse health outcomes including cardiovascular disease, diabetes, and increased risk for all-cause mortality.

INSOMNIA AND CARDIOVASCULAR HEALTH

Although the association of insomnia with cardiovascular health had been noted for several years,[2,3] its association with significant cardiovascular morbidity such as clinical (e.g., hypertension) and subclinical (e.g., heart rate) risk factors and cardiovascular disease (CVD) has remained largely unexplored until recently.[4-6] This renewed interest in the association of insomnia with cardiovascular health is highlighted by the fact that only in the past few years have several systematic reviews and meta-analyses been published on the association of insomnia with hypertension, CVD, or heart rate variability (HRV).[7-10]

Several questionnaire-based studies have shown a significant relationship between insomnia, either defined as a symptom or as a disorder, and hypertension (Table 84-1).[11-20] Based on findings from large longitudinal studies, the estimated risk for incident hypertension associated with insomnia symptoms ranges between 5% and 20%.[7] Furthermore epidemiologic studies have also examined whether insomnia is a risk factor for CVD such as myocardial infarction (MI), coronary heart disease (CHD), heart failure, or, to a lesser extent, stroke (Table 84-2).[21-37] Among these cohort studies, those

*$P < .05$.
†These studies included death from CVD in the definition of incident CVD (see section on Insomnia and Mortality).
CVD, Prevalent or incident cardiovascular diseases in cross-sectional and longitudinal studies, respectively, which primarily included myocardial infarction (MI), coronary heart disease (CHD), heart failure (HF), and, in a few studies, stroke; DIS, difficulty initiating sleep; DMS, difficulty maintaining sleep; DSM-IV, *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition; HR, hazard ratio; ICD, *International Classification of Diseases,* ninth edition; NRS, nonrestorative sleep; OR, odds ratio; RR, relative risk: WHIIRS, Women's Health Initiative Insomnia Rating Scale score.

using a longitudinal design have estimated that the risk for incident CVD associated with insomnia symptoms is about 45% higher than among individuals without insomnia symptoms.[8] More specifically, the relative risk associated with insomnia compared with those without insomnia is 41% for incident MI and 55% for incident CHD or stroke.[9]

Although these large cohort studies have shown a significant association between self-reported insomnia symptoms and hypertension or CVD, most did not include polysomnography (PSG) evaluation and thus could not control for other sleep pathology such as sleep-disordered breathing (SDB). Furthermore, although most studies reported significant associations, the effect sizes reported are modest; in fact, the degree of association found in meta-analyses[2,7-9] had been dismissed as artifact or flawed by some clinicians and researchers.[12,38] However, more recent work has identified a specific high-risk phenotype of individuals with insomnia and PSG-assessed short sleep duration.[5] Two studies from the Penn State Adult Cohort have shown a synergistic effect between insomnia (i.e., a chronic complaint) and PSG-measured short sleep duration (i.e., <6 hours) on the risk for hypertension even after controlling for multiple confounders, including SDB (see Table 84-1).[14,18] Compared with good sleepers, patients with insomnia who slept objectively between 5 and 6 hours and patients with insomnia who slept less than 5 hours had 3.5-fold and 5.1-fold increased cross-sectional odds, respectively, of prevalent hypertension—a degree of association about as high as that between SDB and hypertension. In contrast, insomnia with more than 6 hours of sleep was not significantly associated with prevalent hypertension (odds ratio [OR] = 1.3).[14] Longitudinally, patients with insomnia who slept less than 6 hours had a 3.8-fold odds of incident hypertension compared with good sleepers, whereas insomnia with more than 6 hours of sleep was not significantly associated with incident hypertension (OR = 0.85).[18] The combined effects of short sleep duration and sleep disturbance have been examined in other cohort studies with the limitation of using subjective sleep measures, which may account for some of the inconsistent findings (see Tables 84-1 and 84-2).[16,19,28,32,36]

The association of insomnia with subclinical risk factors for CVD, such as blood pressure dipping, resting HR, or HRV, has been examined primarily in laboratory-based studies. An elevated nighttime systolic blood pressure and a lower day-to-night dipping in systolic blood pressure have been found in a study of normotensive primary insomnia patients.[39] Furthermore nighttime systolic blood pressure was positively correlated with beta activity in the electroencephalogram (EEG) during the night, a marker of cortical hyperarousal.[39] Another study has shown that morning-evening and day-to-day ambulatory blood pressure variability is significantly higher in patients with persistent insomnia compared with subjects without insomnia and that insomnia combined with short sleep duration was associated with even greater variability.[40] A recent study using the Multiple Sleep Latency Test (MSLT) as a measure of physiologic hyperarousal has shown that patients with insomnia who had an MSLT score higher than 14 minutes and those who had an MSLT score higher than 17 minutes had 3.3-fold and 4.3-fold odds, respectively, of high blood pressure, whereas insomnia with a MSLT of 8 to 14 minutes was not significantly associated with high blood pressure (OR = 1.17).[41]

Several studies have shown an elevated resting HR or blunted HRV in patients with insomnia (Table 84-3),[40,42-48] with the latter suggesting a shift of the sympathovagal balance toward a predominance of sympathetic modulation during both wake and nighttime.[10] However, these findings have been inconsistent.[49-53] In those studies reporting a positive association, insomnia patients were carefully defined and presented with objective sleep disturbances. For example, the association between insomnia and alterations in nighttime HR and HRV was examined in a recent study of 58 subjectively defined patients with primary insomnia and 46 healthy controls.[53] Differences between patients with primary insomnia and healthy controls in resting HR were not found, and previous results of blunted HRV[43] could not be replicated. However,

DIS, Difficulty initiating sleep; DMS, difficulty maintaining sleep; HR, resting heart rate; HRV, heart rate variability; PSG, polysomnography.

when the authors used the criterion put forward in previous epidemiologic studies (i.e., PSG-defined short sleep duration),[14] patients with insomnia who slept objectively less than 6 hours had reduced parasympathetic activity compared with healthy controls.[53]

In summary, epidemiologic and experimental studies support an association of insomnia with clinical (e.g., hypertension) and subclinical (e.g., HRV) cardiovascular risk factors as well as CVD per se. A growing literature suggests that the association of insomnia with cardiovascular morbidity is more pronounced when insomnia is associated with objectively measured short sleep duration or other measures of physiologic arousal such as elevated HR, blunted HRV, and longer latencies in MSLT.

INSOMNIA AND DIABETES OR METABOLIC SYNDROME

Relative to CVD morbidity, less research has been conducted on the relationship between insomnia and metabolic dysfunction. Nevertheless, available evidence—especially epidemiologic research—has linked insomnia to poor metabolic function, ranging from overt metabolic disease (i.e., type 2 diabetes) to subclinical manifestations (e.g., metabolic syndrome, insulin resistance) that are risk factors for future diabetes.

Multiple epidemiologic studies have examined the association between insomnia symptoms and type 2 diabetes risk. Although conflicting findings have been observed,[54,55] most cross-sectional and longitudinal studies have reported significant associations between the presence of insomnia symptoms and prevalent or incident diabetes, respectively (Table 84-4).[56-59] For instance, a 2010 meta-analysis of five longitudinal studies found that difficulty initiating sleep and difficulty maintaining sleep were associated with significantly greater risk for developing type 2 diabetes (RR = 1.57 and RR = 1.84, respectively) relative to adults without these complaints.[60] Notably, the diabetes risk associated with these sleep complaints was greater in magnitude than the diabetes risk associated with short (≤5 to 6 hour) or long (>8 to 9 hour) sleep duration (RR = 1.28 and RR = 1.48, respectively).[60]

As previously noted in regard to CVD risk, the risk for type 2 diabetes may be most pronounced among those with insomnia and short sleep duration. In the Penn State Adult Cohort, adults with insomnia along with PSG-assessed short sleep duration (<6 hours) were significantly more likely to have diabetes relative to adults without sleep complaints and 6 hours or more sleep duration (OR = 2.95 for ≤5 hours, OR = 2.07 for 5 to 6 hours).[61] Notably, the odds of having diabetes among adults without sleep complaints but 6 hours or less sleep duration and adults with insomnia and normal sleep duration was not significantly elevated (OR ≤ 1.45 and OR = 1.10, respectively).[61] Conflicting results have been observed in the few other studies that have examined the combined effect of insomnia symptoms and short sleep duration on diabetes risk, perhaps owing to a reliance on self-reported sleep duration.[62,63]

The metabolic syndrome (MetSyn) is a cluster of adverse cardiometabolic factors—obesity, dyslipidemia, insulin resistance or glucose dysregulation, and elevated blood

pressure—that is closely linked to risk for type 2 diabetes. In cross-sectional epidemiologic studies, poor subjective sleep quality has been associated with a greater likelihood of having MetSyn,[64,65] although some studies have failed to demonstrate this relationship (Table 84-5).[66,67] Hall and colleagues observed greater odds for MetSyn with lighter and more fragmented sleep, as assessed by PSG indexes of beta EEG power and sleep efficiency, respectively.[66] Other cross-sectional research has found significantly higher odds of MetSyn among adults who report any insomnia symptoms (i.e., difficulty initiating sleep, difficulty maintaining sleep, or early morning awakening), although individual symptoms were not predictive of MetSyn.[68] However, the only prospective study on the topic found that subjective sleep complaints of difficulty initiating sleep and unrefreshing sleep were associated with incident MetSyn over a 3-year follow-up, although a clinical diagnosis of insomnia was not.[69] No research has evaluated the combination of insomnia symptoms and short sleep duration on MetSyn risk.

Subjective sleep disturbance has also been associated with key preclinical indicators of early progression toward type 2 diabetes, such as impaired fasting glucose levels and insulin

resistance. Adults with difficulty maintaining sleep or early morning awakening are more likely to have impaired fasting glucose levels.[70] Studies have noted greater insulin resistance among adults with poor sleep quality,[64,71-73] insomnia symptoms,[74] or insomnia symptoms in conjunction with hypnotic use.[75] These studies have found little evidence to suggest β-cell dysfunction in those with insomnia.[71,74,75] In the sole longitudinal study, adults with difficulty maintaining sleep were significantly more likely to develop impaired fasting glucose over a 2-year follow-up.[76] Once again, data suggest that short sleep duration may augment the risk associated with insomnia on glucose control: the greatest odds for impaired glucose tolerance were observed with poor sleep quality and less than 6 hours self-reported sleep duration (OR = 6.37).[77]

Overall, epidemiologic research suggests that insomnia symptoms are related to type 2 diabetes and its metabolic precursors. However, limitations in this research cast suspicion on the independent association between insomnia and the risk for metabolic dysfunction. Studies varied widely on their definitions of sleep disturbance or operationalization of insomnia symptoms, and rarely did studies attempt to account for insomnia symptom severity or chronicity. Moreover, many studies neglected or were unable to account for important factors associated with diabetes risk (e.g., depression, sleep medications, SDB). Importantly, because most studies did not use PSG in their assessment of sleep disturbance, subjective sleep complaints may have been due to other sleep disorders rather than insomnia. Therefore studies with well-characterized samples of adults with diagnosed insomnia and objective measures of glucose metabolism have the potential to clarify the commonly observed epidemiologic associations.

Studies incorporating small samples ($n \leq 28$) of adults carefully screened for insomnia without comorbid conditions have failed to replicate the associations seen in most of the epidemiologic studies. Two studies compared adults who met diagnostic criteria for primary insomnia with matched controls on indexes of glucose metabolism derived from laboratory assessments (i.e., oral glucose tolerance test,[78] hyperinsulinemic-euglycemic clamp[79]). Glucose metabolism did not differ between the insomnia and control groups in either study.[78,79] Moreover, in a sample of adults with primary insomnia, those who also had PSG-assessed short sleep duration (≤6 hours) responded to an oral glucose tolerance test with lower insulin secretion in conjunction with greater insulin sensitivity and no difference in glycemic control compared with those with insomnia and more than 6 hours sleep duration.[80] Despite being in opposition to many of the epidemiologic findings, these results are consistent with an epidemiologic study that found that insomnia symptoms combined with poor actigraphic sleep efficiency were associated with lower insulin levels and greater insulin sensitivity among adults without diagnosed diabetes; however, among those with diabetes, these sleep symptoms were associated with worse insulin sensitivity.[81]

Several studies have used experimental sleep disruption to partially model the effects of insomnia on metabolic dysfunction. Although these studies differ from insomnia disorder in several ways (i.e., exogenous stimuli, acute disruption), they are able to increase sleep fragmentation or reduce time spent in slow wave sleep without reducing total sleep time. In one study, two nights of experimental sleep fragmentation across all sleep stages led to reduced insulin sensitivity and reduced glucose effectiveness.[82] Two other studies found that one to three nights of selective slow wave sleep suppression significantly impaired glucose tolerance and insulin sensitivity.[83,84] Despite differences between both the source and duration of sleep disruption, these experimental studies that partially model insomnia provide compelling evidence that experimental sleep disruption causes significant metabolic alterations, independent of sleep duration. Causal associations among insomnia and metabolic function could also be examined in the context of treatment. Yet, we are not aware of any

studies that have examined whether treatment of insomnia, either pharmacologic or behavioral, alters metabolic function in these patients.

In summary, most epidemiologic research suggests a significant association between insomnia and indexes of diabetes risk. These studies also suggest that the metabolic risk associated with insomnia may be augmented further when accompanied by short sleep duration. However, clinical studies involving small samples of adults diagnosed with chronic insomnia have largely failed to corroborate the epidemiologic findings, and studies that have experimentally induced poor sleep quality may generalize to other sleep disorders (e.g., SDB) as well as insomnia. Further research involving better characterization of insomnia samples, assessment of insomnia severity and chronicity, and measurement of potential confounders are needed. Moreover, examining the effects of successful insomnia treatment is necessary to better understand the actual causal role of insomnia in the development and worsening of metabolic dysfunction.

INSOMNIA AND MORTALITY

It has been a decade since Phillips and Mannino evaluated whether insomnia "kills" in a large prospective study in North America; the authors concluded that neither insomnia complaints nor the use of hypnotics were associated with increased risk for death.[85] In this section, we will examine the literature that has been published on this important question. First, we will review studies of large cohorts with subjective sleep data. Then we will assess studies that have used objective sleep data. Finally, we will examine the association of hypnotics and mortality.

Many large epidemiologic studies have examined the association of insomnia with mortality, including all-cause or cardiovascular. Most of these studies were not designed specifically to address the insomnia-mortality link; that is, their main focus was mortality associated with major medical problems, such as cardiovascular disorders or cancer. Thus it is not surprising that the definition of insomnia varies across studies, objective sleep data are not available, length of follow-up is variable, and the number of confounding factors is often limited and differs from study to study. The early studies either failed to find an association between insomnia and mortality[85] or reported a protective effect of insomnia on mortality risk.[86]

Two recent meta-analyses have been published including large cohort studies from the past 20 years. Li and colleagues included 13 studies and evaluated the association between insomnia and risk for cardiovascular mortality. Insomnia overall significantly increased the risk for cardiovascular mortality by 33% compared with individuals without insomnia.[9] Another meta-analysis included 10 published studies that evaluated the association between individual insomnia symptoms and total mortality. The pooled hazard ratios of total mortality were 1.14 (95% confidence interval [CI] = 1.04 to 1.24) for difficulty initiating sleep, 1.08 (95% CI = 0.96 to 1.22) for difficulty maintaining sleep, 1.00 (95% CI = 0.94 to 1.06) for early morning awakenings, and 1.17 (95% CI = 1.01 to 1.36) for nonrestorative sleep relative to individuals without those symptoms.[87] The same authors conducted a meta-analysis using data from six published studies that examined the associations between insomnia symptoms and cardiovascular mortality. The pooled hazard ratios of cardiovascular mortality were 1.45 (95% CI = 1.09 to 1.93) for difficulty initiating sleep, whereas there was no significant association between difficulty maintaining sleep and early morning awakening and mortality. A recent prospective study of 23,447 U.S. adults participating in the Health Professionals Follow-Up Study showed a significant association between difficulty initiating sleep (55% increased risk) and nonrestorative sleep (32% increased risk) and cardiovascular mortality.[5] Collectively, individual studies and meta-analyses provide somewhat equivocal evidence that insomnia is associated with increased risk. Inconsistencies in the assessment of insomnia across studies may contribute to the variability in findings, suggesting that more work is needed to reliably estimate associations among insomnia and mortality. Also warranted is the assessment of sleep apnea, which is also highly prevalent, with known consequences to morbidity and cardiovascular mortality.[88]

In the past few years, following the findings that insomnia with short sleep duration is associated with elevated indexes of physiologic arousal, a series of publications have examined the synergistic effect of insomnia with short sleep duration and cardiometabolic morbidity.[5] As described earlier, insomnia with short sleep duration is associated with a marked, significant, and dose-response risk for hypertension and diabetes. The insomnia–short sleeper phenotype has also been examined in relation to mortality in a random general population sample of 1741 adults who were studied in the sleep laboratory and followed after 10 years (women) and 14 years (men). Insomnia was defined by a complaint of insomnia with duration of at least 1 year. In men, mortality risk was significantly increased in insomniacs who slept less than 6 hours compared with the normal sleep duration and no insomnia group (about 400% increased risk). This risk was even higher in patients with diabetes or hypertension (about 700% increased risk) who suffered from this type of insomnia. No significant association between mortality and insomnia with short sleep duration was found in women.[89] One of the limitations of this study was that the number of deaths was too small to allow analysis for a specific cause, that is, cardiovascular mortality; furthermore the percentage of women who died was only 5% at the time of follow-up, leaving open the question of a gender-specific effect. In a recent reanalysis of the same cohort, but with a longer follow-up period (18 years for men, 14 years for women) and with a mortality rate of about 16% in women, the results remained unchanged. Specifically, in men, there was a significant association of this type of insomnia with mortality, whereas again no such association was found in women. The authors concluded that although insomnia is more prevalent in women, it appears that its biologic effect is more consequential in men.[90]

A recent large study from Norway examined the association of midlife insomnia and subsequent all-cause mortality in more than 6000 participants aged 40 to 45 years. These subjects provided information on insomnia using the Karolinska Sleep Questionnaire (which follows the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders*), various sociodemographic and health behaviors, as well as obstructive sleep apnea symptoms and sleep duration. Insomnia was associated with a 3-fold risk of mortality over 13 to 15 years follow-up. The risk seemed even higher in males or when insomnia was combined with short sleep duration. The

authors concluded that the insomnia-mortality association may be confined to subgroups: males and short sleepers.[91] Although based on subjective data, this study is different from the other similar studies in that the criteria for insomnia were stringent and the presence of obstructive sleep apnea was assessed based on symptoms such as snoring and breathing cessation during sleep reported by the subjects or their bed partners. These differences in methodology may potentially explain the consistencies between this subjective study and studies using objective sleep measures.

Hypnotics are frequently prescribed from physicians to treat insomnia or insomnia symptoms, either as a primary or as an adjunct therapy. In the late 1970s, a paper by Kripke and colleagues, based on data from a large registry of the American Cancer Society, reported that frequent use of sleeping pills was associated with 1.5 times higher mortality compared with that in individuals who had never used sleeping pills.[92] These results were replicated in subsequent studies by the same group with hazard ratios of 1.35 for men and 1.22 for women.[93] Similar results were reported more recently based on data from a large group of community-dwelling older adults in Taiwan; specifically, frequent hypnotic use had an increased mortality risk of about 37%.[94] Another study using an insurance database in Pennsylvania also reported higher mortality risk; specifically, the hazard ratios ranged from 3.6 to 5.3 for several of the common hypnotics, such as zolpidem and temazepam.[95] However, in this study there was no control for confounding factors such as sleep disorders and psychiatric pathology. These limitations seem to be important; a study from France in an elderly general population reported that the increased mortality associated with hypnotics became nonsignificant after adjusting for sleep and psychiatric disorders.[96] The authors concluded that underlying psychiatric disorders appeared to be the principal confounders of the observed association. Overall, it appears that, based on recent published studies, the association of hypnotic use with mortality is rather small but warrants further examination given the widespread use of these medications, particularly in the older, frail population.

The association between insomnia and mortality is rather modest based on studies that have used insomnia symptoms not associated with any severity or chronicity criteria. Furthermore, in these studies, the lack of objective PSG measures raises the question of whether this association is confounded by the presence of other sleep pathology, such as sleep apnea. More recent studies that have used more stringent criteria and PSG measures suggest that mortality in insomnia is marked and significant, particularly in men and in those with short sleep duration. Further studies are needed with larger cohorts, uniform criteria for insomnia disorder, and objective sleep data to confirm these more recent observations.

MECHANISMS LINKING INSOMNIA WITH CARDIOMETABOLIC DISEASE

As summarized earlier, mounting evidence suggests that insomnia is prospectively linked to both the risk for and clinical course of cardiometabolic disease. The evidence is strongest for chronic insomnia disorder, although symptoms of insomnia, too, have been linked to increased risk. Proposed physiologic mechanisms include factors known to change in response to experimental sleep deprivation and restriction, including endocrine dysregulation, increased inflammation, and autonomic imbalance. Early studies in this area focused on stress hormones in light of the hypothesized role of psychological stress in the pathogenesis of insomnia as well as evidence of psychophysiologic hyperarousal in insomnia first documented by Monroe in 1967.[49,97] Most studies reported increased hypothalamic-pituitary-adrenal axis activation in patients with insomnia, including increased cortisol secretion and alterations in the diurnal cortisol profile,[79,98-101] although some have failed to observe group differences.[102,103]

Other studies have focused on inflammation as a pathway through which chronic insomnia may contribute to cardiometabolic disease. Two large-scale epidemiologic studies reported no significant association among C-reactive protein and symptoms of insomnia in community-dwelling adults.[101,104] Two other studies have documented increased inflammation in patients with insomnia compared with good sleepers, as measured by the secretion[105] and diurnal profiles of interleukin-6.[106] At present, differences across studies, including indexes of inflammation and severity and chronicity of insomnia, preclude conclusions about inflammation as a mechanism linking insomnia to cardiometabolic disease, or the extent to which insomnia is a cause, or effect, of inflammation. The insomnia-inflammation pathway is certainly plausible given the effects of experimental sleep deprivation on circulating markers of inflammation and their cellular and molecular upstream pathways.[107,108]

More studies have evaluated autonomic tone in relation in insomnia, perhaps because it can be measured continuously and noninvasively during sleep, and HRV-derived indexes of autonomic tone exhibit greater short-term stability than do measures of the hypothalamic-pituitary-adrenal axis or inflammation.[109] Although non–rapid eye movement sleep is a predominantly parasympathetic state, most studies report decreased parasympathetic activity as indexed by high-frequency HRV during sleep in patients with insomnia compared with controls.[43,45,46,48,52,109] Autonomic imbalance in insomnia may be further compounded by alterations in dynamic indexes of high-frequency HRV[52,110] and increased sympathetic nervous system activity, as measured by impedance cardiography and the ratio of low- to high-frequency HRV (LF/HF ratio), also known as *sympathovagal balance*.[47,53,111] The link between insomnia and the LF/HF ratio has been further instantiated by the demonstration that intradermal, but not sham, acupuncture was associated with improvements in both symptoms of insomnia and the LF/HF ratio in hospitalized stroke patients with insomnia.[112]

Insomnia may also predispose to greater cardiometabolic risk through poor health behaviors. Although the relationships between insomnia symptoms and health behaviors are likely bidirectional,[1,2] adults with insomnia are more likely to use alcohol,[1,3] smoke,[3] and be physically inactive[1] than adults without insomnia; each of these behaviors is associated with increased cardiometabolic risk. Adults with insomnia have also been found to have lower cardiorespiratory fitness,[4] which is a strong independent predictor of cardiovascular morbidity and mortality.[5] Finally, insomnia symptoms may predispose to cardiometabolic risk through poor diet; poor sleep quality, fragmented sleep, and altered sleep architecture (e.g., low slow wave sleep) are associated with dietary macronutrient and micronutrient composition[6,7] and satiety.[8,9] More work is needed to establish whether these putative mechanisms do, in

fact, lie on the causal pathway linking insomnia to cardiometabolic disease.

It is currently unclear whether interventions that reduce symptoms of insomnia are associated with concomitant improvements in physiology (e.g., decreased inflammation, normalization of cortisol and adrenocorticotropic hormone, increased high-frequency HRV) or health behaviors (e.g., increased physical activity, improved diet, decreased alcohol, nicotine, and caffeine use). Also unclear is whether any improvements in physiology and health behaviors associated with improvements in insomnia would attenuate the long-term risk associated with chronic insomnia disorder. Moreover, little is known about factors that may moderate associations among insomnia, insomnia mechanisms, and cardiometabolic risk. Do age and gender matter? Do other comorbidities such as major depression and sleep apnea have an additive or synergistic effect on cardiometabolic risk in patients with insomnia? What is clear is that identification of mechanisms and effect moderators is critical to treatment and prevention of the cardiometabolic consequences of insomnia.

CLINICAL PEARLS

- Several large cohort studies have demonstrated that reports of insomnia, particularly in those with short sleep duration, are associated with incident cardiovascular disease and events.
- Insomnia disorder is associated with increased risk for mortality, particularly in men and in those with short sleep duration. Further studies are needed with larger cohorts, uniform criteria for insomnia disorder, and objective sleep data to confirm these observations.
- Symptoms of insomnia, including difficulty initiating and maintaining sleep, are prospectively associated with incident type 2 diabetes and metabolic syndrome. This effect appears to be stronger in those with objective short sleep duration.

SUMMARY

Mounting evidence suggests that insomnia is associated with subclinical and prognostic indicators of cardiovascular disease, diabetes and metabolic syndrome, and all-cause mortality.[113] Chronicity and severity of symptoms appear to play an important role in risk, although risk profiles differ for CVD and diabetes. The insomnia–short sleeper phenotype, in particular, appears to confer greater risk than insomnia alone. Although data provide several promising hints about possible mechanisms through which insomnia may influence cardiometabolic risk, the cross-sectional nature of this literature limits testing and refinement of mechanistic models. One of the promising aspects of the work on insomnia and cardiometabolic risk is that these data may apply to other disorders and disease outcomes that have been linked to similar mechanisms (e.g., cancer and arthritis with inflammation and hormone dysregulation; cognitive decline and impairment with neuroinflammation and autonomic imbalance). Finally, the advent of ambulatory technologies and Web-based intervention and assessment platforms will extend this work into underserved populations in whom health disparities are most prevalent and where scalable sleep health interventions may do the most good.

Cognitive Behavior Therapies for Insomnia I: Approaches and Efficacy

Charles M. Morin; Judith R. Davidson; Simon Beaulieu-Bonneau

Chapter Highlights

- Cognitive behavior therapies (CBTs) target psychological, behavioral, and cognitive factors that perpetuate or exacerbate sleep difficulties. The main therapeutic components of CBT include sleep restriction, stimulus control, relaxation training, cognitive therapy, sleep hygiene, or a combination of these methods.
- Evidence from randomized controlled trials, meta-analyses, and systematic reviews indicate that CBT is an effective therapeutic approach to improve sleep continuity parameters (e.g., sleep-onset latency, time awake after sleep onset) as well as improve global measures of insomnia severity and sleep quality. These clinical benefits are well sustained over time.
- There is also increasing evidence showing that CBT is effective for insomnia disorder presenting with comorbid psychiatric (e.g., depression) or medical (e.g., cancer, chronic pain) conditions, in older adults, and in patients who are chronic users of hypnotics.
- Despite its well-documented short- and long-term benefits, as well as broad acceptability by patients, CBT remains underused in the management of insomnia. An important challenge for the future will be to develop more efficient strategies and incentives for health practitioners to integrate CBT in their day-to-day clinical practices.

Insomnia can be triggered by a variety of precipitating events and when it becomes a persistent problem, psychological, behavioral, and cognitive factors are instrumental in perpetuating or exacerbating sleep disturbances over time. The effective management of persistent insomnia must target these factors, which involve sleep-scheduling issues, poor sleep habits, conditioning, hyperarousal, excessive worrying, and erroneous beliefs about sleep. Cognitive behavior therapies (CBTs) for persistent insomnia include sleep restriction, stimulus control, relaxation training, cognitive therapy, mindfulness-based interventions, sleep hygiene education, or any combination of those methods. Evidence from controlled clinical trials and systematic reviews indicates that between 70% and 80% of patients with persistent insomnia benefit from CBT, and approximately half of them achieve clinical remission. Treatment produces significant improvements of specific sleep parameters such as sleep-onset latency, wake after sleep onset, sleep efficiency, sleep quality, and reduction of global insomnia severity. These benefits are paralleled by reductions of daytime fatigue, psychological symptoms, and improvements in quality of life. Changes in sleep patterns are well sustained after therapy has ended. Treatment outcomes have been documented primarily with sleep diaries and other self-report measures; studies using polysomnography and actigraphy have also shown sleep improvements but of smaller magnitude. CBT should be the first-line therapy for insomnia disorder. Specific indications include insomnia with or without comorbid medical or psychiatric disorders, insomnia in older adults, and insomnia associated with chronic hypnotic usage. Despite strong evidence supporting its efficacy and effectiveness, CBT remains underused by health care practitioners. An important challenge for the future will be to disseminate more effectively these evidence-based therapies and increase their use in routine clinical practice.

CURRENT TREATMENT PRACTICES

Insomnia is a common condition and carries a significant psychosocial, medical, and economic burden.[1,2] Despite its high prevalence and negative effects, insomnia often remains unrecognized and untreated. Most patients who initiate treatment do so without professional consultation and often resort to alternative remedies (herbal or dietary supplements) of unknown risks and benefits.[3] When insomnia is brought to professional attention, typically to a primary care physician, treatment is often limited to medication. Although hypnotic medications are clinically indicated and useful in selected situations, cognitive and behavior factors are almost always involved in perpetuating sleep disturbances,[4-7] and these factors must be addressed for effective management of chronic insomnia.

With solid evidence supporting its short- and long-term efficacy and clinical utility, as well as its acceptability by patients, CBT is increasingly recognized as the treatment of choice for persistent insomnia.[8,9] This chapter describes clinical procedures that are typically included in CBT for

Box 85-1 COGNITIVE BEHAVIOR THERAPIES FOR PERSISTENT INSOMNIA

Sleep Restriction

A method designed to restrict time spent in bed (i.e., the sleep window) as close as possible to the actual sleep time, thereby strengthening the homeostatic sleep drive. This sleep window is then gradually increased over a period of a few days or weeks until optimal sleep duration is achieved.

Stimulus Control

A set of instructions designed to reinforce the association between the bed and bedroom with sleep and to reestablish a consistent sleep-wake schedule:

- Go to bed only when sleepy
- Get out of bed when unable to sleep
- Use the bed/bedroom for sleep only (no reading, watching TV, etc.)
- Arise at the same time every morning
- No napping

Relaxation Training

Clinical procedures (e.g., progressive muscle relaxation) aimed at reducing autonomic arousal, muscle tension, and intrusive thoughts interfering with sleep. Most relaxation procedures require some professional guidance initially and daily practice over a period of a few weeks.

Cognitive Therapy

Psychological approach using Socratic questioning and behavioral experiments to reduce excessive worrying about sleep and reframe unhelpful beliefs about insomnia and its daytime consequences. Usually requires a trained and skilled clinician. Additional cognitive strategies may involve paradoxical intention technique to alleviate performance anxiety associated with the attempt to fall asleep.

Mindfulness-Based Interventions

The core principle of mindfulness-based interventions is nonjudgmental awareness in the present moment. It involves meditation practice and its most common variant is mindfulness-based stress reduction (MBSR).

Sleep Hygiene Education

General guidelines about health practices (e.g., diet, exercise, substance use) and environmental factors (e.g., light, noise, excessive temperature) that may promote or interfere with sleep. This may also include some basic information about normal sleep and changes in sleep patterns with aging.

Cognitive Behavior Therapy

A multimodal intervention combining some of the above cognitive and behavior (e.g., stimulus control, sleep restriction, relaxation) procedures. Multicomponent behavior therapy would include more than one behavioral procedure but without a cognitive component.

insomnia and summarizes the evidence regarding their efficacy and generalizability. Clinical issues related to feasibility and treatment implementation are addressed only briefly because these issues are the focus of another chapter.

TREATMENTS

Treatment options for insomnia can be grouped in three broad classes of interventions including CBTs, pharmacotherapy, and complementary and alternative therapies. This chapter is about CBTs that have been validated in controlled clinical trials for persistent insomnia. These methods include sleep restriction, stimulus control therapy, relaxation, cognitive strategies, mindfulness-based stress reduction, sleep hygiene education, or a combination of these. CBT is a generic label used to describe a combination of therapeutic methods that include at least one cognitive and one behavioral component. The label *multicomponent behavior therapies* is also used to describe a similar approach involving different components but without cognitive therapy. Sleep hygiene education (i.e., recommendations about health practices and environmental factors that may positively or negatively impact sleep) by itself, although useful, must be distinguished from more formal CBT because it is often insufficient to treat chronic insomnia.[10] A summary of these interventions is provided in Box 85-1; more extensive descriptions are available in other sources.[6,11,12]

Rationale and Indications

The main targets of CBT include psychological, behavioral, and cognitive factors that perpetuate or exacerbate sleep disturbances. Such features may involve counterproductive sleep scheduling, sleep habits (e.g., spending excessive amounts of time in bed), conditioning, hyperarousal, dysfunctional beliefs and excessive worry about sleep, and inadequate sleep hygiene practices.[4,6,13-16] Although numerous factors (e.g., life events, medical illness) can precipitate insomnia, when it becomes a persistent problem, these factors are almost always involved in perpetuating insomnia over time; hence the need to target them directly in treatment.

The main indication for CBT is persistent insomnia, whether it is occurring on its own or in the context of another medical or psychiatric disorder. It is indicated for insomnia in younger and older adults and for patients with prolonged use of hypnotics, although chronic use of hypnotics can interfere with CBT's objectives. There is no evidence for using CBT with acute insomnia and very little evidence for its use in children and adolescents.

There are few contraindications. Sleep restriction should be avoided in patients with a history of seizures, certain parasomnias (e.g., sleepwalking), or manic or hypomanic episodes (as in bipolar disorder) because it may lower the threshold for, or exacerbate, these conditions. Sleep restriction should also be avoided or used very cautiously with patients who need to drive or operate heavy equipment and with those who are already excessively sleepy during the day. Some stimulus control procedures (e.g., getting out of bed when unable to sleep) should be used with caution with frail elderly people, who may be at risk for falls when getting out of bed.[17]

Sleep Restriction

There is a natural tendency among individuals with insomnia to increase the time they spend in bed simply to rest or provide

more opportunity for sleep. Although this strategy may be effective in the short term, in the long run it is more likely to result in fragmented and poor-quality sleep.

Sleep restriction therapy consists of curtailing the amount of time spent in bed as close as possible to the actual amount of time asleep.[18] For example, if a person reports sleeping an average of 6 hours per night out of 8 hours spent in bed, the initial prescribed sleep window (i.e., from initial bedtime to final arising time) would be 6 hours. Time in bed is subsequently adjusted on the basis of sleep efficiency (total sleep time over time in bed × 100%) for a given period, usually 1 week. The sleep window is increased by about 15 to 20 minutes for a given week when sleep efficiency exceeds 85%, it is decreased by the same amount when sleep efficiency is lower than 80%, and it is kept stable when sleep efficiency falls between 80% and 85%. Adjustments are made weekly until optimal sleep duration is achieved. Changes to the prescribed sleep window can be made at the beginning of the night (i.e., postponing bedtime), at the end of the sleep period (i.e., advancing arising time), or at both ends. Some variations in implementation might involve changing the time in bed on the basis of a moving average of the sleep efficiency (e.g., the past 3 to 5 days) or changing it on a weekly basis regardless of changes in sleep efficiency.[19]

Sleep restriction improves sleep through two complementary mechanisms: It strengthens the homeostatic sleep drive through a mild sleep deprivation, and it alleviates some of the sleep anticipatory anxiety by changing the patient's focus of attention (i.e., trying to stay up later rather than going to bed early). Side effects of this intervention include daytime sleepiness, reduced vigilance, and slowed reaction time.[20] To prevent excessive daytime sleepiness, the prescribed time in bed should not be less than 5 hours per night, regardless of reported initial sleep duration. This caution is particularly important for those whose jobs require operating motor vehicles or who have duties in which drowsiness may be a danger to the patient or others.

Stimulus Control Therapy

Stimulus control therapy[21] involves five instructions designed to reassociate temporal (bedtime) and environmental (bed and bedroom) stimuli with rapid sleep onset and to establish a regular circadian sleep-wake rhythm:

- Go to bed only when sleepy—not just fatigued, but sleepy.
- Get out of bed when unable to sleep (e.g., after 20 minutes), go to another room, and return to bed only when sleep is imminent.
- Curtail all sleep-incompatible activities: no eating, watching television, using electronic devices, or planning or problem solving in bed.
- Arise at a regular time every morning regardless of the amount of sleep achieved.
- Avoid daytime napping.

Persons with insomnia often develop apprehension around bedtime and the bedroom and come to associate this particular time of the day and environment with the frustration of being unable to sleep. Over time, the presleep rituals usually associated with relaxation and sleep become cues or stimuli for worrying and wakefulness. In addition, many insomnia patients display counterproductive sleep habits that emerge as a means of coping with sleep disturbances. For example, poor sleep at night can lead to daytime napping or sleeping late into the morning on weekends in an effort to catch up on lost sleep. Individuals might lie in bed for prolonged periods trying to force sleep, only to find themselves becoming more awake. Stimulus control procedures are designed to re-create a positive association between presleep rituals and the bedroom environment.

Stimulus control instructions appear quite simple; however, the challenge for clinicians is to foster strict adherence to these instructions. Several consultation visits held on a weekly or biweekly basis are often necessary to assist patients in implementing these behavioral changes. Stimulus control instructions can be combined with sleep restriction, for example, by having patients stay up until they are sleepy and it is at least their prescribed bedtime ("threshold time for bed").[6] Also, the stimulus control instruction to avoid napping can be modified to allow a short midafternoon nap (e.g., less than 60 minutes starting no later than 3 PM) in the early phase of sleep restriction, particularly in older adults or those who are overly sleepy with the nighttime sleep restriction.

Relaxation-Based Interventions

Because stress, tension, and anxiety are often contributing factors to sleep disturbances, relaxation is probably the most commonly used intervention for insomnia. The goal of this treatment is to reduce arousal at bedtime or on nighttime awakening. Among the different relaxation interventions, some methods (e.g., progressive muscle relaxation) focus primarily on reducing somatic arousal, whereas attention-focusing procedures (e.g., imagery training) target mental arousal in the form of worries, intrusive thoughts, or a racing mind. Biofeedback is designed to train patients to control some physiologic parameters (e.g., tension) through visual or auditory feedback; despite its popularity in the 1980s, this method is not commonly used today.

Selection of a particular method should be based on the patient's preference or the predominant subtype of arousal (somatic versus mental) interfering with sleep. There is no formal contraindication to using relaxation, but some patients might have a paradoxical response and become more anxious when trying to relax. The most critical issue is to encourage daily practice of the selected method for at least 2 to 4 weeks. The focus should be on reducing arousal rather than on inducing sleep, and the relaxation method should be done out of bed, especially if the patient is also using stimulus control therapy. Professional guidance is helpful during initial training, especially to demonstrate the relaxation technique during an in-office session and to support the patient with daily practice.

Cognitive Therapy

Cognitive therapy for insomnia seeks to alter sleep-disruptive cognitions (e.g., beliefs, expectations) and maladaptive cognitive processes (e.g., excessive self-monitoring, worrying) through Socratic questioning and behavioral experiments.[7,22-24] The basic premise of this approach is that appraisal of a given situation (sleeplessness) can trigger negative thoughts and emotions (fear, anxiety) that are incompatible with sleep. For example, worries about the consequences of sleep loss on the next day's performance can lead to further arousal and more sleep disturbance, thus forming a vicious cycle. Likewise, on night waking, a person may engage in self-monitoring (e.g., clock watching to check how many hours are left in the night)

and safety activities (e.g., trying to stop thinking), which can prolong the nocturnal awakenings.[7]

Cognitive therapy is designed to short-circuit the self-fulfilling nature of this vicious cycle through verbal interventions and behavioral homework. Some therapeutic targets for cognitive restructuring include unrealistic expectations ("I must get 8 hours of sleep every night"), faulty causal attributions ("My insomnia is entirely caused by a biochemical imbalance"), and amplification of the consequences of insomnia ("After a poor night's sleep, I can't function the next day"). Key messages to communicate to patients in the context of cognitive therapy include the following:

- Keep realistic expectations with regard to sleep requirements and daytime energy.
- Do not blame insomnia for all daytime impairments because there may be other explanations (worries about family, conflicts with coworkers) for these deficits.
- Never *try* to sleep because it is likely to exacerbate sleep difficulties.
- Do not give too much importance to sleep. Although sleep should be a priority, it should not become the central point of life.
- Do not catastrophize after a poor night's sleep. Insomnia is very unpleasant, but it is not necessarily dangerous to health, at least not in the short term.
- Develop some tolerance to the effects of insomnia. If you are predisposed to insomnia, it is likely that you will remain vulnerable to sleep disturbances even after treatment, and you can develop strategies to cope with these occasional nights of poor sleep.

In addition to these verbal interventions, behavioral experiments can be helpful to change a person's beliefs about sleep and insomnia. For example, if a patient is convinced that bed rest is a good strategy to conserve energy, a behavioral experiment is designed to test the validity of this belief: The patient is instructed to engage specifically in this strategy (bed rest) on a day following insomnia and, on another day, to engage in the opposite behavior, such as performing a series of activities designed to generate energy after a poor night's sleep (e.g., exercising, meeting with friends). Such homework can be quite effective to change a person's belief about ways to preserve or generate energy in the context of insomnia.[24]

Additional cognitive strategies may be useful. For instance, paradoxical intention is a procedure designed to eliminate performance anxiety. In the context of insomnia, any attempt to control or induce sleep voluntarily is likely to generate performance anxiety and to delay sleep onset. With paradoxical intention, the patient is instructed to remain passively awake and to give up any attempt (intention) to fall asleep. To minimize worrying and mental activity interfering with sleep, it is also helpful to instruct patients to set aside a time and a place (other than bedtime and the bedroom) to write down thoughts or worries and plans for the next day. Imagery can also be useful to block out unwanted presleep thoughts.[25]

Mindfulness-Based Interventions

Developed through meditation, mindfulness is based on awareness in the present moment, without judgment. One of the most common mindfulness programs used in health care today is mindfulness-based stress reduction (MBSR). It includes eight weekly group sessions and a 1-day silent retreat. Participants learn various meditation practices, including breathing meditation, the body scan, sitting meditation, Hatha yoga, and walking meditation. Daily personal meditation is expected. The program teaches principles of nonjudging, beginner's mind, trust, nonstriving, acceptance, and letting go. MBSR has been used with various health conditions to reduce symptoms, enhance calmness, and improve quality of life.[26] As used in the context of insomnia, the goal is to reduce stress and psychophysiologic arousal.

Mindfulness-based therapy for insomnia is a group program that integrates behavioral techniques for insomnia, namely sleep restriction, stimulus control therapy, and sleep hygiene, into MBSR.[27,28] The mindfulness principles are believed to complement the conventional behavioral sleep techniques and to replace the need for cognitive therapy. For example, nonstriving is consistent with relinquishing the counterproductive desire to actively control sleep. Also, mindfulness encourages a nonjudgmental observation of one's thoughts as mental events, and this is believed to improve clarity of thought and calmness, thereby reducing arousal.[29]

Several other complementary and alternative therapies, within the nondrug domain, have been used in the treatment of chronic insomnia. These include acupuncture, tai chi, hypnosis, exercise, and electrosleep therapy. Although potentially useful in clinical practice, these methods have not been evaluated extensively in controlled studies.

Sleep Hygiene Education

Sleep hygiene education is intended to provide information about lifestyle (diet, exercise, substance use) and environmental factors (light, noise, temperature) that might either interfere with or promote better sleep.[30] It could also include general sleep-facilitating recommendations, such as allowing enough time to relax before bedtime, avoiding clock watching, and maintaining a regular sleep schedule. Some of these instructions overlap with other behavioral procedures. Sleep hygiene guidelines include the following:

- Avoid stimulants (e.g., caffeine, nicotine) for several hours before bedtime.
- Avoid alcohol around bedtime because it fragments sleep.
- Exercise regularly (especially in late afternoon or early evening).
- Allow at least a 1-hour period to unwind before bedtime.
- Keep the bedroom environment quiet, dark, and comfortable.
- Maintain a regular sleep schedule.
- Remove electronic devices from the bedroom.

Although sleep-hygiene education may be helpful for mild insomnia, it is rarely sufficient for more severe insomnia, which requires more directive and potent behavioral interventions.[31] A didactic approach can also be used to provide basic information about normal sleep, individual differences in sleep need, and changes in sleep physiology with aging. This information is very useful to help some patients distinguish clinical insomnia from normal (age-related) sleep disturbances. Such knowledge can prevent excessive worry and concern, which can also lead to clinical insomnia.

Cognitive Behavior Therapy and Multicomponent Behavior Therapy

Single interventions described to this point can be combined effectively. Multicomponent therapy is becoming the preferred approach to treating insomnia. In a systematic review

of the literature, 26 of 37 clinical studies conducted between 1999 and 2004 had evaluated a multicomponent approach to persistent insomnia.[31] This approach typically included a behavioral (stimulus control, sleep restriction, and, sometimes, relaxation), a cognitive (cognitive restructuring), and an educational component (sleep hygiene); hence the term CBT. This multimodal approach is appealing because it addresses different insomnia features with different therapeutic recommendations, which is consistent with a multidimensional etiologic model of insomnia (see Chapter 82).[4-7,14]

TREATMENT OUTCOME EVIDENCE

Evidence for Efficacy

Several meta-analyses[32-36] and systematic reviews[31,37,38] have summarized the findings from clinical trials evaluating the efficacy of CBT for insomnia. Evidence from these sources shows that treatment produces reliable changes in several sleep parameters (Figure 85-1), including sleep latency (effect sizes, 0.41 to 1.05), wake after sleep onset (0.61 to 1.03), number of awakenings (0.25 to 0.83), total sleep time (0.15 to 0.49), and sleep quality ratings (0.94 to 1.14). These effect sizes are considered large (Cohen's effect size $d > 0.8$) for sleep latency, wake after sleep onset, and sleep quality and moderate ($d > 0.5$) for other sleep parameters. When transformed into a percentile rank metric, these data indicate that approximately 70% to 80% of patients with insomnia benefit from treatment. These effect sizes are similar to those obtained for benzodiazepine-receptor agonists,[34,39] with a slight advantage for CBT on measures of sleep-onset latency and sleep quality and for pharmacotherapy on total sleep time. A more recent meta-analysis of 73 randomized controlled trials found that CBT produced a large effect on the Insomnia Severity Index (ISI) and moderate effects on most sleep diary parameters, apart from total sleep time, which showed a small effect.[36]

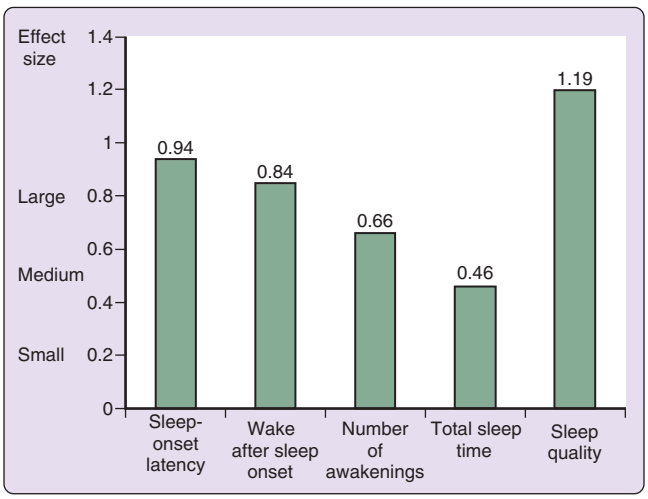

Figure 85-1 Mean effect size (reported as a standardized *z*-score) across sleep parameters. These effect sizes are pooled across three meta-analyses. (Data from Morin CM, Culbert JP, Schwartz SM. Nonpharmacological interventions for insomnia: a meta-analysis of treatment efficacy. *Am J Psychiatry* 1994;151:1172–80; Murtagh DR, Greenwood KM. Identifying effective psychological treatments for insomnia: a meta-analysis. *J Consult Clin Psychol* 1995;63:79–89; and Smith MT, Perlis ML, Park A, et al. Comparative meta-analysis of pharmacotherapy and behavior therapy for persistent insomnia. *Am J Psychiatry* 2002;159:5–11.)

In terms of absolute changes on sleep parameters, treatment reduces subjective (sleep diary) sleep latency and time awake after sleep onset from an average of 60 to 70 minutes at baseline to about 35 minutes after treatment. Total sleep time is increased by an average of 30 minutes, from 6 to 6.5 hours after treatment, with additional gains made after treatment is completed. Thus, for the average patient with persistent insomnia, often exceeding 10 years in duration, CBT may be expected to reduce sleep latency and wake after sleep onset by an average of about 50% and to bring the absolute values of those sleep parameters below or near the 30-minute cutoff criterion initially used to define sleep-onset or sleep-maintenance insomnia. Treatment effects are generally equivalent for sleep-onset and sleep-maintenance problems, although very few studies have targeted specifically the early-morning awakening problems. Overall, findings from meta-analyses represent fairly conservative estimates of treatment effects because they are based on group averages pooled across all CBT interventions, insomnia diagnoses (i.e., primary and comorbid), and age groups. Nonetheless, although most patients benefit from treatment, only about half of them achieve full remission, and a significant number continue to experience residual sleep disturbances after treatment.[31]

Treatment outcome has been documented primarily with prospective daily sleep diaries, although several studies have also complemented those findings with polysomnography (PSG)[40-42] and actigraphy.[43-45] In general, the magnitude of improvements is smaller on PSG measures, but those changes tend to parallel sleep improvements reported in daily sleep diaries. For example, in a study of older adults with sleep-maintenance insomnia,[40] average baseline values for wake after sleep onset were 62 minutes for diaries and 73 minutes for PSG measures. Posttreatment values were 29 minutes for the diary and 35 minutes for PSG, yielding improvement rates of 54% and 51%, respectively, for the two assessment methods. In another study,[44] sleep efficiency increases of 8% and 12% were obtained for PSG and diary measures, respectively, after CBT. Collectively, these findings indicate that CBT not only alters sleep perception on daily diaries but also produces objective changes on EEG-defined sleep-continuity measures. Except for a modest increase in stages 3 and 4 after sleep restriction, there are few changes in sleep stages with CBT.

Clinical Significance

In addition to showing robust changes on sleep-wake parameters, some studies have also shown that CBT produced improvements on secondary end points, including global measures of insomnia severity, sleep quality, fatigue, quality of life, sleep-related beliefs, and psychological symptoms.[46-53] Despite frequent reports of cognitive impairments among insomnia patients, there is no evidence that treatment improves performance-based measures of attention, concentration, and memory. It is unclear whether these negative findings are due to the absence of objective deficits at baseline or to the selection of measures that are not sensitive enough to detect such deficits. Nonetheless, it remains essential to document outcome beyond reduction of insomnia symptoms because it is often the perceived consequences of insomnia, rather than insomnia per se, that prompt treatment seeking. Investigators should incorporate multiple outcome measures, including sleep, functional impairments, psychological symptoms, and quality of life.[54,55]

Generalizability of Treatment Effects to Comorbid Insomnia

Insomnia is often a pervasive problem among patients with medical or psychiatric conditions.[8,56,57] Although it is generally assumed that the sleep disturbance will remit with appropriate treatment of the comorbid condition, often it does not. Insomnia that persists after treatment of the comorbid condition, for instance depression, may actually increase the risk for future relapse of that condition. Thus it is often essential to treat both the sleep and the coexisting disorder. An important study by Manber and colleagues[58] showed that CBT had an augmentation effect when used in combination with antidepressant medication in the treatment of insomnia comorbid with major depression. The addition of CBT for insomnia, relative to antidepressant therapy alone, resulted in higher remission rates of depression (61.5% vs. 33.3%) and insomnia (50% vs. 7.7%) and larger improvements in measures of sleep continuity.

Several additional studies have shown that patients with medical and psychiatric conditions can also benefit from insomnia-specific treatment, even though the outcome with those patients is sometimes more modest compared with insomnia patients without comorbid disorders.[59-66] A systematic review of 16 randomized controlled trials of CBT for insomnia in psychiatric populations found that CBT was effective to improve sleep in patients with comorbid depression, anxiety, posttraumatic stress disorder, and substance abuse disorders. The comorbid disorder also improved after CBT for insomnia in some instances.[67,68] Findings from another review also supports the use of CBT for insomnia in individuals with alcohol-related disorders, although the evidence is more limited for this condition.[69]

Controlled studies have also shown that CBT is effective for treating insomnia comorbid with medical disorders, including chronic pain,[70] fibromyalgia,[71] cancer,[52,72] and various medical conditions in older adults.[35,65,73-75] CBT was generally superior to MBSR for cancer patients with insomnia.[76] Single-case experimental studies also support the use of CBT for insomnia associated with traumatic brain injury.[61] In general, the findings of comorbid insomnia studies indicate that baseline and posttreatment scores on insomnia measures are usually more severe among patients with comorbid disorders relative to those without comorbid conditions, but they can still benefit from treatment. To optimize outcome, it is often necessary to adapt these interventions to disease-specific conditions[56]; for example, the addition of a fatigue management module to standard CBT has proved helpful for insomnia comorbid with cancer[52] and traumatic brain injury.[61]

Treatment of Insomnia in Older Adults

Insomnia is age-related, and its treatment in older adults has received increased attention from clinical investigators (see Chapter 153). Two evidence-based review papers concluded that CBT is effective for managing insomnia in older adults. A meta-analysis[35] showed robust treatment effects in sleep continuity (mean effect sizes, 0.52 for sleep latency and 0.64 for time awake after sleep onset) and sleep quality (0.76) for older adults, with similar effects for CBT, relaxation, and behavioral approaches. Another systematic review reported that multimodal CBT and sleep restriction or sleep compression met criteria for empirically validated therapies, but there was not adequate evidence to support cognitive therapy, relaxation, and sleep hygiene education as stand-alone interventions for insomnia in older adults.[75] A dismantling study comparing stimulus control, sleep restriction, and a multicomponent intervention in older adults found that all three conditions produced significant and sustainable sleep improvements, whereas the multicomponent intervention yielded the highest insomnia remission rate.[77]

Insomnia in elderly people is more likely to be comorbid with another medical condition or even another sleep disorder than to occur on its own. The presence of a comorbid medical disorder, however, is not a contraindication to using CBT for insomnia, unless it is an unstable or advanced illness that precludes the patient from being able to use the techniques. There is increasing evidence that CBT is effective for insomnia in the context of other medical and, to a lesser extent, psychiatric conditions.[65,74,78,79] One study[74] found that older adults with chronic obstructive pulmonary disease, osteoarthritis, or coronary artery disease responded equally well to group CBT relative to control patients. In addition to improving sleep continuity, treatment of insomnia in elderly people is usually associated with enhanced sleep satisfaction and quality of life.

When patients are considered for CBT, they might already have been on hypnotic medication for a long period, which can represent a challenge for clinicians. This clinical situation is more common in older adults, but it can occur with all age groups. Several studies have shown that a supervised, structured, and time-limited withdrawal program, with or without CBT, can facilitate discontinuation of hypnotic medications among patients with prolonged use.[80-84] In a study of 76 older adults who had used benzodiazepines for insomnia for nearly 20 years, treatment was effective in reducing both the quantity (90% reduction) and the frequency (80% reduction) of medication use, and 63% of the patients were drug free within the 10-week intervention.[80] The addition of CBT to the withdrawal program minimized rebound insomnia and reduced worries about drug discontinuation.

Initial Treatment Response versus Long-Term Outcome

Because insomnia is often a recurrent or persistent problem and CBT is a brief intervention, it is important to evaluate outcome beyond initial treatment. A robust finding across clinical trials is that sleep improvements achieved with CBT are well sustained after treatment is completed.[31,33,37] Although sleep restriction may yield only modest increases (and even a reduction) of sleep time during initial therapy, there is generally an increase at follow-up. Long-term outcome must be interpreted cautiously, however, because few studies report follow-up data later than 6 months after treatment and, among those that do, attrition rates increase over time. In addition, it is important to keep in mind that patients with chronic insomnia, even those who benefit from short-term therapy, might remain vulnerable to recurrent episodes of insomnia in the long term.[85,86] The addition of maintenance therapy in the form of booster therapy sessions might facilitate better integration of newly learned self-management skills and contribute to improved long-term outcome.[87]

Comparative Efficacy of Single Therapies

Although multimodal CBT is becoming the standard approach in the field, there is little information on the relative

efficacy and unique contribution of each therapeutic component. Nonetheless, studies comparing the relative efficacy of single therapies have found that stimulus control and sleep restriction therapies are more effective than relaxation alone, which, in turn, is more effective than sleep hygiene education.[31,33,37] Sleep restriction tends to produce better outcomes than stimulus control in terms of sleep efficiency and continuity, but it also decreases sleep time during initial treatment. Relaxation methods focusing on cognitive arousal (e.g., reducing intrusive thoughts) yield slightly greater improvements than those targeting somatic arousal. Sleep hygiene education, when used alone, produces little effect on sleep and insomnia symptoms; this didactic approach should be seen as a minimal intervention. Cognitive therapy, although increasingly used as one therapeutic component of multimodal interventions,[31] has been evaluated as a single treatment in two studies.[24,88] In a dismantling study investigating the relative efficacy and unique contribution of behavior therapy (sleep restriction and stimulus control), cognitive therapy, and combined CBT for insomnia, all three therapies produced significant reductions of insomnia severity symptoms.[88] CBT produced the best outcomes overall, and although behavior therapy produced immediate benefits after treatment, these were not as well sustained 6 months after treatment, although the benefits associated with cognitive therapy were slower to accrue but were more sustained 6 months after treatment. Figure 85-2 illustrates some of these results: all three conditions showed significant improvements on the ISI, and these were well maintained at the 6-month follow-up. Depending on the condition, rates of treatment response (i.e., reduction in ISI score of at least 8) were between 42% and 67% after treatment and between 44% and 67% at follow-up, whereas rates of insomnia remission (i.e., ISI score below 8) were between 31% and 57% after treatment and between 37% and 52% at follow-up.

Based on criteria set forth by the American Psychological Association, there are currently five interventions that have sufficient evidence to meet criteria for well-established psychological treatment for insomnia: CBT, sleep restriction, stimulus control, relaxation, and paradoxical intention.[31] When the evidence is evaluated specifically with older adults, CBT, sleep restriction, and stimulus control meet similar efficacy standards[75] (Table 85-1).

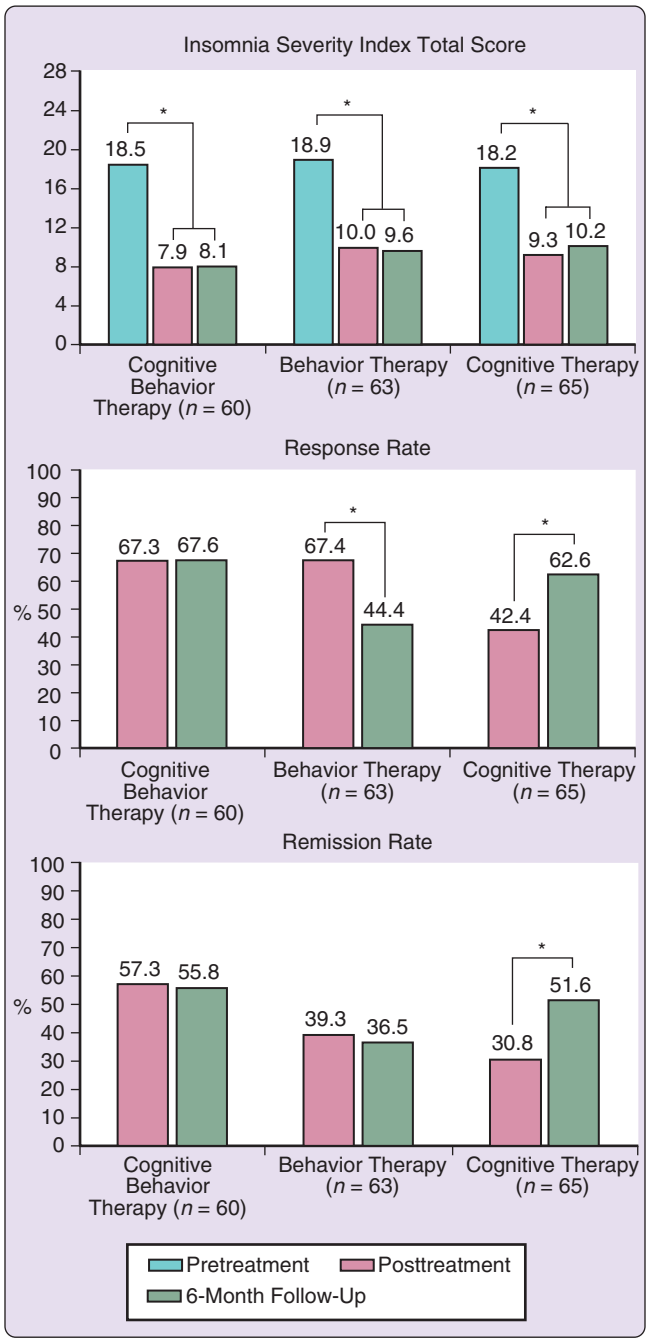

Figure 85-2 Changes in the Insomnia Severity Index (ISI) following cognitive behavior therapy (CBT), behavior therapy (BT), or cognitive therapy (CT). Response was defined as a reduction in total ISI score of at least 8 points from baseline and remission was defined as an ISI score below 8 at posttreatment or 6-month follow-up. Flagged comparisons (*) are significant at $P < .05$. Also significant: greater response rates at posttreatment for CBT and BT compared with CT, greater response rate at follow-up for CBT compared with BT, greater remission rate at posttreatment for CBT compared with CT, and greater remission rate at follow-up for CBT compared with BT. (Data from Harvey AG, Belanger L, Talbot L, et al. Comparative efficacy of behavior therapy, cognitive therapy, and cognitive behavior therapy for chronic insomnia: a randomized controlled trial. *J Consult Clin Psychol* 2014;82:670–83.)

Treatment Specificity and Mechanisms of Changes

Although there is strong evidence supporting the efficacy of CBT, there is little information about the mechanisms responsible for sleep improvements. In a review of 21 randomized controlled trials and 11 secondary analyses, several potential mediators of CBT were examined, including behavioral (time spent in bed, napping), cognitive (sleep effort, self-efficacy), and hyperarousal-related mediators (physiologic or cognitive arousal). It was concluded that although CBT elicits changes in the processes involved in the maintenance of insomnia, it remains unclear whether these changes are responsible for sleep improvements.[89]

With a few notable exceptions, which have used attention-placebo conditions,[19,44,90] most CBT trials have used waitlist control groups, precluding the unequivocal attribution of treatment effects to any specific therapeutic ingredient. The lack of a pill-placebo control equivalent in psychological treatment studies makes it difficult to determine what percentage of the variance in outcomes is the result of specific clinical procedures (e.g., restriction of time in bed, cognitive restructuring), the measurement process (e.g., self-monitoring), or nonspecific factors (e.g., therapist attention, patients' expectations). A recent trial comparing online CBT, attention-placebo

Table 85-1 Evidence Level for Cognitive Behavior Therapies for Persistent Insomnia

Intervention	Level of Evidence*	Key Studies
Sleep restriction	Guideline	Epstein et al, 2012[77] Fernando et al, 2013[114]
Stimulus control	Standard	Epstein et al, 2012[77] Riedel et al, 1998[115]
Relaxation training	Standard	Lichstein et al, 2001[19] Means et al, 2000[116]
Cognitive therapy	Insufficient evidence	Harvey et al, 2007[24] Harvey et al, 2014[88]
Mindfulness-based interventions	Insufficient evidence	Gross et al, 2011[117] Ong et al, 2014[27]
Sleep hygiene education	The evidence indicates that sleep hygiene education alone is not effective	Morin et al, 1999[31]; 2006[37]
Multicomponent cognitive behavior therapy (CBT)	Standard (for CBT with or without relaxation training) Guideline (for CBT without cognitive therapy)	Bothelius et al, 2013[104] Harvey et al, 2014[88] Edinger et al, 2009[66] Morin et al, 1999[40]; 2009[87] Morin et al, 2006[31]

*Level of evidence according to the Practice Parameters for the psychological and behavioral treatment of insomnia,[10] except for mindfulness-based interventions, which were not evaluated in these practice parameters.

(imagery relief therapy), and treatment as usual showed that CBT successfully altered sleep-related attributions, thought content, and depression and anxiety symptoms, and those changes partly mediated sleep improvements.[90]

This issue of mechanism of change has been addressed indirectly by examining predictors of changes and by surveying patients about their perception of the most effective treatment components. In a follow-up study of patients who had completed CBT for insomnia,[91] the most critical ingredients associated with long-term improvements were the use of stimulus control and sleep restriction, followed by cognitive restructuring. Relaxation was the most commonly cited component (79% of respondents), but it did not predict improvement in any of the sleep variables. Other studies have examined the association between changes in sleep beliefs and attitudes and sleep improvements. Reductions of dysfunctional sleep cognitions during treatment were correlated with sleep improvements after treatment, and fewer dysfunctional cognitions after treatment were associated with better maintenance of sleep changes over time.[92] In contrast to these findings, one study found that reductions of dysfunctional sleep beliefs following CBT did not mediate improvements of insomnia symptoms.[93] Thus it is likely that factors yet to be identified are critical in mediating treatment response. With increasing evidence that central nervous system hyperarousal is implicated in insomnia,[94,95] more attention is needed to identify the biologic, as well as the psychological, mechanisms responsible for sleep changes.

Combined Cognitive Behavior Therapy and Medication

CBT and medication can play complementary roles in the management of insomnia.[96] Medication produces fast symptomatic relief, and CBT yields durable benefits over time. Thus combined approaches should, in principle, optimize outcome by capitalizing on the more immediate and potent effects of medication and the more sustained effects of CBT.

Few studies have directly evaluated the combined and differential effects of behavioral and pharmacologic therapies for insomnia.[30,40,41,50,97-101] Three studies compared triazolam with relaxation or sleep hygiene,[30,97,98] and six other studies compared CBT with temazepam,[40,41] zolpidem,[50,87] or zopiclone.[100,101] Collectively, the evidence from those studies indicates that both treatment modalities, when used singly, are effective in the short term. Medication produces rapid improvements, but these benefits are also quickly lost after the drug is discontinued. Sleep improvements obtained with CBT take longer, but they are also well sustained even after treatment ends. There is a slight additive effect of combined approaches relative to medication alone, but not necessarily relative to CBT alone.

The long-term effect of combined versus single approaches is more equivocal. Some studies[97,98] indicate that a combined intervention (e.g., triazolam plus relaxation) produces more sustained benefits than medication alone, and others[30,40,41] report more variable long-term outcomes. Treatment responses vary across individual patients; some patients retain their initial sleep improvements, but others return to their baseline values. Because of the mediating role of psychological factors in chronic insomnia, behavioral and attitudinal changes seem to be essential to sustaining improvements in sleep patterns. When behavioral and drug therapies are combined, patients' attributions of the initial benefits may be critical in determining long-term outcomes. Attribution of therapeutic benefits to the medication alone, without integration of self-management skills, can place a patient at greater risk for insomnia recurrence after the drug is discontinued. In addition, there is a risk that the availability of medications might undermine the patient's effort and motivation to implement behavioral changes in sleep habits and sleep scheduling. Thus,

despite the intuitive appeal of combining therapies, it is not entirely clear when, how, and for whom combining CBT and medication is indicated. Additional research is needed to examine optimal methods for combining or integrating these therapies.[102]

Rather than initiating and discontinuing both treatments simultaneously, it may be preferable to introduce them sequentially to optimize outcome.[103] One study has examined the effect of different treatment sequences when combining CBT with medication.[100] The optimal sequence appeared to be the introduction of CBT early in treatment, either before or concurrently with medication. In another study, medication had a modest augmentation effect on CBT, primarily in terms of improving total sleep time, and this added benefit may be important given that the sleep-restriction component of CBT reduces total sleep time during the initial course of therapy and could lead some patients to discontinue therapy prematurely.[87] Furthermore, CBT combined with medication produced faster sleep improvements, with optimal improvement reached after only 1 week of treatment compared with 2 to 3 weeks for CBT alone.[96] Overall, the best sequence may be a combined approach initially, followed by CBT alone while discontinuing medication.[87]

Efficacy versus Effectiveness

Because the main entry point for professional insomnia treatment is typically in primary care medicine, it is important to examine whether treatment validated in academic research centers is also effective in various clinical settings. Several pragmatic trials[43,49,65,84,104] in which CBT was implemented in the context of primary care practices or sleep clinics have yielded results comparable to those obtained with patients treated within more controlled research protocols. Brief consultation models involving one or two consultations have also been used successfully in primary care.[105] Finally, the effectiveness of insomnia treatment provided in behavioral sleep medicine clinics has been shown in several clinical replication series.[46,59,60]

Methods of Treatment Delivery

Group therapy can be a cost-effective method to deliver CBT for insomnia in clinical settings.[106] Although it might not provide the same flexibility, group therapy is generally as effective as individual therapy.[47] Self-help approaches using printed materials or DVDs can also be useful in insomnia treatment.[51,107,108] For example, studies[51,81] have shown that a self-help treatment program consisting of six printed booklets mailed weekly to participants was effective to treat insomnia and to reduce use of hypnotics; the addition of professional guidance in the form of brief telephone consultation added to the initial outcomes. There is also increasing evidence of the benefits of Internet-based intervention for treating insomnia.[109,110] Collectively, the evidence indicates that CBT for insomnia is effective not only in the context of controlled research studies but also in various clinical settings such as in primary care and in behavioral sleep medicine clinics. Self-help materials, brief consultations, group therapy, and even the Internet can enhance treatment access and facilitate its implementation in clinical practice. However, despite their increasing popularity,[111] self-help therapies should be seen as a complement rather than a replacement for direct face-to-face therapy.

Clinical and Practical Considerations

CBT approaches to treating primary insomnia are time limited, structured, and sleep focused. For typical patients with chronic insomnia, direct consultation time takes between 4 and 6 hours per patient, which is usually spread over a treatment period of 6 to 8 weeks.[44] The amount of direct clinical contact and the number of follow-up visits are likely to vary as a function of several factors, including insomnia severity, comorbidity, use of hypnotic medications, and the patient's motivation and education. This treatment period is considerably shorter than for other forms of psychotherapy, and it is shorter than behavioral approaches applied to other health and psychological problems (e.g., chronic pain, anxiety, depression).

Despite ample evidence supporting the efficacy of CBT for insomnia, there is a dearth of data on the effect of adherence on outcomes. Although there is a need for adding standardized measures of treatment adherence in clinical studies,[112] the success of CBT depends largely on the patient's compliance with the recommended changes. For this reason, it is particularly important to schedule follow-up visits after the initial evaluation to address adherence. Although treatment is generally well accepted by patients, it is more time-consuming and requires more effort than drug therapy for both clinicians and patients. Thus it is crucial to find ways to optimize adherence by using motivational interviewing strategies, soliciting the bed partner's collaboration, and providing feedback and guidance early in treatment.[113] Given the multifactorial nature of insomnia, it is often necessary to combine several clinical procedures rather than to rely on a single treatment modality. Sleep restriction is almost always relevant for an insomnia patient, and the use of this procedure early in therapy is likely to produce rapid therapeutic benefits. Some stimulus control procedures (e.g., getting out of bed when unable to sleep) might not be necessary early on when the initial sleep window is restricted to 5 to 6 hours per night, but those procedures become particularly relevant as the sleep window is increased. Relaxation is helpful for persons with elevated tension or anxiety; however, caution is needed because some patients have a paradoxical response and become more anxious. Cognitive therapy is particularly helpful to challenge some misconceptions about sleep and daytime impairments, to alleviate emotional distress, and to minimize recurrence of sleep disturbances over time. For milder forms of insomnia, basic sleep hygiene education may be sufficient, whereas more severe insomnia often requires multimodal interventions and more frequent follow-up visits.

CLINICAL PEARL

Sleep scheduling factors, conditioning, hyperarousal, and misconceptions about sleep are important contributing factors to persistent insomnia. Effective clinical management of insomnia must address these perpetuating factors. CBT is an effective and well-accepted therapeutic approach for persistent insomnia, and sleep improvements are well sustained over time.

SUMMARY

Significant advances have been made in the development and validation of CBT for insomnia. With increasing

research-based evidence supporting its efficacy and acceptability, CBT is often recognized as the treatment of choice for persistent insomnia. However, there is still a major gap between research evidence and actual clinical practice in that few clinicians, other than behavioral sleep medicine specialists, use this therapeutic approach in their clinical practice. Important challenges remain for professional sleep organizations and public health decision makers to promote wider dissemination and use of CBT for managing insomnia.

Psychological and Behavioral Treatments for Insomnia II: Implementation and Specific Populations

Jack D. Edinger; Melanie K. Leggett; Colleen E. Carney; Rachel Manber

Chapter Highlights

- Psychological and behavioral insomnia therapies have a strong legacy of research support showing their effectiveness for insomnia management. A number of monotherapies including stimulus control, relaxation training, and sleep restriction have shown their value for insomnia management, whereas multicomponent cognitive-behavioral insomnia therapy is now considered a first-line therapy for insomnia complaints.
- Implementation of the psychological and behavioral therapies usually entails a number of tools, such as sleep diaries and actigraphy for insomnia assessment and treatment monitoring, as well as handout materials for patients to reinforce treatment instructions received during clinical visits.
- Psychological and behavioral insomnia therapies can be provided in individual, group, and various self-help formats, and they can be delivered effectively by specialist and nonspecialist providers. The reach of these therapies can be extended by use of abridged treatment protocols in primary care settings or through sophisticated Internet protocols designed to mimic in-person treatment methods.
- The psychological and behavioral insomnia therapies have proved to be effective with various age groups as well as with patients with sleep-disruptive psychiatric and medical comorbidities. This chapter reviews important considerations in the application of these therapies with various types of patients.

As evidenced by the preceding chapter, psychological and behavioral insomnia therapies have a strong legacy of research support. Many of the stand-alone (e.g., stimulus control, sleep restriction) and multicomponent (e.g., cognitive-behavioral therapy for insomnia [CBT-I]) treatments are now regarded as well-established therapies that can and should be considered first-line or adjunctive therapies for many treatment-seeking insomnia patients. This chapter provides a description of some tools commonly employed in implementing psychological therapies for insomnia and a discussion of several issues clinicians may wish to consider when implementing these treatments across clinical settings. The chapter first describes some tools that are useful in delivering these treatments and monitoring their outcomes. The chapter then provides a discussion of treatment formats, the types of providers who might deliver these treatments, treatment dosing, and patients' acceptance and adherence to these therapies. Subsequently, the chapter provides a discussion of implementation issues and the efficacy and potential value of psychological therapies in the management of insomnia among patients with comorbid psychiatric and medical conditions. The chapter concludes by considering the applicability of the psychological and behavioral insomnia therapies with various age groups.

BASIC INTERVENTION TOOLS

The psychological and behavioral insomnia therapies include a diverse group of treatments (e.g., relaxation training, stimulus control, cognitive therapy, sleep restriction).[1,2] Research and clinical experience with these treatments have produced a number of helpful tools for identifying treatment targets, monitoring adherence and response, and delivering and reinforcing treatment instructions. In this section, we discuss some of the commonly used clinical tools for the implementation of these therapies.

Sleep Diaries

A sleep diary is an assessment and intervention tool that provides a daily recording of sleep from the patient's perspective. Sleep diaries are a mainstay of insomnia assessment and treatment as they quantify the severity of the sleep disorder, aid in diagnostic discriminations and case conceptualization, guide the implementation of behavioral interventions by tracking progress and adjustments of the behavioral instructions, identify problems with treatment adherence (e.g., varying from a prescribed sleep schedule), and measure treatment outcomes.[3]

Sleep diaries provide a more accurate and detailed depiction of sleep patterns compared with an individual's retrospective report.[4] They are inexpensive and easily administered as a paper questionnaire. There are many published versions available, resulting in variability among clinicians and researchers in type and amount of information obtained, definitions and calculations of sleep parameters, and response formats.[3] In efforts to standardize insomnia research methodologies, a Consensus Sleep Diary was published in 2012.[5] This sleep diary represents the consensus of a group of insomnia experts in collaboration with focus groups of individuals with and without sleep disorders. The Core version elicits information about the respondent's sleep-onset latency, number of awakenings, wake time during the night, total sleep time, sleep efficiency, and sleep quality in addition to a "comments" section (Figure 86-1). Two expanded versions provide queries about early morning awakenings, napping, feelings of restedness, estimated total sleep time, and use of alcohol or caffeine and medications.

Alternative versions have been developed to meet the needs of different clinical populations, such as children and adolescents, and are widely available on the Internet. For individuals who may have difficulty in accurately completing a traditional diary, such as those with highly erratic sleep patterns or shift workers, an analog or raster-style sleep diary captures a richer picture of sleep continuity. In an analog version, such as that published by the American Academy of Sleep Medicine (Figure 86-2; http://yoursleep.aasmnet.org/pdf/sleepdiary.pdf),[6] individuals are instructed to fill in blocks of time slept during 24-hour cycles.

Disadvantages of the traditional paper sleep diary include inaccurate or incomplete entries, inability to monitor or to confirm daily completion, clinician time required for hand scoring, and potential for scoring errors. These drawbacks can be mitigated with technologies such as electronic sleep diaries on hand-held devices,[7,8] computerized scoring programs,[9] and interactive voice recording systems.[10-12] CBT-i Coach,[13] which can be used in conjunction with face-to-face CBT-I, is a mobile phone application available to anyone with a smartphone (http://www.ptsd.va.gov/professional/materials/apps/cbticoach_app_pro.asp). It includes an interactive sleep diary and sleep calculations for time-in-bed prescriptions. Thus, technology is providing several sleep diary alternatives designed to improve on the traditional paper diary.

Actigraphy

Actigraphy is an objective measurement methodology that assesses limb movement activity by a small recording device usually worn on the wrist (see Chapter 171). Typically, 24-hour activity is recorded for periods of 1 to 2 weeks and is accompanied by sleep diaries so that bedtimes, rise times, and times the device was removed can be determined. Recorded data are subjected to a proprietary algorithm that produces estimates of sleep-wake variables. Current standards of practice outline the primary roles of actigraphy in insomnia as the characterization of circadian or sleep disturbance and

the evaluation of treatment response.[14] In general, studies have shown that actigraphy can reliably differentiate individuals with and without insomnia.[15-17] However, because actigraphy tends to interpret wakeful stillness in bed as sleep, its validity in insomnia patients is less robust than in sleepers without insomnia.[3,15]

Actigraphy is unobtrusive and simple to use, requiring minimal effort from the patient. It can be used in the home environment for extended periods to capture night-to-night variability in sleep patterns characteristic of insomnia. It can also be used to measure sleep in those who may be unable to complete sleep diaries. Because actigraphy records continuously, information on 24-hour rest and activity patterns can be examined to detect unreported daytime naps or day-to-day variations in the sleep schedule. Actigraphy may also be useful in monitoring adherence to behavioral treatment recommendations and for identifying when violations of those recommendations occur.[18] Furthermore, actigraphy provides streamlined electronic data collection and analysis. Although it is more costly than sleep diaries, actigraphy provides an objective estimate of sleep patterns that is much less expensive than polysomnography.

The major disadvantages of actigraphy revolve around a lack of standardization in instrumentation, methodologies, sampling procedures, and analytic algorithms.[15,16] For example, quantitative criteria used to differentiate between insomnia and normal sleepers vary by type of device.[19] Also, data loss may occur if the individual does not follow instructions for using the device (e.g., removes the device or does not depress the device button for documenting events).[20]

Written Behavioral Prescriptions for Home Use

The success of psychological and behavioral insomnia therapies depends on the patient's ability to implement therapeutic techniques in the home environment. Patients may be more successful in adhering to treatment recommendations if they understand the rationale behind the therapy instructions. This knowledge is particularly salient for treatment recommendations that are counterintuitive, such as directives to limit time in bed and to leave the bedroom if not sleeping. Indeed, as has been demonstrated in cognitive-behavioral therapy (CBT) for depression, a patient's acceptance of the treatment rationale enhances the likelihood of a positive treatment outcome.[21] Furthermore, providing a written summary of behavioral prescriptions helps the patient review and remember the information discussed during the therapy session.

Boxes 86-1 to 86-3 exemplify handouts that facilitate the implementation of behavioral treatments. Sleep restriction and stimulus control are efficacious, stand-alone therapies but are more commonly folded into a multicomponent CBT-I. Discussions of how these various treatment components are used in combination are provided in several therapist guidebooks.[1,2,22,23] The following text provides descriptions of the individual CBT-I components.

Behavior Therapy Tools

Sleep Restriction

In its original version,[24] sleep restriction requires the patient to initially limit the time in bed to the average total sleep time shown on 2 weeks of pretherapy sleep diaries. However, 4.5 hours was set as the minimum time in bed. Patients were instructed to go to bed 15 minutes earlier if, after 5 days, sleep efficiency (based on subjective reports) was 90% or more. If sleep efficiency was less than 85%, time in bed was decreased; no change was made if sleep efficiency fell between 85% and 89%.

Although the general principle of sleep restriction (that of inducing mild sleep deprivation to consolidate sleep) endures today, many clinicians relax the original sleep restriction protocol to promote the patient's adherence.[1,2,25-27] Morin[1] provides guidelines for implementing sleep restriction that include flexibility in restricting time in bed to what the patient can tolerate, increasing time in bed (after the initial restriction) at predetermined intervals rather than in response to sleep efficiency improvements in some situations, adjusting the frequency of time in bed alterations on the basis of the patient's comfort, giving patients control in selecting bed and rise times, and reassuring the patient about the transient side effect of daytime sleepiness. Recommending reduction of time in bed may seem counterintuitive to patients and contradict strategies they have tried on their own to manage insomnia. Thus, a clear explanation of the therapy's rationale as shown in Box 86-1 is particularly important to facilitate adherence.

Stimulus Control

The stimulus control instructions, originally published by Bootzin in the 1970s, essentially have remained unchanged since then.[28] The instructions to the patient, along with the rationale for each instruction, are reproduced in Box 86-2.[29] Stimulus control and sleep restriction often are used together in multicomponent insomnia treatments. In such applications, it is necessary to slightly alter the stimulus control instruction to go to bed at night when sleepy, particularly when sleepiness occurs too early to allow adherence to the sleep schedule required for sleep restriction. In these cases, patients are instructed to go to bed when sleepy but not before the earliest bedtime recommended by the sleep restriction schedule. Thus, the bedtime recommended as part of sleep restriction can be viewed as the earliest allowed bedtime, but the patient may choose to stay up later on a given night when not sufficiently sleepy at that time.

Box 86-1 SLEEP RESTRICTION RATIONALE

The following rationale is provided for a patient whose sleep logs show an average total sleep time of 6 hours, with an average time in bed of 8 hours.

Restrict the time you spend in bed to the actual amount of sleep you get. Since you average only 6 hours of sleep per night out of 8 hours spent in bed, your task consists of curtailing the time you spend in bed to these 6 hours. There is no reason for staying in bed any longer than that, since the remaining time is spent awake anyway. Spending excessive amounts of time lying down attempting to relax, rest, nap, or simply find a comfortable body position fragments rather than consolidates sleep. Although it may have been a useful coping strategy early on, it is most likely contributing to maintaining the sleep problem currently. As your sleep becomes more efficient, you will gradually be allowed to spend more time in bed.

From Morin CM. *Insomnia: psychological assessment and management*. New York: Guilford Press; 1993. p. 114.

Sleep Hygiene

Sleep hygiene practices are broadly defined and vary among clinicians, but most recommendations cover four core areas: keeping regular bedtimes and rise times, maintaining a comfortable sleep environment, curbing substance use (e.g., alcohol, nicotine, caffeine), and exercising.[30] As part of a multicomponent treatment package, recommendations about bedtimes and rise times might not be included because they are already subsumed under stimulus control and sleep restriction instructions. Box 86-3 shows a sleep hygiene handout that includes the rationale for each recommendation provided. Sleep hygiene practices can be assessed with instruments such as the Sleep Hygiene Index,[31] the Sleep Hygiene Awareness and Practice Scale,[32] or the Sleep Hygiene Checklist developed by Riedel.[33]

Sleep Education

Including a component of sleep education can cultivate positive patient expectations and maximize treatment adherence. Sleep education may include information about normative sleep patterns, circadian functioning, homeostatic sleep drive, hyperarousal, effects of sleep loss, and realistic sleep expectations.[2,9]

Additional Educational Resources

Patient-oriented educational resources in the public domain (e.g., mobile applications, websites, pamphlets, self-help books) are widely available at minimal cost and can reinforce or supplement nonpharmacologic insomnia treatments. For example, the American Academy of Sleep Medicine (www.sleepeducation.com) and the National Sleep Foundation (www.sleepfoundation.org) provide information about insomnia.

Cognitive Therapy Tools

Psychological and behavioral insomnia therapies also address cognitions that interfere with sleep, mostly by increasing sleep-disruptive cognitive arousal. Cognitive therapy for insomnia is typically combined with the behavioral methods discussed before. A recent trial confirmed that the most effective cognitive therapy outcomes are achieved by combining cognitive therapy with established behavioral therapy methods.[34] The following are a few cognitive therapy tools that help in implementing this therapy.

Worry Control and Structured Problem Solving

Worry in the presleep period is one of the strongest cognitive predictors of delayed sleep-onset latency.[35] For patients who tend to worry in bed, a variety of intervention strategies have proved useful, including stimulus control, relaxation, and techniques more directly focused on sleep-disruptive cognitions.[36-39] One of the original problem-solving cognitive strategies is a presleep writing procedure developed by Espie and Lindsay[38]; this technique is similar to a procedure called constructive worry.[36] The premise of such techniques is that unresolved

Box 86-2 STIMULUS CONTROL RATIONALE AND TREATMENT INSTRUCTIONS

1. Lie down intending to go to sleep only when you are sleepy.

   The goal of this rule is to help the patients become more sensitive to internal cues of sleepiness so that they will be more likely to fall asleep quickly when they go to bed.

2. Do not use your bed for anything except sleep; that is, do not read, watch television, eat, or worry in bed. Sexual activity is the only exception to this rule. On such occasions, the instructions are to be followed afterward when you intend to go to sleep.

   The goals here are to have activities that are associated with arousal occur elsewhere and to break up patterns that are associated with disturbed sleep. If bedtime is the only time patients have for thinking about the day's events and planning the next day, they should spend some quiet time doing that in another room before they go to bed. Many people who do not have insomnia read or listen to music in bed without problem. This is not the case for insomniacs, however. This instruction is used to help those who have sleep problems establish new routines to facilitate sleep onset.

3. If you find yourself unable to fall asleep, get up and go into another room. Stay up as long as you wish and then return to the bedroom to sleep. Although we do not want you to watch the clock, we want you to get out of bed if you do not fall asleep immediately. Remember the goal is to associate your bed with falling asleep *quickly*! If you are in bed more than about 10 minutes without falling asleep and have not gotten up, you are not following this instruction.

   In order to associate the bed with sleep and disassociate it from the frustration and arousal of not being able to sleep, the patients are instructed to get out of bed after about 10 minutes (20 minutes for those over 60 years old). This is also a means of coping with insomnia. By getting out of bed and engaging in other activities, patients are taking control of their problem. Consequently, the problem becomes more manageable and the patient is likely to experience less distress.

4. If you still cannot fall asleep, repeat Step 3. Do this as often as is necessary throughout the night.

   See rationale for earlier.

5. Set your alarm and get up at the same time every morning irrespective of how much sleep you got during the night. This will help your body acquire a consistent sleep rhythm.

   Insomniacs often have irregular sleep rhythms because they try to make up for poor sleep by sleeping late or by napping the next day. Keeping consistent wake times helps patients develop consistent sleep rhythms. In addition, the set wake times mean that the patients will be somewhat sleep deprived after a night of insomnia. This will make it more likely that they will fall asleep quickly the following night, strengthening the cues of the bed and bedroom for sleep. Often insomniacs will want to follow a different sleeping schedule on weekends or nights off than they do during the work week. It is important to have as consistent a schedule as possible, seven nights a week. In our experience, a deviation of no more than one hour in the wake time on days off does not produce problems in establishing a consistent rhythm.

6. Do not nap during the day.

   The goals of this rule are to keep insomniacs from disrupting their sleep patterns by irregular napping and to prevent them from losing the advantage of the sleep loss of the previous night for increasing the likelihood of faster sleep onset the following night. A nap that takes place seven days a week at the same time would be permissible. For those elderly insomniacs who feel that they need to nap, a short daily afternoon nap of 30 to 45 minutes or the use of 20 to 30 minutes of relaxation as a nap substitute is recommended.

From Bootzin RR. Cognitive-behavioral treatment of insomnia: knitting up the ravell'd sleave of care. In: Kenny DT, Carlson JG, McGuigan FJ, Sheppard JL, editors. *Stress and health: research and clinical applications*. Amsterdam: Harwood Academic Publishers; 2000. p. 243-66.

problems lead to worry about such matters and interfere with sleep onset by increased arousal. However, creating a plan to address the problem decreases the likelihood that such worries will follow the person to bed. Within the constructive worry approach, the patient sets aside some time several hours before bedtime (i.e., usually in the early evening) to complete a worksheet containing one column labeled Concerns and a second column labeled Solutions. In the Concerns column, patients list worries that have the greatest likelihood of keeping them awake at night. In the Solutions column, patients generate the next, immediate step they can take toward the goal of solving the problem. Patients are instructed not to write down the ultimate end solution as they may view this solution to be out of reach or difficult to implement. They are refocused on the most immediate step in the sequence. When there are no apparent solutions to solve a problem, patients are encouraged to write down an acceptance-based or self-care strategy. For example, the problem may be that their terminally ill pet will likely die tonight. In such a case, it is helpful to write down plans to implement coping strategies, such as calling a friend for moral support.

Constructive worry was also formally tested as an adjunct to behavioral therapy techniques such as stimulus control and sleep restriction, and the addition of the constructive worry procedure reduced insomnia symptom severity as well as worry to a greater degree than did behavioral therapy alone.[40] Formal problem-solving training (described by Malouff et al[41]) is also a helpful adjunct to behavioral therapy as the effects of combining problem-solving training with behavioral therapy were comparably large to those resulting from combined behavioral therapy and constructive worry.[42] A similar intervention is a writing technique called the Pennebaker writing task.[43] Harvey and Farrell[44] found that poorly sleeping young adults who used this strategy and wrote about their thoughts and negative emotions before going to bed decreased their sleep-onset latencies. A replication of this technique in a clinical sample did not find evidence for a sleep improvement; however, the writing strategy led to greater improvements in self-reported cognitive arousal.[45] Indeed, worry management techniques are likely most helpful to reduce presleep cognitive arousal and worry,[36] rather than producing sleep improvements, when tested alone.

Thought Records

Thought records are a classic cognitive therapy tool for modifying the maladaptive thinking[46] styles implicated in a variety of disorders including insomnia.[47-50] Negative sleep-related thoughts are rated as more compelling or more "believable" by

Box 86-3 SLEEP HYGIENE INSTRUCTIONS AND RATIONALE

The sorts of daytime activities in which you engage, the foods and beverages you consume, and the surroundings in which you sleep may all influence how well you sleep at night and how you feel in the daytime. Thus, you may benefit from making some changes to your lifestyle and bedroom to promote better sleep.

- Limit your use of caffeinated foods and beverages, such as coffee, tea, soft drinks, and chocolate. Caffeine is a stimulant that may make it harder for you to sleep well at night. Caffeine stays in your system for several hours after you consume it. Therefore, we recommend that you limit caffeine to the equivalent of no more than 3 cups of coffee per day and that you not consume caffeine in the late afternoon or evening hours.
- Limit your use of alcohol. Alcoholic beverages may make you fall asleep more easily. However, alcohol also causes sleep to be much more broken and far less refreshing than normal. Therefore, we recommend against using much alcohol in the evening or using alcohol as a sleep aid.
- Try some regular moderate exercise, such as walking, swimming, or bike riding. Generally, such exercise performed in the late afternoon or early evening leads to deeper sleep at night. Also, improving your fitness level will likely improve the quality of your sleep. However, avoid exercise right before bed because it may make it harder to get to sleep quickly.
- Make sure your bedroom is quiet and dark. Noise and even dim light may interrupt or shorten your sleep.
- Make sure the temperature in your bedroom is comfortable. Generally, temperatures above 75 degrees Fahrenheit cause unwanted awakenings from sleep. During hot weather, we suggest you use an air conditioner to control the bedroom temperature.
- Try a light bedtime snack that includes such items as cheese, milk, or nuts. These foods contain chemicals that your body uses to produce sleep and may help bring on drowsiness.

Modified from Edinger J, Carney C. *Overcoming insomnia: a cognitive-behavioral therapy approach—therapist guide.* New York: Oxford University Press; 2015.

those with insomnia[47-51] relative to their "good sleeper" counterparts. More specifically, people with insomnia have cognitions that (1) overestimate the negative effects of insomnia, (2) focus on the belief that sleep is out of one's control, (3) are rigid or unrealistic about how much sleep is needed for functioning, and (4) are misconceptions about the causes of insomnia.[47-50] Moreover, such thoughts seem equally present among insomnia sufferers with and without sleep-disruptive comorbidities.[51] Negative thoughts and moods can exert reciprocal negative influences on each other, and both can perpetuate insomnia. The purpose of the thought record is to observe the connections between negative thoughts and distress and to challenge or to interrupt this process.

This connection of negative thinking and distress is achieved through prospective monitoring using a specially designed thought record worksheet divided into columns. Several versions of thought records are available, including a version specifically designed for use with insomnia patients.[2] The first three columns of an insomnia-focused thought record are labeled (1) Situations, (2) Mood and Mood Intensity Rating (0% to100%), and (3) Thoughts. Observing which situations (Column 1) tend to give rise to distress (Column 2) and subsequent negative sleep-related thoughts (Column 3) can provide insight into a seemingly automatic cognitive-emotional process. Although observing these connections can be helpful in initiating cognitive change, the main use of the thought record is to challenge unhelpful thoughts. This is accomplished by having the patient list some experiences or perspectives that support the thought (Column 4) as well as some experiences or perspectives that refute the thought (Column 5). The patient then constructs a more balanced appraisal of the sleep-wake difficulties that combines the evidence supporting and refuting the original negative thought and writes that in a separate column (Column 6).

Patients often initially have difficulty completing all aspects of the thought record and particularly the task of providing evidence that refutes the unhelpful thought. For example, after a poor night's sleep, an insomnia sufferer may struggle with refuting the negative thought "after a poor night's sleep, I just can't function." For such patients, a series of Socratic questions may prove helpful. Has this thought been true 100% of the time? Is it guaranteed that a poor night's sleep will prevent them from functioning? Will he or she be able to function albeit with somewhat more than usual effort? Are there times when they had a good day even after a poor night's sleep, or a poor day after a good night's sleep? Are there strategies they have used in the past to be able to cope with the negative effects of their insomnia? Could they see how this thought becomes a self-fulfilling prophesy? Through this questioning, the patient may find evidence to refute the thought and develop a more balanced statement, such as "I don't feel well now after my poor night's sleep, but I've always made it through, and things tend to get better as the day goes on anyway." Worry management through the use of thought records or constructive worry is often a helpful adjunct to behavioral therapy. Also, given that patients view mental arousal as one of the most important factors in their insomnia, it is a worthwhile clinical endeavor.[52]

Acceptance-Based Approaches

These approaches, which include acceptance and commitment therapy and mindfulness-based cognitive therapy, represent a relatively new approach to insomnia management and focus on reducing emotional and behavioral reactivity to these anxiety-provoking thoughts about sleep, thus reducing arousal and sleep effort. Specific techniques of this nature are described in a conceptual paper by Ong, Ulmer, and Manber[53] and supported by a recent randomized clinical trial.[54]

SELECTION OF TREATMENT COMPONENTS AND DELIVERY METHODS

As noted thus far, the psychological and behavioral insomnia therapies comprise a diverse group of techniques that can be used individually or in combination to address insomnia patients' sleep-wake complaints. Admittedly, multicomponent CBT-I that combines one or more of the cognitive therapy techniques described before or in the prior chapter with stimulus control therapy, sleep restriction, sleep hygiene education, and perhaps also relaxation training has emerged as the "gold standard" nonmedicinal insomnia therapy. In fact, this form of therapy is regarded as a front-line intervention for insomnia by both the National Institutes of Health in the United States and the British Association of Psychopharmacology.[55,56] Of course, in practice, the specific psychological and behavioral

treatment components selected may be guided by the preferences and biases of practitioners who employ them as well as by patients' acceptance of those techniques. Many other factors also may dictate which treatment components are selected for use and how those treatments are actually delivered. The expertise of providers in the settings wherein the insomnia patient presents, the amount of treatment time that is practical and available in that setting, and some more general considerations about the cost-effectiveness of the treatment may all influence such choices. These considerations, in turn, argue for flexibility in choosing the components actually employed and how they are delivered so as to make these treatments broadly applicable and practical. Fortunately, both research and clinical experience suggest that these treatments afford the practitioner and patient considerable flexibility in regard to their actual composition and method of delivery. Indeed, as the following discussion demonstrates, the treatment components employed, the therapeutic modality used (i.e., individual vs. group vs. self-help), the type of provider delivering treatment, and the means by which treatment instructions are communicated can all vary such that a multitude of effective treatment delivery options can be considered for these therapies.

Individual Treatment Format

Perhaps the best tested and most commonly used method of delivering psychological and behavioral insomnia therapies has been by individualized treatment consisting of one-on-one sessions between a therapist and single patient. Most published studies using this treatment format have employed doctoral-level or graduate student psychologists as therapists primarily because the psychological and behavioral insomnia therapies have, for the most part, been developed by psychologists. Several meta-analyses and systematic reviews suggest that individualized treatment is efficacious for short-term and longer insomnia management.[57-62] Moreover, this literature suggests that individual therapy is effective for the stand-alone therapies, including relaxation training, sleep restriction, paradoxical intention, and stimulus control, as well as for the multicomponent CBT-I protocols. Thus, individualized therapy can be considered a well-established and viable method for delivering these treatments.

As evidenced by previous critical reviews[58,59] as well as meta-analyses,[57,60,61] the literature contains many descriptions of treatment protocols for both the stand-alone and multicomponent psychological and behavioral insomnia treatments provided in individual treatment formats. Publications during the past 25 years suggest that CBT-I and other multicomponent renditions of the behavioral insomnia therapies have become increasingly popular. This trend likely results from the presumption that multicomponent treatments are best able to address the range of cognitive and behavioral mechanisms that perpetuate insomnia.[59] Most available descriptions of these multicomponent interventions come from clinical trials that outline a fixed treatment package, usually in four to eight sessions occurring at predetermined intervals. However, in clinical practice, patients' treatment needs vary, so pretreatment case formulations often guide the specific treatment components and duration of treatment provided. Although no consensus guidelines exist for matching treatment components to patients, some previous clinic-based studies[63,64] describe flexible treatment packages that allow tailoring of therapies to patients.

In deciding on the attractiveness and suitability of individualized therapy for a particular venue, consideration of the advantages and disadvantages of this treatment method is useful. As is the case for individualized treatment in general, this form of insomnia treatment delivery fits well with traditional mental health outpatient and private practice settings wherein one-on-one meetings between providers and patients are the norm. Individualized treatment offers reasonable scheduling flexibility, subject to the common availability of the provider and patient, and it requires only the limited office space to accommodate the patient-provider dyad. It also allows maximum flexibility in tailoring of treatment to best address each patient's problem sleep-related cognitions and behaviors. However, individualized treatment is at the high-intensity end of the treatment continuum. It is relatively costly to the patient and arguably is an inefficient use of the limited number of providers (largely psychologists and other doctoral-level sleep specialists) who have expertise with behavioral insomnia therapies. Yet, some patients prefer individual therapy to other forms of treatment, given the level of confidentiality and treatment tailoring it affords them, despite its relatively high cost. Thus, the patient's preferences may dictate the choice of this approach when knowledgeable providers are available.

Group Treatment Format

To address the noted disadvantages of individualized insomnia therapy, various alternative, more cost-efficient delivery methods have been developed. One common albeit lower intensity treatment delivery method entails the use of a group therapy format. Most previously described group treatment protocols have used CBT-I or other multicomponent packages that are typically provided in four to eight group treatment sessions. Table 86-1 provides a listing and brief descriptions of a sampling of these group protocols. As suggested by this information, there is no one standard brand of group therapy that has been employed universally for insomnia treatment. However, the descriptions presented show that group therapy protocols characteristically include an amalgam of such well-established, stand-alone insomnia treatments as stimulus control, relaxation training, and sleep restriction, and these components are often supplemented by sleep education, sleep hygiene instructions, and cognitive therapy. Thus, group protocols are typically omnibus and include components with well-established efficacy for treating chronic insomnia.

Results of the studies listed in Table 86-1 as well as previous meta-analyses[57,60,65] and critical reviews[58,59] suggest that group therapy is an efficacious delivery format for behavioral insomnia therapy. As shown by Figure 86-3, recent meta-analytic findings suggest that group CBT-I produces medium to large effect sizes for most sleep variables. Both comparisons conducted within patient cohorts receiving group CBT-I and comparisons between cohorts assigned to group CBT-I or a control condition support this contention. As is also apparent from the data presented in Figure 86-3, group CBT-I has durable treatment effects because the effect sizes noted at follow-up assessment conducted 3 to 12 months after treatment cessation indicate reasonable retention of treatment gains. Thus, group delivery of psychological and behavioral insomnia therapy seems a reasonably efficacious treatment methodology.

Whether group and individual insomnia treatments are equally efficacious is not clear. On the one hand, conclusions

Table 86-1 Sampling of CBT-I Group Therapy Approaches for Insomnia

Citation	No. of Sessions	Treatment Components	Types of Patients	No. of Patients per Group	Type of Providers

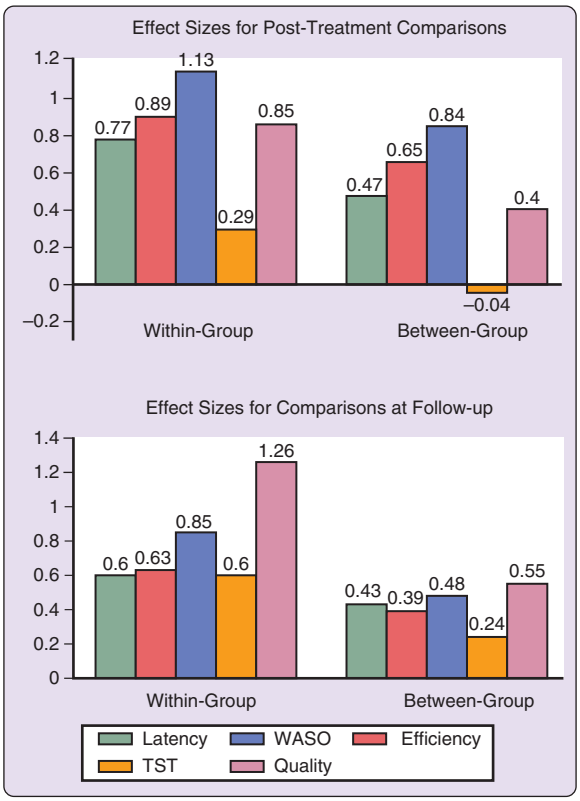

Figure 86-3 Group cognitive-behavioral therapy for insomnia (CBT-I) treatment effect sizes. Data taken from Koffel et al.[65] All data are based on sleep diary assessments. Within-group comparisons are based on pretreatment to posttreatment change within cohorts receiving group CBT-I. Between-group data are based on comparisons between cohorts assigned to group CBT-I and a control group. Latency, Sleep-onset latency; WASO, wake time after sleep onset; Efficiency, sleep efficiency; TST, total sleep time; Quality, subjective sleep quality ratings.

derived from previous meta-analyses conflict; one such report[57] concluded that individually administered treatments are slightly superior to group interventions, whereas another report[60] concluded that the two methods of insomnia treatment produce comparable results. However, conclusions based on meta-analyses should be accepted cautiously because they are based on comparisons of studies that employed different therapists, different patient samples, and often different treatment packages. More trustworthy are randomized trials that provide direct comparisons of group and individual therapy within the same study. Unfortunately, only three such studies have been conducted. Two of these studies[66,67] concluded that the two methods of CBT-I delivery are equally effective, whereas the third reported that individual CBT-I resulted in greater improvement in sleep-onset latency and overall sleep quality than did group CBT-I.[68] Thus, more comparisons of this nature are needed before conclusions can be drawn.

What is clear is that group therapy represents a reasonably efficacious form of insomnia treatment delivery with several advantages that make it an attractive treatment medium. First, as there currently are a limited number of providers competent in behavioral insomnia therapies, group treatment allows multiple patients access to a single trained provider. As such, the group format entails a relatively efficient use of the provider's time. Because of this efficiency, group treatment is generally a less expensive treatment alternative for the patient and third-party payers. Furthermore, the group milieu, composed of many patients with the same sorts of sleep difficulties, offers individual patients some sense of validation and social support that they would likely not derive from individualized treatment. Arguably, these nonspecific factors enhance treatment outcomes for at least a portion of those who attend group insomnia therapies. Yet group treatment offers less scheduling flexibility than one-on-one therapy, and it may afford patients less individualized attention. It may be difficult for all patients to attend all sessions at prescheduled times, and if patients miss group sessions, individual "make-up" sessions may be needed to help patients catch up on missed material. Such occurrences, of course, raise the cost and reduce the efficiency of group intervention. Group treatment may be optimized by the individual prescreening of participants to identify those with special treatment needs (e.g., uncontrolled comorbid psychiatric or medical disorders) or who might be disruptive to the group process. Furthermore, group treatment requires a meeting room sufficiently large to accommodate at least one therapist and several patients. The space needed and the desirability of minimizing the time patients wait for a new group to form may render group treatment unfeasible in some settings because of limited space and patient volume. Nonetheless, group therapy should be considered a viable treatment alternative that has a place in many clinical venues.

Delivery by Nonspecialist Providers

As noted recently,[69] the ranks of sleep specialists who are expert in the behavioral insomnia therapies are currently limited. In efforts to facilitate broad dissemination of behavioral insomnia treatments, some investigators have examined whether nontraditional "therapists" can effectively deliver these interventions. Because insomnia sufferers typically present first in primary care settings, it seems reasonable to consider using health care professionals (e.g., nurses, physician's assistants, general practitioners) who are not sleep specialists to provide behavioral interventions. Several studies designed to test the efficacy of using nontraditional therapists have demonstrated that various general health care staff, including family physicians,[70] nurses,[71-73] nondoctoral rural mental health clinic staff such as mental health counselors and social workers,[74] and primary care counselors,[75] can effectively administer treatments such as stimulus control and multicomponent CBT-I in general practice settings. In several of these trials, the nontraditional therapists received training and supervision from an experienced specialist (i.e., sleep psychologist) such that the therapists employed could be considered specialist provider "extenders." This model wherein the CBT-I specialist assumes a trainer or consultant role may represent a reasonable alternative to higher priced specialty care and prove useful for optimal dissemination of the behavioral insomnia therapies in primary care and other medical settings.

Perhaps the most ambitious effort to train nonspecialists in CBT-I delivery has been the training dissemination program effected by the Department of Veterans Affairs (VA).[9,76-78] This program was devised to train available licensed mental health workers (psychologists, social workers, nurses, and psychiatrists) at VA medical centers across the United States in the delivery of CBT-I to VA patients with insomnia complaints. The training itself requires providers to read a treatment manual and to attend a 3-day workshop as well as 4 months of weekly telephone consultation or supervision

with an expert consultant who provides case consultation and reviews the audio recordings of CBT-I therapy sessions they conduct. The most recent report[78] indicates that this program has successfully trained more than 300 VA providers across the nation, and most of these trainees have gone on to use their CBT-I skills in treating almost 700 insomnia patients at their respective medical centers. Furthermore, the program evaluation data suggest that these providers show acceptable CBT-I proficiency levels as measured by systematic ratings of their recorded therapy sessions and also by patient-reported outcome measures assessing their insomnia symptoms, mood statuses, and quality of life perceptions. Admittedly, this training program was time-consuming to develop and costly to effect. Yet it provides a promising model for optimizing the use of a limited number of CBT-I experts in a consultant role to expand their reach to a much larger population of insomnia patients than they themselves could manage.

Collaboration between a specialist consultant and the nonspecialist health care providers who deliver treatment has obvious appeal. This delivery model represents an efficient use of behavioral sleep medicine specialists and ensures that their expertise is made available, albeit indirectly, in those medical settings where most treatment-seeking insomnia patients present.[79] The training of existing health care personnel to deliver behavioral insomnia therapies also seems reasonable, given the relevant training most such professionals have in the provision of related health care activities. At least one study[73] using this delivery method noted treatment effect sizes that fall short of those usually reported for efficacy studies in which more traditional therapists (PhD or graduate-student psychologists) were employed. In another study,[80] primary care health providers who received CBT-I training solely from a manual helped 47% of the insomnia patients they treated achieve clinically significant improvement after treatment. However, these patients also showed significant deterioration in their symptoms by a subsequent follow-up assessment, a finding contrary to many studies that employed more expert therapists. Whether such differences in treatment outcome are due to "therapist effects" or the presence of more difficult to treat patients encountered by the CBT-I-trained nonspecialists is difficult to determine. Only through studies that directly compare specialist and nonspecialist CBT-I therapists will this question be answered. When licensed health care providers who are not CBT-I specialists can be properly trained and given access to an experienced CBT-I specialist or consultant, this sort of delivery method seems a reasonable alternative to consider. However, the more complex insomnia cases seen in such settings may ultimately benefit by referral to an experienced behavioral sleep medicine specialist for insomnia management.[69]

Abridged Protocols Designed for Primary Care Settings

A large percentage of insomnia patients first seek treatment in primary care settings for their sleep problems. Yet the high patient flow and consequent restrictions on the face-to-face time providers have with their patients obviate use of the relativity time-consuming CBT-I protocols in such venues. Hence, some investigators have developed and tested abridged CBT-I interventions specifically designed for use in primary care settings. In an early study, Edinger and Sampson[81] developed a treatment composed of brief sleep education on the individual differences in sleep needs, the effects of aging on sleep, and the influences of sleep drive and circadian rhythms on sleep along with a condensed set of behavioral treatment recommendations, including (1) eliminate sleep-incompatible activities (television watching, reading, planning, and worrying) in the bed and bedroom, (2) avoid all daytime napping, and (3) follow a consistent sleep-wake schedule by adhering to agreed-on bedtimes and rising times. This treatment was delivered to military veterans with sleep complaints in two biweekly 25-minute sessions with a psychologist. A comparison of this intervention against a sleep hygiene control intervention showed highly favorable results for the abridged treatment.

In two subsequent studies, Germain et al[82] and Buysse et al[83] tested a similar brief behavioral therapy for insomnia (BBTI) against an information control condition for treating the sleep problems of older primary care patients with insomnia. BBTI consisted of brief sleep education about homeostatic and circadian sleep regulation as well as a set of behavioral recommendations, including (1) reduce time in bed, (2) get up at the same time every day, regardless of sleep duration, (3) do not go to bed unless sleepy, and (4) do not stay in bed unless asleep. Napping was also discouraged. BBTI and information control interventions were delivered by a master's-level nurse practitioner who had no prior experience with behavioral insomnia therapies. Both treatments were delivered in one 45- to 60-minute initial face-to-face session followed by a 30-minute visit 2 weeks later and then by additional 20-minute phone calls scheduled 1 and 3 weeks after the latter in-person session. The study results suggest that BBTI was significantly more effective than the control intervention and resulted in a 55% insomnia remission rate. Figure 86-4 shows the treatment effect sizes for selected sleep diary variables in the comparisons conducted between BBTI and information control. Comparisons of these findings with previous studies suggest that BBTI produced more modest treatment effects than found in previous studies using unabridged treatments in middle-aged cohorts but similar effects to such treatments applied to older adults. Nonetheless, considering that the promising effects were obtained with the sort of nurse interventionist that would be found in many primary care settings, this type of intervention holds promise for broad dissemination in primary care venues. However, how best to broadly disseminate the training necessary to the health care providers

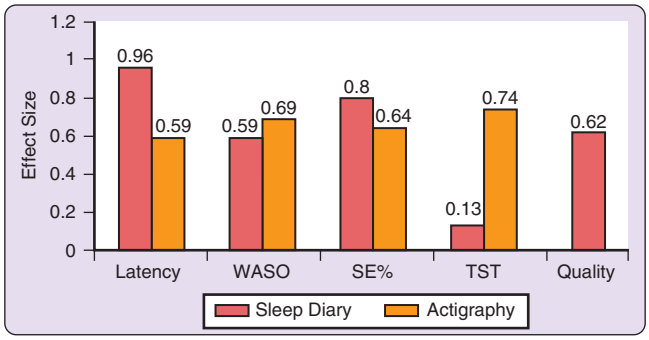

Figure 86-4 Treatment effect sizes for brief behavioral insomnia therapy.[83] Findings taken from Buysse et al.[83] Effect sizes shown are for a brief behavioral insomnia therapy relative to an information control therapy. Latency, Sleep-onset latency; WASO, wake time after sleep onset; SE%, sleep efficiency percentage; TST, total sleep time; Quality, subjective sleep quality rating (rated on a scale of 0 to 100) from sleep diary only.

who might deliver this treatment remains a challenge to be addressed in making this sort of entry-level intervention more generally available.

Self-Help and Remote Treatment Delivery

The various approaches discussed thus far provide a number of delivery methods for disseminating behavioral insomnia treatments. However, these options considered collectively may not meet the needs of all insomnia sufferers. Given the 10% to 22% population prevalence[84-87] of chronic insomnia and the limited number of skilled providers, many patients do not have easy access to such treatment, especially those far outside urban areas where most such providers are found. Others with limited financial resources (e.g., the poor and uninsured) may not have sufficient financial resources to seek professional help for their insomnia. Finally, some insomnia sufferers initially may prefer to use self-help approaches with limited or no provider contact. Thus, they may resist presenting to clinical settings for insomnia treatment.

Given these considerations, several investigators have tested less expensive treatment delivery methods that can be largely initiated in the home by patients themselves. For example, Mimeault and Morin[88] tested a booklet of self-help CBT-I instructions used independently or with therapist guidance provided by telephone against a wait-list control group. Compared with the control, those treated with the self-help therapy showed substantially greater sleep improvements, and the improvements were maintained at a 3-month follow-up. The addition of therapist phone consultations conferred some advantage over the self-help booklet alone, but these benefits disappeared by follow-up. In another study, Currie et al[89] compared individual behavioral insomnia therapy, treatment with a self-help manual, and a waiting list condition for ameliorating insomnia in a group of recovering alcoholics. Results showed that treated patients achieved significantly greater improvements than controls, but no significant differences were noted between the in-person individual therapy and the home-administered self-help program. Bastien et al[66] found comparable effectiveness of cognitive-behavioral insomnia therapy provided in individual, group, and telephone consultation formats. Finally, Rybarczyk et al[90] tested a home-based video CBT-I program for treating older insomnia patients with comorbid medical conditions. This treatment produced greater improvements in sleep and waking functioning than did a wait-list condition, but the improvements fell short of those achieved with CBT-I delivered face to face in a classroom setting. Considered collectively, these findings suggest that self-administered behavioral insomnia treatments are promising, although contact with a therapist by phone consultation may be needed to improve outcome.

To determine whether behavioral insomnia treatments can be delivered effectively without direct provider-patient interaction, some investigators have tested treatment protocols provided through mass media dissemination. Oosterhuis and Klip[91] tested a behavioral insomnia therapy provided through a series of eight 15-minute educational programs broadcast on radio and television in the Netherlands. More than 23,000 people ordered the accompanying course material. Data from a random subset of these showed that sleep improvements and reductions in hypnotic use, medical visits, and physical complaints were achieved among those who took part in this program. However, given the single-group nature of their design, it is difficult to discern how these results might compare with more conventional treatment. More recently, Gehrman[92] described a group CBT-I program for veterans with posttraumatic stress disorder (PTSD) delivered by a remotely located expert therapist by video telehealth connection. The therapist was located at one VA medical center in Philadelphia, whereas the patients were located elsewhere at various VA facilities around the country. The program entailed six group therapy sessions delivered by video conferencing to the remotely located patients. Early results reported improvements in both insomnia and PTSD symptoms, although endpoint data suggest that the treatment effects may fall short of what has been reported for other group CBT-I interventions. Nonetheless, the reported results appear promising, particularly in considering the difficult sleep problems typically presented by the types of patients enrolled in this treatment.

Given its widespread availability and extensive societal reach, the Internet has also been tapped for dissemination of CBT-I. Various websites (particularly those developed by medical organizations and professional sleep societies) offer their readers general sleep hygiene information as well as sleep improvement guidelines derived from interventions such as stimulus control and sleep restriction therapy. These sorts of "interventions" arguably represent a relatively low intensity treatment perhaps best suited for a subset of insomnia sufferers who are highly self-motivated. However, at the other end of the Internet delivery continuum are a number of recently developed, automated and interactive CBT-I interventions designed to mimic therapist-delivered interventions. Several investigators have developed and tested these sorts of interventions with generally positive results.[93-99] In one well-designed trial, Ritterband et al[95] tested an Internet CBT-I intervention composed of video-based material from expert therapists and automated interactive components designed to tailor treatment to individual patients (www.shuti.net). Study results showed that the Internet CBT-I produced significantly greater reductions in overall insomnia severity and greater improvements in sleep efficiency than did a wait-list control. Likewise, Espie et al[99] tested an Internet-based intervention (www.sleepio.com) in the largest ($n = 164$) and only placebo-controlled trial to date against both an Internet placebo therapy and treatment as usual in primary care patients. The intervention is delivered by an engaging animated character, "The Prof," who interacts with program users and provides treatment advice and guidance based on information entered into the program by the user-patient. Study findings showed that this intervention produced significantly greater improvements than did the other two conditions for a range of outcome measures.

Overall, the various self-help and remote delivery methods for CBT-I have several advantages that give them appeal. First, they greatly extend the reach of these insomnia treatments to remote users who would otherwise have no access to such treatments. They also can be considered efficient because they allow access to treatment for a large number of patients at one time. Furthermore, the more sophisticated online delivery programs mimic what occurs in the typical psychological and behavioral insomnia therapy yet do so at a reasonable cost. Although online interventions do charge users for their programs, the costs are notably lower that the costs for in-person interventions. Yet the majority of these interventions require significant independence and self-motivation on the patient's

part to derive benefits. As such, they may not be suited for every patient. Furthermore, they may not be quite as effective as in-person treatment delivery methods. Recent meta-analyses[100,101] that evaluated self-help CBT-I show that treatment effect sizes appear larger when patients are afforded some additional therapist support (e.g., phone consultations) and when they lack sleep-disruptive comorbidities. Thus, further exploration of patient characteristics that best fit these approaches is needed.

Deciding When to Use Each of the CBT-I Treatment Options

The preceding discussion documents the myriad treatment protocols and delivery options that can be considered for behavioral insomnia therapies. It should be understood that the best-tested and well-established forms of delivery are the individual and group therapy protocols directed by those with extensive training backgrounds in the provision of psychotherapy in general and CBT-I specifically. Treatment delivery approaches that diverge from that common paradigm through use of alternative providers, abridged treatments, or no direct provider contact at all currently have relatively less empiric support. This does not mean they are not effective, at least for a subset of insomnia sufferers.

What is clear is that there is a wide array of treatment delivery options for these therapies ranging from the relatively low intensity yet highly accessible self-help interventions to the high-intensity yet more scarcely available individual therapist-directed protocols. Given this range of delivery methods, several insomnia experts[102-104] have suggested use of the stepped care, pyramid-shaped model for treatment allocation shown in Figure 86-5. At the bottom of this pyramid are the lowest intensity albeit most widely available self-help protocols delivered through the Internet and other mass media. A "step up" from these treatments would be the group or individually administered entry-level treatments designed specifically for those patients who actively seek intervention in primary care settings. At the next higher step are individual and group treatments offered by health care providers who have some mental health or psychotherapy expertise and journeyman training in CBT-I yet lack behavioral sleep medicine specialty. At yet a higher and less accessible level of the pyramid are the treatments offered by those with expertise in behavioral sleep medicine. Finally, at the top of the pyramid are the treatments available at sleep centers that employ behavioral sleep medicine specialists and can manage patients who have insomnia comorbid to other primary sleep disorders (e.g., obstructive sleep apnea). In theory, this model would allocate patients to the various levels and intensities of treatment to fit their specific treatment needs. The most motivated and self-sufficient might be best served by treatments at the base of the pyramid, whereas those more complex cases are assigned to higher intensity treatments toward the upper portion of the pyramid. Moreover, those who fail to respond to a lower intensity treatment could be "stepped up" to a higher intensity intervention.

Obviously this treatment model has significant heuristic appeal as it balances treatment intensity and cost against the needs of specific patients, thus resulting in the efficient use of the limited number of providers with a high level of expertise. Unfortunately, to date, there has been limited testing of this model to determine its usefulness. However, a recent study conducted by Vincent and Walsh[104] tested online with therapist-directed CBT interventions in a large medical outpatient setting and provided some insight into the sorts of patients who might need to be stepped up to more intensive in-person therapies. Results of this study showed that patients who were older, unemployed, and presented with poorer sleep quality responded better to a higher intensity therapist-delivered intervention than they did to online CBT-I.

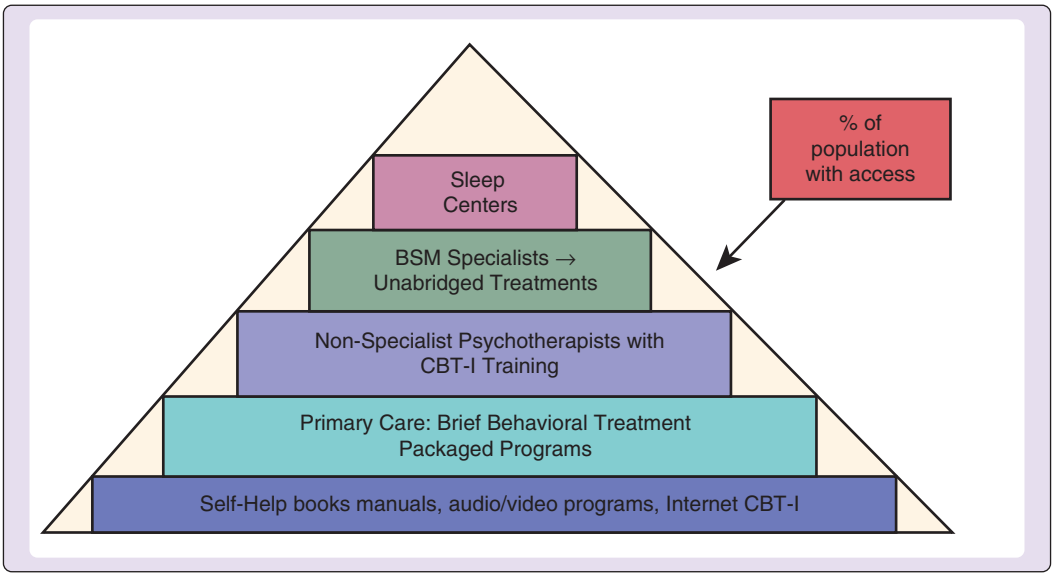

Figure 86-5 Stepped care model for allocation of insomnia patients to treatment options. Stepped care model adapted from Edinger and Carney[102] and Espie.[103] This model shows the varying levels of treatment intensity with provider expertise. The treatments toward the base of the pyramid are most widely accessible to patients, whereas those toward the top of the pyramid represent less accessible levels of care to which the more challenging and complex patients should be referred. BSM, Behavioral sleep medicine; CBT-I, cognitive-behavioral therapy for insomnia.

As noted by Edinger,[105] a number of issues would need to be addressed in placing the stepped care model into general practice. First, we have to decide which treatments should be included in the model at the different levels of delivery to optimize the overall efficacy of treatment allocation. We also need to answer questions such as these: (1) Which patients are likely to benefit from self-help approaches and which are not? (2) Does treatment failure with one of the nontraditional or self-help approaches adversely affect a patient's treatment expectations and subsequent response to a more intensive traditional behavioral insomnia treatment? and (3) In what settings can this model actually be implemented? In regard to the last question, it would admittedly be difficult to effect a stepped care model at a broader societal level in a country such as the United States, given its complex free market health care system. It would seem to better fit within closed health maintenance organizations wherein a finite patient population of health plan enrollees is closely tracked by computer technology. Likewise, it may be possible to implement it in countries that have a socialized, government managed, and centralized health care system. However, even in such settings, the allocation of patients to proper treatment represents a massive triage endeavor requiring systematic patient screenings to optimize the treatment matching process. Admittedly, much has to be learned about patient characteristics that predict treatment response to effectively use this stepped care model.

TREATMENT DOSING

In addition to considering the various methods and providers that can be used to deliver CBT-I, it is also important to consider what constitutes the optimal "dose" of such treatments. Previous studies with multicomponent CBT-I protocols have shown efficacy for interventions delivered in one, two, four, six, and eight individualized sessions and between five and eight group sessions. Yet little is known about how many individual and group sessions are needed on average to achieve optimal treatment outcomes. Despite the ample number of exemplary dose-response studies extant in the pharmacologic literature,[106] research specifically designed to determine the optimal dosing for any of the psychological and behavioral insomnia therapies has generally been lacking.

One exception to this oversight is a study conducted by Edinger et al.[107] The goal was to determine the optimal dosing of their CBT-I model delivered in an individual therapy format. In this study, patients with primary insomnia were randomly assigned to a no-treatment control (wait list) or to active treatment composed of one, two (weeks 1 and 5), four (every other week), or eight (weekly) CBT-I sessions delivered during an 8-week period. Results showed that subjective (sleep diary) and objective (actigraphic) sleep measures favored the one- and four-session CBT-I doses over the other doses and wait-list control. However, comparisons of pretreatment data with data acquired at the 6-month follow-up showed that only the four-session model maintained significant improvements in objective wake time and sleep efficiency measures over time. Moreover, a notably greater percentage of those assigned to the four-session condition achieved 50% or more reduction in the study's primary sleep outcome measure, subjective wake time after sleep onset, than did those in the other conditions. Considered collectively, this study's findings imply that for the specific CBT model tested, a dose of four sessions delivered on an every-other-week schedule appears optimal. However, a more recent study[108] showed that those with insomnia comorbid to a psychiatric condition had less impressive treatment outcomes than did insomnia patients without comorbidities in response to the four-session CBT model shown to be optimal in the aforementioned dose-response study.[107] Thus, concurrent comorbidities may be important factors that affect the optimal dosing of CBT-I.

In addition to the number of treatment sessions provided, an alternative important but largely ignored dosing consideration is the number and types of treatment components composing an insomnia therapy. However, Harvey et al[34] recently investigated the relative effectiveness of treatments composed solely of behavioral therapy (e.g., stimulus control, sleep restriction, and sleep hygiene) or cognitive therapy techniques compared with a multicomponent CBT-I. Cognitive therapy included empiric testing of unhelpful beliefs about sleep through behavioral experiments in addition to using direct verbal challenge by Socratic testing or thought records. Results of this trial showed that behavioral therapy produced more immediate sleep improvements than cognitive therapy but that cognitive therapy provided longer term benefits than behavioral therapy as measured at a follow-up. However, the best outcomes were obtained with the full CBT-I intervention, supporting the notion that combining behavioral therapy and cognitive therapy provides the optimal approach. Of course, the combined treatment entailed longer treatment sessions on average than did the other two treatments (75 minutes vs. 40 to 60 minutes).

TREATMENT ACCEPTABILITY AND ADHERENCE ISSUES

The ultimate success of an insomnia therapy relies on patients' willingness to accept and to engage in treatment as well as their ability and motivation to implement the treatment components at home. Factors related to treatment acceptability and adherence are reviewed in this section.

Treatment Acceptability

Patients' preferences and values play a critical role in treatment response.[109] The most efficacious treatments will have little clinical utility if they are not palatable to the patients. To assess patients' attitudes toward insomnia treatments, Morin and colleagues[1,110] developed the Insomnia Treatment Acceptability Scale. This scale asks respondents to rate their opinions of CBT-I versus a pharmacologic intervention for insomnia. Two different studies conducted with this questionnaire showed that community-dwelling adults with insomnia rated a cognitive-behavioral intervention as more acceptable, more suitable for sleep difficulties, more likely to be effective long term, less likely to produce side effects, and more likely to improve daytime functioning than a pharmacologic intervention for insomnia.[110,111] In a study of older adults with insomnia, those randomized to receive CBT-I reported greater treatment satisfaction than those receiving pharmacotherapy.[112] A survey of hospital patients taking benzodiazepines for insomnia showed that 67% of those surveyed reported they would try an alternative treatment if available, and most (82%) viewed these alternatives as "healthier" than benzodiazepines.[113]

A few studies have compared patient preferences for the various therapeutic components typically composing CBT-I

approaches. In one such study, insomnia patients rated their satisfaction with sleep hygiene, stimulus control, sleep restriction, cognitive therapy, relaxation training, and medication tapering after participation in a group CBT-I treatment.[111] Sleep hygiene was rated the most liked and most useful element, whereas sleep restriction was rated lowest. Interestingly, sleep restriction but not sleep hygiene was related to symptom improvement. In another investigation comparing sleep hygiene, meditation, and stimulus control as treatments for chronic insomnia, participants in the sleep hygiene group were the least satisfied with their treatment despite similar sleep improvements in all three groups.[114] Hospitalized patients rating various insomnia therapies report the strongest preferences for sleep hygiene and relaxation, with sleep restriction and stimulus control holding the least appeal.[113]

Collectively, these findings imply that most patients prefer psychological treatments to medications. Some prefer treatment components that are not necessarily the most efficacious ones. Sleep restriction seems to be unpopular with patients, perhaps because of its counterintuitive nature and the enhanced sleepiness it may cause, particularly during its initial stages.[115] Implementation of sleep restriction may require a particular focus on the therapeutic rationale to foster patients' acceptance. It also may be that original sleep restriction approaches, which limit time in bed to the average total sleep time derived from a baseline sleep diary, may be too restrictive, especially for those patients who grossly underestimate their actual sleep time. For such patients, more lenient approaches proposed by some authors may be more acceptable and effective.[2]

Treatment Adherence

It is not difficult to appreciate the central importance of treatment adherence in ensuring the success of therapies like CBT-I. These treatments require considerable commitment from the patient, and adherence is recognized as one of the most critical factors affecting treatment success.[78,116-118] It has been estimated that approximately 15% of patients who enroll in CBT-I treatment studies fail to complete a full course of such treatment[119]; however, this rate may approach 40% among those who seek treatment in clinical settings.[119,120] Factors linked to nonadherence and attrition include greater sleep impairment, poorer perceived general health, higher levels of depression, less favorable ratings of the treatment, lower levels of support from spouses or partners, and viewing the therapist as critical or confrontive.[111,119-124] Most findings have been based on adherence indicators derived from sleep diaries, although other tools (e.g., actigraphy, patient checklists) can provide supplemental information and sometimes have been used for this purpose.

Studies reporting adherence to CBT-I in research participants are encouraging,[58,125-127] but less favorable outcomes are reported in clinical samples.[117] The percentage of patients reporting continued adherence to treatment recommendations at long-term follow-up ranges from 20% to 74%.[128,129] Higher adherence is related to better treatment outcomes.[126]

Unfortunately, there are few evidence-based data on promoting adherence. One study showed a benefit of modafinil in adherence to CBT-I[130] mainly through the role of this medication in offsetting the enhanced daytime sleepiness resulting from sleep restriction. Suggestions for promoting adherence have included providing the treatment rationale, discussing adherence directly with the patient, enlisting the support of the patient's family, providing encouragement, soliciting the patient's commitment through a verbal or written contract, encouraging questions from the patient, understanding the patient's expectations, and setting realistic goals.[1,117,131] Adherence strategies targeting specific treatment components are described elsewhere.[1,2]

APPLICATIONS TO PATIENTS WITH COMORBID PSYCHIATRIC CONDITIONS

Insomnia is highly prevalent as a coexisting complaint among those with various psychiatric disorders.[132,133] Yet most studies testing the efficacy of CBT-I among patients with psychiatric comorbidities have been published in the past decade or so. This is true because traditionally such insomnia was viewed as a symptom of the comorbid condition. Hence, its management required successfully treating the suspected "primary" psychiatric condition with the expectation that insomnia remission would follow. However, this view ignores findings suggesting that (1) psychiatric patients presenting with chronic insomnia are more difficult to treat than those presenting without insomnia[134,135]; (2) a sizable group of people continue to suffer from insomnia as a clinically significant residual symptom after remission from their so-called primary psychiatric disorder[136-140]; and (3) there is also little evidence to regard insomnia that co-occurs with a psychiatric disorder as categorically distinct from insomnia without a co-occurring disorder because they have the same purported insomnia-maintaining factors targeted by the cognitive and behavioral interventions composing CBT-I as do those with patients presenting solely with an insomnia disorder (e.g.,[141,142]). Hence, insomnia can be regarded as a comorbid disorder when it is observed in patients with concurrent psychiatric disorders.[55] In fact, this change in thinking is reflected in both the newest diagnostic nosologies[143,144] of the American Academy of Sleep Medicine and the American Psychiatric Association, which eliminate the distinction between "primary" and "secondary" insomnia in favor of a more global insomnia disorder diagnosis that can be assigned to patients with and without sleep-disruptive comorbidities.

Given that those with an isolated insomnia disorder and those suffering from insomnia comorbid to a psychiatric disorder have many shared perpetuating factors, we might expect a cognitive-behavioral conceptualization of comorbid insomnia to look something like the model in Figure 86-6. In this conceptualization, stress may be an endogenous event (e.g., a change in neurochemical activity) or a life event (e.g., the birth of a baby). Whether the stressor is an external life event or a physiologic event, it can directly cause either sleep disruption or the comorbid disorder. Alternatively, the stressor may operate through a moderator variable (i.e., a shared vulnerability trait) of insomnia and the comorbid condition. Several potential moderator variables exist, including ruminative tendency[145,146] and specific maladaptive beliefs.[47,51] Once sleep disruption occurs, attempts at coping or compensating for the sleep loss result in behaviors such as sleeping in, increasing time in bed, using alcohol or sleep aids, or avoiding obligations or attending social events. Such behaviors may be linked to circadian or homeostatic disruption, increased arousal, or reinforcement of beliefs that one is helpless to cope with sleep loss. These factors have been posited as perpetuating etiologic

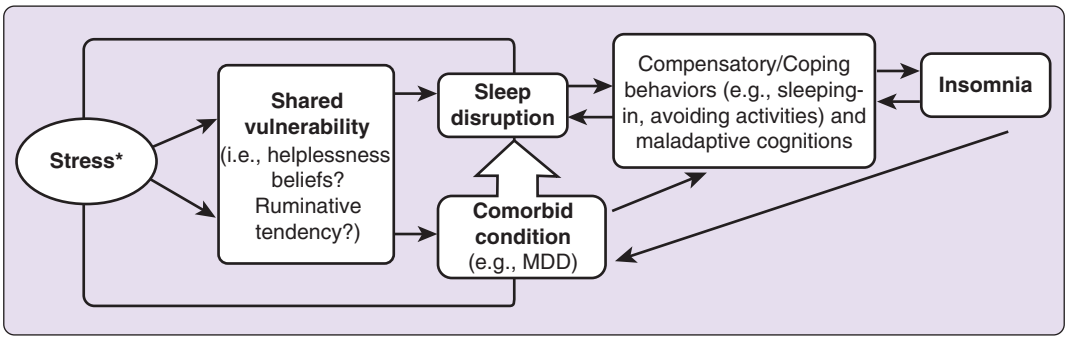

Figure 86-6 Possible etiologic pathways for comorbid insomnia. *Stress may be in the form of an internal (e.g., hormonal change) or external (e.g., interpersonal conflict) event that can directly cause either sleep disruption or a comorbid condition. Compensatory behaviors or arousing cognitions are thought to play a role in causing or maintaining the insomnia. The stressor may also operate through a moderator variable (i.e., a shared vulnerability trait) of insomnia and the comorbid illness. MDD, Major depressive disorder.

factors in insomnia.[1,29,47,147-149] Insomnia would be expected to exert negative influence on the comorbid disorder and in some cases could cause the disorder. Thus, even in cases in which a comorbid disorder may have initially caused the sleep disruption, cognitive and behavioral factors can become perpetuating factors for insomnia that remains after the comorbid condition remits.

To date, there have been a limited number of studies investigating CBT-I among those with comorbid psychiatric conditions.[64,132,150] In several studies, CBT-I has been tested in those with insomnia and depression, and results showed improvements in both sleep and depression symptoms.[151-153] Moreover, some studies have reported significant and clinically meaningful improvements in depression resulting from CBT-I alone.[152-155] Although this is a somewhat surprising finding, these studies tended to enroll small participant samples, so large-scale studies are needed to further investigate whether insomnia therapy alone can markedly improve major depressive disorder. Manber et al[156] reported that augmentation of antidepressant medication with CBT-I produced a far greater remission rate (depression remission rate, 61.5%) than antidepressant therapy alone (depression remission rate, 33%); Carney et al[155] reported the same results in a replication of the randomized controlled trial of Manber and colleagues. Thus, CBT-I is an effective treatment for insomnia in those with comorbid depression; there also appear to be significant benefits to mood by treating insomnia as well.[157]

In addition to the promising results found with depressed patients, CBT-I applications to patients with other psychiatric comorbidities have been promising as well. For example, CBT-I has been used effectively in those with PTSD[158-161] and in those in recovery from alcohol abuse.[89,162] Elements of CBT-I have also been incorporated into an effective nocturnal panic disorder treatment protocol.[163] Given the promising results thus far, much more research is needed to test the applicability and efficacy of CBT-I in patients with other psychiatric conditions.

Most previous studies support the use of standard CBT-I protocols among patients with psychiatric comorbidities. However, as noted by Smith et al,[164] there may be unique delivery issues among comorbid populations that require special alterations of or additions to CBT-I to optimize insomnia treatment outcomes. To date, there has been an absence of studies conducted to test this assumption, and available evidence has only partially supported this idea thus far (e.g.,[120]). Nonetheless, clinical observations suggest that certain subgroups of psychiatric patients present special challenges that may call for some alterations or augmentations of typical CBT-I protocols. For example, it has been noted that depressed patients often show little motivation to face each new day. As such, they have difficulties in getting out of bed in the morning at a scheduled time as required by the stimulus control instructions.[2] For such patients, it may be useful to construct a morning routine that includes attractive breakfast items or comforting activities that invite the patient out of bed at the preplanned time. In contrast, many patients with PTSD, particularly those with military combat experiences, show heightened safety concerns that cause them to delay bedtime by repeatedly checking all the doors and windows in their homes to ensure they are locked and secure before they retire to bed. For such patients, the addition of strategies such as response prevention or placing an agreed on limit on checking behaviors may be useful to prevent this compulsive behavior from interfering with sleep onset. Whereas the sort of CBT-I alterations required may seem obvious from a clinical viewpoint, admittedly more research is warranted to better elucidate the sorts of therapeutic alterations needed to produce optimal responses in patients with various types of psychiatric comorbidities.

APPLICATIONS TO PATIENTS WITH COMORBID MEDICAL CONDITIONS

There is growing evidence that CBT-I is effective for people with comorbid medical conditions including cancer, chronic pain, autoimmune diseases, and human immunodeficiency virus infection.[164] Adaptations may include adding components to address disease-specific symptoms, such as fatigue and pain, or using psychological and behavioral principles to address comorbidity factors that could interfere with adherence to the insomnia treatment.[164] In some studies, researchers adapted standard CBT-I to the specific population studied. For instance, in the context of breast cancer, some investigators have tested protocols that include cognitive and behavioral strategies to directly address fatigue.[165,166] However,

others tested unaltered versions of CBT-I with cancer patients[167] and reported insomnia symptom improvements. Research concerning use of CBT-I for insomnia in patients with medical comorbidities has not directly tested the utility of specific treatment adaptations. However, based on phenomenologic studies and our collective clinical experience, we discuss several issues that are relevant to the implementation of CBT-I for insomnia occurring in the context of medical diseases.

The Impact of Disease-Specific Symptoms on Insomnia

The sleep of patients with medical disorders can be disrupted by physical discomfort, such as pain, night sweats, cough, dyspnea, nocturia, and diarrhea. When such symptoms are disrupting sleep, the clinician needs to include in the treatment plan consultation with the medical team that is involved in the treatment of the comorbid medical condition. The most common symptom encountered among comorbid medical patients is pain. In addition to the direct negative impact of pain on sleep, patients' reactions to pain can sometimes contribute to insomnia indirectly. Examples of reactions to pain that can be detrimental to insomnia include spending much more time in bed at night than is actually needed for sleep, using the bed during the day for resting and napping, and using the bed and bedroom as a "headquarters" for daily activities. These reactions can contribute to insomnia by weakening the sleep drive or by rendering the bed a much weakened cue for sleep. These behaviors are also common reactions to the experience of fatigue, which like pain is common in several medical disorders. Some patients use large amounts of caffeine as a measure to counter fatigue,[168,169] a practice that might also interfere with sleep at night, particularly when the consumption is late in the day. In addition, because impaired sleep quality magnifies pain[170,171] and is associated with reduced energy the next day, patients often are concerned that a night of poor sleep will be followed by increased pain or fatigue on the following day. These concerns are often exaggerated (catastrophic cognitions) and contribute to insomnia by creating sleep-focused anticipatory anxiety.

Addressing Pain and Fatigue

Treatment components that are not included in standard CBT-I protocols for insomnia can be used to modify sleep-interfering behaviors associated with pain and fatigue. These include the following.

Increase Activities

Behavioral activation is an intervention that encourages increased engagement in life's activity. The treatment provider helps the patient identify obstacles to daytime activities and discusses how to overcome these obstacles. Behavioral activation could be easily integrated into CBT-I when pain and fatigue are associated with significant reduction in activities. Used in such situations, activation can help break the vicious circle connecting low level of activity to physical deconditioning, which further reduces activity level.[172] Exercise is a specific form of behavioral activation that has shown efficacy for pain management[173] and reduction of daytime fatigue.[174] Moderate exercise (55% to 75% of heart rate maximum) is safe and well tolerated by many patients with medical comorbidities, including cancer survivors. It effectively reduces cancer-related fatigue during and after various forms of cancer treatment (surgery, transplantation, chemotherapy, radiation therapy, and hormone therapy),[175] although effect sizes among cancer patients are small[176] to moderate.[177] In the context of pain, paced behavioral activation and moderate exercise are often included for pain management.[178]

Schedule Short Naps

Both stimulus control and sleep restriction instruct patients to avoid napping. This is to ensure a strong homeostatic sleep drive at night. However, for patients who find daytime fatigue and sleepiness overwhelming, careful timing of short daytime naps should be considered. Short (10-minute) afternoon naps can improve alertness and performance and do not seem to lead to a meaningful reduction in delta wave activity (an index of the homeostatic drive) in the subsequent night.[179] One advantage of scheduling a nap over unintentional dozing is that it reduces the sense of helplessness. Another advantage is that scheduled naps can reduce the need to cancel scheduled daytime activities because of overwhelming fatigue. Thus, taking short naps can be an effective strategy to combat fatigue and to improve quality of life. However, emphasizing the importance of keeping the naps short and earlier in the day (preferably before 3 PM) is important to ensure strong homeostatic pressure to sleep at bedtime.

Other Considerations for Patients with Chronic Pain

Hypervigilance to environmental stimuli, such as noise and uncomfortable temperatures, is common among chronic pain patients and predicts poor sleep quality.[164] A white noise–generating device can mask extraneous sleep-disruptive sounds and help pain patients maintain sleep. Likewise, encouraging proper temperature regulation to maintain a comfortable sleeping environment is often useful. In addition to these environment-focused strategies, person-focused techniques, such as relaxation training and cognitive distraction, are also useful for pain management in many patients.[178]

The Effects of Treatment for Comorbid Diseases on Insomnia

Treatments including certain antiretroviral medications, cancer chemotherapy, and radiation therapy can disrupt sleep and lead to increased fatigue. When disturbed sleep arises as a treatment-related side effect, development of chronic insomnia can be prevented by educating and preparing patients for this eventuality and discouraging the use of compensatory coping strategies that could perpetuate sleep problems. However, when disease-specific factors affect treatment adherence, they need to be addressed as part of the overall insomnia management strategy. As noted in the following discussion, unhelpful beliefs may need to be addressed to promote treatment adherence, or treatment strategies may need to be altered to prevent exacerbation of the comorbid medical condition.

Unhelpful Sleep-Related Beliefs

Research suggests that patients who have insomnia comorbid with fibromyalgia and other medical or mental disorders have higher scores on measures of dysfunctional beliefs and attitudes about sleep.[51] These beliefs are presumed to contribute to or to perpetuate the insomnia disorder of these patients. Thus, cognitive therapy might need to be emphasized and play a large role in managing insomnia with these patients.

Admittedly, the importance of targeting sleep-interfering thoughts when applying CBT-I with these populations has not been specifically evaluated. Nonetheless, as reductions in sleep-disruptive beliefs have been linked to sleep improvements in insomnia patients who lack sleep-disruptive comorbidities,[47,180,181] such cognitive changes would be expected to be critical to these comorbid insomnia patients as well.

Overconcern that insufficient sleep will worsen a medical disease, impede healing, or lead to a recurrence of the medical problem can increase worry about sleep and sleep-related performance anxiety. These concerns need to be addressed because they may lead to reluctance to restrict time in bed as indicated by the sleep restriction therapy protocol or to get out of bed when unable to sleep as indicated by stimulus control therapy. Helping patients challenge these beliefs by use of cognitive therapy and education can be useful to overcome treatment resistance in many patients with comorbid medical disorders.

Alterations to Standard Behavioral Instructions

Pain and fatigue can contribute to insomnia severity and chronicity and interfere with adherence to prescriptions to curtail time in bed. Because many insomnia patients underestimate their sleep times, their treatment with sleep restriction could result in actual sleep loss, which in turn could produce a hyperalgesic response and impair the functioning of their endogenous pain-inhibitory systems.[182] Such patients may respond better to sleep compression therapy,[183] which gradually shortens sleep opportunity during several weeks instead of drastically curtailing sleep at the onset of therapy. However, it has not been shown that sleep restriction therapy worsens pain or that sleep compression produces better outcomes with pain sufferers. Given the state of the science with respect to this issue, the best approach is to be cognizant of this potential difficulty and to use clinical judgment when implementing this component of treatment.

Addressing Psychological Reactions to the Comorbid Medical Disease

Patients' psychological reactions to their diseases, particularly depression and anxiety (including panic), are common[184-186] and can contribute to sleep disturbance in patients with medical comorbidities. It is therefore important to assess and to treat or refer patients who show such psychiatric symptoms when indicated.

USE WITH YOUNGER AND OLDER AGE GROUPS

Normal sleep and the experience of insomnia are affected by maturational and lifespan issues. Psychological and behavioral treatments for insomnia during childhood actively involve the parents and are based on principles of learning and behavior change, such as reinforcement, extinction, and shaping. There are many unique problems common in childhood sleep difficulties, including nighttime fears,[187] scary dreams,[187] resisting appropriate bedtimes, and needs for parental presence and special circumstances to aid sleep onset. For older children and teenagers, cell phones, computer tablets, and other forms of technology may provide sufficient late-night distraction to cause a delay in bedtimes and adherence to healthy sleep schedules. Such problems require special treatments that lie outside the focus of this chapter. For information about the management of such cases, the reader should consult the writings of Mindell et al[188] or Lewin.[189]

Older Adults

Reviews and meta-analyses have supported the efficacy of cognitive-behavioral therapies for insomnia in older adults.[58,62,190-194] Recent studies suggest that CBT-I is effective for older adults even when they have hypnotic dependence[195] and when the intervention is very brief (two sessions)[82] or delivered by telehealth.[196] Telehealth is a particularly attractive treatment modality for older adults who do not have easy access to in-person care. Several factors specific to older adults need to be considered in implementing CBT-I. These include comorbid medical diseases and life changes that can weaken the homeostatic and circadian regulation of sleep.[197] The latter set of factors includes decreased physical activity, social isolation, and reduced exposure to light, which are particularly relevant to residents of assisted living facilities and people with dementia, including Alzheimer disease. Effective treatment of sleep difficulties in older adults with dementia includes decreasing in-bed time during the day, increasing physical activity and social activation, ensuring daily sunlight (or artificial light) exposure and structured bedtime routines, and, in the case of institutional settings, decreasing nighttime noise and light and involving the caregivers.[198-200] Current evidence shows that increasing social activities improves nocturnal sleep[200] and introducing structured social activities increases slow wave sleep and improved memory.[197] On the other hand, a review of the literature on bright light therapy for older adults with dementia concluded that there is no adequate evidence of the effectiveness of this therapy in managing sleep.[201] Low-impact aerobics, brisk walking, and tai chi all seem to improve sleep of sedentary older adults with moderate sleep disturbance.[202,203] Yet little is known about exercise or tai chi as a single-component intervention for older adults who meet criteria for insomnia disorder. One small study of 17 individuals found that aerobic activity combined with sleep hygiene education is more effective than sleep hygiene alone for patients 55 years or older.[204] Finally, passive body heating (immersing the body in 40°C water for 30 minutes 1.5 to 2 hours before bedtime) has also been used successfully to improve sleep in older women[205,206] and in patients with vascular dementia.[207] This procedure is hypothesized to operate through its action on the thermoregulatory, circadian, and autonomic systems. Nonetheless, it remains to be determined whether such findings can be translated into practical suggestions (e.g., taking a warm bath in the evening) that can be used as a reliable method for managing insomnia complaints in older adults.

CLINICAL PEARL

Psychological and behavioral insomnia therapies have as their heritage a range of tools that aid in their implementation. These treatments can be delivered in a variety of formats ranging from high-intensity individual therapy to low-intensity self-help paradigms. They are effective with a variety of young and older insomnia sufferers who present with isolated and comorbid forms of insomnia disorders. However, alterations or augmentations of these treatments may be indicated for certain age groups and those patients with sleep-disruptive comorbidities.

SUMMARY

Psychological and behavioral insomnia therapies have a strong research legacy that supports their widespread use in clinical practice. Clinicians wishing to use these treatments have a number of useful tools that aid in their implementation, including sleep diaries, written behavioral prescriptions, structured cognitive exercises, and, for selected cases, actigraphy. These treatments can be delivered in different formats, in limited "doses," by various provider types, and in various self-help formats, but the involvement of a specialist in behavioral sleep medicine as either a consultant or therapist appears to enhance treatment outcome. The reach of these therapies can be expanded by telehealth and Internet delivery protocols. The treatments are useful not only for those who present solely with insomnia complaints but also for patients who present with a range of psychiatric and medical comorbidities. Moreover, these therapies have efficacy for the range of younger and older adult insomnia patients encountered in clinical practice. Future research will likely show how best to package these treatments for various clinical settings, varying types of therapy providers, and patients with comorbid conditions. Nonetheless, the guidance provided in this chapter gives clinicians a better understanding of tools that aid in the delivery of treatment and issues that merit consideration in their implementation.

Pharmacologic Treatment of Insomnia: Benzodiazepine Receptor Agonists

James K. Walsh; Thomas Roth

Chapter Highlights

- Considerable evidence indicates that the benzodiazepine receptor agonists (BzRAs) are efficacious in the treatment of insomnia, and somewhat limited data suggest a substantial degree of effectiveness.
- BzRAs are also generally safe as commonly used in clinical practice; common concerns regarding tolerance, misuse, and abuse by insomnia patients are not typical.
- BzRAs produce improvement in daytime symptoms as well as nighttime symptoms of insomnia and may reduce the severity of comorbid illnesses.
- Sufficient differences in pharmacokinetic profiles exist among the BzRAs to provide physicians with therapeutic options that have differing durations of action.
- Individual differences in metabolism and elimination of BzRAs have led to a lowering of recommended starting doses for some BzRAs.

A 2005 National Institutes of Health State of the Science Conference concluded that the benzodiazepine receptor agonists (BzRAs) were the only drugs for which adequate scientific evidence exists to support their use for chronic insomnia.[1] Subsequently, the U.S. Food and Drug Administration (FDA) has approved low-dose doxepin (Silenor) for the treatment of insomnia, and an orexin antagonist (Suvorexant) has recently been approved (see Chapters 42 and 88). The efficacy, effectiveness, and safety of the BzRAs approved for the treatment of insomnia by the FDA is the focus of this chapter. A number of other BzRAs are approved for the treatment of insomnia in other countries, and research with those drugs is highly consistent with the data reviewed here. In addition, implementation and assessment strategies for the pharmacologic treatment of insomnia are discussed.

The group of drugs referred to as "benzodiazepine receptor agonists" are categorized according to the well-described common mechanism of action of these medications. All BzRAs act as allosteric modulators of gamma-aminobutyric acid (GABA) activity by binding to inotropic benzodiazepine receptors at the $GABA_A$ receptor complex. BzRAs serve to increase GABA binding and thus the frequency of chloride ion channel openings, facilitating inhibitory activity. Some of these drugs (Table 87-1) have a benzodiazepine chemical structure (i.e., estazolam, flurazepam, quazepam, temazepam, triazolam), and others do not (i.e., eszopiclone, zaleplon, zolpidem). BzRAs demonstrate affinity for four benzodiazepine receptor subtypes (referred to as α_1, α_2, α_3, and α_5) located at the $GABA_A$ pentameric complex. Benzodiazepines tend toward comparable affinity for the four receptor subtypes, whereas the affinities of zolpidem and zaleplon for the α_1 subtype are higher than for other subtypes. Eszopiclone shows less preference for α_1, having some activity at α_2 or α_3 (or both). The functional significance of these binding differences for effects on sleep or other actions in humans remains unclear. In contrast, preclinical investigations of knock-in rodent strains suggest different functional characteristics of the benzodiazepine receptor subtypes.[2]

The most clinically relevant differences among BzRAs are associated with pharmacokinetic properties of the drugs, particularly terminal elimination half-life, which is the most important determinant of duration of drug action. Distribution characteristics (for single doses) and absorption also contribute to duration of action, although to a much lesser degree. Of course as with all biologic systems, substantial individual differences exist in the metabolism and elimination of BzRAs, with about a 30% intersubject variability that translates into individual differences in duration of action among patients and hence associated efficacy and safety (see recent related FDA dosing recommendations discussed later in the section titled Safety). Finally, factors other than pharmacokinetics also influence duration of action, in particular drug dose and formulation (e.g., extended release, sublingual).

Of the available BzRA hypnotics in the United States, the most rapidly eliminated drugs used at recommended doses in healthy adults have estimated durations of action in the range of 2 to 5 hours (zaleplon, sublingual zolpidem lozenge) and 4 to 7 hours (triazolam, zolpidem), whereas the slowly eliminated drugs (including active metabolites) have durations of action of 24 hours or more (flurazepam, quazepam). Estazolam, temazepam, and eszopiclone have intermediate durations of action.

A number of BzRAs are available in other countries for the treatment of insomnia. They include the short-acting midazolam and brotizolam, intermediate-acting zopiclone, loprazolam, lormetazepam, and long-acting flunitrazepam and nitrazepam. All are benzodiazepines except zopiclone, a cyclopyrrolone; eszopiclone, the active stereoisomer, is available in the United States.

Table 87-1 Characteristics of Benzodiazepine Receptor Agonists with an FDA Indication for Insomnia

Generic Name	Receptor Binding Specificity	Dose Range (mg)	Elimination Half-Life (hr)	Metabolism
Estazolam	Nonspecific	1–2	10–24	CYP3A
Flurazepam	Nonspecific	15–30	48–120*	CYP3A4
Temazepam	Nonspecific	15–30	8–20	None
Triazolam	Nonspecific	0.125–0.25	2–6	CYP3A4
Quazepam	Nonspecific	7.5–15	39–73*	Not available
Eszopiclone	$GABA_A$, $\alpha_{1,2,3}$	1–3	6	CYP3A4, CYP2E1
Zaleplon	$GABA_A$, α_1	5–20	1	Minor: CYP3A4
Zolpidem	$GABA_A$, α_1	5–10	1.5–2.4	CYP3A4, CYP2C9
Zolpidem extended-release	$GABA_A$, α_1	6.25–12.5	1.6–4.5	CYP3A4, CYP2C9
Zolpidem sublingual tablet	$GABA_A$, α_1	5–10	1.5–2.4	CYP3A4, CYP2C9
Zolpidem oral spray	$GABA_A$, α_1	5–10	1.5–2.4	CYP3A4, CYP2C9
Zolpidem sublingual lozenge	$GABA_A$, α_1	1.75–3.5	1.5–2.4	CYP3A4, CYP2C9

*Refers to elimination half-life of active metabolite.
CYP, Cytochrome P-450 (letters and numbers refer to specific CYP enzymes); $GABA_A$, gamma-aminobutyric acid, type A receptor complex.

The BzRAs are generally recommended as first-line hypnotics for several reasons. All BzRAs have been shown to be efficacious, although there are some differences among drugs, associated with pharmacokinetic properties, and marketed dose. Compared with other central nervous system (CNS) drug classes, the margin of safety or therapeutic index (i.e., the effective dose relative to lethal dose) is wide.[3] For example, barbiturates have margins of safety on the order of two to four times the effective dose, whereas for BzRAs, the margin of safety can be as great as 100. Abuse of or dependence on BzRAs is uncommon in the therapeutic context, most likely accounted for by the relatively mild reinforcing effects and self-administration patterns. Summaries of the efficacy, effectiveness, and safety characteristics of BzRAs follow. Unless otherwise stated, the summary material refers to the FDA-approved dosages of the drugs.

EFFICACY AND EFFECTIVENESS

Traditional measures of hypnotic efficacy include polysomnographic (PSG) or patient estimates of induction and maintenance of sleep. Sleep latency (or latency to persistent sleep), whether given by PSG or self-report, is the standard sleep induction variable and is thought to be relevant to a patient report of difficulty falling asleep. Number of awakenings and wake after sleep onset (WASO) are the most common sleep maintenance measures, corresponding to patients' reports of difficulty staying asleep. Total sleep time and sleep efficiency reflect both sleep induction and sleep maintenance properties. Qualitative measures of efficacy such as morning ratings of sleep quality, sleep depth, or global impression ratings performed by either the clinician or the patient are also used in efficacy trials. Given the variability of sleep across individual nights, efficacy is evaluated by averaging across nights and in many cases across a week. Importantly, patient-reported data are typically collected using diaries or questionnaires with an electronic time stamp to determine the time the evaluation was completed.

Given the desire to maximize objective data and to minimize costs, the monitoring of movements or activity with a wrist-worn sensor (actigraphy) has also been used to evaluate hypnotic efficacy. However, to date, actigraphy has been shown to be sensitive only to timing and duration of sleep. This makes actigraphy more valuable in evaluating efficacy in insomnia that is comorbid with circadian rhythm disorders (e.g., phase-delay syndrome).

Primary Insomnia

Most insomnia clinical trials have documented the efficacy of hypnotics using patients' reports, PSG, or both in patients with primary insomnia. A meta-analysis of clinical trials with benzodiazepines and zolpidem found that these drugs in aggregate produce reliable improvements in the sleep of persons with chronic insomnia. Importantly, the median duration of the studies included in the analysis was only 1 week.[4] Other meta-analyses[5-8] largely concur regarding short-term efficacy. However, the utility of meta-analyses to assist the clinician is fairly low because they typically combine data from several different drugs with widely different pharmacokinetic properties, which can affect the outcome variables examined in the meta-analysis. Additionally, two or more doses of a drug may be included in the analysis. It is much more instructive to examine the strengths and weaknesses of individual drugs as opposed to generalizing across all drugs in a category. Simply put, meta-analyses tell us about the pharmacology of a group of drugs, but they are not informative about the properties of individual drugs or what the best drug is for a given patient. Below, important differences among drugs will be emphasized, followed by a discussion of similarities among BzRAs.

At appropriate doses all BzRA hypnotics reduce sleep latency, and most increase total sleep time. The exception is zaleplon, which does not reliably increase total sleep time. The reduction of sleep latency is attributable to a rapid onset of hypnotic effect. The longer the drug's duration of action (i.e., the longer the half-life or the higher the dose, or both), the

more likely it is that the drug will show efficacy on sleep maintenance properties such as number of awakenings or WASO. At doses within the therapeutic range, a dose-response effect is observed on efficacy measures, and little additional effect is generally apparent at supratherapeutic doses. As might be expected, sleep latency shows a relatively flat dose-response curve, and WASO and total sleep time show more pronounced dose-response curves, related to increased duration of action with increased doses.

Tolerance is defined as a reduction of a drug's effect with repeated administration of a constant dose or the need to increase the dose to sustain a specific level of effect. Despite frequent speculations in the medical literature, most studies do not show tolerance to the hypnotic effects of BzRAs in most subjects, at least for therapeutic doses and for the periods of time that have been studied. Investigations that are often cited as evidence for developing tolerance[9] show gradual improvement in sleep over time in the placebo group in the face of a constant effect in the drug group, resulting in loss of statistical significance between groups. Yet the within-group comparison of an early drug effect with a late drug effect fails to show any change in drug activity with repeated use. Thus it cannot be concluded that tolerance has developed, but rather that unspecified changes occur over time with placebo, such as spontaneous remission, regression to the mean (if there are sleep-disruption criteria for entering the study), sleep habit influences inherent in protocol adherence, Hawthorne effects, and true placebo effects.[10] This is further evidenced by the fact that patients rarely escalate the nightly use of hypnotics, even with long-term use.[11]

Nearly 30 years ago, Oswald and colleagues[12] reported that lormetazepam and nitrazepam, two benzodiazepines available in some European countries, retained their effect by some patient estimates of hypnotic efficacy during 24 weeks of nightly use. More recently, in rigorous PSG studies, zolpidem 10 mg and zaleplon 10 mg retained efficacy for 5 weeks of nightly use.[13,14] A 2003 landmark study of several hundred patients with primary insomnia showed continued hypnotic efficacy of eszopiclone for 6 months of nightly use.[15] Patient reports of sleep latency and WASO were significantly reduced with eszopiclone 3 mg compared with placebo at each monthly time point. Total sleep time, number of awakenings, and sleep quality were also better than with placebo at each monthly time point. These 6-month findings have been replicated by Walsh and colleagues[16] (Figure 87-1). Examination of open-label extension data of the 2003 6-month eszopiclone study suggested sustained efficacy for a total of 12 months.[17] Other evidence for sustained efficacy of nightly BzRA use includes a 3-month trial with indiplon, a nonmarketed hypnotic.[18]

Efficacy of non-nightly use of zolpidem 10 mg has been investigated for up to 12 weeks.[19,20] In these studies, ratings of sleep latency, total sleep time, number of awakenings, and sleep quality were all improved on nights when zolpidem was taken (an average of three or four nights per week) compared with placebo (also an average of three or four nights per week). Additionally, investigator global ratings, which considered both medication nights and no-medication nights, indicated reduced insomnia severity with zolpidem. Total sleep time data on nights when a pill (either zolpidem or placebo) was taken or not taken during an 8-week study are shown in Figure 87-2. Importantly, an examination of sleep on nights when no drug was taken immediately after a zolpidem night failed to reveal evidence of rebound insomnia.[14] A 6-month study with an extended-release formulation of zolpidem used three to seven nights per week has generated similar results over the duration of the study.[21]

More recently, a sublingual lozenge formulation (Intermezzo) was approved for the novel indication of middle-of-the-night awakening and difficulty returning to sleep.[22]

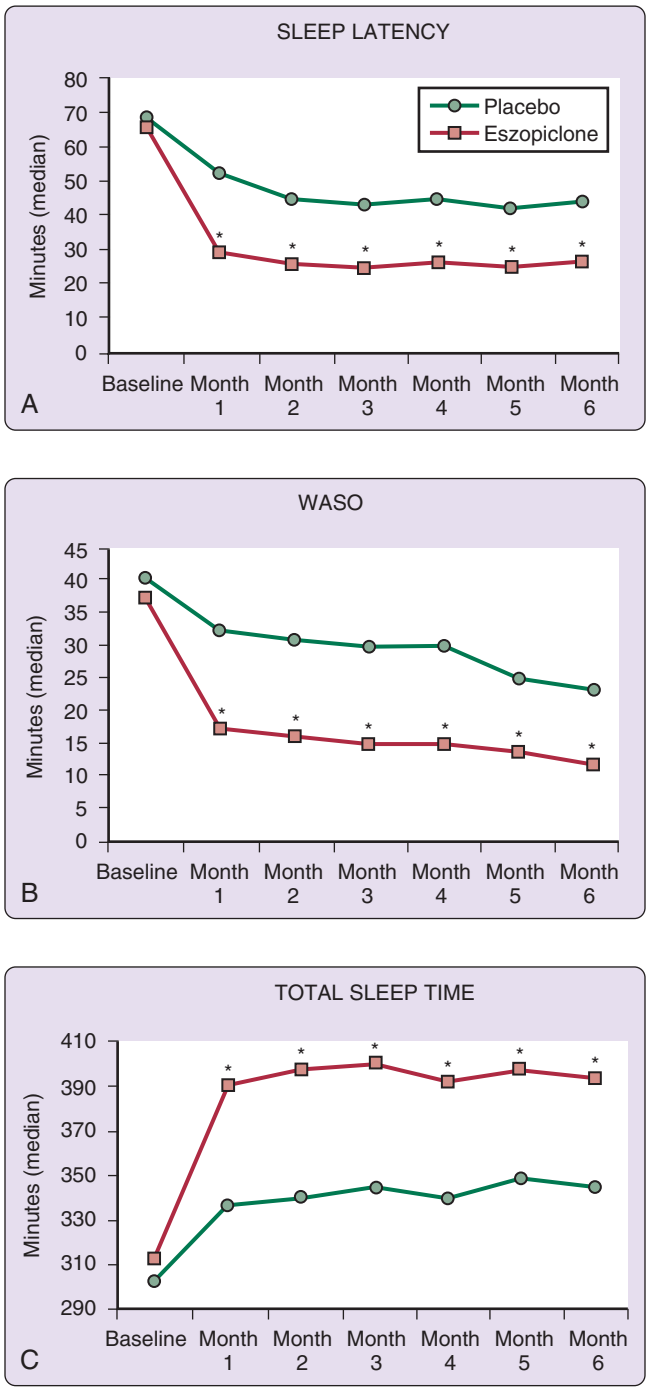

Figure 87-1 Median values for key hypnotic efficacy measures at baseline and during months 1 to 6 of double-blind treatment for eszopiclone (*red*) and placebo (*green*) groups. **A,** Sleep latency. **B,** Wake after sleep onset (WASO). **C,** Total sleep time. *, Change from baseline *P* value versus placebo < .0001. (Modified from Walsh JK, Krystal AD, Amato DA, et al. Nightly treatment of primary insomnia with eszopiclone for six months: effect on sleep, quality of life and work limitations. *Sleep* 2007;30:959–68.)

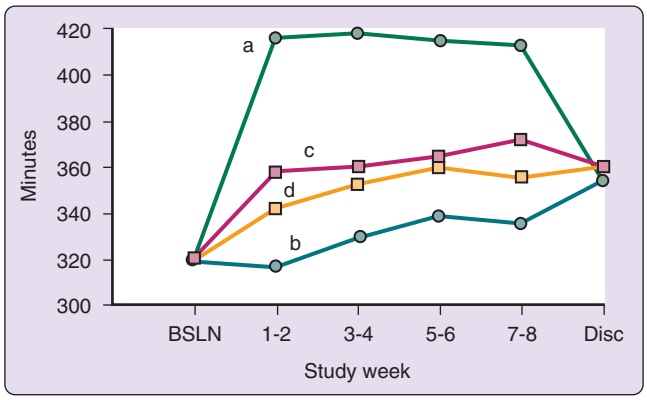

Figure 87-2 Mean subjective total sleep time for 8 weeks: (a) Zolpidem pill nights (*green line* and *green circles*); (b) Zolpidem no-pill nights (*blue line* and *blue circles*); (c) Placebo pill nights (*red line* and *red squares*); and (d) Placebo no-pill nights (*yellow line* and *yellow squares*). $P < .001$ for a versus c and for a versus b, each at study periods 1-2, 3-4, 5-6, and 7-8 weeks. BSLN, baseline (both groups receive placebo, double-blind); Disc, discontinuation week during which both groups received placebo, double-blind. (Modified from Walsh JK, Roth T, Randazzo AC, et al. Eight weeks of non-nightly use of zolpidem for primary insomnia. *Sleep* 2000;23:1087–96.)

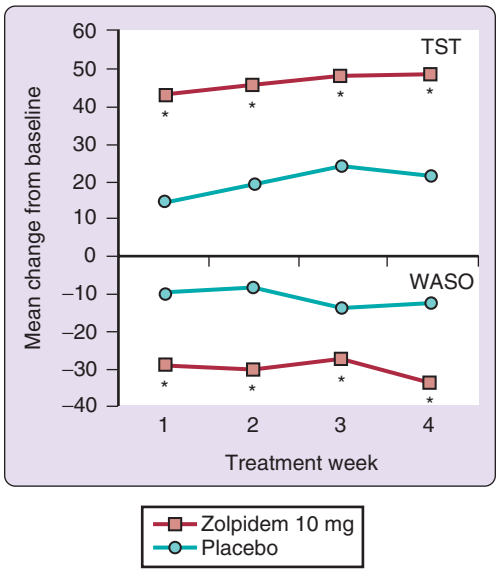

Figure 87-3 Mean weekly change from baseline values for reported total sleep time (TST) (*upper panel*) and wake after sleep onset (WASO) (*lower panel*) in patients with clinically significant insomnia despite effectively treated depressive disorders (treated with fluoxetine, sertraline, or paroxetine). Patients were randomized in double-blind fashion to either zolpidem 10 mg or placebo. *, Indicates the weekly zolpidem value is significantly different from the corresponding placebo value; $P < .05$. (Modified from Asnis GM, Chakraburtty A, DuBoff EA, et al. Zolpidem for persistent insomnia in SSRI-treated depressed patients. *J Clin Psychiatry* 1999;60:68–76.)

Dosages are 1.75 mg for nonelderly women, 3.5 mg for nonelderly men, and 1.75 mg for elderly people. Other zolpidem formulations intended for bedtime use with indications for sleep-onset difficulty include both sublingual (Edular) and oral spray (Zolpimist) forms.

Comorbid Insomnia

Comorbid insomnia refers to insomnia coexistent with other medical or psychiatric conditions. Although BzRAs have not been extensively studied in patients with comorbid insomnia, published data indicate improvements in sleep similar to those seen with primary insomnia. One of the earliest studies relevant to BzRA efficacy in comorbid insomnia examined rheumatoid arthritis patients with insomnia using PSG techniques. Triazolam 0.25 mg was found to reduce sleep latency and number of awakenings and to increase total sleep time across six nights of treatment.[23]

Zolpidem 10 mg increased total sleep time and improved sleep quality in a 4-week placebo-controlled study in depressed patients with refractory insomnia despite adequate control of depressive symptoms with selective serotonin reuptake inhibitor (SSRI) medication.[24] Figure 87-3 contains total sleep time data and wake after sleep time values during that 4-week study. Extended-release zolpidem coadministered with escitalopram improved subjective measures of sleep in patients with comorbid depression[25] and in those with comorbid anxiety,[26] but there were no changes in symptoms of depression or anxiety.

A number of studies have been conducted to assess efficacy of eszopiclone in comorbid insomnia. Eszopiclone combination therapy with fluoxetine was superior to fluoxetine and placebo in improving sleep in patients with newly diagnosed major depressive disorder and comorbid insomnia.[27] In addition, the combination-therapy group was found to have a significantly greater reduction in depressive symptoms, a higher rate of remission, and a faster time to the onset of the antidepressant effect. Similarly, eszopiclone co-therapy with escitalopram was superior to escitalopram plus placebo in improving the sleep of patients with insomnia and generalized anxiety disorder,[28] and anxiety and depressive symptoms were reduced further in patients receiving co-therapy. Insomnia patients treated with eszopiclone 3 mg for 4 weeks during perimenopause or early menopause reported significantly improved sleep throughout the trial, but in addition they had significant improvements in mood, quality of life, and menopause-related symptoms (Figure 87-4).[29] Finally, addition of eszopiclone to a standardized naproxen pain regimen significantly improved sleep, pain, and depression in patients with chronic low back pain.[30]

Effectiveness Studies

Studies of treatment efficacy enroll a selected homogenous sample using a variety of exclusion criteria (e.g., for concomitant medications, many medical conditions). Efficacy trials use highly controlled methods, compare treatment effects to placebo or other active treatments, and typically examine a limited number of outcome variables. In contrast, investigations of treatment effectiveness include patient samples that are much more representative of clinical practice (few exclusion criteria), and the degree of experimental control is minimal. Often no control group is used, and the outcome focus is not only on efficacy measures but also on treatment adherence, patient satisfaction, and quality of life. Hypnotic effectiveness trials, per se, have not been carried out. However, some reports provide information on hypnotic use in the general population that might approximate reports of clinical investigations of effectiveness.

Using an epidemiologic methodology, Ohayon and colleagues[31] reported that of 532 patients describing chronic insomnia and long-term use of hypnotic medications to help them sleep, 67% rated their sleep quality as improved "a lot,"

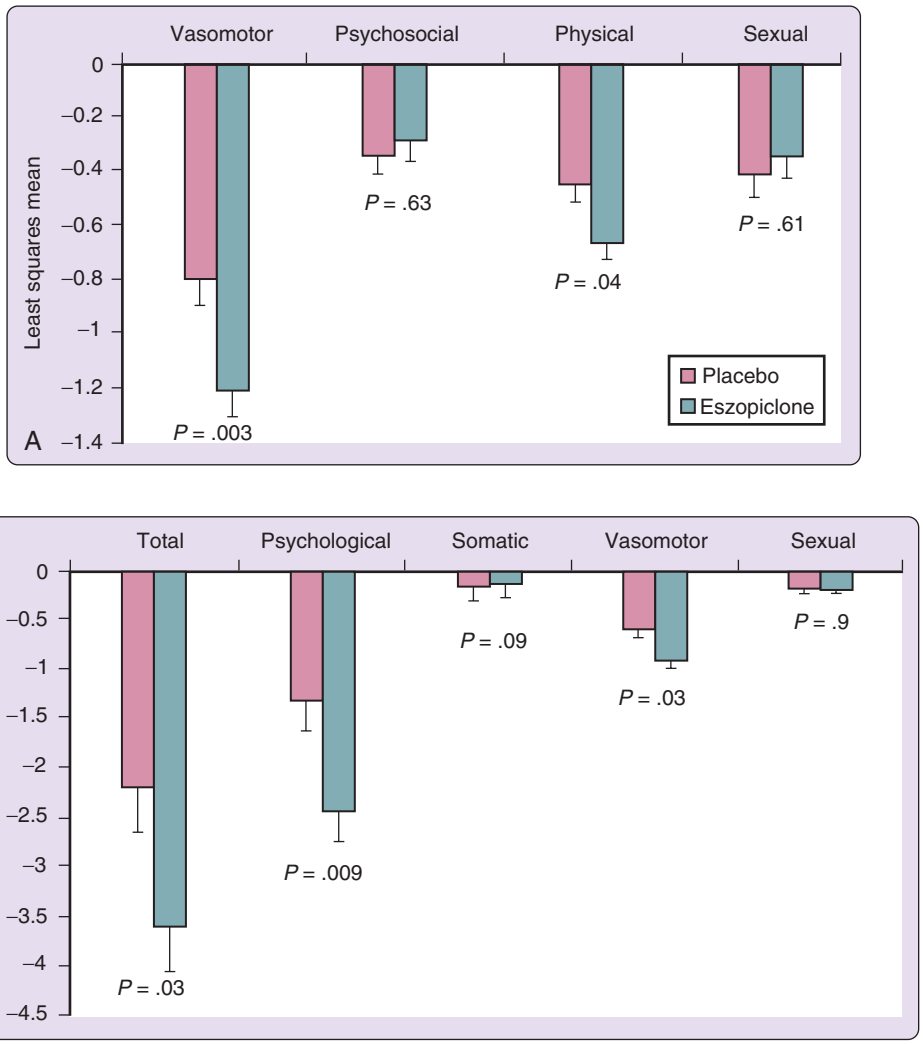

Figure 87-4 Menopause outcomes after 4 weeks of treatment with eszopiclone 3 mg. **A,** Change in menopause-specific quality of life at week 4. **B,** Change in Greene Climacteric Scale at week 4. Data presented are least square means ± standard error of the means. *P* values reflect change from baseline using analysis of covariance. (Modified from Soares CN, Joffe H, Rubens R, et al. Eszopiclone in patients with insomnia during perimenopause and early postmenopause: a randomized controlled trial. *Obstet Gynecol* 2006;108:1402–10).

and only 14.4% reported little or no improvement with medication. Balter and Uhlenhuth[32] interviewed subjects who in the past year either reported significant trouble with insomnia or had taken a medication to help them sleep. They found very high satisfaction rates among users of hypnotics when they asked, "Taking into account both the positive effects on your sleep and daytime functioning and any negative effects you may have experienced, would you take this medication again for the same purpose?" Affirmative responses were received from 84% of those taking triazolam, 82% for flurazepam, 74% for temazepam, and 61% for over-the-counter aids. In summarizing the findings of this intensive interview study, the authors concluded that "the benefits of treatment with prescription hypnotics are substantial and far outweigh the risks as defined in this study." It is important to recognize that in both of these studies, the cited data were obtained from either current users of sleep-promoting medications or those who had used them at some time in the past year. In these studies, the severity or nature of the insomnia was not characterized, nor were the duration, dose, or pattern of hypnotic use or other aspects of the patients. Clearly, effectiveness data in the management of insomnia need to be an important future research priority.

Long-term open-label studies conducted in both adult and elderly subjects in outpatient settings also provide some information about effectiveness.[17,33–36] Zolpidem, zaleplon, and eszopiclone have been evaluated over periods of 6 to 12 months in such studies. In general, patients and physicians report sustained benefit of BzRAs for the duration of the studies, without adverse reactions unique to long-term use. The generalizability of results and the confidence level regarding any conclusions drawn must be tempered by the self-selection of those remaining in these open-label studies.

Impact on Daytime Symptoms of Insomnia and Comorbid Conditions

Diagnostic criteria for insomnia include some form of subjective daytime impairment perceived to be consequent to the sleep disruption, such as fatigue, sleepiness, concentration and memory problems, and mood changes. If the daytime

impairment is mediated by insufficient or disturbed sleep, it should be possible to demonstrate a reduction of impairment with improved sleep. Elimination or reduction of the daytime problem could be viewed as another measure of treatment efficacy. Until recently, few studies have shown daytime consequences of insomnia, especially on laboratory-based tasks of psychomotor and cognitive performance. There is growing evidence, however, that in addition to the perceived daytime dysfunction, insomnia patients have a substantially increased risk for future mood and other psychiatric disorders,[37-40] higher rates of health care use and health care costs,[41-44] elevated risk for falling,[45-47] reduced quality of life,[48,49] and increased absenteeism from work.[41,50,51] Cognitive impairments are reported less often, but recent investigations have differentiated insomniac subjects from normal sleepers.[52,53]

Until recently, the focus of research on the daytime effects of BzRAs used to treat insomnia was the assessment of residual sedation rather than relief of daytime symptoms or other consequences. However, the few studies that have systematically assessed patient-reported daytime measures generally show improvement. For example, in the two 6-month eszopiclone studies of patients with primary insomnia previously discussed,[15,16] patients' reports of daytime alertness, ability to function during the daytime, and physical sense of well-being were all significantly better in the eszopiclone group than in the placebo group.

The waking impact of chronic comorbid insomnia may differ from that of primary insomnia. For example, patients with insomnia and periodic limb movement disorder[54] and those with insomnia and rheumatoid arthritis[55] have been shown to have lower than optimal daytime alertness as determined by Multiple Sleep Latency Test (MSLT) scores, which improve significantly after six nights of treatment with triazolam. Three studies of older adult patients showed increased daytime alertness on the MSLT resulting from increased sleep consolidation and duration with BzRA treatment.[56-58] McCall and colleagues[59] have recently examined health-related quality-of-life metrics in patients with a major depressive episode with insomnia. Combined treatment with fluoxetine and eszopiclone, compared with fluoxetine alone, improved health-related quality-of-life, sleep, and depression severity. In part, the difficulty in finding systematic daytime impairment in chronic insomnia may be the result of differing daytime consequences in subgroups of insomnia patients. More systematic and standardized assessments of daytime function are also needed in hypnotic trials.

SAFETY

In general, BzRAs are well tolerated, with few significant safety concerns. For example, adverse reactions recorded in clinical trials or in clinical practice are seen in the minority of patients, the severity is most commonly rated as mild, and reactions rarely result in abandoning the study or treatment. For inpatient use in a large academic hospital, the median rate of adverse events, across all hypnotics, was found to be about 1 in every 10,000 doses.[60] Data on the incidence of abuse of hypnotic medications, independent of other sedatives, is not available. However, a study in Switzerland in the early 1980s indicated that abuse of all benzodiazepines (not limited to use as a hypnotic) occurred at the rate of 2 per 10,000 prescriptions.[61] A population-based study in the United States indicated that 2.3% of the population reported nonmedical use of sedatives and tranquillizers, and approximately 0.002% of the population met criteria for substance abuse.[62] BzRAs used in COPD patients may increase the risk of respiratory failure.[62a]

The adverse events associated with BzRAs are related to peak plasma concentration (e.g., amnesia, ataxia), which is highly associated with dose, and to duration of action (e.g., residual sedation), which is primarily determined by elimination half-life and dose. Specific safety concerns for hypnotics and their potential mediators are discussed later.

Residual Effects

Many of the side effects associated with BzRAs are mediated by their desired pharmacologic activity, sedation.[63] Residual sedation, which is a prolongation of the hypnotic effect of the drug into the wake period, results in adverse reactions such as drowsy feelings, sleepiness, and impairment in psychomotor performance and driving. The likelihood of residual sedation is determined by the duration of drug activity, which in turn is determined by the elimination half-life and the dose of the drug. Many studies using the MSLT, performance assessments, and simulator or on-road driving tests have shown differences in residual effects between short- and long-acting drugs and between different doses of the same drug.

In the past several years, the FDA has become increasingly concerned about the residual effects of hypnotics,[64] especially as they pertain to driving impairment. Specifically, there is a concern for individuals that metabolize drugs more slowly and hence are at a greater risk for residual sedative effects in the morning. Therefore, the FDA has recommended that clinicians start hypnotic treatment at lower doses and titrate up after a patient has experienced the medication' effects in the morning. As a specific example, the FDA recently released a safety announcement stating: "The U.S. Food and Drug Administration (FDA) is warning that the insomnia drug Lunesta (eszopiclone) can cause next-day impairment of driving and other activities that require alertness. As a result, they have decreased the recommended starting dose of Lunesta to 1 mg at bedtime."

The FDA has also reduced the maximum therapeutic dose of all zolpidem products for women based on sex-related pharmacokinetic differences for zolpidem. At any given dose, women will have higher AUC values than men.[65,66] The mechanism of the gender difference in zolpidem pharmacokinetics is not understood. Importantly, at this time it is not clear whether these pharmacokinetic differences translate into differential efficacy or safety. There are no studies reporting gender differences in efficacy. Other reports of no pharmacodynamic differences[67] require cautious interpretation because these studies were not statistically powered to examine gender differences.

Amnestic Effects

Another adverse effect that is, in part, related to the sedative effects of hypnotics is anterograde amnesia. Anterograde amnesia is memory failure for information presented after administration of the drug. It is associated with all sedative-hypnotics, including all the BzRAs, alcohol, and barbiturates. The extent of amnesia is related to the plasma concentration of the drug. That is, the proximity of information input to peak

plasma concentration determines the degree of amnesia, and higher doses, which increase plasma concentration, are associated with both a greater degree of amnesia and a higher prevalence of amnestic events.[68,69] Furthermore, maintaining wakefulness for 10 to 15 minutes after presentation of memory material, rather than allowing a drug-induced rapid sleep onset, attenuates the amnesia.[70] It is important to recall that sleep itself has amnestic effects. It is not uncommon for people to wake in the middle of the night, and if they fall back to sleep rapidly (within about 5 to 7 minutes), to not remember the awakening. Thus the promotion of rapid sleep onset and a direct drug effect combine to produce the risk for amnesia. There have been reports of global amnesia or traveler's amnesia.[71] These reports are anecdotal and describe persons forgetting long periods of wakefulness after ingestion of a BzRA. These reports tend to be associated with higher doses, drug taken in combination with another CNS depressant drug or alcohol, or drug taken during a period of sleep deprivation.

Discontinuation Effects

The most commonly cited discontinuation effect of BzRA hypnotics is rebound insomnia. Rebound insomnia is defined as a worsening of sleep relative to the patient's status before starting treatment. Unlike other discontinuation effects, rebound insomnia only lasts for one or two nights after the hypnotic is discontinued. Rebound insomnia can occur even after one or two nights' hypnotic use[72] and does not increase in severity with the number of repeated nights of use, at least within the time frame of a few weeks of nightly use. Rebound insomnia is more likely to occur after high doses of short- and intermediate-acting BzRAs. It does not typically occur with long-acting drugs because of the gradual decline in plasma concentration that is inherent in the pharmacology of such drugs. Similarly, it can be minimized with short- and intermediate-acting drugs by gradually tapering the dose over a few nights. A reduction of one clinical dose per week is usually recommended. Importantly, rebound usually can be avoided by using the lowest effective dose.

A critical distinction between rebound and recrudescence is necessary. Recrudescence is a return of symptoms to pretreatment level. This should be expected because BzRAs manage but do not "cure" the symptoms, and hence drug discontinuation is associated with return of symptoms.

One must differentiate rebound insomnia from a withdrawal syndrome. A withdrawal syndrome is the appearance of a new cluster of symptoms (not present before treatment) that are unpleasant and generally last a few days to a few weeks rather than 1 or 2 days. Rebound insomnia is the brief (1 or 2 nights) exacerbation of the original symptom. It does not reflect the presence of a withdrawal syndrome, which would involve the appearance of new symptoms lasting for more than a night or two. Also, rebound insomnia does not increase the likelihood of hypnotic self-administration and behavioral dependence.[72] Withdrawal has been found with both short-acting and long-acting BzRAs, unlike rebound insomnia. Withdrawal phenomena are typically associated with long-term use and importantly can occur with clinical doses. The patient's expectancies can also play a role in the experience of rebound insomnia. Discontinuing placebo pills, that is, stopping pill-taking per se, has been found to produce a sleep disturbance.[73]

Abuse Potential

Dependence on hypnotic medication has continued to be a concern despite only anecdotal evidence to support the concern. Epidemiologic data from representative population samples indicate that most patients do not persist in taking hypnotics for long periods because about 70% use them for 2 weeks or less.[74,75] A percentage of patients use them nightly on a chronic basis (for months or years) but with rare dose escalation.[30] It is unlikely that this pattern of use reflects physical or psychological dependence given the absence of dose escalation and nontherapeutic use of the medications. Although there are reports of physical dependence at therapeutic doses in long-term daytime use of benzodiazepines, none has been reported in 6- to 12-month studies of BzRA hypnotic use.

Daytime studies of the reinforcing effects of these drugs indicate that they have a low to moderate behavioral dependence liability.[76] Studies of their behavioral dependence liability in the context of their use as hypnotics have come to a similar conclusion.[73,77] Among individual patients, the rate of hypnotic administration varies with the severity of the sleep disturbance; within an individual patient, rate of administration depends on the degree of sleep disturbance the prior night.[78] Dose escalation in controlled trials (as in the clinical situation) does not occur, and daytime use is uncommon.[79] The same is true for normal volunteers, the population that best corresponds with patients being treated for transient insomnia. When insomnia patients are given the opportunity in research studies to self-administer hypnotics during the daytime, those that take hypnotic medication during the daytime show the physiologic hyperarousal discussed previously.[79] Hypnotic self-administration in insomniac patients is best explained by therapy-seeking behavior, in that it does not lead to dose escalation, it rarely generalizes to daytime use (i.e., it does not occur outside the therapeutic context), and the rate of self-administration varies as a function of the severity of the sleep problem.

Falls, Cognitive Effects, and Other Considerations for Older Adults

Given the age-related prevalence of insomnia, older adults represent a significant fraction of those using hypnotic medications (see Chapter 153 for more on treatment of insomnia of older patients). The therapeutic index for hypnotics in this population is narrower than for younger adults because of the increased prevalence in older patients of medical, neurologic, and primary sleep disorders, the common use of concomitant medications (particularly other drugs active on the CNS), and changes in drug metabolism and excretion.

Drugs that are primarily metabolized by conjugation are potentially safer for older patients and patients with liver disease. The pharmacokinetics of oxidatively metabolized drugs are altered in these two categories of patients, resulting in increased area under the plasma concentration curve. For some drugs (e.g., triazolam), this alteration is a consequence of increasing the peak plasma concentration, and for others (e.g., flurazepam) it is a consequence of extending the duration of significant blood levels. The lower recommended dose for most hypnotics when treating older patients is related in part to these kinetic changes. However, it is also thought that even with comparable blood levels, elderly people are more sensitive to drug effects.

A number of investigations have demonstrated an increased risk for falls in institutionalized older adults taking benzodiazepines and other psychotropic medications, without regard for the condition being treated or when the medication was taken. Results of early studies of community-dwelling older adults are inconsistent,[80-82] but recent large-scale studies suggest elevated risk. Kelly and colleagues[83] found an elevated risk for an injurious fall for seven categories of medications. When controlling for comorbid illness, the elevated risk remained significant for narcotics, antidepressants, and anticonvulsants but not hypnotics. Ensrud and colleagues[84] reported an elevated risk for falls in older women taking antidepressants (SSRIs or tricyclic antidepressants), anticonvulsants, and benzodiazepines, but not narcotics. Data from the same study, however, showed that risk for a fracture was elevated in those taking narcotics and antidepressants, but it was not affected by use of benzodiazepines and anticonvulsants.[85] Long-acting sedative drugs have been reported to increase risk for falls more than short-acting drugs, but recent data have not borne out this difference.[84] It is important to understand that a variety of CNS-active medications statistically increase fall rates in older adults, and antidepressants often have the highest risks.[86,87]

Investigators have begun to assess the risk for falls in insomniac patients with or without pharmacologic treatment for insomnia. Brassington and coworkers[45] found that reported sleep problems, but not use of psychotropic medication, was an independent risk factor for falls in a large sample of community-dwelling adults aged 64 to 99 years. In another recent study, the risk for falls was statistically significant in patients who had insomnia and did not use hypnotics and in those with insomnia that persisted despite hypnotic use, but not in patients who used hypnotics but did not have insomnia. One interpretation of these findings is that if the hypnotic relieves the insomnia, the hypnotic is not a risk factor for falling.[46] Stone and colleagues studied community-dwelling older women and reported that short sleep duration and fragmented sleep, determined by actigraphy, were associated with an increased risk for falls, independent of benzodiazepine and other BzRA use.[47] Future investigations will need to carefully differentiate between sleep disturbance and its treatment in evaluating contributing factors to falls.

Long-term use of benzodiazepines has been reported to be associated with cognitive decline in older adults,[88] including Alzheimer dementia,[89] although this is certainly not a universal finding.[90] The nature of these investigations (which are predominantly cross-sectional and retrospective) does not allow conclusions regarding causality because it is extremely difficult to implement proper controls for the aging process, the disease being treated, exposure to other drugs, and other factors. The cognitive changes are often subtle,[91] and the clinical significance of these effects has been questioned.[92] Nevertheless, the possibility that cognitive decline might at least in part be attributable to use of hypnotics, or any psychotropic medication, should be kept in mind by the clinician prescribing chronic therapy in elderly patients. However, withholding hypnotic treatment because of the anticipation of cognitive effects does not appear to be warranted on the basis of available information regarding magnitude of risk.

Complex Behavior in Sleep

Reports of idiosyncratic side effects associated with BzRA hypnotics, and other drugs, have appeared periodically in the public press. These reports of "global amnesia," "somnambulism," and "sleep-related eating disorders" are anecdotal. Peer-reviewed case reports describing unusual behavior concurrent with BzRA use also have appeared in the medical literature. Although case reports provide more detail and presumably more accurate information, including assessment of other contributing factors, the level of scientific evidence ascribed to case reports is low. Until a higher level of scientific evidence becomes available through placebo-controlled investigations, the actual risk for complex behavior in sleep and global amnesia will remain unknown. Even if adequate surveillance data were available to assess event frequency, the risk for an event cannot be determined unless the rate of exposure to various medications is known. Moreover, the dose consumed and concomitant medications and substances ingested at the time of the event are unknown.

Somnambulism has been reported with zolpidem and zaleplon.[93,94] These episodes of somnambulism have occurred in persons taking two to three times the clinical doses of the drug, in persons who have a prior history of somnambulism, and in persons who have experienced prior traumatic head injury. Zolpidem-associated somnambulism also has been reported in combination with antidepressant medications and alcohol. In a clinical context, somnambulism is believed to be associated with incomplete arousal from sleep. Although BzRAs increase somnambulism, alcohol and sleep deprivation also produce partial arousals and increase the likelihood of a somnambulistic event.

Sleep-related eating disorder associated with ingestion of BzRAs has also been reported.[95,96] It is disputed whether sleep-related eating disorder is a disorder of partial arousal from sleep with altered levels of consciousness or is the psychiatric disorder of nocturnal eating with awareness and recall. Sleep-related eating disorder is hypothesized to share a common pathophysiology with somnambulism. Zolpidem was reported to exacerbate sleep-related eating disorder and in several cases to induce it de novo. In some of these cases doses of zolpidem greater than 10 mg were being used, and in other cases there was use of sedating antidepressants. Sleep-related eating disorder also has been reported with triazolam. A common thread links much of this case-report information: excessive hypnotic activity or sleep drive. The excessive hypnotic activity can occur as a result of high doses, clinical doses in vulnerable persons (i.e., those who have a past history of sleep disorders or brain injury), the combination of clinical or high doses with prior sleep deprivation caused by stress or illness, or the combination of clinical or high doses with the prior consumption of alcohol.

Mortality

Examination of mortality risk associated with use of medication taken for insomnia and other indications often shows an elevated risk, the explanation for which is unknown.[97-99] Clearly, these findings merit investigation of the mediators and nature of the risk. However, a number of factors limit the conclusions that can be drawn from currently available data.

The epidemiologic nature of the studies (as opposed to controlled experimental trials) prevents any conclusions regarding causality or mediators. It is also important to remember that 90% of insomniac patients have a comorbid condition, and typically they have more than one. Thus the mediators of the mortality are not clear. It would be

important to look at the risk in terms of specific causes of mortality.

The exact medications responsible for the elevated mortality risk are not constant from study to study, and, in fact, they are often unknown. Data for one study were collected in 1959 to 1960,[97] when barbiturates were the most commonly used hypnotics; for the second study[98] data were collected in 1982, when benzodiazepines were the most commonly used hypnotics. Several studies also did not differentiate between prescription and nonprescription drugs. All investigations concluding that an elevated mortality risk exists must include any medication the respondent reports as being taken for sleep, whether a hypnotic or not, and whether the prescribing physician actually intended another indication. The only study that obtained reasonable verification of the actual drugs being taken by respondents found that sedative-hypnotics were not associated with an increased mortality risk. Rather, "other drugs" taken for sleep, which in that study were often analgesics, showed a statistically higher mortality risk.[100]

Long-term, controlled investigations would be needed (although ethical considerations clearly are of concern) to clarify whether any medication used to promote sleep increases mortality risk, or whether the statistical risk is explained by the poor health of the users of sleep-promoting drugs, or by other factors. Alternatively, longitudinal population-based studies aimed at answering this question could better define the risk. Such a study would need to identify the specific hypnotic drug being taken, pattern of drug taking, other drugs being taken, and the nature of the comorbid disorders and should institute adequate experimental and statistical control to allow reasonable inferences about the data. Until such data become available the possibility that hypnotics contribute to mortality risk cannot be discounted.

CONSIDERATIONS FOR PHARMACOTHERAPY

Hypnotic therapy should be considered for insomnia when the patient is significantly distressed by the presence or possibility of disturbed sleep, or when the physician judges the sleep disturbance to be deleterious to the patient's overall safety or health. The 2005 National Institutes of Health State of the Science Conference report on the management of chronic insomnia[1] concluded that BzRAs are the only medications with an established scientific basis (i.e., clearly defined risk and benefit by dose) for use for insomnia. Thus, for most patients with chronic insomnia, pharmacotherapy should be initiated with a BzRA at the lowest effective dose for the shortest clinically necessary period of time. There is also widespread agreement that BzRA hypnotics are an appropriate therapy for short-term insomnia.

The specific BzRA should be carefully chosen, considering the pharmacokinetics of the drug and the patient characteristics (e.g., age, nature of the sleep problem, concurrent illness). The dose and treatment regimen should be individualized, agreed to by the patient, and most importantly monitored by the physician. The hypnotic should be taken only at the time and frequency agreed on. The initial dose should be the lowest clinically indicated dose, and the clinician and patient should jointly determine effectiveness of that dose soon after treatment is initiated (e.g., after three to five nights). The dose can then be adjusted as appropriate based on both efficacy and safety reports from the patient. Patients should generally not be allowed to adjust the dose themselves, particularly during the early portion of therapy, because a fluctuating dose makes interpretation of clinical response very difficult.

Hypnotics can be prescribed to be taken at bedtime nightly, on a predetermined intermittent schedule (e.g., every third night), or as needed. With the exception of zaleplon, all bedtime medications should be taken only when the patient has the opportunity to stay in bed 7 to 8 hours. Zaleplon has been evaluated when administered with 5 hours or less of time in bed remaining and been found to improve sleep without residual effects the next morning.[101,102] As previously mentioned, a sublingual lozenge formulation of zolpidem (Intermezzo) is the only hypnotic approved for nonbedtime use, that is, for middle-of-the-night awakening and difficulty returning to sleep. If nightly hypnotic use is not desirable for individual patients, they can be instructed to attempt sleep without medication and, if unsuccessful, to take the drug later, provided there are 4 to 5 hours remaining before they must rise. Thus, in cases of sleep-maintenance insomnia characterized only by a middle-of-the-night awakening, or in cases of intermittent sleep-onset insomnia, middle-of-the-night administration should be considered.

The physician should specifically inquire about the aspects of sleep and daytime function that were most problematic for the patient before treatment, rather than relying solely on global statements. A sleep diary can be helpful for comparing pretreatment and posttreatment symptoms. In reasonably healthy persons, monthly visits should be sufficient to identify most potential adverse effects. For older adults or others at increased risk for drug interactions, alterations in drug metabolism, incoordination, or cognitive problems, close follow-up is recommended throughout the period that hypnotics are administered. Discontinuation of therapy should be considered if symptoms occur that may be side effects of the medication, to confirm whether they are indeed related to the medication. After long-term use, gradual discontinuation, by dose tapering at a rate of one clinical dose per week, is a reasonable practice.

The primary contraindications to BzRA hypnotic therapy are concomitant illnesses, such as severe COPD, obstructive sleep apnea, substance abuse disorder, or advanced liver disease. All sedative medications have the potential to worsen sleep apnea by blunting arousal from sleep, although central apnea has been reduced by BzRAs in some investigations.[103] The dependence liability of BzRAs and other sedative drugs, although not high, leads to the conclusion that most patients with a history of alcoholism or drug abuse should not receive BzRAs in outpatient settings without close supervision. Caution is advised for moderate users of alcohol because of additive sedative effects with hypnotics, which narrows the wide margin of safety described earlier. Because most BzRAs undergo hepatic metabolism, advanced liver disease requires the use of a lower dose or avoidance of these medications.

Pharmacotherapy for insomnia during pregnancy is also contraindicated; the teratogenic effects of all psychoactive drugs are a matter of concern.[104] People who may be required to awaken and perform duties in the middle of the night should avoid CNS-depressant drugs when on call. All hypnotics have the potential to disrupt alertness and cognitive function for the duration of the sedative activity of the drug, and they can affect motor function.

CLINICAL PEARL

Extensive efficacy and safety evidence supports the use of BzRAs for the treatment of insomnia for as long as it is clinically warranted. Convincing evidence for use of other available medications (e.g., sedating antidepressants) is not currently available. The duration of action between different BzRAs varies greatly, and therefore the desired duration of sleep-promoting action and the need for morning alertness should guide the clinician in the choice of a specific medication and the dose for each person.

SUMMARY

Considerable evidence indicates that the BzRAs are efficacious in the treatment of insomnia, whether primary or comorbid, chronic or transient. Limited data suggest a substantial degree of effectiveness in clinical use. BzRAs are also generally safe as commonly used in clinical practice. Research refutes the common concerns of tolerance, misuse, and abuse by insomnia patients. Sufficient differences in pharmacokinetic profiles exist among the BzRAs to provide physicians with therapeutic options that have differing durations of action. Individual differences in metabolism and elimination of BzRAs have led to a lowering of recommended starting doses for some BzRAs. Several investigations indicate that treatment of insomnia with BzRAs produces improvement in both daytime and nighttime symptoms of insomnia, and some might also reduce the severity of comorbid illnesses. Despite significant advances in understanding the neurobiologic mechanisms of sleep and arousal, which involve multiple neural systems, attempts to produce novel drug treatments for insomnia have not produced clear advances in insomnia pharmacotherapy. BzRAs remain the most effective, safest, and best-understood therapeutic agents for the treatment of insomnia.

Chapter 88

Pharmacologic Treatment of Insomnia: Other Medications

Andrew D. Krystal

Chapter Highlights

- Many different types of agents other than benzodiazepine binding site–positive allosteric modulators (also referred to as benzodiazepine receptor agonists) are used in the treatment of insomnia, including antidepressants, antipsychotics, antihistamines, anticonvulsants, and melatonin agonists.
- Each of these agents has unique properties that should be considered in determining which agent should be selected for use in a given patient with insomnia.
- Awareness of the characteristics of the nonbenzodiazepine receptor agonist agents and of the clinical circumstances in which they might be the preferred pharmacotherapy is important for optimizing the pharmacotherapy of insomnia in clinical practice.

The predominant treatments for insomnia in the twentieth century were medications that bind to the benzodiazepine binding site on the gamma-aminobutyric acid (GABA) receptor complex.[1-3] These agents, often referred to as benzodiazepine receptor agonists (BZRAs), are discussed in detail in Chapter 87. Their therapeutic effects in insomnia patients occur through enhancing the inhibitory effects of GABA, which is believed to be the neurotransmitter that is most important for promoting sleep.[1,2,4] Because of the long-standing and widespread use of BZRAs, this mechanism and the clinical properties of these agents have become almost synonymous with insomnia pharmacotherapy. Experience suggests that these insomnia agents have effects that are proportional to their serum level (maximal effect occurs at peak blood level), have some abuse potential, and have daytime sedation and psychomotor impairment as their primary potential side effects.[2,3] However, there are agents used to treat insomnia that improve sleep by mechanisms other than enhancing GABAergic inhibition, and their clinical properties differ from those of the BZRAs. These agents act through a variety of mechanisms and represent at least 11 different medication classes. The mechanisms of their therapeutic effects on insomnia include melatonin receptor agonism, serotonin receptor antagonism, histamine receptor antagonism, hypocretin/orexin receptor antagonism, norepinephrine receptor antagonism, and possibly antagonism of dopamine and acetylcholine receptors.[3] In addition, these agents have a diverse set of other pharmacologic effects that contribute to their side effect profile and are responsible for their effects on conditions other than insomnia.[3] In fact, all of these agents, with the exception of the melatonin receptor agonist ramelteon, the tricyclic drug doxepin, and the hypocretin/orexin antagonist suvorexant, are indicated for use in conditions other than insomnia by the U.S. Food and Drug Administration (FDA). As a result, they are not usually categorized as insomnia therapies but are typically referred to by their other intended actions as antidepressants, anxiolytics, antipsychotics, anticonvulsants, or antihistamines.

The pharmacology of these agents is reviewed in Chapter 43. In this chapter, we discuss these agents, focusing on their clinical effects and their potential utility in the clinical treatment of insomnia (Table 88-1).

MELATONIN AND MELATONIN RECEPTOR AGONISTS

Melatonin

Overview. Melatonin is a hormone primarily produced by the pineal gland. The release of this hormone occurs during the period of darkness from sundown to sunrise. When it is taken orally, melatonin appears to have sleep-enhancing and circadian rhythm–modifying effects. The circadian rhythm effects of melatonin are discussed in Chapter 40. Here we discuss the sleep-enhancing effects.

Melatonin is available as an over-the-counter medication in the United States. It has a time to maximum concentration (T_{max}) of approximately 0.5 hour and an elimination half-life ($T_{1/2}$) of roughly 1 hour.[5] A BZRA with such a pharmacokinetic profile would be expected to have a short duration of effect and be best suited to treatment of sleep-onset problems. However, this cannot be assumed with melatonin, which works by a mechanism that differs from the BZRAs. Melatonin binds to melatonin receptors, predominantly MT_1 and MT_2 receptors, and the mechanism by which these receptors affect sleep is unknown, although it is clear that the sleep enhancement of this agent is divorced from the serum level. A dose-response relationship does not appear to exist for melatonin, and the means to determine optimal dosing are lacking. Further complicating optimization of the use of melatonin, a number of studies have identified that the timing of sleep enhancement that occurs with melatonin depends on the time of day of administration and may not be manifested for as long as 3 hours after dosing, despite achievement of maximal serum concentration in approximately 30 minutes.[6-8] As a result, attention must be given to the time of day that this agent is administered as well as to the relationship of the time

Table 88-1 Medications Other Than Benzodiazepine Receptor Agonists Used in the Treatment of Insomnia

Medication	FDA Indication	Insomnia Dosage (mg)	T_{max} (h)	$T_{1/2}$ (h)*	Efficacy in Placebo-Controlled Insomnia Trials	Most Frequent Side Effects	Relative Contraindications to Use	Most Promising Clinical Use
Amitriptyline	MDD	10–100	2–5	10–100	—	Sedation Dizziness Weight gain Orthostatic hypotension Dry mouth Blurred vision Constipation Urinary retention	History of myocardial infarction, ischemia, or conduction abnormalities Closed-angle glaucoma Decreased gastrointestinal motility Urinary retention Hypotension History suggestive of bipolar disorder Parkinson disease Seizure disorder Hepatic disease	Insomnia comorbid with MDD, chronic pain, or anxiety
Doxepin	MDD Anxiety	1–25 mg	1.5–4	10–50	5/5	Sedation Dizziness Weight gain Orthostatic hypotension Dry mouth Blurred vision Constipation Urinary retention	History of myocardial infarction, ischemia, or conduction abnormalities Closed-angle glaucoma Decreased gastrointestinal motility Urinary retention Hypotension History suggestive of bipolar disorder Parkinson disease Seizure disorder Hepatic disease	Efficacy with relative absence of side effects in 1–6 mg Insomnia comorbid with MDD, chronic pain, or anxiety Treatment of early morning awakenings
Trimipramine	MDD	25–100	2–8	15–40	2/2	Sedation Dizziness Weight gain Orthostatic hypotension Dry mouth Blurred vision Constipation Urinary retention	History of myocardial infarction, ischemia, or conduction abnormalities Closed-angle glaucoma Decreased gastrointestinal motility Urinary retention Hypotension History suggestive of bipolar disorder Parkinson disease Seizure disorder Hepatic disease	Insomnia comorbid with MDD, chronic pain, or anxiety

FDA, Food and Drug Administration; MDD, major depressive disorder; OTC, over-the-counter; COPD, chronic obstructive pulmonary disease; SDB, sleep disordered breathing.

of administration to desired sleep-enhancing effect. The dosages administered in placebo-controlled trials have ranged from 0.1 to 75 mg; however, the majority of studies used dosages in the range of 2 to 6 mg. The timing of administration varied from 30 minutes to 3 hours before bedtime. There was no clearly predominant administration time. The primary metabolism of melatonin occurs through cytochrome P450 1A2 and 2C19 isoenzymes, so the elimination of melatonin would be expected to be affected by factors that modify the function of these isoenzymes.[9]

Evidence of Efficacy. Placebo-controlled studies of the effects of melatonin on sleep have been carried out in a number of different subject populations, including adults without sleep complaints; children, adults, and elderly insomnia patients; patients with Alzheimer dementia; patients with insomnia comorbid with medical illnesses; mood disorder patients; patients with schizophrenia; children with attention-deficit/hyperactivity disorder; and children with neurodevelopmental disorders.[10-24] However, drawing conclusions from these studies is difficult because they employed widely varying melatonin dosages and different melatonin formulations (immediate and delayed release) and varied substantially in the timing of melatonin administration.[25,26] Despite these limitations, the available self-report, polysomnographic, and actigraphic data suggest that melatonin has a therapeutic effect on sleep onset that is greater and more consistent than its effects on the ability to stay asleep or the duration of sleep.*

Profile of Adverse Effects. No substantive risks of melatonin have been identified. However, no large-scale systematic studies assessing the adverse effects of melatonin have been carried out. The most commonly reported side effect is headache.[12] Slowing of reaction time and sedation have been observed with melatonin after daytime administration, which could impair ability to function.[6,32,33] Melatonin is nonreinforcing, so abuse potential is minimal. Physiologic or psychological dependence does not appear to occur with melatonin therapy, although this has not been systematically evaluated. The longest studies of nightly melatonin therapy have been 8 weeks in duration.[11,24]

Potential Clinical Utility. Melatonin appears to have primary use in addressing problems of sleep onset. It is relatively unique in that data suggest it can be safely administered to children, those with Alzheimer dementia, and children with neurodevelopmental disorders.[10-24] However, the degree of therapeutic effects in these populations is not well established. Given the absence of abuse potential, this medication would also be reasonable to use in substance abuse–prone individuals; however, no studies of melatonin treatment have been carried out in this population.

A number of studies suggest that melatonin regulates reproductive function in both males and females. Some evidence suggests that higher melatonin levels may be associated with reversible inhibition of spermatogenesis and ovulation.[34-37] On this basis, some have suggested that those who are trying to conceive should avoid taking melatonin.[36,37]

*References 10, 12, 14, 18, 19, 27-31.

Ramelteon

Overview. Ramelteon is an agonist at MT_1 and MT_2 melatonin receptors, has a T_{max} of 0.75 to 1 hour, and has a $T_{1/2}$ of 1 to 2.5 hours.[38] Based on this pharmacokinetic profile, ramelteon, like melatonin, would be expected to have effects primarily on sleep onset. Indeed, it is approved by the U.S. FDA with an indicated use in the treatment of sleep-onset difficulty. Ramelteon, like melatonin, has no clear dose-response relationship; however, a therapeutic dosage of 8 mg and timing of dosing 30 minutes before bedtime have been established.[3] Primary metabolism of ramelteon occurs through the cytochrome P450 isoenzymes CYP1A2, CYP2C, and CYP3A4, so that factors affecting these isoenzymes would be expected to alter the metabolism of ramelteon.[39]

Evidence of Efficacy. In placebo-controlled trials, ramelteon consistently shortens sleep latency with an accompanying increase in total sleep time.[3] These effects have been more consistent on polysomnographic than on self-reported measures of sleep. Therapeutic effects on the ability to stay asleep have generally not been noted.

Profile of Adverse Effects. Ramelteon is generally well tolerated; dosages up to 64 mg have been associated with no substantive increase in adverse effects. The most common side effects reported with ramelteon include headache, dizziness, somnolence, fatigue, and nausea.[40,41] There is no evidence for abuse potential or tolerance in studies as long as 5 weeks in duration.[40,41] Statistically significant but not clinically significant elevations of prolactin have been noted with ramelteon compared with placebo in women receiving 6 months of nightly treatment with 16 mg.[42] Several studies suggest that ramelteon does not exacerbate breathing problems when it is used in those with sleep disordered breathing and mild to moderate chronic obstructive pulmonary disease.[43,44]

Potential Clinical Utility. Ramelteon is indicated solely for the treatment of sleep-onset difficulties. The data in patients with sleep disordered breathing and chronic obstructive pulmonary disease suggest that ramelteon can be safely used in these populations of patients when treatment of sleep-onset insomnia is indicated.[43,44] The absence of abuse potential suggests that this medication could also be used in substance abuse–prone individuals, although no studies of the treatment of insomnia with ramelteon have been carried out in this population.

Ramelteon is relatively free of contraindications. The only relative contraindication to use is severe liver failure.

SEDATING ANTIDEPRESSANTS

A number of agents that are approved by the U.S. FDA for the treatment of depression are used in relatively lower dosages for the treatment of insomnia.[3] In fact, for some of these agents, their use in low dosage for insomnia therapy exceeds their use for alleviation of depression.[45] These agents have therapeutic effects on sleep through blocking of the receptors of a number of key wake-promoting neurotransmitters, including serotonin, norepinephrine, and histamine.[3,46] The antidepressants most commonly used to treat insomnia include tricyclic antidepressants, most notably, doxepin,

trimipramine, and amitriptyline; the chlorophenyl piperazine; trazodone; and the tetracyclic antidepressant mirtazapine.[3]

Tricyclic Antidepressants: Doxepin, Amitriptyline, Trimipramine

Overview. Three tricyclic antidepressants—doxepin, amitriptyline, and trimipramine—are used relatively frequently for the treatment of insomnia, presumably because of the sedating effects noted when they have been used to treat major depression.[3,45,47] Interactions with the tricyclic antidepressants may occur through effects on their predominant metabolic pathways, which involve the cytochrome P450 system CYP3A4, CYP2C19, CYP2D6, and CYP2C9 isoenzymes.[48,49] By affecting these isoenzymes or altering hepatic blood flow, a number of factors can increase blood levels of tricyclic antidepressants, including age, antipsychotic medications, methylphenidate, fluoxetine, paroxetine, cimetidine, diltiazem, and grapefruit juice.[50] There is also genetic variation in the capacity to metabolize tricyclic antidepressants in the population, which leads to substantial person-to-person differences in the relationship between dosage and therapeutic and adverse effects.[50] Amitriptyline, doxepin, and trimipramine reach their maximum serum concentration (T_{max}) in 1.5 to 6 hours after oral ingestion and have elimination half-lives ($T_{1/2}$) on the order of 10 to 50 hours.[48-50]

Evidence of Efficacy. These agents have been reported to have therapeutic effects on indices of sleep onset and maintenance in depressed patients.[51] In addition, a number of placebo-controlled trials of the treatment of insomnia have been carried out with doxepin and trimipramine. Trimipramine 50 to 200 mg has been evaluated in two studies of primary insomnia patients, leading to improved sleep quality and polysomnographic sleep efficiency compared with placebo, with no effect on sleep-onset latency.[52,53] Doxepin has been evaluated in three studies at a dosage of 25 to 50 mg and found to improve sleep quality and reported daytime well-being as well as polysomnographic indices of sleep onset and maintenance compared with placebo.[52,54-56] More recently, doxepin has been evaluated in placebo-controlled trials in insomnia patients at dosages of 1 to 6 mg.[57,58] Because the predominant pharmacologic effect of low-dose doxepin is the blockade of H_1 histamine receptors, as the dosage is decreased, doxepin becomes an agent with increasingly specific H_1 antagonist effects.[59] The studies carried out with doxepin 1 to 6 mg have identified evidence of self-reported and polysomnographic efficacy in indices of sleep onset and maintenance with particular effects on maintenance of sleep.[57,58] Notably, the therapeutic effects appear to be largest in the last third of the night, and of particular note, they are greatest in the last hour (hour 8) of the night.[57] This suggests a dissociation of the clinical effects from the serum blood level as the peak blood level occurs between 1.5 and 4 hours after dosing. At the same time, 1 to 6 mg of doxepin was not associated with significant sedation or impairment when subjects were tested after waking 1 hour after the peak sleep-enhancing effect.[57] Daytime somnolence was not noted as an adverse effect more frequently than with placebo in these studies, despite the relatively long half-life of this agent. The absence of daytime impairment with doxepin 1 to 6 mg suggests that an increase in wake-promoting neurotransmitter activity occurs after waking that counteracts the H_1 antagonism.

Profile of Adverse Effects. The side effects of the tricyclic antidepressants primarily derive from their blockade of H_1 histaminergic, M_1 muscarinic cholinergic, serotonergic ($5\text{-}HT_2$), and $alpha_1$- and $alpha_2$-adrenergic receptors. These actions result in potential side effects, such as sedation, orthostatic hypotension (and the attendant risk of falls), weight gain, dry mouth, constipation, urinary retention, cardiac dysrhythmias (increased heart rate and impairment of cardiac electrical conduction, which can lead to heart block in some instances), exacerbation of narrow-angle glaucoma, and, rarely, seizures and anticholinergic delirium.[46,49] These effects are dose dependent. Most published literature relates to their use in dosages used to treat depression and not the lower dosage ranges more commonly used in the treatment of insomnia. The best data on the adverse effects of tricyclic antidepressants when they are used in lower dosages for insomnia therapy exist for doxepin. In dosages of 1, 3, and 6 mg, doxepin has a remarkably favorable side effect profile, in contrast to the side effects noted with its antidepressant use.[57,58] In particular, the available data suggest that doxepin is not associated with significant weight gain, it does not appear to be associated with substantive daytime impairment or sedation, and anticholinergic effects are uncommon.

Potential Clinical Utility. It is natural to consider the use of these antidepressants in patients with insomnia associated with depression. However, there are no data indicating that an antidepressant effect occurs with the dosages of these agents that are generally used to treat insomnia. Low-dose monotherapy with these agents may not have antidepressant effects, but a therapeutic effect on depression might be seen when they are combined with a nonsedating antidepressant (e.g., selective serotonin reuptake inhibitor or serotonin-norepinephrine reuptake inhibitor). At the same time, there may be increased risks when these agents are combined.[60] Tricyclic antidepressants have also been used frequently in the treatment of anxiety and chronic pain and may be useful to treat sleep problems associated with these conditions. However, as with depression, dosage may be an important consideration.[61] Given the lack of abuse potential, the tricyclic antidepressants are a potential option for use in treating the sleep difficulties of individuals with substance abuse history. Doxepin dosed from 1 to 6 mg appears to have unique potential for treating sleep difficulties in the latter part of the night/early morning period. As low-dose doxepin is also a relatively selective H_1 antihistamine, it may be useful in individuals with insomnia occurring in conjunction with allergies.

Relative contraindications to the use of tricyclic antidepressants derive from their risks of cardiac arrhythmias, anticholinergic effects, seizures, and orthostatic hypotension.[46,49] Because of these risks, tricyclic antidepressants should be used with caution in those with a history of myocardial infarction, ischemia, or conduction abnormalities; closed-angle glaucoma; decreased gastrointestinal motility; urinary retention; hypotension; or seizure disorder. Antidepressants should be used with caution in those with bipolar disorder because of the increased risk of precipitating mania.[62] Based on the metabolism of the tricyclic antidepressants, significant hepatic disease is also a relative contraindication to their use. As previously noted, the risks and associated relative contraindications of these agents are dose related and may not be relevant in the lower dosages often used to treat insomnia.

Trazodone

Overview. Trazodone is most frequently used as an "off-label" agent in the treatment of insomnia.[45] Whereas it is generally used at a dosage of 200 to 600 mg in the treatment of depression, the dosage used to treat insomnia typically ranges from 25 to 150 mg. With a T_{max} of 1 to 2 hours and a $T_{1/2}$ of 7 to 15 hours, trazodone has the potential to have therapeutic effects on the initiation and maintenance of sleep.[3] Trazodone is primarily metabolized through CYP3A4 and CYP2D6 pathways and can have significant interactions with other agents that are associated with these liver cytochrome systems.[3] Trazodone has one active metabolite, *m*-chlorophenylpiperazine (mCPP).[63] Significant variation in the effects of trazodone occur because many factors can affect the metabolism of trazodone and mCPP, including genetic polymorphisms that are common in the general population.[64]

Evidence of Efficacy. The primary evidence of a sleep-enhancing effect of trazodone is that sedation was a frequently reported side effect in depression treatment trials. Few studies of the use of trazodone in insomnia patients have been carried out. A small placebo-controlled study in abstinent alcoholics ($n = 16$) found significant improvement in sleep efficiency and awakenings compared with placebo.[65] A double-blind, placebo-controlled, crossover study was carried out in 17 patients with depression who had insomnia while being treated with fluoxetine or bupropion.[66] Compared with placebo, trazodone significantly improved the Pittsburgh Sleep Quality Index and the sleep items of the Yale–New Haven Hospital Depressive Symptom Inventory. One study of the treatment of patients with primary insomnia was also carried out with trazodone.[67] This was a parallel-group, 2-week study comparing trazodone 50 mg, placebo, and zolpidem 10 mg. A number of sleep parameters were significantly improved versus placebo for both trazodone and zolpidem in the first week of treatment. However, by the second week, these differences were not significant because of improvement in the placebo-treated patients.

Profile of Adverse Effects. The most common side effects occurring with trazodone include sedation, dizziness, headache, dry mouth, blurred vision, and orthostatic hypotension. Weight gain may occur in some cases. Individuals who have relatively diminished capacity to metabolize mCPP because of genetic or other factors are likely to experience anxiety or insomnia with trazodone. Priapism, a painful sustained erection, is a relatively uncommon side effect of trazodone that may require surgical intervention and can lead to impotence.[68] There is no evidence that trazodone has significant abuse potential.

Potential Clinical Utility. As with other antidepressants, it is natural to consider the use of trazodone in patients with insomnia associated with depression. One study demonstrated the safe and effective use of trazodone in depressed patients treated with fluoxetine or bupropion.[66] However, trazodone may be associated with increased risks when it is combined with other antidepressants. Further, it is unlikely to have significant antidepressant effects when it is used as monotherapy in the dosing range generally used to treat insomnia (50 to 150 mg), although whether it has antidepressant effects when it is used in combination with other antidepressants is unknown. Given the lack of abuse potential, trazodone is reasonable to consider for use in individuals with substance use disorders. In this regard, one study carried out in abstinent alcoholics reported a therapeutic effect on sleep and a reasonable safety profile.[65]

Trazodone should be used with caution in those at risk for falls because of the risk of orthostatic hypotension. Trazodone should also be administered judiciously in men because of the risk of priapism. Like any antidepressant, trazodone should be used with caution in those with bipolar disorder because of the increased risk of precipitating mania.[62] Based on the metabolism of trazodone, significant hepatic disease and renal disease are also relative contraindications.

Mirtazapine

Overview. Mirtazapine is FDA approved for the treatment of major depression in dosages of 7.5 to 45 mg. The dosages generally used to treat insomnia are 7.5 to 30 mg. The sedating effects of mirtazapine may diminish in dosages larger than 30 mg because of increasing adrenergic effects.[69] The antidepressant, sleep-enhancing, and adverse effects of this agent derive from antagonism of adrenergic ($alpha_1$ and $alpha_2$), serotoninergic ($5\text{-}HT_2$ and $5\text{-}HT_3$), and histaminergic (H_1) receptors.[70] Interactions with mirtazapine can occur through effects on liver cytochrome P450 enzymes CYP2D6, CYP3A4, and CYP1A2.[3] The T_{max} of this agent is 0.25 to 2 hours, and the $T_{1/2}$ is 20 to 40 hours.[3]

Evidence of Efficacy. Mirtazapine has not been evaluated in placebo-controlled trials in insomnia patients. Evidence for effects enhancing sleep onset and sleep maintenance comes from open-label studies of depressed patients and normal sleepers and one double-blind, randomized study comparing the sleep effects of this agent versus fluoxetine.[71-73] However, the *S*-isomer of mirtazapine (*S*-mirtazapine), which has pharmacokinetics comparable to the racemate and like doxepin 3 to 6 mg has a predominant effect of selective H_1 antagonism in the dosages studied, has been evaluated in four placebo-controlled trials in primary insomnia patients. These studies indicate a consistent therapeutic effect on sleep maintenance, with a tendency to improve sleep onset as well, although the onset effect is not as large or consistent and is dose dependent, as are the risks of daytime sedation.[74-77]

Profile of Adverse Effects. The predominant side effects of mirtazapine are increased appetite and weight gain, dry mouth, and constipation.[69] Consistent with the sleep-enhancing effects of this agent, sedation is also a common adverse effect of treatment. Mirtazapine is not associated with significant abuse potential or cardiac or sexual adverse effects.

Potential Clinical Utility. Because of the antidepressant effects of mirtazapine, it is particularly well suited for use in patients with insomnia occurring with major depression. A study suggesting that mirtazapine may decrease the apnea-hypopnea index in those with significant sleep disordered breathing raises the possibility that this agent should be considered in individuals who have insomnia comorbid with sleep disordered breathing.[74] The lack of abuse potential of mirtazapine also suggests its potential use in those with insomnia who are

at risk for substance abuse, although there are no studies of the use of mirtazapine in this population.

Mirtazapine has few relative contraindications. Like other antidepressants, it should be used with caution in those with bipolar disorder because of the risk of precipitating mania.[62] It should also be used with caution in those with obesity, hepatic disease, and renal disease.

HYPOCRETIN/OREXIN ANTAGONISTS

Overview. Orexin A and B (also known as hypocretin A and B) are peptides released by neurons of the lateral hypothalamus that play an important role in mediating wakefulness and arousal.[78] Loss of the neurons releasing orexin is associated with narcolepsy.[78] Because orexin is thought to play an important role in mediating wakefulness, blockade of orexin receptors is expected to enhance sleep and is a mechanism of interest for developing treatments for patients with insomnia. One agent that blocks the receptors for both orexin A and B (as a result, it is referred to as a dual orexin receptor antagonist) is FDA approved for the treatment in dosages from 10 to 20 mg. The T_{max} of suvorexant is 3 hours, and the terminal $T_{1/2}$ is 9 to 13 hours.[79] The primary metabolism of suvorexant occurs through CYP3A and to a lesser degree CYP2C19.

Evidence of Efficacy. Suvorexant has been evaluated in four placebo-controlled trials in insomnia patients, which indicate that this agent has statistically significant dose-dependent therapeutic effects on both sleep onset and maintenance in the range from 10 to 40 mg.[78,80,81] Among these is a study that is unique among insomnia agents, which consisted of a 1-year, placebo-controlled trial of suvorexant 30 to 40 mg followed by a double-blind, randomized, placebo-controlled discontinuation phase.[80] This study demonstrated sustained efficacy over the entire year of dosing. After discontinuation, there was no evidence for an increase in adverse events. Among subjects receiving suvorexant, those continued on suvorexant maintained improvement compared with placebo subjects, whereas those switched to placebo were comparable to those who had been taking placebo throughout the double-blind and discontinuation phases. No statistically significant evidence for rebound insomnia was found after discontinuation of suvorexant, although the proportion of patients who met rebound insomnia criteria was numerically greater in subjects switched from suvorexant to placebo compared with the subjects who stayed on placebo throughout the study. Notably, like doxepin 3 to 6 mg, suvorexant has a therapeutic effect even in the last third of the night. However, unlike with doxepin, there is also evidence for a consistent effect on sleep onset.

Profile of Adverse Effects. The most important side effect of suvorexant is daytime sleepiness and drowsiness. Patients should be cautioned about potential driving impairment with this agent. This agent appears to have no significant risks of weight gain or cardiac or sexual side effects. The use of this agent is contraindicated in those with narcolepsy on the basis of its mechanism of action and the evidence that loss of orexin neurons is associated with this disorder. There is no evidence of dependence occurring during 1 year of regular use.[80] The abuse potential of suvorexant is believed to be comparable to that of zolpidem. One study examined the use of suvorexant 30 to 40 mg in patients with mild to moderate chronic obstructive pulmonary disease and did not find evidence for a respiratory depressant effect in this high-risk population.[82]

Potential Clinical Utility. Suvorexant has therapeutic effects throughout every portion of the night without substantively increasing the risk of morning sedation compared with other agents. This agent shares with doxepin 3 to 6 mg the distinction of being able to improve sleep in the last third of the night at modest or no cost of morning sedation. However, suvorexant, unlike doxepin, also has a consistent sleep-onset effect. As a result, this agent may be particularly well suited for treating patients with early morning awakening who also have difficulty falling asleep. The study in patients with chronic obstructive pulmonary disease also suggests that suvorexant might be particularly useful in this poplation.[82] Suvorexant is also the only drug for which we have systematic, randomized discontinuation data after a year of nightly use.[80] These data support the efficacy and safety of using this agent in those in whom long-term therapy may be needed. Further refinement of the role of suvorexant in insomnia pharmacotherapy will follow more widespread clinical use.

ANTIPSYCHOTICS

Overview. Antipsychotic agents are sometimes used to treat insomnia in clinical practice.[3] In general, these agents are used in dosages that are lower than typically used in their FDA-approved indications, which include the treatment of psychotic disorders (including schizophrenia and schizoaffective disorder), mania, and, in some cases, bipolar and unipolar major depression. The antipsychotic agents most commonly used to treat insomnia include quetiapine and olanzapine.[45,83] When it is used to treat insomnia, quetiapine is generally dosed from 25 to 250 mg; olanzapine is typically administered at a dosage of 2.5 to 20 mg. The primary effects of these agents are antagonism of the following receptors: dopamine, histamine (H_1), serotonin, muscarinic cholinergic, and adrenergic ($alpha_1$).[3] Olanzapine has a T_{max} of 4 to 6 hours and $T_{1/2}$ of 20 to 54 hours, which makes it relatively unlikely to be effective for sleep-onset difficulty when it is taken near bedtime. However, it is likely to have a prolonged sleep-enhancing effect.[3] Olanzapine elimination may be affected by factors that alter the liver enzymes CYP1A2 and CYP2D6. This means that there is slower elimination among females, tobacco smokers, and individuals of Japanese descent. Quetiapine, with a T_{max} of 1 to 2 hours and a $T_{1/2}$ of approximately 7 hours, has the potential to improve sleep onset as well as sleep maintenance on the basis of pharmacokinetics. The metabolism of quetiapine may be affected by factors that alter the CYP3A4 and CYP2D6 liver enzymes.[3]

Evidence of Efficacy. There are no placebo-controlled trials of any antipsychotic agent for the treatment of primary insomnia patients.[3] However, quetiapine 25 to 75 mg improved self-reported and polysomnographic indices of sleep in an open-label study in primary insomnia patients.[84] Both quetiapine and olanzapine have been found to improve sleep in small studies of normal sleepers.[83] These agents have also been found to improve sleep in open-label and placebo-controlled

studies in patients with schizophrenia, mania, bipolar depression, and unipolar depression.[83,85,86]

Profile of Adverse Effects. The primary side effects of the antipsychotic agents used to treat insomnia include orthostatic hypotension, dizziness, dry mouth, constipation, blurred vision, urinary retention, increased appetite, weight gain, and sedation.[82] Because antipsychotics antagonize dopamine receptors, they may lead to extrapyramidal side effects, such as parkinsonism, acute dystonic reactions, akathisia, and tardive dyskinesia.[84] However, these side effects are relatively uncommon in the newer generation antipsychotic agents, which includes those most commonly used to treat insomnia. Olanzapine has also been associated with cognitive impairment, glucose intolerance, and an elevated risk of mortality among patients with dementia.[87] Antipsychotic agents do not have significant abuse potential.

Potential Clinical Utility. Antipsychotic agents are best suited for use in the treatment of insomnia occurring in individuals with psychosis or bipolar disorder. Quetiapine is also FDA approved for use in the treatment of bipolar and unipolar major depression, suggesting its potential use for the treatment of insomnia occurring in patients with these disorders. Given the lack of abuse potential, antipsychotics have potential for use in patients with insomnia and substance abuse.

Because of their adverse effect profiles, antipsychotic agents commonly used to treat insomnia should be used with caution in those with a history of myocardial infarction, ischemia, or conduction abnormalities; closed-angle glaucoma; decreased gastrointestinal motility; urinary retention; or hypotension. These agents should also be used with caution in those with hepatic disease or when weight gain would be of significant concern. Olanzapine is also relatively contraindicated in those with dementia because of a reported increase in risk of mortality in this population.[87]

ANTICONVULSANTS

Gabapentin and Pregabalin

Overview. Gabapentin and pregabalin are structural analogues of GABA but are thought to exert their primary central nervous system effects by binding to the alpha$_2$-delta subunit of N-type voltage-gated calcium channels, thereby diminishing the release of glutamate and norepinephrine.[88,89] Gabapentin and pregabalin are approved by the FDA with indicated use in the treatment of partial seizures and pain. Pregabalin is also indicated for the treatment of fibromyalgia. These agents are also used to treat insomnia, periodic limb movement disorder, restless legs syndrome, and bipolar disorder. Gabapentin has a T_{max} of 3 to 3.5 hours and a $T_{1/2}$ of 5 to 9 hours and is generally used at a dosage of 100 to 900 mg for insomnia therapy. Because of the relatively slow absorption, gabapentin is relatively less likely than other agents to improve sleep onset when it is dosed at bedtime. Pregabalin is more rapidly absorbed with a T_{max} of 1 hour and $T_{1/2}$ of 4.5 to 7 hours. Both agents are eliminated by renal excretion, so factors that affect renal function can affect the elimination of these agents.[88,89]

Evidence of Efficacy. Whereas neither of these agents has been evaluated in a placebo-controlled trial of the treatment of primary insomnia, evidence of a sleep-enhancing effect has been noted in studies of the treatment of normal sleepers, pain patients, patients with restless legs syndrome, patients with generalized anxiety disorder, and epilepsy patients.[90-94] Gabapentin also improved sleep in a small placebo-controlled trial of the treatment of insomnia occurring in alcohol-dependent individuals.[95] A small open-label pilot study also suggests that gabapentin may have utility in treating alcohol withdrawal.[96]

Profile of Adverse Effects. The most common adverse effects of gabapentin are sedation, dizziness, ataxia, and diplopia. The most common side effects of pregabalin include sedation, dizziness, dry mouth, cognitive impairment, and increased appetite. Rarely, leukopenia has been noted with these agents. Gabapentin appears to have minimal abuse potential; however, abuse potential may be a consideration with pregabalin.[97]

Potential Clinical Utility. Gabapentin and pregabalin should be considered for treatment of insomnia occurring in patients with pain or partial seizures because of their efficacy in the treatment of those conditions. Pregabalin, an FDA-approved treatment for fibromyalgia, should be considered in treatment of patients with insomnia occurring with fibromyalgia. Both agents may be useful in treating patients with insomnia occurring with restless legs syndrome or periodic leg movement disorder. On the basis of the two small studies, gabapentin has potential utility in treating insomnia occurring in alcohol-dependent individuals and those undergoing alcohol withdrawal. Given this potential and the absence of abuse liability, gabapentin may also be useful in the treatment of the insomnia that frequently occurs in abstinent alcoholics.

Because both of these agents are renally eliminated, they should be used with caution in individuals with renal impairment or when there is any factor that impedes renal function. Caution should also be used in prescribing pregabalin to abuse-prone individuals.

Tiagabine

Overview. Tiagabine is a GABA reuptake inhibitor that is FDA approved for the treatment of partial seizures. It has been evaluated for the treatment of insomnia at dosages from 2 to 16 mg.[98,99] Tiagabine has a T_{max} of 1 to 1.5 hours and a $T_{1/2}$ of approximately 8 hours. It is primarily metabolized by the liver CYP3A4 isoenzyme, and as a result, factors that affect that enzyme can affect the elimination of tiagabine.

Evidence of Efficacy. Tiagabine has been evaluated in four placebo-controlled trials of the treatment of primary insomnia in adults and the elderly.[98-101] Whereas this agent reliably increases slow wave sleep in a dose-dependent manner, it does not improve sleep onset and has not consistently improved measures of sleep maintenance compared with placebo.

Profile of Adverse Effects. The most frequent side effects of tiagabine in placebo-controlled trials were sedation, dizziness, and nausea. There is also a small risk of precipitating seizures.

Potential Clinical Utility. The use of tiagabine could be considered in those patients requiring treatment for partial seizures who have accompanying insomnia. Tiagabine should be used with caution in those with significant hepatic disease.

ANTIHISTAMINES

The designation of an agent as an antihistamine generally indicates that the agent was developed or marketed with the treatment of allergies as its primary intended use. However, many other agents that are potent antagonists of the H_1 histamine receptor but were developed for the treatment of other conditions are not generally referred to as antihistamines. This includes the antidepressants doxepin and mirtazapine, which have more selective H_1 antagonist effects than any agents designated as antihistamines, as well as antipsychotics including olanzapine and quetiapine.[3] Agents designated as antihistamines that cross the blood-brain barrier include diphenhydramine, doxylamine, chlorpheniramine, and hydroxyzine. Of these, the agents most commonly used to treat insomnia are diphenhydramine and doxylamine, constituents of nearly all over-the-counter insomnia medications.

Diphenhydramine

Overview. Diphenhydramine is generally dosed at 25 to 50 mg for the treatment of insomnia. H_1 antagonism is its greatest effect; muscarinic cholinergic antagonism is the next most important effect of diphenhydramine.[102] This agent has a T_{max} of 2 to 2.5 hours and a $T_{1/2}$ of 5 to 11 hours.[3] The elimination of diphenhydramine primarily involves the CYP2D6, CYP1A2, CYP2C9, and CYP2C19 liver P450 isoenzymes.[3]

Evidence of Efficacy. Sleep-enhancing effects of diphenhydramine have been observed in placebo-controlled trials of sleep disturbance in a mixed group of psychiatric patients, outpatients in a primary care practice, nursing home residents, and primary insomnia patients.[102-107] Of note, the effects appear to be more consistent on sleep maintenance than on sleep onset. Whereas this may, at least in part, reflect the T_{max} of 2 hours, a greater effect on the maintenance of sleep than on sleep initiation was also noted with doxepin in low dose, at which it is a highly selective H_1 antagonist. In a study examining the sedating effects associated with daytime dosing of diphenhydramine, a sedating effect on the first day of treatment was no longer present on the fourth day of treatment.[108]

Profile of Adverse Effects. The most important adverse effects of diphenhydramine include sedation, dizziness, psychomotor impairment, cognitive impairment, dry mouth, blurred vision, constipation, urinary retention, and weight gain. Less commonly, diphenhydramine is associated with agitation and insomnia. Diphenhydramine does not have substantial abuse potential.

Potential Clinical Utility. The most promising use of diphenhydramine would be expected to be in the treatment of individuals with sleep difficulty occurring in conjunction with allergy symptoms or upper respiratory infections. The only data relevant to this potential use are from a study of 100 children with nocturnal cough in which diphenhydramine did not improve sleep compared with placebo according to parental reports.[109]

The primary relative contraindications to diphenhydramine use are closed-angle glaucoma, decreased gastrointestinal motility, urinary retention, asthma, chronic obstructive pulmonary disease, and severe liver disease.

Doxylamine

Overview. The characteristics of doxylamine are similar to those of diphenhydramine. It is generally used for insomnia in the same dosage range (25 to 50 mg) and also has a $T_{1/2}$ of 10 to 12 hours. Doxylamine has a slightly faster absorption with a T_{max} of 1.5 to 2.5 hours.[3] The primary elimination of doxylamine occurs through the CYP2D6, CYP1A2, and CYP2C9 liver isoenzymes.

Evidence of Efficacy. No clinical trials of insomnia treatment with doxylamine have been reported. However, one double-blind placebo-controlled trial demonstrated a significant therapeutic effect on self-reported sleep with doxylamine 25 mg in 2931 postoperative patients.[110]

Profile of Adverse Effects. The adverse effects profile of doxylamine is essentially the same as that of diphenhydramine, with the exception of case reports that coma and rhabdomyolysis can occasionally occur with the use of doxylamine.[111]

Potential Clinical Utility. The most promising clinical use of doxylamine is as a treatment of insomnia in those with associated allergy symptoms or upper respiratory infections. Relative contraindications to the use of doxylamine are the same as with diphenhydramine: closed-angle glaucoma, decreased gastrointestinal motility, urinary retention, asthma, chronic obstructive pulmonary disease, and severe liver disease.

CHLORAL HYDRATE

Overview. Chloral hydrate is thought to exert its effect through its metabolite trichloroethanol, which modulates $GABA_A$ receptors in a manner similar to the barbiturates.[112] The T_{max} of the active metabolite of chloral hydrate is approximately 30 minutes, and the $T_{1/2}$ is 7 to 10 hours. The dosage range for the treatment of insomnia is 250 mg to 2 g. Trichloroethanol undergoes hepatic conjugation with subsequent renal elimination.

Evidence of Efficacy. Chloral hydrate has been studied in placebo-controlled trials in elderly insomnia patients and mildly demented older adults.[113,114] A significant advantage over placebo was found only in the trial carried out in the mildly demented patients.[114]

Profile of Adverse Effects. The primary adverse effects of chloral hydrate include sedation, nausea, diarrhea, psychomotor impairment, and parasomnias.[112] There is significant abuse and dependence potential with this agent.[112] Hepatic and renal damage can also occur with chloral hydrate treatment. There is also a significant risk of death with overdoses of chloral hydrate.[112]

Potential Clinical Utility. Given the potential for serious adverse effects with this agent and that there are no conditions for which it has unique efficacy, it has been reasonably argued that this agent should not be used for the treatment of insomnia.[101] Whereas chloral hydrate is not recommended for insomnia therapy, there are some conditions for which its use is of special concern. This includes those at risk for suicide, neonates, substance abuse–prone individuals, those with

gastritis, patients with intermittent porphyria, and those with hepatic or renal failure.

SODIUM OXYBATE

Overview. Sodium oxybate is indicated by the FDA for the treatment of cataplexy and daytime sleepiness in those with narcolepsy. The mechanisms of action of this agent are unknown. It is dosed in the range of 2.5 to 4 g. The T_{max} is 0.5 to 0.8 hours and the $T_{1/2}$ is 0.3 to 1.2 hours.[51] Because the half-life is so short, it is dosed both at bedtime and again in the middle of the night. The metabolism of sodium oxybate is incompletely understood; however, enzymatic breakdown appears to be the most important element, involving a cytosolic enzyme gamma-hydroxybutyrate dehydrogenase and a mitochondrial transhydrogenase.

Evidence of Efficacy. Sleep-promoting effects of sodium oxybate have been demonstrated in terms of both onset and maintenance of sleep in placebo-controlled trials in patients with narcolepsy and fibromyalgia.[114,115] No trials of this agent have been carried out in any other groups of insomnia patients.

Profile of Adverse Effects. The primary adverse effects of sodium oxybate are headache, nausea and vomiting, excess salivation, parasomnias, and amnesia. Sodium oxybate has significant abuse and dependence potential. It can lead to coma and delirium in overdose.[51]

Potential Clinical Utility. Sodium oxybate should be considered a potential therapy for the treatment of sleep disturbance in narcolepsy patients and in those with fibromyalgia. Because of the side effect profile of sodium oxybate, it is relatively contraindicated in individuals vulnerable to respiratory depression, those with sleep disordered breathing, patients with chronic obstructive pulmonary disease, and those at risk for substance abuse.[51]

HERBALS

The use of plants for medicinal purposes dates back to antiquity. In the United States, herbals that are not claimed to treat a disorder are regulated differently from drugs. Such herbals are regulated by the Dietary Supplement Health and Education Act of 1994 and not according to the procedures the U.S. FDA employs for approving and overseeing prescription medications. Whereas herbal dietary supplements undergo regulation in terms of safety, it is critical to note that manufacturers of herbal remedies are not required to provide data on the safety, efficacy, or purity of their products. As a result, the constituents, effectiveness, and side effect profile of any given product remain uncertain.[116] Further complicating the situation for practitioners and consumers is that for many herbals, the active constituents and their interactions are not fully established. At the same time, as plant derivatives, the constituents of herbal preparations will vary according to the particular species of plant, where and when it was cultivated, and how it was processed.[116] Despite these limitations, herbal medications are frequently used around the world for the treatment of insomnia. Valerian, one of the most common herbal insomnia therapies, is reviewed here. This review is limited by uncertainty as to the identity of the active constituents and the composition of any of the valerian preparations studied.

Valerian

Overview. Valerian is an herbal substance derived from one of the more than 150 plants of the *Valeriana* genus that grow in temperate regions in North America, Europe, and Asia.[116] Of these plants, the most commonly used for medicinal purposes is *Valeriana officinalis L.* It is believed that this substance has been used for therapeutic purposes for more than a thousand years. Because the active ingredients of valerian are unknown, it is not possible to establish its pharmacokinetics or route of metabolism. The dosages of valerian most commonly employed in studies of insomnia treatment are 400 to 900 mg/day.

Evidence of Efficacy. Because of the uncertainty as to the dosing of active ingredients in the preparations of valerian studied, the evidence for efficacy in placebo-controlled studies of insomnia treatment with valerian can be reviewed only in general terms. Whereas a few studies have reported a therapeutic effect on sleep, the majority of placebo-controlled trials of the treatment of insomnia with valerian preparations have failed to find a therapeutic benefit over placebo.[117-120] At this point, it must be concluded that the efficacy of valerian in the treatment of insomnia is unestablished.

Profile of Adverse Effects. Valerian preparations have been associated with few side effects. Most studies have noted comparable rates of adverse effects in valerian- and placebo-treated patients. There is no evidence for significant abuse potential, and daytime sedation appears to be relatively uncommon.

Potential Clinical Utility. Given the uncertainty as to the efficacy of valerian preparations, it makes sense to limit the clinical use of this herbal therapy to individuals who are specifically interested in taking an herbal therapy for their insomnia. Four cases of hepatitis have been reported in individuals taking valerian in combination with skullcap, another herbal therapy.[116] The role of valerian in causing the hepatitis is uncertain; however, it is recommended that caution be used in combining valerian with skullcap and in treating those with liver disease.

SUMMARY OF CLINICAL CIRCUMSTANCES IN WHICH AGENTS OTHER THAN BZRAs MIGHT BE PREFERRED

As discussed, there are a number of circumstances in which the agents reviewed in this chapter might be preferred to BZRAs for the treatment of insomnia. One of these is when patients appear to be nonresponsive to or intolerant of several BZRAs. The other circumstances include the treatment of insomnia in individuals with substance abuse, allergies, psychosis, mania, or hypomania and the treatment of insomnia in individuals with major depression or chronic pain for whom single-agent therapy is desired.

Substance Use Disorders

Unlike the BZRAs, nearly all of the agents discussed in this chapter have minimal abuse potential. As a result, they might

be preferred in the treatment of those with a predisposition to substance abuse or those who are experiencing insomnia in the setting of substance abuse. The exceptions to this are sodium oxybate, chloral hydrate, pregabalin, and suvorexant, which have abuse potential. Among the non-BZRAs without abuse potential, only gabapentin and trazodone have been studied for the treatment of insomnia in substance abuse populations. Gabapentin was found to improve sleep and to have an acceptable safety profile in small studies of alcohol-dependent individuals and those going through alcohol withdrawal. Trazodone was found to be an effective treatment for insomnia in abstinent alcoholics in a placebo-controlled study. The utility of other non-BZRAs in the treatment of insomnia in those with substance use disorders remains to be evaluated.

Allergy-Associated Sleep Disturbance

A number of the non-BZRA agents appear to have sleep-enhancing effects as well as significant antihistaminergic effects (H_1 antagonism). As a result, they might be expected to be particularly useful in the treatment of insomnia occurring in association with allergies. These agents include doxepin, mirtazapine, diphenhydramine, doxylamine, amitriptyline, trimipramine, trazodone, olanzapine, and quetiapine. No placebo-controlled trials of the treatment of insomnia occurring with allergic rhinitis have been carried out.

Insomnia Occurring with Psychosis

Quetiapine and olanzapine are agents with antipsychotic efficacy that have been used to treat insomnia. The sleep-enhancing effects of these agents have been demonstrated in trials in normal sleepers or small open-label studies in those with schizophrenia.[83] Olanzapine and quetiapine should be considered for the treatment of sleep disturbance in individuals with psychosis. No placebo-controlled trials of the treatment of insomnia in patients with psychosis have been carried out.

Insomnia Occurring with Mania or Hypomania

Quetiapine and olanzapine also are indicated for the treatment of mania. These agents would be natural to consider for sleep difficulties in individuals with mania or hypomania, although no systematic trials of their effects specifically on sleep in this setting have been carried out.

Single-Agent Therapy for Insomnia Occurring with Major Depression

Several BZRAs may be effective and safe for the treatment of insomnia occurring with major depression. These studies have evaluated eszopiclone, zolpidem, zolpidem CR, and clonazepam as adjunctive therapy to antidepressant medications.[3] However, in some instances, single-agent therapy that addresses both the depression and the sleep disturbance may be preferred. Such instances include those in which cost or the complexity of the medication regimen is the primary concern. The importance of the complexity of the medication regimen is that it may contribute to nonadherence in some patients, particularly those in whom cognitive function is impaired. In such instances, a single agent that has established antidepressant effects as well as sleep-enhancing effects may be preferred. Of the non-BZRAs discussed in this chapter, a number of agents have demonstrated antidepressant effects and are therefore promising for use in this setting. These include amitriptyline, trimipramine, doxepin, mirtazapine, trazodone, and quetiapine. Of these, only trimipramine and doxepin have demonstrated efficacy in the treatment of insomnia in placebo-controlled trials. Another consideration is that for some agents, the antidepressant dosage is substantially higher than what is typically used to treat insomnia. Such a difference in dosage range precludes their utility for single-agent therapy for insomnia and depression or anxiety. Agents for which the dosing range for depression and insomnia is not substantially different and, as a result, could be considered for this purpose include trimipramine, doxepin, amitriptyline, mirtazapine, and quetiapine.

Single-Agent Therapy for Insomnia Occurring with Chronic Pain

The BZRAs eszopiclone and triazolam have been found to be safe and effective for the treatment of insomnia occurring with chronic pain.[3] However, as with single-agent therapy for insomnia occurring with depression, there may be circumstances in which single-agent therapy for insomnia occurring with chronic pain is desirable. Agents with sleep-enhancing effects that appear to have therapeutic effects on chronic pain include amitriptyline, doxepin, trimipramine, gabapentin, and pregabalin. Whereas none of these medications has been evaluated in controlled trials for the treatment of insomnia occurring with chronic pain, these agents could be considered for use when single-agent therapy for these conditions is indicated.

CLINICAL PEARL

Whereas the empiric support for the efficacy and safety of BZRAs in the treatment of insomnia is generally stronger than for non-BZRAs, there are some clinical circumstances in which non-BZRAs would be preferred to BZRAs, including intolerance of BZRAs, nonresponse to BZRAs, treatment of insomnia occurring with substance use disorders, allergy-associated sleep disturbance, insomnia occurring with psychosis, insomnia occurring with mania or hypomania, insomnia occurring with depression for which single-agent therapy is desired, and insomnia occurring with chronic pain for which single-agent therapy is desired.

SUMMARY

A number of agents other than BZRAs are used in the treatment of insomnia. This includes agents classified as antidepressants, antipsychotics, antihistamines, anticonvulsants, melatonin agonists, and herbals as well as chloral hydrate and sodium oxybate. These agents vary in the extent to which studies have been carried out on their efficacy and safety in the treatment of insomnia. In general, the empiric support for the efficacy and safety of the BZRAs is far greater than for the non-BZRA agents. Exceptions to this include doxepin, trimipramine, melatonin, and ramelteon. Each of the non-BZRA agents has unique properties that should be considered in determining whether they might be of utility for the treatment of a given patient with insomnia. In addition, there are some clinical circumstances in which non-BZRAs would be preferred to BZRAs. Awareness of the characteristics of the non-BZRA agents and of the clinical circumstances in which they might be the preferred pharmacotherapy is important for

optimizing the pharmacotherapy of insomnia in clinical practice.

Neurologic Disorders

Chapter 89

Narcolepsy: Genetics, Immunology, and Pathophysiology

Emmanuel Mignot

Chapter Highlights

- Narcolepsy is a sleep disorder characterized by excessive daytime sleepiness and abnormal transitions to REM sleep.
- When cataplexy is present, the cause is almost always an immune-mediated destruction of the hypocretin-producing (also called orexin) neurons in the hypothalamus, an abnormality that can be documented by measuring cerebrospinal fluid hypocretin-1. This disorder is now called *type 1 narcolepsy* in the new classification of sleep disorders.
- The treatment of narcolepsy typically uses two or three of the following drug classes: antidepressants (for cataplexy, acting on adrenergic and serotoninergic uptake), modafinil or amphetamine-like stimulants (for sleepiness, most likely acting on dopamine), and sodium oxybate (a sedative acting on all symptoms, most likely acting on gamma-aminobutyric acid B receptors).

In the original consensus description, narcolepsy was characterized by "excessive daytime sleepiness associated with cataplexy and other REM sleep phenomena such as sleep paralysis and hypnagogic hallucinations."[1] Cataplexy, the sudden occurrence of muscle weakness in association with laughing, joking, or anger, has long been considered a pathognomonic symptom for the disorder.[2-4] Because cataplexy is generally easy to recognize, a large number of studies have shown that the prevalence of narcolepsy with cataplexy is approximately 0.02% to 0.05%.[5-7] Slowly, a broader definition of narcolepsy has emerged that includes patients with sleepiness and abnormal rapid eye movement (REM) sleep, such as sleep-onset REM periods (SOREMPs) during the Multiple Sleep Latency Test (MSLT), sleep paralysis, or hypnagogic hallucinations ("narcolepsy without cataplexy"). Disturbed nocturnal sleep is less frequently mentioned but is also frequent and disabling.[8]

The definition of narcolepsy has recently been revised owing to rapidly evolving scientific discoveries.[9] In most narcolepsy patients with cataplexy and in a few without cataplexy, a deficiency in the hypocretin neuropeptide system is causal,[10-13] and this entity has been renamed *type 1 narcolepsy*.[9] Further, an increasing number of patients have been recognized in early childhood or close to disease onset, and in these individuals, cataplexy can be atypical, with spontaneous grimaces or jaw opening episodes with tongue thrusting or global hypotonia without any obvious emotional triggers.[14] A tight genetic

Table 89-1 International Classification of Sleep Disorders: Definitions and Pathophysiology

Condition	Diagnostic Criteria*	Pathophysiology
Type 1 narcolepsy	Presence of ≥2 of the following: cataplexy, positive MSLT, and low CSF hypocretin-1	Hypocretin deficiency 98% HLA-DQB1*06:02
Type 2 narcolepsy	Positive MSLT; most often with no or unclear cataplexy	Unknown, heterogenous ~16% Hypocretin deficiency ~40% HLA-DQB1*0602
Secondary narcolepsy	As above, but due to neurologic conditions	With or without hypocretin deficiency; various disorders (see Table 89-3)
Idiopathic hypersomnia	No cataplexy, no SOREMPs during the MSLT	Unknown, likely heterogeneous

*Abnormal Multiple Sleep Latency Test (MSLT): sleep latency ≤8 min, ≥2 sleep-onset REM periods (SOREMPs), including a nocturnal SOREMP. For details, see *International Classification of Sleep Disorders*, third edition.[9]
CSF, Cerebrospinal fluid.

association with the human leukocyte antigen (HLA)-DQB1*06:02 is also found in patients with cataplexy,[15] suggesting an autoimmune mediation of the hypocretin cell loss. In contrast, narcolepsy without cataplexy (type 2) is generally associated with normal cerebrospinal fluid (CSF) hypocretin and may not be HLA positive, suggesting a different etiology. The prevalence of type 2 narcolepsy is unknown[16] because systematic MSLT testing in large portion of the general population would need to be performed, with exclusion of confounding etiologies. Studies have shown several percent of the population have a positive MSLT,[17,18] but only approximately 0.2% may have real narcolepsy,[18] and only 0.02% are diagnosed.[6] As a result, in the most recent revision of the *International Classification of Sleep Disorders*, narcolepsy with and without involvement of hypocretin has been separated (Table 89-1).[9]

Narcolepsy treatments have also rapidly evolved, yet all remain symptomatically based.[19,20] Excessive daytime sleepiness is typically treated by amphetamine-like stimulants or modafinil. These compounds are effective in reducing daytime sleepiness but have little effect on cataplexy and abnormal REM sleep. Conversely, the most commonly used treatments for cataplexy, antidepressant drugs, alleviate cataplexy and other REM sleep abnormalities but have little effect on daytime sleepiness. Gamma-hydroxybutyrate (GHB or sodium oxybate) is effective in alleviating disturbed nocturnal sleep, cataplexy, and to a lesser extent daytime sleepiness. In this chapter, information regarding the pathophysiology and pharmacology of narcolepsy will be reviewed. The clinical, diagnostic, and therapeutic aspects are discussed in Chapter 90.

ANIMAL MODELS OF TYPE 1 NARCOLEPSY

In the past 20 years, narcolepsy research has been facilitated by the existence of a unique animal model, canine narcolepsy. Knecht and colleagues[21] and Mitler and Dement[22] first reported the existence of canine narcolepsy in 1973. Early attempts to establish genetic transmission were unsuccessful, suggesting a nongenetic etiology in most cases of canine narcolepsy. In 1975, two narcoleptic Dobermans were reported in a single litter.[23] Subsequent breeding experiments found autosomal recessive transmission with full penetrance, allowing the establishment of a Doberman Pinscher colony at Stanford University. Familial canine narcolepsy was also

Figure 89-1 Narcoleptic Doberman pinschers during attacks of cataplexy. Note that the eyes are open. Autosomal recessive forms of canine narcolepsy are due to mutations in the hypocretin receptor-2 gene.[28]

reported in Labrador Retrievers and Dachshunds.[23,24] Interestingly, experiments indicate that animals heterozygous for the canine narcolepsy gene have subclinical abnormalities; for example, the administration of drugs that increase cholinergic and reduce monoaminergic transmission (manipulations known to promote REM sleep) has been shown to induce cataplexy at specific developmental times.[25]

The parallel between human type 1 narcolepsy and canine narcolepsy is striking. In MSLT-like procedures, narcoleptic canines have been shown to have short sleep and REM sleep latencies.[19] Twenty-four-hour recording studies show increased sleep fragmentation and proportionally more daytime sleep than in control animals.[26] Finally, as in human narcolepsy, sudden episodes of muscle weakness akin to cataplexy can be observed in association with strong positive emotions, most typically during the presentation of appetizing food or while at play (Figure 89-1). These episodes usually last a few seconds and preferentially affect the hind legs, neck, or face. Cataplexy may also escalate into complete muscle paralysis with abolition of tendon reflexes. During these episodes, the animal is conscious and most often able to visually track nearby movement (see Video 89-1). Polygraphic recording indicates a desynchronized, wakelike electroencephalogram (EEG) pattern at the onset of cataplexy, followed by

increased theta activity and genuine REM sleep in long-lasting episodes.[27]

The cause of autosomal recessive canine narcolepsy was identified in 1999 through positional cloning.[24,28] The pathology was found to be due to mutations in a receptor for the newly identified neuropeptide system hypocretin (hypocretin receptor-2, also known as orexin receptor-2). Three different mutations causing a complete dysfunction of the receptor were identified in Doberman, Labrador, and Dachshund pedigrees.[24,28] Sporadic cases of canine narcolepsy were later shown to be associated with low CSF hypocretin and almost absent brain hypocretin peptide content,[29] as found in human narcolepsy.[11,12]

Several rodent models of narcolepsy are now available. Chemelli and colleagues[30] developed preprohypocretin knockout mice, reporting fragmented sleep, rapid transitions from wakefulness into REM sleep, and a reversible state of paralysis akin to cataplexy.[30] In another model, toxic transgenes are driven by the hypocretin promoter, producing various level of hypocretin-containing cell loss and narcolepsy.[31,32] In this model, cell loss higher than 90% produces a syndrome similar to that of the preprohypocretin knockout mice. A rat model with partial hypocretin cell loss[33] and mice lacking either of the two hypocretin receptors, hypocretin receptor-1 and -2, are now also available.[34-37] In these models, only hypocretin receptor-2 knockout animals experience behavioral arrest episodes similar to cataplexy, although the episodes are few and not as clear as in hypocretin knockout mice.[34] Interestingly, hypocretin receptor-1 knockout animals are almost normal, having only mildly fragmented sleep and REM sleep abnormalities but no behavioral arrests.[35] Dual hypocretin receptor-1 and -2 knockout mice, however, recapitulate the phenotype of hypocretin knockout. Overall, data in mice suggest a role for hypocretin receptor-1 in increasing the severity of the phenotype.[34]

The use of these new rodent models, together with recent developments that make it possible to increase firing rate selectively in hypocretin cells through optogenic stimulation,[38] is revolutionizing research in this area. It is important to keep in mind, however, that humans are more genetically diverse than inbred rodent lines and have distinct ecologic niches, most likely explaining interspecies differences in the regulation and functions of hypocretin.[39] This may explain why hypocretin receptor-2 mutants have more clear cataplexy in dogs versus mice, or why hypocretin receptor-2 mutations causing narcolepsy have not yet been identified in humans (e.g., the phenotype may be too mild to raise concern). Similarly, food deprivation (up to 31 hours) in mice increases wakefulness, most likely because of the acute need to search for food, but this response is severely blunted in mice lacking hypocretin.[40] Yet, metabolically, mice have high metabolic demands and low energy reserves, unlike humans. Further, in contrast to these results, patients with narcolepsy/hypocretin frequently use food restriction to stay awake and have binge eating abnormalities, especially at night.[41-43] Similarly, we found that the small decrease in food intake found in rodents with hypocretin deficiency could largely be explained by wake fragmentation in these models.[33] Finally, as discussed later, pharmacologic responses may vary across species. As an example, the α_2 antagonist yohimbine is a strong wake-promoting compound and anticataplectic agent in canines, yet it has little if any effect in humans.[19]

PHARMACOLOGY OF NARCOLEPSY

Adrenergic Uptake Inhibition Mediates the Anticataplectic Effects of Antidepressants

In the past, the most commonly prescribed anticataplectic agents were tricyclic antidepressants, and clomipramine is still widely used as a treatment in some countries. More recently, more selective monoaminergic reuptake inhibitors have become available. These compounds have a complex pharmacologic profile that includes monoamine (serotonin, norepinephrine, epinephrine, and dopamine) uptake inhibition and, for older tricyclic antidepressants, cholinergic, histaminic, and α-adrenergic blocking effects.[19,,45] Whereas cataplexy is difficult to quantify in humans (because it is unpredictable) or mouse models (because it is difficult to differentiate from REM sleep or sleep paralysis), this symptom can be easily measured in narcoleptic canines using a simple behavioral tool, the Food Elicited Cataplexy Test. In this test, pieces of dog food are lined up on the floor, and the animal is released in the room.[19] A normal animal will complete the test in less than 10 seconds, whereas narcoleptic dogs, excited by the food, exhibit multiple partial or complete cataplexy attacks that can be recorded in number and duration. This test has been used to pharmacologically dissect the mode of action of currently prescribed anticataplectic agents.[19]

In narcoleptic canines, the therapeutic efficacy of antidepressants is mainly due to inhibition of adrenergic but not dopaminergic or serotonergic uptake.[44,45] This observation fits well with available human pharmacologic data (Table 89-2).[19] Indeed, protriptyline, desipramine, viloxazine, and atomoxetine, four adrenergic-specific uptake blockers with no effect on serotonin transmission, are effective and potent anticataplectic agents (see Table 89-2). In contrast, escitalopram, zimelidine, fluoxetine, and other serotonin-specific reuptake inhibitors suppress cataplexy only at relatively high doses, an effect probably mediated by the weak adrenergic uptake effects of these compounds and their metabolites.[44] Alternatively, it may be that, in humans, blocking the serotonin reuptake site has minor therapeutic effects on cataplexy in contrast to canines because of increased genetic diversity in humans or species differences.

The observation that adrenergic uptake blockers are anticataplectic agents correlates well with the potent inhibitory effects of these compounds on REM sleep. It is well established that adrenergic transmission is reduced during REM sleep, and firing in the locus coeruleus nearly ceases during cataplexy in narcoleptic canines.[46] Adrenergic uptake blockers might thus increase adrenergic tone in projection sites involved in REM sleep regulation. This effect would lessen the effect of decreased locus coeruleus impulse flow normally occurring during natural REM sleep. The fact that serotonergic uptake blockers, also known to have inhibitory effects on REM sleep, have less or no effect on cataplexy is more surprising. Like adrenergic cells of the locus coeruleus, serotonergic cells of the raphe nuclei dramatically decrease their activity during REM sleep. This discrepancy could be explained by a preferential effect of serotonergic projections on REM sleep features other than atonia (e.g., in the control of eye movements). In this model, adrenergic projections may be more important than serotonergic transmission in the regulation of REM sleep atonia and thus cataplexy.[44] In favor of this hypothesis, serotonergic activity decreases moderately during cataplexy

Table 89-2 Commonly Prescribed Treatments and Their Pharmacologic Properties

Compound	Pharmacologic Properties
Stimulants	
Amphetamine	Increases monoamine release (DA > NE ≫ 5-HT); blocks monoamine reuptake and MAO at high doses. The D-isomer is more specific for DA transmission and is a more effective stimulant
Methamphetamine	More lipophilic and potent than amphetamine; increased CNS penetration; proportionally less peripheral side effects
Methylphenidate	Blocks monoamine uptake at lower dose than amphetamine; slightly less effect on monoamine release; short half-life
Pemoline	DA uptake inhibition; low potency; hepatotoxicity
Selegiline (L-deprenyl)	Monoamine oxidase B inhibitor; in vivo conversion into amphetamine
Modafinil	Fewer peripheral side effects. Mode of action is likely DA uptake inhibition. R-modafinil is the major active, long-lasting enantiomer
Anticataplexy Compounds	
Venlafaxine	Specific serotonin and adrenergic reuptake blocker (5-HT = NE); very effective but some nausea
Atomoxetine	Specific NE reuptake blocker; also improves daytime sleepiness
Fluoxetine	Specific 5-HT uptake blocker (5-HT ≫ NE = DA). Active metabolite norfluoxetine has more NE effects. High therapeutic doses are often needed
Protriptyline	Tricyclic antidepressant; monoamine uptake blocker (NE > 5-HT > DA); anticholinergic effects
Imipramine	Tricyclic antidepressant; monoamine uptake blocker (NE = 5-HT > DA); anticholinergic effects Desipramine is an active metabolite
Desipramine	Tricyclic antidepressant; monoamine uptake blocker (NE ≫ 5-HT > DA); anticholinergic effects
Clomipramine	Tricyclic antidepressant; monoamine uptake blocker (5-HT > NE ≫ DA); anticholinergic effects Desmethyl-clomipramine (NE ≫ 5-HT > DA) is an active metabolite. No specificity in vivo

5-HT, Serotonin; CNS, central nervous system; DA, dopamine; MAO, monoamine oxidase; NE, norepinephrine.

in narcoleptic canines,[47] in contrast with locus coeruleus activity.[46]

Increased Dopaminergic Transmission Mediates the Wake-Promoting Effects of Stimulants

Commonly prescribed stimulant compounds include amphetamine-like drugs, such as dextroamphetamine, methamphetamine, methylphenidate, pemoline, and modafinil (see Table 89-2). Like tricyclic antidepressants, amphetamine-like drugs are nonspecific pharmacologically. Their main effect is to globally increase monoaminergic transmission by stimulating monoamine release and blocking monoamine reuptake. Abuse and dose escalation can occur with amphetamines, especially in patients without cataplexy. Less abuse is reported with methylphenidate, and modafinil is not believed to be addictive. Recent studies have shown that the wake-promoting effect of these compounds is secondary to dopamine release and reuptake inhibition.[48,49] The mode of action of modafinil is debated, but this compound also selectively inhibits dopamine uptake.[50,51] All these compounds are ineffective in dopamine transporter knockout mice, suggesting a primary promotion of wake through dopaminergic systems.[49] Interestingly, compounds selective for dopaminergic transmission have no effect on cataplexy, whereas amphetamine-like compounds with combined dopaminergic and adrenergic effects have some anticataplectic properties at high doses.[44,52] Adrenergic effects of amphetamine-like stimulants also correlate with the respective effects of these compounds on normal REM sleep.[19,52] Dopaminergic-specific uptake blockers have little effect on REM sleep compared with adrenergic or serotonergic compounds.[19] The most important effects of dopaminergic uptake blockers are to reduce total sleep time and slow wave sleep.[53] This preferential effect of dopaminergic uptake blockers on non–rapid eye movement (NREM) sleep correlates with electrophysiologic data; as opposed to adrenergic or serotonergic neurons, the firing rate of dopaminergic neurons remains relatively constant during REM sleep.[54,55]

Interestingly, studies in humans and narcoleptic canines have shown that large doses of stimulants are needed to polygraphically "normalize" narcolepsy symptoms. In our narcoleptic Doberman population, doses equivalent to 60 mg/day were needed to reduce daytime sleep to control levels.[26] In both control and narcoleptic animals, however, dose-response curves for modafinil or amphetamine were parallel. This result suggests that there is no difference in sensitivity to stimulants in narcoleptic animals but rather that higher doses are needed in narcoleptic animals because of their extreme baseline sleepiness.[26] However, a recent study has suggested increased wake-promoting effects of modafinil in rodents with hypocretin deficiency.[56]

Sodium Oxybate (Gamma-Hydroxybutyrate)

Sodium oxybate, also called GHB, is a sedative known to increase slow wave sleep and, to a lesser extent, REM sleep.[19] Abuse in the context of rave parties has been reported, and the prescription of the compound is highly regulated, with

distribution centralized by one pharmacy in the United States. Because slow wave sleep is associated with growth hormone release, GHB also induces growth hormone release and has been abused by athletes. When administered at night, it consolidates sleep and improves daytime functioning. Because of its short half-life (approximately 30 minutes),[57] it must be administered twice a night. Interestingly, cataplexy and daytime alertness improve gradually, and sometimes the full therapeutic effect is achieved only after several months of treatment and dose adjustments.[20]

The mode of action of GHB on sleep and narcolepsy is unclear. GHB has a major effect on dopamine transmission, reducing firing rate and raising brain content of dopamine.[19,58,59] Other effects on opioid, glutamatergic, and cholinergic transmission have been reported.[58] Specific GHB receptors have been identified, but the compound is also a gamma-aminobutyric acid B ($GABA_B$) agonist.[58,59] Most studies to date suggest that the sedative hypnotic effect is mediated through $GABA_B$ agonist activity.[58-61] Whether this effect also mediates the anticataplectic effects after long-term administration is unknown.

Other Known Modulators of Narcolepsy Symptoms

The effects of more than 200 compounds with various modes of action have been examined in human patients and narcoleptic canines.[19] In almost all cases except a few, similar effects were found in humans and canines.[19] Almost all the significant effects have been reported for monoaminergic and cholinergic compounds. Because cataplexy is easier to study than sleep in canines, most research in narcoleptic dogs has focused on cataplexy. For cataplexy, the findings were generally consistent with pharmacologic studies of REM sleep. As is the case for REM sleep, the regulation of cataplexy is modulated positively by cholinergic systems and negatively by monoaminergic tone.[19] Muscarinic M_2 or M_3 receptors mediate the cholinergic effects, whereas monoaminergic effects are mostly modulated by postsynaptic α_1-adrenergic receptors and presynaptic D_2/D_3 autoreceptors.[19]

Although the primary cause of narcolepsy is hypocretin deficiency, studies have shown abnormal cholinergic and monoaminergic receptor density and neurotransmitter levels in human or canine narcolepsy brain and CSF samples.[19,62-66] Local injection studies in selected brain areas of narcoleptic canines have also shown functional relevance for some of these abnormalities.[67-69] As a result, cholinergic hypersensitivity, dopaminergic abnormalities, and abnormal histaminergic tone are likely to be critical downstream mediators of hypocretin deficiency in the expression of the narcolepsy symptoms.[63,66-69] The cholinergic-monoaminergic imbalances observed in narcolepsy are best illustrated by the finding that in asymptomatic animals heterozygous for the hypocretin receptor-2 mutation, a combination of cholinergic agonists with an α_1 blocker or a D_2/D_3 agonist can trigger cataplexy.[25] Further, recent results suggest an increased number of histaminergic cells in the brains of narcolepsy patients[64,65] and rescue of sleepiness in hypocretin receptor-2 mutant animals by expression of the receptor in the posterior hypothalamus.[37] A possible application of these findings is illustrated by the recent development of histamine-3 (H_3) antagonists, drugs that are known to stimulate histamine release through the H_3 receptor, as novel wake-promoting stimulants for the treatment of narcolepsy.[70,71]

HYPOCRETIN INVOLVEMENT IN NARCOLEPSY

Anatomy and Physiology of the Hypocretin (Orexin) Neuropeptide System

The hypocretin-orexin system was discovered almost simultaneously by two groups of scientists, hence the two conflicting names. De Lecea and colleagues first isolated the preprohypocretin transcript and suggested the existence of two resulting processed neuropeptides sharing extensive homology with each other and weak homology with secretin.[72] These neuropeptides were called *hypocretin 1* and *hypocretin 2*, to indicate *hypo*thalamic peptides of the in*cretin* family. Meanwhile, using cell lines expressing various orphan G-protein-coupled receptors (GPCRs), Sakurai and colleagues screened tissue extracts for GPCR agonist activity.[73] Two mature peptides were isolated and called orexin-A and orexin-B.[74] The name was chosen from Greek *orexis* (for "appetite") based on associated studies suggesting stimulation of appetite after central administration. Sakurai and colleagues[74] also identified a second receptor with high homology. The two G-protein-coupled receptors were initially called orexin receptor-1 and orexin receptor-2,[74] but their official names are hypocretin receptor-1 and hypocretin receptor-2 in genetic databases. Hypocretin receptor-1 binds hypocretin-1 (OxA) selectively, whereas hypocretin receptor-2 (OxR2) binds both hypocretin-1 (OxA) and hypocretin-2 (OxB) with similar affinity.[73] The two receptors mostly couple with Gq and stimulate cellular activity in most cell types.[24,75,76]

Only a few thousand cell bodies containing these two peptides are found in the entire brain, all within the perifornical area of the posterior hypothalamus. Contrasting with this discrete perikaria localization, the neurons project widely in the central nervous system.[24,75,76] Limbic system areas (including amygdala and nucleus accumbens), monoaminergic cell groups (adrenergic locus coeruleus), serotoninergic raphe nuclei, dopaminergic ventral tegmental area and substantia nigra, histaminergic tuberomammillary nuclei, other hypothalmic nuclei, and various periventricular organs are densely innervated.[24,75,76] Hypocretin immunoreactive varicose terminals are also seen in the cerebral cortex, spinal cord, and thalamus. The strongest extrahypothalamic hypocretin projection is found in the locus coeruleus. Hypocretin has also been suggested to be present in selected peripheral tissue (testis, gut) at very low levels of expression.

Hypocretin (Orexin) Deficiency and Type 1 Narcolepsy

As expected from the observation that most cases of human narcolepsy are sporadic and not fully genetic as in dogs or mice, extensive genetic screening studies did not identify preprohypocretin or hypocretin receptor mutations in human narcolepsy.[11,24,77] Surprisingly, even familial cases of narcolepsy (some of which were HLA-DQB1*06:02 negative) did not have any hypocretin mutations, suggesting further heterogeneity in genetic cases.[11] Rather, only one person with a signal peptide mutation of the preprohypocretin gene has been identified. This individual had an extremely early onset (6 months), severe narcolepsy-cataplexy, DQB1*06:02 negativity, and undetectable hypocretin-1 CSF levels.[78] This important observation indicates that hypocretin system gene mutations can cause narcolepsy like in animal models.

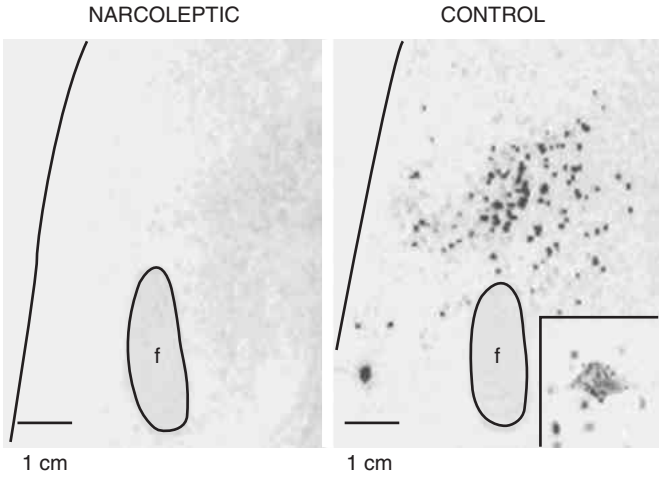

Figure 89-2 Hypocretin in the hypothalamus of control and narcoleptic subjects. Preprohypocretin messenger RNA molecules are detected in the hypothalamus of a control (*right*) but not a patient with narcolepsy (*left*). *Insert* shows exemplar high magnification of a preprohypocretin-positive neuron. f, Fornix, 3rd V, third ventricle. (Modified from Peyron C, Faraco J, Rogers W, et al. A mutation in a case of early onset narcolepsy and a generalized absence of hypocretin peptides in human narcoleptic brains. *Nat Med* 2000;6[9]:991–7.)

Following on the cloning of the canine narcolepsy gene, we have also found that most sporadic, HLA-DQB1*06:02-positive narcolepsy patients with cataplexy have undetectable or low (≤110 pg/m) hypocretin-1 immunoreactivity in CSF.[10,79-83] Subsequent neuropathologic studies in 10 narcolepsy patients also indicated dramatic loss of hypocretin-1, hypocretin-2, and preprohypocretin messenger RNA (mRNA) in the brain and hypothalami of narcolepsy patients (Figure 89-2).[11,12] As mentioned earlier, these subjects have no hypocretin gene mutations and a peripubertal or postpubertal disease onset[84] as opposed to a 6-month onset in the subject with a preprohypocretin mutation.[11] Together with the tight HLA association,[85-87] a likely pathophysiologic mechanism in most narcolepsy patients could thus involve an autoimmune injury to hypocretin containing neurons in the central nervous system.

Hypocretin (Orexin) Transmission in Sleep Regulation

Since the discovery of the hypocretins, much has been learned about how they regulate sleep. Central (intracerebroventricular or local injections) but not peripheral administration of hypocretin-1 stimulates wakefulness and reduces REM sleep. Hypocretin antagonists are NREM and REM sleep promoting, including in humans.[88,89] In rats and monkeys, cisternal CSF hypocretin-1 fluctuates, with maximal levels at the end of the active period (night in rodents) and minimal levels at the end of the inactive period (amplitude is about 40% of the maximum).[90-92] Using in vivo dialysis, a similar profile is observed in rat brain tissue extracellular fluid.[90] In diurnal, wake-consolidated squirrel monkeys, cisternal hypocretin-1 levels also peak in the late evening, around bedtime (amplitude about 40%).[92] These results suggest that hypocretin may be important to promote wakefulness in the evening (in humans). In this model, hypocretin would oppose the sleep pressure that has accumulated since early morning, allowing a constant level of wakefulness through the day.[92] Additional studies suggest that diurnal fluctuations in hypocretin release are driven both directly by the circadian clock and indirectly by the increased sleep pressure.[39] It is also still unclear how hypocretin release and activity fluctuate across the various sleep stages (REM vs. NREM sleep). Of note, lumbar CSF hypocretin-1 only has limited diurnal fluctuation (10%), suggesting a dampening and delay of changes when reaching the lumbar sac (minimal levels in morning).[93] This finding is of practical importance because time of CSF collection has no significant effect for narcolepsy diagnostic purposes.[13,94]

The most dense reported hypocretin projections are to the monoaminergic cell groups of the locus coeruleus (norepinephrine), substantia nigra and ventral tegmental area (dopamine), raphe magnus (serotonin), and tuberomammillary (histamine) neurons. Dopamine and histamine cell groups have a very high hypocretin receptor-2 density[95] and may be especially important.[24,75,76,96] Increased dopamine level in the amygdala is one of the most consistent neurochemical abnormalities reported in canine narcolepsy.[62,66] Decreased histamine levels are also observed in the brain of narcoleptic canines,[97] although in humans, increased numbers of histidine decarboxylase–positive cells have been reported,[64,65] with decreased levels in the CSF.[98-100] In vivo dialysis studies have indicated a critical role for the dopamine mesolimbic and mesocortical system in the regulation of alertness and the triggering of cataplexy by emotions. Histaminergic transmission has long been recognized as a critical wake-promoting neurotransmitter.[101] Dopamine and histaminergic projections may thus be centrally involved in controlling both cataplexy and alertness.[37] Similar to REM sleep, cataplexy is controlled by pontine cholinergic REM-on cells and aminergic locus coeruleus REM-off cells.[19] Loss of excitatory hypocretin projections to monoamine cell groups could decrease monoaminergic tone and produce a cholinergic-aminergic imbalance, resulting in the sleepiness and abnormal REM sleep of narcolepsy. Hypocretin projections to the basal forebrain area, an area with cholinergic hypersensitivity in narcoleptic animals, are also likely to be involved.[19] It is also likely that hypocretin helps integrate sleep regulation with metabolic status, although the importance of this effect could be species dependent.

GENETIC EPIDEMIOLOGY OF HUMAN NARCOLEPSY

Familial Aspects of Human Narcolepsy

Westphal[102] was the first to report familial occurrence of narcolepsy-cataplexy in 1877. In recent studies, the risk for a first-degree relative to develop narcolepsy-cataplexy has been shown to be 1% to 2%.[5] A larger portion of relatives (4% to 5%) may have isolated daytime sleepiness, when other causes of daytime sleepiness have been excluded.[5] These figures are important to keep in mind because they are helpful in reassuring patients regarding the risk to their children and relatives. A 1% to 2% risk is 10- to 40-fold higher than in the general population but remains manageable. A 4% to 5% risk for daytime sleepiness is not negligible, but similar values have been reported for excessive daytime sleepiness in the general population independent of narcolepsy.[103-105]

Twin Studies and Environmental Factors in Narcolepsy

Approximately 25 reports of monozygotic twins with narcolepsy are available in the literature.[5] Seven to nine are

concordant for narcolepsy, depending how strictly concordance is determined clinically.[5,106-108] This low concordance thus suggests that narcolepsy requires the influence of stochastic and environmental factors for the pathology to develop. This is also substantiated by the fact that onset is not at birth but rather in adolescence,[84,109] suggesting the existence of triggering factors.

Upper Airway Infections such as Pandemic H1N1 2009 as Triggers of Narcolepsy

Upper airway infections such as influenza and *Streptococcus pyogenes* are now known to be triggers of narcolepsy onset, at least in children. In the past, head trauma,[110-112] sudden change in sleep-wake habits,[113] or various infections[114,115] were often cited. Starting in the 2000s, increased recognition of younger children seen closer to onset led to the realization that narcolepsy often followed strep throat and that recent-onset subjects were often positive for antistreptolysin-*O*, a marker of streptococcus pyogenes.[116] Epidemiologic studies also indicated a link.[7] Han and associates studying onset in more than 1000 Chinese patients found strong annual fluctuations of onset of narcolepsy in children, with onsets six times more frequent in spring and summer than in winter (Figure 89-3), suggesting that winter infections may trigger a process that over a few months results in hypocretin cell loss.[117]

In the spring of 2010, a number of events converged to indicate that the 2009 H1N1 pandemic influenza significantly triggered the onset of narcolepsy in young children (see Figure 89-3). To review the background: In the spring of 2009, a new strain of influenza A (H1N1), likely of swine origin, appeared in Mexico, spreading rapidly in humans and affecting young adults with a high reported case fatality rate of 0.4%.[118] This caused alarm, as with such a high mortality rate, millions of death were likely worldwide when the new virus would hit the world population the following winter. Faced with such a threat, the World Health Organization (WHO) and other organizations encouraged vaccine makers to initiate large-scale production of vaccines targeting the new strain, which had not been included in the 2009–2010 regular trivalent seasonal flu vaccine.[119] To generate these vaccines, almost all manufacturers used a A/California/7/2009 (H1N1)-pdm09-like reassortant virus containing hemagglutinin HA type 1, neuraminidase NA type 1 (thus H1N1), and polymerase basic 1 (PB1) proteins from A/California/7/2009, on a backbone H1N1 virus PR8, derived from an older, A/Puerto Rico/8/1934, H1N1 virus.[120,121]

As predicted, pandemic 2009 H1N1 spread rapidly and became the dominant influenza strain the following winter. Fortunately, however, mortality was not as high as anticipated, ranging closer to that of a regular seasonal flu.[122] Soon after, in the spring of 2010, we noted that a much higher number of children with recent-onset narcolepsy were referred to Stanford compared with prior years.[123] Further, in China the number of children with new-onset narcolepsy increased threefold to fivefold over prior years in the spring and summer of 2010 (see Figure 89-3, *B*), peaking 4 to 6 months after the peak in H1N1 infections.[117,124]

In parallel with this and perhaps most strikingly, in both Finland[125,126] and Sweden[127] cases of childhood-onset narcolepsy were reported a few months after vaccination with a particular pH1N1 vaccine formulation called Pandemrix, documenting about a 10-fold increased risk for developing narcolepsy after vaccination.[123] Other studies confirmed that this particular vaccine had similar effects in Norway,[128] England,[129] France,[130] and Ireland,[131] although it is important to realize that only approximately 1 in 15,000 children vaccinated with Pandemrix developed narcolepsy (including DQ0602 siblings and in at least one case a discordant twin). Interestingly, however, it is unclear whether other pH1N1 vaccines increase the predisposition to narcolepsy.

Pandemrix is a unique vaccine, manufactured by GlaxoSmithKline using a manufacturing process to isolate surface antigens (typically purifying mostly the HA protein, which is dosed at 3.75 mcg in this vaccine).[120,121,132] In addition, a specific adjuvant, AS03A, a mix of squalene, DL-α-tocopherol, and polysorbate 80, was added. The AS03A adjuvant is potent at stimulating $CD4^+$ T-cell responses,[134] and it is clear that vaccine efficacy was high; one injection was sufficient to obtain high coverage as measured by the hemagglutinin inhibition assay (an assay measuring antibodies targeting the HA protein).[120,121]

Other H1N1 vaccines were manufactured using different protocols to isolate surface antigens or different adjuvants. Arepanrix, a vaccine also produced by GlaxoSmithKline is identical to Pandemrix, except that it was made at a different site using a slightly different process for isolating surface antigens (the Flulaval process).[121,132,133] Focetria, a Novartis vaccine, is another vaccine relatively similar to Pandemrix. It uses a MF59 adjuvant, containing squalene and 7.5 μg of H1 and of polysorbate and contains a more pure H1 preparation.[120,132] Arepanrix, which was used in Canada, also increased the risk for narcolepsy, but much more weakly, 1.5- to 3-fold.[135] Although no study has been formally done, Focetria has not been reported to trigger narcolepsy.

In the United States, only nonadjuvanted or live attenuated H1N1 vaccines were used. Of interest is the fact all seasonal trivalent split or subunit vaccines that have been used since 2009 still contain A/California/7/2009 (H1N1)-pdm09-like reassortant as one of the three strains covered. Although this has not been well studied and sporadic cases have been reported, the narcolepsy risk of these vaccines appears small or nonexistent.[136]

In summary, it appears that in the spring and summer of 2010, a larger than usual number of children with narcolepsy were observed in China and probably in other countries independent of any vaccination. In addition, narcolepsy in children also occurred in reaction to Pandemrix, although overall risk was small. The effects of other pH1N1 vaccines was either much milder or nonexistent. Antigens common to the wild-type virus and Pandemrix may have been involved.[121,133]

HUMAN LEUKOCYTE ANTIGEN IN NARCOLEPSY

HLA genes, also called major histocompatibility complex genes, are a specialized set of immune-regulatory genes located on human chromosome 6. These genes and resulting proteins are unusual because they are extremely polymorphic, thus the need for matching HLA in transplantation. Importantly, however, all the polymorphisms are located in a small region of the protein that functions as a peptide-binding area. Within this area, HLA molecules present foreign antigens (e.g., peptide fragments derived from a virus or bacteria) to T cells, the major effector cells of the immune system. Because each

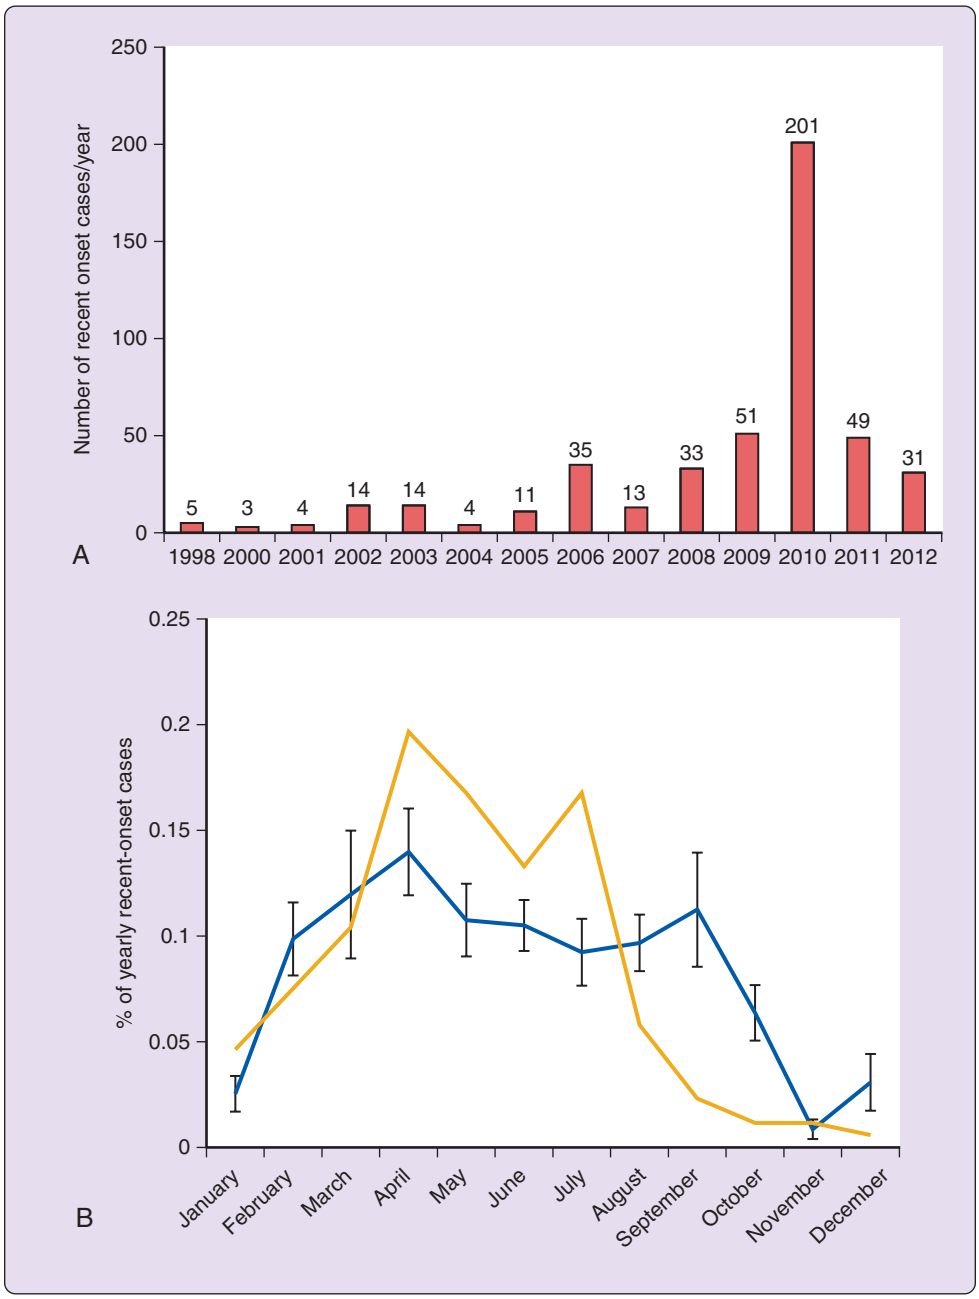

Figure 89-3 **A,** Yearly occurrence of recent onset (diagnosis within 1 year of onset) showing a dramatic increase in 2010, following the H1N1 pandemic of 2009, with return to baseline condition the following years.[117,124] **B,** Seasonal pattern of onset of narcolepsy in Chinese patients showing highly increased risk in spring and summer versus early winter. Data are represented as a yearly fraction of 12 months, that 0.083 (8.3%) would be the expected value of each month if onsets were randomly distributed across the year. The *blue line* represents the mean ±SEM of this yearly fraction for the years 2002 to 2009, with very low levels of new onset in late winter. The *orange line* represents the numbers for 2010, following the 2009 pH1N1 pandemic, and shows a more pronounced circannual pattern peaking in spring and summer.

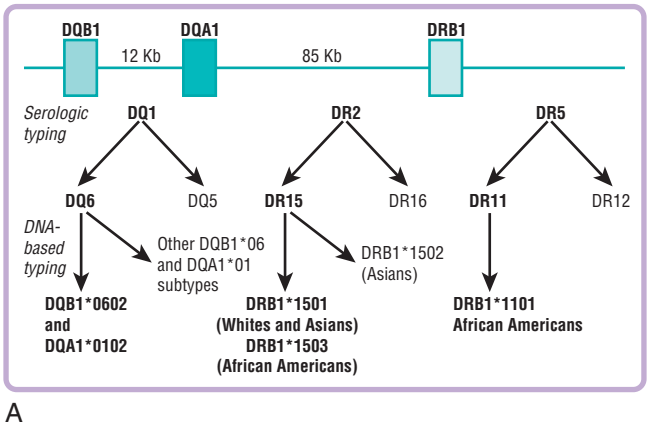
person has a specific set of HLA genes, these bind slightly different sets of peptide antigens (peptide repertoire), and thus T cells of each individual can only "see" a specific set of antigenic peptides. HLA polymorphisms are therefore at the origin of much of the interindividual genetic variation in immune responses. As such, immune responses to infection vary with HLA subtype (and these genes are submitted to strong evolutionary pressure), although because most infections involve thousands of epitopes and multiple genes, the effect at the level of individual genes is modest, and HLA polymorphisms modulate infectious disease severity rather than occurrence. Rather, discussed later, most of the diseases that are strongly associated with HLA are autoimmune, likely involving the presentation of a few specific autoantigens by specific HLA subtypes and therefore explaining the strong associations.

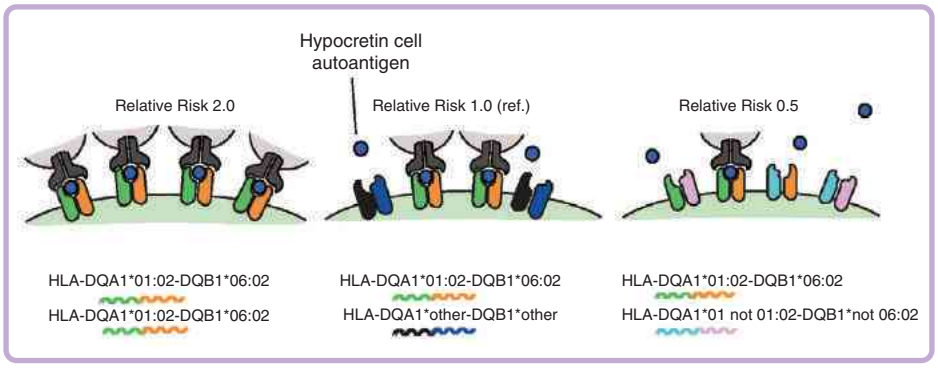
HLA-DQA1*01:02-DQB1*06:02 (DQ0602) Is Associated with Narcolepsy

The observation that narcolepsy was strongly associated with HLA was first reported in Japan[85,137] with HLA-DR2 and -DQ1. It was quickly confirmed in Europe[138-141] and North America,[142,143] with 90% to 100% of all patients with cataplexy carrying the HLA-DR2 subtype. Since this discovery, HLA-DR and -DQ typing has changed from serologic to molecularly based, and the broad DR2 and DQ1 subtypes were further divided into DR15, DQ6, and then DRB1*15:01, DQA1*01:02, and DQB1*06:02 (Figure 89-4, *A*). The key gene involved was then found to be DQB1*06:02, a subtype of DQ1. This is especially important in African American patients, many of whom are DQB1*06:02 positive but DR2 negative.[86,144-146] Subjects were also found to be DQA1*01:02 positive,[146-148] a less specific marker than DQB1*0602. Novel DNA markers developed in the HLA-DQ region have been tested to further map the narcolepsy susceptibility region within the DQA1-DQB1 interval.[149] This segment was entirely sequenced and the gene segment (haplotype) shown to contain no new genes.[149]

In all narcolepsy susceptibility DR-DQ haplotypes identified, two polymorphic genes, DQA1*01:02 and DQB1*06:02, are always present together as a single block within a very small segment of 20 kb.[147] The functional HLA-DQ protein is a heterodimer composed of a DQα (encoded by DQA) and a DQβ (encoded by DQB) chain, and because these genes are located close together, there is high linkage disequilibrium between these two genes so that specific combinations of DQA1 and DQB1 alleles are found as haplotypes. The presence of these nonrandom combinations of DQA1-DQB1 haplotype has been shaped by evolutionary constraints because some DQα and DQβ chains can bind together. Indeed, functional studies have shown that the DQα chains of the broad DQ1 subtype (subseparated into DQ5 and DQ6) can heterodimerize together, but not with other subtypes that are very distinct in term of their sequence homology. The sequence homology is reflected by the nomenclature, with gene products of the DQ1 family being associated with DQA1*01 and DQB1*05 or DQB1*06 subtypes. As a consequence, only very rarely would a DQB1*06 subtype be found adjacent to a non-DQA1*01 DQα chain because in these case a nonfunctional heterodimer would result.



A



B

Figure 89-4 Human leukocyte antigen (HLA)-DR and HLA-DQ alleles typically observed in narcolepsy. **A,** The DR and DQ genes are located very close to each other onto chromosome 6p21 and are part of the HLA class II family of HLA genes. These genes encode heterodimeric HLA proteins composed of an α and a β chain that interact with T-cell receptors (TCRs) located on $CD4^+$ T cells. In the DQ locus, both the DQα and DQβ chains have numerous polymorphic residues and are encoded by two polymorphic genes, DQA1 and DQB1, respectively. Polymorphism at the DR(αβ) level is mostly encoded by the *DRB1* gene, so only this locus is depicted in this figure. DQB1*06:02, a molecular subtype of the serologically defined DQ1 antigen (later split into DQ5 and DQ6) is the most specific marker for narcolepsy across all ethnic groups. It is always associated with the DQA1 subtype, DQA1*01:02, forming the DQ(αβ) heterodimer DQ0602. **(B).** Studies suggest that the allelic dose of DQ0602 influence narcolepsy risk. Because of this, homozygotes are at approximately twice the risk for developing narcolepsy, whereas subjects heterozygous with other DQ1 subtypes are at reduced risk. (Modified from Ollila HM, Fernandez-Vina M, Mignot E. HLA-DQ allele competition in narcolepsy: a comment on Tafti et al. DQB1 locus alone explains most of the risk and protection in narcolepsy with cataplexy in Europe. *Sleep* 2014;38:147–51.)

A number of other DR-DQ DQ1 haplotypes in the population carry DQA1*01:02 without DQB1*06:02, and those do not predispose to narcolepsy.[146] Conversely, although DQB1*06:02 subjects are almost always DQA1*01:02 positive, rare haplotypes with DQB1*06:02 but without DQA1*01:02 are observed in the control population but not in narcolepsy subjects.[146] Thus both the DQA1*01:02 and the DQB1*06:02 alleles (the DQ0602 heterodimer) are likely needed for narcolepsy predisposition,[146] which is logical because polymorphism in both the DQα and DQβ regions contributes to peptide binding.

Dosage of DQ0602 Influences Type 1 Narcolepsy Risk

Across multiple ethnic groups, DQ0602 (the combination of DQA1*01:02 and DQB1*06:02) is a near prerequisite for developing narcolepsy, and individuals homozygous for DQ0602 are at approximately two times greater risk for developing narcolepsy,[86,87,150,151] suggesting that the amount of DQ0602 heterodimer increases risk.[152] In addition, DQB1*05:01, DQB1*06:01, DQB1*06:03, and other DQ1 alleles that are non-DQ0602 appear protective.[86,87,151,153-155] As mentioned earlier, DQ1 is a broad DQ subtype that includes the DQα alleles encoded by DQA1*01 and DQβ alleles encoded by DQB1*05 and 06 subtypes. These DQ1 alleles, unlike those of the other broad DQ groups (DQ2, 3, and 4), are "compatible" with each other, meaning that they have sequence similarity and proper folding as selected by invariant chain binding (in contrast, non-DQ1 subtypes such as DQ2 and DQ3 are generally compatible with each other). Estimating relative risk, we noted that risk for DQ0602/other DQ1 is about one half of DQ0602/other, suggesting that there is competition of *trans*-encoded DQ1 alleles that are non-DQ0602, reducing the amount of DQ0602 and thus risk, a phenomenon we call *allele competition*[87,151] (see Figure 89-4, *B*).

HLA-DQB1*03:01 Influences Age of Onset

Intriguingly, DQ0602/DQB1*03:01 increases risk versus other combinations,[86,87,151,153] an effect difficult to explain because it occurs in the context of multiple DQα-associated alleles (DQA1*03:01, DQA1*03:02, DQA1*05:05, and DQA1*06:01), suggesting it is not mediated through DQα/β heterodimers. This effect also occurs in trios using transmission dysequilibrium tests, a design in which power is enhanced by the removal of alleles that are located together with DQ0602 in DQ0602-positive parents and thus never transmitted.[156] The reason for this additional effect is unclear, but unlike DQ0602 dose, the presence of DQB1*03:01 reduces age of onset, so the association is stronger in patients with early-onset narcolepsy.[157] The mechanism mediating this effect is unknown.

DP and HLA Class I Also Modulate Narcolepsy Risk

Although HLA-DQ is the primary genetic factor associated with narcolepsy (DQ0602 dose and DQB1*03:01 for early onset), additional effects within the HLA region add further modulation. In a recent study, Ollila and colleagues[15] compared controls and narcolepsy subjects fully matched for HLA-DQ and found protective effects of DPB1*04:02 (odds ratio [OR] = approximately 0.5) and susceptibility effects of the Asian subtype DPB1*0501 (OR = approximately 2). Additional matching for HLA-DP (i.e., matching for DR, DQ, and DP) revealed weak but significant residual effects in the HLA class I region (Figure 89-5).

These results are reminiscent of findings obtained in other HLA class II–associated autoimmune diseases such as type 1 diabetes, in which the primary association is with HLA-DR or -DQ, even though additional HLA-DP and class I effects can be detected. Because HLA class II interacts with $CD4^+$ T cells (see later), whereas HLA class I interacts with $CD8^+$ T and NK cells, these data suggest that multiple immune populations are likely involved in the pathophysiology of narcolepsy.

Role of HLA Typing in Clinical Practice

The usefulness of HLA typing in clinical practice is limited by many factors. First, the HLA association is very high (98%) only in patients with hypocretin deficiency/type 1 narcolepsy, and most of these patients have clear cataplexy, so the diagnosis can be made on clinical grounds alone. Second, a large

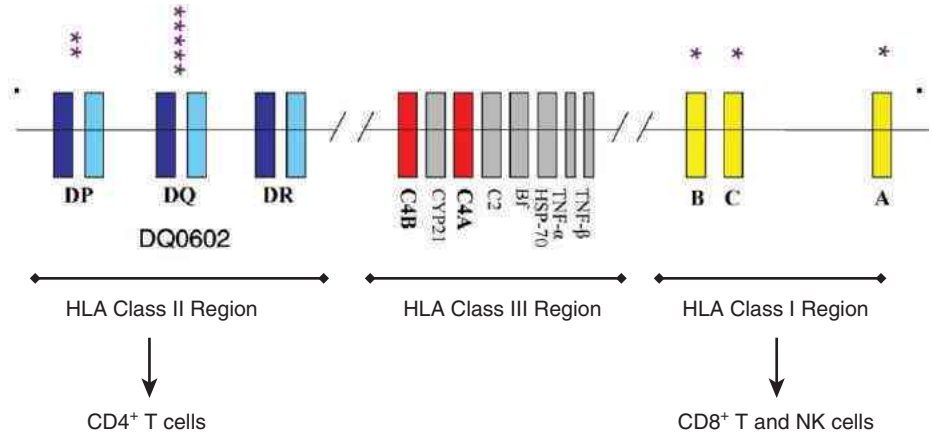


Figure 89-5 Effects of HLA loci other than HLA-DQ. HLA loci other than DQ also influence narcolepsy, notably HLA class II genes DPB1*04:02 (protective) and DPB1*05:01 (predisposing). In addition, effects of specific HLA class I gene alleles are also evident. HLA class I "A, B, C" genes present peptides to T-cell receptors located on $CD8^+$ cytotoxic T cells, or they may interact with natural killer cells, suggesting involvement of these cells in the pathophysiology of narcolepsy.[15] C4A, C4B, complement C4 genes; TNF, tumor necrosis factor.

number of control individuals (approximately 12% in Japan, 25% in whites and Chinese, 38% in African Americans) have the HLA-DQB1*06:02 marker without having narcolepsy. Third, low CSF hypocretin cannot be interpreted in the context of coma or serious neurologic defects (e.g., head trauma) because it can be reversibly low.[158] It is also interesting to note that in a recent study, 40% of nine non-DQB1*06:02 subjects with documented low CSF hypocretin-1 were DPB1*09:01 positive, a rare subtype in most ethnic groups (approximately 3%).[159] Practically, determining whether a patient carries DQB1*06:02 is only helpful if the clinician wishes to exclude hypocretin deficiency as the cause of the clinical complaint, especially before a lumbar puncture for CSF hypocretin-1 determination. Whether having an ultimate biologic basis for symptoms is important is a matter of individual clinician preference. In my opinion, clarification of hypocretin status helps clinicians decide whether to be more aggressive with selected therapies, whereas symptoms without a clear cause must lead to a constant reevaluation of the situation.

GENETIC FACTORS OTHER THAN HLA

As mentioned previously, genetic factors other than HLA are likely to be involved in narcolepsy predisposition. The increased familial risk in first-degree relatives (10-fold in Japanese, 20- to 40-fold in whites) cannot be solely explained by the sharing of HLA subtypes, estimated to explain a 2- to 3-fold increased risk.[5] Other results indicate that a polymorphism in the catechol-*O*-methyltransferase gene, a key enzyme in the degradation of catecholamines, also modulate disease severity.[160,161]

Additionally, the existence of rare HLA-negative families suggests disease heterogeneity and the possible involvement of other genes in HLA-negative narcolepsy. Many of these individuals have normal CSF hypocretin but lack mutations in hypocretin receptor genes.[159] Linkage analysis in HLA-DQB1*0602-positive Japanese families has suggested the existence of a susceptibility gene on 4q13-23.[162] Finally, in a rare multiplex family with DQB1*06:02 negativity and low CSF hypocretin levels, a mutation in myelin oligodendrocyte glycoprotein was found to be associated with narcolepsy.[163] Myelin oligodendrocyte glycoprotein mutations have not yet been found in any other HLA-negative patients with low CSF hypocretin.[159,159] Interestingly, however, a single case of prepro-hypocretin mutation was found in a very early-onset (6 months of age) individual with cataplexy and HLA negativity.[11]

More recently, studies have moved toward systematic genome coverage using genome-wide association (GWA) designs.[155,157,164-167] In a study of 222 patients and 389 controls and replication in 159 patients versus 190 controls, Miyagawa and colleagues[164] found involvement of rs5770917, a polymorphism located between *CPT1B* and *CHKB*, two genes that regulate cholinergic metabolism and β-chain fatty acid oxidation, respectively. A similar effect of rs5770917 (and a significant HLA association) was also observed in patients with "essential hypersomnia syndrome," a milder form of narcolepsy without cataplexy defined in Japan by sleepiness, refreshing naps, and no cataplexy,[164] suggesting a disease continuum. Interestingly, however, although the effect replicated weakly in Koreans,[164] the same polymorphism had no effect in a large sample of white[165] and Chinese[168] narcolepsy patients

Using a larger sample of whites and Asians, Hallmayer and colleagues[165] found that narcolepsy is strongly associated not only with HLA but also with a specific polymorphism in the T-cell receptor-α (TCR-α) gene.[165] Although genetic risk was not high (OR = ~2) when compared with effects found with HLA polymorphism, the finding was nonetheless remarkable because it further demonstrated a role of the immune system in narcolepsy. It was also unusual because none of the other autoimmune disorders subjected to GWA analysis have TCR loci as a susceptibility factor.

Further studies in larger samples that also included other ethnic groups, notably Chinese, Japanese, and African Americans, have led to the identification of other associated genes, most known to be involved in other autoimmune diseases.[157,166,167] Other associated loci include the TCR-α and -β genes; TNFSF4 (also called OX40L), a costimulatory receptor for T-cell activation and associated with multiple autoimmune diseases; cathepsin H, an enzyme likely involved in antigen processing and associated with type 1 diabetes; ZNF365, a transcription factor associated with inflammatory bowel disease (IBD); and IL10RB-IFNAR1, a region associated with IBD and other autoimmune diseases.

Of additional interest is the association with the PPAN-P2RY11-EIF3G gene region, 10 kb from the DNA methylase gene 1 (*DNMT1*).[166] This finding is notable because this gene region is not known to be associated with other autoimmune diseases, although P2RY11, an adenosine triphosphate receptor, regulates cell death, notably in immune cell subsets. Interestingly, in a parallel exome sequencing project of rare dominant phenotypes with narcolepsy, we found that a rare disease consisting of late-onset narcolepsy with deafness, cerebellar ataxia, and dementia (ADCA-DN) was secondary to a mutation in exon 21 of the *DNMT1* gene, resulting in late-onset neurodegeneration, with a likely effect on hypocretin cells[169] (see Narcolepsy in Genetic Syndromes). Further mapping of the GWA signal confirmed location within P2RY11-EIF3G and not extending to *DNMT1*, although regulatory elements for the latter could still lie within the nearby region. In favor of this hypothesis, although P2RY11 is a pseudogene in rodents, the syntenic block containing PPAN-P2RY11-EIF3G-DNMT1 is conserved from zebrafish through mammals.

ELLUSIVE AUTOIMMUNE MECHANISM IN TYPE 1 NARCOLEPSY

The finding of hypocretin cell loss in narcolepsy, together with the demonstration that HLA-DQ0602 is responsible for most of the association signal within the HLA region, has rekindled the hypothesis of autoimmunity, with hypocretin cells as the logical target. Surprisingly, however, autoantibodies targeting hypocretin peptides have not been found,[170-172] and immunostaining of hypothalamic tissue with human narcolepsy sera has not revealed autoantibodies targeting colocalized antigens on these neurons.[173-175] Several nonreproducible findings were made. Passive transfer experiments of human sera in mice have been published,[176,177] suggesting the presence of functional autoantibodies with modulating effects on spontaneous colonic migrating motor complex contractions or reactions of rodent bladder strips to muscarinic stimulation,[178,179] but we could not replicate the finding (data not shown). These investigators also suggested that peripheral

injections of human narcolepsy sera in mice caused narcolepsy symptoms, but when we attempted replication, all mice had seizures causing behavioral arrests that may have been confused with narcolepsy events. Two of the five treated animals died, and hypocretin neurons were intact postmortem in all animals, including the three animals after recovery. Further, we sent blinded sera samples for the bladder strip assays, but opposite results to the initial findings were returned to us. Using a BAC-based transgenic animal model expressing a Flag-tagged poly(A)-binding protein (*Pabpc1*) cyclic DNA sequence in hypocretin neurons, Cvetkovic-Lopes and colleagues[180] isolated transcripts believed to be increased in hypocretin cells, including the protein Tribbles homologue 2 (Trib2). The authors went on to demonstrate increased Trib2 autoantibodies in individuals with recent-onset narcolepsy and some cross-reactivity of sera with hypocretin neurons.[173-175]

Unfortunately, however, these authors may have been on the right track for the wrong reasons. Shortly after the TRIB2 publication, the TRIB2 antibody finding was replicated[181,182] using sera samples from subjects collected between 1990 and 2005, but staining of hypocretin neurons with narcolepsy sera was not observed.[173-175,183] Further studies using a similar approach but an mRNA binding protein other than Pabpc1, the protein P10, also found that few of the genes expressed in hypocretin neurons as reported by Cvetkovic-Lopes and colleagues,[180] including *TRIB2*, were enriched in hypocretin neurons.[184] These latter results were also confirmed by our own multiple expression array studies.[185,186] Pursuing this line of investigation, TRIB2 autoantibodies were later found to be generally absent in more recent narcolepsy samples.[123] It is our hypothesis that TRIB2 autoantibodies may have marked a coinfection present together with a narcolepsy trigger in some patients with disease onset in the 1990s and 2000s, a result substantiated by the finding of a correlation between A/H1N1 and TRIB2 autoantibody levels in a recent study.[89] Interestingly, a recent study, reminiscent of the older Australian studies mentioned previously,[176] reported that local injections of purified immunoglobulins of narcolepsy-TRIB2-positive individuals, but not controls, produced hypocretin cell loss and narcolepsy symptoms.[177] Careful reading of this manuscript, however, does not support the conclusion of the study because no hypocretin cell count statistics were provided, only an exemplar hypothalamic section showing widespread local cell loss that is more extensive than just hypocretin loss. Further, the authors reported "narcolepsy-like immobilization attacks" without associated EEG studies in six animals, which may have been seizures considering their mean duration (66 to 464 seconds), much longer than typically reported in murine cataplexy (2 to 60 seconds).[30]

Finally, a recent report from our group suggested that specific portions of hypocretin that bind to DQ0602 were the likely autoantigen and that T-cell cross-reactivity and molecular mimicry with pH1N1 was involved.[187,188] We felt a blood test for narcolepsy might be close at hand, but on finding these data were invalid, we withdrew the paper.[187,188]

Unfortunately, although rare cases of type 1 narcolepsy coexisting with multiple sclerosis, lupus, or other common autoimmune conditions have been reported, there are no systematic studies of co-occurrence in cases or family members. Rather, the possibility that narcolepsy is an autoimmune disease is supported by the rare existence of autoimmune narcolepsy with documented hypocretin deficiency as part of two other autoimmune diseases. The first is a rare paraneoplastic syndrome associated with anti-ma2 antibodies in the context of seminomas.[189,190] Interestingly, in one case, a $CD8^+$ T-cell infiltration largely restricted to the hypothalamus and an almost complete loss of hypocretin neurons were observed.[191] Similarly, in one case of late-onset hypoventilation syndrome, a disorder with reported hypothalamic abnormalities,[192] we found very low CSF hypocretin-1 levels in an individual with otherwise unexplained sleepiness and cataplexy-like episodes.[13] More recently, this disorder has been renamed rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD) and suggested to be autoimmune based on the finding of extensive infiltrates of lymphocytes and histiocytes in the hypothalamus of some patients.[193,194] An excellent response to anticataplectic therapy was observed in this patient.

This brief discussion exemplifies the difficulties of narcolepsy research. Currently, the circumstantial evidence strongly suggests that narcolepsy is an autoimmune disease, but we believe like others[195] that, as yet, there is no direct evidence for this hypothesis. Figure 89-6 summarizes the likely autoimmune process involved in narcolepsy, with the hypothesis that $CD8^+$ T cells are involved.

CEREBROSPINAL FLUID HYPOCRETIN-1 AS A DIAGNOSTIC TOOL FOR TYPE 1 NARCOLEPSY

The observation that CSF hypocretin-1 levels are decreased in patients with narcolepsy provides a new test to diagnose this disorder (Figure 89-7; see Table 89-1). Using a large sample of patients and controls, we recently conducted a quality receiver operating curve (QROC) analysis to determine the CSF hypocretin-1 values most specific and sensitive to diagnose narcolepsy.[13] A cutoff value of 110 pg/mL was the most predictive in patients with cataplexy (30% of mean control values). In patients without cataplexy, QROC analysis indicated that a cutoff value of 200 pg/mL is most predictive, suggesting that in some of these patients, partial hypocretin deficiency could be present (some patients may evolve to more complete symptomatology with cataplexy and even lower levels[196]). Most positive samples had undetectable levels of hypocretin-1 (<40 pg/mL in most assays), whereas a few samples had detectable but very diminished levels. Hypocretin levels appear normal in patients with idiopathic hypersomnia, sleep apnea, restless legs syndrome, or insomnia.

Using the 110 pg/mL cutoff, the measurement of CSF hypocretin-1 is especially predictive in patients with definite cataplexy (100% specificity, 83% sensitivity). Sensitivity and specificity are higher for this test than for the MSLT. In most case series, approximately 12% of narcolepsy patients with cataplexy or hypocretin deficiency do not have a positive MSLT. Measuring CSF hypocretin may therefore be helpful in patients with cataplexy when the MSLT is negative, to exclude a possible conversion disorder. CSF hypocretin-1 measurements have a more limited predictive power in cases with atypical or absent cataplexy. Specificity of the CSF hypocretin-1 measurement is still extremely high (99%), but sensitivity is low (16%) for CSF levels below 110 pg/mL (see Figure 89-6),[13] with most patients having normal levels.[13,81,83] Raising the cutoff of CSF hypocretin-1 to 200 pg/mL after demonstrating HLA positivity increases sensitivity to 41%,

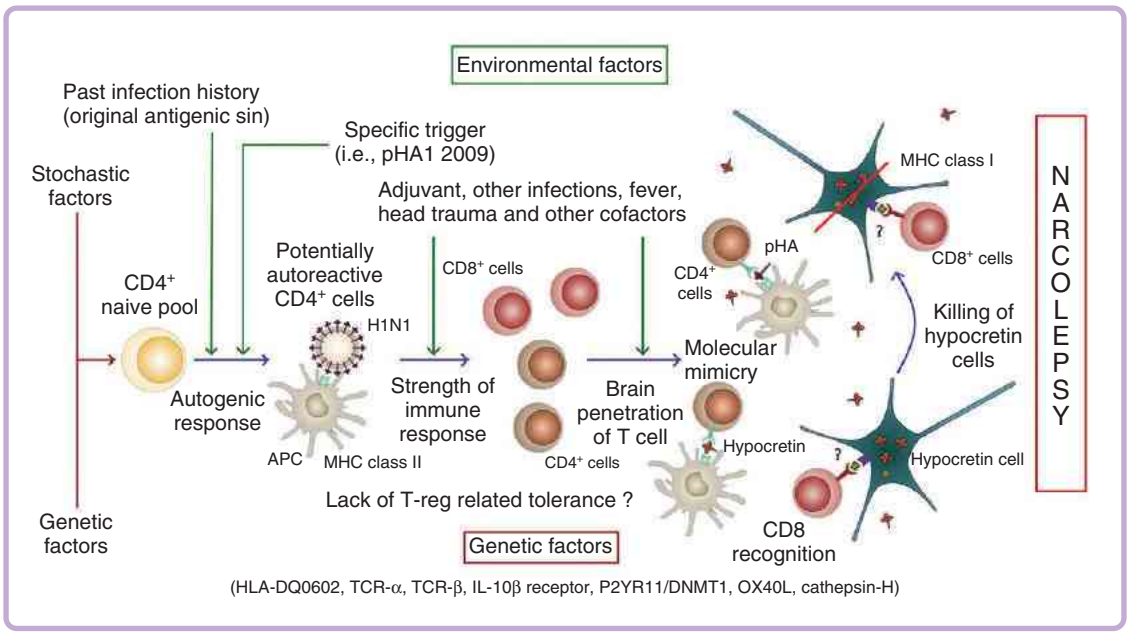

Figure 89-6 Hypothetical pathophysiologic model for autoimmune narcolepsy. Narcolepsy is likely an autoimmune disease involving specific subpopulations of $CD4^+$ and $CD8^+$ T cells and may have little if any B-cell, autoantibody involvement. The development of narcolepsy probably results from many unlikely events. First, DQ0602 must almost always be present, and genetic background at other loci also influence predisposition. $CD4^+$ T cells bearing specific receptors are generated stochastically, although with influence of T-cell receptor (TCR) loci polymorphisms, and autoreactive cells are removed by the thymus, whereas others are released as naïve T cells. We hypothesize that only a subset of the population may have naïve T cells with the potential to become pathogenic and narcolepsy inducing. In many cases, these cells may become anergic or will be moved into a regulatory T-cell compartment that rather inhibits autoimmunity. In some unlucky individuals, an immune reaction to an external infection such as 2009 H1N1 may engage these pathogenic, cross-reactive naïve T cells. These cross-reactive T cells recognize a yet unknown autoantigen on hypocretin cells. This may be more likely to occur in younger individuals with a particular history of infections (or lack of). Indeed, in many subjects, such infection would first stimulate memory $CD4^+$ T cells that recognize shared epitopes and are not pathogenic. Other factors that may participate in tilting the balance toward developing narcolepsy could be the strength of the immune response (coinfection, adjuvant), a leaky blood–brain barrier, etc. Following engagement of $CD4^+$ T cells, $CD8^+$ T cells are also likely to be involved and may be important in mediating the actual hypocretin cell killing.

suggesting that 200 pg/mL may be more appropriate in these cases after HLA typing, although specificity may be more questionable if other neurologic disorders are present.[158] For the patient, the diagnostic value of CSF hypocretin-1 measurement needs to be weighed against the trauma associated with obtaining CSF. Because HLA is positive in 98% of cases when CSF hypocretin is below 110 pg/mL, we advise measuring CSF hypocretin-1 only after verifying that the subject is DQB1*06:02 positive. If the subject is negative, low hypocretin is very unlikely, about 2% probability if the subject has cataplexy and probably less without cataplexy.

Another potential application for CSF hypocretin-1 testing lies in the complex field of narcolepsy and hypersomnia related to neurologic disorders associated with trauma, tumor, infection, degenerative diseases, and genetic disorders (Table 89-3). Von Economo was the first to suggest that narcolepsy may have its origins in the posterior hypothalamus. In his classic study of encephalitis lethargica, von Economo recognized three categories of patients: a group with hypersomnia and eye movement abnormalities (somnolent-ophthalmoplegic), a group with insomnia and hyperkinetic movement disorder (sometimes with reversal of the sleep cycle), and a group with parkinsonism ("amyostatic-akinetic," often as a residual form).[197] Neuropathologic studies revealed involvement of the midbrain periaqueductal gray matter and posterior hypothalamus in the hypersomnolent variant (with extension to the oculomotor nuclei, explaining the oculomotor symptoms). Involvement of the anterior hypothalamus with extension into basal ganglia was observed in the insomnia variant (explaining the frequently co-occurring chorea). This led von Economo to speculate that the anterior hypothalamus contained a sleep-promoting area, whereas an area spanning from the posterior wall of the third ventricle to the third nerve (encompassing part of the posterior hypothalamus and the periaqueductal midbrain region) was involved in promoting wakefulness. The cause of idiopathic narcolepsy that had been described some 50 years earlier[102] was also speculated to involve this general area.[198] This hypothesis was further refined by others, who noted that tumors or lesions located close to the third ventricle were also associated with secondary narcolepsy.[110,199] A postulated hypothalamic cause of narcolepsy was widespread until the 1940s but was subsequently ignored during the psychoanalytic boom, to be replaced by a brainstem hypothesis.[200] Interestingly, only two cases of postencephalitis genuine narcolepsy with cataplexy had even been clearly documented, and in one case reversal of symptoms was reported with recovery.[201,202]

Reports of lesions near the third ventricle (hypothalamus and upper midbrain) in association with narcolepsy (such as tumors) have been described for more than 80

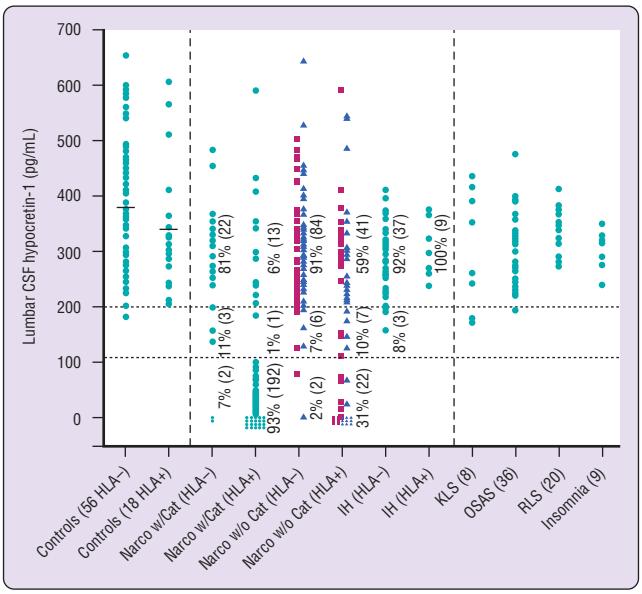

Figure 89-7 Lumbar cerebrospinal fluid (CSF) hypocretin-1 concentrations in controls versus subjects with narcolepsy and other sleep disorders (from the Stanford Center for Narcolepsy Research database). Each point represents the concentration of hypocretin-1 as measured in unextracted lumbar CSF of a single individual. Subjects are differentiated according to HLA-DQB1*06:02 status and include controls (samples taken during both night and day). Patients are classified as having narcolepsy with or without cataplexy, and individuals without cataplexy are subdivided into those with atypical (*triangle*) and no (*squares*) cataplexy. Clinical subgroups include narcolepsy patients (Narco) with (w) and without (w/o) cataplexy (Cat), idiopathic hypersomnia (IH), Kleine-Levin syndrome (KLS), obstructive sleep apnea syndrome (OSAS), restless legs syndrome (RLS), and insomnia. Individuals with secondary narcolepsy/hypersomnia are not included. The *dashed lines* indicate hypocretin levels that are low (<110 pg/mL), intermediate (111–200 pg/mL), or normal (>200 pg/ml). Note that these pg/mL values are largely artificial and are meant to represent approximately 30% of mean control value as tested in a given center using direct radioimmunoassay and a set of healthy controls.[13] Mean CSF hypocretin-1 concentration was not significantly different between HLA-DQB1*06:02 positive and negative controls. The percentage and number of subjects are specified for each group of subjects according to the two CSF hypocretin thresholds.

years.[198,199,201-203] Narcolepsy-like symptoms have also been reported after traumatic brain injury, acute disseminated encephalomyelitis, hypothalamic sarcoidosis or histiocytosis X, and in association with multiple sclerosis and Parkinson disease.[158,204,205] In some patients, lesions of the hypothalamic hypocretin neuron region have been clearly identified using magnetic resonance imaging, as in bilateral multiple sclerosis or anti-aquaporin-4 lesions in the hypothalamus, and tumors of the third ventricle.[158,204,205] Cataplexy may be present in these individuals, and CSF hypocretin-1 levels may be either in the narcolepsy range (<110 pg/mL) or in the intermediate range[13,158] (see Table 89-3). Similarly, postmortem studies have shown a 30% and 50% decrease in hypocretin cell counts in Huntington and Parkinson diseases,[158] respectively, with maintenance of normal CSF hypocretin-1 levels.[13] Such intermediate or normal levels may reflect damage to nearby hypocretin projection sites, with sufficient preservation of cell bodies to maintain detectable levels of hypocretin-1. Alternatively (or additionally), other regions in the upper midbrain may also contribute symptoms, especially sleepiness, as initially proposed by von Economo.[198]

Therefore, as illustrated previously, CSF hypocretin-1 levels can be helpful in complex clinical situations in which the history, polysomnography, or MSLT data may be difficult to interpret (Table 89-4). Hypocretin values, however, should be cautiously interpreted. In a large series of individuals with various neurologic disorders, we found that up to 15% had CSF hypocretin-1 values within the intermediate range; most of these patients had severe brain pathology, most notably head trauma, encephalitis, and subarachnoid hemorrhage.[79,158] Decreased hypocretin-1 levels in these patients may reflect damage to hypocretin-1 transmission or may be related to changes in CSF flow. Other authors have shown that CSF hypocretin-1 increases with locomotor activity and decreases with treatment with serotonin reuptake inhibitors (but never to near-undetectable, narcolepsy-like levels).[93] Therefore the finding of hypocretin-1 levels in this intermediate range should alert the clinician to the possibility of underlying brain pathology, which may require additional clinical evaluation, laboratory testing, or imaging. Whether genuine hypocretin deficiency explains abnormal sleep in these neurologic disorders is in need of further investigation.[158]

NARCOLEPSY IN GENETIC SYNDROMES

Genetic disorders such as ADCA-DN (MIM 604121, *DNMT1* mutations), Coffin-Lowry Syndrome (MIM 303600, *RSK2* mutations),[206] Moebius syndrome (MIM 157900, heterogeneous),[207-209] myotonic dystrophy (MIM 160900 and 602668, *MD1* and *MD2* mutations),[210] Niemann-Pick disease type C1 (MIM 257219, *NPC1*),[13,211-213] Norrie disease (MIM 310600, Xp11.4-p11.23 deletions encompassing the *NDP* and in cases with cataplexy, the *MAO* genes),[207,214,215] and Prader-Willi syndrome (MIM 176270, most often due to 15q11.2 deletions encompassing the paternal copies of the imprinted *SNRPN* and *NDN* genes)[13,207] can result in daytime sleepiness, SOREMPs, and cataplexy-like symptoms. HLA may be negative or positive by chance in these patients. We have explored CSF hypocretin-1 levels in such pathologies and have found that most have normal or intermediate CSF hypocretin-1 levels (<110 pg/mL).[13] These special etiologies are described subsequently.

ADCA-DN, a syndrome first described by Melberg and associates,[216] is a late-onset neurodegenerative disorder (ages 30 to 40 years) with ataxia, deafness, and narcolepsy-cataplexy and intermediate to low CSF hypocretin-1. Narcolepsy is an early manifestation, and at this stage CSF hypocretin-1 may be normal, dropping only in the late stage of the disorder.[169,216,217] Deafness is an early symptom, followed by cerebellar ataxia, ocular nerve atrophy, and neurodegeneration, leading to death in 5 to 10 years. The disorder was recently found to be caused by mutations in exon 21 of the DNA methylase 1 (*DNMT1*) gene, in a regulatory region of the gene.[169] It is closely related to *DMNT1* mutations in exon 20 and hereditary sensory and autonomic neuropathy type 2 (MIM 614116), in which the syndrome is similar but manifests first with a peripheral neuropathy, a symptom that is rarely the primary, early manifestation of ADCA-DN.[217]

In Coffin-Lowry syndrome, mental retardation is present, and cataplexy is atypical and more likely to represent atonic seizures because other types of events; for example, tonic-clonic or absence seizures can be induced by emotions such

Table 89-3 Cerebrospinal Fluid Hypocretin-1 Measurements in Secondary Narcolepsy and Hypersomnia*

Secondary hypersomnia with hypocretin-1 <110 pg/mL
Acute disseminated encephalomyelitis (ADEM) with sleepiness
Autosomal dominant cerebellar ataxia, deafness, and narcolepsy (*DNMT1* mutations)
Large pituitary adenoma with probable hypothalamic involvement
Late-onset hypoventilation syndrome, probably rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD)
Multiple sclerosis cases with bilateral hypothalamic plaques
Paraneoplastic syndrome (seminoma) with anti-Ma2 and sleepiness, cataplexy
Hypothalamic tumors and surgery after removal of such tumors
Prader-Willi syndrome (15q11-q13)
Steroid-responsive encephalopathy associated with autoimmune thyroiditis
Whipple disease with central nervous system involvement (with hypersomnia)†
Secondary hypersomnia with intermediate hypocretin-1 levels (110–200 pg/mL)
Autosomal dominant cerebellar ataxia, deafness, and narcolepsy (*DNMT1* mutations)
Moebius syndrome
Niemann-Pick disease type C with cataplexy (*NPC1* mutations)
Norrie syndrome (deletion of *MAO* genes on the X chromosome)
After diencephalic stroke with hypothalamic and midbrain lesions
After head trauma (but unclear if mediating symptoms)
Prader-Willi syndrome (15q11-q13)
Secondary hypersomnia with normal hypocretin-1 levels(>200 pg/mL)
Acute disseminated encephalomyelitis (ADEM) with sleepiness
Human immunodeficiency virus encephalopathy with sleepiness
Hypersomnia with depression
Hypersomnia in association with Parkinson disease
Hypersomnia in association with myotonic dystrophy type 1 (*DM1* mutations)
Myotonic dystrophy type 1 (*DM1* mutations)
Neurocysticercosis cysts in the hypothalamus and other locations
Niemann-Pick disease type C without cataplexy (*NPC1* mutations)
Narcolepsy-cataplexy after hypothalamic irradiation
Pontine lesions
Thalamocortical strokes
Other pathologies with intermediate or low levels (no reported but possible sleep symptoms)‡
Traumatic brain injury (probably transient)
Encephalitis of infectious origin
Guillain-Barré syndrome and other inflammatory neuropathies
Coma caused by infection or trauma

*Cases tested at Stanford University or in centers that used the same standard cerebrospinal fluid (CSF) samples for comparisons are included; measurements in other laboratories cannot be compared.
†In another patient with Whipple disease with long-lasting resistant insomnia without hypersomnia, intermediate CSF hypocretin levels were found.
‡These may reflect nonspecific effects or be indirectly affecting the hypothalamus, with potentially reversible changes in CSF hypocretin-1.

as surprise at a sudden noise.[206] In our opinion, the disorder is not genuinely associated with true narcolepsy.

Moebius syndrome is a heterogeneous set of brainstem anomalies involving minimally the sixth and seventh cranial nerves with resulting congenital facial palsy and impairment of ocular abduction; it is often associated with a 13q12.2 deletion encompassing the *MBS1* gene and occasionally other skeletal abnormalities. Cataplexy with or without other sleep abnormality has been reported in several cases (all without skeletal abnormalities),[207,209] and in one case in which CSF hypocretin was measured, it was intermediate.[208] One case was responsive to antidepressant. In these cases, brainstem impairment affecting REM regulating centers of the pons is likely causal. The condition can be complicated by the existence of sleep-disordered breathing.

In its typical manifestation, Norrie disease is a X-linked recessive disorder characterized by very early childhood blindness due to degenerative and proliferative changes of retinal neurons, and frequently hearing deficits and neuropsychiatric symptoms.[218] Many cases are secondary to a Xp11.3-p11.4 deletion that encompass the *NRD* gene. Because mutations of *NRD* also cause Norrie disease with its ocular manifestations, the syndrome is causal to this gene. Cases with cataplexy have been described in various microdeletion syndromes but with isolated *NDP* mutations.[215,207,214] Further, families or cases with deletion encompassing both *MAO* genes and that did not affect the *NDP* gene show severe developmental delay, intermittent hypotonia, and stereotypical hand movements.[219,220] The author saw one patient with cataplexy, mental retardation without ocular symptoms, and a deletion limited to the *MAO* genes, suggesting these monoaminergic genes are indeed crucial to this manifestation. This observation may be of interest considering that optogenetic stimulation of the adrenergic locus coeruleus has recently been shown to produce arousal followed by behavioral arrests.[221]

Niemann-Pick disease type C is a lysosomal storage disease associated with mutations in *NPC1* and *NPC2* genes and abnormal cholesterol metabolism. Onset is usually before 10 years of age (with death before 20 years), but the disease can manifest at much later age. Niemann-Pick disease type C has

Table 89-4 Cerebrospinal Fluid Hypocretin-1 and HLA Results: Selected Examples in Secondary Narcolepsy and Hypersomnias

Clinical Case	CSF Hypocretin-1	Notes
An 8-year-old boy without cataplexy (onset within 6 mo)	88 pg/mL HLA+, MSLT+	Type 1 narcolepsy, treatment with modafinil, later developed cataplexy and treated with venlafaxine
A 17-year-old boy with rape hallucinations, suspicious and difficult to interview, possible cataplexy	Undetectable (<40 pg/mL) HLA+, refused MSLT testing	Type 1 narcolepsy, associated with psychosis, positive effect of venlafaxine
A 16-year-old woman with a 5-year history of depression and drug-resistant insomnia; cataplexy on interview	Undetectable (<40 pg/mL) HLA+, MSLT not interpretable	Type 1 narcolepsy, now successfully treated with sodium oxybate, modafinil, and atomoxetine
A 32-year-old man, after resection of hypothalamic craniopharyngioma, very impaired, possible cataplexy	152 pg/mL HLA–, MSLT impossible	Secondary narcolepsy, possibly lesions of other areas, partial effect of stimulants
A 33-year-old woman successfully treated with D-amphetamine and fluoxetine; no cataplexy; no MSLT	Undetectable (<40 pg/mL) HLA+	Type 1 narcolepsy, no change in treatment but considering modafinil
A 15-year-old girl with sleepiness, no cataplexy	310 pg/mL HLA+, MSLT+	Type 2 narcolepsy, treatment with modafinil
A 67-year-man diagnosed with narcolepsy without cataplexy at age 50 years, currently with falls not typically triggered, AHI = 25 events/hr, CPAP noncompliant	Undetectable (<40 pg/mL) HLA+	Type 1 narcolepsy, first tried on venlafaxine without effect, then on sodium oxybate with very positive response

AHI, Apnea-hypopnea index; CPAP, continuous positive airway pressure; CSF, cerebrospinal fluid; HLA+, HLA-DQB1*06:02 positive; MSLT+, Mean Sleep Latency Test positive (mean sleep latency <8 min, ≥2 sleep-onset REM periods [SOREMPs] including a nocturnal SOREMP).

a wide clinical spectrum that may include hepatosplenomegaly and a wide range of neurologic abnormalities (cerebellar ataxia, tremor, seizures, dysphagia, dysarthria, hypotonia, dystonia, psychosis, dementia, and other psychiatric symptoms). Vertical gaze palsy with involvement of the third cranial nerve is often an early and typical feature This condition is remarkable because cataplexy can be clear, triggered by typical emotions (laughing),[211] and partially responsive to anticataplectic treatment. To our knowledge, all cases with cataplexy have been reported in young children with *NPC1* mutations. CSF hypocretin-1 has been measured in multiple patients, and intermediate levels have been found in several cases with cataplexy.[13,213]

Some diseases are associated with the development of both narcolepsy and sleep-disordered breathing, such as myotonic dystrophy[210] and Prader-Willi syndrome[13]; in such patients, primary hypersomnia should only be diagnosed if excessive daytime sleepiness does not improve after adequate treatment of sleep-disordered breathing. Mytotonic dystrophy due to *DM1* mutations, the most common, is X-linked and is pleiotropic in its clinical manifestations. It is due to a germline and subsequently somatic expansion of a CTG trinucleotide repeat in the noncoding region of *DMPK* that can vary across tissue and causes a misregulation of alternative splicing events. It is characterized by progressive muscle wasting or weakness, cataracts, cardiac conduction defects, gastrointestinal motility defects, baldness, endocrinopathies, and infertility. Age of onset can be extremely variable. Because of the muscle weakness, hypoventilation and sleep-disordered breathing are common. Cataplexy has never been reported in myotonic dystrophy, but positive narcolepsy-like MSLTs and cognitive abnormalities are well demonstrated to be independent of sleep-disordered breathing. CSF hypocretin is generally normal.

Prader-Willi syndrome is caused by a loss of function of genes in the 15q11.2 region, with likely involvement of the small nuclear ribonucleoprotein polypeptide N *(SNRPN)* and nectin (*NDN*) genes leading to a complex cascade of genetic dysregulations. Most cases (70%) are due to a deletion of paternal origin (in this case a loss of function occurs when the maternal copy is imprinted), and most of the other cases are due to maternal uniparental disomy (inheritance of two inactivated maternal copies). Prader-Willi syndrome is characterized by a typical facial appearance, mental retardation, hypotonia, hyperphagia, and many other symptoms. Because of obesity and hypotonia, hypoventilation plus sleep-disordered breathing is a complication that can contribute to sleepiness, although MSLTs with SOREMPs are typically observed and central nervous system effects are almost surely involved.[222] Prader-Willi syndrome is interesting because cataplexy, although rare, can be typical, triggered by laughing. In one patient with a 15q deletion, obesity was not a striking feature thanks to food restriction, and cataplexy was improved by the adrenergic reuptake inhibitor atomoxetine, although at higher dose it exacerbated absence seizures also observed in this patient. CSF hypocretin is generally intermediate.[223]

In conclusion, a few genetic disorders are associated with REM sleep abnormalities and cataplexy-like features. It is likely that the study of the downstream mechanisms involved could shed light on REM sleep regulation and type 2 narcolepsy.

HYPOCRETIN COMPOUNDS AS POTENTIAL THERAPEUTIC TARGETS

Researchers have studied the effects of hypocretin on sleep after nasal, systemic, and central administration (e.g., intracerebroventricular injection or local perfusion in selected brain areas). Central administration of hypocretin-1, for example, into the lateral ventricle of wild-type rodents or normal canines, is strongly wake promoting[224] and reverses cataplexy and sleep abnormalities in narcoleptic mice.[225] The effect is likely to be partially mediated by the hypocretin receptor-2 as intracerebroventricular hypocretin-1 at the same dose (10 to 30 nmol) has no effect in hypocretin receptor-2 mutated narcoleptic canines.[224] Interestingly, hypocretin-2 administration has few if any central effects even in normal animals, perhaps because it is biologically unstable and rapidly degraded. The instability may also explain why hypocretin-1 but not hypocretin-2 is detectable in native CSF.[226]

Experiments conducted after intravenous administration of hypocretin-1 have been performed in hypocretin receptor-2 mutated canines and in two hypocretin-deficient narcoleptic dogs. Despite a previous report,[227] we were unable to detect any significant effect even at extremely high doses in hypocretin receptor-2 mutated animals. This result was not surprising considering the lack of effects after central administration of the same dose in these animals lacking hypocretin receptor-2 (see earlier).[224] More interestingly, a possible very slight and short-lasting suppression of cataplexy was observed in a single hypocretin-deficient narcoleptic animal at extremely high doses.[224]

The effect of hypocretin-1 intranasal administration in rodents and humans has also been studied,[228-231] with the hope that hypocretin-1 would penetrate into the brain through the cribriform region. Deadwyler and colleagues found a significant reversal of magnetic resonance imaging abnormalities induced by sleep deprivation after intranasal administration of hypocretin-1 (1 μg/kg) in rhesus monkeys. Weinhold and colleagues[231] found improved attention, decreased wake-REM sleep transitions, and less REM sleep in narcolepsy patients after intranasal hypocretin-1 (435 nmol), but no effects on daytime tests of maintenance of wakefulness, suggesting limited clinical significance. We also examined the possibility of intrathecal administration (up to the very large dose of 96 μg/kg) by implanting a Medtronic pump with catheterization of the cisterna magna in a single hypocretin-deficient narcoleptic canine.[232] Our hope was that at high dose, some reverse flow would occur back into deeper brain structure, providing therapeutic relief. A positive result would have had therapeutic application because these pumps are frequently used in humans for the treatment of pain or spasticity using intrathecal administration. Disappointingly, however, we did not observe any significant effect on cataplexy,[232] probably because the hypocretin did not diffuse into upper ventricular compartments. Additional studies using intraventricular rather than intracisternal injections will be needed to verify that hypocretin-deficient narcoleptic canines are responsive to supplementation.[228]

The discovery of hypocretin and its involvement in narcolepsy has led some drug companies to develop hypocretin receptor antagonists for insomnia. One of these compounds, suvorexant, a dual hypocretin receptor-1 and -2 antagonist (called DORA, or dual orexin receptor antagonist), has been approved for the treatment of insomnia.[89] More relevant to narcolepsy, hypocretin agonists are being sought by companies and academic laboratories. Although the discovery of agonists with brain penetration has been difficult, it is likely that such compounds will become available in the future, to the benefit of patients with type 1 narcolepsy.

CLINICAL PEARLS

- Cataplexy is the most predictive symptom of hypocretin deficiency and therefore should be carefully defined. In children close to onset, cataplexy can be atypical and severe, presenting as episodes of tongue protrusion, jaw openings, or generalized weakness not necessarily triggered by emotions. Later in the life of the patient or in adults, cataplexy becomes typical, triggered by emotions such as laughing, joking, and anger. Cataplexy can improve with age and with the introduction of sodium oxybate; some patients do not have any residual cataplexy when well treated.
- Type 1 narcolepsy is a lifelong disease, whereas little is known about the evaluation of type 2 narcolepsy. For this reason, treatment of type 2 narcolepsy should be more conservative.
- HLA-DQB1*06:02 typing is useful to request before measuring CSF hypocretin. If HLA is negative the probability that the patient has hypocretin deficiency is extremely low, especially if the patient does not have clear cataplexy.
- Rapid weight gain is a troubling symptom that often occurs in children when onset is abrupt. Aggressive treatment close to onset is important in these cases.
- Hypocretin receptor antagonists, also called DORAs, have recently been introduced as hypnotic compounds. Based on animal data, these compounds are likely to exacerbate narcolepsy because patients still have a few hypocretin cells left. Hypocretin agonists, compounds that should be beneficial in narcolepsy, are under development.
- Pandemrix, a flu vaccine directed against the 2009 H1N1 swine flu, was shown to have significantly increased the risk for developing narcolepsy in Europe. No other vaccine, including U.S. preparations, has been implicated.

SUMMARY

Type 1 narcolepsy is both a common neurologic disorder and a model disorder to further our understanding of REM sleep and sleepiness regulation. During the past 50 years, research has been greatly facilitated by the existence of a canine narcolepsy model, now rapidly replaced by rodent models. Narcolepsy-cataplexy, now reclassified as type 1 narcolepsy, is most commonly caused by a loss of hypocretin-producing neurons in the hypothalamus. Low CSF hypocretin-1 can be used to diagnose type 1 narcolepsy. The disorder is associated with HLA-DQB1*06:02, other HLA genes, and polymorphisms in immune system genes, indicating that the cause in most patients is an autoimmune destruction of these neurons. Studies in narcoleptic canines have substantiated a tight parallel between the pharmacologic control of cataplexy and that of REM sleep. Using this model, it was found that the mode of action of stimulant medications is presynaptic stimulation of dopaminergic transmission, whereas anticataplectic compounds exert their therapeutic effects primarily through adrenergic uptake inhibition. The hypocretin system

sends strong excitatory projections onto monoaminergic cells. The loss of hypocretin is likely to create a cholinergic-monoaminergic imbalance in narcolepsy. Abnormally sensitive cholinergic transmission and depressed dopaminergic and histaminergic transmission are believed to underlie abnormal REM sleep and daytime sleepiness in canine narcolepsy (see Pharmacology of Narcolepsy).

Although most cases of narcolepsy-cataplexy are caused by hypocretin neuron loss, some patients with cataplexy and most without cataplexy have normal CSF hypocretin-1 levels. This may either reflect disease heterogeneity or a partial loss of hypocretin neurons without significant CSF hypocretin-1 decrements. A critical area in need of further inquiry is the role of CSF hypocretin-1 testing in predicting therapeutic response to medications already in use to treat the symptoms of narcolepsy.[94] Developing an assay that could reliably measure hypocretin-1 in plasma may be possible and would also be extremely useful if low levels were observed in narcolepsy.[94] Measuring hypocretin-1 levels may some day facilitate development of therapies that interrupt or delay the development of disease. Additional work comparing drug responses in patients with type 1 and 2 narcolepsy is needed.

There is increasing evidence that the autoimmune destruction of hypocretin cells is triggered by upper airway infections. In children, when narcolepsy onset is often more abrupt, a history of strep throat is often reported. The onset of narcolepsy in children is seasonal and peaks in spring and summer, strongly suggesting that winter infections may precipitate narcolepsy a few months later. Most strikingly, increased incidence of childhood narcolepsy was found in early 2010 in China, following the 2009 H1N1 swine flu pandemic, and possibly in the United States as well. Strongly suggesting that H1N1 itself is involved, H1N1 vaccinations in Europe using Pandemrix increased the number of new narcolepsy cases many fold. More mysteriously, however, risk was not increased with other vaccines, maybe because the content of the various vaccines varied and AS03 is a particularly strong adjuvant for stimulating $CD4^+$ T cells.

Explaining the link between the HLA-TCR association and hypocretin deficiency must be a high priority. It may be possible to use CSF hypocretin-1 testing to evaluate the extent of hypocretin cell loss in early stages of the disease (e.g., in children), thus facilitating the development of treatments that may arrest or at least delay disease progression. Similar strategies using immunosuppression have been used in other autoimmune diseases, such as type 1 diabetes mellitus. In one case, 2 months after an abrupt onset, we tried high-dose prednisone but did not observe significant effects on symptoms and CSF hypocretin-1 levels[233]; however, in this case, very low hypocretin-1 levels were already observed, suggesting the possibility that irreversible damage to cells had already occurred. In other patients with recent onset, intravenous immunoglobulin administration was reported to have positive effects in some open-label studies,[234,235,234-239] suggesting the need for placebo-controlled studies.[240] We anticipate that in time, patients at risk for narcolepsy will be identified through genetic typing monitored with biomarkers (e.g., measuring T-cell populations bearing specific TCR idiotypes, occurrence of specific infections), therefore allowing early intervention to stop hypocretin cell immune destruction.

Chapter 90

Chapter Highlights

- Narcolepsy disrupts the maintenance and orderly occurrence of wake and sleep stages. Cataplexy is a highly specific symptom of narcolepsy, but many other symptoms can be seen in a variety of sleep disorders.
- The diagnosis of narcolepsy with cataplexy (type 1) is straightforward; however, the diagnosis of narcolepsy without cataplexy (type 2) is challenging and requires a good understanding of available diagnostic tests and their limitations.
- Narcolepsy with cataplexy is caused by loss of the hypocretin-producing neurons. As hypocretins influence many neurologic functions, narcolepsy is associated with multiple comorbidities, and it is important to recognize and to treat these comorbid conditions in addition to treating narcolepsy.
- Although there is no cure for narcolepsy, treatments are often effective and include both behavioral and pharmacologic approaches.

Gélineau[1] first coined the term narcolepsy in 1880 to designate a pathologic condition characterized by irresistible and brief episodes of sleep recurring at close intervals. Although Westphal[2] and Fisher[3] previously published reports of patients with excessive daytime sleepiness (EDS) and episodic muscle weakness, Gélineau was the first to characterize narcolepsy as a distinct syndrome. He wrote that falls, or "astasias," sometimes accompanied attacks. Henneberg[4] later referred to these attacks as cataplexy. In the 1930s, Daniels[5] emphasized the association of daytime sleepiness, cataplexy, sleep paralysis, and hypnagogic hallucinations with the syndrome. Referring to these symptoms as the clinical tetrad, Yoss and Daly[6] and Vogel[7] reported nocturnal sleep-onset rapid eye movement (REM) periods in narcolepsy patients, a finding confirmed in the following years.[8-11] However, it was von Economo who first hypothesized that narcolepsy is caused by injury to neurons in the lateral hypothalamus. He also indicated an association between narcolepsy and the influenza pandemic that occurred in 1918–1919.[9,10]

The discovery of the hypocretin peptides (often called orexins by basic researchers),[11,12] the mapping of hypocretin projections from the lateral hypothalamus to many parts of the brain (including the sleep-wake and autonomic nervous regulatory system),[13] and the discovery that the hypocretin-producing neurons are destroyed in the brains of people with narcolepsy[14,15] are key elements in our current understanding of narcolepsy. Honda and Juji[16] were the first to discover that narcolepsy is strongly associated with human leukocyte antigen (HLA) DQB1*06:02. Further findings of other immune function genes strongly support the concept that narcolepsy with cataplexy in its most common form is likely an autoimmune disorder of the brain (see Chapter 89).[17] Although this is the most common cause of narcolepsy, destruction of the hypocretin neurons or their projections by other pathologic processes (e.g., trauma, tumors, infections)[18] can cause secondary cataplexy.[19]

Hypocretins control many functions, and narcolepsy is more than just sleepiness or dysfunctional REM sleep. Narcolepsy causes instability of wake and sleep stages; patients have the capacity to achieve wakefulness and non-REM (NREM) and REM sleep but are unable to maintain these states. In addition, patients with narcolepsy can have intermixed fragments of sleep states, such as cataplexy, which likely represents a combination of the waking state and the paralysis of REM sleep.[20]

CLINICAL FEATURES

The third edition of the *International Classification of Sleep Disorders* reclassified this syndrome into narcolepsy type 1 (narcolepsy with cataplexy, Na-1) and narcolepsy type 2 (narcolepsy without cataplexy, Na-2).[21] The classic tetrad of symptoms includes EDS with variable amounts of cataplexy, sleep paralysis, and hypnagogic hallucinations. EDS occurs in all patients with narcolepsy, but only about one third of patients have all four of these symptoms. Automatic behaviors and disrupted nighttime sleep also commonly occur. Symptoms suggestive of narcolepsy can occur in any person who is severely sleep deprived, but *only* cataplexy is unique to narcolepsy. Narcolepsy has a population prevalence of 0.02% to 0.06%[22-25] and affects both sexes equally.

Sleepiness

Unwanted episodes of sleep recur several times a day, not only under favorable circumstances, such as during monotonous sedentary activity or after a heavy meal, but also in situations in which the patient is fully involved in a task. The duration of sleep may vary from a few seconds to several minutes if the patient is in an uncomfortable position to longer than 1 hour if the patient is reclining. Narcolepsy patients characteristically wake up feeling refreshed, and there is a refractory period of relative alertness for 1 hour to several hours before the next

episode occurs. These relatively short but refreshing naps can help differentiate patients with narcolepsy from patients with idiopathic hypersomnia, who often take long and unrefreshing naps. Despite feeling sleepy during the day, narcolepsy patients generally do not sleep more in 24 hours compared with those without narcolepsy. Apart from sleep attacks, patients complain of feeling abnormally drowsy, resulting in poor performance at work, memory lapses, and even gestural, ambulatory, or speech automatisms. These lapses are related to unconscious microsleep episodes that can become more frequent as the patient fights against falling asleep.

Cataplexy

Cataplexy occurs in 60% to 70% of narcolepsy patients.[21,26] It is an abrupt and reversible decrease or loss of muscle tone, most frequently elicited by strong emotions such as laughter, anger, and surprise. It may involve certain muscles or the entire voluntary musculature. Most typically, the jaw sags, the head falls forward, the arms drop to the side, and the knees buckle. Awareness is preserved throughout the attack.

The severity and extent of cataplexy attacks can vary from a state of absolute powerlessness, which seems to involve the entire voluntary musculature, to limited involvement of certain muscle groups or to no more than a fleeting sensation of weakness. Some patients may report blurred vision, possibly due to eyelid or extraocular muscle weakness. Speech may be impaired, and respiration may become irregular during an attack. Apneas have never been recorded, but short pauses similar to those seen during nocturnal REM sleep in healthy subjects may occur.

Rarely in a cataplexy attack, there is complete loss of muscle tone that can lead to total body collapse and serious injuries, such as skull or other bone fractures. However, in most cases, cataplexy is not that extreme and may even go unnoticed by individuals nearby. An attack may consist of only slight buckling of the knees. Patients may perceive this abrupt and short-lasting weakness and simply stop or stand against a wall. Speech may be broken or slurred because of intermittent weakness affecting the voice. If the weakness involves only the jaw or speech, the patient may present with wide masticatory movement or an unusual attack of stuttering speech. If it involves the upper limbs, the patient may complain of "clumsiness," reporting activity such as dropping cups or plates or spilling liquids when surprised, laughing, and the like. Many patients have both complete and partial attacks. At the onset of cataplexy, the abrupt muscle inhibition can be interrupted by recurrent bursts of normal muscle tone that can mimic a tremor.

Short attacks are the most common presentation of cataplexy. Because they do not resemble the "classic" full-blown attack of cataplexy, they are often missed even by skilled physicians without the aid of electromyographic recording.[27] By the same token, the skilled physician must be cautious not to overdiagnose normal phenomena, such as the "rubber knees" that precede the anxiety of public speaking or "rolling on the ground laughing." The duration of each cataplexy attack—whether partial or complete—is variable, lasting from a few seconds to 30 minutes, but in most cases it is 30 seconds to 2 minutes. Status cataplecticus is a rare manifestation of cataplexy, characterized by prolonged cataplexy lasting hours, and it can be triggered by sudden withdrawal of cataplexy-suppressing medications or insufficient sleep.

Attacks can be elicited by emotion or stress. Laughter and anger seem to be the most common triggers, although "laughing excitedly" is a more potent trigger than simple laughter.[28] These attacks can also be induced by a feeling of elation while listening to music, reading a book, or watching a movie, but a certain intensity of the associated emotion triggered by the abrupt new situation is an important element. Cataplexy can be induced merely by remembering a happy or funny situation, and it may rarely occur without clear precipitating acts or emotions, particularly if the patient is sleepy. It often occurs when the patient is telling a joke and frequently occurs when the patient simply anticipates saying something humorous. A large phenotypical diversity has been reported for cataplexy that may render it difficult to recognize.[28]

The following features are seen in narcolepsy but can also occur in normal individuals.

Sleep Paralysis

This is a terrifying experience that occurs on falling asleep or awakening from sleep. Patients find themselves paralyzed, suddenly unable to move the limbs, to speak, or even to breathe deeply. The patient is fully aware of the condition and can recall it completely later. This state is frequently accompanied by hallucinations. In many episodes of sleep paralysis, but especially the first occurrence, the patient may experience extreme anxiety associated with fear of dying. This anxiety is often greatly intensified by the terrifying hallucinations that may accompany the sleep paralysis. Patients often interpret the experience as being "scared stiff." With more experience with the phenomenon, however, the patient usually learns that episodes are brief and benign, rarely lasting longer than a few minutes and always ending spontaneously. Sleep paralysis may occur as an independent and isolated phenomenon, and 3% to 5% of the general population may be affected by it.[29]

Hallucinations

Patients may have vivid and often unpleasant auditory or visual hypnagogic hallucinations at sleep onset, either during daytime naps or at night.[30] Hallucinations may occur on awakening; these hypnopompic hallucinations may be more characteristic of narcolepsy than the hypnagogic ones at sleep onset. The visual hallucinations usually consist of simple forms (colored circles, parts of objects) that are either constant or changing in size. The image of an animal or a person may present abruptly and more often in color. Auditory hallucinations are also common, although other senses are seldom involved. The auditory hallucinations can range from a collection of sounds to an elaborate melody. Hypnopompic hallucinations are often perceived as so vividly realistic that the patient acts on them on awakening. For example, patients with narcolepsy have been known to call the police because of intruders being in the home, only to discover after authorities have searched the house that it was all a hallucination. The exact boundary between hypnagogic/hypnopompic hallucinations and dreams is not a clear one. In some cases of unrecognized narcolepsy with daytime hypnagogic/hypnopompic hallucinations, the patient may be mistakenly diagnosed as having a psychosis.[31]

Another common and interesting type of hallucination reported at sleep onset involves elementary feelings (i.e., experiencing picking, rubbing, or light touching), changes in location of body parts (e.g., arm or leg), or feelings of levitation

or extracorporeal experiences (e.g., the body in space or floating above the bed) that may be elaborate. For example, the patient may report, "I am above my bed and I can also see my body below" or "I am a few feet up and people are jumping over my body." The abrupt motor inhibition that involves the spinal cord motor neurons may alter the feedback of information that is normally used by the central nervous system to gauge the position of the body and limbs.

Sleep Disruption

Narcolepsy patients commonly experience fragmented nocturnal sleep. Night sleep is often interrupted by repeated awakenings and sometimes accompanied by terrifying dreams. Ironically, patients complain of difficulty in staying asleep at night, although they may fall asleep repeatedly during daytime. Rarely, insomnia and secondary daytime tiredness are the initial complaints. The sleep disruption may be enhanced by the presence of periodic limb movements, REM sleep behavior disorder, or obstructive sleep apnea (OSA), which appear to be common in narcolepsy patients.[32,33]

COMORBID ASSOCIATIONS

Narcolepsy is caused by loss of the hypocretin neurons, and this can result in additional symptoms as hypocretins regulate other functions in addition to sleep-wake regulation. Weight gain is common, and it seems to be worse in younger children at the onset of narcolepsy. Particularly in Chinese children, body mass index tends to increase and fatty infiltration of the tongue may occur, decreasing the size of the upper airway and consequently leading to OSA. The association with OSA was noted years ago,[32] but its high frequency was appreciated only in later years.[33]

Hypocretin deficiency affecting the autonomic nervous system can affect blood pressure and heart rate.[34,35] It also affects core body temperature, which can affect sleep tendencies.[36] Sexual dysfunction (difficulty with erection and ejaculation)[37] was also documented long ago, a problem that may be worsened by some anticataplexy drugs. Increased frequency of migraines has also been reported.[38] Increase in pain threshold and chronic pain is also frequent in narcolepsy.[39]

Psychiatric comorbidities are frequent, especially major depressive disorder, with one study reporting an increased risk of suicide.[40] In Chinese children who developed narcolepsy with cataplexy during prepubertal age, severe schizophrenia was noted in about 10% of these children. The schizophrenia poorly responded to treatment and was also associated with abnormalities particularly in the prefrontal lobe documented by positron emission tomography studies compared with other patients with narcolepsy or schizophrenia.[41]

These comorbidities may impair quality of life, not only for the patient but also for the caretaker. Poor quality of life in this group has been documented in studies from multiple countries.[42-45] A large study in the United States involving 55,871 subjects, including 9312 in the narcolepsy group and 46,559 matched controls, characterized health care utilization, costs, and productivity in a large population of patients diagnosed with narcolepsy; it showed that narcolepsy with its comorbidities was associated with substantial personal and economic burdens, as indicated by significantly higher rates of health care utilization and medical costs. Narcolepsy is also associated with higher rates of accidents, employee absence due to short-term disability, job dismissal, and early retirement.[46]

ONSET OF CLINICAL SYMPTOMS

In white people, the first symptom often develops near the age of puberty; the peak age at which reported symptoms occur is 15 to 25 years,[47] but narcolepsy and other symptoms have been noted as early as 2 years and at 6 months of age in one child with a hypocretin gene mutation.[48] In China, the onset of narcolepsy often occurs during the prepubertal years.[49] A few years ago, many children and adolescents developed narcolepsy with cataplexy soon after receiving Pandemrix, a specific brand of H1N1 influenza vaccine no longer in use. In these post-vaccination patients, narcolepsy with cataplexy began at an earlier age than previously reported in white children.[50-52]

A survey of 157 narcolepsy patients found that about 80% experienced symptoms before the age of 30 years,[53] but a second, small peak of onset has been noted between 35 and 45 years and near menopause in women. In those who developed narcolepsy at age 60 years or later, cataplexy was the most common initial symptom.[53] Diagnosis of narcolepsy is often delayed more than 10 years, especially if cataplexy is initially absent.[54]

EDS and irresistible sleep attacks usually occur as the first symptoms, either independently or associated with one or more symptoms. Sleep attacks are enhanced by high environmental temperature, indoor activity, and idleness. Symptoms may lessen with age but never resolve completely. When cataplexy occurs years after onset, the diagnosis of narcolepsy type 1 versus type 2 can be challenging. Cataplexy occasionally occurs before the abnormal sleep episodes or EDS, in which case it is a major source of difficulty in diagnosis. Cataplexy can vary in frequency from a few episodes during the patient's entire lifetime to one or several episodes per day. Cataplexy attacks have an overall tendency to decrease in frequency with aging. Disturbed nocturnal sleep usually worsens with age.[54]

DIAGNOSIS OF NARCOLEPSY

The diagnosis of narcolepsy requires a clinical history of EDS and a positive Multiple Sleep Latency Test (MSLT) result, with a mean sleep-onset latency of 8 minutes or less and two or more sleep-onset REM periods (SOREMPs).[21] It is important to categorize narcolepsy as type 1 (Na-1, narcolepsy with cataplexy) or type 2 (Na-2, narcolepsy without cataplexy). Na-1 is a distinct phenomenon with consensus on presentation and diagnostic criteria. Na-2, however, remains an "evolving diagnosis," and there is much debate among researchers on whether it is a distinct phenomenon or part of the spectrum of narcolepsy and idiopathic hypersomnia.

Na-1 requires a history of EDS and at least one of the following: (1) cataplexy and a positive MSLT result or (2) cerebrospinal fluid (CSF) hypocretin-1 deficiency. Hypocretin-1 deficiency is defined as CSF hypocretin-1 level less than one third of normal (or ≤110 pg/mL if analyzed using the Stanford reference). Low CSF hypocretin-1 levels are highly specific for Na-1 and can confirm the diagnosis.[55] Nocturnal SOREMPs (within 15 minutes of sleep onset) can be included in the tally of SOREMPs.[21]

The diagnosis of Na-2 is more of a problem and challenging even to the most experienced clinician.[56] Na-2 requires a history of EDS and a positive MSLT result. Na-2 is a clinical diagnosis or rather a diagnosis of exclusion. A positive MSLT result is not specific for narcolepsy; many symptoms of narcolepsy are nonspecific, and biomarkers are lacking in Na-2. CSF hypocretin-1 levels are almost always normal, and cataplexy is absent. Moscovitch et al[57] also cautioned against the diagnosis of narcolepsy if EDS and two or more SOREMPs on MSLT are the only positive findings. The authors also found that only 84% of individuals with complaints of EDS and cataplexy presented with two or more SOREMPs on MSLT, a replication of findings by van den Hoed et al[58] 10 years earlier. When the MSLT was repeated daily for 4 days, all subjects with EDS and cataplexy had two or more SOREMPs in at least one MSLT. A recent consensus paper addresses the challenges of diagnosing narcolepsy without cataplexy and in standardizing its definition and diagnostic criteria.[56]

EVALUATION OF SLEEPINESS

The Stanford Sleepiness Scale,[59] a 7-point scale, was developed to quantify the subjective sleepiness of patients throughout the day, but it is often difficult for patients to accurately rate themselves every 15 to 20 minutes. The Epworth Sleepiness Scale is more commonly used as an index of subjective sleepiness in adults (see Chapter 169). The Pediatric Daytime Sleepiness Scale is validated for use in children and teenagers.

Multiple Sleep Latency Test

The MSLT (see Chapter 169) was designed to measure physiologic sleep tendencies in the absence of alerting factors.[60] This test consists of five scheduled naps, usually at 10 AM, noon, and 2, 4, and 6 PM, during which the subject is polygraphically monitored in a comfortable, soundproof, dark bedroom while wearing street clothes. The MSLT records the latency for each nap (time between lights out and sleep onset), the mean sleep latency, and the presence or absence of REM sleep during any of the naps.[61] On the basis of polygraphic recording, REM sleep that occurs within 15 minutes of sleep onset is considered a SOREMP.[62] After each 20-minute monitoring period, the patient stays awake until the next scheduled nap. A positive MSLT result requires a mean sleep-onset latency of 8 minutes or less plus two SOREMPs.

There is controversy about the reliance on a positive MSLT result in diagnosing narcolepsy. With increasing age, there is a progressive decrease in the number of SOREMPs and an increase in the mean sleep latency on the MSLT, suggesting that the standard criteria may be too stringent in older patients.[63] General population investigations have shown that normal subjects can present with two or more SOREMPs, and there seems to be a greater chance of having narcolepsy with the presence of two or more SOREMPs, but the likelihood of having narcolepsy in relation to an increasing number of SOREMPs is unknown.[64] In Japan, there is less reliance on the MSLT, and a positive history of cataplexy associated with EDS is systematically required for the diagnosis of narcolepsy.[65] Cataplexy is pathognomonic of narcolepsy, but it may be difficult to rely on this symptom alone, particularly when cataplexy is partial (i.e., limited to the head and neck or neck and upper arms). Anic-Labat et al[66] developed a self-administered questionnaire that validated cataplexy in 1000 subjects.

Although the MSLT is an objective measurement of sleepiness, it comes with limitations. A positive MSLT result is not specific for narcolepsy. Studies have found a high prevalence of SOREMPs and a positive MSLT result in the general population.[64,67] In the normal population, MSLT scores vary with age, sex, and puberty. Prepubertal children between the ages of 6 and 11 years appear to be hyperalert. In postpubertal subjects, mean MSLT scores below 8 minutes are generally considered to be in the pathologic range; those above 10 minutes are considered to be normal. Mean latencies of 8 to 10 minutes represent a gray area.[57] There is a progressive decrease in the number of SOREMPs and an increase in the mean sleep latency on the MSLT as a function of age.[63] Recent data from the Wisconsin Sleep Cohort reported that in older adults, the diagnostic value of the MSLT is strongly affected by shift work and chronic sleep deprivation.[68] The MSLT can produce false-positive results in these groups. Therefore, it is especially important to document prior sleep history by use of actigraphy or sleep log. Data from the Wisconsin cohort also found that positive MSLT results were much more common in men.[68]

An MSLT performed alone has drawbacks and should not be valid as it measures sleepiness regardless of its cause, which may simply be due to sleep deprivation or another sleep disorder. The MSLT also ignores repetitive microsleeps that can lead, in borderline cases, to daytime impairment not scored by conventional analysis. It is important to exclude factors or other sleep disorders that may cause false-positive results with the MSLT, such as sleep apnea, sleep deprivation, shift work, or medications.[69-73] Another potential drawback of the MSLT is related to methodology. Despite published guidelines from the American Academy of Sleep Medicine on how to conduct the test,[74] sleep laboratories vary widely in methodology, including interscorer reliability in identifying SOREMPs. On the night preceding the MSLT, the subject should undergo standard nocturnal polysomnography. Throughout the total nocturnal sleep period, any sleep-related biologic abnormalities responsible for sleep fragmentation and sleep deprivation are recorded. Unfortunately, some sleep laboratories do not uniformly perform polysomnography on the preceding night or use actigraphy or sleep log before conducting the MSLT. Guidelines on when to discontinue medications that may interfere with SOREMPs are also lacking, and protocols are not uniform across sleep laboratories.

Finally, actigraphy for 2 weeks (or sleep logs if actigraphy is not available) should be performed before the sleep study to document sleep-wake schedules and to rule out circadian disorders or insufficient sleep. Once the nocturnal sleep recording has eliminated specific diseases, the MSLT aids in the diagnosis of narcolepsy with a mean sleep latency of 8 minutes or less and the presence of two or more SOREMPs. To date, the MSLT is the best test available in diagnosing Na-2.

Browman et al[75] proposed adding to the MSLT a test for the maintenance of wakefulness (MWT). The MWT tests the patient's ability to remain awake in a comfortable sitting position in a dark room for different trials given at 2-hour intervals during the daytime. Traditionally, the test was composed of five sessions at 2-hour intervals (10 AM, noon, and 2, 4, and 6 PM), similar to the MSLT. Each opportunity for remaining

awake lasts 20 minutes. More recently, the test consists of four 40-minute sessions administered at 2-hour intervals (9 and 11 AM, 1 and 3 PM), with a cutoff point around 30 minutes before falling asleep. The MWT has been validated with different performance tests, including driving simulation.[76] The MWT may be helpful in drug trials, in evaluating a patient's response to treatment, and in evaluating the risk of falling asleep associated with specific jobs or activities.[75]

Polysomnography

Overnight polysomnography is used to rule out other sleep disorders and to evaluate sleep quality and quantity. The occurrence of REM sleep within 15 minutes of sleep onset on the preceding polysomnogram before the MSLT can now be included in the requirement of two or more SOREMPs on the MSLT.[21] This new recommendation is based on the finding that the occurrence of REM sleep 15 minutes or less after sleep onset is highly specific for Na-1 and associated with low CSF hypocretin-1 levels.[73]

Genetic Testing

Genetic testing is sometimes used in the clinical diagnosis of narcolepsy. HLA DQB1*06:02 is the most specific genetic marker for narcolepsy across all ethnic groups, and it is found in 95% of patients with Na-1 (with cataplexy).[17,77] In Na-2 (no cataplexy), only 40% of subjects have DQB1*06:02,[17] so HLA testing is generally unhelpful. Furthermore, genetic testing alone is insufficient for the diagnosis of narcolepsy as DQB1*06:02 is found in 18% to 35% of the general population. However, previous studies indicated that homozygosity for DQB1*06:02 doubles to quadruples the risk for narcolepsy. The investigation of children in East Asia led to the recognition of an HLA association between HLA DQB1*06:02 and DQB1*03:01 that also increased the risk for narcolepsy. Conversely, the presence of DQB1*05:01 and DQB1*06:01 in heterozygote individuals decreased the risk for development of narcolepsy.[66,78,79]

Hypocretin-1 Measurement in Cerebrospinal Fluid

Hypocretin neurons are selectively damaged in patients with narcolepsy with cataplexy.[80] By a lumbar puncture, a very low or nonexistent level of hypocretin can confirm the diagnosis of narcolepsy with cataplexy.[81-85] CSF hypocretin-1 levels below 110 ng/L (measured using the Stanford University technique) have a high positive predictive value (94%) for narcolepsy type 1.[55,80] In Na-2, however, hypocretin-1 levels are usually normal. A study by Andlauer et al[86] found that only 24% of Na-2 patients had low CSF hypocretin-1 levels (defined as <110 pg/mL). A low CSF hypocretin-1 level without cataplexy is also more common in African Americans.[86] Currently, CSF hypocretin-1 measurement is the most accurate diagnostic technique available. CSF hypocretin-1 can help confirm narcolepsy and distinguish between type 1 and type 2. In rare cases, low CSF hypocretin-1 levels may be due to a neurologic condition that injures the hypocretin neurons, such as brain tumors, encephalitis, vascular diseases, and brain trauma.[80]

CHILDREN AND NARCOLEPSY

Prepubertal children developing narcolepsy often present with severe symptoms, with cataplexy and partial cataplexy predominantly involving the face, and a variable amount of movement abnormalities, such as "tics" or other neurologic problems, may be simultaneously noted.[87] Frequent irritability and aggressive behavior have been mentioned in large series. Rapid and tremendous weight gain is common in these early appearance cases.[88] In one series, rapid development of obesity in children with narcolepsy was associated with later development of schizophrenia.[41] Children with early narcolepsy onset may also present with precocious puberty.[89]

TREATMENT

The goal of all therapeutic approaches is to optimize control of narcolepsy symptoms and to allow the patient to have a full personal and professional life. Treatment goals should focus on improving EDS, cataplexy attacks, hypnagogic/hypnopompic hallucinations, sleep paralysis, nocturnal sleep, and psychosocial difficulties. When selecting medications, clinicians must take into account possible side effects because narcolepsy is a lifelong illness and patients will have to receive medication for years. Tolerance or addiction may occur with some compounds. In addition, hypertension and psychosis are the most commonly reported complications associated with the long-term use of stimulant medications. The treatment of narcolepsy must balance the maintenance of an active life with the avoidance of side effects and tolerance to medications.[90]

Behavioral Approaches

Part of the difficulty in treating patients with narcolepsy involves the patient's frustration over the delay in diagnosis. The consequence of this, particularly in a young patient, is the development of reactive depressive symptoms. One of the most important initial treatments is a referral to patient support groups organized by sleep disorders centers, such as those sponsored by the U.S. National Sleep Foundation and the Narcolepsy Network. Other support groups exist in most western European countries and in North America. Patients can also find helpful information on the websites of the American Academy of Sleep Medicine, Stanford University, and Harvard University.

Career counseling is also important because patients and their employers must be educated about jobs that patients with narcolepsy should avoid, including shift work, on-call schedules, driving and the transportation industry, and any job necessitating continuous attention for long hours without breaks, particularly under monotonous conditions. Some of these difficulties can be overcome if the employer recognizes the importance of short 15- to 20-minute naps every 4 hours during the daytime. In addition to scheduled naps, other important behavioral treatment targets include a regular sleep-wake schedule, avoidance of frequent time zone changes, and overall good sleep hygiene (Tables 90-1 and 90-2).

Pharmacologic Treatments

Pharmacologic treatments are listed in Tables 90-1 to 90-3.

All Major Symptoms of Narcolepsy (Excessive Daytime Sleepiness, Cataplexy, Disturbed Nocturnal Sleep)

Sodium Oxybate. Sodium oxybate is the sodium salt of gamma-hydroxybutyrate (GHB) and is approved by the Food and Drug Administration for the treatment of cataplexy and sleepiness in narcolepsy. In 1979, Broughton and Mamelak[91]

Table 90-1 Examples of Initial Treatment Packages for Children

Prepubertal Children	Adolescents
General Measures	
Contact school to alert teachers	Contact school to alert teachers
Nap at lunchtime	Emphasize need for regular nocturnal sleep schedule
Nap at 4 or 5 PM	Try to obtain 9 hours of nocturnal sleep
	Nap at lunchtime and 4 or 5 PM
Medications for Sleepiness	
Modafinil 100–200 mg*	Modafinil 100–400 mg*
Sodium oxybate 6–8 g	Sodium oxybate 6–9 g
Methylphenidate 5 mg (2–4 tablets†)	Methylphenidate 5 mg (2–6 tablets†) or 20 mg sustained-release tablet in AM (on empty stomach)
Atomoxetine 10–25 mg	Atomoxetine 10–25 mg
Medications for Cataplexy‡	
Sodium oxybate 6–8 g	Sodium oxybate 6–9 g
Venlafaxine XR 75–150 mg in AM	Venlafaxine XR 75–150 mg in AM
Fluoxetine 10–20 mg in AM	Fluoxetine 10–40 mg in AM

*Modafinil is started at 100 mg in the morning for 5 days, and a second dose of 100 mg is then added at lunchtime, if needed. This is usually sufficient in prepubertal children. Pubertal children may require a further increase (after 5 days) to an additional 100 mg in the morning and, if still needed later, another 100 mg at noon.
†Usually 10 mg when waking up on an empty stomach, 5 mg around lunchtime, and 5 mg at 3 PM.
‡No medications have specifically received approval by the Food and Drug Administration for use in patients with narcolepsy younger than 16 years. The use of antidepressants for cataplexy has not been approved by the Food and Drug Administration.

first suggested that GHB improved cataplexy, daytime sleepiness, and disturbed nocturnal sleep in patients with narcolepsy. GHB, a naturally occurring central nervous system metabolite found in highest concentrations in the hypothalamus and basal ganglia, acts as a sedative to consolidate sleep. Sodium oxybate is now a treatment of choice for narcolepsy with cataplexy. In addition to its use as an anticataplexy medication, it also improves EDS and nocturnal sleep disturbances. Sodium oxybate treats cataplexy through an unknown mechanism that is thought to be related either to its consolidation of REM sleep or to a secondary interaction with dopamine secretion.[91-96]

GHB is a neurotransmitter and neuromodulator that affects dopamine, serotonin, gamma-aminobutyric acid (GABA), and endogenous opioids. It is postulated to act mainly through $GABA_B$ receptors as mice lacking $GABA_B$ receptors show little response to GHB and similar drugs. In large, multicenter studies, sodium oxybate has shown efficacy in improving the EDS and cataplexy of narcolepsy.[95,97] The drug is normally taken at bedtime with the patient already in bed to avoid falls. A second dose is taken approximately 2.5 to 4 hours after the first one while the patient is in bed. Its half-life is 90 to 120 minutes. Many patients start with a total nightly dose of 4.5 to 6 g, and the dose is gradually titrated up during 2 to 3 months to 6 to 9 g, based on improvements in EDS and cataplexy. These doses produce a small increase in nocturnal total sleep time and a decrease in sleep paralysis, hypnagogic hallucinations, and nightmares. Deeper nighttime sleep is apparent early in treatment, but it may take more than 3 months to see the full benefits of the medication on EDS and cataplexy. Overall, a positive effect on cataplexy is reported. The response is gradual but is seen much more rapidly than the effect on alertness, with a significant decrease in the frequency of cataplexy attacks. If patients wake 1 to 2 hours after dosing, they may be confused and disoriented, and they may have episodes of enuresis, particularly at a high dosage of 9 g and also during initial use of the drug. Nausea as well as sluggishness in the early mornings may be seen with high dosage. In clinical trials, sodium oxybate produced dose-related improvements in cataplexy and EDS, with no acute rebound effect with withdrawal after 4 weeks of therapy. There is a sustained increase in efficacy on cataplexy during 12 months, with maintenance of efficacy on daytime sleepiness. Sodium oxybate shows a dose-related increase in slow wave sleep and reduction in nocturnal awakenings at doses of 7.5 to 9 g. Studies have not shown negative effects on respiratory parameters.[95-104] It is not recommended in pregnancy.

Atomoxetine. Atomoxetine, a selective noradrenergic reuptake inhibitor also used in the treatment of cataplexy, has been effective in improving daytime sleepiness, particularly in children. It may allow prescription of only one medication to deal with both main symptoms (daytime sleepiness and cataplexy), but it is less effective than modafinil and sodium oxybate in older teenagers and adults.[105-107]

Excessive Daytime Sleepiness

Modafinil. Modafinil is a first-line pharmacologic treatment for EDS in narcolepsy. Modafinil is a wake-promoting drug whose mechanism is unknown, but it has been hypothesized to selectively activate wake-generating sites in the hypothalamus. The mechanism of action of modafinil (2-[(diphenylmethyl)sulfinyl]acetamide) is different from that of the amphetamines.[108-111] In narcoleptic dogs, the drug increases extracellular dopamine in a hypocretin receptor 2–independent manner.[111] In dopamine transporter knockout mice, the lack of response to the wake-promoting action of modafinil indicates that dopamine transporters do play a role and are necessary for wake-promoting actions of this drug.[111]

Modafinil improves EDS in narcolepsy patients with relatively few side effects. Headache is the most common complaint, followed by nervousness, nausea, and dry mouth. These symptoms can be reduced by a slow and progressive increase in dosage. Blood pressure should be monitored as the drug may cause elevated pressures. Modafinil is not addictive and has a low potential for abuse. There is no evidence that tolerance develops to the effects of modafinil on EDS. Most European studies suggest twice-daily administration in the morning and at lunchtime. Its elimination half-life is 10 to 12 hours. Modafinil can be administered concurrently with anticataplexy medications. Modafinil can reduce the efficacy of oral contraceptives, and therefore patients should use alternative methods of birth control.

Table 90-2 Examples of Initial Treatment Packages for Adults

General Measures

Avoid shifts in sleep schedule.
Avoid heavy meals and alcohol intake.
Regular timing of nocturnal sleep: 10:30 PM to 7 AM
Naps: Strategically timed naps if possible (e.g., 15 minutes at lunchtime, 15 minutes at 5:30 PM)

Medications for Sleepiness

The effects of stimulant medications vary widely among patients. The dosing and timing of medications should be individualized to optimize performance. Additional doses, as needed, may be suggested for periods of anticipated sleepiness.
Modafinil* 100–200 mg (taken when waking up in the morning) and 100–200 mg at lunchtime *or*
Sodium oxybate† at bedtime: dosage must start low at 2.25 g taken twice while in bed (at bedtime and 2.5–4 hours after bedtime); increase to total dosage of 5 to 6 g within 2–4 weeks. This initial dose is usually ineffective, so increase to 3 g at bedtime and 3 g approximately 2.5 to 4 hours after bedtime if tolerated. Depending on response, dosage can be increased to as high as 9 g total nightly dose. Do not increase above 9 g because of risk of serious side effects during sleep. It may take more than 2 months for daytime symptoms to improve, and cataplexy may improve faster than excessive daytime sleepiness. If the patient is already taking a daytime stimulant, it may be possible to reduce the stimulant dose or to discontinue it once a therapeutic dosage of sodium oxybate has been reached.
Methylphenidate 5 mg (3 or 4 tablets; 10 mg when waking up; 5 mg 30 minutes before lunch; 5 mg near 3 pm; better action is always obtained if the drug is taken on an empty stomach) or 20 mg SR in the morning (on an empty stomach)

If Persistent Difficulties

Modafinil 200 mg in the morning and 200 mg at lunch (total daily dosage, 400 mg) *or*
Add sodium oxybate (GHB) at bedtime: dosage must start low as indicated above
Methylphenidate (SR): 20 mg in the morning; 5 mg after noon nap; 5 mg at 4 pm *or*
Possibly (more in teenagers) atomoxetine: start at 0.5 mg/kg within 1 week to appropriate dosage of 1 to 1.2 mg/kg taken in the morning

If No Response

Dextroamphetamine sulfate: 15 mg on awakening; 5 mg after noon nap; 5 mg at 3:30 or 4 PM (or 15 mg at awakening and 15 mg after noon nap)

Medications for Cataplexy‡

Sodium oxybate (see above)
Venlafaxine 150–300 mg
Fluoxetine 20–60 mg
Duloxetine 60 mg

If No Response

Clomipramine 75–125 mg, *or*
Viloxazine 150–200 mg, *or*
Imipramine 75–125 mg

*Modafinil works best in naive subjects. It should be the drug of first choice in children and adults.
†Response to sodium oxybate is slow.
‡Medications may be taken in the evening near bedtime (sodium oxybate, clomipramine, imipramine), only in the morning (fluoxetine), or in the morning and at lunchtime (viloxazine, venlafaxine). The only medications specifically approved for use in narcolepsy by the Food and Drug Administration are modafinil and sodium oxybate.
SR, Sustained-release tablet.

As modafinil mainly blocks dopamine reuptake, it can be less potent and have fewer side effects than amphetamine, which can block reuptake of dopamine, norepinephrine, and serotonin. As a consequence, when patients are switched from an amphetamine to modafinil, they may report "less control over sleepiness" and worse cataplexy. The combination of modafinil and venlafaxine can provide better control of cataplexy.

Armodafinil. Armodafinil is the active *R*-enantiomer of modafinil and is approved by the Food and Drug Administration for the treatment of EDS in narcolepsy. In a multicenter, randomized, double-blind, placebo-controlled trial of 196 subjects with narcolepsy, armodafinil significantly improved EDS throughout the day.[112,113] It may produce slightly longer improvements in EDS than regular modafinil. The usual dosing is 150 to 250 mg/day. Side effects are similar to those of modafinil, which include headache, nausea, dizziness, and insomnia.

Amphetamines and Amphetamine-like Central Nervous System Stimulants. Stimulants include amphetamines, such as dextroamphetamine and methamphetamine, and amphetamine-like drugs, including methylphenidate. Like modafinil, these drugs block the reuptake of dopamine, but they also block the reuptake of norepinephrine and serotonin and can cause efflux of these monoamine neurotransmitters from nerve terminals. These neurotransmitters all promote

Table 90-3 Narcolepsy Drugs Currently Available

Drug	Usual Dosage* (All Drugs Administered Orally)
Treatment of EDS	
Stimulants†	
Modafinil	100–400 mg/day
Sodium oxybate	6–9 g/day (divided in two doses)
Methylphenidate	10–60 mg/day
Atomoxetine	10–25 mg/day
Dextroamphetamine	5–60 mg/day
Methamphetamine	20–25 mg/day
Treatment of Auxiliary Effects (e.g., Cataplexy)	
Sodium oxybate (gamma-hydroxybutyrate)	6–9 g/day (divided in two doses)
Antidepressants‡	
Without Atropinic Side Effects	
Venlafaxine XR	75–300 mg/day
Fluoxetine	20–60 mg/day
Viloxazine	50–200 mg/day
Duloxetine	60 mg/day
With Atropinic Side Effects	
Protriptyline	2.5–20 mg/day
Imipramine	25–200 mg/day
Clomipramine	25–200 mg/day
Desipramine	25–200 mg/day

*On occasion, depending on clinical response, the dose may be outside the usual dosage range.
†Most stimulants should be administered in divided doses, commonly in the morning and at lunchtime. This is recommended for amphetamines and modafinil. Methylphenidate has a fast elimination rate, so the slow-release (SR) formula may be helpful in the morning (e.g., 20 mg SR). If it is administered by 5-mg increments, the usual timing of methylphenidate administration is every 3 to 4 hours until 3 PM.
‡The only medications approved for use in narcolepsy by the Food and Drug Administration are modafinil and sodium oxybate.
EDS, Excessive daytime sleepiness.

wakefulness and suppress REM sleep, and consequently, stimulants improve EDS, increase the latency to NREM and REM sleep, and reduce the percentage of REM sleep. At standard doses, amphetamines can enhance performance on simple motor and cognitive tasks; improve coordination; and increase strength, endurance, and mental and physical alertness, especially in monotonous situations.[114]

In adults, methylphenidate and amphetamines at dosages of more than 60 mg/day tend to produce side effects, including frequent worsening of the nocturnal sleep disruption and higher frequency of psychosis, paranoia, and psychiatric hospitalizations. Rebound hypersomnia is more frequent with higher dosages of amphetamines. These stimulants have a high potential for abuse and development of tolerance and therefore should be administered at the lowest effective doses. The drug is usually administered in three divided doses with a maximum of 20 mg in the morning, 20 mg at lunch, and 20 mg no later than 3 PM as these medications can disrupt sleep. The slow-release form may provide gradual and delayed responses during the daytime.

Our patients subjectively rate the effectiveness of methylphenidate on a level similar to that of modafinil. Black and Houghton[115] performed a double-blind placebo controlled comparison trial between modafinil, sodium oxybate, or the combination for the treatment of EDS in 270 adult narcolepsy patients and found that both drugs are effective in treating EDS and are additive when used together. Both the stimulant medications and the anticataplexy drugs are hepatically metabolized, so any liver dysfunction will affect both classes of drug. Thus, checking baseline liver function is recommended.

Cataplexy and REM Sleep–Related Symptoms

Cataplexy is thought to be an intrusion of REM sleep atonia into wakefulness. REM sleep is strongly suppressed by norepinephrine and serotonin, and drugs that increase levels of these neurotransmitters are often effective in suppressing cataplexy.

Monoamine Nonspecific Reuptake Inhibitors. Tricyclic antidepressants were the first medications used to treat cataplexy. The older tricyclics include imipramine, clomipramine, and protryptiline.[116-118] Tricyclic antidepressants inhibit monoamine (serotonin, norepinephrine, dopamine) reuptake and block cholinergic, histaminic, and alpha-adrenergic transmission and were the first drugs of choice, particularly protriptyline. However, they have significant anticholinergic side effects, including dry mouth, sweating, constipation, tachycardia, difficulty in urinating, and particularly sexual dysfunction that led to impotence in more than 40% of male narcolepsy patients. Tricyclic antidepressants are now rarely used to treat cataplexy long term as better options are available.

Selective Serotonin Reuptake Inhibitors. Several selective serotonin reuptake inhibitors have an active noradrenergic reuptake blocker metabolite; the prototype is fluoxetine and its active metabolite norfluoxetine.[119] We recommend starting with 20 mg of fluoxetine in the morning and increasing to 60 to 80 mg/day in two divided doses if needed. Fluvoxamine at 25 to 200 mg/day has been shown to be mildly effective for cataplexy. Compared with the classic tricyclic antidepressants, selective serotonin reuptake inhibitors can be less efficacious but have fewer side effects. Adverse effects include insomnia, nausea, and sexual difficulties. Tolerance to this class does not develop.

Serotonin-Norepinephrine Reuptake Inhibitors. These newer antidepressants have been found to be effective for cataplexy, sleep paralysis, and hypnagogic/hypnopompic hallucinations and are the recommended drugs because of fewer side effects and greater efficacy. The most commonly used drug of this class is venlafaxine XR, a potent inhibitor of serotonin and noradrenergic reuptake and a weak inhibitor of dopamine reuptake. At a dose of 75 to 150 mg, venlafaxine has been the most widely used of these compounds both in adults and in children; it has good efficacy and is better tolerated than the tricyclics. Duloxetine (60 mg each morning) is another serotonin-norepinephrine reuptake inhibitor that reduces cataplexy.[120] Atomoxetine (18 to 100 mg once a day or in two divided doses) is a highly specific noradrenergic reuptake inhibitor and has been tried in cases of resistant cataplexy after failure of fluoxetine, venlafaxine, and other serotonin reuptake inhibitors.

Serotonin-norepinephrine reuptake inhibitors and selective serotonin reuptake inhibitors are category C drugs when they are used during the last trimester of pregnancy and may lead to serious respiratory and feeding side effects in the neonate immediately after birth. Pregnant women may need to be progressively withdrawn from these medications before the third trimester. The withdrawal must be slow to avoid a marked cataplexy rebound that usually occurs on day 3 or 4 and peaks near day 10 after completion of withdrawal.

Medication Side Effects

Common side effects have been well described in previous reports, but some side effects that are rarely mentioned may be more important in narcolepsy patients, such as the appearance of periodic limb movements during sleep[121,122] and the development of REM sleep behavior disorder, particularly in older subjects.[63] Rebound cataplexy and other REM sleep–related symptoms, such as sleep paralysis and hypnagogic/hypnopompic hallucinations, can be seen with abrupt drug withdrawal. Patients should be withdrawn from these medications slowly after chronic drug use; the recommended withdrawal schedule is one dose every 4 days.[123]

Treatment of Children

On the basis of our clinical experience,[124] we recommend modafinil for the treatment of EDS in children with narcolepsy. A study of 13 children (mean age, 11.0 years) receiving modafinil (mean dose, 346 mg/day) showed reduction in sleep attacks in 90% of subjects and prolongation of sleep latency on MSLT (from 6.6 minutes to 10.2 minutes), and it appeared to be safe and well tolerated for more than a year.[125] Modafinil seems to work best when it is administered in the morning and at noon, but this may be a problem with children, so a single dose in the morning can been prescribed. The drawback of single-dose administration is that the therapeutic effect may not last late into the day. A 5-mg methylphenidate tablet may be added when the child returns from school, if needed. The drug must not be given too late to avoid inducing sleep-onset insomnia.

If modafinil cannot be prescribed, methylphenidate is the second best option; it has a short half-life and is available in a slow-release form.[126] In children, the recommended dose is based on weight, and we try to maintain a maximum of 30 mg/day administered as the slow-release form. The drug is given in the morning (15 mg) and at lunchtime (15 mg maximum) in the best case or as a 20- or 30-mg slow-release preparation in the morning.

In our experience, sodium oxybate also improves EDS and cataplexy in children with narcolepsy. The therapeutic response was sustained over time and without development of tolerance. Nausea, constipation, and mood changes were reported as initial side effects, and in a small series, side effects occurred in 40% of the children but rarely led to discontinuation of the drug. NREM parasomnias (e.g., sleep walking, night terrors) and enuretic episodes have also been reported, particularly at higher dosages.[127] Worsening of untreated OSA has been reported, and risk is probably higher in obese children.

Emerging Therapies and Pharmacologic Agents Under Investigation

Emerging treatments for narcolepsy can be classified into five broad categories, which include hypocretin-based treatments, immunotherapy, thyrotropin (TRH) analogues and promoters, histamine (H_3) antagonists, and combinations of or variations of currently used therapies and other therapies.[128,129]

A major limitation to hypocretin-1 replacement therapy is that it has to cross the blood-brain barrier to reach the central nervous system.[130-134] Because of the connections between the central nervous system to the outside environment through olfactory and trigeminal nerves, intranasal administration may deliver hypocretin into the nervous system.[129] A double-blind, randomized, crossover, placebo-controlled, within-subject design study administered human recombinant hypocretin-1 intranasally to eight Na-1 patients at bedtime and showed a reduction in REM sleep time and fewer wake to REM sleep transitions. A study of the same design conducted in 14 Na-1 subjects with MWT, attention testing, and second night of polysomnography[131] showed less REM sleep and less wake-REM transitions with treatment. Asahi et al[134] and Lang et al[135] found that the entire hypocretin protein is not necessary for biologic activity and selectivity for the corresponding receptors.[134,135] They determined the minimal sequences needed for receptor activation by synthesizing different combinations of C-terminal and N-terminal truncated peptides, in addition to fragments of central sequences of hypocretin-1 and hypocretin-2. They reported several analogues that selectively activated hypocretin-2 receptors.

Transplantation techniques, such as those used in Parkinson disease for dopaminergic neurons, could be applied, although survival of grafted hypocretin-producing neurons and immune reactions are limiting factors.[134] There is some evidence that TRH and TRH agonists have stimulant, antidepressant, and neurotrophic effects, and TRH has been shown to increase wakefulness and to decrease cataplexy in canine narcolepsy.[128]

Drugs that increase histamine signaling may be useful for improving EDS in narcolepsy.[129,136] Histamine signaling promotes wakefulness, whereas decreased activity leads to sleepiness. Histamine H_3 receptors are inhibitory autoreceptors on histamine and other monoamine neurons, and thus drugs that block these receptors (H_3 receptor antagonists or inverse agonists) should improve EDS. Thioperamide, a potent H_3 antagonist, significantly enhances wakefulness in hypocretin/orexin-deficient narcoleptic mice.[137] In a phase II study of people with narcolepsy, the H_3 inverse agonist pitolisant (40 mg each day) improved EDS compared with placebo. The most frequent side effects were headache, nausea, insomnia, and a fainting sensation. This study did not examine the effect of pitolisant on other symptoms of narcolepsy, such as cataplexy.[138] In 2012, a case series of four teenagers with narcolepsy with cataplexy was published demonstrating some positive data for off-label use of pitolisant for 13 months.[139]

The hypothesis of an autoimmune etiology has led some investigators to explore immunotherapy as a treatment for narcolepsy, including corticosteroids, plasmapheresis, and intravenous immune globulin.[140-143] The cases studies reported limited success and reduction of symptoms, suggesting that if a therapeutic benefit is obtained, it may be limited by timing of treatment (i.e., at onset of disease). Case reports present opposite findings.[142,143] Currently, intravenous immune globulin and corticosteroids are not recommended, and further trials are needed to determine the possible role of immunomodulators in the treatment of narcolepsy.[143]

ADX-N05, a unique phenylalanine derivative with dopamine and noradrenergic activities, is being investigated for the treatment of daytime sleepiness in narcolepsy patients.[144]

Preliminary findings show that at doses of 150 to 300 mg/day, the agent is well tolerated and significantly improved objective and subjective symptoms of sleepiness in 100 adults with narcolepsy. At 12 weeks, the average sleep-onset latency on the MWT was 12.8 minutes with the active drug compared with 2.1 minutes with placebo. Epworth Sleepiness Scale scores also significantly improved with active drug.

CLINICAL PEARLS

- Narcolepsy is characterized by the clinical tetrad of EDS, cataplexy, sleep paralysis, and hypnagogic/hypnopompic hallucinations. All narcolepsy patients have EDS, but other symptoms are present only in some individuals. Cataplexy is unique to narcolepsy, but other symptoms are nonspecific.
- Narcolepsy is associated with multiple comorbid conditions, including childhood obesity, sleep apnea, and psychiatric disorders including depression.
- The diagnosis of narcolepsy type 1 requires a history of EDS and one of the following: (1) low CSF hypocretin-1 level or (2) cataplexy and a positive MSLT result. The diagnosis of narcolepsy type 2 requires a history of EDS and a positive MSLT result.
- Genetic testing for HLA DQB1*06:02 is positive in 95% of patients with narcolepsy type 1, in 40% of patients with narcolepsy type 2, and in 18% to 35% of the general population without narcolepsy. Therefore, HLA testing is not recommended as a diagnostic tool.
- The MSLT must be preceded by nighttime polysomnography to rule out other sleep disorders and to document adequate sleep. The MSLT result can be falsely positive in other sleep disorders, such as shift work, sleep apnea, or sleep deprivation, and it is influenced by age, sex, and puberty.
- Sodium oxybate (GHB) can improve cataplexy, EDS, and fragmented sleep.
- Modafinil and armodafinil can reduce EDS without many of the side effects associated with older stimulants.

SUMMARY

Narcolepsy is a chronic neurologic sleep disorder due to hypocretin neuron loss resulting in EDS, disturbed nocturnal sleep, and intrusions of aspects of REM sleep in wakefulness, such as cataplexy, sleep paralysis, and hypnopompic/hypnagogic hallucinations. The syndrome is associated with multiple comorbidities. Multiple sleep latency testing after overnight polysomnography shows short sleep latencies (mean sleep-onset latency of 8 minutes or less) and two or more SOREMPs. In its most classic presentation, narcolepsy is associated with destruction of hypocretin neurons located in the lateral hypothalamus and absence of or significant reduction of hypocretin-1 measured in CSF. The destruction of hypocretin neurons is thought to be related to an autoimmune process. The treatment of narcolepsy has improved over time, with the newest compounds providing fewer side effects compared with classic stimulants for EDS and tricyclic antidepressants for cataplexy. Modafinil or armodafinil improves daytime sleepiness, and sodium oxybate improves both cataplexy and daytime sleepiness, and these are the drugs of choice. Narcolepsy is a complex syndrome that involves dysfunction in the timing of changes in wake and sleep stages. Medications with an alerting effect can help but will not completely control the multifaceted problems associated with this syndrome.

Chapter 91

Idiopathic Hypersomnia

Yves Dauvilliers; Claudio L. Bassetti

Chapter Highlights

- Idiopathic hypersomnia (IH) is a rare etiology of central nervous system hypersomnolence characterized clinically by excessive daytime sleepiness with long and unrefreshing naps, prolonged and undisturbed nocturnal sleep, and great difficulty waking up and "getting going" (sleep drunkenness) after sleep.
- Polysomnography often shows normal nighttime sleep with high sleep efficiency and slow wave sleep percentages, without sleep apneas or periodic limb movements. A short mean sleep latency (<8 minutes) on the Multiple Sleep Latency Test is required with no, or a maximum of one, sleep-onset REM periods, or a prolonged sleep time on prolonged continuous polysomnography or actigraphy (total sleep time ≥11 hours on 24-hour monitoring).
- The pathophysiology of IH remains unclear. In the absence of a specific biologic marker, IH is a diagnosis of exclusion with a broad differential diagnosis, including atypical forms of depression, narcolepsy without cataplexy, sleep apnea syndrome, and behaviorally induced insufficient sleep syndrome.
- Pharmacologic options for IH are similar to the treatments for narcolepsy, including modafinil, methylphenidate, pitolisant, mazindol, and dextroamphetamine.
- Symptoms of IH may be severe and long lasting, but spontaneous improvement in hypersomnolence can occur in one fourth of patients.

HISTORY

The term idiopathic hypersomnia (IH) was used as early as 1829 (*"die idiopathische chronische Schlafsucht"*) for excessive daytime sleepiness (EDS) of undetermined origin.[1] Bedrich Roth was the first in the late 1950s to describe a syndrome characterized by EDS, prolonged sleep, and sleep drunkenness and by the absence of "sleep attacks," cataplexy, sleep paralysis, and hallucinations. The terms "independent sleep drunkenness" and "hypersomnia with sleep drunkenness" were initially suggested.[2-5] Overlapping features with narcolepsy were identified from the beginning and led to the use of such labels as essential narcolepsy, independent narcolepsy, and non–rapid eye movement (NREM) sleep narcolepsy.[6,7] Other terms, including idiopathic central nervous system hypersomnolence, functional hypersomnia, hypersomnia with automatic behavior, harmonious hypersomnia, and IH, were also put forward in the 1990 version of the *International Classification of Sleep Disorders* (ICSD). The 2005 version of the ICSD differentiated between IH with long sleep time (>10 hours; (polysymptomatic, classic form of IH) and IH without long sleep time (monosymptomatic form). The recent ICSD3 now pools both conditions (with and without long sleep time) into one heterogeneous condition because researchers were unable to objectively separate both forms of the disease based on the length of nocturnal sleep; patients above the cut-off of 10 hours of sleep showed no significant differences in daytime sleepiness assessed by the Epworth Sleepiness Scale (ESS), Multiple Sleep Latency Test (MSLT), and percentage of subjects with sleep drunkenness or unrefreshing naps.[8,9]

Although recent research provides some intriguing findings, the pathophysiology of IH remains unclear. The absence of a specific biomarker for IH, together with the presence of subtle forms of sleep-disordered breathing and chronic sleep insufficiency that may mimic IH, raises questions about the "true" frequency and clinical picture of IH.

EPIDEMIOLOGY

In the absence of systematic studies, the exact prevalence and incidence of IH remain unknown. A few reports suggest that IH patients represent only about 1% of patients seen in neurologic sleep centers and are 5 to 10 times less common than patients with narcolepsy.[8,10] Hence, the prevalence of IH in the general population may be estimated at approximately $50/10^6$, a figure much lower than the 300 to $600/10^6$ suggested until the early 1980s.[4,5,11] In a large series recently published, patients with IH represented 1% of 6000 patients seen at a single respiratory sleep center. Because IH was 60% as prevalent as narcolepsy, questions about the diagnostic accuracy arise.[12]

The age of onset of symptoms varies, but it is frequently between 10 and 30 years. In contrast to narcolepsy with cataplexy, the age of onset is sometimes difficult to pinpoint

because of the insidious onset of the condition over several weeks or months. When established, symptoms are generally stable and long lasting. Spontaneous improvement in EDS may be observed, however, in up to one fourth of patients.[10,12,13]

A female preponderance was found in some but not all series.[9,10,12,13] In one to two thirds of cases (see later), IH appears to be familial.

PATHOGENESIS

Genetic and Environmental Factors

IH can present in families, and these individuals are more likely to have long sleep time. On rare occasions, IH and narcolepsy may occur in the same family.[10,8,14] An autosomal dominant mode of inheritance has been discussed, and females may be affected more frequently[9]; however, no well-done studies in the field have been performed. In a few series, an association with diabetes or obesity was observed.[10,15]

Given the existence of overlapping features between IH and narcolepsy (see later), there has been an interest in potential HLA markers for IH. Despite reports of an increase in HLA-DQ1,[10] -DR5, -Cw2,[16] and -DQ3,[17] and of a decrease of HLA-Cw3,[18] no consistent findings have emerged. HLA typing currently does not play a role in the diagnosis of IH.

A recent study investigated the dynamics of the expression of circadian clock genes in dermal fibroblasts of 10 patients with IH compared with healthy controls. The amplitude of the rhythmically expressed *BMAL1, PER1,* and *PER2* was dampened in cells from IH patients over two circadian periods, and the overall expression of *BMAL1* was significantly reduced.[19]

Hypersomnia usually starts insidiously. Occasionally, EDS is first experienced after transient insomnia, abrupt changes in sleep-wake habits, overexertion, mood change, general anesthesia, viral illness, or mild head trauma.[10]

Neurochemistry

Montplaisir and colleagues found a decrease in dopamine and indoleacetic acid in both patients with IH and those with narcolepsy.[20] Faull and associates found dysregulation of the dopamine system in narcolepsy and of the norepinephrine system in IH.[21-23] These metabolic data suggest the possibility of a dysfunction of aminergic arousal systems in IH. Additional experimental and human data give some support to this hypothesis. In the cat, both hypersomnia and disturbances of monoamines can be induced by a lesion of ascending noradrenergic pathways.[24] Cerebrospinal fluid (CSF) hypocretin-1 levels are normal in IH.[15,25-27] Several studies have examined CSF levels of histamine in patients with IH and other central hypersomnias with discordant results.[28,29] Based on a highly sensitive and selective ultraperformance liquid chromatography tandem mass spectrometry assay to quantify simultaneously histamine and its major metabolite tele-methylhistamine, Dauvilliers and colleagues found no differences for these two amines between patients with narcolepsy with or without cataplexy or IH and patients with a complaint of EDS without any objective underlying etiologies.[30] Moreover, no association was found between CSF histamine and tele-methylhistamine, subjective or objective daytime sleepiness, or use of psychostimulants.

Rye and associates examined modulators of gamma-aminobutyric acid (GABA) signaling in patients with non-hypocretin-deficient central nervous system hypersomnia, some of whom met criteria for IH. They found that in the presence of GABA, CSF from these patients enhanced $GABA_A$ receptor function in an in vitro electrophysiologic assay (i.e., a whole-cell patch-clamp recording to measure the potentiation of $GABA_A$ receptor currents).[31] In this assay, inhibitory chloride currents were increased when cells were exposed to GABA combined with CSF from patients with hypersomnia compared with controls. Moreover, flumazenil, a drug that antagonizes the sedative-hypnotic actions of benzodiazepines, reversed this enhancement of $GABA_A$ signaling and may have improved vigilance in some hypersomnolent patients. This recent discovery is exciting but requires replication because CSF alone from IH patients had no effect on $GABA_A$ signaling. Also, no differences were observed between different diagnostic categories, and no correlation was found between GABA potentiation and measures of vigilance. Finally the bioactive CSF component remains unknown.

Neurophysiology

Researchers have hypothesized that the sleepiness of IH could be caused by homeostatic and circadian disturbances of sleep regulation as well as deficient activity in arousal systems.

Some investigators have reported an abnormally high level of slow wave activity (SWA) due either to an abnormal slow decay of SWA or to a normal decay of an enhanced level of SWA.[32,33] A recent study showed more sleep instability (i.e., more sleep stage shifts and more time spent in stage 1 sleep) in lighter sleep in IH than in narcolepsy with cataplexy (NC); more stable slow wave sleep (SWS) in IH than in normal subjects; and reduced cyclic alternating pattern (CAP) rate in IH, with higher values than NC in light NREM sleep and lower than normal subjects in SWS. These findings suggested an alteration of sleep microstructure in IH, with potentially less restorative sleep and daytime sleepiness in IH.[34]

Reports of increased sleep spindles activity at the beginning and at the end of sleep and of a delayed start (and decline) of melatonin and cortisol secretion suggest a primary circadian deficit in IH.[35,36] Unfortunately, core temperature recordings have not yet been reported in IH.

The detection of delayed and smaller P300 potentials after awakening in IH documents a cortical activation problem in these patients, but the origin of this phenomena is unknown.[33,37]

CLINICAL FEATURES

Excessive Daytime Sleepiness

Patients describe a constant, daily excessive daytime sleepiness (EDS) that only rarely leads to involuntary naps ("sleep attacks"). The ESS score is typically high (>11/24). As with other forms of EDS, alcohol, exercise, heavy meals, and warm environments can accentuate EDS. Daytime drowsiness leads to naps that are usually prolonged (typically >1 hour) and frequently unrefreshing. The unrefreshing quality of napping and the sleep drunkenness associated with awakenings lead patients to fight sleepiness as long as they can.

Patients who do not nap are particularly prone to episodes of drowsiness and automatic behavior, which are usually signaled by blank stares. During these episodes, patients act in

an unplanned and often inappropriate way. Patients have reported finding themselves miles from their homes while driving or performing inappropriate actions such as sprinkling salt on coffee, putting dirty plates in a clothes dryer and turning on the machine, writing incoherent sentences during classes, having loud and irrelevant bursts of speech, and so on. Amnesia of such occurrences is common, although patients are usually aware that they have had one of their "drowsy" episodes when they are later confronted with the results of their automatic behavior.

Some IH patients may present with symptoms that overlap with narcolepsy. A few patients with IH may report occasional episodes of irresistible sleep as well as short and refreshing naps.[10] Conversely, patients with narcolepsy with cataplexy may have nonimperative EDS, prolonged naps, and prolonged nocturnal sleep, and both conditions can occur in the same family (see earlier).

Nocturnal Sleep

Nocturnal sleep is typically subjectively long and undisturbed, with more than 10 hours of sleep. A few patients may report sleep times of 12 to 19 hours per day on weekends and holidays. In most IH patients, EDS does not improve with prolonged sleep, so extreme sleep times (sleep >12 hours per day) during weekdays is uncommon.[10]

Awakening after nocturnal sleep is typically difficult. Sleep drunkenness, confusional arousal (also called *syndrome d'Elpénor* after the youngest of Ulysses' comrades who killed himself during an episode of incomplete awakening) is reported by 40% to 60% of patients[5,10,12] but can be seen also in other forms of EDS. Patients are hard to awaken; they can be aggressive and verbally and physically abusive during that twilight state if they are awakened, even at their own request. The patient may be confused and unable to react adequately to external stimuli on awakening. The time it takes to "get going" in the morning may be as long as 2 to 3 hours (sleep inertia); when severe, it is sometimes called sleep drunkenness. Sleep inertia is also common when patients are awakened from naps.

Associated Features

Sleep paralysis and hallucinations are common in narcolepsy but less frequent in IH.[10,27,38] Cataplexy-like episodes and nightmares are also possible.

Depressive symptoms were noted in 15% to 25% of patients in Roth's series and confirmed in later studies.[5,10,14,39,40] Mood changes not qualifying for the diagnosis of affective disorder may precede or follow the onset of EDS and evolve independently. The presence of major depression is incompatible with the diagnosis of IH (see later).

Headache is a frequent symptom in patients with EDS. Migraine- and tension-type headaches are reported in about 30% of patients with IH. Pain complaints of other localizations are occasionally observed.

Patients with IH were found to have lower scores in most domains of the quality-of-life inventory, excluding "bodily pain," "social functioning," and "mental health," whereas treatment seems to have a positive influence only on "role limitations due to emotional problems" and "mental health."[41]

Neurovegetative symptoms such as cold hands or feet, lightheadedness on standing up, orthostatic hypotension, or syncope have been observed.[3,10,13,42,43] The frequency of these symptoms is, however, similar in narcolepsy and IH.[13]

An increased body mass index has been noted in a few series.[10,15]

DIAGNOSIS

Definition Criteria

The ICSD3 has redefined the criteria of IH, resulting in a more heterogeneous diagnosis than in the previous classification (ICSD2), which distinguished two forms with and without long sleep time. ICSD3 diagnostic criteria include the following:

1. Daily periods of irresistible need to sleep or daytime lapses into sleep for more than 3 months
2. Absence of cataplexy
3. MSLT showing <2 sleep-onset REM periods (SOREMPs) or no SOREMPs if the REM sleep latency on the preceding polysomnogram is 15 minutes or less
4. The presence of at least one of the following:
   - - MSLT showing a mean sleep latency of 8 minutes or less
   - - Total 24-hour sleep time of 660 minutes or longer (typically 12 to 14 hours) on 24-hour polysomnography (PSG) monitoring (performed after the correction of chronic sleep deprivation) *or* by wrist actigraphy in association with a sleep log (averaged over at least 7 days with unrestricted sleep)
5. Insufficient sleep syndrome ruled out (if deemed necessary, by lack of improvement of sleepiness after an adequate trial of increased nocturnal time in bed, preferably confirmed by at least 1 week of wrist actigraphy)
6. Hypersomnolence or MSLT findings that are not better explained by another sleep disorder, medical or neurologic disorder, mental disorder, medication use, or substance abuse. Drugs known to affect sleep, sleep latency, and daytime alertness must be carefully evaluated and should be withdrawn for a minimum of 2 weeks before objective tests.

Polysomnography

PSG findings of IH include a short sleep latency, a high sleep efficiency (usually >90%), and increased amounts of deep (slow wave) NREM sleep (Figures 91-1 and 91-2).[3,10,12,43] These findings are nonspecific and can be seen also in patients with behaviorally induced insufficient sleep syndrome (BIISS; see later). Amounts of sleep spindles (throughout the sleep period or at the beginning and end of the night) have been occasionally reported to be elevated in IH[8,35] (Figure 91-3).

In IH, sleep-onset REM sleep episodes are rare, and typically the arousal, apnea-hypopnea, and periodic limb movements indexes are less than 5 to 10 per hour. Some authors believe, however, that periodic limb movements in patients with EDS but without restless legs symptoms may not necessarily preclude the diagnosis of IH. In a few patients otherwise satisfying all other criteria for IH, higher indexes have been observed.[10,12,44,45]

Multiple Sleep Latency Test

MSLT typically shows a mean sleep latency score of less than 8 minutes, and a few IH patients have mean sleep latencies of less than 5 minutes.[9,10,12] SOREMPs occur in 3% to 4% of naps, but never more than once.[10,12] Subjective

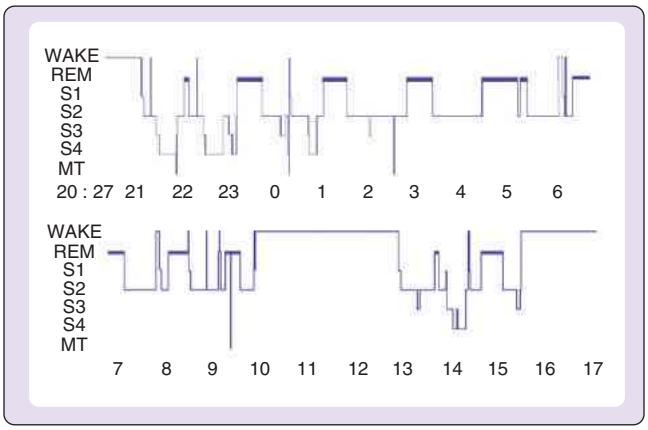

Figure 91-1 A 24-Hour Continuous Hypnogram in Idiopathic Hypersomnia. A 24-year-old woman presented with excessive daytime sleepiness (EDS), prolonged unrefreshing sleep, and sleep drunkenness. Her Epworth Sleepiness Scale score was 18/24. She had frequent hallucinations while falling asleep or on awakening, but no sleep paralysis or cataplexy. Her body mass index was 24, and she had a positive family history for EDS. The polysomnogram was notable for a sleep efficiency of 98%, sleep latency to NREM 2 sleep of 10 minutes, and slow wave sleep 26% of total sleep time. She had no snoring, apneas, or periodic limb movements. Her Multiple Sleep Latency Test showed a mean sleep latency of 4.8 minutes but no sleep-onset REM period. A 24-hour continuous polysomnogram revealed a total nighttime sleep time of 12 hours, 44 minutes and daytime sleep of 2 hours, 36 minutes (a single long nap). Hypocretin-1 in cerebrospinal fluid was normal. HLA-DQB1*0602 positive. Psychiatric assessment was normal. Her EDS improved slightly with modafinil up to 600 mg/day, but her sleep inertia was unchanged.

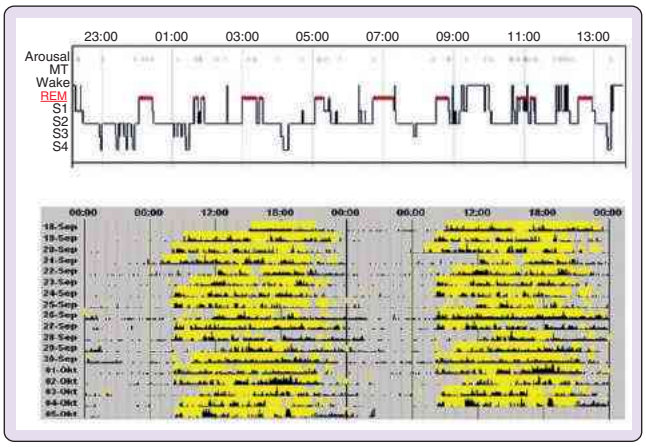

Figure 91-2 Hypnogram and Actigraphy in Idiopathic Hypersomnia. A 32-year-old man presented with excessive daytime sleepiness (EDS), prolonged unrefreshing sleep up to 13 to 18 hours, and sleep drunkenness. His Epworth Sleepiness Scale score was 19/24. He had occasional sleep paralysis and hallucinations. He had migraine headaches, a body mass index of 27, and no family history of EDS. Polysomnography ad libitum over 16 hours showed a sleep efficiency of 92% with a total sleep time of 14.7 hours, latency to NREM 2 sleep of 22 minutes, and slow wave sleep 6% (of sleep period time). He had no snoring, apneas, or periodic limb movements. His Multiple Sleep Latency Test showed a mean sleep latency of 4.3 minutes and no sleep-onset REM period (SOREMP). His Maintenance of Wakefulness Test showed a mean sleep latency of 4.3 minutes and no SOREMP. Two weeks of actigraphy revealed a mean sleep time (rest/sleep) over 48% of the recording time. His cerebrospinal fluid hypocretin-1 level was normal, and HLA-DQB1*0602 was negative. Psychiatric assessment was normal. He did not improve with modafinil, methylphenidate, or melatonin.

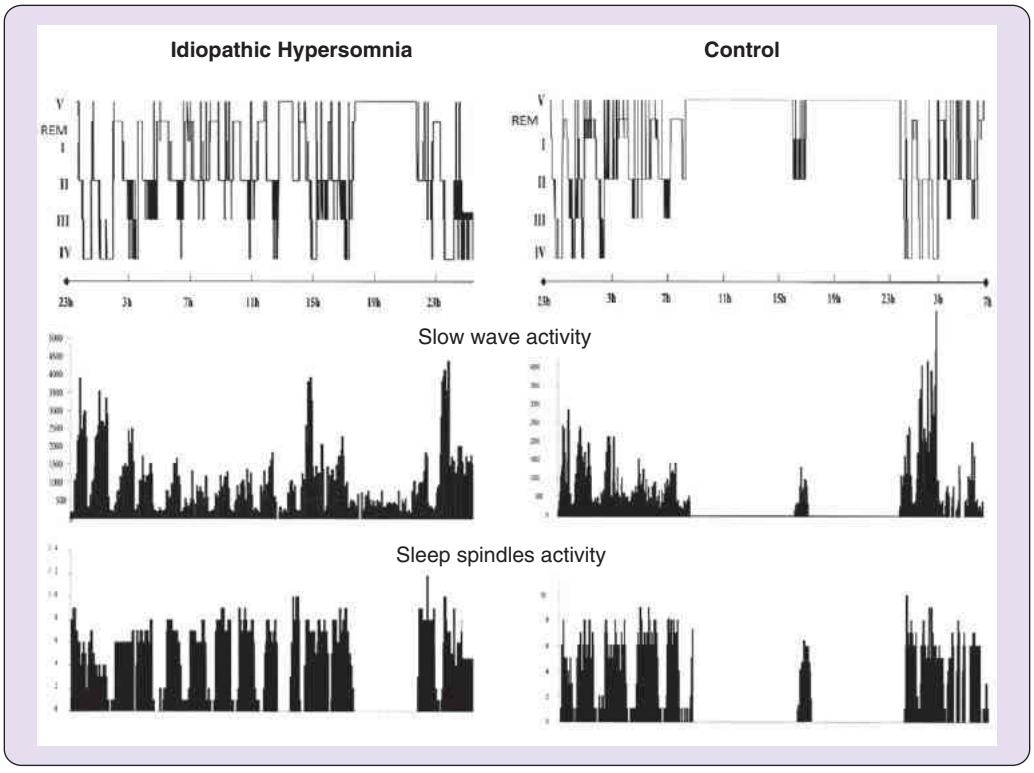

Figure 91-3 Increased Sleep, Slow Waves, and Spindles in Idiopathic Hypersomnia (IH). Prolonged (32 hours) polysomnograms in a 26-year-old woman with IH and long sleep time (*left*) and a 28-year-old control (*right*). The patient with IH has increased total sleep time, persistently high slow wave activity (SWA), and persistent sleep spindles. This patient also has an increase in daytime sleep, including high SWA at about 3 PM.

awareness of sleep during naps is often higher than in patients with narcolepsy.

MSLT is of limited diagnostic value in IH patients with long sleep time.[8,9] The first reason is the usual difficulty keeping the patient awake before the test and between sessions of the test. The second reason is the obligation to wake the patient in the morning to perform the MSLT, thus precluding the recording of prolonged nighttime sleep, which is a typical symptom of IH with long sleep time. Regarding these limits, some patients may have mean sleep latencies longer than 8 or even 10 minutes.[8,9,10,12] In addition, a recent study of 36 patients demonstrated poor test-retest reliability of the MSLT in a clinical population of patients with non-hypocretin-deficient central nervous system hypersomnias.[46] No correlation was found between the mean sleep latencies on the first and second tests, with a change in diagnosis occurring in 42% of patients because of differences in the mean sleep latencies.

Other Polysomnography Protocols

As a result of the limits mentioned earlier of the PSG-MSLT procedure, a prolonged (up to 24 to 32 hours) continuous PSG on an ad libitum sleep-wake protocol was proposed as a diagnostic tool for IH.[8] This protocol allows the documentation of a major sleep episode (>10 hours) and of daytime sleep episodes of more than 1 hour's duration (see Figures 91-2 and 91-3). Spontaneous sleep periods of up to 19 hours were previously reported in IH, with normal MSLT latency.[47] In a series of 11 patients, a total sleep time of 699 ± 130 minutes at night was observed.[48] Several 24-hour recordings have even been suggested to ensure that the patient is saturated with sleep.[43,49]

These protocols, however, have several drawbacks. First, standardization and validation, especially regarding the level of physical and social activity allowed during the recording, is still lacking. (Does the patient remain in bed during the full recording or perform some physical activity, and to what degree? Do these prolonged polysomnograms need to be performed in an ambulatory or only in laboratory setting? Do age and gender modify both night and daytime quantity of sleep obtained in normal controls and in IH patients?). Second, prolonged sleep times are not specific for IH and are also seen in patients with hypersomnia related to neurologic disorders and rarely in depressed patients with EDS.[50-53] Third, a standard MSLT for the diagnosis of narcolepsy without cataplexy would still need to be performed separately. Fourth, a prolonged PSG recording adds considerable cost to the diagnostic workup.

Other Findings

Instead of additional 24-hour PSG, ambulatory actigraphy monitoring over several days can demonstrate the prolonged rest episodes characteristic of IH (see Figure 91-2).[15] In addition, actigraphy is helpful to rule out BIISS (see later) and other circadian disorders that may lead to EDS. However, actigraphy protocols have not been standardized or validated in IH and the differentiation between sleep and rest while awake (clinophilia) may be difficult, especially in the context of mild depression.

Brain magnetic resonance imaging, HLA typing, and assessment of CSF hypocretin-1 levels are not useful in the diagnosis of IH (see earlier) but may be considered to rule out other causes of EDS. Testing for abnormal $GABA_A$ receptor functioning in patients with IH should be considered experimental until it is further validated (see earlier).

DIFFERENTIAL DIAGNOSIS

Narcolepsy with and without Cataplexy

Narcolepsy is a common differential diagnostic consideration, but it is not the most difficult, as demonstrated also by large comparative studies.[8,10,12,13] The presence of EDS with clear-cut (definite) cataplexy, two or more SOREMPs on the MSLT, and low or undetectable CSF hypocretin-1 levels are diagnostic for type 1 narcolepsy (ICSD3). Conversely, long sleep times, sleep drunkenness, long unrefreshing naps, high sleep efficiency, high amounts of SWS on PSG, and absence of (or one at maximum) SOREMPs during MSLT suggests the diagnosis of IH. As pointed out before, some patients fulfilling the current international criteria for IH report a variable EDS associated with irresistible sleep episodes, as well as short and refreshing naps. On the other hand, a few patients with narcolepsy with cataplexy present with nonimperative EDS, prolonged naps, and nocturnal sleep.[10,38,54] Patients with narcolepsy may initially present as EDS without or with mild or rare cataplexy, and the positive diagnosis may be in doubt for months or even years. Finally, an overlap may exist between IH and narcolepsy without cataplexy because similar clinical symptoms may be shared in both conditions, and changes in the number of SOREMPs over two consecutive MSLTs occur in patients with central hypersomnia that may modify the diagnosis.

Unfortunately, CSF hypocretin-1 level has been found to be normal in most patients with either narcolepsy without cataplexy (80% of patients) or IH (100% of patients).[15,25,26]

Sleep-Disordered Breathing Syndromes

IH should be distinguished from sleep-disordered breathing syndromes, including upper airway resistance syndrome (UARS).[55] Patients with UARS complain of isolated EDS and snoring. Examinations reveal a triangular face or a steep mandibular plane, a highly arched palate, a class II malocclusion, and, at times, retroposition of the mandible, but patients need not be obese. Cephalometric radiographs have indicated the presence of a small space behind the base of the tongue (posterior airway space), often near the location of the hyoid bone. These subjects presented repetitive short ("transient") alpha electroencephalographic arousals lasting 3 to 14 seconds that regularly interrupted the abnormally high inspiratory efforts.[55] Standard PSG recordings of these subjects evoked the diagnosis of UARS from the presence of these repetitive transient arousals, increases in snoring just before the arousal, and an increase in inspiratory time and a decrease in expiratory time, which were determined with the use of well-calibrated sensors. No significant change in Sao_2 was seen, and the respiratory disturbance index was low (<5).

A nasal pressure cannula and, in rare, doubtful cases, esophageal pressure monitoring must be included in all sleep studies to confirm the diagnosis of UARS. In patients with isolated snoring and IH, a continuous positive airway pressure trial may be warranted. Lack of improvement would support the latter diagnosis.[10,45]

Behaviorally Induced Insufficient Sleep Syndrome, Chronic Sleep Insufficiency, and Long Sleepers

A careful history is needed to differentiate patients with IH from those with BIISS (chronic insufficient nocturnal sleep) who present with EDS.[56,57] The patient should establish a regular sleep-wake schedule and complete sleep diaries (or actigraphy) for at least 2 weeks before PSG. Typically, BIISS patients sleep 2 to 3 hours longer on weekends than weekdays. PSG and MSLT findings in BIISS may be similar to those in IH (see earlier).

Actigraphy is often necessary to rule out BIIS because the history may be misleading or inconclusive. Particularly difficult is recognizing relative sleep insufficiency in long sleepers. It is possible that besides long sleepers, other individuals may also be more prone to develop hypersomnia in association with sleep insufficiency (Figure 91-4).

Some authors have suggested that IH may represent an extreme phenotype of long sleepers.[8,33] However, patients with insufficient sleep, but rarely those with IH, exhibit a subjective and objective improvement of EDS with prolongation of sleep times or when allowed to sleep ad libitum.

Hypersomnia Associated with Psychiatric Disorders

Hypersomnia associated with psychiatric disorders (atypical depression, bipolar depression, dysthymia or neurotic depression, neurotic hypersomnia) can be difficult to differentiate from IH. Both conditions can include nonimperative EDS, long unrefreshing naps, long sleep times, sleep inertia, and depressed mood. The term *atypical* or *vegetative depression* has been used for the association of major depression with these symptoms. Particularly difficult is the differential diagnosis between IH and mild depression or dysthymia. PSG findings may be very similar, although patients with hypersomnia associated with psychiatric disorders generally have higher amounts of NREM stage 1, less SWS, and lower sleep efficiency.[58] In patients with hypersomnia associated with psychiatric disorders, the MSLT typically shows normal mean sleep latencies. In addition, these patients may spend a large amount of time in bed and acknowledge resting more than sleeping (clinophilia). Patients with hypersomnia associated with psychiatric disorders may exhibit mean sleep times of up to 50% to 60% of the entire actigraphy recording times.[15] Finally, worse EDS in winter months, obesity, and improved EDS with antidepressants are other typical features of atypical depression.

Hypersomnia associated with psychiatric disorders may also, however, be accompanied by abnormal MSLT findings (in 36% of cases in one series[59]), and conversely, patients with IH may exhibit normal MSLT findings.[11,15,60] In unclear cases, formal psychiatric assessment is needed. Treatment with activating antidepressants (selective serotonin reuptake inhibitors [SSRIs], monoamine oxidase inhibitors [MAOIs], norepinephrine reuptake inhibitors) rather than stimulants may be considered in patients in whom a psychiatric disorder is likely to cause the EDS.

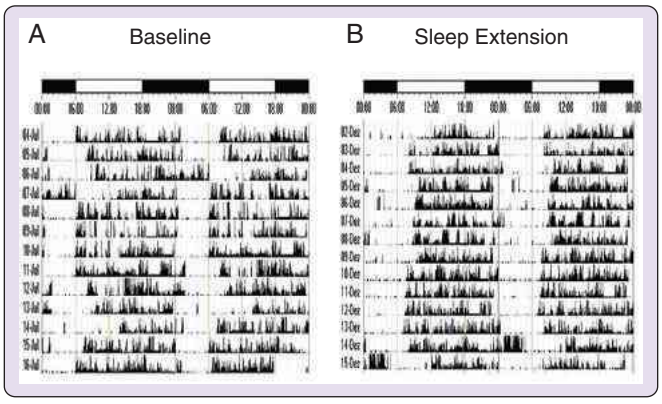

Figure 91-4 Actigraphy in Hypersomnia Associated with Chronic Sleep Insufficiency. A 22-year old man presented with excessive daytime sleepiness (EDS) and sleep drunkenness. His initial Epworth Sleepiness Scale (ESS) score was 20/24. He had occasional sleep paralysis on awakening. He had no cataplexy or hallucinations. His body mass index was 24, and there was no family history of EDS. Initially, he denied sleep deficiency. His Multiple Sleep Latency Test showed a mean sleep latency of 6 minutes and 3 sleep-onset REM periods. **A,** Two weeks of actigraphy (during working days) showed irregular sleep-wake rhythms with a mean sleep time (rest/sleep) more than 35% of the recording time. Hypocretin-1 in cerebrospinal fluid was normal. HLA-DQB1*0602 was positive. Psychiatric assessment was normal. **B,** After sleep extension of more than 1 hour/day, with a mean sleep time (rest/sleep) more than 41% of the recording time, he had complete resolution of his subjective sleepiness and normalization of the ESS score (4/24).

Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS) is characterized by persistent or relapsing fatigue that does not resolve with sleep or rest. One of the clinical difficulties is that CFS is a poorly defined diagnosis, and patients and clinicians may have difficulty differentiating fatigue from a desire for sleep, EDS, and need for sleep. The clinical presentation of CFS is similar to that seen in patients with hypersomnia associated with psychiatric disorders. In addition to fatigue, patients complain of cognitive difficulties, poor mood, anxiety, fever, and myalgias. PSG may show decreased sleep efficiency and recurrent alpha intrusions unlike IH. The MSLT is typically normal. A few patients with CFS may have a specific sleep diagnosis (e.g., sleep apnea, restless legs syndrome [RLS], periodic limb movement disorder [PLMD]).[61]

Restless Legs Syndrome and Sleep-Related Movement Disorders

Sleep-related movement disorders include several conditions such as RLS and PLMD. Patients or bed partners may complain of movements before or during sleep. Nocturnal sleep disturbances and complaints of fatigue and EDS are common.[62]

A clinical interview should address symptoms such as nocturnal restlessness and discomfort of the extremities during periods of inactivity that are relieved with movement. PSG shows periodic and highly stereotyped limb movements during sleep, exceeding more than 10 to 15 per hour in adults. PLMD must be interpreted in the context of a patient's related complaint, with an important overlap between symptomatic and asymptomatic patients according to the leg movement index.

Circadian Disorders

Rarely, EDS during the morning hours in patients with a delayed sleep phase syndrome and EDS during the afternoon hours in patients with advanced sleep phase syndrome may lead to questions regarding the diagnosis, but an appropriate sleep history, sleep logs covering 15 days, and, if needed,

actigraphy indicate a normal total sleep time but abnormal sleep-onset and wake-up times.

Hypersomnia and Neurologic and Medical Disorders

A medical condition may produce hypersomnia and mimic IH with EDS, automatic behaviors, prolonged sleep episodes, and sleep drunkenness. EDS is usually associated with other manifestations of the underlying condition. Rarely, hypersomnia, EDS, or fatigue may be the only or main symptom.

Several neurologic disorders may cause hypersomnia and EDS, with large variation in severity and clinical presentation.[63-65] Brain tumors, encephalitis, stroke, and other lesions in thalamus, hypothalamus, or brainstem can cause hypersomnia that may mimic clinical symptoms of IH but typically also including alteration in sleep continuity.[66] Neurodegenerative conditions such as Alzheimer disease, Parkinson disease, or multiple-system atrophy are also associated with EDS and hypersomnia.[67] Although intrinsic hypersomnia exists in those neurologic disorders, other possible causes of EDS, such as sleep-disordered breathing, drugs, and periodic limb movements, need to be excluded.

Several genetic disorders (Norrie disease, Niemann-Pick type C, Prader-Willi syndrome, myotonic dystrophy) may be associated with central hypersomnia but also with sleep-related breathing disorders or periodic limb movements that may lead to EDS.

Hypersomnia and EDS are occasionally observed in diabetes, metabolic encephalopathy (e.g., hepatic, uremic, hypercarbic), hypothyroidism, and acromegaly, and these disorders can also cause sleep-related breathing and PLMD. Hypophyseal insufficiency and obesity without sleep-disordered breathing can be associated with apathy, EDS, or hypersomnia.[68,69]

Posttraumatic hypersomnia is another etiology of neurologic hypersomnia and is discussed in detail in Chapter 99. Abnormal sleepiness may be observed within 6 to 18 months after head trauma.[70] Clinical symptoms may be similar to IH, but with poor sleep efficiency and frequent association with headaches, memory loss, and lack of concentration. Posttraumatic complaints of EDS have been associated with variable degrees of impaired daytime functioning.

After an acute viral infection (e.g., mononucleosis, pneumonia), patients may develop a (postviral) syndrome of EDS with features similar to those of chronic fatigue and IH.[71] In some of these patients, an encephalitic process or elevated levels of inflammatory cytokines may play a role.[72,73]

Human African trypanosomiasis, which is due to the transmission of trypanosomes by tsetse flies, is a frequent cause of severe hypersomnia in western Africa (*Trypanosoma brucei ganbiense*) and eastern Africa (*Trypanosoma brucei rhodesiense*). After an extensive immune reaction during the initial stage, severe sleep and wakefulness impairment follows, and the disorder at this point is referred to as "sleeping sickness." The possibility of human African trypanosomiasis needs to be assessed in travelers and individuals migrating from Africa with EDS.

Periodic Hypersomnias

Periodic and recurrent hypersomnias, including the Kleine-Levin syndrome and the recurrent hypersomnia associated with the menstrual cycle, occasionally alternating with episodes of hypersomnia, are usually easy to differentiate from the chronic sleepiness of IH by history alone.[74-78]

Drugs and Substance Use and Abuse

Many medications can cause fatigue, EDS, and hypersomnia, including beta blockers, other antihypertensive agents, dopaminergic agents, antidepressants, and opioids.[79] In doubtful cases, it may be helpful to screen for drugs in urine at the time of MSLT.

TREATMENT

The underlying causes of IH are unknown, and therefore treatment is symptomatic. Prolongation of sleep times has been suggested by Roth but has generally proved to be of no help.[10] Behavioral approaches and sleep hygiene are always recommended to prevent insufficient sleep. Restriction of time in bed and short duration of planned naps may be advantageous to decrease sleep inertia on awakening but may have little positive impact alone.

The pharmacologic options for IH are similar to the treatments of EDS in narcolepsy. Treatment response, however, is often less frequent and robust than in narcolepsy and especially in patients with prolonged nighttime sleep.[10] The list of medications that have been prescribed for IH patients is extensive and includes mainly the stimulant drugs (i.e., modafinil, methylphenidate, mazindol, and dextroamphetamine) but also tricyclic antidepressants, MAOIs, SSRIs, clonidine, levodopa (isolated or in combination), bromocriptine, selegiline, and amantadine. Overall, only about 50% to 70% of patients report significant improvement, most commonly with modafinil or amphetamines.[10,12]

Modafinil is a first-line treatment for IH. The dose of is typically started at 100 mg and gradually increased to effectiveness to a maximum of 600 mg. The most common side effect is headache, and this negative effect may be reduced if the dose is increased gradually. A positive effect has also been observed in children.[80] In some series, a good treatment response was found in a more than half of IH patients.[10,12,81,82] Modafinil seems to have good benefit-to-risk ratio in IH, similar to its effect in narcolepsy.[82] Differences between studies are probably due to the more or less strict criteria used by different authors to exclude other causes of hypersomnia (some of which respond to stimulants). A recent randomized, placebo-controlled study including 33 patients with IH reported efficacy of modafinil compared with placebo on ESS but not on the Maintenance of Wakefulness Test.[83] Another randomized, crossover, double-blind placebo-controlled trial showed improvement on driving performance with modafinil in patients with IH in the same way as in narcolepsy.[84]

Other medications that increase monoamine signaling may be effective in IH. Recently, two retrospective studies reported a favorable benefit-to-risk ratio of mazindol (a tricyclic, anorectic, nonamphetamine stimulant) and pitolisant (a wake-enhancing drug that increases the histamine release in the brain by blocking presynaptic histamine-3 reuptake)[85] in drug-resistant patients with hypersomnia including IH.[86,87] However, postawakening confusion (sleep drunkenness) often persists in IH despite medication.[8] Treatment with activating antidepressants (SSRIs and MAOIs) rather than stimulants may be first considered in patients in whom a psychiatric or

depressive disorder cannot be ruled out with certainty. Fantini and Montplaisir reported improvement in half of their 10 patients, in whom melatonin (2 mg of slow-release form at bedtime) was attempted.[45] One of the authors could not confirm this observation (CB, unpublished observation). Sodium oxybate may be also of interest in certain patients, but it has not been studied systematically.

Based on recent evidence for abnormal $GABA_A$ receptor activity in IH, single-blind interventions using oral flumazenil were proposed in a few patients with hypersomnia, with improvement of vigilance as assessed on psychomotor vigilance and subjective alertness tests.[31] Because flumazenil is formulated and approved only for intravenous use, clarithromycin, an oral agent with potential antagonism of the $GABA_A$, receptor has been used in a single sleep center. Clinical experience with clarithromycin has been reported in 53 patients with hypersomnia refractory to conventional psychostimulants, whose spinal fluid potentiated $GABA_A$ receptor function in vitro.[88] Two thirds of the patients reported subjective improvement in sleepiness during short-term treatment and 38% with long-term treatment, but potential side effects include gastrointestinal problems, antibiotic resistance, and infection. This clinical intervention was single-blinded, and further studies are needed to confirm these preliminary data.

To date, no drug had been approved by the U.S. Food and Drug Administration or other agencies specifically for the treatment of IH. These recommendations for treating the EDS of IH with stimulants is based on expert opinion only.

CLINICAL COURSE AND PREVENTION

The overall psychosocial burden of IH is similar to that of narcolepsy.[89-91] At times, the severity of the impairment can place lives in jeopardy; for example, patients with IH have sustained third-degree burns during automatic behavior episodes or have turned on gas furnaces or stoves without lighting them, leading in one case to a severe explosion.[91] In IH, symptoms may be stable and long lasting, but spontaneous improvement in EDS may occur in up to one fourth of patients.[10,12,13,46] No prevention is possible in this disorder.

PITFALLS

Because IH is rare and essentially a diagnosis of exclusion, the main pitfall is not making an accurate diagnosis. The terms IH and hypersomnia of unknown origin are not synonymous. Different research groups have historically used different diagnostic criteria, making comparisons across studies difficult. This is particularly true of case series that did not exclude mild forms of sleep-disordered breathing, BIISS, and hypersomnia associated with psychiatric disorders.

Careful history, sleep questionnaire or actigraphy, full physical examination, overnight PSG, and MSLT are essential for diagnosis and, more important, to rule out other causes of EDS. Demonstration of increased sleep times using prolonged PSG or actigraphy, formal psychiatric testing, CSF hypocretin-1 measurements, and brain magnetic resonance imaging may be necessary in unclear cases to confirm the diagnosis and rule out other causes of EDS. Treatment with stimulants is not always satisfactory.

The main controversies relate to (1) the clinical and neurophysiologic overlap between IH and hypersomnia associated with psychiatric disorders, mild sleep apnea, narcolepsy without cataplexy, and BIISS; (2) the potential for spontaneous improvement or change in diagnostic category; and (3) the currently unknown pathophysiology of IH. Further studies are required to understand the pathophysiology of IH, to determine whether there are different clinical subtypes of IH (forms with and without long sleep time), and to validate the specificity and sensitivity of biomarkers involved with diagnostic and therapeutic significance. Finally, prospective studies are needed to obtain objective evidence for the efficacy of medications in treating IH and to clarify whether mood changes in IH are consequent to difficulty adapting to the disease or indicate a primary brain dysfunction.[92]

CLINICAL PEARLS

- Clinicians should consider IH in the differential diagnosis of young patients with EDS (mean age at onset, 15 to 25 years), prolonged unrefreshing sleep, and difficulty waking up in the morning or after a nap.
- Before diagnosing IH, clinicians should rule out insufficient sleep syndrome, atypical forms of depression, sleep apnea syndrome, and narcolepsy.
- The symptoms of IH are often severe and long lasting, and treatment requires stimulant drugs as in narcolepsy.
- IH can remit in about 25% of patients, and clinicians should periodically reevaluate the diagnosis and treatment plan.

SUMMARY

IH is a rare disorder characterized clinically by EDS with long and unrefreshing naps, prolonged and undisturbed nocturnal sleep, and great difficulty waking up and "getting going" (sleep inertia) after sleep. Physiologically, the key features of IH are high sleep efficiency and SWS percentages on PSG, decreased mean sleep latencies, one or no SOREMs on MSLT, and long sleep times on prolonged PSG or actigraphy. The pathophysiology of IH is unknown but may include genetic factors and deficient monoaminergic and GABAergic signaling. In the absence of a specific biologic marker, IH is a diagnosis of exclusion with a broad differential diagnosis, including narcolepsy without cataplexy, atypical forms of depression, and BIISS. The response to stimulants is variable, and remission is possible.

Parkinsonism

Claudia Trenkwalder; Isabelle Arnulf; Ronald Postuma

Chapter Highlights

- Sleep problems are extremely common in Parkinson disease (PD) and are a major cause of disability. They are primarily caused by neurodegeneration in sleep regulatory structures and motor impairment.
- Although sleep apnea is not clearly increased in PD, treatment of severe apnea may be useful for severe somnolence in some patients. Inspiratory nighttime stridor can be associated with sudden respiratory death and mandates continuous positive airway pressure treatment in most cases.
- Insomnia is generally characterized by sleep maintenance problems and can be treated with optimization of nighttime motor treatment, eszopiclone, doxepin, cognitive behavioral therapy, and possibly atypical neuroleptics.
- Somnolence is more common in advanced PD and is usually caused by degeneration of arousal systems and medications for PD. Treatment options include medication reduction, modafinil, caffeine, or methylphenidate.
- REM sleep behavior disorder occurs in up to 50% of PD patients and notably often starts years before motor manifestations. Primary treatments include bed safety measures, clonazepam, and melatonin.

Parkinsonism is a frequent and disabling condition that affects 2% to 3% of adults older than 65 years. During the past decades, there have been major advances in optimizing the treatment of motor symptoms, at least in idiopathic Parkinson disease (PD), and treatment-resistant symptoms (e.g., falls, dementia) are now major determinants of prognosis. The contribution of sleep disorders to this already complex picture has become increasingly recognized within the movement disorders community. In the past, abnormal sleep in parkinsonian patients was mostly considered "collateral damage" until key observations were made during the past decade. This increasing interest in nonmotor symptoms of PD has led to the first treatment trials for sleep and other nonmotor symptoms of PD.

DEFINITIONS

Parkinsonism

Parkinsonism describes a syndrome characterized by rigidity, a 4- to 6-Hz "pill-rolling" tremor, and bradykinesia, of which PD is the most common cause. Motor PD is characterized by asymmetrical parkinsonism; a slow, progressive worsening; and a good, sustained response to levodopa.[1,2] In recent years, symptoms at onset and disease progression have been fully characterized and correlated to specific areas of neurodegeneration, with a final common clinical spectrum of motor and cognitive sympoms.[3] PD is caused by diffuse synuclein-mediated degeneration of neurons, often first involving lower brainstem areas (e.g., nucleus of the vagus nerve) before spreading to the substantia nigra and eventually the cortex.[4] PD is primarily a disease of aging. Its prevalence increases with age from about 0.9% among persons aged 65 to 69 years to 5% among persons older than 80 years, with a 1.5-fold male preponderance. Only a small percentage develop parkinsonism before age 45 years. Young-onset patients are more likely to have genetic causes. The most important genetic causes include mutations in *Parkin*, PINK-1, LRRK2, glucocerebrosidase, and the α-synuclein gene.[5]

Since the introduction of L-dopa and dopamine agonists, relatively few major therapeutic advances have been accomplished in the treatment of motor PD, except functional neurosurgery. Often, after several years of "honeymoon" on dopaminergic treatment, patients develop motor complications, including dyskinesias (abnormal involuntary movements) at the peak of effect, and generalized slowing and painful dystonia (often confused with cramps) when the effect of L-dopa wears off. Patients then use dopaminergic treatment on daily schedules that become stricter and more frequent as the disease progresses. It is not uncommon for patients with a 10-year duration of PD to take 20 tablets per day, including frequent doses of levodopa, dopamine agonists, monoamine oxidase inhibitors, and various medications to avoid the side effects (nausea, orthostatic hypotension, hallucinations) of motor treatments or to treat nonmotor symptoms.

Recently, there has been increasing recognition that PD is not simply a motor disease. Pathologic staging systems of PD have documented that a variety of structures, including those involved in control of autonomic regulation, olfaction, mood, and sleep, degenerate early in PD, whereas cognition is impaired mostly later in the disease.[6] In fact, prodromal

symptoms of PD can include diverse nonmotor symptoms such as constipation, urinary dysfunction, orthostatic hypotension, depression, anxiety, sleep disorders such as REM sleep behavior disorder (RBD), olfactory loss, and cognitive and behavioral changes. These symptoms are generally not levodopa responsive and may occur years before the first motor symptoms.[7] After PD has commenced, further levodopa-resistant symptoms, such as falls, freezing, dysarthria, drooling, and swallowing dysfunction, often occur.

Especially prominent in PD pathology is widespread degeneration of brainstem nuclei that control sleep and wakefulness. Sleep disturbances include fragmented sleep with reduced sleep maintenance insomnia, abnormal movements during sleep (periodic limb movements during sleep [PLMS], RBD, and rarely fragmented myoclonus), excessive daytime sleepiness, and even sleep apnea. Many of these difficulties worsen with increasing duration of disease and are exacerbated by medications used in PD. A detailed interview, sometimes followed by a video polysomnogram, is an essential tool to understand and adequately treat these patients.

Atypical Parkinsonism

It is important to differentiate PD from *atypical parkinsonism* because treatment and prognosis are different. Indeed, more than 10% of patients have atypical parkinsonism characterized by different neuropathologies, primarily other synucleinopathies such as multiple system atrophy (MSA)[8] or tauopathies. The tauopathies comprise progressive supranuclear palsy (either Parkinson subtype or the Steele-Richardson-Olszewski type with parkinsonism, saccade slowing, vertical gaze impairment, swallowing problems, dysarthria, frontal cognitive impairment, and early falls)[9] and the corticobasal syndrome.[10] All these diseases show reduced or absent dopaminergic response; high doses usually improve the condition only partially. In general, the prognosis of atypical parkinsonism is worse. Compared with PD, sleep problems can be even more frequent and severe in atypical parkinsonism, especially in MSA. A specific sleep-associated respiratory symptom, stridor, occurs in some patients with MSA and must be looked for because it can be associated with severe nocturnal oxygen desaturation and sudden death. Stridor has also been recently described in a rare antibody-mediated tauopathy.[11] Vascular parkinsonism results from multiple infarcts in the basal ganglia and occurs either as a separate disease or as a comorbidity of PD, especially in patients with hypertension and hypercholesterolemia. It is characterized by prominent gait dysfunction and symmetrical akinetic-rigid symptoms without most nonmotor features. Further rare diseases are Guadeloupean parkinsonism,[12] Parkinson-dementia complex of Guam, and Parkinson-hypoventilation syndrome.[13]

Finally, dementia with Lewy bodies (DLB) is the second most frequent cause of dementia after Alzheimer disease. These patients develop cognitive impairment mostly affecting visual-spatial performance, early hallucinations, and parkinsonism (frequently levodopa sensitive), with fluctuations of alertness and vigilance over days or weeks.[14] Like PD, DLB is a synucleinopathy that overlaps profoundly with PD; many consider these to be on the same disease spectrum.[3,15] A recent pathologic study suggested that RBD was rare in Alzheimer disease and other non–Lewy body dementias and that the existence of RBD in a dementia syndrome is a strong diagnostic marker for DLB.[16,17] Mild parkinsonian symptoms can also be observed in patients with Huntington disease and those with spinocerebellar ataxia. All these neurodegenerative disorders are classified according to the mechanism of neuronal loss (Table 92-1), whether it is associated with a deposit of α-synuclein in Lewy bodies, of *tau* protein, or secondary to a genetic polyglutamine disease. Although the major emphasis in this chapter is on PD, much of the discussion also applies to the other degenerative disorders associated with parkinsonism.[18]

Table 92-1 Prevalence of REM Sleep Behavior Disorder in Neurodegenerative Diseases

Disease	Prevalence (%)
Synucleinopathies	
Parkinson disease[32,36,132,133]	15–60
Multiple system atrophy[34,134]	88–90
Dementia with Lewy bodies[16,17]	76–86
Tauopathies	
Progressive supranuclear palsy[55,56]	10–11
Alzheimer disease[135]	4.5–7
Corticobasal degeneration[17]	Case reports
Frontotemporal dementia[17]	0
Pallidopontonigral degeneration[136]	0
Guadeloupean parkinsonism[137]	78
Genetic Diseases	
Huntington disease[138]	8
Spinocerebellar ataxia type 3[139]	56
Parkin mutation[140,141]	9–60

CLINICAL FEATURES

In clinical practice, parkinsonian patients are usually referred to sleep centers for three main complaints: insomnia, abnormal movements when asleep, and daytime sleepiness. These symptoms may arise alone or in association.

Insomnia and Causes of Sleep Fragmentation

The sleep history in PD should include all the features the physician would obtain from any patient with a sleep complaint. Additionally, the physician should query disease-specific questions on nocturnal akinesia, daytime fatigue in relation to medication intake, and psychiatric symptoms. A careful description from the bed partner is essential to determine the presence and frequency of movements during sleep (and their timing), arousals and awakenings, and periods of daytime sleepiness. Two scales, the PD Sleep Scale and the SCOPA-sleep can be helpful for research purposes on sleep quality in PD.[19,20] A checklist of useful questions when investigating a sleep complaint in a PD patient is displayed in Table 92-2.

In PD, many patients report two to five long awakenings during the night (twice more than controls), lasting 30% to 40% of the night.[21] Generally, PD patients have more problems with sleep maintenance—especially in the second half of the night—than with sleep onset.[22] In patients with moderate to severe PD, special attention should be paid to anxiety, depression, hallucinations, and sensory-motor symptoms

Table 92-2 Sleep and Night Problems in Parkinson Disease

Problem	Potential Diagnosis	Proposed Management
Frequent Nocturia (≥2 episodes/night)		
Normal volumes	Sleep apnea syndrome	Check for sleep apnea and treat appropriately
Small volumes, poor stream	Prostatism	Refer to urologist
Small volumes, good stream	Parkinsonism-associated nocturia	Intranasal desmopressin, oral amitriptyline, or transdermal rotigotine patch; if detrusor instability: oxybutynin, tolterodine
		Decrease evening fluid intake; empty bladder prior to bed; avoid evening dosing with diuretics, antihypertensives, and vasodilators; have a urinal at the bedside table
Difficulty Initiating Sleep		
Early in the evening	Too early lights-off	Switch off lights later
	Anxiety, or behavioral insomnia	Sleep hygiene; treat anxiety; evening melatonin, eszopiclone, doxepin
With restlessness	Restless legs syndrome	Check for low ferritin; remove antidepressant drugs; if the diagnosis is uncertain, consider polysomnography with legs monitoring; try gabapentin or opiates such as tramadol if not confused
Late in the night	Altered circadian cycle	Sleep hygiene; decrease levodopa/dopamine agonists in the evening; melatonin 1–2 hours before the desired bedtime
Late in night, hypomanic	Assess for impulse control disorder	Decrease dopamine agonists; keep on levodopa monotherapy; close neuropsychological follow-up
Difficulty Resuming Sleep		
With cramps, muscle pain, slowness	Nocturnal bradykinesia	Immediate-release levodopa with a glass of water during awakenings; continuous drug delivery (ropinirole transdermal patch, pramipexole or ropinirole extended-release, apomorphine infusion; intrajejunal levodopa-carbidopa infusion)
		Satin bed sheets to aid movement in bed
With restlessness	Restless legs syndrome	See above
With anxiety	Anxious disorder	Evening antidepressants (mirtazapine, amitriptyline, doxepin, paroxetine)
With low mood	Depressive disorder	Treat the depression
Nightmares, Agitation		
Confused at night when awake	Hallucinations, psychosis, confusion	Remove or reduce the evening dose of dopamine agonist or antidepressant; assess for sleep apnea; antipsychotics (quetiapine, clozapine)
Kicks, shouts, slaps	REM sleep behavior disorders	Secure the bed environment; discontinue antidepressant; assess likelihood of sleep apnea (video-polysomnogram before treating); melatonin 3–9 mg in the evening; clonazepam 0.5–2 mg in the evening
Daytime Sleepiness		
Falls asleep unexpectedly	Sleep attack	Check for possible sedating drugs (e.g., dopamine agonists) and remove or change them; warn patient not to drive
Falls asleep more often than before		Consider the Epworth sleepiness score; ask about associated hallucinations; consider polysomnogram and Multiple Sleep Latency Test
		Treat sleep apnea if severe
		Decrease/stop the dopamine agonist during daytime, and other sedative drugs
		Caffeine; modafinil; methylphenidate

during the night. Sensory discomfort during the night is common in PD. It includes a variety of symptoms such as pain, motor restlessness, and painful dystonia. Restless legs syndrome occurs in 12% to 21% of PD patients (it can be difficult to distinguish from leg pain because the urge to move is common in PD).[23] Early-morning dystonia is common and often severe; it consists of long-lasting, painful contractions of the toes in flexion or extension (sometimes with internal rotation of the ankle) that occur both during the end of the night and on awakening and that make walking difficult. Severe dystonia or rigidity of the leg, neck, and back muscles may occur only at night, when dopamine levels are low. Patients also commonly experience nighttime bradykinesia, with difficulty turning in bed, readjusting the blankets or pillow, sitting up, and walking to the toilet.[24] Difficulty moving during the night can further increase anxiety levels. All these symptoms may curtail sleep by one third if not more, with mostly long intranight awakenings. If nocturnal bradykinesia is present, nighttime dopaminergic therapy should be considered. On the other hand, a deleterious effect on sleep of dopaminergic agonists (which can be considered stimulants) when given at bedtime can be observed.[25] At the extreme of this spectrum, some patients may use supraoptimal doses of levodopa and dopamine agonists day and night, and stay awake and hyperactive at night, using computers, gambling, shopping compulsively on the Internet, or experiencing hypersexuality. This impulse control disorder affects up to 11% patients with PD and is mostly seen with high doses of dopamine agonists.[26]

Abnormal Movements During Sleep and REM Sleep Behavior Disorder

Abnormal movements during sleep are usually either a parasomnia or PLMS. If movements are stereotyped and periodic, then PLMS is likely. Nonstereotyped movements suggest a parasomnia, usually RBD. Other potential sleep movements include myoclonus, rest tremor, dystonia, and bruxism (which are absent in sleep but can emerge during arousals).

RBD consists of dream-enactment behavior such as laughing, talking, crying, kicking, fighting invisible enemies during sleep, and so forth.[27] RBD is covered in detail in Chapter 103. RBD can be violent enough to disrupt sleep and induce self-injury or bed-partner injury, although this is relatively uncommon in PD (Video 92-1). Compared with patients with idiopathic RBD, who were usually selectively referred for violent behaviors, RBD in PD is less frequent and violent.[28] Indeed, quiet behaviors, including drinking soup, singing a song, or giving a lecture, are often mentioned incidentally by the bed-partner.[29] In addition to fully expressed complex behaviors, patients can also have abrupt movements and jerks, such as simple, aborted, proximal or distal movements of the limbs. In general, RBD is the most frequent parasomnia in parkinsonism. Unlike non-REM parasomnia, RBD patients generally do not walk, do not interact with the environment (e.g., they may grab something in their immediate vicinity, but will not reach for objects), and will not talk back to bed partners during an episode.[30] The eyes are usually closed. If woken from an episode, RBD patients usually have a normal level of consciousness, whereas non-REM parasomnia patients appear only half-awake. Some of the patients remember a dream, but not always. These features can usually distinguish a non-REM parasomnia from RBD with reasonable reliability. One should note, however, that PD patients with both sleepwalking and RBD (i.e., parasomnia overlap) have been occasionally reported.[31] Patients with RBD generally have normal sleep patterns except for higher numbers of PLMS than those without. RBD does not generally cause daytime sleepiness or insomnia. Some PD patients are disturbed by nightmares and awakenings because of vocalizations or by violent movements, including falling from bed.

A new area of research pertains to the disappearance of parkinsonism during an RBD episode. In a large series, spouses of PD patients reported that the patients had unusually strong and rapid movements during RBD, as if they were transiently cured of PD.[32] This clinical improvement has been confirmed on sleep and video monitoring, performed after a 12-hour withdrawal of dopaminergic drugs (Video 92-2). Similar findings have been reported in MSA and progressive supranuclear palsy.[33,34] Understanding the cause of this spontaneous improvement could lead to development of novel treatments (e.g., novel surgical targets) and shed light on motor control during sleep.

Whereas RBD is experienced by 30% to 59% of PD patients, there is increasing evidence that RBD marks a subtype of PD. Patients with RBD have less tremor, more falls and freezing, more cardiovascular autonomic dysfunction (especially orthostatic hypotension), and more cognitive dysfunction on detailed neuropsychological testing in an early population.[35] These associations have not always been detected.[36] Of special significance is a link to PD dementia; in prospective studies, the presence of baseline RBD was strongly linked to the risk for dementia (with relative risks ranging from 5 to 50).[35,37]

Arguably, the most important implication of RBD is that it can predict development of PD and other synucleinopathies. In a 5-year follow-up of their original idiopathic RBD cohort, Schenck and colleagues found that 38% eventually developed PD.[38] On continued follow-up, 81% developed a neurodegenerative disease.[39] This finding has now been confirmed in three independent cohort studies. The Barcelona cohort reported a 45% risk for neurodegenerative disease at 5 years follow-up, which rose to 76% at 10 years and 91% at 14 years.[40,41] The Montreal cohort recently reported 60% conversion to defined neurodegenerative disease at 6 years. Slightly lower risks (38% at 9 years) were reported from a Hong Kong cohort.[42] Finally, a clinical history suggestive of dream enactment behavior (i.e., possible RBD) was linked to risk for mild cognitive impairment and dementia in a population-based study.[43] Most cohorts find that patients are at approximately equal risk for both primary parkinsonism (PD and MSA) and DLB. This very high risk has critical implications for neuroprotective therapy against PD because idiopathic RBD patients are ideal candidates for neuroprotective trials and future candidates for definitive neuroprotective therapy when it becomes available.

Daytime Sleepiness

Some patients with PD experience sleep attacks (or sudden onset of sleep) when treated with dopamine agonists.[44] Examples of sleep attacks include patients falling asleep during stimulating life conditions, such as while eating a meal (the head drooping in the plate), walking, attending work, carrying a child in an escalator, and the most dangerous situation, driving a car. Because of the high risk for accidents in sleepy

drivers, the level of daytime sleepiness must be regularly checked in PD patients, especially when dopaminergic treatment is changed. This is particularly true in de novo, young PD patients who often receive high doses of dopamine agonists. Daytime sleepiness in PD can be self-reported but is usually more reliably reported by the caregiver because some patients are unaware of being abnormally sleepy.[45] Napping after lunch is frequent in PD patients and often perceived as beneficial. The Epworth sleepiness score has been well validated in PD,[46] with an abnormal threshold above 10, but it is poorly predictive of sleep attacks.[47] Some authors have added specific questions on the ability to fall asleep when driving, eating, working, or having a home routine activity,[47] which better predicts the risk for driving accidents. Questioning patients with daytime sleepiness about hallucinations, and vice versa, is useful because these two symptoms are often associated and are underreported (because many patients are afraid of being considered mentally ill).

Stridor

Stridor is caused by partial obstruction of the larynx, resulting in a harsh, high-pitched inspiratory noise (Video 92-3). Unlike obstructive sleep apnea, which does not expose patients to immediate risk, stridor is a life-threatening condition. The larynx obstruction usually begins during the night and is observed in 42% of unselected patients with MSA.[48] It can be recognized quite easily by mimicking it to the caregiver, or by an audio recording during the night, but is not detected on usual apnea monitoring devices. Of interest, nighttime stridor is alleviated by the application of nasal continuous positive airway pressure (CPAP), which can avoid tracheotomy and provides a long-term benefit on quality of sleep and median survival time.[48,49] Recently, a new syndrome associating rapid eye movement (REM) and non–rapid eye movement (NREM) parasomnia, severe stridor, hypoventilation, and early death has been described, in association with a brainstem tauopathy and antibodies against a neuronal cell adhesion molecule.[11]

Sleep Benefit

In PD, a specific, positive restoration of fluent mobility may happen on awakening from sleep, before drug intake, and is named *sleep benefit*. Based on questionnaires, the frequency of this phenomenon varies from 10% to 55% of patients.[50,51] The restored mobility lasts a mean of 84 minutes, and patients may be able to skip their first dose of levodopa.[50] When examining 10 patients with sleep benefit on awakening after a polysomnogram, however, the motor benefit was small and unrelated to the sleep structure, levodopa serum levels, or sleep chronotype.[52]

EPIDEMIOLOGY OF SLEEP DISORDERS IN PARKINSONISM

Insomnia

Sleep problems, and especially insomnia, are common in all forms of parkinsonism. A community-based survey determined that 60% of PD patients had sleep problems, significantly more than in patients with diabetes mellitus (45%) or in aged controls (33%).[22] These percentages increase up to 76% of PD patients who claim having "broken sleep" in hospital samples.[24] As many as 53% of patients with MSA complain of sleep fragmentation, compared with 39% of PD patients.[53] The most severe and specific insomnia is observed in patients with progressive supranuclear palsy.[54-56]

REM Sleep Behavior Disorder

REM sleep behavior disorder affects 30% to 90% of patients with synucleinopathies but is rare in other neurodegenerative disorders.[17] The prevalence of RBD in the various diseases with parkinsonism is shown in Table 92-1. Cross-sectional studies generally find that one third of PD patients report at least one RBD episode per week.[32,57] Studies using polysomnograms (which can detect asymptomatic RBD or asymptomatic loss of REM atonia), generally find RBD in 40% to 60%.[32,36] Note that RBD often waxes and wanes throughout the course of disease, so the lifetime prevalence of RBD in PD is likely higher. Most,[28,57] but not all,[32,36] series of RBD patients with parkinsonism contain more men than women, a ratio that is less consistently observed than in idiopathic RBD.[58] Of note, RBD is very common in other synucleinopathies, occurring in approximately 75% of patients with MSA and DLB.

Excessive Daytime Sleepiness

Excessive daytime sleepiness affects on average one third of patients with PD. Case-control studies performed in various countries consistently find higher sleepiness scores and higher percentage of subjects with abnormal somnolence in PD patients (16% to 74%) than in age- and sex-matched controls.[21,59,60] Sleepiness is infrequent at PD onset in the absence of medications[61] but develops with time, with an incidence of 6% per year in a prospective series.[62] Sleepiness may, however, precede the onset of PD because sleepy adults in a large Asian longitudinal study developed PD later in life 3.3 times more often than nonsleepy adults.[63] The percentage of PD patients having experienced sleep attacks or "sudden onset of sleep without a prodrome" varies from 1% to 14%, whereas 1% to 4% of PD patients report having experienced sleep attacks while driving.[47,64] Fortunately, most patients have some warning beforehand.

PATHOGENESIS

The disruption of the normal sleep and wakefulness in patients with parkinsonism may be caused by neurodegenerative damage in brain areas responsible for sleep and arousal regulation; by behavioral, respiratory, and motor system phenomena accompanying the disease; and by deleterious effects of medications that may induce nightmares, nocturnal movements, insomnia, or sleepiness. These three elements contribute in various degrees to the clinical symptoms. There is stronger evidence for neuronal loss as the primary cause of RBD than there is for insomnia.

Insomnia and Sleep Fragmentation

Insomnia is a nonspecific symptom that does not necessarily result from a selective lesion in any sleep system, except in progressive supranuclear palsy, in which brainstem cholinergic neuron loss may disrupt the REM sleep executive systems.[65] General factors, such as aging, anxiety, and depression, may account for some nocturnal sleep disruption in PD. Poor sleep quality correlates with depression and anxiety scores,[66] but motor phenomena and disability at night are perhaps the major causes of trouble maintaining sleep.[67] The frequency of

insomnia increases with advanced motor stages of PD and a need for higher daily dose of dopaminergic therapy, an indicator of dopamine denervation.[68] Slow movements, nocturnal akinesia with difficulties turning in bed and adjusting blankets, pain, cramps, nocturnal and early morning dystonia (a clawlike contraction of the toes), and frequent need to urinate are reported by patients with advanced PD as main causes of their insomnia.[24] The difficulty moving during the night can further increase anxiety, whereas depression, present in one third of patients with PD, also affects sleep. This may lead to early awakenings as in patients with major depression. Older patients with on-off phenomena and those with hallucinations are particularly likely to have severe sleep disruption.[69] In patients with advanced PD, the alleviation of nocturnal bradykinesia and painful dystonia using subthalamic nucleus stimulation at night can severely decrease time awake at night[70] and improve subjective sleep quality.[71]

Restless legs syndrome (RLS), a frequent cause of insomnia in the general population, has a 15% to 20.8% prevalence in PD.[23] Except in patients with a family history of RLS, they seem to reflect a secondary phenomenon. There is no evidence that RLS symptoms early in life predispose to the subsequent development of PD.[23,72] In clinical practice, RLS may be difficult to distinguish from leg pains, which are frequent in patients with PD,[73] and from the urge to move, which is common in patients with motor fluctuations. PD patients with RLS have lower ferritin levels than those without.[23]

There is still controversy about whether the circadian system is affected in PD, especially in patients displaying nighttime insomnia and daytime sleepiness. Some patients may have circadian phase advance because even patients with mild PD (i.e., without any motor problem) consistently report an early-to-bed and early-to-rise pattern. The nocturnal profile of body core temperature is similar in patients with PD and in controls, whereas the nocturnal temperature fall is blunted in patients with MSA.[74] However, recent studies have suggested a blunting of the circadian rhythm of melatonin secretion in PD, more pronounced in patients with somnolence.[75]

In addition, deleterious effects on sleep of medications can be observed because dopaminergic agents are considered as stimulants, and selegiline is metabolized to amphetamines. Therefore, attempts to improve motor state can also paradoxically worsen sleep in patients prone to hallucinations or psychosis.

REM Sleep Behavior Disorder

The exact cause of RBD in parkinsonism is unknown, but a nondopaminergic lesion of the system controlling atonia during REM sleep is highly suspected.[76,77] The substantia nigra does not seem to be implicated in generating RBD. There is no consistent evidence that levodopa or dopamine agonists can trigger RBD or elicit REM sleep without atonia and no strong evidence that RBD can be treated by dopaminergics.[78] Of interest, animal models of RBD have been created by lesioning the locus coeruleus peri-alpha (pons) in the cat, an area adjacent to the noradrenergic locus coeruleus. These animals displayed complex behaviors during REM sleep, including grooming, leaping, being on watch, and hunting invisible prey.[79] Muscle atonia is also reduced in rat models after lesion of an analogous region, the sublaterodorsal nucleus.[80,81]

The equivalent of these nuclei in humans is the subcoeruleus nucleus, a pontine region known to degenerate in both PD and MSA.[40,82] Notably, the MRI-neuromelanin signal in the coeruleus-subcoeruleus complex is decreased in PD patients with RBD (and not in PD patients without RBD and controls), in proportion to the loss of muscle atonia in REM sleep.[83] Cholinergic neurons located in the pedunculopontine tegmental nucleus have also been hypothesized to contribute to muscle atonia during REM sleep, but they are similarly damaged in DLB and MSA patients with and without RBD.[84]

In murine models, phasic and tonic REM sleep muscle activities are controlled by different mechanisms, and the role of glutamate and glycine and their altered pathways to spinal motor activity may be the substrate for the disinhibition of motor phenomena during RBD.[85] This could explain the clinical observation that REM sleep without atonia may occur without dream enactment behaviors in some patients, whereas others have retained chin muscle atonia yet have prominent phasic limb activity.

In addition, RBD can be triggered or exacerbated pharmacologically, especially by the use of antidepressants like serotonin reuptake inhibitors. This may be due to direct serotonergic activation of motor neurons.[77] Because RBD symptoms in PD are associated with relative neocortical, limbic cortical, and thalamic cholinergic denervation but not with differential serotoninergic or nigrostriatal dopaminergic denervation,[86] the presence of RBD symptoms might signal cholinergic system degeneration.

In atypical parkinsonism, the lesions are extensive, complicating clinicopathologic correlations. As shown in Table 92-1, synucleinopathies are more often associated with RBD than the tauopathies and polyglutamine diseases, suggesting that the neurons responsible for muscle atonia in REM sleep are more vulnerable to α-synuclein-related neurodegeneration than to other mechanisms of damage.

The key regions that cause RBD degenerate early in PD. Lewy bodies containing α-synuclein deposits are detected in the brain of 10% to 15% of clinically normal people older than 60 years; when not associated with PD, this is termed *incidental Lewy body disease*. The subcoeruleus-coeruleus complex is frequently affected in incidental Lewy body disease.[87] Moreover, recent staging systems of PD have proposed that α-synucleinopathy initially affects the olfactory areas and medulla oblongata and progresses to more rostral brain areas in a hierarchical sequence.[87] In this model, the subcoeruleus nucleus, which is located in the pons, should be affected earlier than the substantia nigra, located in the mesencephalon. This provides a pathologic basis for the fact that RBD anticipates PD. It should be noted, however, that only one third of patients with PD develop RBD before parkinsonism onset, and RBD prevalence is not 100% even in patients with advanced PD, suggesting that this staging is not perfectly followed (at least clinically).

Excessive Daytime Sleepiness

The mechanisms of sleepiness and sleep attacks in PD may include complex drug-disease interactions. Most arousal systems (Table 92-3) are affected by neuronal loss and Lewy bodies in PD brains, including the noradrenaline neurons in the locus coeruleus,[88] the serotonin neurons in the raphe,[88] the hypocretin neurons (also affected in primary narcolepsy) in

Table 92-3 Neuronal Loss in Arousal Systems in Patients with Parkinson Disease

Nucleus	Main Neurotransmitter	Neuronal Loss in PD Brain, %
Locus coeruleus[88]	Noradrenaline	40–50
Median raphe [88]	Serotonin	20–40
Ventral periaqueductal gray matter[142]	Dopamine	9
Pedunculopontine tegmental nucleus[143]	Acetylcholine	50
Tuberomammillary nucleus[94]	Histamine	Unchanged enzymatic activity
Lateral hypothalamus[89,90]	Hypocretin	23–62
Basal forebrain[88]	Acetylcholine	32–93

the hypothalamus,[89,90] and the cholinergic neurons in the pedunculopontine tegmental nucleus and basal forebrain.[88] Of note, deep brain stimulation of the pedunculopontine nucleus area in patients with PD can cause immediate sleepiness when the nucleus is blocked by high-frequency current and alertness when it is stimulated by low-frequency current.[91,92] In contrast, the wake-active dopamine neurons in the ventral periaqueductal gray matter and the histamine neurons in the hypothalamus are intact in PD brains.[93,94] In MSA, there is also a marked decrease of hypocretin neurons.[95] As many as 28% of patients with MSA complain of daytime sleepiness,[96] whereas 36% of MSA patients show a narcolepsy-like phenotype.[60]

In PD, sleepiness is more frequent in patients with advanced disease.[59] Sleep deprivation due to insomnia is often considered the cause of somnolence, but in PD, daytime sleepiness is actually associated with longer sleep time at night, suggesting a central hypersomnia.[97-99] Similarly, sleep apnea (observed in 20% to 30% of PD patients), PLMS, and sleep fragmentation do not correlate with daytime sleepiness,[97-99] suggesting they do not contribute much to the mechanisms of sleepiness (although this assertion could be wrong in individual cases). As mentioned previously, dopamine medications increase the risk for sleep attacks.[64,100] In contrast, levodopa is less often sedative, although some patients may sleep half an hour after levodopa intake. Why drugs that are supposed to stimulate the alerting brain system (and do so when given at bedtime) can also be sedating is yet unknown. This effect cannot be explained, at these high doses, by the biphasic effect (presynaptic sedative effect at low dose, postsynaptic alerting effect at high dose) of dopamine agonist that has been described in animals.[101] Rather, a different selectivity for D1 or D2 receptors may be important; D1 agonists and small doses of dopamine increase the firing of hypocretin neurons in rat hypothalamus, whereas high concentrations of dopamine and D2 agonists decrease or even block this firing.[102] If one applies this concept to PD, patients with a partial hypocretin deficiency would be sedated by D2 and D3 agonists or high doses of levodopa.

POLYSOMNOGRAPHY OF PARKINSON DISEASE

As with other diseases, the clinical interview is key for diagnosing the causes of sleep complaints in patients with parkinsonism (see Table 92-2). However, in parkinsonism, the information brought by videopolysomnography is important and useful, provided that all aspects of the disease (motor aspects, during both sleep and wake) and sleep are carefully analyzed. The recording of a patient with parkinsonism in a sleep unit can be difficult when the team is not used to monitoring disabled, anxious patients, who may get up several times to urinate and who may need to be given drugs every 3 hours, to be helped regularly during the night, to receive massage when they have violent cramps or dystonia, and to be reassured when they are confused or subject to hallucinations.

The minimal montage should include the usual sleep montage (electroencephalogram [EEG], electrooculogram [EOG], chin electromyogram [EMG]), electrocardiogram [ECG], nasal pressure, thorax and abdomen efforts, oxygen saturation, and leg EMG, but also audio monitoring because stridor may be mistaken for snoring. If RBD is suspected, a synchronized infrared video and upper-limb EMG electrode (hand rather than shoulder or arm muscles) increases the sensitivity to detect RBD.[103] The video monitoring also allows recognition of other frequent night-related motor problems in PD, including cramps, dystonia, tremor, and restless legs behavior, and even dyskinesias and their role in prolonging awakenings. Sleep scoring may be particularly difficult and time-consuming in patients with parkinsonism. Video monitoring is also helpful for scoring sleep in these patients because EEG features of sleep may altered, RBD may be confused with wakeful behaviors, and stridor needs to be identified. For example, the number of sleep spindles during NREM is reduced in PD,[104] and EEG alpha activity may occur in all sleep stages in PD, giving the false picture of complete wakefulness throughout the night. By contrast, in patients suffering DLB or progressive supranuclear palsy, the alpha background rhythm during wakefulness may turn to a slow, regular rhythm closer to 5 to 7.5 Hz, with a further shift of all NREM sleep frequencies toward slow wave activity, so that an awake patient with open eyes may have a concomitant EEG suggesting full-blown N3 sleep. In addition, sequences of slow or rapid eye movements may be observed during NREM sleep.[105]

In contrast to the quiescence of sleep in normal persons, increased muscle tone and abnormal simple and complex movements are common and also complicate the scoring of polysomnograms in PD patients. Tremor may produce a 4- to 6-Hz regular artifact at the level of the chin or the legs during wakefulness (Figure 92-1), and it disappears with the onset of N1 sleep.[106] It may persist as a polygraphic finding rather than a clinical movement in N1 with awakenings, arousals, and body movements.[107] Patterns of simple motor activity during sleep include repeated blinking at sleep onset, rapid eye

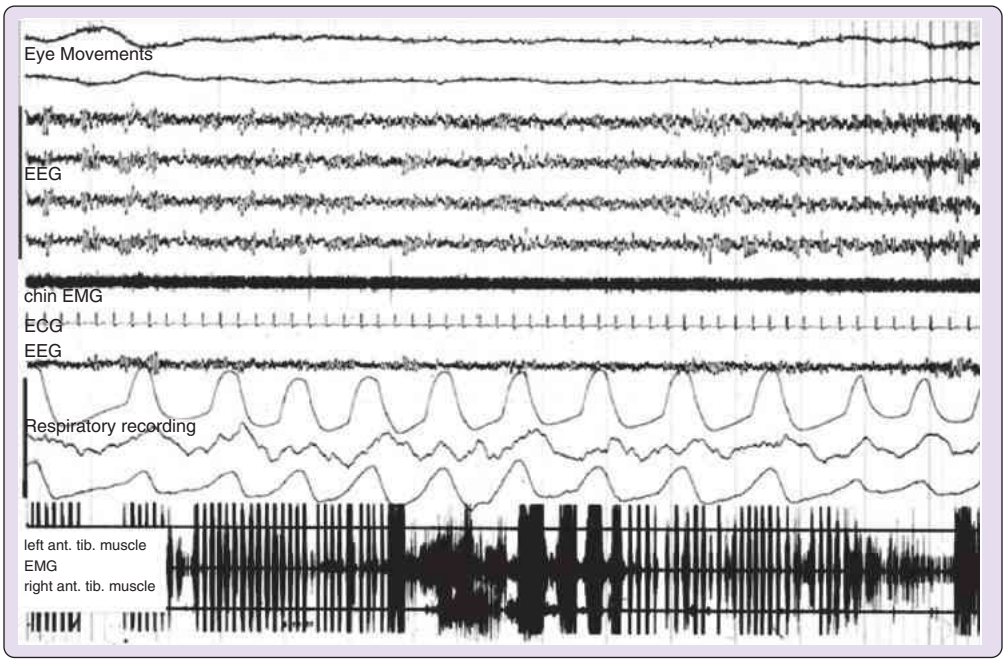

Figure 92-1 Polysomnogram in a patient with Parkinson disease and nocturnal rest tremor of the left leg occurring between wakefulness and stage 1 sleep. The regular unilateral rest tremor is interrupted by bilateral motor activity. Channels from top to bottom: 1–2: eye movements; 3–6: electroencephalogram (EEG); 7: chin electromyogram (EMG); 8: electrocardiogram (ECG); 9: additional EEG; 10–12: respiratory recording with thoracic and abdominal belts; 13: no recording; 14: EMG of right anterior tibialis muscle; 15: EMG of left anterior tibialis muscle.

movements during NREM sleep, blepharospasm at REM sleep onset, and prolonged tonic muscle activity of limb extensor or flexor muscles during NREM sleep.[108] Chin muscle tone may be enhanced during REM sleep, a feature frequently associated with clinical RBD. An example of sleep recordings during an RBD episode is shown in Figure 92-2.

After the EEG and the video are analyzed, and nighttime sleep and Multiple Sleep Latency Test (MSLT) are analyzed, the hypnogram generally shows severely fragmented sleep. The first part of the sleep report should include a description of the EEG aspect, and especially the frequency of the alpha background rhythm, because slow (e.g., 6.5 to 7.8 Hz) rhythms have been associated with RBD and possibly cortex degeneration. The presence of abnormal sleep stages, including eye movements during NREM sleep, and REM sleep without atonia should also be specified. As many as 51% patients with de novo PD (vs. 15% of controls) exhibit minor behavioral events during REM sleep that do not qualify for RBD but may precede its onset.[109]

Sleep architecture has been studied in two large, case-control series. At PD onset, there is no change in sleep structure compared with controls, except for longer REM sleep latency.[109] Patients with treated or more advanced PD have shorter total sleep time, lower sleep efficiency, longer REM latency, higher N1 percentage, and lower REM sleep percentage than controls.[110] Examples of hypnograms obtained in PD patients are shown in Figure 92-3. As for the MSLT, in a series of 54 PD patients, more than half of sleepy patients fell asleep within 5 minutes, a sign of pathologic sleepiness.[97] Moreover, 41% of sleepy patients had REM sleep in two or more MSLT naps.[97,111] This "narcolepsy-like" pattern of sleepiness with multiple sleep-onset REM periods on MSLT was observed in 15% of unselected PD patients,[98] in some cases of MSA, and in dementia with Lewy bodies, but not in progressive supranuclear palsy.[60] In PD patients with severe hallucinations, the hallucinations are temporally associated with REM sleep during the night and with sleep onset in REM periods during the daytime, as in narcolepsy.[105,112] In other PD patients, hallucinations occur after REM sleep during the night and during wakefulness or N1 sleep during the daytime.[113] Sleep attacks may also consist of rapid transitions into N2 sleep.[114]

TREATMENT

The management of sleep disorders in parkinsonism depends on the causes identified by the history and sleep laboratory tests. A list of common problems and corresponding, experience-based management is given in Table 92-3.

Insomnia

The comfort of the PD patient during the night can be improved by using sheets that enable easy movement, silk pajamas without buttons, levodopa tablets and a bottle of water on the bed table, and transitory blockade of nighttime polyuria with an evening intranasal dose of desmopressin. In advanced stages of the disease, the patient's spouse might be inclined to sleep in a different bed or room, but unfortunately these patients are in most need of a nocturnal caregiver for getting out of bed, using the bathroom, and taking their nocturnal levodopa; inadequate rest for the spouse or other caregiver may make the patient's sleep disturbance intolerable and lead to institutionalization. Despite the fact that insomnia is frequent in PD, little research has focused on its treatment. The treatment of PD insomnia is therefore not codified and is more experience than evidence based.[115] Two

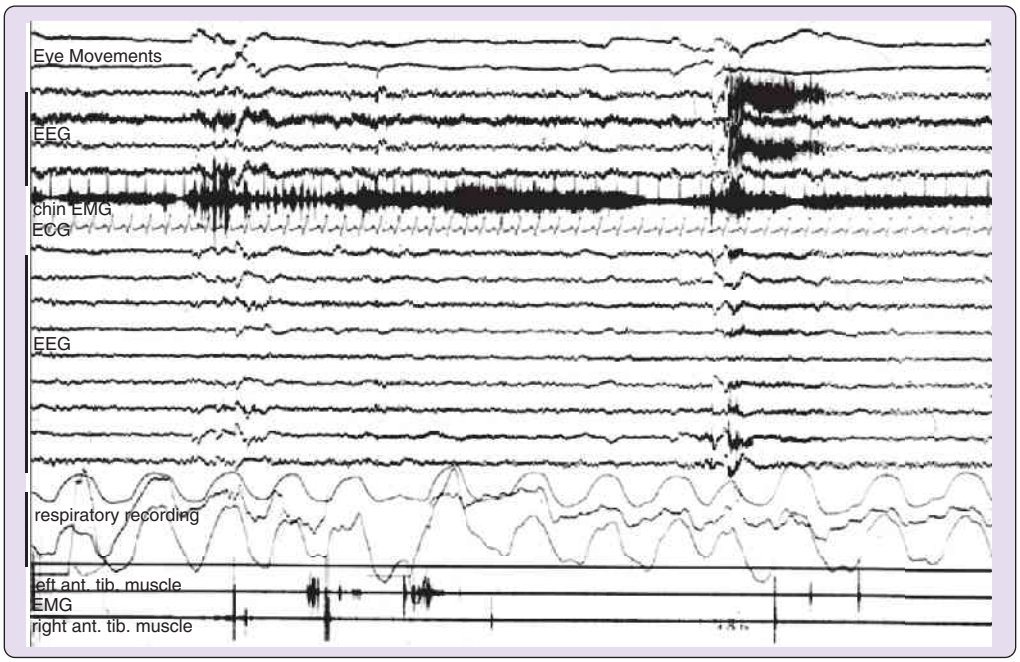

Figure 92-2 Polysomnogram in a patient with Parkinson disease with REM sleep behavior disorder. The chin electromyogram (EMG) shows a highly elevated muscle tone, and motor activity occurs in the recording, with typical muscle twitches in the EMG channels of both legs. Channels from top to bottom: 1–2: eye movements showing a typical REM sleep pattern; 3–6: electroencephalogram (EEG); 7: chin EMG with increased muscle tone; 8: electrocardiogram (ECG); 9–17: further EEG channels, showing muscle artifacts of eye movements; 18–20: respiratory recording with thoracic and abdominal belts; 21: no recording; 22–23: EMG of right and left anterior tibialis muscle.

directions can be drawn: (1) to improve sleep continuity (and in this case, the sleeping patient will not need any nocturnal dopamine treatment); and (2) to reduce movements and muscle tone during the night. Recent randomized control trials have shown equivocal benefit of eszopiclone.[116] A small three-arm study suggested benefits of doxepin and cognitive-behavioral therapy.[117] Pimavanserin, a serotonin 5-HT2A inverse agonist now under development, had beneficial effects on sleep disturbances in PD patients with psychosis.[118] Hypnotics and small doses of sedative antidepressants (provided they do not worsen preexisting RLS, RBD, hallucinations, or daytime sleepiness) are frequently used in clinical practice. When disturbing hallucinations are present, patients can benefit from the combined antihallucination and sedative effects of small, evening dose of atypical neuroleptics such as clozapine (with an appropriate monitoring of leukocyte count) or quetiapine.

Reestablishing continuous dopaminergic stimulation during day and night can be a strategy to improve nighttime motor disability. A careful record of the time of the symptoms, in correlation with time of drug intake, can help identify a nighttime gap in dopaminergic stimulation. The benefit of dopaminergic agents in the evening and night has, however, to be weighed against their alerting effect. As an example, pergolide in the evening worsened sleep efficiency and fragmentation in patients with repeated nocturnal awakenings caused by PD symptoms.[25] In contrast, the use of transdermal rotigotine during the day and night improved most aspects of sleep and night quality, including early-morning akinesia.[119] When comparing rotigotine to oral pramipexole three times a day for motor symptoms, similar results were obtained in advanced PD.[120] The use of levodopa 200 mg in the evening or at bedtime improves subjective sleep quality and decreases night-time movements.[121] Sustained-release forms of levodopa in the evening have not been compared systematically to normal-release forms of levodopa. Sustained-release preparations do not improve subjective aspects of sleep (general quality, sleep-onset latency, total sleep time, number of awakenings), but they have a mild benefit on nocturnal akinesia in small, unblinded trials. We have had good experience with rapid release (dispersible) forms of levodopa soluble in water during the night taken on demand. In contrast, subthalamic nucleus stimulation consistently improves sleep duration, reduces nocturnal awakenings, and reduces early morning dystonia in patients with advanced PD,[70,71,122] but can worsen restless legs symptoms (probably owing to decrease of dopamine agonists).

The treatment of nocturnal RLS in PD may be complex, apart from iron supplementation when it is deficient. Evening gabapentin and derivatives, and more rarely opiates (in non-demented patients without hallucinations), can be tried. No studies or guidelines are available for this purpose. The emergence of RLS and PLMS during subthalamic stimulation suggests that RLS is not controlled by the basal ganglia.[70,123] RLS might correspond to a deficit of dopamine stimulation at night (i.e., would benefit from an evening additional dose of dopamine agonist) or, on the contrary, to "augmentation" from chronic dopaminergic treatment of otherwise subclinical RLS (which would benefit from decreasing the daily dopamine dose which is usually impractical given motor disability). The occurrence of RLS years after (and not before) the onset of parkinsonism supports this last hypothesis.

Figure 92-3 Twenty-four-hour hypnograms in the following patients: a healthy 60-year-old woman with normal sleep **(A)**; a 54-year-old woman with Parkinson disease (PD) treated with levodopa 300 mg/day and bromocriptine 30 mg/day, reporting frequent night-time awakenings, daytime sleepiness and hallucinations (indicated by the *arrow*: saw a stranger in the room, here synchronous with abnormal daytime REM sleep onsets [narcolepsy-like phenotype]) **(B)**; an 80-year-old man with mild PD, complaining of falling asleep 2 to 3 hours after each levodopa intake (*arrow*), who displayed severe hypersomnia **(C)**; and a 72-year-old man with advanced PD and on-off motor fluctuations **(D)**. After a midnight awakening (*arrow*), he developed severe bradykinesia with an axial, painful dystonia that prevented him from resuming sleep. Later, at 4:30 AM, he had foot dystonia (early morning dystonia). All these motor phenomena lengthened his time awake. The *x* axis displays the time of night and day (clock hours), the *y* axis displays the stages of sleep and wakefulness, with awakening (A); non-REM sleep stage 1 (1), stage 2 (2), stage 3 (3), and stage 4 (4); and REM sleep (R).

REM Sleep Behavior Disorder

For patients with potentially dangerous manifestations of RBD, it is important to secure their sleeping environment and ensure the safety of their bed partner. This might include placing a barrier between them and their partner, using twin beds, placing the mattress directly on the floor, and removing objects close to the bed. If antidepressants triggered the RBD and are no longer necessary, they should be stopped (although paradoxically, in established RBD, antidepressants may actually reduce RBD episodes by reducing REM sleep).

Clonazepam (0.5 to 2 mg at bedtime) was the first medication described as useful for RBD.[58] The mechanism of action is unclear; it has no clear effect on tonic REM sleep but may reduce phasic EMG activity and reduce aggressiveness of dream content.[58] In a recent systematic observational study, clonazepam treatment provided moderate or greater improvement in 78% of patients.[124] Although generally well tolerated, in PD clonazepam can cause daytime somnolence, worsen sleep apnea, exacerbate cognitive impairment, and increase risk for falls. Therefore careful monitoring for these side effects is required.

Melatonin (3 to 9 mg at bedtime) is the other major therapy for RBD and may directly increase atonic REM sleep. The effectiveness of melatonin was confirmed in a small, preliminary, randomized trial.[125] In a systematic observational study, melatonin provided moderate or greater improvement in 48% of patients (lower than clonazepam), but with a mean reduction in a visual analogue scale similar to clonazepam.[124] However, melatonin may have less cognitive or gait side effects than clonazepam; 61% of patients on clonazepam reported side effects compared with 33% on melatonin.[124] Therefore

melatonin may be first-line therapy for RBD in PD, if symptoms are mild or moderate.

Otherwise there are some reports that dopaminergic therapy helps in RBD; one prospective study suggested benefit, but others have found none. We have personally experienced variable effects of dopaminergic therapy on RBD, including both reduction and exacerbation of dream enactment. Other potential treatments, which have been documented only in case studies or small series, include donepezil, levodopa, and zopiclone.[126]

Excessive Daytime Sleepiness

Finding and treating the cause of daytime sleepiness in PD requires a careful interview on nocturnal disturbances, hallucinations, recent changes in dopaminergic and psychotropic treatment, and sometimes a nighttime polysomnogram followed by MSLT. These tests may identify treatable severe sleep apnea or a central disorder of arousal. Although sleep apnea syndrome is no more frequent in PD than in aged controls, the benefit of CPAP on sleepiness (measured with MSLT but not with the Epworth Sleepiness Scale) was recently demonstrated in the short term in PD patients with sleepiness and a moderately increased apnea-hypopnea index.[127] If efforts to reduce any sedative drugs (clonazepam, other benzodiazepines, dopamine agonists, sedative antidepressants, opioids, atypical neuroleptics) are without effect or worsen the motor symptoms, the solution could be to add a psychostimulant during the daytime. Caffeine provided a borderline improvement in Epworth Sleepiness Scale score, with a positive clinical global impression of change.[128] Modafinil is well tolerated in PD patients[129] and is reported to have neuroprotective effects in animal models of dopamine depletion.[130] The alerting effect is limited, however, with less than one third responding.[129] Methylphenidate is another option because this drug given at 1 mg/kg decreased excessive daytime sleepiness (by 3 points on Epworth Sleepiness Scale) without worsening sleep quality in a recent controlled trial aiming at alleviating freezing of gait.[131] Caution is required in using stimulants in cognitively impaired patients because confusion and violent behaviors may occur.

CLINICAL PEARLS

- In patients with parkinsonism, clinicians should inquire about nighttime bradykinesia, off-dystonia, early morning akinesia, tremor, RLS, respiratory disturbances, insomnia, RBD, or psychosis from medication-associated factors and their contribution to the sleep problem.
- Specific interventions may then improve quality of sleep and reduce daytime sleepiness, thus enhancing quality of life in patients with PD.
- Nocturnal stridor is a life-threatening symptom in MSA that can benefit from continuous positive airway pressure.

SUMMARY

Altered sleep and vigilance are among the most frequent nonmotor symptoms in parkinsonism. As many as 60% patients with PD suffer from insomnia, 30% to 60% from REM sleep behavior disorder, and 30% from excessive daytime sleepiness. These frequencies can be even higher in atypical parkinsonism. The disruption of sleep and wakefulness in parkinsonism is caused by a combination of neurodegenerative damage in brain areas responsible for sleep, arousal, and circadian regulation; behavioral, respiratory, and motor system phenomena accompanying the disease; and side effects of medications. Sleep maintenance insomnia may be intrinsic to PD, but it is also promoted by motor disability, painful dystonia, RLS, dysuria, anxiety, and depression. Improving motor control during the night with levodopa or long-acting dopamine agonists, benzodiazepine receptor agonists, doxepin, pimavanserin, and quetiapine can help, as does the specific treatment of nocturia, anxiety, and depression. RBD is often violent, enacted dreaming that can cause nighttime injuries to patients and bed partners, generally caused by neurodegeneration in the REM sleep atonia system. Recent longitudinal studies indicate that RBD often precedes parkinsonism (or dementia with Lewy bodies), with up to 90% of idiopathic RBD patients eventually developing a synucleinopathy. Accordingly, idiopathic RBD patients often have other signs of neurodegeneration, including olfactory, cognitive, and autonomic disturbances; decreased dopaminergic transmission in functional imaging; and slowed EEG rhythms. Parkinsonism can be temporarily reversed during RBD episodes in some PD patients. Among PD patients, those with RBD have more gait dysfunction, cardiovascular autonomic loss, hallucinations, and cognitive impairment than patients without RBD. When bothersome or potentially dangerous, RBD is treated primarily with melatonin and clonazepam. Daytime sleepiness and a narcolepsy-like phenotype are also seen in PD. In addition, dopaminergic medications can increase risk for sleep attacks, notably when driving, suggesting a drug-disease interaction. Patients with multiple system atrophy also can develop a progressive, life-threatening laryngeal obstruction (stridor) during sleep that should be rapidly treated with positive airway pressure. Sleep problems in parkinsonism are common, disabling, and treatable; therefore prompt recognition and treatment can substantially improve the patient's quality of life.

Chapter 93

Sleep and Stroke

Claudio L. Bassetti

Chapter Highlights

- Sleep-wake disorders and stroke are common and intertwined neurologic problems; each may cause the other, and they can arise from similar predisposing factors.
- Clinicians who treat patients with sleep-wake disorders or stroke should be aware of this potential comorbidity and its clinical implications.
- In patients with stroke, treatment of sleep-disordered breathing and other sleep-wake disorders can reduce the risk for subsequent stroke and improve short- and long-term outcomes.

Since the 1990s, the link between sleep and stroke, which was suggested already in the nineteenth century, has received increasing attention. This is mainly a result of better recognition of the strong link between sleep-disordered breathing (SDB) and cardiovascular and cerebrovascular diseases, the high incidence of sleep-wake disturbances in stroke victims, and the effect that SDB, sleep-wake disturbances, and their treatment have on the risk for and outcome of stroke.

STROKE

Stroke is a focal neurologic deficit of acute onset and vascular origin. Stroke has an incidence rate of 2 to 3 per 1000 per year and is the most common neurologic cause of hospitalization. Among patients with stroke, about 65% have ischemic strokes, 15% intracerebral hemorrhage, and 20% transient ischemic attacks (TIAs), in which neurologic deficits typically resolve within 1 hour. Risk factors for stroke include atrial fibrillation, arterial hypertension, dyslipidemia, disorders of glucose metabolism, overweight (abnormal waist-to hip ratio), excessive alcohol consumption, cigarette smoking, and physical inactivity.[1] Patients with heart disease, asymptomatic carotid stenosis, history of TIA, depression, psychosocial stress, and age older than 65 years are also at higher risk for stroke.[1]

Primary prevention of stroke includes treatment of risk factors, regular physical exercise, reduction of body mass index to less than 25, anticoagulation for atrial fibrillation, and endarterectomy in patients with at least 70% carotid stenosis.[2] Emergency treatment includes the systemic use of fibrinolytic agents within the first 4.5 hours and endovascular treatment (thrombectomy) within the first 12 hours after onset of symptoms.[3] Management of acute stroke includes placement of patients in a stroke unit, early recognition of medical complications, and prescription of agents that inhibit platelet aggregation. Surgery may be considered in patients with accessible (e.g., cerebellar) hemorrhages and malignant middle cerebral artery strokes. After stroke, therapies for preventing further events includes platelet antiaggregants, blood pressure–lowering medications, statins, treatment of risk factors, and in selected patients anticoagulation and endarterectomy.[2]

SLEEP-DISORDERED BREATHING AND STROKE

Epidemiology

Sleep-Disordered Breathing as a Risk Factor for Stroke

SDB is strongly associated with stroke. Habitual snoring is an independent risk factor for stroke with a pooled risk of about 1.5.[4] A study of 1022 patients showed that obstructive sleep apnea (OSA) is associated with an increased odds ratio (OR) of 2.0 for stroke and death, even after adjusting for multiple cardiovascular risk factors. The risk was even higher (OR = 3.3) in patients with severe OSA (apnea-hypoxia index [AHI] >36/hour).[5] In a single center study of 1387 male patients with OSA followed for up to 10 years, patients with severe OSA (AHI >30/hour) had a significantly higher incidence of fatal and nonfatal cardiovascular events including stroke compared with patients with mild to moderate OSA, OSA patients treated with continuous positive airway pressure (CPAP), 377 simple snorers, and 264 controls.[6] Other studies have confirmed that SDB is associated with an increased risk for stroke.[7,8] A meta-analysis of prospective studies showed that OSA was associated with incident stroke (OR = 2.24, 95% confidence interval [CI] = 1.57 to 3.19), and cardiovascular mortality (OR = 2.09, 95% CI = 1.20 to 3.65), especially in patients with a high AHI.[9]

SDB is also linked with white matter disease on magnetic resonance imaging and silent strokes.[10-12] In a recent study of 503 elderly individuals who were free of previously diagnosed cardiovascular and neurologic diseases, moderate to severe OSA (AHI ≥15) was independently associated with the presence of white matter changes (OR = 2.08, 95% CI = 1.05 to 4.13) compared with no OSA even after adjustment for hypertension.[12]

Sleep-Disordered Breathing in Acute and Postacute Stroke Patients

In the 1990s, three large, systematic studies demonstrated a very high frequency of SDB in patients with stroke and TIA.[13-15] In a meta-analysis of 29 studies with a total of 2343 ischemic or hemorrhagic stroke and TIA patients, the frequency of SDB with AHI greater than 5 was 72% and with AHI greater than 20 was 38%. Males had a higher percentage of SDB (AHI >10) than females (65% vs. 48%; $P = .001$). Patients with recurrent strokes had a higher prevalence of SDB (AHI >10) than those with first strokes (74% vs. 57%).[16] In a literature search until December 31, 2014, we found 54 publications in which SDB frequency was assessed on a total of 4293 stroke patients, solidly confirming these findings.

A few studies have assessed the prevalence of SDB in patients with TIA and have found it to be similar to that of patients with stroke.[16] A few studies have reported a higher frequency of SDB in specific stroke subgroups such as hemorrhagic, brainstem, nocturnal/wake-up, and recurrent strokes.[17-19]

SDB often improves across the acute to the subacute phase.[20-23] In general, central events improve more than obstructive events. One study suggested a greater improvement in SDB in hemorrhagic compared with ischemic strokes.[24]

Clinical Features

Breathing Disturbances During Sleep

The most common form of SDB in stroke patients is OSA (Figure 93-1). Moderate to severe OSA (AHI >30) is found in about 20% to 30% of patients with stroke.[16] Occasionally, patients may present with both OSA and Cheyne-Stokes breathing (CSB) (Figure 93-2). OSA is often worse in rapid eye movement (REM) sleep, whereas CSB is usually worse in light non–rapid eye movement (NREM) sleep.[13,25] In the first few days after stroke, CSB and other forms of central periodic breathing are present during at least 10% of the recording time in about one third of patients.[20,26-28]

Breathing Disturbances During Wakefulness

Different breathing abnormalities can occur during wakefulness after hemispheric strokes. Abnormalities include selective impairment of behavioral or volitional respiratory control.

Hemispheric strokes in the frontal cortex, basal ganglia, or internal capsule may cause respiratory apraxia, with impaired voluntary modulation of breathing amplitude and frequency, leaving patients unable to take a deep breath or hold the breath.[29,30]

Brainstem strokes can be associated with different forms of abnormal breathing patterns. Sustained respiratory rates above 25 to 30/min in the absence of hypoxemia (neurogenic hyperventilation) were originally described in six comatose patients with ventrotegmental pontine strokes but were subsequently attributed to pulmonary edema (and stimulation of lung and chest wall afferent reflexes).[31] Neurogenic hyperventilation after stroke usually indicates a poor prognosis.[32] Inspiratory breath holding (apneustic breathing), originally described in two patients with bilateral ventrotegmental mediocaudal (infratrigeminal) pontine stroke,[33] is rare and usually secondary to basilar artery occlusion. Erratic variations in breathing frequency and amplitude (ataxic or Biot breathing) and failure of automatic breathing (central sleep apnea or

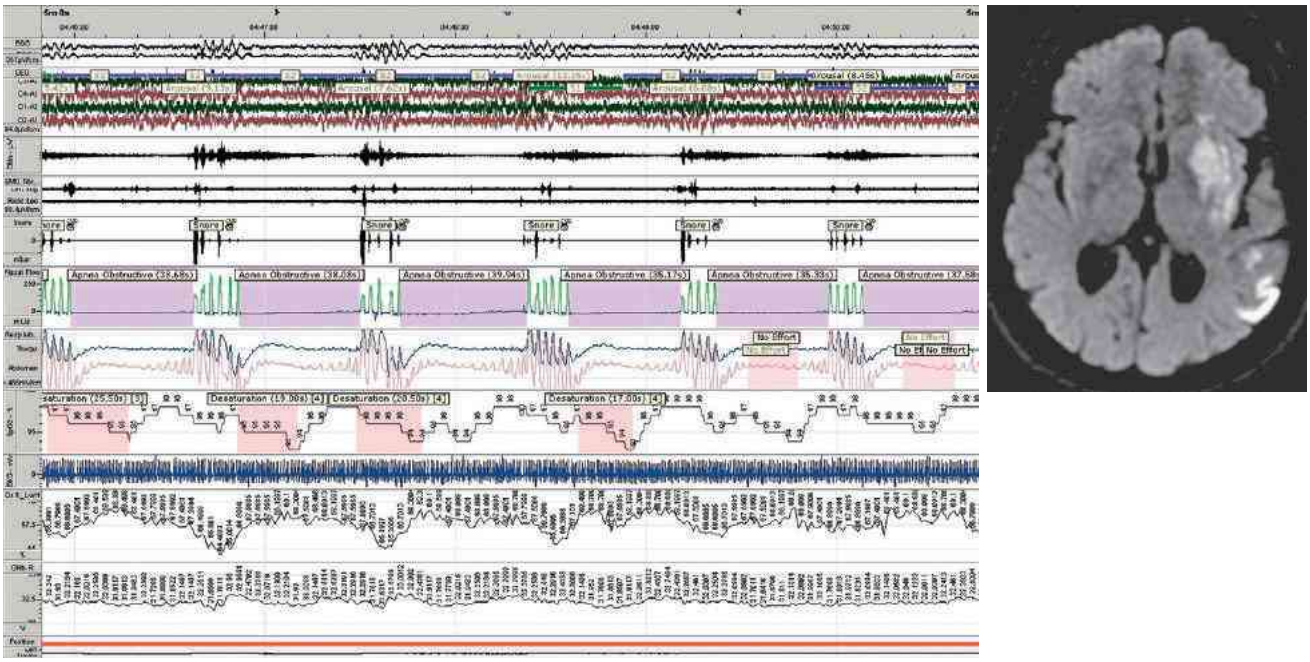

Figure 93-1 Obstructive sleep apnea in acute ischemic stroke. This 70-year-old man has left middle cerebral artery stroke, carotid artery occlusion, and atrial fibrillation. He has habitual snoring but no excessive daytime sleepiness. Aphasia and severe hemiparesis are clinically apparent. National Institutes of Health stroke score is 16, and there are no signs of heart failure. Polysomnography 2 days after stroke onset shows an apnea-hypoxia index (AHI) of 79 and minimum oxygen desaturation of 85%. The AHI normalized (<5/hr) with continuous positive airway pressure. (MRI pictures courtesy Professor A. Valavanis, Institute of Neuroradiology, University Hospital, Zürich, Switzerland.)

Figure 93-2 Central sleep apnea in acute ischemic stroke. This 63-year-old man had a left subcortical stroke of unknown origin, with arterial hypertension and habitual snoring but no excessive daytime sleepiness. He had a mild hemiparesis, with a National Institutes of Health stroke score of 8 and no signs of heart failure (cardiac ejection fraction, 55%). Polysomnography the first night after stroke onset showed an apnea-hypoxia index (AHI) of 53 (mainly central apneas). The patient spontaneously improved after 1 week (AHI 16). (MRI pictures courtesy Professor G. Schroth, Institute of Neuroradiology, University Hospital, Bern, Switzerland.)

Ondine's curse), usually imply a lateral medullary stroke, often bilateral.[34,35] Damage to the medullary reticular formation and nucleus ambiguous may cause a loss of automatic breathing, whereas a lesion that includes the nucleus of the solitary tract is necessary to cause failure of both automatic and voluntary respiration.[36] Volitional breathing can be impaired by brainstem strokes involving corticobulbar and corticospinal pathways at pontine and medullary levels.[30]

Spinal cord stroke can impair both automatic and voluntary breathing. Anterior spinal artery strokes can affect reticulospinal pathways, located anteriorly in the lateral columns of the first three cervical segments, which are crucial for automatic breathing.[37] In contrast, posterior spinal artery strokes can damage corticospinal pathways in the dorsolateral spinal cord and impair voluntary control of breathing.[38] Strokes that extend up to the C1 level usually cause severe respiratory insufficiency and necessitate ventilatory support.

Repetitive yawning can accompany hypersomnia (e.g., in patients with thalamic or posterior hypothalamus stroke) and can also occur as a release phenomenon in patients with brainstem and supratentorial lesions. Yawning can also occur with insular and caudate lesions.[39]

Pathophysiology

Several acute and chronic consequences of nocturnal respiratory events may explain the link between SDB and increased risk for stroke. Sympathetic hyperactivation, intermittent hypoxemia and oxidative stress, and inflammation likely increase the risk for atherosclerosis and cardiovascular morbidities. However, this link has been difficult to prove because sleep apnea and stroke share many of the same risk factors such as obesity and diabetes.

Sleep-Disordered Breathing as a Risk Factor for Stroke: Acute Effects

Acutely, apneas and hypopneas during sleep can be accompanied by decreased cardiac output, cardiac arrhythmias, systemic hypotension or hypertension, vasodilation due to hypoxia and hypercapnia, and increased intracranial pressure. These factors lead to a roughly 15% to 20% reduction in cerebral blood flow velocities during respiratory events.[40,41] Large fluctuations in cerebral blood velocities (and flow) may be particularly detrimental because patients with SDB have been shown to have diminished vasodilator reserve and impaired cerebral autoregulation.[41]

Type, duration, and timing of respiratory events affect hemodynamic consequences. Near infrared spectroscopy (NIRS) studies have shown that SDB can disrupt autoregulatory mechanisms and cause brain hypoxia, particularly with severe SDB (AHI > 30)[42] (Figure 93-3). These effects may be particularly detrimental to the ischemic region (penumbra) bordering the stroke.[43] Transcranial Doppler studies have shown that obstructive apneas of long duration and occurring during REM sleep may also be particularly detrimental.[44] CSB and central apneas also can alter cerebral blood flow.[44] Paradoxical embolization due to right-to-left shunting in patients with patent foramen ovale during long apneas is another potential mechanism of stroke.[17,45,46]

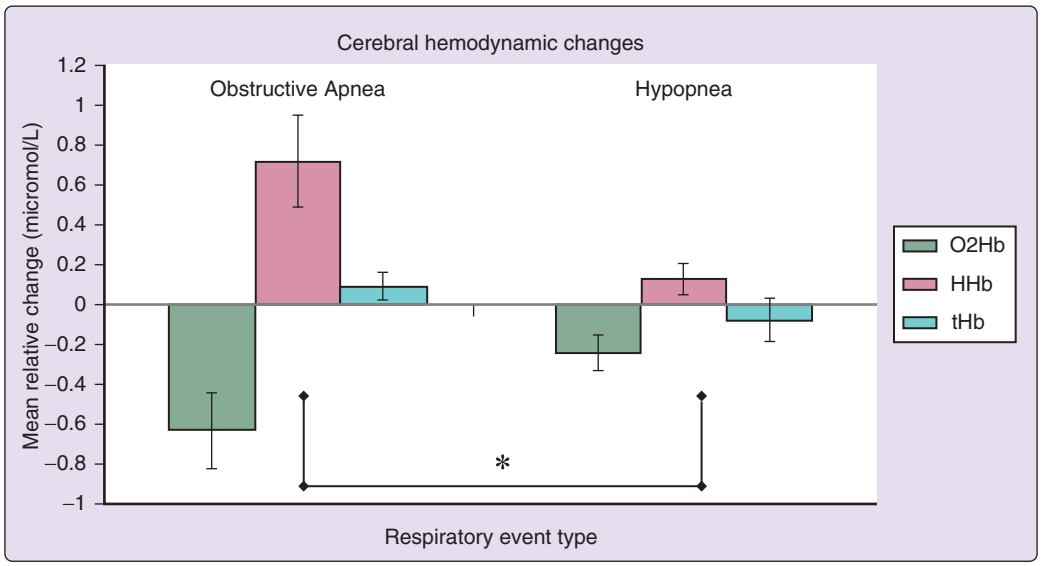

Figure 93-3 Cerebral hemodynamic alterations in patients with sleep-disordered breathing as estimated by near infrared spectroscopy (NIRS). Patients with snoring (n = 7, apnea-hypopnea index [AHI] = 2 ± 2/h); mild SDB (n = 7, AHI = 14 ± 8/h, range); and severe obstructive sleep apnea syndrome (n = 5, AHI = 79 ± 20/h) were studied. NIRS data associated with different respiratory events (obstructive apnea and hypopnea) were averaged for each patient. Subsequently, corresponding cerebral hemodynamic (and peripheral oxygen saturation, SpO_2) relative changes were assessed via integrals adjusted for duration. The relative changes in brain tissue parameters (concentrations of oxyhemoglobin [O_2Hb], deoxyhemoglobin [HHb], and total hemoglobin [tHb]) were significantly larger during obstructive apneas than during hypopneas.[42]

In light of these observations, it is not surprising that snoring and SDB have been associated with the onset of cerebrovascular events at night and strokes that are apparent on awakening (so-called wake-up strokes).[23,46-48]

Sleep-Disordered Breathing as a Risk Factor for Stroke: Chronic Effects

Chronically, SDB and even habitual snoring are associated with hypertension, which is a major risk factor for stroke. In the Wisconsin sleep cohort, an AHI of greater than 15 was independently associated with a threefold increased risk for developing new hypertension within a 4-year period.[49] In a prospective cohort study of 1889 participants without hypertension, Marin and colleagues found an increased risk for incident hypertension within a 12-year period in patients with an AHI of 5 or greater who were ineligible for CPAP therapy (OR = 1.33, 95% CI = 1.01 to 1.75), among those who declined CPAP therapy (1.96; 95% CI = 1.44 to 2.66), and among those nonadherent to CPAP therapy (1.78; 95% CI = 1.23 to 2.58), whereas the risk was lower in patients with AHI of 5 or greater who were treated with CPAP therapy (0.71, 95% CI = 0.53 to 0.94).[50] Importantly, these effects were independent from changes in body weight.

SDB is associated also with coronary heart disease, myocardial infarction, heart failure, and atrial fibrillation, all of which are also risk factors for stroke.[51,52]

Several observations support the hypothesis that SDB worsens atherogenesis. The intima media thickness of the common carotid artery is increased in SDB patients compared with controls matched for age and vascular risk factors.[53] Patients with SDB have increased arterial stiffness, a recognized marker of cardiovascular risk and long-term morbidity.[54]

A few studies have shown that CPAP produces reductions in mean arterial blood pressure. Pepperell and colleagues reported that therapeutic CPAP reduced mean arterial blood pressure by 2.5 mm Hg, whereas subtherapeutic CPAP levels increased blood pressure by 0.8 mm Hg. Such an effect could reduce stroke risk by about 20%.[55] Although the effects of CPAP on hypertension and cardiovascular events are debated, CPAP has been shown to reduce blood pressure in OSA patients with cardiovascular disease or multiple cardiovascular risk factors.[56,57] Treatment with CPAP also can improve other detrimental hemodynamic, neural, and molecular effects of SDB such as factor VII clotting activity, fibrinogen levels, and platelet activation or aggregation.[58]

Sleep-Disordered Breathing as a Consequence of Stroke

Although patients at risk for cerebrovascular disease frequently have SDB before they experience a stroke, some develop SDB as a consequence of stroke. The observation that recovery from stroke may be accompanied by improvement of nocturnal respiratory parameters indirectly supports the hypothesis that SDB can worsen or may even appear de novo after stroke (see earlier). Several factors may be involved.

First, CSB was traditionally attributed to CO_2 hypersensitivity secondary to bilateral and severe strokes with heart failure and a decreased level of consciousness,[59] but subsequent studies have challenged this view.[26,28,60] Changes in ventilatory sensitivity to inhaled CO_2 can also occur in patients with rostrolateral medullary lesions and with unilateral, small strokes of the central autonomic network (including the insula) and without heart failure.[28] Noteworthy, strokes in these areas can also cause acute cardioautonomic changes, including atrial fibrillation.[61] Nonneurogenic factors including older age, left ventricular failure, coronary heart disease,

acute caudorostral fluid shifts related to the nocturnal recumbent body position, and carotid stenosis may also contribute to the appearance of CSB.[26,28,62,63] Of note, CSB in the context of asymptomatic carotid stenosis (in 39% of patients in one study) was associated with a shift in sympathicovagal balance secondary to an increased baroreflex and chemoreflex sensitivities in the carotid body.[64]

Second, patients with stroke may have SDB from weak upper airway muscles or poor coordination between upper airway, intercostal, and diaphragmatic muscles due to brainstem or hemispheric lesions that impair cranial nerve function.[65] Accordingly, dysphagia and hypoglossal nerve dysfunction are associated with poststroke SDB.[66,67]

Third, acute brain damage may affect respiratory drive (see earlier).

Finally, other factors such as hypoxemia due to aspiration or respiratory infections, reduction of voluntary chest movements on the paralyzed side, supine position, and sleep fragmentation secondary to stroke or stroke complications can also lead to SDB.

Acute and Chronic Clinical Effects and Consequences

SDB in patients with cerebrovascular disorders can have a variety of detrimental effects. Acutely, SDB detected the first night after brain infarction is associated with early neurologic worsening, longer hospitalization, and detrimental physiologic changes such as higher blood pressure and reductions in cerebral oxygenation[43,47,68,69] Higher blood pressure in the acute phase of stroke is linked with a poorer clinical outcome.

Chronically, habitual snoring and SDB also worsen stroke outcome. A recent systematic review of the effects of SDB on recurrence and death of stroke and TIA patients generally supports a dose-response relationship between severity of SDB and risk for recurrent events and all-cause mortality.[70]

SDB can also worsen functional outcome. Stroke patients with nocturnal oxygen desaturations had a poorer functional outcome than those without desaturations.[71] In 61 patients in a stroke rehabilitation unit, OSA was associated with more functional impairment and longer hospitalization.[72] In a series of 120 stroke patients, those with an AHI of more than 10 within 24 hours of stroke onset had worse functional outcome (as assessed by the Barthel Index) and higher mortality at 6 months.[73] Similarly, in a study of 60 patients, patients with an AHI of more than 15 had a poorer functional outcome at 6 months.[74] More recent studies have shown that SDB may negatively affect clinical outcome within the first weeks after stroke onset.[75-77]

Diagnosis

Based on SDB's impact on stroke outcome and treatability, the American Heart Association and American Stroke Association now recommend that assessment of SDB should be considered in all patients with TIA and stroke.[2] On a practical level, screening and treatment of SDB in stroke patients are also cost-effective.[78]

The suspicion of SDB should be particularly high in obese male patients with a history of habitual snoring, witnessed apneas, hypertension, diabetes mellitus, and sleep-onset/wake-up stroke.[15,23,47] In clinical practice, asking the patients and relatives about sleep-related breathing symptoms (using, e.g., the Berlin Questionnaire) and excessive daytime sleepiness preceding the onset of stroke was shown to be helpful.[79,80]

Bedside assessment of sleep breathing can provide more accurate estimates of SDB. Different forms of unattended respirography or polysomnography (e.g., AutoSet, ApneaLink, and LifeShirt) may be sufficiently accurate to diagnose SDB and estimate its severity even in the acute setting.[19,23,69,81] Full polysomnography is eventually needed only in a minority of patients.

The optimal timing of sleep studies after stroke or TIA is unknown. Although studies within days of a stroke might be less representative of the patient's baseline, treatment of SDB soon after stroke could potentially minimize further brain injury and improve outcome.

Treatment of Sleep-Disordered Breathing

Treatment of SDB in stroke patients can be a clinical, technical, and logistical challenge. Treatment strategies should always include prevention and early treatment of secondary complications (e.g., aspiration, respiratory infections, pain) and cautious use or avoidance of alcohol and sedatives that may worsen breathing during sleep. Patient positioning in the acute phase can improve oxygen saturation and reduce severity of OSA by 20%.[82-84] In heart failure patients, a lateral sleeping position was shown to reduce the severity of central sleep apnea.[85]

The effect of supplemental oxygen in the acute phase after stroke is unclear.[86] Even the most recent guidelines of the European Stroke Organization and American Heart Association/Stroke Association, while pointing to the necessity to keep oxygen saturations above 92% to 94%, do not specify how to measure or correct nocturnal oxygen saturation.[87] In a recent trial of SDB patients, oxygen was found to be inferior to CPAP in reducing blood pressure levels in patients with high cardiovascular risk.[57]

Initial reports questioned the feasibility and utility of treatment with CPAP and other nocturnal ventilator devices in stroke patients. Based on a review of the 26 studies published until December 31, 2014 including a total of 901 treated patients, we recommend a more optimistic approach to treatment (see later).

Treatment of Obstructive Sleep-Disordered Breathing

CPAP is usually the treatment of choice for obstructive SDB, but CPAP compliance can be a challenge because most patients with stroke and SDB lack excessive daytime sleepiness and may not perceive much benefit from CPAP. In addition, stroke patients may have trouble using CPAP if they have dementia, delirium, aphasia, anosognosia, pseudobulbar or bulbar palsy, or severe motor impairment.

Initially, CPAP studies were mainly performed in the subacute phase of stroke (>1 month after onset). In a study of 105 stroke patients treated in a rehabilitation unit, CPAP was accepted by 70%, and poor acceptance was associated with aphasia and severe stroke. CPAP use over 10 days led to an improvement of subjective well-being and lower night-time blood pressure values.[88] CPAP compliance was poor (29%) over the first month of treatment in a series of 51 patients,[89] but over the next 18 months, CPAP use was associated with a five times reduction in vascular events. In a subsequent study, 5-year mortality was reduced in 28 stroke patients with mild to moderate SDB (AHI ≥20) who were treated with CPAP compared with 68 patients with SDB who did not tolerate treatment.[90]

More recently, several studies have examined the feasibility and effects of CPAP treatment started in the acute setting. Sandberg and colleagues reported a good effect on depressive symptoms even when CPAP was started within 2 to 4 weeks from stroke onset.[91] First series emphasized poor CPAP compliance in this clinical setting (ranging from 12% to 22% in patients followed for 2 to 60 months).[22,23,92,93] Recent studies on this topic reported better compliance when CPAP treatment was begun in the first one to three nights after hospitalization. These better results may have arisen from careful selection of patients, the use of new respiratory devices (including adaptive servoventilation [ASV] machines) and headgears, higher motivation and instruction of the treating teams, and frequent contact with patients.[75,94] One randomized trial showed a favorable effect on stroke severity (National Institutes of Health stroke scale) in patients treated with auto-CPAP within 48 hours of hospitalization.[75] In 45 patients with acute TIA, auto-CPAP had acceptable adherence and reduced the risk for recurrent stroke 82% over a treatment period of 90 days.[95] In stroke patients treated within 24 hours with CPAP, stroke severity was improved in those using CPAP more than 4 hours/night.[77] In the largest study thus far, Parra and colleagues reported an improved 1-month neurologic recovery and fewer cardiovascular events by 24 months in 71 patients with moderate to severe SDB (AHI ≥20) started on CPAP within the first 3 to 6 days after stroke onset compared with 69 untreated SDB patients.[81] At 5 years, the treated SDB patients also had better survival than the untreated SDB stroke group.[96]

Treatment of Central Sleep-Disordered Breathing

In patients with mainly central apneas and CSB, breathing disturbances can be improved with oxygen and possibly also lateral sleeping position (see earlier). Clinical experience and a few studies suggest that adaptive ASV may be effective in poststroke CSB and central sleep apnea patients, including those nonresponsive to conventional CPAP.[97]

Tracheostomy and mechanical ventilation may become necessary in patients with central hypoventilation, central apneas, and ataxic breathing.

Hiccups can be treated with neuroleptics or baclofen.

In sum, current data suggest the feasibility of CPAP and ASV treatment in patients with poststroke obstructive and central SDB with an acceptable compliance even when diagnosis and treatment take place in the acute setting. Further studies are needed to better define the best approach in different patient subpopulations according to type and severity of SDB and interval after the acute cerebrovascular event.

SLEEP-WAKE DISTURBANCES AND STROKE

Epidemiology

Sleep-Wake Disturbances and Short Sleep Duration as Risk Factors for Stroke

Several studies have linked insomnia with increased risk for cardiovascular events and death.[98,99] Two meta-analyses have confirmed that short sleep duration (≤6 hours) slightly increases the risk for ischemic stroke (OR = 1.2, 95% CI = 1.0 to 1.3).[100,101] A large study of 21,438 Asian insomniac patients and 64,314 matched noninsomniac patients found a 54% higher risk for stroke over a 4-year follow-up period.[102] Another large study of 30,934 U.S. subjects reported that short sleep duration (<5 hours) independently increased the risk for stroke 61%.[103] This increase in risk may be due to an increase in sympathetic activity secondary to sleep loss and fragmentation and recurrent arousals with consequent hypertension and impaired glucose metabolism.[104,105]

Conversely, a few studies have suggested an association between long sleep duration or excessive daytime sleepiness and an increased risk for stroke.[100,101,103,106] In a study of 2088 elderly community residents, more than 44% of the cohort reported no daytime dozing, 47% some dozing, and 9% significant daytime dozing. Compared with those reporting no daytime dozing, individuals reporting significant dozing had a 74% increased risk for ischemic stroke.[106]

Restless legs syndrome (RLS) and periodic limb movements during sleep (PLMS) may also increase the risk for cardiovascular diseases, including stroke.[105,107]

Whether shift work increases the risk for stroke remains controversial.[108]

Sleep-Wake Disturbances in Stroke Patients

Clinical experience and a few studies suggest that SWD are frequent after strokes, but few studies have assessed their prevalence and determinants systematically.

In a series of 100 consecutive stroke patients assessed in the acute phase, 22% had an Epworth Sleepiness Scale score of 10 or higher (excessive daytime sleepiness) or increased sleep need (2 or more hours sleep per 24 hours compared with the prestroke situation).[109]

In a series of 235 patients assessed 0.3 to 2 years after stroke, 46% reported abnormal fatigue (fatigue severity scale ≥4.0).[110] Other studies have suggested similarly high frequencies (up to 70% of patients) of poststroke fatigue, making it the most common SWD in stroke survivors.[110-112]

In a series of 277 consecutive patients evaluated 3 months after stroke, insomnia was reported by 38% of patients, and in 18% of these insomnia patients, their insomnia appeared de novo after stroke.[113] In a recent Brazilian study, insomnia was found in 38% of 40 stroke patients.[114]

In a series of 137 patients assessed 1 month after stroke, RLS symptoms were found de novo in 12% of patients.[115]

Other SWD after strokes include an abnormal transition from wakefulness to sleep and vice versa, with dream-reality confusion (oneiric state), dream changes, and an altered perception of time (*Zeitgefühl*).[116,117]

Clinical Features, Pathophysiology, and Treatment

Hypersomnia and Excessive Daytime Sleepiness

After a stroke, some patients may require more sleep (hypersomnia) and or have excessive daytime sleepiness (EDS). Reduced arousal because of lesions involving the ascending arousal pathways is the most common cause of poststroke hypersomnia.[109] The most severe and persistent hypersomnia occurs in patients with bilateral lesions of the thalamus (Figure 93-4), subthalamic and hypothalamic area, tegmental midbrain, and pons (Figure 93-5), where fibers of the ascending arousal pathways are bundled and can be severely injured even by single small lesions. Hypersomnia after hemispheric stroke (Figure 93-6) usually occurs with large lesions, on the left more than on the right, and anteriorly more than posteriorly.[118-121] In large hemispheric strokes, loss of arousal and coma can occur with injury to the upper brainstem secondary to brain edema and herniation.

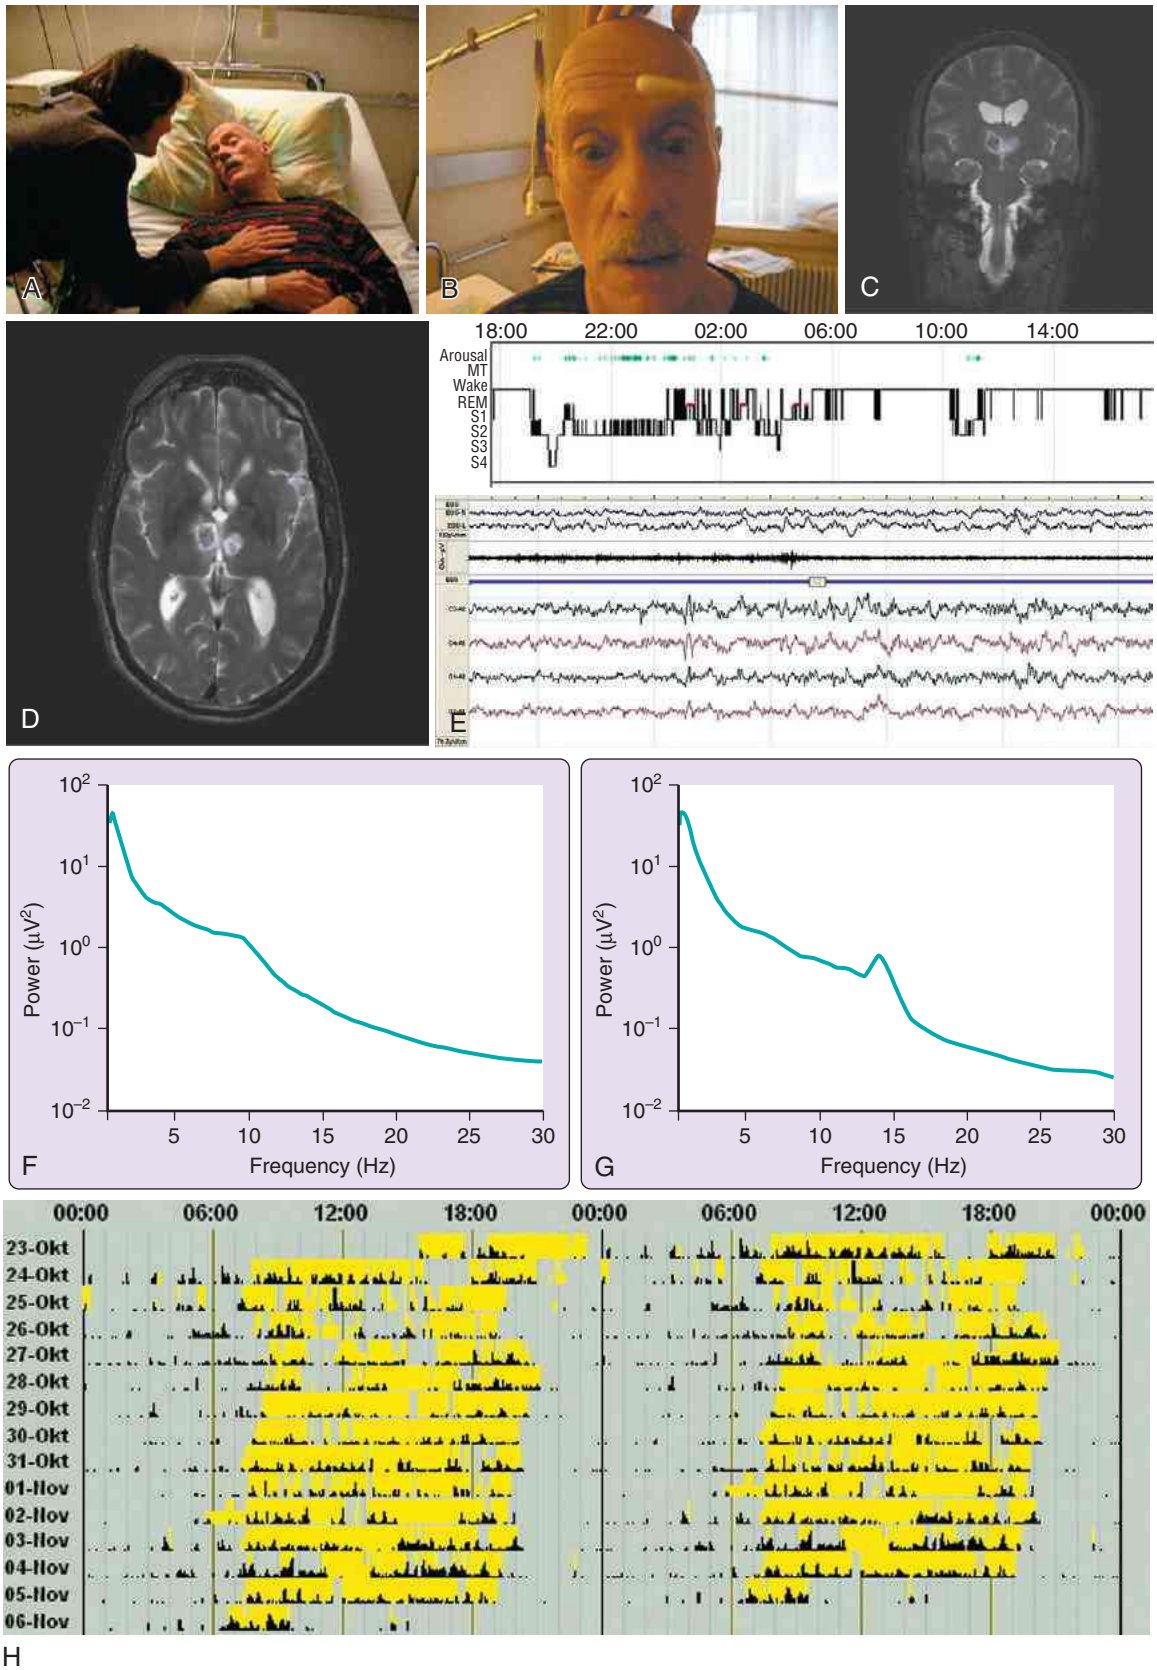

Figure 93-4 Hypersomnia after bilateral paramedian thalamic stroke. This 65-year-old man had initial coma, followed by severe hypersomnia **(A),** vertical gaze palsy **(B),** amnesia, and disturbed time perception (Zeitgefühl). Brain magnetic resonance imaging (MRI) showed bilateral paramedian thalamic strokes **(C, D).** Polysomnography 12 days after stroke onset demonstrated a drastic reduction of sleep spindles **(E)** and loss of spindle peak **(F)** (12 to 14 Hz activity) on spectral analysis (compared with a normal control **[G]**). Severe central apnea (apnea-hypopnea index, 54/hr, >90% central) was observed in the acute phase (in the absence of any signs of cardiac dysfunction) but not on follow-up a few months later. Actigraphy performed in the first month after stroke shows time "asleep" (rest or sleep) was 61% of the recording time (2 weeks) **(H).** One year after stroke, the patient still reported increased sleep need (15 hours per day), apathy (athymormia), and attentional and memory deficits. Modafinil at a dose of 200 mg per day improved his hypersomnia. (MRI pictures courtesy of Professor A. Valavanis, Institute of Neuroradiology, University Hospital, Zürich, Switzerland.) (From Bassetti CL, Hermann DM. Sleep and stroke. In: Vinken PJ, Bruyn GW. *Handbook of Clinical Neurology: Sleep Disorders.* New York: Elsevier; 2010.)

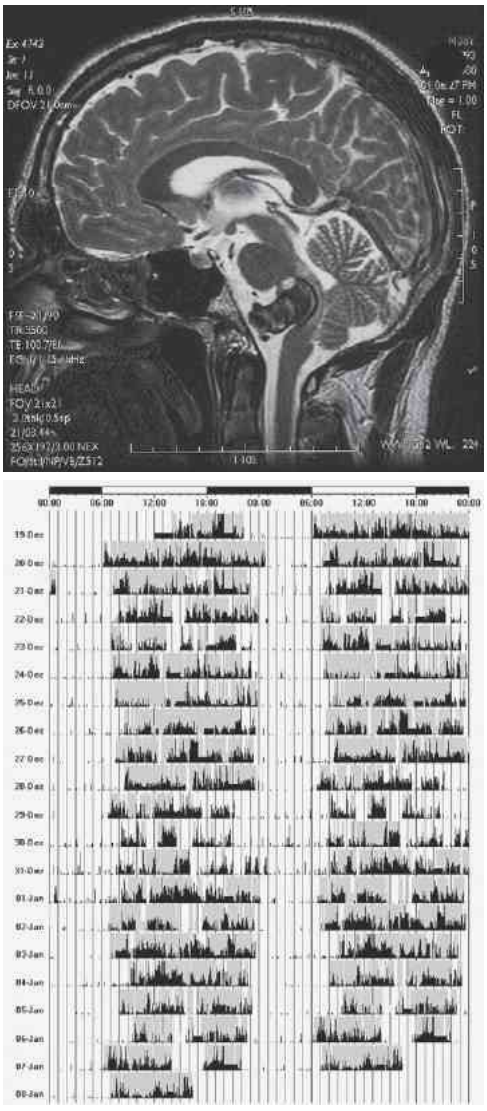

Figure 93-5 Hypersomnia and excessive daytime sleepiness after pontomedullary stroke. This 39-year-old man had pontomedullary ischemia following subarachnoid hemorrhage and embolization of a giant aneurysm of the basilar artery. This resulted in a brainstem syndrome with hiccups; left IX, X, XII palsies; dysarthria; gait ataxia; and mild left hemiparesis. Sleep symptoms postintervention were severe excessive daytime sleepiness (Epworth Sleepiness Scale score of 23/24) and increased sleep need (12 to 14 hours/day). Polysomnography showed sleep efficiency 97%, slow wave sleep 8% of total sleep time, no sleep apnea, and no periodic limb movements in sleep. The Multiple Sleep Latency Test showed mean sleep latency of 1 minute and no sleep-onset rapid eye movement periods. Actigraphy showed that time "asleep" (rest or sleep) was 43% of the recording time (2 weeks). Cerebrospinal fluid levels of hypocretin-1 were normal. (MRI pictures courtesy Professor A. Valavanis, Institute of Neuroradiology, University Hospital, Zürich, Switzerland.)

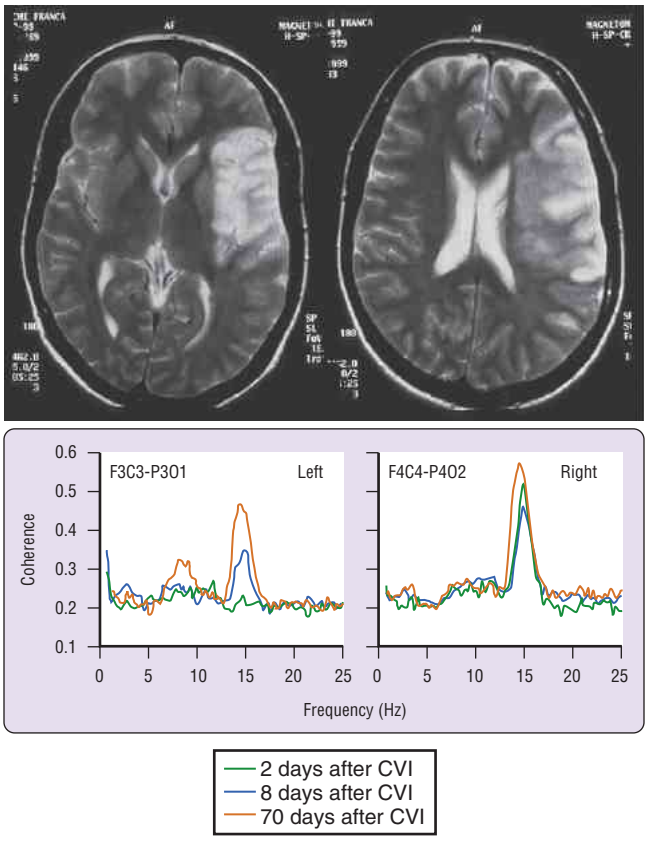

Figure 93-6 Hypersomnia and altered sleep architecture after middle cerebral artery stroke. This 39-year-old woman had aphasia, right hemiparesis, depressed mood, and crying spells. National Institutes of Health stroke score was 16. Before her stroke, the patient slept 7 hours/day, but in the first 1 to 2 weeks after her stroke, she slept 12 hours/day and had mild excessive daytime sleepiness (Epworth Sleepiness Scale score of 12). At 12 months, the patient reported an improvement in sleep need to 10 hours/day. Repeated polysomnograms on day 2, day 8, and day 70 after stroke demonstrated progressive recovery of spindling activity (coherent activity at about 12 Hz) over both the affected (*left*) and the unaffected (*right*) hemisphere. CVI, chronic venous insufficiency. (MRI pictures courtesy Professor G. Schroth, Institute of Neuroradiology, University Hospital, Bern, Switzerland.)

Hypersomnia has occasionally been documented polysomnographically in patients with thalamic, mesencephalic, and pontine strokes.[122-124] Such strokes may cause initial coma or, conversely, manic delirium, hyperalertness, and insomnia before hypersomnia evolves. Mental arousal seems to be affected more severely by medial lesions, whereas motor arousal (including spontaneous motor activities) is impaired more strongly by lateral lesions.[125,126]

In patients with strokes that injure arousal pathways or the paramedian thalamus, hypersomnia may alternate with insomnia (see earlier). For example, one 78-year-old patient with a tegmental mesencephalic infarct had severe, persistent hypersomnia accompanied by an inversion of the sleep-wake cycle with nocturnal agitation.[127]

With deep (subcortical) hemispheric and thalamic strokes, patients may exhibit so-called presleep behavior, during which they yawn, stretch, close their eyes, curl up, and assume a normal sleeping posture, while complaining of a constant sleep urge.[128] Some of these patients are able to control this behavior when stimulated or given explicit, active tasks to perform. This "presleep behavior" may be compulsive in that removal of the patient from bed can result in repeated attempts to lie down and adopt a sleeping posture. However, during what appear to be daytime sleep periods, relatively quick responses to questions or requests suggest wakefulness. For this peculiar dissociation between lack of autoactivation (spontaneous engagement in mental and motor activities) in the presence of preserved heteroactivation (mental and motor activities secondary to external stimulation), Laplane suggested the term athymormia, or "pure psychic akinesia".[129]

In some patients, hypersomnia evolves to extreme apathy with lack of spontaneity and initiative, slowness, poverty of movement, and catalepsy, a condition for which the term akinetic mutism was coined. Akinetic mutism, and its less severe form—usually referred to as abulia—may persist despite normalization of vigilance or even after appearance of insomnia. Some of these patients are eventually diagnosed to have poststroke fatigue (see later) or poststroke depression.

Narcolepsy-like phenotypes (with, however, atypical or questionable cataplexy) are rare with strokes but can occur in the absence of HLA positivity and cerebrospinal fluid hypocretin-1 deficiency. One 23-year-old patient had hypersomnia from bilateral diencephalic strokes; his hypocretin-1 levels were low, suggesting a link between poststroke hypersomnia and deficient hypocretin neurotransmission.[130]

Treatment of poststroke hypersomnia is often difficult, but improvements have been reported with amphetamines, modafinil, methylphenidate, and dopaminergic agents.[109,123] Bromocriptine may improve apathy and presleep behavior.[128] Treatment of an associated depression with stimulating antidepressants may also improve poststroke hypersomnia. It is noteworthy that a favorable influence on early poststroke rehabilitation was reported for both methylphenidate (5–30 mg/day, 3 weeks' trial) and levodopa (100 mg/d, 3 weeks-trial), an effect that may be partially related to improved arousal.[131,132]

Fatigue

A continuum exists among hypersomnia, depression, and fatigue, which is defined as a feeling of physical tiredness, exhaustion with lack of energy accompanied by a strong desire for sleep with usually normal or (paradoxically decreased) sleep propensity. Fatigue may be more common with brainstem strokes.[133] The Epworth sleepiness scale can sometimes help differentiate fatigue from EDS.[134]

An overlap exists between poststroke fatigue and poststroke depression. Psychological stress in coping with stroke probably plays an important role, as suggested by the absence of a correlation between poststroke fatigue and stroke size and site and by a similarly high frequency of fatigue after myocardial infarction (without brain damage).[135] Some have proposed that poststroke fatigue is caused by dysfunction of arousal and attentional circuits.[133] Activating antidepressants and amantadine can be tried for poststroke fatigue.[136] One study reported no benefit with fluoxetine.[137]

Insomnia

On rare occasions, strokes can cause insomnia directly, presumably through disruption of sleep mechanisms. One patient with a pontomesencephalic stroke had almost complete insomnia for more than 2 months.[138] Two patients with locked-in syndrome due to pontomesencephalic or bilateral basal pontine strokes had almost no sleep for more than 1 month.[139,140] Patients with caudate or subcortical (Figure 93-7), thalamic, thalamomesencephalic, and tegmental pontine stroke can have insomnia accompanied by an inversion of the sleep-wake cycle, with insomnia and agitation during the night and hypersomnia during the day.[138,140-142]

Aside from the brain damage, other factors may contribute to poststroke insomnia, including anxiety, dementia, medical disorders (e.g., heart failure, pulmonary disease), SDB, psychotropic medications, infections and fever, inactivity, environmental disturbances, stress, and depression.[113]

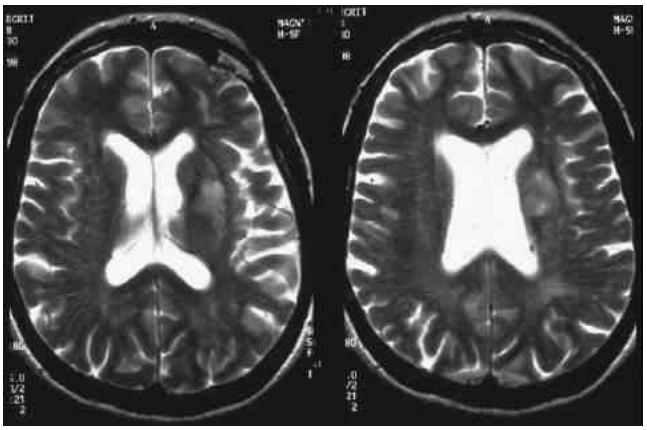

Figure 93-7 Insomnia after subcortical stroke. This 68-year-old woman had a left subcortical stroke in the corona radiata, with mild right motor hemiparesis. National Institutes of Health stroke score was 6. In the first poststroke week, she had almost complete insomnia and excessive daytime sleepiness (EDS). Two weeks later, her EDS was improved and she was sleeping 2 to 3 hours/night. Sleep-wake functions normalized after 4 weeks. (MRI pictures courtesy Professor G. Schroth, Institute of Neuroradiology, University Hospital, Bern, Switzerland.)

Treatment of poststroke insomnia should focus on behavioral measures such as placing patients in private rooms at night, protection from nocturnal noise and light, and mobilization with exposure to light during the day. If necessary, one could consider temporary use of hypnotics that are relatively free of cognitive side effects, such as zolpidem, zopiclone, and some benzodiazepines.[143,144] Still, these substances should be used cautiously because they can cause delirium and worsen neurologic deficits.[145]

Sleep-Related Movement Disorders and Parasomnias

REM sleep behavior disorder (RBD) has been reported to occur after strokes in the tegmentum of the pons.[146-148]

RLS has been observed de novo after stroke.[149-152] In a recent series of 137 patients with stroke, RLS was found mainly after pontine, thalamic, basal ganglia, and corona radiata strokes.[115] Most commonly, RLS was bilateral, appeared within 1 week after stroke, and was accompanied by PLMS in sleep.

After stroke, PLMS can worsen (and even appear de novo) and lead to insomnia (Figure 93-8). PLMS may also occur after unilateral hemispheric and spinal strokes.[105,153]

Hallucinations and Altered Dreams

Patients with strokes in the pons, midbrain, or paramedian thalamus may experience peduncular hallucinosis, characterized by complex, often colorful, dreamlike visual hallucinations, particularly in the evening and at sleep onset (Figure 93-9).[154-157] Peduncular hallucinosis may represent a release of REM sleep mentation. It can be associated with insomnia and usually resolves spontaneously within a few days.

The Charles Bonnet syndrome generally involves less complex visual hallucinations that also occur in the setting of diminished arousal. These hallucinations maybe limited to a hemianopic field and may be a "release phenomenon" in response to the lack of sensory input.[158,159]

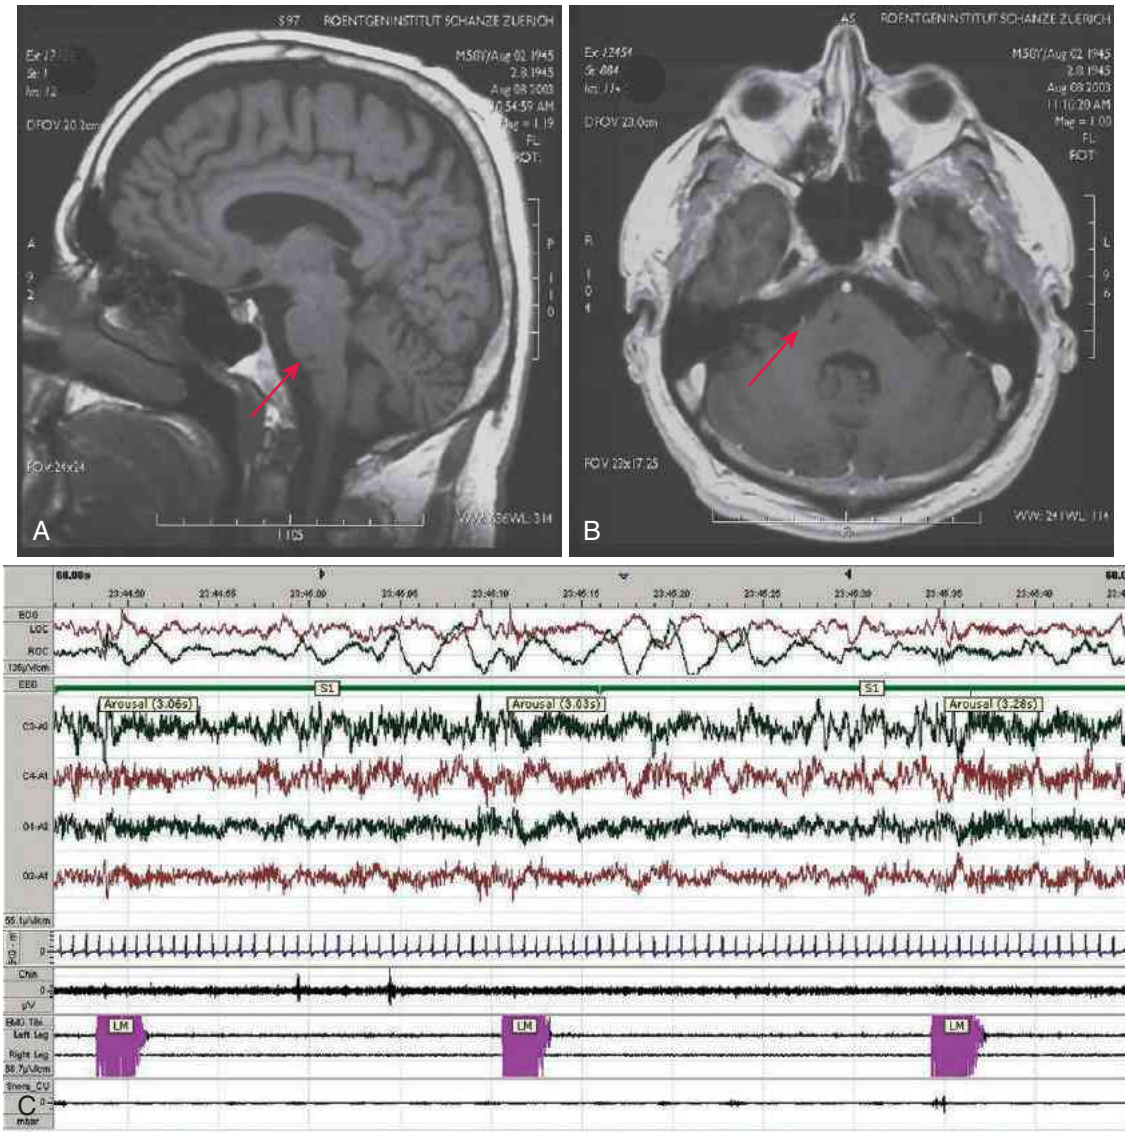

Figure 93-8 Insomnia and left-sided periodic limb movements after right paramedian pontine stroke. This 60-year-old man had a unilateral lacunar stroke in the right paramedian pons **(A** and **B).** He acutely developed severe insomnia, with involuntary, jerky, and tremorlike movements of the left leg and arm appearing intermittently at sleep onset and during sleep (periodic limb movements [LM]) **(C).** The patient denied restless legs symptoms. (MRI pictures courtesy Professor A. Valavanis, Institute of Neuroradiology, University Hospital, Zürich, Switzerland.)

Cessation or reduction of dreaming occurs in the Charcot-Wilbrand syndrome and is occasionally limited to alteration of the visual component of the dream.[160,161] This syndrome can occur in patients with parietooccipital, occipital, or deep frontal strokes, and the lesions are often bilateral.[162-165] Patients frequently show a deficient revisualization (i.e., an impairment to picture again something seen that was previously seen), topographic amnesia, and prosopagnosia. Conversely, REM sleep characteristics may be normal.[164] Severe insomnia and loss of dreaming have been reported with lateral medullary stroke.[142]

Focal (temporal) seizures secondary to stroke can lead to the syndrome of dream-reality confusion or to recurrent nightmares, which may be more frequent with right-sided lesions and can be controlled with antiepileptics.[166]

An increased frequency or vividness of dreaming may occur after stroke, particularly with thalamic, parietal, and occipital strokes.[162]

A few patients with severe motor deficits may report the persistence of seemingly normal motor function within their dreams for up to several years after stroke. Waking up in the morning is a source of great distress in these patients. In other patients, motor handicap may, conversely, be apparent in incorporated in dreams within a few days of stroke onset.

Clinical Significance of Sleep-Wake Disorder after Stroke

Considering the strong evidence that sleep promotes neuroplasticity and the importance of neuroplasticity in recovery after brain damage, it is possible that good quality sleep may

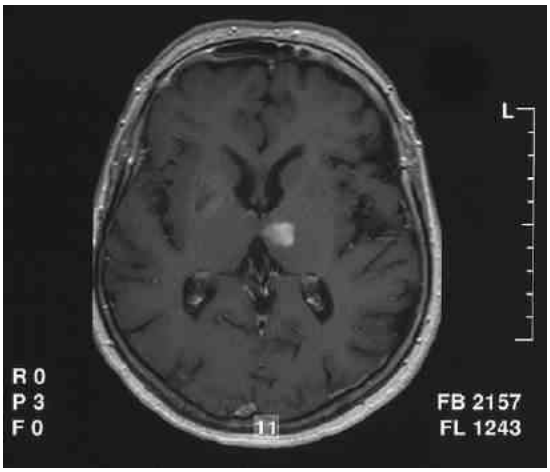

Figure 93-9 Dreamlike hallucinations after unilateral paramedian thalamic stroke. This 62-year-old woman had a left paramedian thalamic stroke and presented with confusion, abulia, anomia, and moderate to severe amnesia in the absence of major sleep-wake disturbances. In the first few days after stroke, the patient had recurrent episodes of visual and acoustic hallucinations in the form of human figures (mostly relatives, partial insight) seen on the right side of the visual field, which the patient described as dreamlike. At 7 months after stroke, the patient had persistent memory problems and reported almost daily episodes of psychic hallucinations ("sensed presence") and a disturbed time perception (Zeitgefühl). On polysomnography, she had no significant changes in rapid eye movement sleep. (MRI pictures courtesy Professor A. Valavanis, Institute of Neuroradiology, University Hospital, Zürich, Switzerland.)

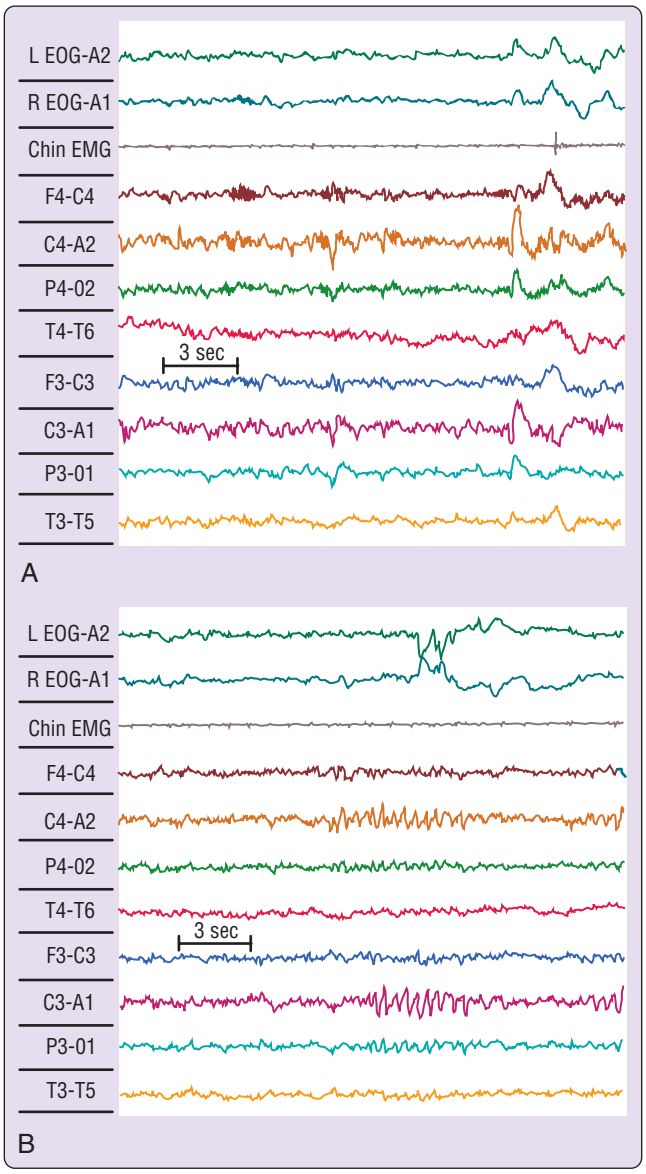

Figure 93-10 Sleep spindles and sawtooth waves after severe middle cerebral artery stroke. This 58-year-old man had a moderately severe left middle cerebral artery stroke (Scandinavian Stroke Scale score, 33/58). Polysomnography 9 days after stroke showed mild obstructive sleep apnea (apnea-hypoxia index = 16). **A,** In NREM sleep, spindling decreased ipsilaterally, with three spindles per hour recorded at C3 and 172 per hour at C4. **B,** In rapid eye movement sleep, sawtooth waves were symmetrical.

improve outcome after stroke. However, the evidence thus far is only indirect.

Several studies have shown that SWD disturbances after stroke are associated with cognitive and psychiatric (depression, anxiety) disturbances and worse outcome.[113,124,167-169] Fatigue at 2 years after stroke has been found to predict institutionalization and mortality.[170] Poststroke RLS also predicts a worse outcome at 3 and 12 months.[171] In humans, sleep between rehabilitation sessions was recently shown to positively influence motor recovery and learning.[172]

In animal models of stroke, sleep deprivation and fragmentation worsened stroke evolution and outcome, whereas sleep-promoting drugs improved functional outcome.[173-176] Sleep deprivation and disturbance in rats worsens functional recovery from stroke and underlying neuroplasticity processes.[177,178] Although the exact underlying molecular mechanisms remain unclear, axonal sprouting and synaptogenesis were significantly inhibited in rats that underwent sleep deprivation during the acute phase of stroke.[178] Conversely, sleep-promoting drugs such as γ-hydroxybutyrate and baclofen were found in both mice and rats to improve functional outcome and neuroplasticity after stroke.[173]

SLEEP ARCHITECTURE CHANGES

Abnormalities in sleep macrostructure and microstructure are common after acute stroke but result only in part from acute brain damage. Changes in sleep architecture depend on (1) health before the stroke (e.g., age, respiratory disturbances); (2) topography of the lesion; (3) complications of stroke (e.g., SDB, fever, infections, cardiovascular disturbances, depression, anxiety); (4) medications; and (5) time after stroke onset. Even acute myocardial infarction patients without brain damage who are admitted to an intensive care unit often have decreases in total sleep time, sleep efficiency, REM sleep, and slow wave sleep.[179]

Some changes in sleep architecture are more specifically related to brain damage, such as persistent alterations of spindling and slow wave sleep with supratentorial strokes and REM sleep abnormalities with infratentorial stroke.

Supratentorial Strokes

Reductions in NREM sleep, total sleep time, and sleep efficiency can follow acute supratentorial stroke.[180-186]

Reduced spindling can be observed with thalamic and cortical-subcortical strokes (see Figure 93-4; Figure 93-10).[168,187-190] With unilateral thalamic strokes, sleep

spindles may be preserved.[124,168,183,191] Rarely, spindling and slow wave sleep increase in the acute stage of large middle cerebral artery stroke.[182,189,192] In some cases, the increase in scored slow wave sleep may reflect an increase in delta activity during both sleep and wakefulness.[185,193]

Transient reductions in REM sleep can occur in the first days after supratentorial stroke.[183,189] Changes in REM sleep may persist after large hemispheric strokes with poor outcome.[182,186] Sawtooth waves can be decreased bilaterally in large hemispheric strokes, especially those that involve the right side.[183,194] Cortical blindness has been associated with a reduction of rapid eye movements.[195]

Paramedian thalamic strokes often reduce spindling and, to a lesser degree, slow wave activity and K-complexes.[124,168,191] These strokes can produce severe hypersomnia with an almost continuous state of light NREM stage 1 sleep, perhaps reflecting an inability to produce full wakefulness.[124] In these patients, REM sleep can occur at night and during the day.[124]

Like the electroencephalogram (EEG) of wakefulness, the sleep EEG reorganizes after acute damage, but data on this subject are scarce.[186,196,197] In patients with paramedian thalamic stroke, recovery from hypersomnia may occur despite the persistence of significant NREM sleep changes.[124,168,198] In hemispheric stroke, conversely, sleep EEG changes usually recover over time, even in patients with severe stroke (>50 mL in volume).[184] Some of these changes may reflect neuroplasticity during functional recovery and therapeutic interventions.[197,199,200] Low sleep efficiency, decreased spindles, K-complexes, slow wave sleep, and REM sleep predict poor outcome when found after hemispheric strokes.

Infratentorial Strokes

Bilateral, paramedian infarcts in the pontine tegmentum or large bilateral infarcts in the ventrotegmental pons can reduce NREM and, especially, REM sleep.[122,201-206] Normal sleep EEG features such as sleep spindles, K-complexes, and vertex waves may be completely lost.[202,207]

Patients with abnormal sleep architecture may complain of insomnia, but isolated REM sleep loss can persist for years without obvious cognitive or behavioral consequences.[204,208]

Bilateral infarction adjacent to the pontine tegmentum, or unilateral infarction of this area, usually does not alter sleep architecture.[122,207,209]

Occasionally, NREM or REM sleep may be altered selectively. Strokes that affect the pontomesencephalic junction tegmentum and the raphe nucleus can moderately decrease NREM sleep with no major changes in REM sleep.[124,139] Infarctions of the paramedian thalamus and of the lower pons have been associated with absence of slow wave sleep but preservation of REM sleep and appearance of REM sleep at sleep onset.[124,203] In contrast, infarction in the lower pons can cause an almost completely selective decrease in REM sleep.[207] Conversely, midbrain strokes can increase REM sleep.[205,210]

CIRCADIAN ASPECTS AND DISTURBANCES

Ischemic stroke, like myocardial infarction and sudden death, occurs most frequently in the morning hours, particularly after awakening, between 6 AM and noon. A meta-analysis of 31 publications reporting the circadian timing of 11,816 strokes found a 49% increase in stroke of all types (ischemic stroke, hemorrhagic stroke, TIA) between 6 AM and noon.[211] Another study reported that thrombotic, lacunar, and embolic strokes are 20% to 30% more frequent in the morning.[212] Possible explanations for this pattern have focused on circadian or postural changes in platelet aggregation, thrombolysis, blood pressure, heart rate, and catecholamine levels that occur with awakening and resumption of physical and mental activities.[213] In addition, the most prolonged REM sleep period, during which autonomic system instability is known to occur,[214-216] occurs close to awakening. The highest incidence in the early hours of the morning can be overestimated because of patients who awaken with stroke. Treatment with aspirin does not modify the circadian pattern of stroke onset.[217,218]

Whereas intracerebral and subarachnoid hemorrhages rarely occur at night, 20% to 40% of ischemic strokes present at night.[219] This suggests that sleep may represent a vulnerable phase for a subset of patients with cerebrovascular disease, and clinicians should consider evaluation for SDB.

Acute brain infarction—particularly when the right hemisphere and the insula are affected—can disturb normal circadian variation in autonomic functions (e.g., heart rate, blood pressure, temperature control) and breathing and contribute to increased poststroke cardiovascular morbidity.[28,220-226] Acute stroke also may alter other circadian functions such as sleep-related secretion of growth hormone and melatonin.[192,225] A loss of physiologic blood pressure dipping is found in about 50% of patients with acute stroke and predicts a less favorable outcome.[226,227] Hyperthermia can occur with diencephalic strokes and is often associated with a poor prognosis.[228]

CLINICAL PEARLS

- Clinicians should consider SDB and sleep-wake disorders as potential risk factors for stroke as well as modulators of its outcome.
- The study of SDB and sleep-wake functions in poststroke patients offers a unique opportunity to expand our knowledge about the brain mechanisms involved in sleep-wake regulation.

SUMMARY

SDB independently increases the risk for stroke. SDB occurs in 50% to 70% of acute stroke and TIA patients. Although obstructive SDB is more commonly observed, mixed SDB and even central SDB (the latter particularly in the first days after stroke) are also more common in stroke patients than in the general population. In the subacute phase of stroke, SDB (particularly central events) can improve. Treatment of SDB is feasible even in the acute phase and can improve short- and long-term stroke outcome. It remains unclear which treatment should be chosen for which patients, with which severity of SBD, and at which interval after stroke.

Sleep loss or insomnia, EDS, hypersomnia, and RLS are potential risk factors for stroke. These sleep-wake disturbances are also observed in 20% to 50% of stroke victims and negatively affect stroke outcome. Brain damage and stroke complications (e.g., pain, mood changes, immobilization, drugs) are pathophysiologically involved. More systematic data are needed on frequency, characteristics, and management of poststroke sleep-wake disturbances and their effects on stroke outcome.

Sleep EEG changes reflect the topography and severity of stroke but also are influenced by neuroplastic changes during recovery from stroke. High-density sleep EEG may become a sensitive tool not only to monitor brain reorganization after stroke but also the effects of treatment interventions.

Animal experiments support the hypothesis that sleep loss and disturbances negatively affect stroke evolution, and conversely, sleep enhancement (e.g., pharmacologic) may positively influence stroke outcome. The molecular mechanisms involved remain to be elucidated.

Sleep and Neuromuscular Diseases

Michelle T. Cao; Christian Guilleminault

Chapter Highlights

- Patients with neuromuscular diseases are at risk for sleep-related problems, including sleep-disordered breathing and sleep hypoventilation, and when most severe, diurnal hypoventilation or respiratory insufficiency.
- Many factors can cause poor sleep quantity and quality in neuromuscular disease.
- The greatest advances in medical treatment of neuromuscular disease patients are in respiratory-related sleep disorders. The use of noninvasive ventilatory support devices has improved morbidity and mortality in this patient group.

Neuromuscular disorders are diseases of the motor unit comprising the lower motor neuron, nerve root, peripheral nerve, myoneural junction, and muscle. Any classification of neuromuscular disease may be somewhat arbitrary, and the astute clinician must keep in mind that the pathologic process may involve several segments of the nervous system and muscle. For example, neuropathies can lead to progressive, peripheral motor and sensory impairment along with autonomic dysfunction. Disorders such as amyotrophic lateral sclerosis (ALS) may progress rapidly toward death, whereas certain chronic polyneuropathies such as Charcot-Marie-Tooth disease, or autonomic syndromes such as familial dysautonomia, may have a slower evolution.

Patients with neuromuscular syndromes are at risk for sleep-related problems. Weakness, rigidity, and spasticity limit movement and posture changes during sleep, leading to discomfort, pain, and disrupted sleep. Difficulty maintaining comfortable positions may lead to cramping, abnormal uncontrolled movements, and weakness, which also contribute to poor sleep. Abnormal sphincter control may induce nocturia, incomplete emptying or incontinence, constipation, or painful defecation.

Sleep-related changes in respiration put the patient with a neuromuscular disorder at risk by impairing ventilation. Chronic respiratory muscle failure usually develops over years. It may initially present with sleep-disordered breathing (SDB), followed by progression to nocturnal hypoventilation, then diurnal hypoventilation, cor pulmonale, and eventual respiratory failure and end-stage disease. The slow progression of ventilatory failure in some disorders may go undetected for some time and contribute to increased mortality.

Limited attention is paid to the impact of sleep-related issues in this population, particularly because most clinics see a limited number of patients with neuromuscular disorders. Even in specialized neuromuscular clinics, a minority of patients are asked about their sleep problems or have been given a prior sleep evaluation.[1] Moreover, sleep specialists rarely manage the common problems in this population, such as spasticity, sphincter dysfunction, pain, abnormal movement, confusional arousal that can result in sleep fragmentation, insomnia, parasomnias, daytime fatigue, and hypersomnolence. Thus a multidisciplinary approach to treatment should be the standard of care in patients with neuromuscular disorders.

EPIDEMIOLOGY AND GENETICS

Each neuromuscular syndrome has distinct epidemiology and etiology. For example, ALS affects 0.005% of the U.S. population, and multiple sclerosis, a neurodegenerative disorder, affects 0.11%. There are no cumulative prevalence data that include all neuromuscular disorders. Many neurologic disorders, such as maltase deficiency, myopathy, myotonic dystrophy (MD), Rett syndrome, and familial dysautonomia, have a clear genetic origin. Other neuromuscular disorders can be secondary to traumatic, infectious, vascular, malignant, or degenerative diseases.

Although much research has addressed abnormal sleep and breathing in patients with neuromuscular diseases,[2-5] there are few large studies that examine the prevalence of SDB in these patients. One study from New Mexico[1] attempted to gather information from its entire neuromuscular clinic population. Although complete data were available for only 60 patients (20% of the clinic population), the investigators demonstrated that sleep and breathing abnormalities were present in more than 40% of patients.[1] Such a high prevalence is not surprising given the vulnerability of such patients to sleep-related reductions in muscle tone and overall ventilation. Patients with spinal cord injury (SCI) have been better studied. Compared with the normal population, individuals with SCI have significantly greater difficulties falling asleep and subjectively poor sleep; they also frequently require sleeping pill prescriptions, sleep more hours, take more and longer naps, and snore more.[6]

PATHOPHYSIOLOGY

The diaphragm is the major muscle of respiration during wakefulness and sleep. During non–rapid eye movement (NREM) sleep, there is an overall reduction in ventilation due

to altered chemosensation and increased impedance of the respiratory system. However, rib cage activity is maintained (albeit reduced), as is diaphragmatic activity. The importance of the diaphragm is particularly evident during rapid eye movement (REM) sleep. During REM sleep, there is postsynaptic inhibition of somatic motor neurons, causing further reduction or complete loss of tone in the intercostals and other muscles of respiration, but the diaphragm is relatively unaffected. Any process affecting the diaphragm, whether a myopathy or a process involving its innervation, can significantly reduce ventilation and oxygenation during REM sleep. In patients with bilateral diaphragmatic paralysis who are dependent on other respiratory muscles for breathing, marked oxygen desaturations can occur during REM sleep.[7,8] The REM sleep-related inhibition of intercostal and accessory muscles leads to profound hypoventilation during this sleep stage. As noted previously, the suppression of accessory respiratory muscle tone is a normal process of REM sleep and is seen in normal subjects.[9-11]

In some genetic neuromuscular disorders, muscle weakness can begin early in development, interfering with normal development of the skull and facial bones. For example, orofacial muscle weakness can affect growth of the maxilla and mandible, resulting in in the "long face" seen in congenital MD.[12] In rhesus monkeys, experimental reduction of nostril size by ligature with consequent impairment of nasal breathing leads to abnormal facial muscle contraction and secondary abnormal orofacial bone growth.[13,14] Similarly in humans, impaired nasal breathing leads to abnormal masseter contractions, consequently limiting orofacial growth.[15] Narrowing of dental arches, reduction in maxillary arch length, anterior crossbite, maxillary overjet, and overall narrowing of the facial skeleton are a result of changes in muscle contractions. These facial skeletal changes decrease upper airway diameter, consequently increasing its collapsibility during sleep.

Depending on the type of neuromuscular disorder, sleep-related breathing abnormalities may present as central apneas, obstructive apneas, nasal airflow limitation, or periods of prolonged hypoventilation, or there may be a combination that renders the neuromuscular patient at times difficult to treat. Sleep disruption with frequent cortical arousals may be due to discomfort with certain positions, muscle spasm, difficulty in clearing secretions, sphincter control, or increase in upper airway resistance from muscle weakness and secondary craniofacial changes. Periods of hypoventilation can contribute to arousals, reduced sleep time, and sleep deprivation from ventilatory and arousal responses to changes in oxygen and carbon dioxide (CO_2) levels. Although these changes may protect ventilation in the short term, over time ventilatory responses to changes in oxygen and CO_2 levels become blunted. This blunting leads to further worsening of hypoventilation, eventually occurring during both wakefulness and sleep.

CLINICAL FEATURES COMMON TO MOST NEUROMUSCULAR DISORDERS

Nonspecific complaints such as increased fatigue, daytime hypersomnolence, or disrupted sleep can be the initial manifestations of a slowly evolving neuromuscular disease of adult onset.[1] Such nonspecific complaints may also be the sole indication of a progressive neuromuscular disorder. Problems with clearance such as managing saliva or gastric contents can lead to significant drooling, esophageal reflux, or pulmonary infections from aspiration or retained secretions. Impairment of cough mechanisms may further impair the ability to clear secretions.

Autonomic dysfunction may be present in the form of abnormal sensitivity to temperature or pressure, with discomfort related to the use of sheets and blankets. The disease may psychologically affect individuals, leading to anxiety, depression, and insomnia, as can be seen with many other chronic illnesses. Pharmacologic agents that are prescribed in the evening may have alerting effects, whereas others used in the morning may lead to daytime sleepiness. In all, patients with chronic neuromuscular disorders can have many factors disrupting sleep, consequently worsening daytime function and quality of life. The addition of sleep-related problems complicates their already existing neurologic issues.

Neurodegenerative Diseases Involving the Motor Neuron

ALS is a degenerative motor neuron disease involving upper and lower motor neurons, leading to muscle weakness and atrophy throughout the body. Although ALS has not been shown to directly affect the sleep-regulating areas of the brain, it is likely that indirect effects of the disease contribute to sleep disruption.[16-18] Periodic limb movements associated with arousals and SDB may cause sleep disruption in ALS patients. SDB is reported in 17% to 76% of patients with ALS.[19] ALS patients with normal respiratory function, normal phrenic motor responses, and preserved motor units on electromyography may still have SDB with periodic oxygen desaturations independent of sleep stage (REM or NREM).[20] However, respiratory-related sleep disruption is generally not significant until phrenic motor neurons are involved and the diaphragm becomes weak. When there is involvement of the diaphragm, severe hypoventilation and hypoxemia occur during REM sleep, and nearly all these patients will need some form of ventilatory support. Some ALS patients without any respiratory disturbance or periodic limb movements still experience sleep fragmentation, independent of age. This suggests that other factors contribute to disturbed sleep, such as anxiety, depression, pain, choking, excessive secretions, fasciculation, cramps, and the inability to find a comfortable position or turn oneself freely in bed. Orthopnea, a frequent complaint in ALS, may also contribute to sleep disruption.[17,18]

Spinal Cord Disease

Poliovirus infection targets the nervous system in several ways by injuring cranial motor nuclei and spinal cord anterior horn cells, resulting in acute paresis. As a result, there are many effects on respiration. Abnormalities in central regulation of breathing in patients with acute and convalescent poliomyelitis were described in 1958 by Plum and Swanson.[21] Subsequently, central, mixed, and obstructive apneas have been noted.[22] Sleep and breathing abnormalities are seen not only in patients who are on respiratory assistance (e.g., rocking beds) during sleep but also before ventilatory assistance is initiated.[23] Sleep abnormalities include decreased sleep efficiency, increased arousal frequency, and varying degrees of apnea and hypopnea. After treatment of sleep and breathing abnormalities, many symptoms frequently attributed to the postpolio syndrome do improve. Although not all symptoms

can be explained,[24] excessive daytime sleepiness and fatigue can be explained by poor sleep quality related to abnormal respiration during sleep.[25]

Poliomyelitis can alter central and peripheral respiratory function decades after the acute infection, an important element of postpolio syndrome.[24] Muscle atrophy and immobility can lead to kyphoscoliosis and restricted ventilation. The anatomic deformities resulting from poliomyelitis may cause chronic pain and consequent sleep abnormalities. Also, bulbar involvement may affect upper airway muscles. SDB is reported in 31% of patients with postpolio syndrome.[24] Prolongation of REM sleep latency may result from prolonged recruitment time related to damaged neurons in the pontine tegmentum.[26]

Inherited metabolic diseases such as subacute necrotizing encephalomyelopathy (Leigh disease) typically appear in childhood and may be associated with respiratory disturbance. Rarely, this disease may appear in adulthood with respiratory failure during sleep.[27] Syringomyelia can be associated with central, mixed, and obstructive apneas when it involves the bulbar and high cervical neurons.[28] Malformations of the skull base or high cervical junction (platybasia, Chiari malformations) may cause both central and obstructive types of sleep apnea.[29]

SCI has dramatically increased in frequency over the past 30 years owing to an increase in traffic accidents and military conflicts. Incidence rates are highest in the second to fourth decades of life, and with improvements in long-term supportive care providing longer life expectancy,[30] the prevalence of SCI is destined to grow in the coming years. Overall, morbidity and mortality are higher with cervical and high thoracic spinal cord lesions, especially in ventilator-dependent individuals.[31-33] In a Stockholm, Sweden, epidemiologic survey,[6] muscle spasm, pain, paresthesias, and voiding problems were reported as the most important causes of sleep disturbance.

Gastrointestinal problems related to autonomic dysfunction are more often considered secondary problems. Gastrointestinal motility is also affected, and reflux is common.[32,33] In tetraplegic patients, the higher the spinal cord lesion, the more significant the impairment, not only with diaphragm, intercostal, and abdominal muscle weakness but also with impaired cough and other reflexes for laryngeal and lung clearance.[32,33] All these elements together can impair breathing, especially during sleep.[33,34] High cord lesions can interrupt pathways to the superior cervical sympathetic ganglion that regulate melatonin secretion.[35,36]

Pharmacologic agents used by patients with SCI (antispasmodic, analgesics, drugs for autonomic dysfunction, psychoactive substances) can also disrupt sleep and wakefulness. An important feature seen in cervical lesions is progressive ventilatory impairment during sleep noted between the 15th day and the 13th week after the injury, often after the patient has been released from an acute care setting. Such worsening may lead to a higher percentage of deaths during sleep, as reported in a cohort of patients with mid to lower cervical SCI during this time period.[37]

Polyneuropathies

The most common polyneuropathy associated with SDB is Charcot-Marie-Tooth disease.[38] It is characterized by chronic degeneration of peripheral nerves and roots, resulting in distal muscle atrophy that begins at the feet and legs and later involves the hands. SDB can occur in these patients as result of a pharyngeal neuropathy leading to upper airway obstruction (obstructive apnea, upper airway resistance syndrome)[39] or with diaphragmatic dysfunction.[40] Autonomic neuropathy, particularly when secondary to type 1 diabetes, may be associated with impaired chemosensitivity to CO_2, although the effects on sleep and breathing are inconsistent.[41]

Neuromuscular Junction Diseases

Myasthenia gravis (MG) is a disorder of the neuromuscular junction characterized by weakness and fatigability of skeletal muscles. Sleep breathing abnormalities can occur as a result of diaphragmatic or pharyngeal weakness. Risk factors for the development of sleep-related ventilatory problems in patients with MG include age, restrictive pulmonary syndrome, diaphragmatic weakness, and daytime hypoventilation.[42] Younger patients with a shorter duration of illness are less likely to experience sleep-related hypoventilation or hypoxemia,[43] whereas older patients with increased body mass index, abnormal total lung capacity, and abnormal daytime blood gases are more likely to develop hypopneas or apneas, particularly during REM sleep.[44] Sleep apnea was diagnosed in 60% of patients with MG even when the disease was in a clinically stable stage.[45,46] A prospective study by Nicolle and colleagues found that obstructive sleep apnea (OSA) was the predominant abnormality, occurring in 36% of MG patients, with significant associations with older age, male gender, elevated body mass index, and corticosteroid use.[47]

Other neuromuscular disorders that can disturb sleep include congenital myasthenic syndromes,[48] botulism, hypermagnesemia, and tick paralysis. Taking a careful history is extremely helpful in making the diagnosis in these circumstances. Dyspnea that worsens with activity, morning headache, paroxysmal nocturnal dyspnea, fragmented sleep, and daytime somnolence are among the symptoms that suggest SDB in these syndromes.

Muscle Diseases

Myotonic Dystrophy

MD is an autosomal dominant disorder that causes myotonia, muscle weakness, and daytime sleepiness. In this illness, there is consistent involvement of facial, masseter, levator palpebrae, sternocleidomastoid, forearm, hand, and pretibial muscles; MD is, in a sense, a distal myopathy. However, pharyngeal and laryngeal muscles may also be involved, as well as respiratory muscles, in particular the diaphragm.

Central nervous system abnormalities also occur in MD, causing excessive daytime sleepiness by different mechanisms.[12,48-51] For example, neurodegeneration in the dorsomedial nuclei of the thalamus can lead to a medial thalamic syndrome characterized by apathy, memory loss, and mental deterioration. Loss of 5-hydroxytryptamine (serotonin) neurons of the dorsal raphe nucleus and the superior central nucleus,[52] as well as dysfunction of the hypothalamic hypocretin-orexin system,[53] can result in short sleep latencies and sleep-onset REM periods on the Multiple Sleep Latency Test.[49,50] Excessive daytime sleepiness occurs in 33% to 77% of MD patients.[54]

Involvement of the respiratory muscles may result in SDB, including alveolar hypoventilation predominantly in REM sleep,[55-58] obstructive apneas,[59] and central apneas.[60] However, the development of SDB abnormalities in MD is not simply

caused by muscle weakness. When patients with MD were compared with patients with nonmyotonic respiratory muscle weakness, periods of hypoventilation and apneas (central and obstructive) occurred at higher frequencies in those with MD than in nonmyotonic patients who had the same degree of muscle weakness (measured by maximal inspiratory and expiratory pressures).[61] This finding suggests that changes in the central nervous system control of respiration contribute to abnormal breathing in patients with MD.

Similarly, decreased ventilatory responses to hypoxia and hypercapnia[62-64] and extreme sensitivity to sedative drugs suggest a central origin of the breathing impairments in MD. The differential diagnosis requires further testing. A standard technique for assessing control of respiration is to study the increase in ventilation as a response to increased arterial CO_2. However, when respiratory muscles are weak, as in MD, it may be difficult to interpret a reduced ventilatory response. That is, chemoreceptor activity and efferent signaling to respiratory muscles may be intact, but weak or inefficient respiratory muscles may not produce a normal ventilatory response to a hypercapnic or hypoxic stimulus. Another method of assessing impairment of respiratory center output is measurement of mouth pressure developed at the beginning of a transiently occluded breath (occlusion pressure, $P_{0.1}$).[65] In patients with MD, $P_{0.1}$ may be as high or higher than that of control subjects at rest and during stimulated breathing, although overall ventilation is lower.[63,66] The finding of a high transdiaphragmatic pressure (P_{di}) despite overall lower ventilation suggests that increased impedance of the respiratory system accounts for incomplete transformation into ventilation of normal or increased respiratory center output.

Magnetic stimulation of the cortex, in conjunction with phrenic nerve recordings, can also be used to test the corticospinal tract to phrenic motor neuron pathways and is a reliable method for diagnosing and monitoring patients with impaired central respiratory drive.[67] The use of transcortical and cervical magnetic stimulation demonstrates that greater than 20% of MD patients have impaired central respiratory drive.[68] The finding of neuronal loss in the dorsal central, ventral central, and subtrigeminal medullary nuclei in MD patients with alveolar hypoventilation[69] and the severe neuronal loss and gliosis in the tegmentum of the brainstem[70] also support a central abnormality.

Another problem in MD patients is orofacial growth impairment early in life. Craniofacial muscle weakness can negatively affect bone growth during development, particularly on orofacial muscles that are involved with stimulation of particular growth areas such as the intermaxillary synchondrosis that usually becomes inactive near 15 years of age. As a result of such muscular weakness, development of craniofacial structures in patients with MD is impaired. They experience more vertical facial growth than normal subjects and have more narrowed maxillary arches and narrow palate as measured between the palatal shelves, with deeper depths. These craniofacial changes may contribute to the development of obstructive sleep apnea owing to a smaller maxilla and mandible, consequently restricting the size of the upper airway and leading to upper airway collapse during sleep.

Other Myopathies

Abnormalities in sleep and breathing have been reported in isolated series of patients with various neuromuscular disorders, such as congenital myopathies (nemaline or congenital fiber-type disproportion myopathy)[71-73] or metabolic myopathies (mitochondrial myopathy such as Kearns-Sayre syndrome[74-77] and acid maltase deficiency[78,79]). In all these cases, there are various alterations in respiratory control and breathing pattern changes, including hypoventilation, obstructive apneas, and central apneas. All genetic myopathies with orofacial weakness have similar risks for impaired bone growth, particularly on the maxilla and mandible, as in MD.[13-15] Severe central sleep apnea and marked hypoxemia, particularly during REM sleep, resulting in hypoxia-induced pulmonary hypertension, excessive daytime sleepiness, heart failure, morning headaches, and rare nocturnal seizures, may be seen in patients with congenital muscular dystrophy.[80] OSA has also been described in Thomsen disease (myotonia congenita).[81]

Myopathies such as Duchenne muscular dystrophy (DMD) can cause restrictive lung disease and chest wall deformities.[82,83] These changes also contribute to ventilatory impairment, fragmented sleep, hypercapnia and hypoxemia (more profound during REM sleep),[84,85] development of deformities, chronic pain, and discomfort. There is a bimodal presentation of SDB in children with DMD, whereby OSA is more common in younger children in the first decade of life.[86,87] In younger children with DMD, OSA can improve with adenotonsillectomy, whereas in older children who have already developed hypoventilation, OSA is better managed with noninvasive ventilation.

Acid maltase deficiency myopathy can cause SDB, with rapid and significant diaphragmatic impairment noted long before the weakness of other skeletal muscles.[88] In fact, SDB and the secondary daytime fatigue may be presenting symptoms of the myopathy.[88]

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant disease and the third most frequent form of muscular dystrophy, after DMD and MD. Della Marca and colleagues evaluated FSHD patients and found that impaired sleep quality was directly correlated to the severity of the disease.[89] Among 46 FSHD patients, 27 had snoring and 12 reported respiratory pauses during sleep.[89]

DIAGNOSTIC EVALUATION

The evaluation should consider the type of neurologic disorder, the degree of sensory and motor impairment and the resulting disability, the associated autonomic defects, and the impact of the illness on the patient's mood. Understanding the patient's interaction with society and family is an important factor for subsequent treatment decisions. A detailed sleep history is required to outline the severity and type of sleep-related problems. General assessment should also determine the degree of pain and discomfort (particularly in the supine position and during sleep), the presence or absence of sphincter problems and urinary or digestive dysfunction during wake and sleep, and any evidence of autonomic dysfunction already present during wakefulness and suspected during sleep. A number of additional diagnostic tests may supplement the evaluation of sleep in the patient with neuromuscular disease. These include a disability index scale,[1] a sleep disorder questionnaire, and a sleep log or actigraphy (helpful for the investigation of daily rhythms and sleep-wake disturbances during the 24-hour period). The severe respiratory insufficiency questionnaire, a

multidimensional health-related quality-of-life instrument, may be used for patients with neuromuscular disorders on assisted ventilation.[90]

Clinicians should carefully look for craniofacial abnormalities, including high and narrow hard palate, teeth crowding, tongue indentations, and Mallampati or Friedman rating scales[90,91] evaluating the size of upper airway. Routine measures of pulmonary function (spirometry, lung volumes, diffusing capacity) and gas exchange (Pao_2 and $Paco_2$) should be performed in all patients at initial presentation. Static lung volume measurements, both upright and after 15 minutes in supine position, often demonstrate significant changes caused by respiratory muscle weakness, particularly diaphragmatic weakness. A forced expiratory volume in 1 second (FEV_1) or forced vital capacity (FVC) less than 40% of predicted, a $Paco_2$ greater than 45 mm Hg, and a base excess of 4 mmol/L or greater may indicate increased risk for sleep-related hypoventilation, and overnight polysomnography should be performed. Supine inspiratory vital capacity measurements of less than 40%, 25%, and 12% will likely result in hypoventilation during REM sleep, full night, and daytime, respectively.[83,92,93]

Overnight polysomnography is the key to a definitive evaluation of sleep and breathing in these patients. Although it can be done in many settings, including at home, in-laboratory evaluation allows additional measures such as video monitoring. More important, measurement of transcutaneous or end-tidal CO_2 allows continuous tracking of overall ventilation during sleep and can help guide the decision for nocturnal ventilatory assistance.

TREATMENT OF SLEEP ABNORMALITIES IN PATIENTS WITH NEUROMUSCULAR DISEASE

The greatest advances in the medical treatment of neuromuscular disorders have been for sleep-related abnormalities.[51] The goal is restoration of normal sleep architecture, with subsequent improvement of sleep, daytime function, and quality of life. Simple measures such as bedding are often overlooked. Specialized beds and mattresses are available with specifications allowing ease of positional changes, avoidance of skin lesions at pressure points, and segmental inflation or deflation (e.g., air mattresses), thus improving autonomic dysfunction, cramps, spastic contraction, and rigidity. Great efforts should be made to diminish pain and discomfort of any type. Treatment of abnormal behavior and confusional arousals may necessitate use of sedatives such as benzodiazepines, but such therapy should be considered only after careful evaluation of ventilatory function and risk for worsening the sleep-related abnormal breathing.

Judicious use of wake-promoting drugs, such as modafinil or armodafinil, can improve daytime alertness without nocturnal sleep disruption. Prior reports of patients with MD and ALS have shown beneficial effects of modafinil in improving daytime fatigue.[94-104] Baclofen can reduce muscle spasms and help nocturnal sleep but may worsen daytime sleepiness. Treatment of pain with opioids can complicate treatment of SDB by inducing sleep hypoventilation or central sleep apnea. Treatment of abnormal breathing during sleep should be based on polysomnographic findings and should be adjusted with regular follow-up considering clinical symptoms and polysomnographic studies. Various therapies may improve nocturnal hypoventilation or offset the attendant oxygen desaturation.

Supplemental oxygen has been used to alleviate the REM sleep–related oxygen desaturation in patients with DMD but does not clearly improve sleep.[105] Repeated nocturnal hypoxia may worsen muscle weakness, which begets further oxygen desaturation, and reversal of the hypoxemia may arrest the muscle weakness. In one patient with acid maltase deficiency treated with nocturnal oxygen, hypoxemia and muscle weakness did not progress over an 8-year period.[106] Because most of the hypoventilation occurs during REM sleep, pharmacologic suppression of REM sleep with a tricyclic antidepressant is a theoretical option. In a small study of patients with DMD, protriptyline markedly improved the nocturnal oxygen saturation profile.[107,108] However, anticholinergic side effects limit the widespread use of such therapy. Inspiratory muscle training has improved waking respiration in one patient with acid maltase deficiency,[88] with major improvement in the nocturnal oxygen saturation. In general, muscle training is often helpful in neuromuscular patients.[109]

In children, two syndromes have a high prevalence of sleep hypoventilation: DMD and spinal muscular atrophy. Both conditions can cause progressive hypoventilation during sleep and, as the disease progresses, hypoventilation during wakefulness. In this young age group, the appropriate time to begin airway clearance and to introduce noninvasive ventilatory support that can preserve or enhance lung growth and chest wall mobility must be carefully assessed. The presence of an imbalance between mechanical load and the capacity of the respiratory muscles must be evaluated because fatigue may occur, leading to respiratory failure. Inspiratory muscle training can significantly improve respiratory parameters after 1 month of training.[110-112] Children with impaired orofacial bone development as a consequence of abnormal muscle contractions secondary to the genetically induced generalized muscle dystrophy may benefit from myofunctional reeducation (i.e., orofacial muscle exercises aiming at improving suction, mastication, swallowing, and nasal breathing).[113-115]

Noninvasive Positive Airway Pressure

Mechanical ventilation has been a mainstay in supporting ventilation since the days of the poliomyelitis epidemic. Rocking beds, negative-pressure tank ventilators, positive-pressure ventilation through tracheostomy, and cuirass ventilation have been long-term options in the past.[116] However, all these options are cumbersome, severely limit the mobility of patients, and in the case of tracheostomy, may have unwanted complications. Therefore other forms of assisted ventilation have been developed, including phrenic nerve pacing,[117] and noninvasive positive-pressure ventilation devices.[118,119]

Positive airway pressure devices, including continuous positive airway pressure, bilevel positive airway pressure with or without backup respiratory rate (a noninvasive positive-pressure ventilation device), and the advanced devices targeting minute ventilation by way of pressure support have been used to treat hypoventilation of various causes. Treatment of hypoventilation requires adequate delivery of tidal volume and maintaining minute ventilation to effectively eliminate CO_2, therefore illustrating the limitations of continuous positive airway pressure in treating hypoventilation. Because bilevel positive airway pressure acts as a noninvasive ventilator and supports ventilation, it also treats CO_2 retention, which is

commonly seen in patients with advanced neuromuscular disorders. Low-flow oxygen can be bled into the nasal mask during nocturnal sleep to maintain adequate oxygenation if needed.

In the past two decades, noninvasive positive-pressure ventilation has improved the natural course of neuromuscular disorders, and it is often the treatment of choice. Noninvasive positive-pressure ventilation has been shown to improve quality of life and increase survival in neuromuscular disorders.[120-128] In postpolio syndrome, the median time for prolongation of life expectancy is more than 20 years. In patients with spinal muscular dystrophy types 2 and 3, DMD, and acid maltase deficiency, the median improvement in life expectancy is 10 years. In MD, the median improvement in life expectancy is 4 years, and in ALS it is 1 year.[120,121,124] Compared with ventilation through tracheostomy, noninvasive positive-pressure ventilation through nasal interfaces and portable ventilators is becoming the preferred means of assisting ventilation because it is much simpler to administer, is more comfortable, and reduces costs.

Nocturnal noninvasive positive-pressure ventilation had been used predominantly for patients with postpoliomyelitis and other neuromuscular disorders. With eradication of poliomyelitis in most of the world, ALS has become the most common neuromuscular disorder for which noninvasive positive-pressure ventilation is used. In ALS patients with orthopnea, maximum inspiratory pressure less than 60% of predicted, or symptomatic daytime hypercapnia, noninvasive positive-pressure ventilation significantly improved quality of life, sleep-related symptoms, and survival in those without severe bulbar dysfunction.[120] These improvements were greater than those achievable with any currently available pharmacotherapy. Therefore a trial of noninvasive positive-pressure ventilation in ALS patients is warranted even in those with severe bulbar dysfunction for palliative reasons.

Bilevel positive airway pressure therapy is an effective treatment for a number of neuromuscular diseases and in early stages of the disease may be as effective as an invasive conventional ventilator. However, patients may need better control of their hypoventilation during sleep and require more ventilatory support, particularly with progressive muscle weakness. Advanced noninvasive positive-pressure ventilation devices are available specifically for treatment of hypoventilation during sleep by targeting tidal volume or minute ventilation (e.g., average volume assured pressure support [AVAPS] and intelligent volume assured pressure support [iVAPS]).[129] Because the AVAPS and iVAPS devices adjust pressure support based on the patient's respiratory cycle breath by breath, they adapt to changes in severity of disease and therefore are ideal for sleep hypoventilation or respiratory insufficiency. Adaptive servoventilation, an anticyclic positive airway pressure device, has been considered when opioid intake complicates the clinical presentation because of a high number of central apneas, provided that hypoventilation is not significant.[130,131]

The choice of settings when choosing noninvasive positive-pressure ventilation can influence sleep architecture and quality in patients with various neuromuscular diseases. Tailoring the settings (options available depending on portable ventilator used) to the individual's respiratory effort rather than the usual or default parameters is associated with better nighttime gas exchange, percentage of REM sleep, and sleep quality.[132] The AVAPS mode, for example, requires predetermined tidal volume that is calculated from the patient's ideal body weight, with a recommended 6- to 8-mL/kg of ideal body weight used instead of actual body weight. However, if rib cage and abdominal muscles are weak, the recommended volume setting for the patient may be too high, and pain may develop during chest expansion; in these cases we recommend decreasing the predetermined tidal volume to 6 to 7 mL/kg.

Another parameter that is an important component in the patient's comfort and compliance is the "rise time" (i.e., the speed at which airflow is delivered from expiration to inspiration in 10ths of a second). It should be adjusted based on the severity of thoracic muscle weakness, lung inflation capabilities, and amount of secretion accumulated in the airway. This adjustment may be critical because the patient may not tolerate noninvasive positive-pressure ventilation if the rise time is inadequate for the condition.

In endotracheally intubated patients or those with a tracheostomy, the differential between inspiratory and expiratory positive airway pressure on the ventilator can be wide. However, unlike an endotracheal or tracheostomy tube, the upper airway is not rigid, and as a result there is variability in airway dilator contraction during inspiration due to multiple factors: the degree of local muscle impairment, sleep stage, sleep state, neck position, and narrowing because of anatomic factors (deviated septum, enlargement of nasal turbinates, presence of adenoids and tonsils). If the bilevel "pressure differential" becomes too wide, in the presence of nonlinear flow (turbulence) there will be a greater tendency for upper airway obstruction that translates into airflow limitation (visible when studying nasal flow during polysomnography).[133] We generally keep a differential of 6 cm H_2O to avoid induction of variable abnormal upper airway resistance. Besides determination of appropriate inspiratory and expiratory pressures during overnight polysomnography, the need for a backup respiratory rate may also be assessed if central sleep apnea complicates the picture. The backup rate is commonly set at about 8 to 10 breaths/min but will need adjustment over time based on the severity and evolution of the syndrome. In all, the use of noninvasive positive-pressure ventilation allows patients to return to work and even travel, something previously impossible when constrained by reliance on a rocking bed or the complications of tracheostomy for nocturnal ventilatory support.

Decision to Assist Nocturnal Ventilation

When patients present with disrupted sleep, snoring, excessive daytime sleepiness, and unexplained development of peripheral edema or polycythemia, sleep studies can help characterize a breathing disorder, and the decision to assist with ventilation is generally straightforward, with addition of low-flow oxygen bled into mask if needed. For a detailed review of noninvasive ventilation, see Chapter 115.

Nocturnal noninvasive positive-pressure ventilation should be started when nocturnal hypoventilation is present. Clinical symptoms and physiologic markers of hypoventilation assess disease severity and assist in the decision to initiate nocturnal noninvasive positive-pressure ventilation. Patients usually first develop nocturnal hypoventilation followed by diurnal hypoventilation with associated clinical symptoms, which can lead to acute respiratory failure. Continuous monitoring of arterial CO_2 by end-tidal CO_2 or transcutaneous CO_2 during an overnight sleep study is necessary to document

nocturnal hypoventilation, which may occur exclusively during REM sleep. Arterial blood gas and serum chemistry can document daytime hypoventilation with elevated arterial CO_2 ($Paco_2$), low arterial oxygen (Pao_2), relatively normal pH, and high serum bicarbonate. Many clinicians consider starting noninvasive positive-pressure ventilation with an arterial Pco_2 greater than 45 mm Hg and an arterial Po_2 less than 70 mm Hg. An isolated change in nocturnal oxygen saturation alone is insufficient for deciding whether the patient needs ventilatory assistance. However, sustained nocturnal oxygen desaturations may be an indicator of nocturnal hypoventilation.

In summary, there is long-standing consensus[134-136] on the management of severe progressive neuromuscular disorders in which respiratory failure plays a significant part of the natural history of the disease. The positive impact of noninvasive ventilatory support in neuromuscular disease patients has become clear in the past two decades. The most effective time to introduce noninvasive positive-pressure ventilation is when SDB develops, including nocturnal hypoventilation. Issues such as quality of life must be taken into account. Each patient must be assessed in detail, and the clinician must bear in mind that nocturnal (and later, 24-hour) ventilation will treat only one (albeit important) aspect of the disorder.

CLINICAL PEARLS

- Sleep is a vulnerable state for patients with neuromuscular disorders because normal REM sleep–related changes in ventilation are magnified as a result of muscle weakness, resulting in hypoventilation and oxygen desaturation.
- In addition to SDB, sleep may also be disturbed by spasticity, poor secretion clearance, sphincter dysfunction, inability to turn, pain, and autonomic dysfunction. All of these factors can impair sleep and worsen daytime disability.
- Noninvasive ventilation can aid neuromuscular disease patients by reducing morbidity and improving life expectancy.
- The most effective time to introduce noninvasive ventilatory support is when SDB develops, including nocturnal hypoventilation.
- New advanced noninvasive ventilatory equipment, such as AVAPS or iVAPS, is ideal for ventilatory insufficiency in neuromuscular patients because it targets tidal volume or minute ventilation and therefore treats hypoventilation and CO_2 retention.

SUMMARY

Neuromuscular disorders consist of central and peripheral neurologic disorders with impairment of the motor system. The disability of patients with a neuromuscular disorder worsens during sleep, and the abnormal sleep and secondary impairment of daytime function further degrade quality of life. Nocturnal sleep disruption can result from pain and discomfort related to weakness, rigidity, or spasticity that limits movement and posture. Sleep disruption may also be caused by autonomic dysfunction, poor sphincter control, problems with clearance of secretions, and abnormal movements and behaviors during sleep. Most important, sleep-related hypoventilation is common with neuromuscular disorders, and overlooking this may lead to death. Daytime evaluation will determine the severity of the disability but may not identify the presence and severity of an associated sleep-related disorder. Nonspecific symptoms of daytime fatigue and sleepiness can indicate poor sleep in these patients. Polysomnography with continuous monitoring of CO_2 is the only test that can objectively identify and evaluate the severity of sleep-related disorders as well as ventilatory impairment. By recognizing and treating sleep-related problems, these patients can enjoy improved survival and better quality of life.

Restless Legs Syndrome and Periodic Limb Movements During Sleep

Chapter 95

Richard P. Allen; Jacques Montplaisir; Arthur Scott Walters; Luigi Ferini-Strambi; Birgit Högl

Chapter Highlights

- Restless legs syndrome, also called Willis-Ekbom disease (RLS/WED), is defined by its clinical symptoms involving an urge to move the legs while resting in the evening and night. It has a motor sign of periodic limb movements during sleep that is present in almost all patients. This chapter describes how to make the diagnosis and also when to use medical and sleep tests for RLS/WED.
- RLS/WED varies both in severity from annoying to disabling and in natural course from intermittent (remission and reoccurrence) to gradually progressive. More severe disease affects work productivity, quality of life, and cardiovascular health.
- The close relation between iron status and RLS/WED is described in this chapter for epidemiology, biology, and clinical treatments. In some patients, iron treatment may improve disease course.
- The need for long-term pharmacologic treatment of RLS/WED alters treatment choices. Ropinirole and pramipexole, when given for 1 year or longer, may cause RLS/WED augmentation, altering the disease process to create worse RLS/WED symptoms. Newer drugs are as effective, with no risk for augmentation with α2δ ligands and possibly reduced risk with longer acting dopamine agonists.

DESCRIPTION AND CLINICAL CHARACTERISTICS

Sensory and Motor Manifestations

Restless legs syndrome, also called Willis-Ekbom disease (RLS/WED), has been described for centuries, with an early description by Willis in 1672,[1,2] but only in 1945 was it singled out as a distinct clinical entity by the Swedish neurologist Carl Ekbom.[3] Patients with RLS/WED report an urge to move (akathisia) focused on the legs usually, but not always associated with dysesthesia when at rest.[4] Patients with dysesthesias describe them very differently (e.g., uncomfortable, unpleasant, creepy-crawly, jittery, internal itch, or shocklike feelings); up to 50% of RLS/WED patients describe their sensations as painful. Some, however, describe only an urge to move, and they are unaware of a sensory component. Symptoms are usually felt over large areas of the thighs or calves (or both) and are usually experienced as coming from deep within the legs rather than as superficial.

The original term RLS fails to adequately describe the condition. First, the leg akathisia is not the fidgety, jittery overall restlessness that occurs when waiting or sitting too long; rather it comes as a focused strange feeling of an urge to move specific parts of the body that must involve at least part of one leg. Second, the disorder can also involve the arms and other body parts in addition to the leg, particularly when more severe. Almost 50% of patients with moderate to severe RLS/WED in one tertiary care population reported symptoms in the arms.[5] Given the problems of the term *restless legs*, the International Restless Legs Syndrome Study Group (IRLSSG) and several patient groups have adopted the new name *Willis–Ekbom disease*, recognizing those most responsible for defining the disease.[4]

Three critical features specify occurrence of the sensory symptoms defining RLS/WED (Box 95-1). First, the symptoms are engendered or worsened by rest or inactivity (Videos 95-1, 95-2, and 95-3).[4] Typically, patients describe exacerbation of symptoms in soporific situations, such as watching television, driving or flying long distances, and attending meetings. Symptoms worsen with a decrease in alertness. Second, activity relieves the symptoms.[4] Patients use different motor strategies to relieve the discomfort, producing motor features characteristic of the disease, such as moving their legs vigorously or flexing, stretching, or crossing the legs one over the other. In severe cases, they might walk around for hours in the evening or night to relieve the discomfort. The relief usually begins immediately or soon after the activity starts and persists as long as the activity continues. The symptoms, however, may return after movement stops, sometimes quickly in cases of more severe disease. Relief with walking is often complete, but some with more severe RLS/WED may find only little symptom relief even from strenuous movement. Third, the symptoms are worse in the evening or during the night.[4] The usual decreased activity and alertness in the evening do not account for this nocturnal increase in symptoms. Three studies using modified constant routine protocols investigated the pattern of RLS/WED symptom occurrence.[6-8] These demonstrated a circadian rhythm of the symptoms, maximal after midnight independent of effects of activity. The

Box 95-1 DIAGNOSTIC CRITERIA ESTABLISHED BY THE INTERNATIONAL RESTLESS LEGS SYNDROME STUDY GROUP

Essential Features*

1. An urge to move the legs usually accompanied by, or felt to be caused by, uncomfortable and unpleasant sensations in the legs
2. The urge to move the legs, with any accompanying unpleasant sensations beginning or worsening during periods of rest or inactivity, such as lying down or sitting
3. The urge to move the legs, with any accompanying unpleasant sensations partially or totally relieved by movement, such as walking or stretching, at least as long as the activity continues
4. The urge to move the legs, with any accompanying unpleasant sensations during rest or inactivity only occurring or worsening in the evening or night as opposed to during the day
5. Occurrence of the above features not solely accounted for as symptoms primary to another medical or a behavioral condition (e.g., myalgia, venous stasis, leg edema, arthritis, leg cramps, positional discomfort, habitual foot tapping)

Specifiers for Clinical Course

A. Chronic-persistent restless legs syndrome/Willis-Ekbom disease (RLS/WED): Symptoms when not treated would occur on average at least twice weekly for the past year
B. Intermittent RLS/WED: Symptoms when not treated would occur on average more than twice weekly for the past year, with at least five lifetime events

Specifier for Clinical Significance

- Symptoms of RLS/WED cause significant distress or impairment in social, occupational, educational, or other important areas of functioning by their effect on sleep, energy and vitality, daily activities, behavior, cognition, or mood

Nonessential but Common Features

1. Periodic limb movements: presence of periodic leg movements during sleep or resting wake at rates or intensity greater than expected for age or medical and medication status
2. Dopaminergic treatment response: reduction in symptoms at least initially with dopaminergic treatment
3. Family history of RLS/WED among first-degree relatives
4. Lack of profound daytime sleepiness

*All 5 must be met to make a diagnosis.

Modified from Allen RP, Picchietti DL, Garcia-Borreguero D, et al. Restless legs syndrome/Willis-Ekbom disease diagnostic criteria: updated International Restless Legs Syndrome Study Group (IRLSSG) consensus criteria—history, rationale, description, and significance. *Sleep Med* 2014;15(8):860–73.

symptom's circadian rhythm correlated with that of subjective vigilance, core body temperature, and salivary melatonin secretion.

The primary motor sign of RLS/WED is periodic limb movements during sleep (PLMS). These occur mostly as physiologic flexor leg movements repeated about every 20 to 40 seconds during NREM sleep and also sometimes when lying down resting awake, called periodic leg movement during wake (PLMW). Almost all RLS/WED patients are found to have these movements but only when observed over three to five nights.[9] PLMS are a sensitive but nonspecific motor sign of RLS/WED. Video 95-4 shows classic periodic leg movement flexion at the ankle with extension of the large toe.

RLS/WED symptom intensity ranges from mild and annoying to a disabling compulsion to keep moving. Symptom frequency also varies from less than yearly to daily. A large population-based study in Europe and the United States found that 37% of patients with RLS/WED symptoms had moderate to severe disease (bothersome symptoms two or more times a week).[10] Videos 95-5, 95-6, 95-7 and 95-8 show the wide range of RLS/WED severity from mild foot to whole body movements.

Most patients with moderate to severe RLS/WED complain of poor sleep. In a study of 133 patients, 85% often experienced difficulty falling asleep at night because of RLS/WED, and 86% were frequently woken by symptoms.[11] Sleep laboratory studies confirm the poor sleep of RLS/WED patients compared with controls, characterized by increased wake after sleep onset and decreased sleep time. Most often, stage 2 sleep is decreased with little or no change in rapid eye movement (REM) sleep.

Daytime fatigue is commonly reported, but usually not sleepiness. Most RLS/WED patients do not report the level of sleepiness expected for their degree of sleep loss.[12] Thus RLS/WED appears to occur with some increased arousal process counteracting the sleep loss effects.

Clinical Course

RLS/WED can start at any age from childhood into late adult life. Familial cases of RLS/WED have an earlier age of onset, typically before the age of 30 years.[13-15] Symptom severity and frequency often fluctuate throughout life. Some report remissions, lasting for months or even years, and also relapses, both without any apparent reason.[16] More severely affected patients commonly report a progressive increase in symptom severity with advancing age.[16]

EPIDEMIOLOGY AND BURDEN OF DISEASE

Epidemiology

RLS/WED is one of the most common sleep-related disorders. The prevalence in European and American populations is about 7%[10] for any RLS/WED symptoms during a year and 2.7% for moderate to severe symptoms.[10] Physician-identified, medically significant RLS/WED occurs in 2.7% of patients seen in general medical practices in Europe.[17] The prevalence of moderate to severe RLS/WED symptoms increases with age from about 0.5% for children to 5% for those older than 70 years.[10] In adults older than 40 years, RLS/WED occurs about twice as often in women than men, but there is no gender difference for children[18] or young adults.[10] The gender difference appears to relate to pregnancy because nulliparous women have the same rate of RLS/WED as men.[19]

Burden of the Illness

Mild to minimal RLS/WED does not appear to have significant social or medical impact.[17] In contrast, moderate to severe RLS/WED significantly adversely affects work performance, quality of life, cognition, and health. Work productivity is diminished by 20% for moderate to severe RLS/WED and by 50% for very severe RLS/WED.[20] Quality of life is similarly significantly diminished as shown by marked

impairment in SF-36 quality-of-life dimensions of vitality, role physical, pain, physical functioning, and general health and somewhat less impairment in social functioning, role emotional, and mental health.[10] This disruption in quality of life is at least as great as the disruption caused by other chronic medical conditions, such as diabetes mellitus, depression, osteoarthritis, or hypertension.[10] RLS/WED patients also show impaired cognitive function involving mostly prefrontal cognitive tasks sensitive to sleep loss.[21,22]

Cardiovascular Disease and Stroke

Two large epidemiologic studies, the Wisconsin Sleep Cohort[23] and the Sleep Heart Health Study,[24] reported a significant relationship between RLS/WED and cardiovascular disease even after controlling for other significant factors. A prospective study showed that among 1986 men followed for 10 years there was a 67% increase in the adjusted relative odds for stroke in those with compared with those without RLS/WED (95% confidence interval [CI] = 1.07 to 2.60; $P = .024$).[25] The prospective Nurses Health Study of 70,977 women found that women who had RLS/WED for more than 3 years had an increased hazard ratio for development of coronary heart disease after controlling for arthritis or diabetes (hazard ratio = 1.94; 95% CI = 1.11 to 3.37) and snoring (hazard ratio = 1.80; 95% CI = 1.09 to 2.97).[26] The prospective study by Szentkiralyi and colleagues, however, showed the converse result of cardiovascular disease increasing the risk for developing RLS.[27] Another prospective study showed no relation of RLS/WED to development of cardiovascular disease.[28]

Observational sleep laboratory studies have found that PLMS or RLS/WED was related to increased nocturnal hypertension, including a nondipping pattern,[29,30] and increased daytime hypertension.[31] A higher prevalence of RLS/WED and periodic limb movements is reported after stroke[32-35] and in patients with congestive heart failure.[36-38] High rates of PLMS have been related to the subsequent development of atrial fibrillation[39] and of cardiovascular disease.[40]

These epidemiologic studies suggest an association among PLMS, RLS/WED, and risk for cardiovascular disease. The underlying mechanisms remain unclear[41-43] but may include the large pulse and blood pressure rises with frequent PLMS in RLS/WED.[44-46]

DIAGNOSIS AND SEVERITY ASSESSMENT

Clinical Diagnosis

No biologic assay is available for diagnosing RLS/WED; thus the diagnosis is based on the clinical evaluation of the patient. In 1995, the IRLSSG established four essential criteria for the diagnosis of RLS/WED. These four criteria were further refined at a National Institutes of Health RLS/WED consensus workshop.[47] They have provided reliable diagnostic standards for clinical practice. Nevertheless, when participants in population-based surveys were asked only about these four criteria, about half of those clinically identified with RLS/WED seemed to lack the disease.[17] Several conditions can produce symptoms very close to those of RLS/WED, and these mimics need to be excluded by a careful differential diagnosis. The revised 2012 IRLSSG official diagnostic criteria, therefore, include a fifth criterion requiring differential diagnoses to exclude mimicking conditions. The current five essential RLS/WED diagnostic criteria[4] are listed in Box 95-1. These also address clinical significance and clinical course, emphasizing heterogeneity of RLS/WED manifestations and the need to code these important disease dimensions. These criteria take care not to confound diagnosis of a neurologic disease with the decision about clinical significance of its symptoms. In addition, diagnostic uncertainty can also be reduced by supportive clinical features such as a family history of RLS/WED and a therapeutic response to dopaminergic medications.

Medical Evaluation

The medical evaluation must include a fasting morning iron evaluation. The patient should also be evaluated for clinical indications of commonly associated medical conditions of neuropathy and uremia. Medication history should be reviewed for any temporal relation to exacerbation or onset of RLS/WED, particularly for antidepressants, dopamine antagonists, and antihistamines.

Sleep Laboratory Test

Although not routinely indicated, polysomnography can be used to measure PLMS, the motor sign of RLS/WED. PLMS provide useful objective support for both diagnosis and assessment of disease severity. The World Association of Sleep Medicine and the IRLSSG established the standards for recording and scoring PLMS.[48] Leg movements are defined as anterior tibialis electromyography (EMG) signals greater than 8 mV above baseline that last 0.5 to 10 seconds and are separated by at least 0.5 second of EMG activity within 2 mV of baseline. Periodic leg movements occur as four or more consecutive leg movements with onsets separated (intermovement interval) by 5 to 90 seconds. Recent studies indicate that an intermovement interval of 10 to 90 seconds is preferred for future studies. A PLMS index (number of periodic leg movements per hour of sleep) greater than 5 for the night was considered pathologic and is still used for children and younger persons, but an index greater than 15 is now often used as a cutoff for adults.

The number of periodic leg movements varies over nights. Periodic leg movements occur mostly in non–rapid eye movement (NREM) sleep and cluster into episodes lasting several minutes or hours. The percentage of all leg movements that are PLMS with an intermovement interval of 10 to 90 seconds, the periodicity index, is 6.5 times less variable than the periodic leg movements index in RLS/WED patients.[49] Diagnostic polysomnography includes central electroencephalography (EEG), electrooculography (EOG), submental EMG, and bilateral EMG of the anterior tibialis muscles. The electrographic picture of a leg movement can vary from one sustained contraction to a polyclonic burst with a frequency of approximately 5 Hz. In RLS/WED patients, approximately one third of all PLMS are associated with EEG signs of arousal.[50] Movements can be seen on Videos 95-9, 95-10, 95-11, 95-12, 95-13, 95-14 and 95-15.

Regardless of the presence of EEG arousals, almost every periodic leg movement is associated with transient tachycardia for 5 to 10 beats followed by a bradycardia[50] plus increased systolic and diastolic blood pressure (on average, 22 mm Hg and 11 mm Hg) (Figure 95-1).[44,45] These are substantial changes that are greater in older patients and when associated with EEG arousals.

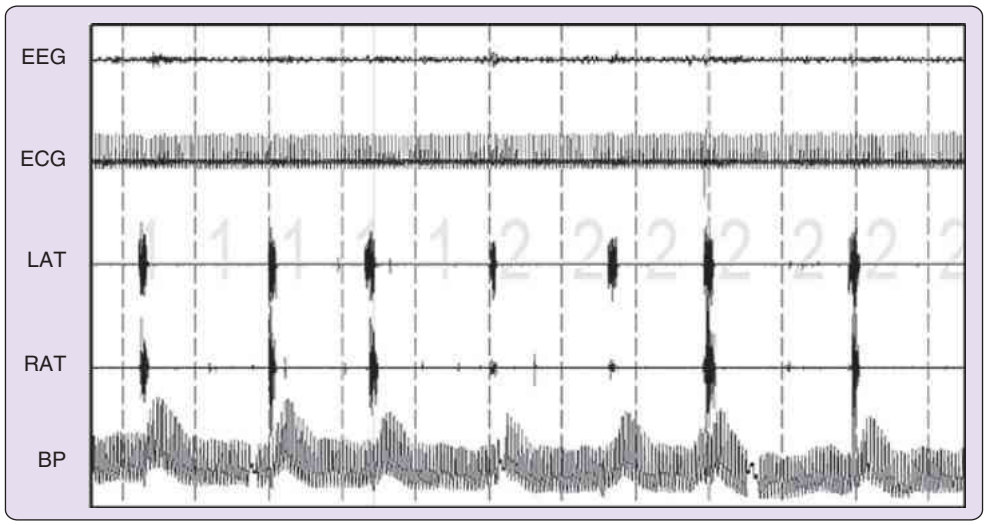

Figure 95-1 Polysomnogram of a patient with restless legs syndrome. Polysomnogram of a patient with restless legs syndrome and periodic limb movements in sleep. The figure shows the periodicity of leg movements and reveals significant increases in blood pressure associated with every periodic limb movement. BP, Blood pressure; ECG, electrocardiogram; EEG, left central electroencephalogram; LAT, left anterior tibialis electromyogram; RAT, right anterior tibialis electromyogram.

Periodic leg movements were first polygraphically documented in RLS/WED.[51] However, they also occur in a wide range of sleep disorders. Five or more PLMS per hour occur in 80% to 90% of patients with RLS/WED, about 70% with RBD, and 45% to 65% with narcolepsy. In RBD, periodic leg movements are often present without arousals during NREM sleep but can also continue into REM sleep, which is unusual for all other conditions. Periodic leg movements were also reported in subjects without any sleep complaint. Although they are rare in young persons, they are relatively common in older adults.[52]

PLMS in patients who complain of primary sleep-onset or sleep-maintenance insomnia or of primary hypersomnia are called periodic limb movement disorder (PLMD) if they have no other cause for the PLMS. Previously, it was assumed that periodic leg movements are responsible for nonrestorative sleep and daytime somnolence in these patients. Although some studies suggested that periodic leg movements may be associated with sleep-wake complaints, most authors have now concluded that periodic leg movements with or without EEG arousals have little effect on nocturnal sleep or daytime vigilance.[53-56] Thus the diagnosis of PLMD should be used with caution given the limited data indicating that PLMS per se disrupt sleep or waking. Despite controversy about their functional significance, PLMS have been useful for sleep laboratory assessments of RLS/WED. In one study, the PLMS index was greater than 5 for 84% and greater than 10 for 70% of RLS/WED patients compared with 36% and 18%, respectively, for controls.[57]

Suggested Immobilization Test

The suggested immobilization test (SIT) was designed to quantify both sensory and motor manifestations of RLS/WED in wakefulness.[57] During the test, patients remain in bed, reclined at a 45-degree angle with their legs outstretched and eyes open. They are instructed to avoid moving voluntarily for the entire duration of the test, which is designed to last an hour and takes place in the evening before bedtime (Video 95-16). Periodic leg movements are measured during waking with the same criteria for PLMS, except the maximal duration of EMG activity is 15 seconds. In addition, every 5 minutes during the test, the patient gives a leg discomfort score. A mean of the 12 discomfort scores has been found to discriminate RLS/WED patients from controls with a sensitivity of 82% and a specificity of 84%. The PLMS index during the SIT was less sensitive.[58]

A possible limitation of the SIT is the single administration time (9:00 PM) because RLS/WED symptoms fluctuate over the course of the afternoon and evening. A multiple SIT (mSIT) consisting of four 60-minute SITs spaced 2 hours apart starting from 6:00 PM helps capture the symptom variability.[59] The mSIT was designed for clinical trials, but its standardized methods may have some use in clinical laboratory assessment of RLS/WED.

Severity Assessments

The 10-question IRLSSG RLS severity scale is a well-validated assessment of RLS severity.[32] (For a sample copy, go to IRLSSG.org.) It has a total score (range 0-40) and two subscales: symptoms and symptom-impact scales.[60] Scores of less than 10 indicate minimal symptoms, and scores of more than 24 indicate moderate to severe symptoms.[61] Scores greater than 15 are required for entry into most clinical trials. This scale and the standard clinical global impression of change are used in pharmacologic clinical trials. Another standard for clinically significant disease often used in surveys is symptoms at least twice a week described as at least moderately bothersome.

RESTLESS LEGS SYNDROME IN CHILDHOOD

Diagnostic Criteria

RLS/WED and PLMS occur in children,[62-64] as shown in Video 95-17. The pediatric diagnosis of RLS/WED[64] requires

meeting the adult criteria (see Box 95-1). Older children should describe the leg discomfort in their own words. Like adults, children with RLS/WED respond to dopaminergic therapy.[65]

Prevalence

The Peds REST study of 10,523 families in the United States and Great Britain found that 1.9% of 8- to 11-year-olds and 2% of 12- to 17-year-olds met criteria for RLS/WED. At least moderately distressing symptoms occurred two or more times a week in 0.5% and 1% of these age groups, respectively.[18]

Relationship to Attention Deficit/Hyperactivity Disorder and Other Medical Conditions

A large meta-analysis confirmed co-occurrence of PLMS and attention deficit/hyperactivity disorder (ADHD).[66] A PLMS index greater than 5 has been reported for 26% to 64% of children with ADHD.[67,68] Those with both ADHD and PLMS showed increased incidence of both personal and family history of RLS/WED.[67,68] Children with ADHD have more PLMS and RLS/WED,[69] and conversely about 44% of children with PLMS are reported to have symptoms of ADHD.[70] Dopaminergic agents improve symptoms of RLS/WED with PLMS but do not clearly reduce ADHD symptoms.[65,71] ADHD occurs with lower serum ferritin and is also responsive to iron therapy for some.[72]

Growing pains, characterized by intense leg pains children experience mostly during the night, are also comorbid with RLS/WED. Growing pains occurred in 80.6% of children with RLS/WED versus 63.2% of those without RLS/WED in the Peds REST study.[18] RLS/WED in children, like in adults, is comorbid with migraine headaches[73] and chronic kidney disease.[74]

RESTLESS LEGS SYNDROME COMORBID CONDITIONS

RLS/WED and PLMS have been related to several other medical and psychiatric conditions but in only a few cases is the association well documented. Three of these conditions have a very strong comorbid relation indicating that development of RLS/WED symptoms may be caused by the other condition. Resolution of these conditions often leads to complete resolution of the RLS/WED. The relation between RLS/WED and the other comorbid conditions is less clear.

Strong Comorbid Relation: Uremia

RLS/WED occurs with uremia, and 15% to 40% of patients on hemodialysis have RLS/WED. Several factors can predispose uremic patients to RLS/WED, particularly anemia and compromised iron regulation. The iron status appears to be critical because intravenous (IV) iron can reduce RLS/WED symptoms.[75] The presence of RLS/WED relates to increased mortality rate in patients with end-stage renal disease.[76] Kidney transplantation often leads to complete resolution of RLS/WED, and the return of RLS/WED symptoms can be an early indicator of transplant failure.[77]

Strong Comorbid Relation: Anemia

RLS/WED occurs in about 35% of patients with iron deficiency anemia[78,79] and at only a slightly lower rate in patients with iron deficiency without anemia.[80] IV iron treatment resolving the anemia also completely resolves the associated RLS/WED in many patients.[81]

Strong Comorbid Relation: Pregnancy

RLS/WED occurs in about 15% to 30% of pregnant women, mostly during the last trimester. It may abate shortly before delivery and generally resolves quickly afterward.[82-84] Iron deficiency is common during pregnancy and has been related to the co-occurrence of RLS/WED.[85,86] IV iron treatment reduced or resolved the RLS/WED during pregnancy for two women with low serum ferritin (≤50 mcg/L),[87] further indicating that iron compromise during pregnancy is a primary factor driving the development of the associated RLS/WED.

Other Comorbid Medical Conditions

Neuropathy appears to increase the risk for RLS/WED. The studies, however, are complicated by problems of both differential diagnosis of neuropathy and RLS/WED and also by the limited use of controls for possible confounding pain effects. One study using a pain control group and carefully validated diagnostic procedures found that RLS/WED occurred in 8% of patients with diabetic neuropathy compared with 3.9% with osteoarthritis.[88] It is, however, unclear whether these results would generalize to all neuropathies. One study showed a high rate (32%) of subclinical small-fiber neuropathy in RLS/WED patients that significantly related to no family history and later age of symptom onset of RLS/WED.[89] Another study reported that RLS/WED patients with neuropathy compared with those without neuropathy had a later age of onset of RLS/WED and less family history.[89] Thus it seems there is some as yet unexplained relation between neuropathy and RLS/WED.

Parkinson disease (PD) deserves special mention because RLS/WED occurs commonly in patients with PD and the major dopaminergic drugs for RLS/WED are also used for PD. RLS/WED in PD often appears after starting dopamine treatment for PD, and the prevalence of RLS/WED is not increased in untreated PD.[90] Thus RLS/WED is not comorbid with PD; rather, treatment of PD with dopaminergic agents will often engender RLS/WED.

Several other comorbid medical conditions have been found to be associated with RLS/WED at a significantly high rate. All conditions associated with iron deficiency appear to show increased risk for RLS/WED, including celiac disease,[91] frequent blood donation,[80] and irritable bowel syndrome.[92] RLS/WED has also been associated with a wide range of other medical conditions, such as hypothyroidism and hyperthyroidism, chronic lung disease, leukemia, Isaac syndrome, stiff-man syndrome, Huntington chorea, multiple sclerosis, essential tremor, migraine, and amyotrophic lateral sclerosis. Considering the high prevalence and the differential diagnostic uncertainty of RLS/WED in the methods used for many of these studies, these associations should be interpreted with caution. However, the rate of occurrence of RLS/WED may increase in patients with multiple comorbid medical conditions,[93] suggesting multiple, complicated interactions increasing the expression of RLS/WED.

Comorbid Psychiatric Conditions

One population-based sample of 1024 participants using excellent diagnostic procedures found the odds ratios (95%

confidence range) of psychiatric conditions occurrence in the past year for those with RLS/WED compared with those without RLS/WED was 2.0 (0.6 to 7.3) for generalized anxiety disorder, 2.7 (1.1 to 6.7) for major depressive disorder, 5.6 (1.4 to 21.9) for obsessive compulsive disorder, and 5.3 (2.0 to 14.0) for panic disorder.[94] In these cases, it appears that RLS/WED increases the risk for having these other disorders rather than the reverse, possibly because of some shared biologic features or a response to the stress of living with RLS/WED.

Substances Associated with Disease

Several substances or medications can induce or worsen RLS/WED or PLMS. These include tricyclics or other antidepressants, lithium carbonate, dopamine D_2 receptor–blocking agents, (neuroleptics, antiemetics), antihistamines, and alcohol.

MEDICAL INVESTIGATION

Given the aforementioned associations between anemia or iron deficiency, iron status should be evaluated in every patient. Iron deficiency cannot be determined by history and can occur with normal hemoglobin, so the standard complete blood count does not suffice. Every patient should have a full iron assessment (i.e., morning fasting serum values for iron, ferritin, total iron-binding capacity, and transferrin saturation). When these levels are abnormal, further medical evaluation is recommended to determine any possible cause, usually involving blood loss. An iron-poor diet may in some cases be a problem.[95] In a patient with RLS/WED, either a serum ferritin level of less than 75 mcg/L or transferrin saturation of less than 17% indicates possible iron deficiency, and iron treatment should be considered.[96]

Medications should be reviewed to reduce, if possible, substances associated with RLS/WED. Because a significant number of RLS/WED patients have peripheral neuropathy,[89,97] a careful clinical examination of sensory and motor functions should be performed with further evaluation if indicated for neuropathy. When taking the history, RLS/WED and PLMS should be differentiated from other state-dependent sensorimotor disorders, such as positional discomfort, hypnic myoclonus, painful legs and moving toes syndrome, nocturnal leg cramps, neuroleptic-induced akathisia, and vascular or neurogenic intermittent claudication. Whenever the diagnosis is doubtful, a polysomnographic recording should be considered, particularly if there is a report of somewhat atypical features such as daytime sleepiness. Leg activity meters provide an alternative for evaluation of PLMS when sleep-disordered breathing is not an issue. Leg activity meters have the major advantage of providing data over 3 to 5 days needed to correct for the large internight variability of PLMS.[9]

ETIOLOGY AND PHYSIOPATHOLOGY

Genetics

Substantial evidence suggests a genetic contribution to RLS/WED. More than 50% of idiopathic cases report a positive family history of RLS/WED.[3,13,16,98,99] In most pedigrees, it segregates in an autosomal dominant fashion, with a penetrance rate of more than 90%.[13]

Multiple linkage studies of familial RLS/WED have, however, identified mostly marginal associations over a wide range of chromosomes. Thus far, none has identified any specific gene associated with RLS/WED. In contrast, modestly large, genome-wide association studies have discovered specific common allelic variants strongly associated with increased risk for RLS/WED occurring at loci for specific genomic regions of *MEIS1, BTBD9, PTPRD, MAP2k/SKOR1,* and *TOX3/BC034767* and at an intergenic region on chromosome 2 (rs6747972). Variants in *MEIS1* appear to carry the largest risk for RLS/WED, and this may indicate an important role for developmental differences in RLS/WED consistent with the role of this gene in early development. The *BTBD9* variants are also strongly associated with PLMS independent of RLS/WED,[100] and most of the variants associated with RLS/WED also relate to some degree to PLMS.[101] The *BTBD9* variant is also associated with reduced serum ferritin[100] for RLS/WED, suggesting a role in iron management consistent with the role of iron deficiency in RLS/WED. The known common variants associated with RLS/WED, however, account for only 7% of RLS heritability.[102,103] The missing genetic factors may involve as yet undetected common alleles, rare variants, or epigenetic features. For example, rare allelic variants of *MEIS1* altering transcription have been associated with RLS/WED.[103]

Neural Substrates

Thus far there is no evidence of significant cell loss or degeneration in the central or peripheral nervous system in RLS/WED. Autopsy studies show no overall histopathologic abnormalities for RLS/WED brains[104] and, in particular, none for the major dopaminergic areas thought to be important for RLS/WED (substantia nigra[104] and A11[105]). Magnetic resonance imaging studies generally find no morphologic abnormalities or loss of gray matter in RLS/WED.[106,107] White matter, however, may be decreased in patients with RLS/WED,[108] particularly in the corpus callosum, anterior cingulum, and precentral gyrus,[109] and there may be an abnormal loss of myelination consistent with that seen in iron-deprived animals.[109]

Abnormalities in central nervous system (CNS) functioning appear to be widespread in RLS/WED. Changes in cortical[110,111] and spinal[112] excitability have been reported, although the latter may result from loss of cortical inhibition.[113] Thalamic connectivity in the resting state seems to be altered.[112] Little is known about the cause of these diffuse functional abnormalities or their significance for RLS/WED.

Neurotransmitter Dysfunction

Dopamine

The therapeutic effects of levodopa and dopamine agonists on RLS/WED and PLMS support the hypothesis that alterations in dopamine signaling may be involved in the pathophysiology of these conditions. Dopamine antagonists generally exacerbate RLS/WED symptoms, and in one study, they precipitated an increase in PLMW in all but one of the patients evaluated.[114] Brain-imaging studies appear to have somewhat conflicting results, but recent analyses have indicated overall consistent findings. Two positron emission tomography (PET) studies reported in the same article confirm decreased membrane-bound dopamine transporter in RLS/WED,[115] whereas overall dopamine transporter

(DAT) evaluated by single-photon emission computed tomography is not changed.[116,117] Iron-deprived animals similarly show a decrease mostly in membrane-bound DAT.[118] Raclopride binding for dopamine receptors is decreased in PET studies of patients with more severe RLS/WED,[119] and in an autopsy study, striatal D_2 receptors had a significant decrease correlated with RLS/WED severity.[120] The decreases in DAT and the D_2 receptors are most consistent with increased striatal dopamine.[119] Cerebrospinal fluid (CSF) studies showed increased 3-orthymethyldopamine, indicating possible increased dopamine production.[121] Thus, overall, RLS/WED appears to have increased, not decreased, presynaptic dopaminergic activation. Increased presynaptic activity leads to a compensatory decreased postsynaptic response that appears to be adequate for most of the usual daily variation in dopamine activity, except at the low point of dopamine activity in the evening and night. When the daily dopamine signal is low, the postsynaptic decreased responsiveness overcompensates for the increased dopamine, producing a failure to respond adequately and accordingly expression of the RLS symptoms. Adding a small amount of dopamine can then increase the stimulation enough to compensate for the excessive postsynaptic decreased responsiveness and reduce the RLS symptoms. Overall, RLS/WED appears best characterized as an increased dopaminergic state, with decreased response to dopamine.[122]

Opioid

The positive pharmacologic response to opioid treatment in RLS/WED and the reversal of that treatment with the opiate receptor blocker naloxone have also been used as an argument in favor of the hypothesis of an endogenous opiate system dysfunction in RLS/WED and PLMS.[123] Pharmacologic data suggest that opiates affect dopamine signaling. An opiate receptor PET scan study showed no difference in postsynaptic opiate receptor binding between RLS/WED patients and controls, but there was an inverse correlation between the degree of opiate receptor binding and the severity of RLS/WED.[124] A preliminary autopsy study showed decreased levels of the endogenous opioids β-endorphin and met-enkephalin in RLS/WED patients compared with controls.[125]

Other Neurotransmitters

Hypocretin (orexin) has been reported to be significantly increased in the CSF of early-onset RLS/WED patients in one study,[126] but this increase was not significant in a second study.[127] Hypocretins increase histamine signaling, and it was found that RLS/WED symptoms can be severely exacerbated by antihistamines, suggesting a histaminergic abnormality that might be related to increased hypocretin.

Iron

Ekbom was among the first to note that RLS/WED commonly occurs with iron deficiency anemia.[85] All conditions producing iron deficiency also engender RLS/WED. Treatment of iron deficiency anemia can completely resolve all RLS/WED symptoms for many patients.[128-130]

One study showed no significant differences in serum ferritin or iron, but the CSF ferritin was reduced and transferrin was increased, consistent with a CNS iron deficiency despite apparently normal peripheral iron status.[131] Magnetic resonance imaging and ultrasound studies of regional brain iron content have consistently shown reduced brain iron, particularly in the substantia nigra of subjects with RLS/WED compared with age-matched control subjects.[132-134] Autopsy analyses of substantia nigra tissue from patients with RLS/WED compared with age-matched control subjects have revealed a complex pattern of iron-related abnormalities.[104] Recent studies with more sensitive methods for measuring iron have found the brain iron deficiency in RLS/WED occurs in other areas beside the substantia nigra and the striatum and in particular occurs in the thalamus.[135] The complex nature of brain iron metabolism in RLS/WED is shown by increased mitochondria ferritin despite decreased cytosolic ferritin,[136] decreased transferrin receptor despite iron deficiency, altered regulation at the blood-brain interface,[137] and association with increased hypoxia inducible factor, indicating activation of hypoxic responses occurring even without actual hypoxia..[138]

These findings, combined with the success of intravenous iron treatments, support the putative concept that a brain iron deficiency causes RLS/WED in many patients. Of interest is the role of iron in dopaminergic transmission in the CNS. Iron deficiency is associated with increased extracellular dopamine, decreased dopamine transporter, and decreased D_2 and D_1 receptors in the striatum of rats similar to the findings in RLS/WED.[122] Thus abnormalities in iron metabolism or environmental factors producing brain iron deficiency may be a primary cause of RLS/WED symptoms or they may be factors contributing to the development of RLS/WED. In this regard, the striking finding that pregnancy increases the risk for RLS/WED in later life raises the interesting concept that this and other environmental factors with significant iron deficiency may alter genetic factors to increase susceptibility to RLS/WED.

TREATMENT

Nonpharmacologic

It is important that patients maintain good sleep hygiene to prevent the development of psychophysiologic insomnia, which is frequently encountered in RLS/WED. Patients should also refrain from drinking alcohol in the evening because it aggravates symptoms in most patients. Some patients report staying active in the evening and delaying their sleep times to later in the night and early morning when the RLS/WED symptoms have abated.[139]

Pharmacologic

Treatment of moderate to severe RLS/WED generally involves many years of continuing essentially palliative treatments. Unfortunately, most of the controlled clinical treatment studies for RLS/WED last only 3 months, with a few lasting 6 months, but some of the significant RLS/WED treatment complications arise after the first 6 months of treatment, particularly as noted later for the dopaminergic treatments.[140] The following emphasizes medication choices assuming long-term treatment.

Four categories of medications are commonly prescribed to treat RLS/WED: dopaminergic agents, alpha-2-delta (α2δ) ligands (a class of anticonvulsants acting upon calcium channels), opioids, and benzodiazepines.

Dopaminergic Medications

Dopaminergic medications have been the most commonly prescribed medications for RLS/WED. The extensive, excellent responses seen with short-term clinical experience and in short-term clinical studies have produced a false impression that these are the most effective medications for RLS/WED. However, one blinded, controlled treatment trial comparing standard dopaminergic treatment to an α2δ ligand showed that an α2δ ligand was as effective in reducing RLS/WED symptoms.[140] Although dopaminergic medications generally produce an excellent immediate and short-term treatment response, clinicians need be aware of the potential for adverse effects emerging with long-term treatment.

Augmentation and Other Long-Term Complications with Dopaminergic Treatments

Three major problems can occur with long-term dopaminergic treatment: (1) Augmentation (worsening of the underlying RLS/WED symptoms) develops in most patients, usually insidiously and often longer duration of treatment.[141] (2) Compulsive behaviors and profound sleepiness develop in a few patients, mostly with higher doses.[142] (3) Stopping the medication is difficult for many because of the strong withdrawal symptoms and significant sleep loss that occur when a dose is missed.

RLS/WED augmentation is a phenomenon in which RLS/WED symptoms become worse than they were before treatment: Symptoms can occur earlier in the day, have greater intensity when present, involve more of the body (e.g., more of the legs, arms as well as legs), have increased periodic leg movements, and have shorter periods of relief after taking the medication.[143] Augmentation leads to a need for increased dose to control symptoms and doses earlier in the day to block the earlier onset of symptoms. Thus, in clinical practice, the most common symptoms of augmentation are increasing and earlier in the day dosing (afternoon, morning) to block the augmentation effects.[141] Augmentation can become a serious medical problem, producing RLS/WED symptoms 24 hours a day even with high doses of dopaminergic medications. The extreme distress with severe RLS/WED augmentation is shown in Video 95-8 for sensory-motor symptoms and in Video 95-7 for in-bed continuous movement. The rate of augmentation varies by medications and is generally higher with shorter acting medications. The augmentation process can develop over at least 10 years.[144] Thus, over 1 to 8 years of treatment using the short- to intermediate-acting dopaminergic agents, about 75% of patients in one large treatment-population study eventually developed symptoms of augmentation.[141]

The risk for augmentation can be reduced by keeping the dose low and in particular by not exceeding the approved dose levels and also not increasing the dose after stable treatment has been established. A clinical need to increase the dose should be considered a warning sign of possible augmentation, and increasing the dose should be done carefully and preferably not more than once.

The recommended treatment for augmentation is reducing the dose, discontinuing the dopaminergic medication, and then switching to an alternate treatment. Switching to a nondopaminergic drug is preferred, although some have used higher doses of a very long-acting dopaminergic, such as rotigotine. It may take several weeks to months to fully recover from augmentation.[145] After augmentation has occurred with long-term treatment, it may reoccur more rapidly if the dopaminergic agent is restarted after withdrawal,[146] suggesting augmentation may produce long-term changes in sensitivity to dopaminergic stimulation.

Compulsive behavior and sleepiness can occur with long-term use of the higher doses of dopamine agonists, presumably related to overstimulation of D_2-like receptors by the currently used agonists.[142,147] All patients being treated for RLS/WED with dopaminergics should be cautioned about these problems, especially because they may not be aware of compulsive behavior or sleepiness. Dopamine agonists have produced excessive gambling with significant financial loss and also inappropriate sexual behaviors. The patient, however, will generally not recognize these as abnormal behaviors. Profound sleepiness appears to occur only rarely and at higher dopaminergic doses.[142]

Abrupt discontinuation of dopamine agonists can produce insomnia and increased RLS/WED symptoms for at least the first 2 to 4 days off the medication. This can occur after missing a single dose and even when the dose is gradually tapered before stopping the medication. This increase in RLS/WED symptoms complicates efforts to consider changing treatments. Withdrawal symptoms appear less common with nondopaminergic medications.

Commonly Used Dopaminergic Medications

Levodopa. Several open-label and placebo-controlled studies have documented the benefits of levodopa, given with a dopa-decarboxylase inhibitor, either benserazide or carbidopa, in idiopathic RLS/WED and RLS/WED associated with uremia. Several adverse effects were reported in patients treated with levodopa, including nausea, vomiting, tachycardia, orthostatic hypotension, hallucinations, insomnia, daytime fatigue, and daytime sleepiness. Morning rebound of RLS/WED symptoms can occur, with symptoms presenting in the morning at the end-of-dose efficacy. Augmentation is common (60% to 82%) and may be severe, requiring medication adjustment.[143,148] It can occur within the first 6 months of treatment even with a low dose (50 mg levodopa).[148] Given these problems, use of levodopa is often limited to as needed not to exceed two or three lower doses (50 to 200 mg) a week.

Dopamine Agonists. Because they are more effective and produce fewer adverse effects (especially augmentation) than L-dopa, dopamine agonists have become one of the first-line treatments for RLS/WED, although now they are used more cautiously at lower doses to avoid long-term treatment complications. Several agonists have been studied in RLS/WED. An older long-acting ergoline-derivative drug, cabergoline, has been found effective for treatment of RLS.[149,150] Cabergoline and the other ergot dopamine agonists have been associated with rare but serious retroperitoneal and pleuropulmonary fibrosis.[151] They are not recommended for RLS/WED treatment except when the lack of alternatives justifies the fibrosis risk.

Two intermediate-duration non–ergoline-derivative agonists, pramipexole and ropinirole, have been extensively studied for the treatment of RLS/WED. Pramipexole, a full agonist for the D_2 subfamily of receptors with preferential

affinity for the D_3 receptor subtype, was found very effective in treating RLS/WED and in suppressing PLMS in double-blind, placebo-controlled studies with sustained efficacy for 3 to 12 months. [152-155] Pramipexole is approved for treatment of moderate to severe RLS/WED at doses of 0.25 to 0.5 mg by the U.S. Food and Drug Administration (FDA) and at doses of 0.25 to 0.75 mg by the European Medicines Agency (EMEA), both with doses to be taken about 2 hours before bed. Augmentation was found in 32% of patients over 3 years of treatment[154,156] and has an annual rate of occurrence of 7% to 8% for at least 8 to 10 years, eventually leading to as many as 75% having experienced some indication of agumentation.[141,144]

Ropinirole, a dopaminergic agonist with a pharmacologic profile similar to that of pramipexole, was also found effective in treating RLS/WED in placebo-controlled studies,[157,158] with sustained efficacy for 12 months.[159] Like pramipexole, ropinirole is well tolerated and rarely requires the adjunctive use of domperidone for nausea. Ropinirole is approved by the FDA and EMEA for treatment of moderate to severe RLS/WED at doses up to 4 mg taken before bed. The rate at which patients develop augmentation with ropinirole is similar to that of pramipexole.[141]

The dopamine agonist rotigotine, with 24-hour transdermal delivery, provides continuous dopamine stimulation and is very effective for treatment of RLS/WED.[160-163] It has high affinities for the D_2 receptor family and also, unlike pramipexole and ropinirole, has significant affinity for D_1, D_5, and α_{2B}-adrenergic receptors. Rotigotine is approved by the FDA and EMEA for treatment of moderate to severe RLS/WED at doses of 1 to 3 mg per 24 hours. This is the only medication that has been prospectively evaluated for very long-term treatment. In that study rotigotine produced an excellent response over 5 years of treatment for the 43% of the patients who continued on the drug, and 39% of these patients were considered free of all RLS/WED symptoms. Nineteen percent of patients discontinued rotigotine for application site reactions. The annual rate of clinically significant augmentation over the 5 years with rotigotine was 2.9%,[164] less than for pramipexole or rotigotine in shorter term studies.

A2δ Ligands (Anticonvulsants)

These ligands act on the α2δ subunit of voltage-dependent calcium channels to reduce the influx of calcium ions into the neuron, thereby reducing release of some neurotransmitters, particularly glutamate, norepinephrine, and substance P. Unlike the dopaminergics, these drugs do not appear to cause augmentation with long-term treatment. They are a first-line treatment for RLS/WED when their adverse effects are not a problem. The primary adverse effects for these drugs are dizziness, somnolence, nasopharyngitis, and weight gain. This class of drugs has been marked by the FDA for possible development of suicidal ideation. This has not been documented as a problem in the RLS/WED studies, but caution is advised when prescribing these drugs for patients with major depression. In general, these drugs should be started at low doses with a gradual increase in dose about once a week until therapeutic levels are reached. Unlike the dopamine agonists, the response to these drugs may not occur on the first few nights of treatment; rather, the clinical response may be delayed by the need to gradually increase the dose to therapeutic levels.

Three α2δ agents are currently used to treat RLS/WED. Gabapentin enacarbil is an oral prodrug for gabapentin that provides better absorption and allows for obtaining a higher continuous blood level compared with oral gabapentin. It has been found to be very effective for treatment of RLS/WED over a full 24-hour period, reducing daytime as well as evening and nighttime symptoms.[165-169] It is approved by the FDA for treatment of RLS/WED at a dose of 600 mg daily. Pregabalin is commonly used to reduce pain. Pregabalin 300 mg is as effective as 0.5 mg pramipexole and more effective than 0.25 mg pramipexole over 12 months of treatment.[140] It has an augmentation rate over a full year of 1.7%, significantly less than the 9.0% for pramipexole 0.5 mg[140] and about the same as the placebo rate of 1% to 2% per year.[170] Thus this low rate may represent a nonpharmacologic process in the natural course of the disease, either symptom fluctuation or gradual progression of the disease rather than augmentation (Figure 95-2).

Gabapentin has been widely used to reduce neuropathic pain, and several very small open-label trials[171-175] and one small placebo-controlled, crossover study[176] showed it is also effective for treatment of moderate to severe RLS/WED. Its efficacy is limited by problems with absorption that limit the actual doses that can be achieved, and serum levels can be variable for a given dose.[177] Neither pregabalin nor gabapentin have been approved by the FDA or EMEA for treatment of RLS/WED.

Opioids

The therapeutic effects of opioids were noted by Ekbom[3] and confirmed in several open-label and controlled clinical trials.[178-181] Persisting efficacy of opioids was demonstrated in long-term follow-up studies.[179,180] Opioids are often prescribed for severe cases of RLS/WED, especially in patients unresponsive to other treatments. A prolonged-release oxycodone combined with naloxone (doses of 5 to 40 mg oxycodone and 2.5 to 20 mg naloxone, twice daily) was found in a placebo-controlled study to provide significant benefit for RLS/WED patients not responding well to their current, mostly dopaminergic, medications.[181] This medication is approved for use in Europe as a second-line treatment. Methadone has also been used for treatment of severe RLS/WED in patients with inadequate responses to other medications. The dose of methadone for RLS/WED is usually 2.5 to 20 mg a day, lower than the usual dose for analgesia.

Although there is little evidence of tolerance or addiction to opioids in the RLS/WED literature, the data are sparse, and therefore prescription of opioids should be restricted to patients without a previous history of substance abuse. Opioids should also be used cautiously in patients who snore and are at risk for having sleep apnea syndrome. Constipation, lethargy, and sleepiness are common adverse effects of opioid treatments.

Benzodiazepines

Several studies have shown that benzodiazepines, including clonazepam,[182] nitrazepam,[183] and temazepam,[46] improve sleep quality and reduce arousals with PLMS in patients with RLS/WED and PLMS. However, the therapeutic effects of benzodiazepines on subjective ratings of RLS/WED symptoms were either modest or not significant. Therefore

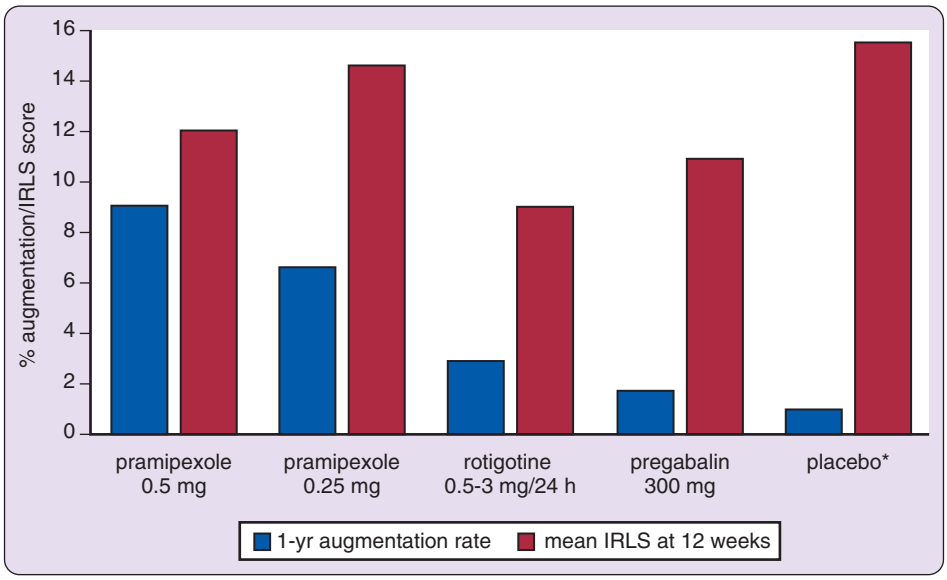

Figure 95-2 Efficacy and augmentation with restless legs syndrome treatments. Restless legs syndrome (RLS) augmentation rate per year and efficacy after 1 year of treatment (mean International Restless Legs Scale [IRLS] score) showing that pregabalin 300 mg is as or more effective than pramipexole (0.5 or 0.25 mg) and that both pregabalin and rotigotine have augmentation rates close to that of placebo, indicating natural progression rather than augmentation. Data are from blinded, controlled 1-year studies of pregabalin,[140] pramipexole,[140] and rotigotine.[164] The data for placebo are prorated from a blinded 6-month study.[170]

benzodiazepines are mostly used to improve sleep continuity in RLS/WED patients.

Iron: Oral and Intravenous

Oral iron as supplemental treatment is indicated when the patient's ferritin level is less than 75 mcg/L.[96] Ferrous sulfate 325 mg, or its equivalent, with vitamin C 100 to 200 mg can be taken twice a day, preferably on an empty stomach, depending on how well the iron is tolerated.

IV iron formulations with tightly bound iron appear to be very effective treatment for 40% to 60% of RLS/WED patients in open-label studies using iron dextran[184-186] and in one placebo-controlled study using ferric caboxymaltose.[187] In these studies, about 20% of patients reported essentially complete remission of their RLS/WED lasting several months. In two controlled studies, iron sucrose, a formulation that more rapidly releases iron for cellular uptake, did not provide the same level of benefit.[188,189] The duration of benefit from IV iron vary considerably, and repeated doses have been found to be useful in a small sample of patients,[190] but care has to be taken to avoid iron overload. IV iron is tolerated well with few adverse effects, except that the high-molecular-weight dextran can produce severe anaphylaxis. Anaphylaxis seems to be related to the iron-dextran formulation and almost exclusively to the high-molecular-weight iron dextran. There appear to be no significant risks for anaphylaxis with the other iron formulations,[191] but given the history of this problem with IV iron, standard treatment options should be readily available for rapid intervention if anaphylaxis occurs.

Clinical Management

In summary, α2δ ligands are considered a good first choice for treatment because they provide excellent long-term treatment when they are tolerated. They are specifically preferred for patients with anxiety, sleep disturbance, and pain, either RLS or neuropathic. They should also be considered if the RLS/WED course is intermittent and future trials off medication are contemplated. Among these medications, only gabapentin enacarbil has been approved by the FDA for RLS/WED treatment. Because of gabapentin absorption problems some patients who fail to respond to gabapentin may respond to gabapentin enacarbil or pregabalin. Dopamine agonists are also a first-line treatment and should be considered particularly for patients with depression and increased risk for falls. They have the major advantage of often producing a rapid therapeutic response with relatively limited immediate adverse effects. Ropinirole, pramipexole, and rotigotine are the only dopamine agonists with FDA and EMEA approval. Some patients who respond poorly to the shorter acting dopamine agonists may respond better to a longer-acting medication. The significant problems with long-term use of dopamine agonists can be reduced by keeping the dose low and not exceeding the FDA-approved daily doses (0.5 mg pramipexole, 4 mg ropinirole, and 3 mg rotigotine). Rather than increasing dose beyond this range, consideration should be given to adding another class of medication or switching medications.

RLS/WED symptoms can spontaneously remit for weeks or even months. Pharmacologic treatments may permit PRN use of medications during symptomatic periods. Daily pharmacologic treatment should be considered if patients complain of RLS/WED occurring at least two nights per week and find the symptoms distressing and affecting their functioning. An occasional drug holiday can be considered to evaluate the need for continuing the treatment. All pharmacologic treatments, except possibly iron, are palliative and do not reduce the underlying disease process. Iron appears in some patients to possibly alter the disease process by improving the well-established RLS abnormality of decreased brain

Table 95-1 Management of Restless Legs Syndrome LS/WED

Agent and Daily Dosage	Side Effects	Countermeasures
Step 1: A2δ Agents		
First-line treatment, particularly if sleep disturbance, pain, or anxiety is present		
Gabapentin enacarbil, 300-600 mg	Dizziness	Reduce dose and add alternate medication class as needed. If fall risk, then discontinue and change to alternate medication class.
Pregabalin, 50-450 mg*	Somnolence, daytime fatigue	Reduce dose and add alternate medication class as needed.
Gabapentin, 100-1800 mg*		If significant, discontinue and change to alternate medication class.
	Tolerance	Discontinue, take drug holiday with return to medication. Switch to alternate medication class.
	Weight gain	Reduce dose and add alternate medication class as needed. If significant, discontinue and change to alternate medication class.
Step 2: Dopamine Agonists		
Alternative first line treatment if depression is present and dose kept low.		
Pramipexole, 0.125-0.5 mg* (0.75 mg in Europe)	Nausea and orthostatic hypotension	Slowly increase dosage or use domperidone if available (10-30 mg).
Ropinirole, 0.5-4.0 mg*	Insomnia	Add or switch to α2δ agent.
Rotigotine, 1-3 mg/24 h		Use a small dose of benzodiazepines in association with dopamine agonists.
	Daytime fatigue and somnolence	Reduce dosage or discontinue dopamine agonists.
	Compulsive or impulsive behavior	Reduce dose and add alternate medication class as needed. If significant, discontinue and change to alternate medication class.
	Tolerance	Discontinue and switch to longer acting dopamine agonist or alternate medication class.
	Augmentation	Discontinue and switch to alternate medication class or longer acting dopamine agonist.
Step 3: Dopamine Precursors		
Useful for intermittent treatment, such as twice a week		
Levodopa-benserazide or levodopa-carbidopa (regular or slow release), 100/25 or 200/50 mg†	Same as for dopamine agonists	See countermeasures for dopamine agonists.
	Morning rebound or augmentation of restless legs syndrome in early evening	Use small extra dose of levodopa during daytime or reduce dosage or combine levodopa with dopamine agonists or benzodiazepines or discontinue levodopa (if severe and persistent).
	Augmentation	Do not used daily. Discontinue and switch to dopamine agonists or a nondopamine medication.
Benzodiazepines		
Useful for sleep promotion		
Clonazepam, 0.5-2.0 mg‡	Daytime somnolence	Reduce dosage.
Temazepam, 15-30 mg‡	Tolerance	Take drug holiday for 2 weeks then return to lower dosage.
Nitrazepam, 5-10 mg*		
Opiates		
Second-line treatment		
Oxycodone-naloxone, 10/5-40/20 mg/day	Constipation	Use for symptom treatment.
Methadone, 2.5-20 mg	Dependency	Take a drug holiday. Discontinue and switch to alternate medication.
Oxycodone, 5-40 mg		
Oral Iron		
Always consider if serum iron ≤75mcg/L *or* transferrin saturation ≤17%		
Ferrous sulfate, 650 mg (325 mg with vitamin C, 100 mg twice a day)	Constipation, stomach upset and pain	Reduce dose, discontinue, take with food.
	Diarrhea, nausea, vomiting	Reduce dose, discontinue, take with food.

*One hour before onset of symptoms in the evening or 1-2 hours before bedtime if symptoms are not present in the evening.
†Considered most appropriate for PRN dosing not more than 3 times a week rather than daily use.
‡Before bedtime usually to promote sleep with restless legs syndrome.

iron insufficiency. This effect of IV iron has been demonstrated in preclinical studies.[192] The dopaminergic medications, in contrast, may produce RLS/WED augmentation, making the underlying RLS symptoms worse than before treatment. Therefore the clinician should carefully assess the therapeutic benefit of the treatments for long-term care versus the severity of adverse effects. Choice of treatment should also consider cost differences.

A therapeutic flowchart is shown in Table 95-1. Each drug is presented with its commonly used therapeutic dosage, its most common side effects, and the appropriate countermeasures to adopt. Higher doses may be considered with caution for all drugs but particularly for dopaminergic medications, for which the risk for augmentation increases with dose.[140] If augmentation develops on a dopaminergic medication, the clinician should consider switching to a very long-acting dopamine agonist, an α2δ ligand, or an opiate. It is still unclear whether the very long-acting dopamine agonists will also in time produce significant augmentation, but their rate of augmentation appears somewhat lower than with the shorter acting dopaminergics. Prolonged-release oxycodone-naloxone,[181] methadone,[180] and IV iron[186] are considered good second-line treatments.

CLINICAL PEARLS

- RLS/WED is a common and underdiagnosed condition with a strong genetic component.
- α2δ Agents provide effective long-term treatment with less risk for augmentation than with levodopa and dopamine agonists.
- Dopamine agonists are effective, and the risk for RLS/WED augmentation with long-term treatment can be reduced by not exceeding regulatory approved dose levels and using longer acting agonists.
- Good second-line treatment options include prolonged-release oxycodone-naloxone, methadone, and IV iron.
- Iron deficiency engenders or exacerbates RLS/WED. Iron deficiency can occur with a normal hemoglobin. Check for serum ferritin of 75 mcg/L or less or percent transferrin saturation of 17% or less, and if either is the case, consider oral iron treatment while also providing any other treatment needed. In some patients, oral iron can lead to complete remission from the RLS/WED.

SUMMARY

RLS/WED is a neurologic disease defined by its primary clinical features of an urge to move the legs, often with abnormal sensations that occur during resting in the evening and night more than the morning or day. The diagnosis is based on clinical history and can be supported by PLMS and a family history. Its severity ranges from annoying to disabling. Moderately severe RLS/WED reduces sleep, quality of life, and work productivity. It is associated with increased risk for cardiovascular disease. Moderate to severe RLS/WED occurs in about 1% to 3% of adults and 0.5% of children.

RLS/WED occurs with many medical conditions. It is closely related to iron status, as documented by epidemiology, biology, and iron treatments. RLS/WED often occurs in families. Genome-wide association studies have identified common allelic variations that increase the risk for RLS/WED.

Short- to intermediate-acting dopamine medications provide excellent initial treatment but with long-term use often produce augmentation (worsening) of the disease. α2δ Agents provide as effective initial treatment as dopaminergics with less risk for augmentation. Longer-acting dopamine agonists also have reduced augmentation. Various iron treatments appear for some to improve the disease process.

Chapter 96

Chapter Highlights

- This chapter gives an overview of sleep disturbances, characteristics of sleep architecture and microstructure, and quantitative analyses of wakefulness and sleep electroencephalography (EEG) in several dementias, including Alzheimer disease, progressive supranuclear palsy, Parkinson disease, dementia with Lewy bodies, vascular dementia, Huntington disease, Creutzfeldt-Jakob disease, and frontotemporal dementia.
- To identify patients at risk for developing an overt neurodegenerative disorder, recent research has focused on EEG markers for phenoconversion to dementia in patients with mild cognitive impairment (MCI).
- Certain sleep disorders, including rapid eye movement (REM) sleep behavior disorder (RBD) combined with MCI, substantially increase the risk for developing dementia and parkinsonism.
- Treatment of sleep disturbances in patients with dementia should focus on managing specific symptoms, including insomnia or fragmented sleep; excessive daytime sleepiness; alterations in the sleep-wake circadian rhythm; and excessive motor activity during the night, including RBD, periodic leg movements during sleep, and nocturnal agitation or wandering.

With the steady increase in life expectancy, the prevalence of dementia and neurodegenerative diseases is rising at a rapid pace. It is estimated that the prevalence of dementia doubles every 5 years after age 65 years. With neurodegeneration comes myriad sleep disorders that, if left untreated, can aggravate cognitive deficits, worsen the patient's and caretaker's quality of life, and lead to premature institutionalization. On the other hand, sleep and quantitative electroencephalography (EEG) can sometimes help in making a differential diagnosis or in predicting who is at short-term risk for developing dementia.

ALZHEIMER DISEASE

Alzheimer disease (AD) is a neurodegenerative disorder characterized by progressive decline in memory and other cognitive domains. AD is the primary cause of irreversible dementia in old age. Diagnostic criteria, first established by the National Institute of Neurological Disorders and Stroke—Alzheimer's Disease and Related Disorders Association Work Group, were revised in 2011[1] in light of the discovery of new markers, brain imaging findings, and analyses of amyloid B and tau proteins in cerebrospinal fluid. Accumulation of abnormal tau proteins appears to mediate neuronal dysfunction more so than amyloid deposition. The most highly affected structures early in AD include the entorhinal cortex, hippocampus, amygdala, and nucleus basalis of Meynert, with eventual more diffuse involvement of the suprachiasmatic nucleus (SCN), intralaminar nuclei of the thalamus, locus coeruleus, raphe nuclei, central autonomic systems, and the neocortex. Neuropathology findings include neurofibrillary tangles, neuritic plaques, and neuronal loss. Interestingly, sleep may play a protective role in warding off toxic protein accumulation, with new evidence demonstrating that the brain's "glymphatic" system, the interstitial space surrounding glia and neurons, has substantially higher clearance of amyloid beta during sleep and drug-induced anesthesia compared with wakefulness.[2] Additional animal and human research will be necessary to demonstrate whether this "housekeeping" role of the brain's glymphatic system during sleep reduces potentially toxic protein accumulation and the eventual evolution of neurodegeneration.

Sleep Problems

Sleep disturbance may occur in up to 25% of patients with mild to moderate AD and in about 50% with moderate to severe AD. Several types of sleep problems can be seen, with likely multifactorial causes, including both excessive daytime sleepiness and insomnia with difficulties in both falling and maintaining sleep due to frequent nocturnal awakenings and premature morning awakening (as described in a recent review[3]). These sleep problems pose additional functional consequences; daytime sleepiness is associated with greater impairments in AD patients independent of the level of cognitive impairment.[4] Sleep disturbances are also a major cause of early institutionalization.

Perhaps the most burdensome sleep problem of patients with AD is sundowning, a delirium-like state characterized by confusion, agitation, anxiety, and frequent aggression in the evening or night, with potentially injurious nocturnal wandering. This phenomenon can be explained, at least in part, by an alteration in the biologic clock due to impaired functioning of the hypothalamic SCN.[5] The secretion rhythm of many hormones is affected in elderly people, but it is even more disrupted in AD patients.[6] The timing of the biologic clock is

shifted earlier, as evidenced by two common markers: core body temperature and plasma melatonin.[6]

A series of pathophysiologic findings has shed some light on the circadian rhythm disorder of AD patients. Melatonin production and rhythm are disrupted,[7] even in the early preclinical stages of AD.[8] This might be caused by dysfunction in the sympathetic regulation of pineal melatonin secretion by the SCN.[7] The SCN is under the modulatory influence of the nucleus basalis of Meynert,[9] which degenerates early in AD. In addition, sundowning could result from defective nucleus basalis control of arousal signal processing to the neocortex.[9]

Obstructive sleep apnea (OSA) is more frequent in AD patients than in the general population.[10] A relationship between AD and apolipoprotein E (ApoE), a lipoprotein made in the liver and brain and involved in cholesterol transport and deposition, was first noted in the early 1990s.[11] The risk for developing AD is associated with ApoE-ε4 allele homozygosity and heterozygosity. An association has been also found between the ApoE-ε4 allele and OSA.[12]

Finally, rapid eye movement (REM) sleep behavior disorder (RBD) has also rarely been reported in association with AD. RBD has been reported in one case of mixed AD and Lewy body dementia (DLB) confirmed on autopsy[13] and in 1 out of 15 consecutive patients with AD.[14] The latter study also showed that 3 more patients with AD had REM sleep without atonia. Whether a minority of patients with pure AD truly have RBD, or some AD cases are misdiagnosed, or some AD cases have coexisting DLB (at least in the brainstem) remains unclear. Recent evidence suggests that most RBD cases are associated with synucleinopathy neurodegeneration rather than other proteinopathies.[15]

Polysomnography Findings

Sleep architecture is often abnormal in patients with AD. Certain sleep changes seem to be an exaggeration of those that normally appear with aging. Patients with AD show an increased number and duration of arousals and a concomitant increased percentage of stage N1. Compared with elderly controls, AD patients also show a reduced percentage of slow wave sleep (SWS),[16] the most consistently reported change in mild to moderate AD. Sleep disturbances tend to worsen with increasing severity of AD.[16]

Another change in sleep architecture that looks like accelerated aging in AD is a loss of the specific EEG features of stage N2. Sleep spindles and K-complexes are poorly formed and of lower amplitude, shorter duration, and lower number than those seen in age-matched controls.[17,18] This reduction in fast spindles has been linked to worse immediate recall in AD.[19] With advancing AD severity, it becomes more difficult to distinguish stage N2 from N1 given the absence of characteristic EEG features. The proportion of indeterminate non–rapid eye movement (NREM) sleep increases even further with the disappearance of high voltage (>75 uV) delta waves of SWS.

Conversely, other sleep changes observed in AD are not consistent with the manifestations of accelerated aging. The percentage of REM sleep remains stable in normal aging but is reduced in AD patients compared with controls, mostly because of decreased mean REM sleep episode duration.[17] Variables pertaining to initiation of REM sleep and to its characteristic features are usually unchanged in mild AD, such as REM density, number of REM sleep episodes, REM sleep latency, muscle atonia, and phasic electromyographic activity in REM sleep in most patients without RBD,[17,20] probably because these aspects of REM are under the control of cholinergic neurons in the mesopontine tegmentum that are relatively spared in mild AD. However, lower REM sleep percentage could be due to degeneration of the cholinergic nucleus basalis of Meynert, which normally exerts an inhibitory influence on the thalamic nucleus reticularis.[21] Without strong long-lasting inhibition, the rhythm generator of the thalamus can trigger spindle oscillations, thus curtailing the REM periods (see Chapters 7 and 8).

Quantitative Electroencephalography in Alzheimer Disease

In AD, waking EEG activity is characterized by a slower dominant occipital rhythm than in healthy older people, with increased theta and delta activity compared with age-matched controls. Several studies have attempted to correlate quantitative waking EEG with clinical severity of AD, with variable results. Some demonstrated that relative theta power could aid in distinguishing healthy older adults from those with mild, moderate, and severe dementia, and that decreased alpha and beta band power and increased delta band power were correlated with AD severity.[22,23]

EEG slowing (as indexed by the [(delta + theta)/(alpha + beta)] power ratio) is more apparent during REM sleep than during wakefulness in AD patients.[24,25] Moreover, the distinctive topographic pattern of temporoparietal and frontal regional REM sleep EEG slowing in AD patients[25] parallels findings from neuroradiologic[26] and neuropathologic[27] studies, a pattern not observed for the waking EEG. The REM sleep EEG power ratio, but not the waking EEG power ratio, was also correlated with the Mini-Mental State Examination and with a measure of interhemispheric asymmetry of regional cerebral blood flow in AD.[28] Possibly, the superiority of REM sleep EEG over wakefulness EEG to identify AD-related neurodegeneration is due to the fact that the basal forebrain cholinergic neurons (among the first to degenerate in AD) are usually more active during REM sleep than during wakefulness[29] and cholinergic activity is not as masked by other activating neurotransmitter systems as it is during wakefulness.

Because EEG delta activity is prominent throughout sleep, distinguishing pathologic from normal physiologic delta waves during NREM sleep is particularly challenging. Patients with AD have shown less frequent and lower amplitude elicited K-complexes in response to auditory stimulation than age-matched controls,[30] suggesting that AD patients may have an impaired ability to generate normal physiologic high-amplitude slow waves during NREM sleep. In these patients, the probability of eliciting a K-complex was also correlated negatively with dementia.[30]

Mild Cognitive Impairment as a Prodrome of Alzheimer Disease

One of the major advances in AD research during the past 20 years is an improved understanding of the prodromal phase known as mild cognitive impairment (MCI). The conversion rate from MCI to AD is about 50% over 3 years.[31] The amnestic MCI subtype is more likely to evolve toward AD, whereas nonamnestic MCI more frequently converts to DLB. Sleep problems are one of the four most common neuropsychiatric symptoms of MCI. A meta-analysis confirmed that 15% to

59% of MCI subjects report sleep disturbances.[32] MCI subjects, especially in ApoE-ε4 carriers, have a higher density of SWS arousals and shorter REM sleep duration than controls.[33] Amnestic MCI patients also show fewer sleep spindles and spend less time in SWS.[34] MCI subjects also have greater wake after sleep onset, increased REM sleep latency, and earlier dim-light melatonin onset relative to controls (but similar levels of total melatonin secreted).[35] This advanced melatonin onset is associated with poorer memory in MCI patients.[35]

Several studies have explored resting-state EEG markers for identifying MCI subjects at risk for progression to AD. Four specific biomarkers were recommended for the early diagnosis of AD by the National Institute on Aging–Alzheimer's Association workgroup in 2011: cerebrospinal fluid A-beta amyloid–to-tau ratio, positron emission tomography amyloid, positron emission tomography–fluorodeoxyglucose hypometabolism in specific brain regions, and magnetic resonance imaging–determined atrophy of the hippocampus.[36] However, quantitative EEG (qEEG) markers have several advantages over those measures because qEEG is a noninvasive, low-cost, and widely accessible method to test a large number of at-risk patients. Two basic study designs of qEEG markers have been undertaken in AD. First, studies have compared subjects at different stages of cognitive functioning (controls, MCI, and AD subjects), correlating EEG measures with known AD degenerative markers. Second, longitudinal studies have determined EEG markers at baseline in MCI subjects who subsequently converted to AD at follow-up, in comparison to nonconverters. In the cross-sectional studies, theta power during wakefulness has been correlated with cognitive decline,[37,38] hippocampal body volume,[39] and cerebrospinal fluid P-tau and T-tau, the earliest markers of neurodegeneration in AD.[40] Higher high-to-low alpha ratio correlated with temporoparietal cortical thinning,[41] hippocampal atrophy,[42] atrophy of the ventral basal ganglia and pulvinar,[43] and theta frequency activity.[44] Total coherence of low alpha activity was also negatively correlated with white-matter damage in the cholinergic basal forebrain of amnestic MCI subjects.[45] Longitudinal qEEG studies identified increased theta power, sometimes coupled with decreased alpha power, at baseline in MCI subjects who later converted to AD; these changes were not seen in nonconverters.[46-48] However, increased theta-to-gamma ratio was predictive of developing either AD or non-AD dementia, whereas the ratio of the 2-Hz band just above the individual alpha frequency over the 2-Hz band just below the individual alpha frequency was found to be specifically associated with AD conversion.[48] Reduced alpha power over posterior leads at baseline differentiated stable from progressing MCI.[49] One study found increased theta power only at 21-month follow-up in progressing compared with stable MCI patients.[50] In general, proposed predictive electrophysiologic tools do not yet allow confident classification of subjects at the individual level. One study recommended combining six EEG biomarkers for optimal sensitivity and specificity in predicting which MCI subjects would develop AD within a 2-year period.[51]

PROGRESSIVE SUPRANUCLEAR PALSY

Progressive supranuclear palsy (PSP), also called Steele-Richardson-Olszewski syndrome, is a neurodegenerative tauopathy characterized by progressive axial rigidity, postural instability, and supranuclear gaze palsy. Dementia in PSP primarily reflects dysfunction in the frontal subcortical neural networks.[52]

Excessive daytime somnolence is common in PSP. Hypocretin 1 (orexin A) levels were found to be low in PSP, and these levels were inversely correlated with the duration of PSP.[53] Moreover, sleep efficiency is greatly reduced in PSP, even more so than in PD.[54] RLS is frequent in PSP and may contribute to reduced sleep efficiency and duration.[55] REM sleep may be severely reduced or absent in PSP patients, especially with disease progression and decline in cognitive functioning.[56,57] RBD and REM sleep without atonia has been reported in 15% to 20% of patients with PSP despite reductions in REM sleep duration,[58,59] therefore less frequently than in patients with PD.[54,60] RBD is, however, much more prevalent (78%) in a Guadeloupean form of PSP.[61]

Cognitive decline is, in turn, reflected by a slowing of the EEG. One qEEG study of PSP found predominant frontal slowing during wakefulness compared with controls, but no significant between-group differences during REM sleep for any of the 16 regions studied.[56] Slowing of the frontal EEG during waking is consistent with numerous neuropsychological studies showing frontal lobe functional deficits. Absence of EEG slowing during REM sleep suggests that waking EEG slowing is likely not due to a cholinergic deficit, consistent with findings of normal neocortical and hippocampal choline acetyltransferase activity in PSP.[62] However, dopamine levels are severely reduced in the caudate, putamen, and substantia nigra in PSP patients.[62] Frontal deafferentation resulting from striatopallidal complex dopaminergic deficiency may be responsible for PSP impairments because there are extensive fiber connections between these deep nuclei and the prefrontal region, as suggested by positive correlations between the degree of frontal neuropsychological task impairments and EEG slowing observed in PSP patients.[56]

PARKINSON DISEASE WITH DEMENTIA

Parkinson disease (PD) is a progressive neurologic disorder characterized by rigidity, resting tremor, bradykinesia, and an impairment of postural reflexes and gait that is caused in part by degeneration of dopaminergic neurons in the substantia nigra. Sleep alterations experienced by patients with PD are discussed in Chapter 94; therefore only information relevant to dementia associated with PD is reviewed here.

The incidence of overt dementia in PD is relatively high. In a population-based study of dementia in PD, approximately 80% of nondemented PD patients developed dementia within 8 years.[63] Risk factors include advanced age at onset of symptoms, severe motor symptoms (particularly bradykinesia), levodopa-related confusion or hallucinations, speech and axial involvement, depression, and atypical neurologic features, such as modest response to dopaminergic agents or early autonomic dysfunction.[64]

Demented patients with PD often experience hallucinations. One study found that patients with REM sleep anomalies have more hallucinations than patients without such anomalies.[65] Sleep reduction, particularly REM sleep reduction, could trigger hallucinations due to emergence of REM sleep features during wakefulness. Hallucinations are significantly correlated with the presence of RBD and the amount

of dopaminergic medication, independently of age, gender, disease duration, or Unified Parkinson's Disease Rating Scale score.[66] There is growing evidence that RBD is an early manifestation of a neurodegenerative disorder, particularly the synucleinopathies (e.g., DLB, PD, and multiple system atrophy).[67,68] The occurrence of RBD in PD was estimated at 15% with a structured questionnaire[69] but at 33% using polysomnographic recordings[70]; only half of these cases had been detected at the clinical interview. The phenomenon of REM sleep without atonia could explain the reduction in REM sleep reported in patients with PD when sleep staging has been performed according to the standard criteria because specific alternative criteria need to be used to permit the scoring of REM sleep in the context of REM sleep without atonia.[71]

Approximately one third of patients with PD have EEG slowing regardless of the presence of dementia.[66] Focal temporal-occipital and frontal regional EEG slowing occurs even in some nondemented PD patients.[72] However, only PD-RBD patients have EEG slowing of the dominant occipital frequency.[73] PD-RBD patients have higher theta power during wakefulness in frontal, temporal, parietal, and occipital regions compared with patients who have PD without RBD and control subjects. EEG slowing in patients with PD-RBD might be related to the presence of RBD itself or represent a different synucleinopathy phenotype such as prodromal DLB, rather than being an evolutional stage of PD. In support of that hypothesis is that idiopathic RBD patients without PD have higher theta power in the frontal, temporal, and occipital regions during wakefulness.[74] PSG EEG characteristics have also been found to be altered with PD and dementia. Sleep spindle density is reduced in most studies of PD,[75-77] except for one study.[78] Sleep spindle parameters also predict conversion to dementia in PD patients. Sleep spindle density and amplitude are lower in baseline PSG recordings (parietal and occipital regions) of PD patients who later develop dementia than in PD patients who do not develop dementia.[79]

Patients with PD-RBD also have significantly worse performance on standardized tests of episodic verbal memory, executive functions, and visuospatial and visuoperceptual processing compared with both patients with PD without RBD and control subjects.[80] Interestingly, patients with idiopathic RBD also have worse performance on tests of executive function and verbal memory compared with control subjects.[81]

The association of RBD with dementia in PD was more directly demonstrated by one study.[82] Of 65 patients with PD, 24 had RBD. The frequency of RBD was significantly higher in the PD with dementia group compared with the PD without dementia group (77% vs. 27%). Patients who had PD without RBD had a lower rate of dementia (7.3%) compared with patients with PD-RBD (42%).

There are compelling reasons to believe that RBD may often represent prodromal PD with dementia or DLB. The topography of EEG slowing observed in PD-RBD is similar to that of DLB-associated functional neuroimaging hypoperfusion and hypometabolism.[83,84] Also, the profile of cognitive impairments noted in PD-RBD resembles that of DLB,[85] and many RBD patients later develop DLB.[86,87] Thus, the presence of RBD in patients with PD may be an early sign of an evolution toward dementia. Some evidence suggests that cortical Lewy body–type degeneration is the main source of dementia in PD.[88] Other studies have suggested that α-synuclein–positive cortical (especially frontal) Lewy bodies are associated with cognitive impairment, independent of AD-type pathologic process.[89,90] More studies are necessary to determine the pathologic and neurochemical underpinnings of dementia in PD.

DEMENTIA WITH LEWY BODIES

Dementia with Lewy bodies (DLB) is the second most common neurodegenerative cause of dementia in old age. The core clinical features of DLB are progressive cognitive decline, spontaneous parkinsonism, recurrent visual hallucinations, and fluctuating cognition and vigilance.[91] Autonomic dysfunction is often present.[91] DLB is characterized by the presence of Lewy bodies in limbic and neocortical structures.

A questionnaire study showed that patients with DLB had more overall sleep disturbances, more movement disorders while asleep, and more daytime sleepiness than AD patients.[92] Based on results from the Epworth Sleepiness Scale, 50% of patients with DLB experience excessive daytime sleepiness.[93] However, normal hypocretin-1 levels were found in the cerebrospinal fluid of DLB patients with daytime sleepiness, suggesting that sleepiness in DLB is not related primarily to dysfunctional hypocretin neurotransmission.[53,94] Moreover, contrary to popular belief, fluctuating daytime alertness as measured by objective methods was not found to be related to fluctuations in cognition.[95] A polysomnographic study[96] found that 72% of patients with DLB had a sleep efficiency lower than 80%. Sleep efficiency was not, however, correlated with dementia severity. A high proportion of these patients had pathologic respiratory disturbances indices (70.5%) or periodic leg movements during sleep (PLMS) associated with arousal (45%).[96] As in PD, restless legs syndrome (RLS) and PLMS are indeed common in DLB and can play a part in sleep-onset insomnia, nocturnal arousals, and awakenings.[97] However, a significant proportion of DLB patients have high arousal indices not accounted for by PLMS or respiratory disturbances.[96]

A number of studies or review papers have reported that RBD is common in DLB.[86,87] In a large cohort of 78 DLB patients, 96% had a history of recurrent dream-enactment behaviors, and REM sleep without atonia with or without behavioral manifestations was confirmed in 83% of patients.[96] Inclusion of RBD in the list of core criteria improves sensitivity and specificity of DLB diagnosis.[85,87,98] RBD now figures as a suggestive feature for the diagnosis of DLB in the third report of the DLB consortium.[91] Interestingly, the presence or absence of concomitant RBD was found to be associated with distinct clinical and pathologic characteristics of DLB; patients with concomitant RBD had earlier onset of parkinsonism and visual hallucinations, shorter duration of dementia, lower Braak stage, and lower neuritic plaque scores.[99]

A few quantitative EEG studies have reported EEG slowing during wakefulness in DLB, expressed as a loss of alpha combined with slower dominant[100] and nondominant rhythms,[101] or increased theta activity,[100,102,103] which correlates with the severity of dementia.[100,102] Frontal intermittent rhythmic delta activity has also been reported.[103] Fluctuating cognition, one of the core features of DLB, was also shown to be reflected by the variability of the mean EEG power in DLB patients compared with both AD patients and elderly control subjects.[100,104]

VASCULAR DEMENTIA

The term *vascular dementia* covers a range of problems of various etiologies and includes the entities known as multi-infarct dementia (MID; now a rather outdated term), subcortical ischemic vascular dementia, and Binswanger disease. The most studied form of vascular dementia in sleep medicine is probably MID. An actigraphy study found that patients with MID had a significantly greater disruption of sleep-wake cycles associated with poor sleep quality than AD patients.[105] There was no correlation, however, between the degree of sleep disruption and the severity of intellectual deterioration. OSA was more strongly associated with MID than with AD or other dementias.[106,107] Sleep apnea is considered a risk factor for vascular dementia.[108] Patients with vascular dementia were found to have twice the risk for suffering from insomnia compared with AD patients.[107] A population cohort also demonstrated that, compared with men without sleep disturbances, elderly men with daytime sleepiness at baseline had 4.44 times the risk for developing dementia of vascular origin 10 years later (even after adjustment for possible confounding factors, including cognitive function).[109]

Spectral analysis of the waking EEG of patients with vascular dementia revealed a lower dominant occipital frequency,[110,111] higher theta[110,112,113] and delta power,[112] and lower alpha[110,112] and beta power[112] compared with control subjects. Lower beta power was found to correlate with cognitive performance as measured by the Rey auditory verbal learning test and the Mini-Mental State Examination,[112] but no correlation between qEEG variables and dementia severity was found in another study.[113] In addition, in patients with MID, alpha had migrated to more anterior regions. There was no gender difference in the qEEG of patients with MID.[110,111] Compared with AD patients, patients with vascular dementia had lower delta power,[113] the mean frequency in temporal derivations discriminated the two groups in patients with mild to moderate dementia, and the alpha-to-delta ratio distinguished the two groups in patients with moderate dementia.[114] Larger EEG source fluctuations were found in patients with vascular dementia compared with AD patients and controls, possibly reflecting decreased vigilance control and increased cognitive fluctuations.[115]

HUNTINGTON DISEASE

Huntington disease (HD) is an autosomal dominant hereditary condition associated with atrophy of basal ganglia structures, especially the caudate nucleus, and characterized by choreic movements and progressive dementia associated with psychotic features. A CAG trinucleotide repeat in the *HTT* gene located on the short arm of chromosome 4 is the cause of this condition.[116]

Patients with HD have a disrupted night-day activity pattern, and similar patterns are seen in animal models. Transgenic mice carrying the HD mutation showed a disruption of night-day activity, which worsened as the degeneration progressed, but also showed a marked reduction in the expression of *mPer2* and disrupted expression of *Bmal1* in the SCN, the motor cortex, and the striatum.[117] Ubiquitin-proteasome dysfunction has been suggested to play a role in the pathogenesis of HD,[118] and such inclusions have also been found in the SCN of HD transgenic mice.[119] In humans, a postmortem study found that patients with HD had 85% fewer vasoactive intestinal peptide neurons and 33% fewer arginine-vasopressin neurons in the SCN.[120] Dim-light melatonin onset was delayed by 1½ hours in HD patients, and daytime melatonin levels were correlated with severity of functional impairment.[121] Delayed sleep phase was also associated with depression and poorer cognitive performance in HD patients.[122] Daily treatment with alprazolam in HD transgenic mice reversed dysregulated expression of Per2 and Prok2, an output factor of the SCN that controls behavioral rhythms, and also markedly improved cognitive performance in a visual discrimination task.[123] The combination of bright-light treatment and restricted periods of voluntary exercise was also shown to improve the behavioral synchronization to the light-dark cycle and to delay the disintegration of the rest-activity rhythm in the transgenic mouse model.[124] In an HD sheep model, the circadian behavioral abnormalities were among the earliest symptoms.[125] Restoring circadian rhythms in HD patients might thus improve cognitive dysfunction, the most devastating feature of HD.

Disturbed sleep architecture has also been reported in HD patients. Specifically, they showed longer sleep latency, lower sleep efficiency, frequent nocturnal awakenings, and less SWS than age-matched controls.[126,127] A polysomnography study of a large number of HD patients and controls replicated most of these findings, except for sleep latency, which was unchanged, and REM sleep latency, which was found to be longer instead of shorter.[128] REM sleep duration was significantly reduced in presymptomatic carriers of abnormal CAG repeat expansion in the *HTT* gene and decreased as disease severity increased. Three out of 25 patients with HD had RBD. Finally, patients with HD did not have more daytime sleepiness but had more PLMS than controls. Contrary to patients with other neurodegenerative diseases, HD patients showed a higher density of sleep spindles compared with healthy controls.[76,127] Sleep disturbances, including less SWS and more time spent awake, correlate with the degree of caudate atrophy and the severity of clinical symptoms.[127] In fact, one study found sleep disturbances only in moderate to severe cases of HD, and none in mild cases.[126] However, no correlation was found between CAG repeat length and sleep disturbances.[128] Finally, no difference was found on sleep respiratory variables between patients with HD and control subjects.[128]

On visual inspection, waking EEG exhibits gradual slowing and diminished amplitude as the disease progresses. Waking qEEG in HD demonstrated increased theta and decreased alpha activity in HD compared with controls; patients with HD were similar to patients with AD.[129]

CREUTZFELDT-JAKOB DISEASE

Creutzfeldt-Jakob disease (CJD) is a prion-related transmissible spongiform encephalopathy causing extensive neuronal degeneration and pathologic changes, especially in the cortex, resulting in myoclonic jerks and rapidly evolving dementia and leading to death. CJD typically develops between the fifth and the seventh decades of life. Younger age of onset is associated with an increased likelihood of sleep disturbances and other symptoms.[130] The mean survival duration is 4 to 8 months,[131] although 5% to 10% of patients have a clinical course that spans 2 years or more.

Two large-sample studies[132,133] reported that half of CJD patients experienced sleep disturbances, mostly severe insomnia. In some patients, sleep disturbances were a prodromal or presenting symptom.[132] In fact, there is a continuum between CJD and fatal familial insomnia (FFI).[134-136] A mutation of the prion protein at codon 178 is present in both CJD and FFI. A concomitant polymorphism at codon 129 (valine versus methionine) appears to determine whether CJD or FFI will ensue. However, the 129 polymorphism alone (common in the general population) does not appear to be associated with important changes in polysomnogram variables or insomnia complaints.[137] Predominant thalamic pathology with little cortical involvement is characteristic of FFI, whereas progressive cortical dysfunction without major thalamic changes is usually seen in CJD. However, this is not always the case.[138] Polysomnographic studies of CJD reveal disorganized sleep patterns with sudden transitions between sleep stage, few sleep spindles and K-complexes in N2 (which may be difficult to distinguish from N3), decreased slow waves, and lower REM sleep percentage and REM density.[134,139,140] Episodes of nocturnal oneiric, sometimes aggressive behavior with dream-reality confusion, have been reported in some patients.[132,140] An indeterminate state (neither clear wakefulness nor clear sleep) has also been observed in these patients[134,140] and in patients with FFI.[141] Sleep apneas, central or obstructive, are prevalent in this condition.

The hallmark awake EEG feature in patients with CJD is periodic sharp wave complexes within a background of generalized slow but low-voltage EEG, consistent with diffuse cerebral pathology.[131] Periodic sharp wave complexes, usually generalized biphasic complexes, are invariably present by the time patients evolve clinically evident myoclonus, and typically present by 3 months after symptom onset.[142] Periodic sharp wave complexes are part of the diagnostic criteria for probable CJD[143] because they are present in about two thirds of patients and show a high specificity (occurring in only 9% of patients with another neurodegenerative disorder).[144] Sleep EEG studies also report the presence of periodic sharp wave complexes as early as 1 to 3 months after the onset of symptoms.[145,146] Cyclic changes with periodic complex phases alternating with semirhythmic theta-delta activities have been described.[145,146]

FRONTOTEMPORAL DEMENTIA

Frontotemporal dementia (FTD) is a neurobehavioral syndrome associated with accumulation of tau (e.g., Pick disease, corticobasal degeneration, progressive supranuclear palsy) or TAR DNA binding protein molecular weight 43. FTD is a progressive, degenerative condition characterized by loss of executive or language abilities and several other neurobehavioral features, such as loss of insight, overactivity, lack of social awareness, disinhibition, and lack of personal hygiene.[147] Approximately 5% to 15% of patients with dementia have a disorder within the FTD spectrum. FTD is likely underdiagnosed because of its similarities with AD, especially later in the progression of the disease. However, unlike AD, FTD initially manifests with progressive aphasia and personality changes, whereas memory tends to remain relatively intact. Structural and functional brain imaging shows atrophy, reduced cerebral blood flow, or diminished glucose metabolism in frontal and anterior temporal areas.[147]

As in AD, FTD is generally accompanied by a disturbance of the alpha rhythm and of the sleep-wake rhythm, which worsens with the progression of the disease.[148] Patients with FTD show more nighttime activity,[149] particularly the behavioral-FTD variant (85%) compared with the semantic variant (3%),[150] less morning activity, and lower sleep efficiency compared with control subjects.[149] For a comparable level of cognitive impairment, patients with FTD showed more sleep disruption and a worse sleep macrostructure than patients with AD, regardless of sleep apnea or other primary sleep disorders.[151] Sleep-disordered breathing seems as prevalent in FTD as in AD.[152] REM sleep parameters, however, were found to be more altered in AD than in FTD.[153]

Electroencephalographic slowing during wakefulness is observed in FTD. One study[154] found increased theta power, and another[155] reported increased delta and theta power more prominently in anterior regions in most patients. However, 31% had normal EEGs, and most patients had a preserved dominant occipital frequency.[155] EEG measures of functional connectivity were found normal in patients with mild to moderate FTD.[156]

TREATMENT OF SLEEP DISORDERS IN PATIENTS WITH DEMENTIA

One useful approach to address sleep disorders in the demented patient involves considering symptoms within four major categories: insomnia or fragmented sleep, excessive daytime sleepiness, alteration in the sleep-wake circadian rhythm, and excessive motor activity during the night, including RBD, PLMS, and nocturnal agitation or wandering.[157] One should keep in mind that some of these disturbances could be due to RLS, OSA, malnutrition, infections, medication effects (often polypharmacy), depression, bladder catheterization, fecal impactions, or disturbing environmental factors. Management frequently requires identification and treatment of underlying medical or psychiatric disorders. For each of these four categories of sleep disorders, we review the appropriate pharmacologic and nonpharmacologic treatment strategies. A summary of selected medications with suggested dosage and titration schedule also appears in Table 96-1.

Insomnia

Insomnia may affect as many as 40% to 60% of patients with dementia.[152] Insomnia that is comorbid with other sleep disturbances is a common occurrence in patients with dementia (described in a recent review[158]). Patients with cognitive impairment are often unable to explain why they are unable to sleep through the night, so caregivers and physicians should carefully investigate possible sources for insomnia. Evaluations of pain, concomitant medical conditions, and medications are essential to treat the patient successfully. For example, both untreated depression and some antidepressant medications (venlafaxine, fluoxetine, and bupropion) can lead to insomnia. Cholinesterase inhibitors such as donepezil, which can improve cognitive and behavioral symptoms in AD patients, can also cause insomnia. "Activating" antidepressants, cholinesterase inhibitors, and stimulants may cause or aggravate insomnia, especially when given at night. This problem usually can be avoided if the medication is administered no later than the evening meal, although in some patients these medications must be given no later than lunchtime. Melatonin

Table 96-1 Sleep Disorders and Disturbances in Dementia: Selected Medications with Suggested Dosing Schedules*

Initial Medication	Starting Dose	Suggested Titrating Schedule	Typical Therapeutic Range
Insomnia			
Trazodone	25 mg qhs	Increase in 25-mg increments q3-5 d	50–200 mg/night
Chloral hydrate	500 mg qhs	Increase in 500-mg increments q5-7d	500–1500 mg/night
Melatonin	3 mg qhs	3–6 mg nightly	3–12 mg/night
Quetiapine	25 mg qhs	Increase in 25-mg increments q3d	25–100 mg/night
Zolpidem	5 mg qhs	Increase to 10 mg qhs if necessary	5–10 mg/night
Restless Legs Syndrome, Periodic Limb Movements in Sleep			
Pramipexole	0.125 mg qhs	Increase in 0.125-mg increments q2-3d	0.25–0.75 mg/night
Gabapentin	100 mg qhs	Increase in 100-mg increments q2-3d	300–1800 mg/night
Pregabalin	25–50 mg qhs	Increase in 25–50 mg increments q3-7d	100–600 mg/night
Excessive Daytime Somnolence			
Methylphenidate	2.5 mg q AM	Increase in 2.5- to 5-mg increments q3-5d in bid dosing (AM and noon)	5 mg q AM to 30 mg bid
Modafinil	100 mg q AM	Increase in 100-mg increments q5-7d in bid dosing (AM and noon)	100 mg q AM to 400 mg/day (400 mg q AM or 200 mg bid)
Armodafinil	50 mg q AM	Begin with 50 mg q AM, increase gradually up to 250 mg q AM	50–250 mg q AM
Amphetamine/ dextroamphetamine	5 mg q AM	Increase in 5-mg increments q7d in qd-bid dosing (AM and noon)	5 mg q AM to 20 mg bid
REM Sleep Behavior Disorder			
Clonazepam	0.25 mg qhs	Increase in 0.25-mg increments q7d	0.25–0.75 mg/night
Melatonin	3 mg	3–6 mg/night	3–12 mg/night
Psychotic Features, Behavior Dyscontrol, Nocturnal Agitation, Nocturnal Wandering			
Donepezil	5 mg q AM	Increase to 10 mg q AM 4 wk later	5–10 mg q AM
Rivastigmine†	1.5 mg bid	Increase in 1.5-mg increments q4wk in bid dosing (AM and hs)	3–6 mg bid
Galantamine†	4 mg bid	Increase in 4-mg increments q4wk in bid dosing (AM and hs)	4–12 mg bid
Risperidone	0.5 mg qhs	Increase in 0.5-mg increments q7d in bid dosing (AM and hs)	0.5 mg qhs to 1.5 mg bid
Olanzapine	5 mg qhs	Increase in 5-mg increments q7d in bid dosing (AM and hs)	5 mg qhs to 10 mg bid
Clozapine‡	12.5 mg qhs	Increase in 12.5-mg increments q2-3d	12.5–50 mg qhs
Quetiapine	25 mg qhs	Increase in 25-mg increments q3d	25–100 mg qhs
Valproic acid‡	125 mg qhs	Increase in 125-mg increments q3-7d in bid to tid dosing	250 mg qhs to 500 mg tid
Carbamazepine‡	100 mg qhs	Increase in 100-mg increments q3-7d in bid to tid dosing	200 mg qhs to 200 mg tid

**Disclaimer:* The choice of which agents to use and which dosing schedules to recommend must be individualized. It is the responsibility of the clinician to consider potential side effects, drug interactions, allergic response, life-threatening reactions (e.g., leukopenia with clozapine), dosing changes due to renal or hepatic dysfunction, etc., before administering any drug to any patient, including those listed above. Drs. Petit, Montplaisir, St. Louis, Boeve, their respective institutions, and Elsevier will not be held responsible for any adverse reactions of any kind to any patient regarding the content of this information.

†If insomnia is problematic, the second dose should be given no later than the evening meal.

‡Requires periodic laboratory monitoring; refer to the manufacturer's instructions for laboratory monitoring.

Modified from Boeve BF. Update on the diagnosis and management of sleep disturbances in dementia. *Sleep Med Clin* 2008;3(3):347–60.

was ineffective in treating insomnia in patients with AD in multicenter, placebo-controlled trials.[159,160]

Simple but effective interventions should be tried first, such as instituting proper sleep hygiene (e.g., regular schedule, bedtime routine), limiting caffeine and alcohol intake, and increasing activity and exercise during the daytime with avoidance of prolonged daytime napping. One recent randomized controlled trial of walking, bright-light exposure, or combination therapy in community-dwelling adults with possible or probable AD found that all three active interventions decreased night time spent awake.[161] Before prescribing medication to treat insomnia, the clinician should keep in mind that many hypnotic agents (especially benzodiazepines) can exacerbate cognitive deficits and OSA and can even induce daytime sleepiness because of carryover effects. Use of sedative-hypnotics is associated with longer hospital stays and significantly increased fall risk in the acute care setting.[162] If no cause is found for the insomnia, trazodone or chloral hydrate may be considered, although some studies have shown little alteration in actigraphic sleep parameters in institutionalized patients with dementia receiving sedative-hypnotic medications.[159,163]

In some cases, insomnia can result from unrecognized or untreated RLS. In two recent studies, RLS occurred in approximately 4% to 5% of patients with dementia, and RLS is probably at least as common as in the general population.[152,164] RLS may be difficult to diagnose in patients with cognitive impairment, and in one recent study analyzing probable RLS in 59 patients with dementia, two expert raters found that probable RLS occurred in 24% of patients and that probable RLS was associated with nocturnal agitation behaviors.[165] In another recent study, patients with RLS and early dementia often showed repetitive mannerisms and restlessness, and RLS behaviors were associated with selective serotonin reuptake inhibitor use and a polysomnographic PLMS index greater than 15 per hour.[166] Several medications, especially dopamine agonists, have been proved efficacious and well tolerated in nondemented persons with RLS (for review, see Chapter 97). However, to our knowledge, no study has assessed the efficacy and safety of these agents in demented patients. In some patients, dopaminergic agents can cause insomnia because of their stimulating effects or can trigger or exacerbate psychosis.

Excessive Daytime Sleepiness

Excessive sleepiness during the day has been reported mainly in PD. Daytime sleepiness may result from poor sleep, dopaminergic therapy, or comorbid OSA, or it may be due to PD itself.[167] Somnolence not resulting from another primary sleep problem can also affect patients with AD, DLB, and FTD. In such cases, methylphenidate (at a low dose), modafinil, or armodafinil can be effective in improving alertness without producing significant adverse effects, although careful monitoring of blood pressure is indicated to ensure hypertension does not evolve during stimulant medication administration.

Hypersomnolence can also result from OSA, a condition often associated with degenerative disorders, especially AD and MID. The relationship between sleep apnea syndrome and dementia is complex. On one hand, it is known that sleep apnea is associated with cognitive deficits, some of which may be improved with continuous positive airway pressure (CPAP) therapy.[168] There have been cases of patients with OSA in whom dementia was subsequently diagnosed and whose dementia subsided with CPAP therapy.[169] One study showed that long-term CPAP treatment succeeded in slowing the cognitive deterioration and improving sleep and mood in patients with AD and OSA.[170] However, our clinical experience indicates that only a minority of patients with a dementing illness significantly improve both functionally and on psychometric testing with CPAP therapy, but a significant proportion of patients tolerate CPAP and use it nightly, and spouses enjoy a more consolidated sleep when their bed partners with dementia are on CPAP therapy.[170]

Circadian Rhythm Disorders

Several studies have demonstrated disruption of the sleep-wake rhythm in patients with dementia, especially in AD and FTD. In fact, insomnia and excessive daytime somnolence can be the manifestation of a primary circadian disorder. Degenerative changes in the biologic clock, the SCN of the hypothalamus, and the pineal gland, resulting in reduced melatonin production, may be responsible for the disorganization and flattening of the circadian rhythms.[6,8] Melatonin can be helpful for sleep-wake cycle disturbances in patients with dementia, improving sleep, reducing sundowning, and slowing the progression of functional impairment in AD.[171,172] Bright-light therapy administered in the evening has been found effective to alleviate sleep-wake cycle disturbances in patients with dementia and to better consolidate their nighttime sleep.[173-175] In some patients, regular daylight exposure is also effective for day-night reversal problems.

Excessive Motor Activity during the Night

RBD is prevalent in various degenerative conditions, especially in the synucleinopathies, compared with AD, FTD, and PSP.[15] There is a high interpatient variability in the severity of RBD, but the symptoms generally decrease with disease progression. It is important to differentiate RDB from nocturnal wandering by taking a careful history. When diagnosis is uncertain and the potential for injury is present, a polysomnographic and video recording is justified. The first step in the management of RBD is to ensure the safety of the patient by removing potentially dangerous objects from the bedroom, placing a soft mattress on the floor next to the bed, and removing any firearms from the bedroom. Clonazepam, the traditional treatment of choice for RBD in nondemented persons, can potentially worsen cognition and can aggravate OSA. Before prescribing this agent, it is essential to ensure that the patient does not experience OSA or that patients with OSA are adherent to nasal CPAP therapy at an effective treatment pressure. Clinical experience suggests that clonazepam is well tolerated and produces few or no cognitive side effects in most patients with dementia and concomitant RBD. Melatonin has also been shown to improve RBD symptoms.[176-179] If depression is also present, treatments other than nefazodone should be considered because this drug increases REM sleep, contrary to most other antidepressants, and can therefore potentiate RBD; agomelatine, a melatonergic antidepressant, was recently reported to improve RBD symptoms and may be promising for use in those with RBD and comorbid depression.[180] The cholinesterase inhibitor rivastigmine also improved RBD symptom frequency in a pilot treatment trial in patients with PD.[181] A higher level of evidence from well-powered, definitive randomized controlled

treatment trials is necessary to support specific RBD treatments.[182]

The prevalence of PLMS in dementia has not been estimated exactly. However, it is known to be elevated, especially in the synucleinopathies.[183] Without a polysomnographic recording, the severity and clinical significance of PLMS are difficult to assess. If they are bothersome to the patient or cause daytime sleepiness as a result of sleep fragmentation, treatment with dopaminergic agonists can be considered. Dopaminergic agents should be used particularly cautiously in patients with psychotic features.

One of the heavier burdens on families of elderly demented patients and a primary cause of institutionalization is the lack of sleep because of nocturnal agitation or nocturnal wandering. Nocturnal agitation could be the result of discomfort (constipation, full bladder, clothing, heat, cold), pain (pressure sores, infection), or environmental interruptions (staff noise, light); hence, verifying potential sources of discomfort and pain is crucial. As for insomnia management, eliminating alcohol and restricting caffeine intake to the morning can improve nocturnal agitation. Behavioral techniques should be tried before resorting to psychotropic or sedative-hypnotic medications. However, if necessary, medication options including atypical neuroleptics (risperidone, olanzapine, clozapine, quetiapine), antiepileptic drugs (carbamazepine, lamotrigine, valproic acid, gabapentin), benzodiazepines (clonazepam, lorazepam), trazodone, or chloral hydrate can be effective in treating nocturnal agitation (see Table 96-1 for dosages and titration schedule). Cholinesterase inhibitors can significantly reduce hallucinations for patients who are frightened or significantly bothered by them. In these patients, medications with hallucinatory side effects (levodopa, dopamine agonists, anticholinergics, amantadine, selegiline) should be decreased or eliminated.

CONCLUSIONS

Sleep disturbances are frequent in patients with dementia. Although a common pattern of sleep impairment can be observed in dementia, the study of sleep variables and quantitative EEG in different states are valuable tools in aiding diagnosis and evaluating for pharmacologic treatment.

CLINICAL PEARLS

- Patients with dementia often have important and disturbing sleep problems that can lead to premature institutionalization.
- When managing sleep disturbances in patients with dementia, clinicians should carefully look for underlying causes.
- Nonpharmacologic treatments and basic sleep hygiene principles should be undertaken before considering psychotropic or sedative-hypnotic medications that could exacerbate cognitive deficits or OSA, which should also be promptly diagnosed and treated when identified.
- When a pharmacologic treatment is necessary, one useful approach is to directly target the symptoms, which can be grouped in four categories: (1) insomnia or fragmented sleep, (2) excessive daytime sleepiness, (3) alteration in the sleep-wake circadian rhythm, and (4) excessive motor activity during the night, including RBD, PLMS, and nocturnal agitation or wandering.

SUMMARY

Sleep disturbances are frequent in patients with dementia. Sleep is usually more fragmented, with more frequent awakenings and a longer duration of time awake; SWS is decreased; sleep spindles and K-complexes are less well formed or less numerous, so sleep stages are more difficult to distinguish; and REM sleep may be reduced. Quantitative analyses often show slowing of the EEG during wakefulness and, in AD, during REM sleep. Patients with dementia frequently present with comorbid sleep disorders, including OSA, PLMS, and RBD. As dementia advances, sleep disturbances and EEG slowing typically worsen in parallel with progression of neurodegeneration.

Epilepsy, Sleep, and Sleep Disorders

Milena K. Pavlova; Sanjeev V. Kothare

Chapter Highlights

- Seizures may disrupt sleep, whereas sleep loss and sleep disorders may worsen epilepsy. This chapter describes the complex and bidirectional interactions of sleep and epilepsy.
- Epilepsy is a chronic disease, and seizures often occur at specific times of day and in certain stages of sleep.
- This chapter describes epilepsy syndromes that are manifested with predominantly nocturnal seizures.
- The differentiation between nocturnal seizures and parasomnias can be challenging, and this chapter provides clinical pearls that help better identify seizures.

Epilepsy and sleep disorders are considered by many to be common bedfellows. Sleep can affect seizure occurrence, threshold, and spread, whereas epilepsy can have a profound effect on the sleep-wake cycle and sleep architecture. Many factors can contribute to sleep disruption in patients with epilepsy, including inadequate sleep hygiene, coexisting sleep disorders, circadian rhythm disturbances, epilepsy per se, seizure frequency, and effect of antiepileptic medications.

WHAT IS EPILEPSY?

Epilepsy is characterized by the tendency to have repeated, unprovoked seizures. The seizures can occur spontaneously or be triggered reflexively by flashing lights or other sensory stimuli. The diagnosis of epilepsy[1] requires one of the following:

- At least two unprovoked (or reflex) seizures occurring more than 24 hours apart
- One unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring during the next 10 years
- A diagnosis of an epilepsy syndrome

Epilepsy may result from genetic, structural, metabolic, traumatic, infectious, or unknown causes.

An individual seizure is the transient occurrence of signs or symptoms due to abnormal, excessive, or synchronous neuronal activity in the brain. A seizure can be focal (or partial) if it originates from a process within one hemisphere or generalized if it arises from both hemispheres. The seizure can be further classified by the type of motor activity observed as hypomotor, hypermotor, or automotor; it may include tonic or clonic movements; or it may be atonic (sudden loss of muscle tone) or myoclonic. When the seizure is focal, a variety of activity can be observed, depending on the brain region that leads to the seizures (epileptogenic zone), such as a stereotypic phrase or movement; stereotypic sensation (e.g., a specific sense of smell or hallucination); versive movement of head, eyes, or extremities; automatisms; or sometimes an abrupt cessation of activity. These abnormalities may be associated with alteration of consciousness.

Seizures can be identified electrographically by distinct, rhythmic, epileptiform patterns (Figure 97-1) that disrupt the normal electroencephalographic (EEG) background, evolve in amplitude and frequency, often spread to involve other brain regions, and end abruptly, often followed by slowing or suppression of the EEG rhythms of the affected area. In between seizures, patients with epilepsy frequently have EEG abnormalities called spikes and sharp waves, which are sharply contoured waves that stand out from the background and are often followed by a slow wave (Figure 97-2). Spikes are usually 30 to 70 microseconds in duration, whereas sharp waves are 70 to 200 microseconds in duration. Both have similar clinical significance.

Epilepsy Syndromes

Many patients exhibit a constellation of specific clinical and electrographic characteristics that allow identification of a specific epilepsy syndrome. In others, the epilepsy is nonsyndromic. More than 50 distinct epilepsy syndromes have been defined, and the next sections review several of the syndromes that have a consistent association with sleep.

SLEEP-RELATED EPILEPSY SYNDROMES

Syndromes in Childhood

Benign Rolandic Epilepsy

Also called benign epilepsy with centrotemporal spikes, benign rolandic epilepsy is the most common partial epilepsy syndrome in children, with an onset between the ages of 3 and 13 years and remission in adolescence.[2] The typical presentation is a partial seizure with paresthesias and tonic or clonic activity of the lower face, associated with drooling and dysarthria. The seizures are mostly nocturnal, with 55% to 59% of patients having seizures exclusively during sleep.[3] The electroencephalogram shows characteristic central and temporal spikes that occur bilaterally but independently and are potentiated during non–rapid eye movement (NREM) sleep. The discharge rate is increased during drowsiness and light sleep compared with the waking record, with no change in spike morphology. Despite the increased frequency of seizures and spikes during sleep, the sleep architecture is unaffected,

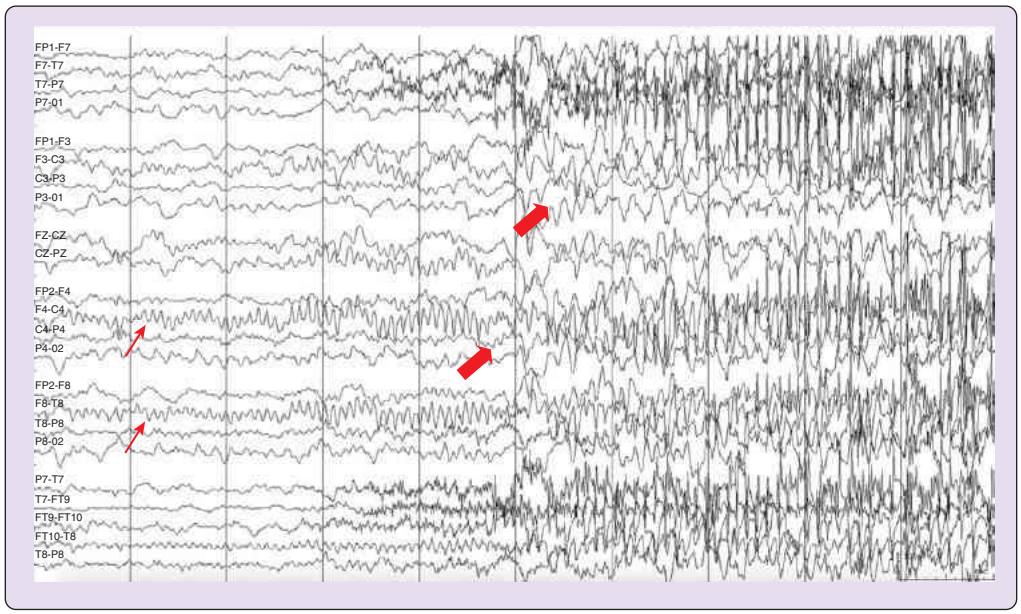

Figure 97-1 Electroencephalogram depicting a focal seizure with secondary generalization. Rhythmic activity starts in the centrotemporal area (F4/C4-F8/T8, *small arrows*), and in the next several seconds, it spreads to both hemispheres (*large arrows*).

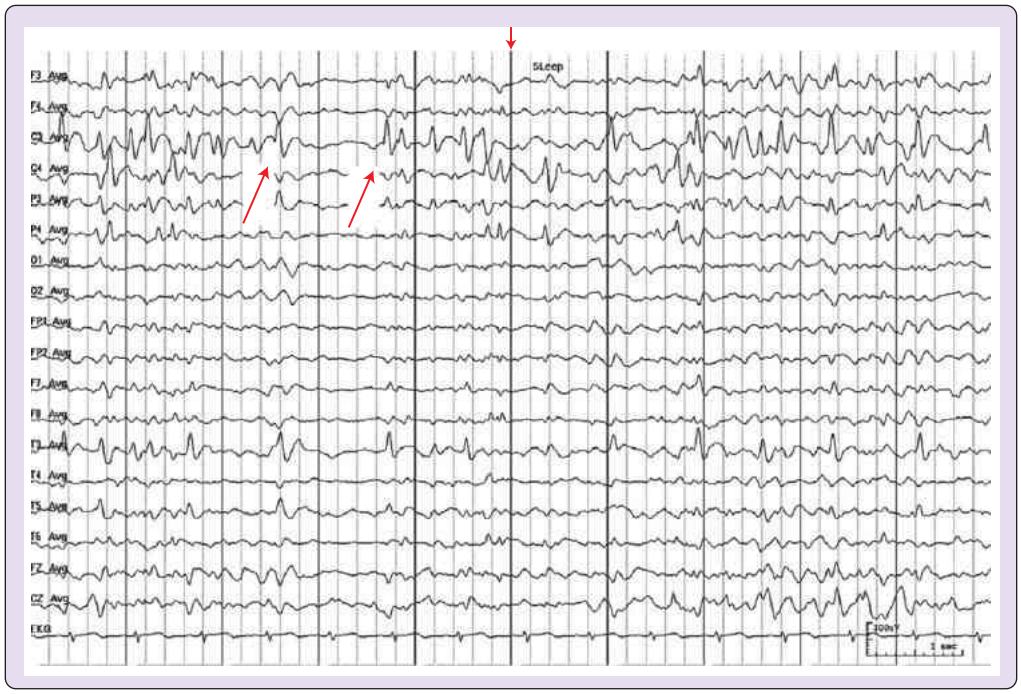

Figure 97-2 Spikes—abnormalities that are commonly seen on the electroencephalogram of patients with epilepsy. Multiple spikes (*arrows*) are seen in a patient with benign epilepsy with centrotemporal spikes. The spikes are maximal in the centrotemporal areas bilaterally, but they occur independently (channels C3-T3-C4-T4).

and sleep is not disrupted. The response to medications is excellent, and the prognosis is universally benign from an epilepsy perspective. However, these children often have deficits in visuospatial short-term memory, attention and cognitive flexibility, picture naming, visuoperceptual skills, and visuomotor coordination. These deficits may be related to nocturnal spiking. Reducing the nocturnal spike index has resulted in improved cognition, albeit at the cost of significant side effects.[4] These spikes are often seen incidentally in patients undergoing sleep studies to rule out obstructive sleep apnea (OSA) who have never had overt seizures.[5]

Benign Occipital Lobe Epilepsy

This infantile variant of benign epilepsy of childhood with occipital paroxysms (also known as Panayiotopoulos syndrome) is another benign epilepsy syndrome seen in children aged 2 to 6 years. It is characterized by prolonged periods of eye deviation and autonomic instability (temperature,

heart rate, respiration, blood pressure), hemiconvulsive and generalized tonic-clonic seizures in sleep, and vomiting on awakening. Interictal electroencephalograms show occipital spikes, whereas ictal electroencephalograms show electrographic seizures emanating from the occipital region during sleep.[6] Almost always, the epilepsy goes into remission within 2 years of onset.

Electrical Status Epilepticus in Slow Wave Sleep

Electrical status epilepticus in slow wave sleep (ESES) is characterized by spike wave complexes "continuously" during NREM sleep but not during wake or REM sleep.[7] The term continuous is applied only to EEG abnormalities with spikes occurring frequently (≥85% or epochs) during NREM sleep, persisting on three or more recordings during a period of 1 month.

Seizure onset typically occurs at 4 to 5 years of age. These seizures are partial or generalized and occur predominantly during sleep, with staring spells (atypical absence seizures) when awake, along with behavioral and language regression. Cognitive decline and mental retardation are noted in 50% of patients. Aggressive treatments to abolish paroxysmal EEG changes include corticosteroids, intravenous gamma globulins, and high-dose antiepileptic medications.

Landau-Kleffner Syndrome

Landau-Kleffner syndrome (LKS) is an acquired disorder with epileptic aphasia in which children, usually 3 to 8 years of age and who have developed age-appropriate speech, experience language regression with verbal auditory agnosia, epileptiform activity during sleep, behavioral disturbances, and sometimes overt seizures, more often in sleep.[7] Seizures arise out of sleep (focal clonic, atypical absences) and are less frequent and less severe than in ESES (absent in 20% to 30%). Behavioral problems are also less severe than in ESES.

There are several similarities between ESES and LKS. Both conditions demonstrate a normal EEG background during wakefulness, with rare focal or generalized spike wave discharges. In ESES, however, discharges during sleep are generalized, whereas in LKS, spike wave activity is mainly in the temporal channels. In ESES, epileptiform activity becomes virtually continuous during NREM sleep, such that it may be impossible to distinguish sleep stages.

Infantile Spasms

This is a catastrophic epilepsy syndrome characterized by a triad of epileptic flexor-extensor spasms of the body, variable intellectual disability, and chaotic (otherwise termed hypsarrhythmic) EEG pattern, with onset between the ages of 3 and 18 months. Interestingly, these spasms tend to cluster on awakening in the morning.[8]

Syndromes Predominantly in Adulthood

Acetylcholine Receptor Mutations

Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) is an adult epilepsy syndrome that is manifested with nocturnal seizures. Typical onset is in young adulthood (in the 20s), but it may also start in childhood and teenage years.[9] The clinical manifestations vary among individuals, although within the same individual, the seizures are stereotypic. These behaviors can include sudden awakenings with dystonic or dyskinetic movements (in 42% of patients from recent literature),[10] complex behaviors (13%), and sleep-related violent behavior (5%). The corresponding EEG findings include ictal epileptiform abnormalities predominantly over frontal areas in 31% of patients or rhythmic ictal slow wave activity over larger anterior cortical areas in another 47%. The disorder likely results from a mutation in the genes coding for the $alpha_4$ and $beta_2$ subunits of the nicotinic acetylcholine receptor (*CHRNA4* or *CHRNB2*). Currently, this is the only epilepsy syndrome in which the identified cause is an abnormal receptor that is also involved in the regulation of sleep. A third of patients also have associated NREM parasomnias.

Other Epilepsies with Relation to Sleep

Distinct, syndrome-specific patterns of seizures have been described with other syndromes as well. For example, as the name suggests, generalized tonic-clonic seizures on awakening include generalized seizures that occur in the morning. Juvenile myoclonic epilepsy is characterized by myoclonic, absence, and generalized tonic-clonic seizures, and the myoclonic seizures tend to occur in the morning. A common symptom is myoclonus (a jerk of an extremity) soon after awakening, often before breakfast. In addition to ADNFLE, frontal lobe seizures generally occur at night and during sleep, as described in further detail later.

PATTERNS OF SEIZURE FREQUENCY

The timing of seizures from any cause (e.g., mesial temporal sclerosis, tumor, vascular malformations) often follows a pattern. It depends on time of day and stage of sleep and varies by the epileptogenic onset zone (the part of the brain that leads to the individual seizure).

Effect of Sleep Stage on Seizures

Many studies have examined the frequency of seizures in specific sleep stages and in wakefulness. The most striking and consistent finding is that seizures are extremely rare in REM sleep. A review of 42 studies (scalp and intracranial EEG recordings) that included a total of 1458 patients reported that the lowest number of seizures are seen in REM sleep compared with all other states.[11] More specifically, compared with REM sleep, in wakefulness there are eight times more focal seizures. The highest proportion of seizures occurs in N1 and N2 stages of NREM sleep (respectively, 87 and 68 times more than in REM sleep), whereas in N3 sleep, seizures are slightly less frequent (51 times more than in REM sleep).

It is unclear what characteristics of REM sleep physiology are responsible for this unusual phenomenon. Some researchers hypothesize that the EEG desynchronization of REM sleep may reflect a unique pattern of neuronal connectivity that provides some protection against seizures.

Effect of Circadian Rhythms on Seizures

Even within the same state, the frequency of seizures varies with time of day, possibly because of the effects of endogenous circadian rhythms on brain activity. Several studies have described seizures captured in the hospital during continuous EEG monitoring. Early studies have reported a midafternoon peak in the frequency of temporal lobe seizures[12] with a similar cosinor distribution of seizures in adults with temporal lobe epilepsy, as also observed in an animal model.[13] Seizures originating from different brain locations

had different times of occurrence[13]; 50% of all temporal lobe seizures occurred between 15:00 and 19:00, whereas extratemporal seizures had a different distribution, suggesting that the peak time of seizure frequency varies by epileptogenic region. Further studies in adults using more precise localization techniques (performed with intracranial electrodes) confirmed consistent peaks in the timing of seizures by their location: occipital, between 16:00 and 19:00; parietal, between 4:00 and 7:00; frontal, between 4:00 and 7:00; and mesial temporal, between 16:00 and 19:00, with a smaller peak in the morning between 7:00 and 10:00.[14,15]

In children, the patterns are slightly different. Clonic, atonic, hypomotor, and myoclonic seizures are more common in the daytime, whereas nighttime predominance was noted for automotor and hypermotor seizures, especially during sleep.[16] Generalized and occipital seizures were more common during the day (6:00 to 18:00), whereas a nighttime pattern (18:00 to 6:00) was noted for temporal and frontal seizures, which tend to arise from wakefulness and sleep, respectfully.

All of these studies have significant limitations. All were performed within the hospital, where many activities occur at regular intervals (vital signs, scheduled examinations). Light levels are generally higher, and this may affect circadian rhythms by suppressing melatonin secretion or alter its pattern of secretion. In addition, weaning of antiepileptic medications (often done to facilitate recording of seizures) may also affect the timing of seizures. One study addressed this limitation by including patients with continuous home EEG recording and a diary of symptoms. It revealed a nocturnal pattern for frontal lobe seizures and an evening predominance for temporal lobe seizures.[17]

Dosing of Antiepileptic Medications to Reduce Nocturnal Seizures

The knowledge of this pattern of seizure frequency may be used to optimize therapy. A study[18] reported treatment of 17 children with nocturnal or early-morning seizures who were switched to a proportionally higher dose of antiepileptic medications in the evening and were retrospectively reviewed for seizure outcome and side effects. This differential dosing improved the patient's health, with seizure freedom in 65% of patients (11 of 17) and more than 50% reductions in seizures in 88% (15 of 17).

EFFECTS OF EPILEPSY ON SLEEP

Patients with epilepsy frequently have fragmented sleep as well as excessive daytime somnolence.[19-21] Causes include primary sleep disorders that disrupt sleep (e.g., sleep apnea, limb movements), nocturnal seizures that cause sleep fragmentation, and effects of medications. Insomnia is reported by 40% to 51% of epilepsy patients.[22,23] Furthermore, epilepsy patients with insomnia also have a higher frequency of depressive symptoms as well as poorer quality of life.[22]

Sleep fragmentation is a common complaint, and in many, the cause of sleep disruption may be nocturnal seizures. An early publication included a visual example of individual seizures causing awakenings during polysomnography of a patient with epilepsy who was not treated with antiepileptic medication.[24] After treatment, the patient's sleep became more continuous.

Sleep architecture may also be altered in patients with epilepsy. A decreased amount of REM sleep has been reported by several researchers.[25,26]

Primary sleep disorders are relatively common in patients with epilepsy. A report included the results from a cohort of 40 children with epilepsy[27] who underwent a sleep study because of various sleep complaints. Thirty-three patients (83%) exhibited snoring (42.5%), sleep disordered breathing (obstructive hypoventilation in 12.5%, OSA in 20%, and upper airway resistance syndrome in 7.5%), or periodic limb movements of sleep (10%). Children with poor seizure control had significantly lower sleep efficiency, a higher arousal index, and a higher percentage of REM sleep compared with children who were seizure free or exhibited good seizure control. Patients with epilepsy and OSA had significantly higher body mass index, longer sleep latency, higher arousal index, and lower apnea-hypopnea index but significantly more severe desaturation compared with patients with uncomplicated OSA. A significant proportion of children with epilepsy referred for polysomnography with diverse sleep problems manifested sleep disordered breathing, including OSA, and adults with epilepsy also have a higher prevalence of OSA.[28]

EFFECTS OF SLEEP ON EPILEPSY

Effects of Sleep Deprivation on Seizures

Epilepsy patients frequently identify sleep loss as a major factor that provokes seizures. In a recent study,[29] more than 97% of patients with epilepsy reported at least one factor that provokes seizures, and the top three are acute and probably also chronic sleep loss, fatigue, and stress.

Sleep deprivation is often used in epilepsy monitoring units to increase the frequency of seizures. In addition, interictal epileptiform discharges are also more apparent after sleep deprivation.[30]

Effects of Obstructive Sleep Apnea on Epilepsy

When polysomnography was performed on patients with medication-resistant epilepsy,[31] one third of the patients were found to have OSA (apnea-hypopnea index ≥ 5). Furthermore, older adults with poorly controlled seizures have more frequent OSA.[32] A pilot placebo-controlled trial of the effectiveness of continuous positive airway pressure (CPAP) to help seizure control revealed that among epilepsy patients with OSA, a 50% reduction in seizure frequency was seen more frequently among those who were treated with therapeutic CPAP (32%) than among those receiving sham CPAP (15%). Some patients in this study with large reductions in seizure frequency had only mild OSA.[33] Although this study was not powered to detect subtle differences or for stratification by apnea severity or patient characteristics, the study's overall findings support the notion that treatment of the sleep apnea leads to better seizure control.

In a study of CPAP compliance in adults with epilepsy and OSA, 28 patients were CPAP compliant and 13 were not CPAP compliant.[34] In the compliant group, CPAP use reduced seizure frequency from 1.8 per month to 1 per month ($P = .01$). In the noncompliant group, no significant difference in seizure frequency was noted between baseline (2.1 per month) and follow-up at 6 months (1.8 per month; $P = .36$). Sixteen of the 28 CPAP-compliant subjects became seizure

free, whereas only 3 of 13 non–CPAP-compliant subjects were seizure free (relative risk, 1.54; $P = .05$). Thus, good CPAP compliance in patients with epilepsy and OSA can reduce the frequency of seizures.

Similar findings have been seen in children. A study observed 27 children with epilepsy and OSA who were treated with adenotonsillectomy.[35] Three months after the surgery, 10 patients (37%) became seizure free, 3 (11%) had more than 50% seizure reduction, and 6 (22%) had smaller reductions in seizure frequency, whereas 2 (7%) demonstrated unchanged seizure frequency and 6 (22%) manifested a worsening of seizure frequency. The median seizure frequency per month was 8.5 (interquartile range, 2–90) before surgery and 3 (interquartile range, 0–75) after surgery, with a 53% median seizure reduction. Multivariate analysis demonstrated a trend toward seizure freedom with each percentile increase in body mass index and early age at surgery. Thus, adenotonsillectomy for OSA in children may decrease seizure frequency, especially in children with elevated body mass index scores and younger age at time of surgery.

EFFECT OF EPILEPSY TREATMENTS ON SLEEP

Antiepileptic treatment may affect sleep.[36-38] Effects vary by type of medication and comorbidities. In general, with improvement of seizure control, the regularity of the sleep cycle improves and sleep becomes more consolidated. However, some antiepileptic medications have been associated with insomnia, and others with excessive daytime sleepiness.[36]

Vagus nerve stimulation (VNS) is a nonpharmacologic therapy approved for use in patients with refractory epilepsy. An implanted device is programmed to stimulate the vagus nerve with electrical impulses and is typically used when pharmacologic therapy has been unsuccessful. VNS may also affect sleep, specifically sleep architecture and breathing. Some studies have found improvement of sleepiness and sleep architecture with VNS treatment.[39] However, VNS may also increase the incidence of sleep-related breathing disturbances, leading to OSA.[40] Therefore, evaluation and treatment of OSA, if it is present, may be warranted for patients undergoing VNS therapy.

DIFFERENTIAL DIAGNOSIS OF NOCTURNAL SEIZURES FROM OTHER EVENTS

Clinically, it can be a challenge to distinguish nocturnal epileptic seizures from movement disorders, psychogenic nonepileptic seizures, and parasomnias. Unlike in periodic limb movement disorder, the rhythmic movements seen during an epileptic convulsion are much faster in frequency and have a distinct beginning, evolution, and end. Psychogenic nonepileptic seizures rarely arise during sleep, although individual patients have been described.[41] Psychogenic events are usually longer, have a waxing-waning pattern, and usually occur when the event can be witnessed by others (Table 97-1).

Most critical is distinguishing nocturnal seizures from a NREM parasomnia. As the events occur at night, history is often sparse, and the immediately available test results can be difficult to interpret, which can lead to incorrect diagnosis. For example, several authors reported that more than half of the patients with ADNFLE have been incorrectly diagnosed with a parasomnia.[10,41] The distinction is difficult because both disorders occur at night, impair sleep, and can be worsened by stress or sleep fragmentation. In addition, both types of events can be associated with amnesia for the event, and the interictal epileptiform abnormalities, which are so helpful in the positive identification of epilepsy, are uncommon in patients with any form of frontal lobe epilepsy and thus may be absent on a routine 30-minute electroencephalogram or even overnight recording.

Helpful elements in the presenting history include age at onset, duration, occurrence of multiple events in the same

Table 97-1 Differential Diagnosis of Nocturnal Seizures Versus Parasomnia

Characteristic	Seizure	Parasomnia
Age at onset	Variable	Usually childhood onset
Course over time	Stable	Typically disappears in adulthood
Stage of sleep	NREM, more frequently N2	Slow wave sleep
Time of night	Any time, often first half	Typically first third of the night
Duration	~30 seconds to 2–3 minutes	Few minutes, may last as long as ~30 minutes
Course of the individual event	Beginning, evolution, and end	Can be waxing-waning
Type of behavior	Stereotypic, nonpurposeful versive movements and dystonic posture can be seen	Complex, variable from event to event; can appear purposeful
End of the event	Abrupt	Gradual emergence of consciousness
Number of events in the same night	Often multiple (>3)	1–2
Electroencephalography during the event	When visible, focal rhythmic activity with evolution in time and space and abrupt end can occur; muscle artifact may often obscure the recording	Normal; muscle artifact may often obscure the recording
Electroencephalography between events	Interictal discharges are highly specific; however, a normal recording does not rule out epilepsy	Normal

night, event frequency, and any description of the events. Derry et al[42] created a standardized instrument, the Frontal Lobe Epilepsy and Parasomnias scale, which systematizes the approach to history. Typically, characteristics that indicate a higher likelihood of nocturnal seizures include a relatively short duration (<2 minutes), stereotypic behaviors, clustering (multiple events in the same night), and prominent dystonic posturing or tonic limb extension. This scale has been successfully used in clinical practice.[43]

Capturing an event on a video or EEG recording is extremely helpful. However, the absence of typical EEG features does not completely rule out seizures. Muscle artifact from movement can obscure the EEG findings, and a focal seizure may simply not be visible with a standard polysomnogram montage.[44] Using an extended EEG montage better detects focal seizures as well as interictal discharges.[45]

Regarding analysis of the video recording, Derry et al[46] proposed a decision tree to distinguish seizures from NREM parasomnias, based on the following characteristics:

- Whether there is a clear arousal to full consciousness and how this occurs: if the patient does arouse, whether this occurs abruptly or gradually and whether the patient remains supine or prone or engages in more complex behaviors with sitting or getting up from bed after the event.
- Presence of any versive movements or dystonic posturing during the event. Versive movements or dystonic posture, or an abrupt ending with the patient remaining prone, would suggest a seizure. Complex behaviors and getting up from bed would point toward parasomnia.

Capturing the individual events on a single-night polysomnogram is difficult as these events are relatively rare, and they may not occur on the night of recording. Extending the length of the recording may be helpful in many clinical situations. The most reliable diagnosis is achieved by hospital admission with continuous video-EEG monitoring with the goal of capturing one or more events. This allows a long recording, which increases the likelihood of capturing interictal abnormalities; examination of the EEG recording for ictal abnormalities; and review of the video for any typical ictal phenomena or, if multiple events are captured, for stereotypy. In situations in which this is not economically or logistically feasible, an outpatient continuous EEG recording can be considered. The yield of outpatient testing is limited by lack of video as well as by the potential for loss of EEG signal from disconnected electrodes. The typical length of ambulatory EEG recordings is 48 to 72 hours. Longer recordings are technically possible, but with the multitude of activities and movements the patients engage in, the EEG signal progressively deteriorates and eventually becomes difficult to interpret.

CONSEQUENCES OF EPILEPSY

Cardiorespiratory Abnormalities During Seizures

Epilepsy is associated with increased morbidity and mortality. The most devastating consequence is sudden unexpected death in epilepsy patients, a leading cause of death in young and otherwise healthy patients with epilepsy. Sudden death is at least 20 times more common in epilepsy patients than in patients without epilepsy. A significant proportion of patients with epilepsy experience cardiac and respiratory complications during seizures that may contribute to sudden unexpected death.

Respiratory changes often occur with generalized as well as with focal seizures, especially those arising out of the mesial temporal structures. These include central and obstructive apneas; hypoventilation with hypercapnia and oxygen desaturation; and respiratory and metabolic acidosis, bradypnea, and tachypnea[47] (Figure 97-3). Cardiac abnormalities include tachycardia, bradycardia, hypotension, hypertension, tachyarrhythmias, bradyarrhythmias including asystole, and prolongation of the QTc interval.[48]

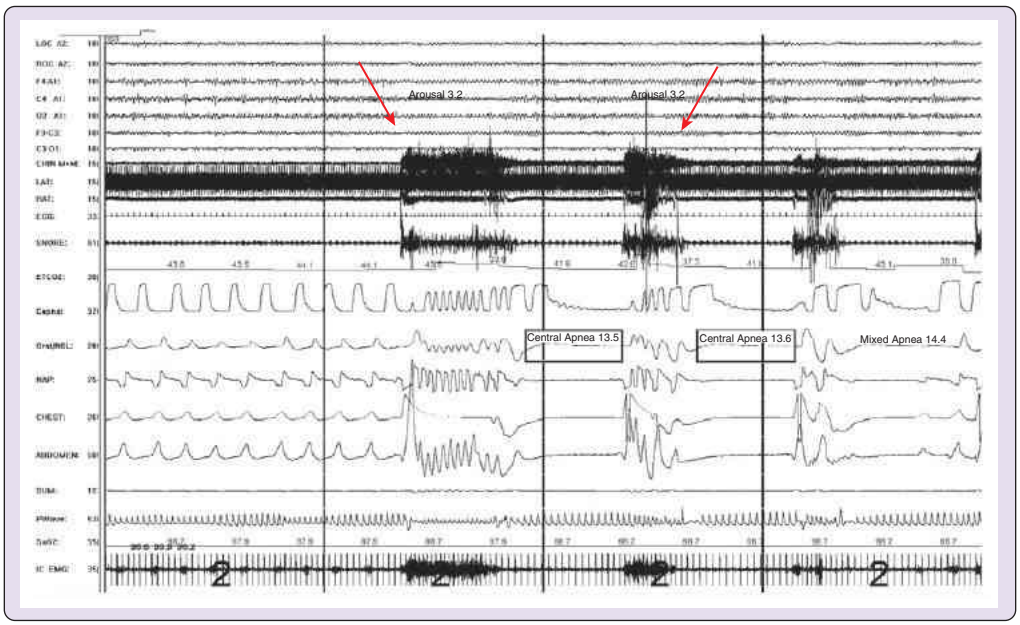

Figure 97-3 Tonic seizures (*arrows*) with tachypnea and tachycardia during the events followed by central apneas.

CLINICAL PEARLS

- Patients with epilepsy have frequent sleep complaints, and sleep disorders may worsen epilepsy.
- Treatment of sleep disorders may improve control of epilepsy.
- Seizures occur in patterns that depend on sleep stage and circadian factors. Integrating the treatment of seizures with knowledge of the chronobiologic pattern may improve treatment.
- Distinguishing seizures from NREM parasomnias is sometimes difficult. Clustering (multiple events in the same night), stereotypic behaviors, and dystonic posture or versive movements suggest seizures, whereas longer duration and complex behaviors are more common with parasomnias.

SUMMARY

Epilepsy is a chronic disease characterized by recurrent seizures. The frequency of seizures can be influenced by sleep stage and circadian rhythms, depending on the seizure focus. Several epilepsy syndromes are manifested with predominantly or exclusively nocturnal seizures. These include syndromes with benign prognosis in childhood, such as benign epilepsy with centrotemporal spikes and benign occipital epilepsy; some adult epilepsies, such as ADNFLE; and other syndromes with poorer prognosis, such as ESES. Other seizures, such as those from temporal lobe origin, tend to occur during wakefulness, most often in the mid to late afternoon.

Nocturnal seizures should be differentiated from movement disorders as well as from parasomnias. Behaviorally, seizures have stereotypic presentation, short duration (30 seconds to 2 minutes), and a tendency for clustering (multiple events in the same night), whereas parasomnias have a more fluctuating course during the night and may include complex, nonstereotypic behaviors. Adequate diagnosis is established by identifying typical EEG patterns (ictal or interictal) as well as by careful analysis of any events captured on video for stereotypic features.

Chapter 98

Other Neurologic Disorders

Antonio Culebras

Chapter Highlights

- Many neurologic conditions can cause sleep abnormalities, especially if they produce lesions in strategic locations such as the brainstem, diencephalon, or thalamus that extensively disturb brain function. Acute processes include stroke, head trauma, diffuse encephalopathies, and the encephalitides, and chronic diseases include multiple sclerosis and neurodegenerative disorders.
- Some chronic neurologic disorders not associated with structural brain alterations, such as headache syndromes, show a peculiar but well-established association with sleep anomalies. Stage-specific headaches include migraine, cluster headache, chronic paroxysmal hemicrania, and hypnic headache.
- The occurrence of stage-specific headaches and the linkage between rapid eye movement sleep and acute headache attacks point to the influence of circadian rhythms and sleep on headaches.
- Severe obstructive sleep apnea may be associated with a high burden of periventricular white matter disease and contribute to vascular cognitive impairment.
- Upper cervical cord lesions may be associated with hypoventilation and obstructive sleep apnea syndrome.
- Brain tumors may be associated with a variety of sleep disorders, depending on their location.

Sleep is a function of the brain. In consequence, sleep disorders can occur when the brain falters. Many structural brain lesions like stroke, multiple sclerosis, tumors, trauma, and the like, as well as dysfunctions without obvious structural alteration, like migraine and cluster headache, can cause sleep alterations that complicate or aggravate the clinical course. Thus it is important for the sleep specialist to be acquainted with neurologic conditions that can contribute to or be associated with sleep pathology.

SLEEP-RELATED HEADACHE

There is an intimate relationship between some headache syndromes and sleep.[1] Practitioners and patients have been aware of the peculiar effect of sleep on terminating attacks of headache,[2] and patients have many times complained of being awakened at night or of waking up in the morning with a headache. The discovery of stage-specific headaches and the intriguing linkage between rapid eye movement (REM) sleep and acute headache attacks[3] highlight the influence that circadian rhythms and sleep can have on the triggering of headaches. In addition, several well-defined sleep disorders are commonly associated with headaches. These include sleep apnea syndrome with headache on awakening, sleep stage–related headache, and parasomnias and headache.

Epidemiologic studies conducted in headache clinics have noted that 17% of the total headache group reports headaches at night or in the early morning before the final awakening period.[4] Up to 55% of patients in the sleep-related headache subgroup had a specific sleep disorder identified by polysomnographic monitoring in a sleep center.

The *International Classification of Sleep Disorders*, third edition,[5] recognizes the category of sleep-related headaches, classified under other sleep disorders. The common expression is the occurrence during sleep or immediately on awakening.

Stage-Specific Headaches

Migraine Headaches

Migraine headaches can occur at night during N3 or REM sleep. Sleep-related migraine attacks are characterized by unilateral throbbing head pain in association with nausea, vomiting, scotomas, visual field defects, photophobia, paresthesias, and even hemiparesis and aphasia. Not all symptoms may be present given the idiosyncratic nature of migraine headaches. Attacks can last for hours to several days. Migraine attacks in children younger than 8 years often resolve after an interval of sleep.[6] Children with migraine can have an increased incidence of disturbed sleep and parasomnias[7] such as somnambulism, night terrors, and enuresis.[8] Prolonged deep sleep is a risk factor for the provocation of sleep terrors and somnambulism as well as for triggering migraine attacks in susceptible patients at any age.[9] Fifty-four percent (64% women, 35% men) of patients with narcolepsy report migraine with the full complement of the International Headache Society criteria.[10]

Although migraine headaches may be provoked by sleep, the most common association is the onset of sleep following a migraine attack. The therapeutic effect of sleep[11] in some

attacks of migraine may be related to serotonin metabolism, but proof is lacking. The trigeminovascular system, which promotes vasodilation and release of calcitonin gene–related peptide and substance P,[12] has been implicated in the mechanism of migraines because calcitonin gene-related peptide is elevated in the jugular venous blood of migraineurs during the attack.[13]

Migraine attacks have been linked to the release of serotonin (5-HT). During migraine headaches, 5-HT is released from platelets and 5-hydroxyindoleacetic acid, the main metabolite of serotonin, is excreted in excess in the urine following the attack.[14] Sumatriptan (an agonist of the 5-HT_1 receptor found in cerebral arteries, where it has an inhibitory effect) aborts the migraine headache. Methysergide (an antagonist of the 5-HT_2 receptor found mainly in temporal arteries, where it has an excitatory effect) also terminates migraines.

Abnormal patterns of hypothalamic hormone secretion such as decreased nocturnal prolactin peak, increased cortisol concentrations, a delayed nocturnal melatonin peak, and lower melatonin concentrations have been reported in patients with chronic migraine.[15]

Proper sleep hygiene is paramount to help prevent sleep-related migraine headaches. Bruni and coworkers[16] evaluated the effect of improving sleep habits in 70 migraineurs with poor sleep hygiene. In their study, the mean duration and frequency of migraine attacks were significantly reduced when proper sleep hygiene was maintained.

Cluster Headaches

Cluster headaches occur in 0.4% of men and 0.8% of women.[17] They are characterized by severe unilateral, periorbital, malar, and temporal pain with lacrimation, rhinorrhea, nasal mucosa engorgement, forehead perspiration, and flushing of the malar area. Attacks are of abrupt onset and termination, often at the same time each day, generally last 2 hours or less, and can recur several times during a 24-hour period. Seventy-five percent of cluster headaches occur predominantly at night between 9 PM and 10 AM.[18] Cluster headaches have been linked with REM sleep and with sleeping late in the morning, a situation that promotes REM sleep, a possible triggering factor. Spontaneous remissions lasting several months are the norm.

Chronic Paroxysmal Hemicrania

Chronic paroxysmal hemicrania is characterized by attacks of severe pain also associated with conjunctival hyperemia, rhinorrhea, and, more rarely, Horner syndrome. Attacks may appear predominantly at night, usually waking the patient at the same hour, sometimes in close linkage with REM sleep, leading to the term *REM* sleep–locked headache. Chronic paroxysmal hemicrania is considered a variant of cluster headache that features several attacks per day of intense pain of 30 minutes' duration or less. The therapeutic response to the administration of indomethacin is quasi-specific and helps confirm the diagnosis of chronic paroxysmal hemicranias.

Hypnic Headache

Hypnic headache is an idiopathic headache disorder of rare occurrence, observed in older age groups. The mean age of onset is 63 years, with a range of 36 to 83 years.[19] The alternative names—clockwise headache and alarm headache—also attest to its regularity and exclusive occurrence at night. Unlike cluster headache and chronic paroxysmal hemicrania, hypnic headache occurs in a diffuse localization in two thirds of patients. Its intensity varies widely, and only one third of patients complain of severe pain. The pain usually lasts longer than 1 hour, and generally there is only one attack per night. Most patients experience the attack during the middle third of the night and report regularity in its occurrence. Less than 10% of patients have associated autonomic symptoms such as lacrimation, nasal congestion, or rhinorrhea, and these are usually mild when they occur.

Results of laboratory tests, including magnetic resonance imaging (MRI) of the head, electroencephalography, and Doppler ultrasound have been invariably normal. Polysomnography has shown occurrence of headache attacks during REM and non-REM sleep.[20] The appearance of hypnic headaches at the same time during the night has led others to suggest this is a chronobiologic disorder.

Hemicrania Horologica

Hemicrania horologica, or clocklike hemicrania,[21] is a very rare disorder, with headaches lasting 15 minutes. They occur with clocklike precision every 60 minutes, day and night. Hemicrania horologica differs from chronic paroxysmal hemicrania in the lack of autonomic signs, the clocklike regularity over 24 hours, and the response to nonsteroidal antiinflammatory drugs or indomethacin. Unlike hypnic headache, attacks also occur during the day.

Headache on Awakening

Headache on awakening occurs in half of patients with sleep apnea syndrome. In at least one study, the frequency of headaches was unrelated to the severity of the sleep apnea.[22] The headache is generally diffuse and of mild to moderate intensity, with a tendency to disappear as the patient becomes active. Successful treatment of sleep apnea syndrome is associated with significant improvement of the headache in 30% of patients.[23] Prolonged afternoon naps may also be followed by headache.

Headaches on awakening in patients with sleep apnea syndrome have been associated with a variety of mechanisms, including hypoxemia, hypercapnia, altered cerebral blood flow, and depression. Headaches on awakening may occur with other disorders. These are common in children with brain tumors, but they appear in only 5% of adults with brain tumors. They may also appear in relation to bruxism, systemic hypertension, depression, muscle tension, alcohol intoxication, and sinus inflammation.

Bruxism, or clenching and grinding of teeth, is a parasomnia that occurs predominantly in stages 1 and 2 non–rapid eye movement (NREM) sleep and sometimes in REM sleep, occasionally leading to headache on awakening (see Chapter 144).

Insomnia and Headache

Insomnia and headache often occur together. In the postconcussion syndrome, insomnia and headache are prominent symptoms. On the other hand, insomnia and daytime fatigue are commonly reported by patients with chronic headache. Chronic headache sufferers feel more tired (especially women) and do not sleep as well at night (especially men).[24] Fibromyalgia occurs in 35.6% of patients with chronic migraine, also known as transformed migraine; this group of patients has a higher incidence of insomnia.[25]

Headaches in Children

Chronic headaches in children are often associated with sleep alterations. Common sleep disorders are decreased duration of sleep at night, poor sleep hygiene, increased number of nocturnal awakenings, somnambulism, somniloquy, enuresis, and snoring.[26] One study found that children with headaches have a significantly higher prevalence of excessive daytime sleepiness, narcolepsy, and insomnia compared with children without headaches.[27] This contradicts previous work stating that children with headaches have a higher prevalence of sleep apnea, restlessness, and parasomnias, an association that may be more specific for genuine migraines and not for headaches in general. The authors conclude that pediatricians should inquire about daytime sleepiness, narcolepsy, and insomnia in children with headaches.

Drugs and Headache

A variety of drugs used for the treatment of sleep disorders can cause headache as a prominent adverse event. In an analysis of several placebo-controlled studies, modafinil was associated with headache in 34% of subjects compared with 23% of those taking placebo.[28] Headache has also been cited as a common adverse effect of both melatonin and ramelteon for treatment of insomnia.[29,30] Common side effects of amphetamines during long-term treatment in patients with narcolepsy include headache along with irritability, bad temper, and profuse sweating.[31]

Exploding Head Syndrome

Exploding head syndrome is typically considered in the differential diagnosis of sleep-related headaches because although it does not cause head pain, it occurs during sleep and patients localize symptoms in the head. This syndrome is characterized by abrupt flashing lights and noises perceived inside the head during the night.[32,33] The attacks last only seconds and terrify patients despite the absence of pain. The episodes have been shown by polysomnography to appear during any stage of sleep.[34] Generally the exploding head syndrome occurs in persons older than 50 years and has a benign prognosis.[35] Reassurance and administration of clomipramine are curative in most instances of exploding head syndrome.

Differential Diagnosis and Diagnostic Workup

Nocturnal migraine, cluster headache, nocturnal paroxysmal hemicrania, and hypnic headache need to be differentiated from other acute severe headaches, such as those associated with intracranial brain tumors, ruptured aneurysm, and meningitis. Patients with intracranial tumors who are awakened at night by headache report improvement on getting out of bed. Headaches on awakening, as observed in sleep apnea patients, are also seen in patients with severe hypertension, depression, intracranial tumor, muscle-contraction headache, alcohol intoxication, and craniofacial sinus disease. Hypnic headache differs from migraine headache, cluster headache, and chronic paroxysmal hemicrania because the pain is commonly diffuse or bilateral and patients are older. Autonomic symptoms are more prominent in cluster headache and chronic paroxysmal hemicrania. The following characteristics should help make a diagnosis of hypnic headache: older age group, punctuality of attack occurrence, mild or no autonomic symptoms, diffuse location, duration of 1 hour to a maximum of 2 hours, tendency to appear in relation to dreams, and no symptoms characteristic of migraine such as photophobia, phonophobia, or nausea.

Causes for concern are first or worst-ever headache, associated neurologic symptoms or signs, progressive worsening of headache over days or weeks, intractable nausea or vomiting, fever, lethargy, confusion, and stiff neck. Patients who exhibit causes for concern should have a neurology consultation, neuroimaging studies, or lumbar puncture. Nocturnal polysomnography is indicated for the study of patients suspected of having sleep apnea syndrome or recurrent parasomnias. Videotaping should always be included in the polysomnographic study of parasomnias.

Patients with migraine, cluster headache, and hypnic headache can wake up with an acute attack more often during REM sleep than during other stages of sleep, and those with cluster headache and chronic paroxysmal hemicrania can suffer the attack at the same time of the night every night. Attacks of chronic paroxysmal hemicrania may be so closely linked to REM sleep that they have been termed REM sleep locked. Polysomnography has been recommended in patients complaining of early morning and nocturnal headaches.[36] In a study of 25 patients with headache, Paiva and coworkers found 21 patients with disturbed sleep, and in 13 of these, the clinical diagnosis had to be reassessed after polysomnography owing to the finding of obstructive sleep apnea (OSA), periodic limb movements in sleep (PLMS), alpha-delta sleep, and insomnia.

MANAGEMENT

Preventive treatment of migraine, cluster headaches, and chronic paroxysmal hemicrania includes good sleep hygiene, with avoidance of precipitating factors such as sleep deprivation, excessive sleep, stress, trauma, and ingestion of certain idiosyncratic foods, including alcohol. Pharmacologic prevention of migraine includes administration of beta blockers, flunarizine, valproic acid, topiramate, calcium channel blockers, serotonin receptor antagonists (methysergide, only for use in periods not to exceed 4 weeks), and 5-HT_2 antagonists (cyproheptadine and methylergonovine). Prevention may also be achieved with antidepressants that interact with serotoninergic receptors such as tricyclic antidepressants, monoamine oxidase inhibitors, and selective serotonin reuptake inhibitors (fluoxetine and sertraline); anticonvulsants, particularly in children with abnormal electroencephalography; and nonsteroidal antiinflammatory agents.[37] Migraine attacks may be aborted with administration of sumatriptan, a serotonin 5-$HT_{1B/1D}$ receptor agonist, given by subcutaneous injection (6 mg, may repeat after 1 hour; limit is two injections in 24 hours). Other abortive medications include ergotamine tartrate, dihydroergotamine, naratriptan, rizatriptan, zolmitriptan, electriptan, frovatriptan, and isometheptene mucate. Rizatriptan and zolmitriptan come in a melting tablet version that can be taken without water. Nonvasoconstrictive abortive agents are butorphanol tartrate for subcutaneous injection and nasal spray. Emergency department management may include narcotic injections with promethazine or hydroxyzine for nausea. Acetaminophen, corticosteroids, and nonsteroidal antiinflammatory derivatives complete the list of medications used to abort attacks of migraine. Symptomatic treatment for migraine attacks includes nonsteroidal antiinflammatory

derivatives, mixed barbiturate and analgesics, antiemetics (promethazine, 50 mg), and, if pain is severe, meperidine (50 mg) or codeine sulfate (30 mg).

Cluster headaches may be prevented with ergotamine derivatives at bedtime (1 to 3 mg sublingual), amitriptyline (150 mg daily), methysergide (6 to 8 mg daily), prednisone (40 mg daily), and lithium carbonate (initial dose 250 mg). For long-term prophylaxis other medications in isolation or in combination may be used; these include verapamil, topiramate, and divalproex. Acute attacks are terminated with inhalation of oxygen; parenteral triptans and dihydroergotamine by mouth may be effective too. Chronic paroxysmal hemicrania responds specifically to indomethacin (50 mg at bedtime or 25 mg three times a day). Morning headaches related to sleep apnea syndrome generally disappear with successful management of the sleep apnea condition. Hypnic headaches have responded to any of the following regimens at bedtime: coffee; ergotamine tartrate, 0.6 mg; phenobarbital, 40 mg, with belladonna, 0.2 mg; atenolol, 25 mg; aspirin, 325 mg, with caffeine, 40 mg; indomethacin, 25 mg; and flunarizine, 5 mg. Successful prophylaxis with lithium carbonate has also been reported. Postconcussion headaches sometimes respond to tricyclic antidepressants. Drug-related headaches tend to respond to conventional analgesics, gradually improve with continued use of the drug, and disappear with discontinuation of the drug.

MULTIPLE SCLEROSIS

Epidemiology

Sleep disorders are more common in multiple sclerosis (MS) than expected by chance. Reports published in the first half of the twentieth century cite cases of MS associated with sleep attacks.[38-40] Subsequently, cases of narcolepsy with cataplexy in MS, familial or not, were reported.[41,42] Some patients with hypersomnia have lesions on MRI that suggest plaques in the hypothalamus as well as undetectable levels of hypocretin in spinal fluid.[43] In general, sleep disturbance is common in MS and can be caused by multiple factors ranging from depression to specific lesions.[44]

There is coincidence of genetic susceptibility between MS and narcolepsy. The susceptibility to MS is coded by genes within or close to the human leukocyte antigen (HLA) DR-DQ subregion.[45] On the other hand, patients with narcolepsy exhibit the highest known association between the HLA-DR2 and -DQw1 antigens and a disease entity. This has led some authors to postulate a common immunogenetic etiology.[46] Others have postulated that the HLA-Dw2 haplotype in patients with MS and narcolepsy extends to the DRB5 locus 76. An overwhelming portion of genetic risk for narcolepsy with cataplexy may be found at the DQB1 locus.[47,48] Formally, however, narcolepsy does not yet qualify as an autoimmune disease in that pathogenic autoantibodies or T cells have not been found to date.

Restless legs syndrome (RLS) is significantly associated with MS, especially in patients with severe pyramidal and sensory disability. The results of a multicenter study involving 861 patients with MS[49] strengthen the idea that the inflammatory damage correlated with MS can induce a secondary form of RLS. In this study, the prevalence of RLS was 19% in MS compared with 4.2% in control subjects. RLS in patients with MS has a significant impact on sleep quality; therefore it should be searched for, particularly in the presence of insomnia unresponsive to treatment with common hypnotic drugs.

Clinical Manifestations

Chronic fatigue is common in MS and can confound the interpretation of sleep disturbances. Patients report difficulty falling asleep, restless sleep, nonrestorative sleep, and early morning awakenings more often than control subjects.[50] A variety of underlying physical and emotional factors (bladder problems, spasticity, muscle spasms, periodic leg movements, depression, and anxiety) that converge to disturb nocturnal sleep should be considered. Excessive daytime somnolence may be secondary to sleep disruption, which is likely amenable to proper management.

In a study of 28 consecutive patients with MS, 54% reported sleep-related problems,[51] including difficulty initiating or maintaining sleep, frequent awakenings because of leg spasms, habitual snoring, and nocturia. Sleep apnea syndrome occurred in two patients, and three showed episodes of nocturnal desaturation. MRI of the brain was abnormal in 20 of 22 cases studied. OSA, in particular, may be highly prevalent and an underrecognized contributor to fatigue in patients with MS.[52]

A polysomnographic study of 25 patients with definite MS showed significantly reduced sleep efficiency and more awakenings during sleep, suggesting a multifactorial etiology of the sleep disorder.[53] Periodic leg movements were found in 36% of patients compared with 8% of controls. Central sleep apneas were found in two patients. MRI of the brain showed more lesions in the cerebellum and brainstem of MS patients with periodic leg movements.

Management

Fatigue is the most pervasive symptom in MS. Amantadine and modafinil have been suggested to improve chronic fatigue in these patients.[54,55] In a single-blind study involving 72 patients with MS, modafinil (200 mg/day) significantly improved fatigue and was well tolerated.[56] Some authors have reported a regression of symptoms of sleep disturbance with dexamethasone[57] or prednisolone therapy.[58] Dopaminergic agonists may be useful for control of RLS and PLMS.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis is an acute inflammatory demyelinating disease of the central nervous system (CNS) following viral illness or vaccination. The disorder is probably mediated by immunologic mechanisms.

There is a report of hypersomnia in a 5-year-old girl who presented with hypersomnia due to acute disseminated encephalomyelitis affecting the posterior hypothalamus, brainstem, and basal ganglia.[59] Her total sleep time and slow-wave sleep were increased, but REM sleep was within the normal range. Hypocretin levels in cerebrospinal fluid (CSF) were not assayed. After treatment with intravenous dexamethasone, her hypersomnia improved and the lesions disappeared.

HEREDITARY NEURODEGENERATIVE AND METABOLIC DISORDERS

The occurrence of sleep disorders in this large group of neurologic conditions is limited to case reports and small series

of patients. The list continues to expand with the addition of new reports from the literature.

Clinical Manifestations

Neurodegenerative disorders may have predominantly cerebellar dysfunction as in some forms of multiple system atrophy, extrapyramidal manifestations as in the synucleinopathies, or a combination of cerebellar and sensorimotor signs as in the spinocerebellar atrophies. Patients with neurodegenerative disorders have many sleep-related complaints, including insomnia, hypersomnia, circadian dysrhythmia, abnormal movements, and abnormal behavior during sleep. They are also at risk for the development of sleep apnea syndrome and PLMS. Excessive daytime somnolence secondary to fragmentation of nocturnal sleep caused by sleep apnea, PLMS, or other factors is a common complaint.

Diagnosis

The sleep evaluation of patients with a neurodegenerative disorder should include overnight polysomnography with video monitoring followed by a Multiple Sleep Latency Test (MSLT) in specific cases of associated hypersomnia. The objectives are to assess the presence of sleep apnea syndrome, PLMS, and REM sleep without atonia and to measure excessive daytime somnolence. In some cases, the MSLT shows REM sleep in daytime naps with short-onset REM sleep latencies suggestive of narcolepsy. Actigraphy has been used in some laboratories to document motor activity during sleep and waking that may unveil a circadian dysrhythmia.

Treatment

Management of sleep disorders in patients with neurodegenerative disorders follows the general guidelines. Sedatives and hypnotics should be administered with caution to this group of patients to avoid aggravation of muscle weakness or gait ataxia, not only during daytime hours but also during nocturnal awakenings with ambulation in the dark.

Illustrative Neurodegenerative Disorders

Machado-Joseph Disease

Machado-Joseph disease[60] is also known as type 3 spinocerebellar ataxia. Increased prevalence of RLS and PLMS has been reported in this condition. The clinical evaluation of patients with spinocerebellar ataxia type 3 should pursue possible presence of sleep apnea syndrome and PLMS. REM sleep behavior disorder, a condition also prevalent in the synucleinopathies, has been reported in association with Machado-Joseph disease and may be related to striatal monoaminergic deficit.[61,62] Vocal cord abductor paralysis and stridor have been described in Machado-Joseph disease.[63]

Charcot-Marie-Tooth Disease

Charcot-Marie-Tooth (CMT) disease is a hereditary motor and sensory polyneuropathy characterized by degeneration of peripheral nerves and roots. Patients exhibit distal muscle weakness, atrophy, and sensory impairment. Phrenic neuropathy can cause dysfunction of the diaphragm, leading to chronic hypoventilation, particularly in REM sleep.[64] Vocal cord dysfunction, possibly owing to laryngeal nerve involvement, is found in association with several CMT types and can often mimic asthma.

Patients with CMT disease have a high incidence of significant sleep apnea events whose severity is highly correlated with the severity of their peripheral neuropathy. In one study of 14 patients with CMT type 1, the apnea-hypopnea index (AHI) correlated with neurologic disability but not with body mass index and age. Researchers have hypothesized that sleep apnea in CMT disease can be caused by pharyngeal neuropathy affecting the function of pharyngeal dilator muscles, a phenomenon that increases the collapsibility of the upper airway, leading to recurring obstructive respiratory events.[65,66] Bilevel positive airway pressure may be more appropriate than continuous positive airway pressure (CPAP) for treating sleep apnea in patients with airway weakness, especially those with concomitant restrictive pulmonary impairment.[67]

Niemann-Pick Disease

Niemann-Pick disease type C is a rare autosomal recessive condition characterized by the accumulation of unesterified cholesterol in many tissues and storage of sphingolipids in liver and brain. Adult patients exhibit ataxia, dystonia, dementia, and vertical supranuclear palsy along with hepatosplenomegaly. Some patients report hypersomnia and cataplexy. Recent investigations have shown reduced CSF levels of hypocretin in this condition, which are likely responsible for sleep abnormalities and cataplexy.[68]

ACUTE ENCEPHALITIDES

Sleeping Sickness

Sleeping sickness is a meningoencephalitis caused by the protozoan *Trypanosoma brucei*. The parasite is transmitted to humans by the sting of the tsetse fly in Africa, where 20,000 new cases are reported each year. Sleeping sickness begins with a phase of systemic disease, after which the parasite invades the CNS with manifestations of insomnia and daytime hypersomnia, followed by psychomotor retardation. The disease can progress to extrapyramidal manifestations, ataxia, gait disorder, seizures, coma, and death. Polysomnography reveals sleep-onset REM sleep periods shortly after CNS invasion by trypanosomes, then high-amplitude slow waves, suggesting a diffuse encephalopathy, with preservation of REM sleep parameters until the final phases of the disease.[69,70] CSF analysis has shown increases in cell count, high protein content, and increased immunoglobulin M levels.[71] Neuropathologic studies have shown demyelinating lesions in cerebral hemispheres and brainstem.[72]

Limbic Encephalitis

There are published case reports of severe sleep alterations, including REM sleep behavior disorder, hypersomnia, and insomnia associated with limbic encephalitis that were in some instances reversed with immunotherapy and steroid administration.[73,74]

Nonspecific Viral Encephalopathies

Transient OSA has been described in association with a case of presumed viral encephalopathy.[75] Paradoxical respiratory efforts during sleep, along with frequent episodes of tachycardia, bradycardia, and asystole, led to suspicion of OSA syndrome, which was documented with portable polysomnography. All apnea events and cardiovascular concomitants resolved with CPAP. This case illustrates the occurrence of

sleep-related transient respiratory obstructions in diffuse acute encephalopathy that, if undetected, can lead to serious cardiovascular consequences.

Encephalitis Lethargica

Encephalitis lethargica was described by von Economo and others in the early part of the twentieth century but has now virtually disappeared.[76] The clinical and neuropathologic study of this form of encephalitis brought to light the correlation between hypothalamic lesions and sleep disorders and contributed to understanding the links between basal ganglia lesions and extrapyramidal movement disorders.[77] The most common presentation was acute fever, severe lethargy, and ophthalmoplegia followed by hyperkinesia.[78] In the subsequent months to years, many of these patients developed a postencephalitic syndrome with prominent parkinsonian features.[76]

BRAIN TUMORS

Brain tumors can disrupt sleep-wake cycles by virtue of their location or indirectly by causing intracranial hypertension or hydrocephalus, or both. For example, symptomatic narcolepsy can occur with craniopharyngiomas compressing the floor of the third ventricle that presumably injure the orexin/hypocretin-producing neurons (Figure 98-1).[79] Symptomatic narcolepsy has also been reported with gliomas and colloid cysts of the third ventricle as well as with pituitary adenomas and midbrain gliomas.[80] Sleepiness following hypothalamic injury in the course of resection of an astrocytoma has been reported in association with a low concentration of hypocretin in CSF.[81] Lower brainstem tumors have been associated with severe hypoventilation and respiratory failure during sleep (Ondine's curse) requiring tracheotomy and assisted ventilation. Increased intracranial hypertension and obstructive hydrocephalus have been associated with subalertness and lethargy. Fatigue and drowsiness are prominent symptoms in patients with systemic cancer and brain metastases.[82]

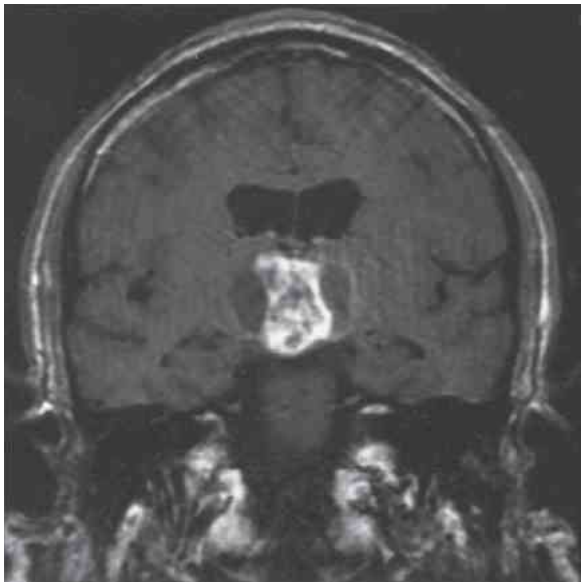

Figure 98-1 Brain magnetic resonance imaging of a 55-year-old man complaining of headaches and excessive daytime somnolence that was initially diagnosed as sleep apnea syndrome. The large cystic mass compressing the diencephalon and floor of the third ventricle was found at operation to be a craniopharyngioma. (From Culebras A. *Clinical handbook of sleep disorders.* Boston: Butterworth-Heinemann; 1996, with permission.)

COGNITIVE IMPAIRMENT AND OBSTRUCTIVE SLEEP APNEA

Clinical evidence suggests that moderate to severe OSA is a risk factor for development of cognitive impairment.

In a prospective study of sleep and cognition in 298 women without dementia, Yaffe and colleagues showed that older women (mean age, 82.3 years) with OSA (defined as an AHI >15 events per hour of sleep) were more likely to develop cognitive impairment.[83] Results were adjusted for age, race, body mass index, education level, smoking status, presence of diabetes, presence of hypertension, medication use, and baseline cognitive scores. The authors found that compared with the 193 women without sleep-disordered breathing, the 105 women with sleep-disordered breathing were more likely to develop mild cognitive impairment or dementia (31% vs. 45%); intermittent hypoxia in apnea or hypopnea also was predictive of mild cognitive impairment or dementia.

Cognitive impairment may be the result of small silent infarctions or subcortical small vessel disease,[84,85] also known as leukoaraiosis. Kim and associates performed polysomnograms in 503 individuals (mean age, 60 years) who were free of previously diagnosed cardiovascular and neurologic diseases.[85] Using MRI, they identified white matter disease in 40%, and regression analysis revealed an association with moderate to severe OSA (AHI >15). The authors concluded that moderate to severe OSA is an independent risk factor for white matter changes in middle-aged and older individuals. Another study showed an association between poor sleep quality and white matter hyperintensity severity as shown by MRI of brain.[85a]

The presence of silent cerebral infarctions in individuals with OSA was investigated in another study.[86] The authors did polysomnograms and brain MRI on 746 participants aged 50 to 79 years and found that 12% of subjects had moderate to severe OSA (AHI ≥15). Subjects with OSA older than 65 years were 2.4-fold more likely to have silent cerebral infarctions and 3.5-fold more likely to have lacunar infarction.

The cause of these vascular lesions is not entirely clear, but intermittent nocturnal hypoxia may contribute to ischemic damage in the cerebral periventricular territory of long penetrating terminal arteries.[87] Intermittent hypoxia adds ischemic burden to this vascular border zone territory with blood flow that may be already precarious as a result of diabetes with vascular autonomic dysregulation and poorly controlled hypertension. Ischemic damage to the cerebral periventricular white matter may disturb the connections of the cortex with the thalamus, leading to a form of subcortical dementia characterized by apathy, decreased executive functions, poor memory, and in advanced cases difficulty walking and urinary incontinence (Binswanger disease).

Treatment of OSA with CPAP may lower cerebrovascular risk by decreasing 24-hour urinary catecholamine excretion, improving arterial stiffness and baroreflex sensitivity, and reducing mean 24-hour ambulatory blood pressure.[88,89] However, CPAP applications will not modify structural

lesions of the brain, and therefore early diagnosis and treatment of sleep apnea before structural brain damage ensues is strongly recommended, particularly in patients with several risk factors for stroke.

SPINAL CORD DISEASE

Pathophysiology

Ventilation depends on the integrity of the spinal cord, and in patients with spinal cord lesions, respiratory dysfunction and consequent sleep disturbances are common. The diaphragm is controlled by the phrenic nerves, which originate in the ventral horn, extending from C3 to the caudal part of C5.

The descending respiratory pathway is formed by crossed fibers situated deep in the anterior white column in the vicinity of the anterior horn projecting mainly from the ventral respiratory group in the medulla. High cervical lesions and phrenic nerve damage can cause unilateral or bilateral paralysis of the diaphragm, depending on the extent of the lesion.

The intercostal muscles receive their innervation through descending pathways located dorsal to diaphragmatic pathways in the vicinity of the lateral spinothalamic tract. Voluntary respiration is mediated by fibers in the lateral pyramidal tract, whereas involuntary automatic respiration is mediated by reticulospinal fibers emerging from the brainstem respiratory centers. Spinal motor nuclei situated in segments T1 to T11 give rise to intercostal nerves that innervate intercostal muscles.

Accessory respiratory muscles receive innervation from cranial nerves XI and nerves C1 to C8. Upper airway muscles involved in nasal, pharyngeal, and laryngeal dilation are innervated by cranial nerves V (tensor veli palatini muscles), VII (levator alae nasi muscles), X (cricothyroid and thyroarytenoid muscles), XII (genioglossus, geniohyoid, sternohyoid, and sternothyroid muscles), and C1 to C4 (geniohyoid, sternothyroid, and sternohyoid muscles). These muscles are unaffected by spinal cord lesions below C5, a lesion compatible with a respirator-free life.

Lesions of the phrenic and intercostal motor neurons in the spinal cord can occur with spinal cord tumors, spinal trauma, spinal surgery (e.g., cervical cordotomy or anterior spinal surgery), and myelitis. Patients with syringomyelia and syringobulbia (fluid-filled cavities in the spinal cord or brainstem, respectively) with dysphonia and dysphagia are particularly prone to severe respiratory disturbances during sleep.[90] In one study of 22 patients with stable spinal cord lesions above T10,[91] 45% had some evidence of OSA syndrome. Cognitive changes in patients with tetraplegia may be related to sleep apnea syndrome.[92] Although excessive daytime somnolence secondary to sleep-related respiratory dysfunction is the most common symptom, patients with spinal cord diseases can complain of insomnia as a result of immobility, neck pain, and central pain syndrome.

Phrenic nerve damage leads to diaphragmatic paralysis. Unilateral paralysis is asymptomatic, but bilateral paralysis is invariably symptomatic and may be life-threatening. Paresis or weakness with partial diaphragmatic dysfunction can cause sleep-related ventilatory insufficiency. In the supine position, patients complain of profound difficulty breathing because of decreased lung volume and increased respiratory effort as the abdominal contents press into the thorax. With bilateral severe or acute phrenic nerve injury, patients present with nocturnal orthopnea, cyanosis, and fragmented sleep followed by morning headaches, vomiting, and daytime lethargy. Phrenic nerve weakness or paralysis is most prominent during REM sleep when the diaphragm is the only functional respiratory muscle. Upper airway resistance is also higher in REM sleep, contributing to decreased ventilatory efficiency. Patients with weak pharyngeal dilator muscles and a weak diaphragm as a result of a diffuse neuromuscular disorder or bilateral phrenic nerve paralysis exhibit the most serious respiratory compromise in REM sleep[93] (see Chapter 96).

Craniovertebral junction malformations or Chiari malformations, with or without syringomyelia and basilar invagination, can produce dysfunction of neurons in the brainstem, cerebellum, cranial nerves, and upper spinal cord. The incidence of OSA is significantly higher in patients with craniovertebral junction malformations, especially if basilar invagination is present.[94] OSA can appear after anterior cervical spine fusion. Guilleminault and coworkers[95] found that placement of anterior cervical plates at the C2 to C4 level reduced the size of the upper airway, causing OSA syndrome. The condition was controlled with positive airway pressure applications.

RLS and PLMS can appear in patients with acute transverse myelitis.[96] PLMS has been reported in patients with syringomyelia.[97]

Treatment

Treatment of sleep-disordered breathing in spinal cord diseases should follow the same general principles as those suggested for neuromuscular disorders. Noninvasive nocturnal ventilation has improved the quality of life and increased survival in many neuromuscular disorders. Patients with significant neuromuscular disorders or high spinal cord disease should be considered candidates for evaluation with polysomnography. In most patients with neuromuscular conditions, the most effective time to introduce noninvasive ventilation is when symptomatic sleep-disordered breathing develops.[98]

A word of caution comes from a study[99] showing that obese patients who have spinal cord injury and are taking antispasticity medications might have a higher risk for developing snoring and OSA. The greatest risk appeared in patients taking diazepam or diazepam and baclofen in combination.

CLINICAL PEARLS

- Headaches on awakening, as observed in sleep apnea patients, are also seen in patients with severe hypertension, depression, intracranial tumors, muscle-tension headache, alcohol intoxication, and craniofacial sinus disease.
- In headache patients, causes for concern are first or worst-ever headache, associated neurologic symptoms or signs, progressive worsening of headache over days or weeks, intractable nausea or vomiting, fever, lethargy, confusion, and stiff neck.
- The association between MS and sleep disorders is more common than expected by chance.
- Sleep apnea in patients with Charcot-Marie-Tooth disease may be a consequence of pharyngeal neuropathy affecting the function of pharyngeal dilator muscles.
- Severe sleep apnea may contribute to vascular cognitive impairment.

SUMMARY

As a function of the brain, sleep is disrupted by neurologic conditions that affect brain mechanisms. Some alterations may be structural, like brain tumors, stroke, and MS, but others are nonstructural like migraine and cluster headaches. Lesions that affect the brainstem, hypothalamus, and thalamus tend to be more disruptive of sleep. There is an intimate relationship between some headache syndromes and sleep. Clinicians have been aware of the peculiar effect of sleep on terminating attacks of headache, and patients often report being awakened at night or of waking up in the morning with a headache. Sleep stage–specific headaches are well known and confirm the intimate relationship between headaches and sleep. The management of sleep-related headaches includes prominently the regularization of sleep patterns and sleep duration. Patients with MS complain prominently of fatigue that may be the consequence of multifactorial sleep alterations. Some sleep disturbances associated with MS like sleep apnea are treatable and should be considered in the overall management of MS. Brainstem disorders of any origin, whether chronic neurodegenerative, acute, or tumoral, can disrupt sleep and wakefulness. There is growing evidence supporting the role of sleep apnea in adding burden to subcortical small vessel disease, a very common condition in old age and a contributor to cognitive decline. In summary, sleep disturbances complicate the course of many neurologic conditions, and their proper management should help alleviate the manifestations of neurologic disease.

Sleep Disorders After Traumatic Brain Injury

Chapter 99

Philipp O. Valko; Christian R. Baumann

Chapter Highlights

- Traumatic brain injury (TBI) is among the most frequent causes of chronic disability, especially in younger adults, but the high prevalence and burden of sleep-wake disorders after TBI have only recently been recognized.
- The most frequent sleep-wake disturbances after TBI are conditions with impaired arousal, including excessive daytime sleepiness, hypersomnia (increased sleep need per 24 hours, more than 2 hours/day compared with before TBI), and fatigue. Insomnia is also frequent but probably overdiagnosed because disturbed nighttime sleep due to posttraumatic circadian sleep-wake disorders is often mistaken for posttraumatic insomnia.
- TBI survivors sometimes misperceive their sleep-wake disturbances, and marked underestimation of various sleep-wake disturbances is particularly common after moderate to severe TBI. Because overlooked sleep-wake disturbances may compromise recovery from TBI and impair quality of life, careful examination is mandatory even if TBI patients deny any disturbances.
- Many factors can cause sleep-wake disturbances after TBI, including post traumatic stress disorder and obstructive sleep apnea, and the approach to such patients is therefore challenging and should be multidisciplinary. Current treatment strategies are limited, but recent insights into the underlying pathophysiology give hope for the development of novel and tailored therapeutics.

Each year, roughly 10 million people worldwide sustain a traumatic brain injury (TBI), and men are more often victims than women.[1] TBI represents the leading cause of death and long-term disability among children and young adults.[2,3] Based on a literature review covering the period from 1990 to 2005, the annual incidence of TBI is estimated between 108 and 332 cases per 100,000.[4] Because a large proportion of patients with mild TBI never seek medical attention, the true incidence of TBI is likely far greater; according to a recent epidemiologic study from New Zealand, the incidence may be as high as 749 new TBI cases per 100,000/year.[5] Motor vehicle crashes are the most frequent cause of TBI among young adults, whereas the growing proportion of elderly people has led to an increased frequency of TBI due to falls.[2] Other common causes of TBI are high-contact sports such as American football and boxing and warfare-related events, including blast injuries, blunt force trauma, and penetrating injuries.[6,7]

From a clinical perspective, the acute phase of TBI is characterized by loss of consciousness, anterograde and retrograde amnesia, and other neurologic symptoms. The severity of TBI is clinically classified using the Glasgow Coma Scale (GCS) as mild (GCS 13 to 15), moderate (GCS 9 to 13), and severe (GCS 3 to 8) TBI (Figure 99-1).[8] The core neurologic deficit in acute TBI is a quantitative and qualitative impairment of vigilance, ranging from coma in severe TBI to drowsiness and inattention in mild TBI.

Recovery from TBI may take many months up to several years. Because of the marked heterogeneity in etiology, mechanical impact, secondary injuries (in particular, brain swelling with increased intracranial pressure and subsequent impairment of cerebral perfusion), comorbidities, and individual vulnerability, it is challenging to predict outcome after TBI (Figure 99-2). However, the number of TBI survivors is steadily growing because the incidence of TBI continues to rise, the identification of patients with mild TBI has improved, and mortality after severe TBI has decreased from about 55% to 20% over the past two decades.[9-11] As a consequence, medical and public awareness of the long-term neurologic and neuropsychiatric sequelae has substantially improved over the past years, including better recognition of sleep-wake disturbances.[12-15]

This chapter reviews the current knowledge on sleep-wake disturbances after TBI from a clinical perspective and outlines the management the authors have found useful over the years. For a review of the physiological changes after TBI see Chapter 25.

OVERVIEW OF SLEEP-WAKE DISTURBANCES AFTER TRAUMATIC BRAIN INJURY

In 1949, the British neurosurgeon Sir Hugh Cairns focused his Victor Horsley memorial lecture on disturbances of consciousness and reported on several patients with acute coma induced by TBI.[16] One patient, a young soldier, had sustained severe TBI with prolonged coma and remained hospitalized for more than 5 months. It took him several weeks to regain full consciousness, and after 5 months, he still complained of difficulty "in grasping the meaning of pictures." When observing this gradual recovery of consciousness, Cairns

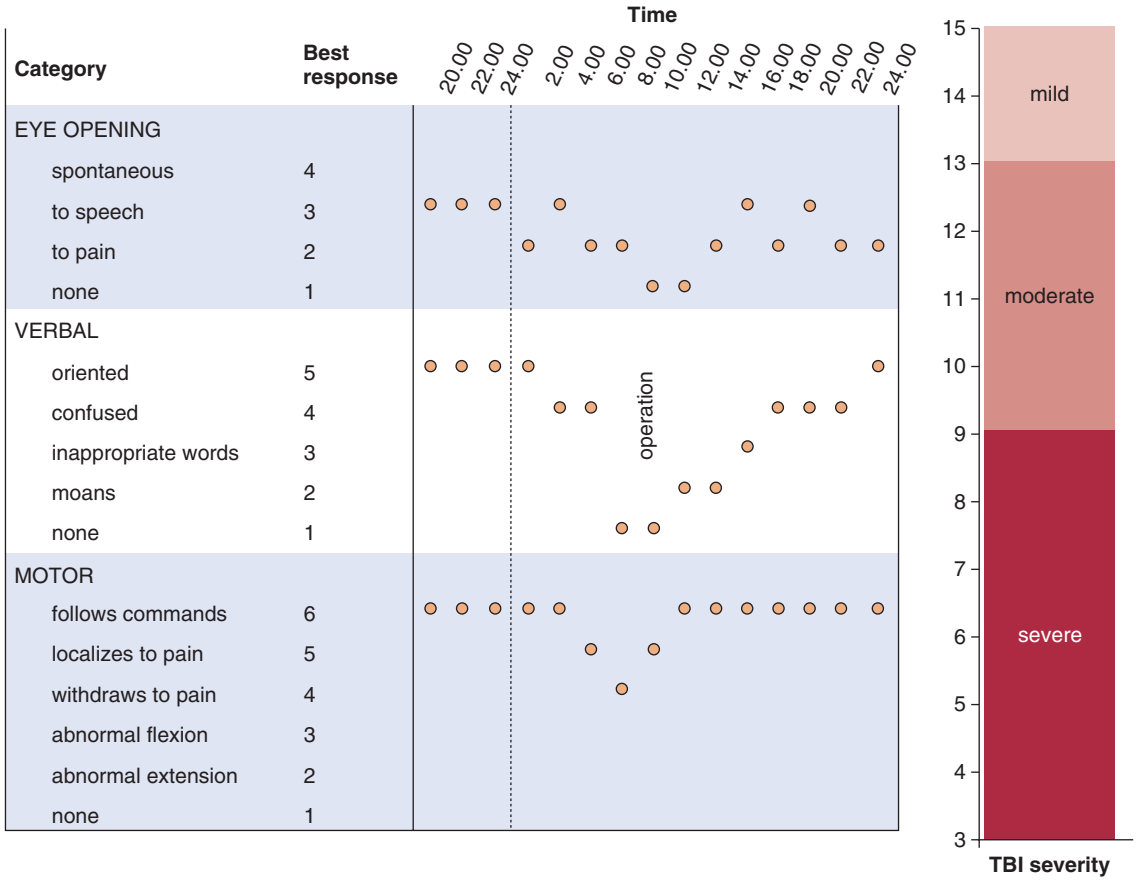

Figure 99-1 Glasgow Coma Scale (GCS), modified from the original 1974 publication of Teasdale and Jennett.[8] The GCS is used for initial classification of traumatic brain injury (TBI) severity and for serial assessment. The figure illustrates how the three items of the GCS in a single patient can be continuously recorded during hospitalization.

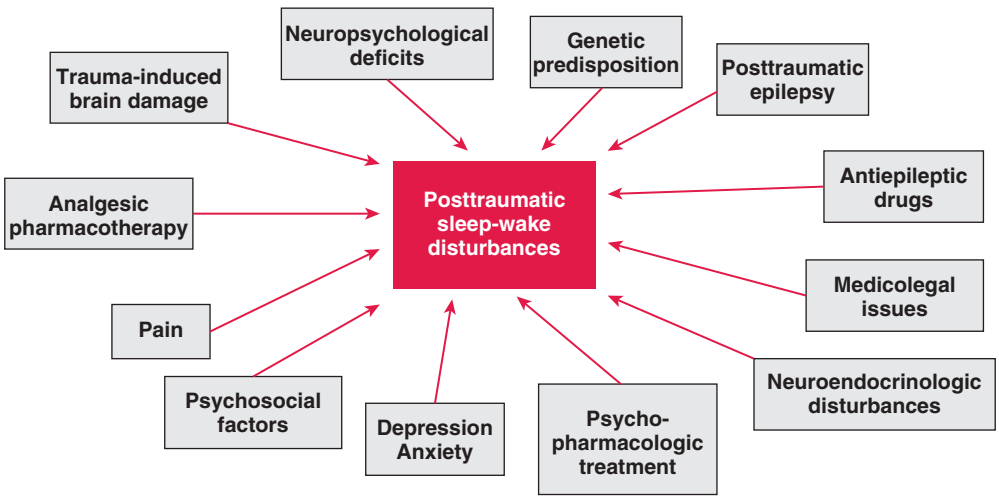

Figure 99-2 Potential contributors to posttraumatic sleep-wake disturbances.

noted: "We have no words to describe these states which lie between coma and full consciousness."[16] This account can be read as an early illustration of the wide range of posttraumatic arousal disturbances. Although Cairns did not use such words as arousal, sleepiness, increased sleep need or fatigue, there is nevertheless no doubt that his patient had all these arousal disturbances at different times. After 5 months, the soldier still had some kind of mental fatigue, but whether he continued to suffer from posttraumatic sleep-wake disturbances is unknown.

In the scientific literature, the problem of posttraumatic sleep-wake disturbances was neglected for a long time. When researchers from Oklahoma some 30 years later observed differences in sleep recordings between controls and TBI patients 6 to 59 months after injury, they wondered, "Do patients continue to show sleep abnormalities more than six months after injury?"[17] Another decade later, a questionnaire-based study from Israel compared frequency and type of subacute and chronic posttraumatic sleep-wake disturbances in 22 inpatients from a rehabilitation center and 77 already discharged patients.[18] Among the hospitalized TBI patients (median, 3.5 months after injury), 73% had sleep-wake disturbances, whereas in the second group, with a median latency since TBI of 29.5 months, still more than half (52%) suffered from sleep-wake disturbances. The two groups, however, differed with regard to the type of their complaints. During the subacute phase, 81.2% of all patients with sleep-wake disturbances had insomnia, namely difficulty initiating and maintaining sleep, whereas excessive daytime sleepiness (EDS) was the predominant symptom in the chronic TBI group, accounting for 72.5% of sleep-wake disturbances.[18] Importantly, the authors also noted a negative effect of sleep-wake disturbances after TBI on occupational outcome and emphasized the need to manage sleep-wake disturbances after TBI early in the rehabilitation process.

The first systematic and prospective studies in this regard appeared only in 2007.[19,20] We now know that sleep-wake disturbances are highly prevalent 3 to 6 months after TBI and may persist for several years.[19-21] Six months after TBI, 47 of 65 consecutive patients (72%) presented with de novo sleep-wake disturbances; that is, the patients deny having similar complaints before the accident.[19] Arousal disturbances were the most common type, with EDS or fatigue in 55% and hypersomnia (defined as needing ≥2 hours more sleep per 24 hours compared with before TBI) in 22% of patients.[19] Furthermore, 43% of patients had no identifiable etiology of the posttraumatic sleep-wake disturbance (e.g., obstructive sleep apnea [OSA] syndrome, depression, insufficient sleep syndrome), suggesting a direct causative role of the trauma-induced brain damage (Figure 99-3). In a follow-up study, the authors reevaluated 51 patients 3 years after TBI, and the prevalence of posttraumatic sleep-wake disturbances was still remarkably high: 67% of patients still had symptoms, including fatigue (35%), hypersomnia (27%), EDS (12%), and insomnia (10%).[21] Another prospective clinical and sleep laboratory study performed 3 months or more after TBI

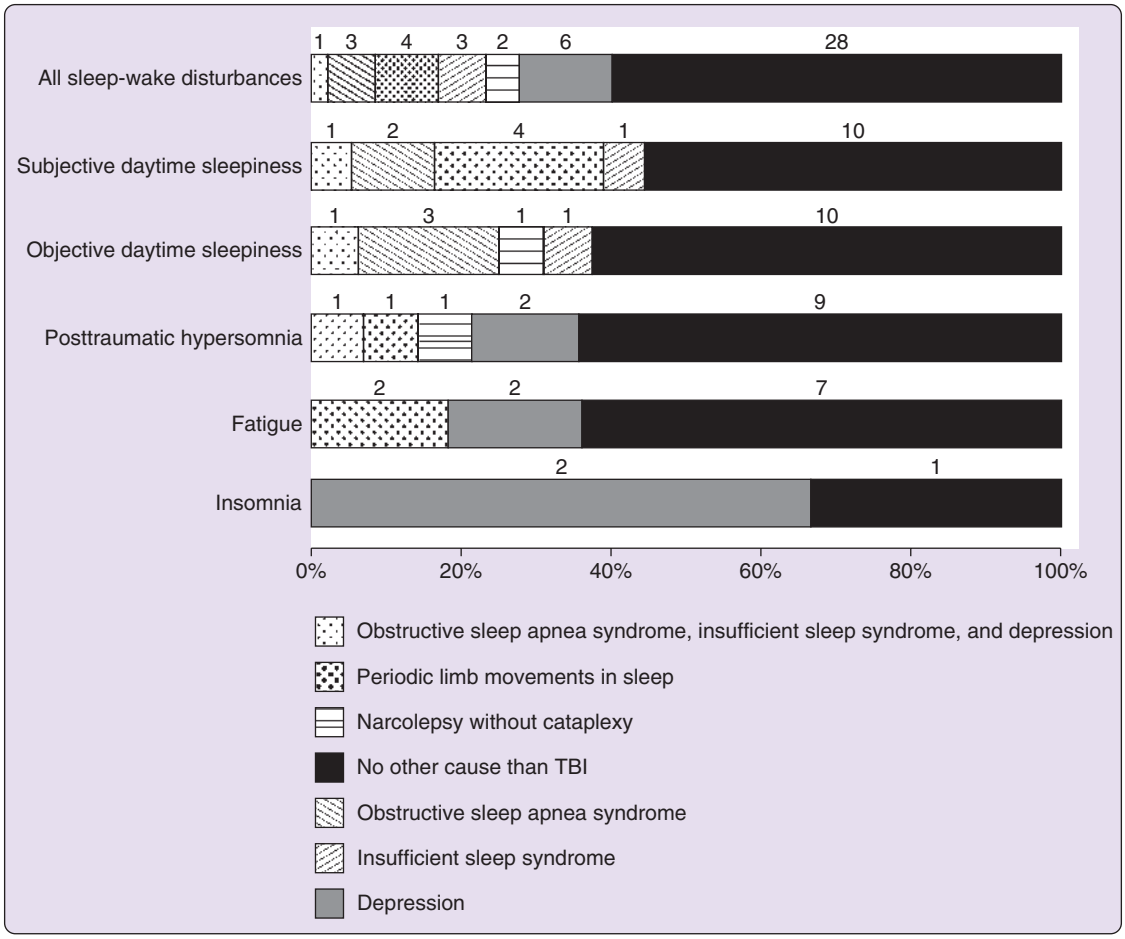

Figure 99-3 Conditions and comorbidities identified as likely causes of posttraumatic sleep-wake disturbances. In a substantial proportion of patients, the etiology remained unclear despite extensive diagnostic workup. In these patients, trauma-induced brain damage was likely the primary cause of the sleep-wake disturbances. TBI, Traumatic brain injury. (From Baumann CR, Werth E, Stocker R, et al. Sleep-wake disturbances 6 months after traumatic brain injury: a prospective study. *Brain* 2007;130:1873–83.)

showed similar results, with sleep-wake disturbances in 46% of patients and EDS in 25%.[20]

CLINICAL SIGNIFICANCE OF SLEEP-WAKE DISTURBANCES AFTER TRAUMATIC BRAIN INJURY

Increasing evidence demonstrates the importance of timely diagnosis and treatment of posttraumatic sleep-wake disturbances. Posttraumatic sleep-wake disturbances compromise health-related quality of life and rehabilitation outcome.[22,23] In one study, TBI patients with disrupted nighttime sleep patterns had worse daytime function and required longer stays in both acute and rehabilitation settings.[24] The presence of posttraumatic sleep-wake disturbances can trigger or worsen other TBI-related symptoms, such as pain, irritability, headaches, fatigue, and cognitive deficits.[25] In addition, long-term functional outcomes are reduced in patients with posttraumatic sleep-wake disturbances.[26]

There is also a meaningful association between reduced sleep quality and posttraumatic psychological distress. In a recent, prospective, longitudinal survey of 29,640 U.S. Navy and Marine Corps men, sleep problems were identified as an early marker of increased risk for developing posttraumatic stress disorder (PTSD) at a later time point.[27] Specifically, many service members with a medical history of TBI reported sleep problems on return from deployment yet manifested depression or PTSD only several months later.[27]

Finally, many TBI survivors struggle with medicolegal issues. More than 50% of patients with posttraumatic EDS may have exhausting discussions with their insurance companies and other financial problems.[28] In addition, patients with sleep-wake disturbances after TBI may exhibit worse occupational outcome.[29]

EXCESSIVE DAYTIME SLEEPINESS AFTER TRAUMATIC BRAIN INJURY

Despite major methodologic differences, most studies identify EDS as one of the most prevalent posttraumatic arousal disturbance. EDS can be defined by subjective (e.g., Epworth Sleepiness Scale [ESS] score ≥10) or objective (e.g., short mean sleep latency on Multiple Sleep Latency Test [MSLT] or Maintenance of Wakefulness Test [MWT]) criteria. The correlation between ESS scores and MSLT findings is generally poor.[30,31] For example, no correlation was apparent between ESS scores and mean sleep latency on MSLT in 71 adults examined 38 ± 60 months after TBI.[32] In this study, 47% had a mean MSLT sleep latency of 10 minutes or less, and 18% had latencies of 5 minutes or less.[32] Of note, 30% had objective EDS but normal respiratory and periodic limb movement indices on the polysomnogram, suggesting that the cause of posttraumatic EDS is not disturbed sleep. This is in contrast to an earlier study that suggested OSA may be the main cause of posttraumatic EDS,[33] whereas other groups have failed to uncover any major sleep-wake or other neurologic disturbances responsible for posttraumatic EDS.[19] Prospective longitudinal studies have suggested a gradual decrease in the frequency of posttraumatic EDS.[21,34] Still, some of these patients who recover from EDS subsequently suffer from persistent fatigue.[21] However, many older studies are not controlled, and large population-based cohort studies suggest that short mean sleep latencies on MSLT are more prevalent in the normal population than formerly suspected.[35] In a controlled prospective approach, we have recently confirmed an increased prevalence of posttraumatic EDS compared with healthy matched controls.[36] In the same study, EDS as assessed by MSLT was more pronounced and more frequent than subjective EDS measured by the ESS.[36] This indicates that patients may underestimate posttraumatic EDS, a fact that must be borne in mind when dealing with medicolegal questions like the capability of TBI survivors to drive motor vehicles.

Posttraumatic EDS can be severe and may sometimes resemble narcolepsy. This diagnostic challenge is discussed later.

HYPERSOMNIA AFTER TRAUMATIC BRAIN INJURY

Increased sleep need is a major problem after TBI and has hitherto been referred to as *posttraumatic hypersomnia*. However, the definition of hypersomnia is inconsistent and is often used interchangeably for *sleepiness*.[34,37] Importantly, increased sleep need after TBI is not always accompanied by EDS, yet significantly prolonged sleep times may represent a debilitating symptom even in the absence of EDS. Affected patients may face difficult limitations on their social, family, and work-related activities. Thus it became necessary to find a more appropriate term for this apparently frequent condition in TBI patients, and we recently proposed the word *pleiosomnia*, originating from the Greek word *pleio* (more, excessive) and the Roman word *somnus* (sleep).[38] We define pleiosomnia as increased sleep need of 2 hours or more per 24 hours compared with pre-TBI conditions.

In a large, prospective study, 22% of our TBI patients had pleiosomnia.[19] In a follow-up study to more specifically characterize posttraumatic pleiosomnia, two in three patients with posttraumatic pleiosomnia had no subjective EDS but had longer sleep times per 24 hours and increased slow wave sleep.[38] Likewise, on MSLT only 42% of the patients had a mean sleep latency of less than 8 minutes, that is, objective EDS (Figure 99-4). One important observation was that actigraphy displayed increased sleep on weekends in several patients with posttraumatic pleiosomnia, indicating insufficient sleep syndrome. Thus patients with posttraumatic pleiosomnia may be at risk for secondary development of EDS as a consequence of insufficient sleep syndrome, especially younger patients returning to work and those parenting small children.

Last, TBI patients may underestimate their actual amounts of sleep; pleiosomnia patients' reports of sleep times per 24 hours on sleep logs are significantly shorter than simultaneous actigraphy measures.[19,36,38]

FATIGUE AFTER TRAUMATIC BRAIN INJURY

Fatigue is usually defined as a subjective feeling of exhaustion, physical and mental tiredness, apathy, and a persistent lack of energy.[39,40] The current literature offers a large variety of self-report questionnaires on fatigue, but there is no objective measure. It is thus unsurprising that the research on posttraumatic fatigue provides inconsistent and often divergent results. The prevalence of fatigue in TBI survivors ranges from 16% to 80%.[41] Posttraumatic fatigue is one of the most

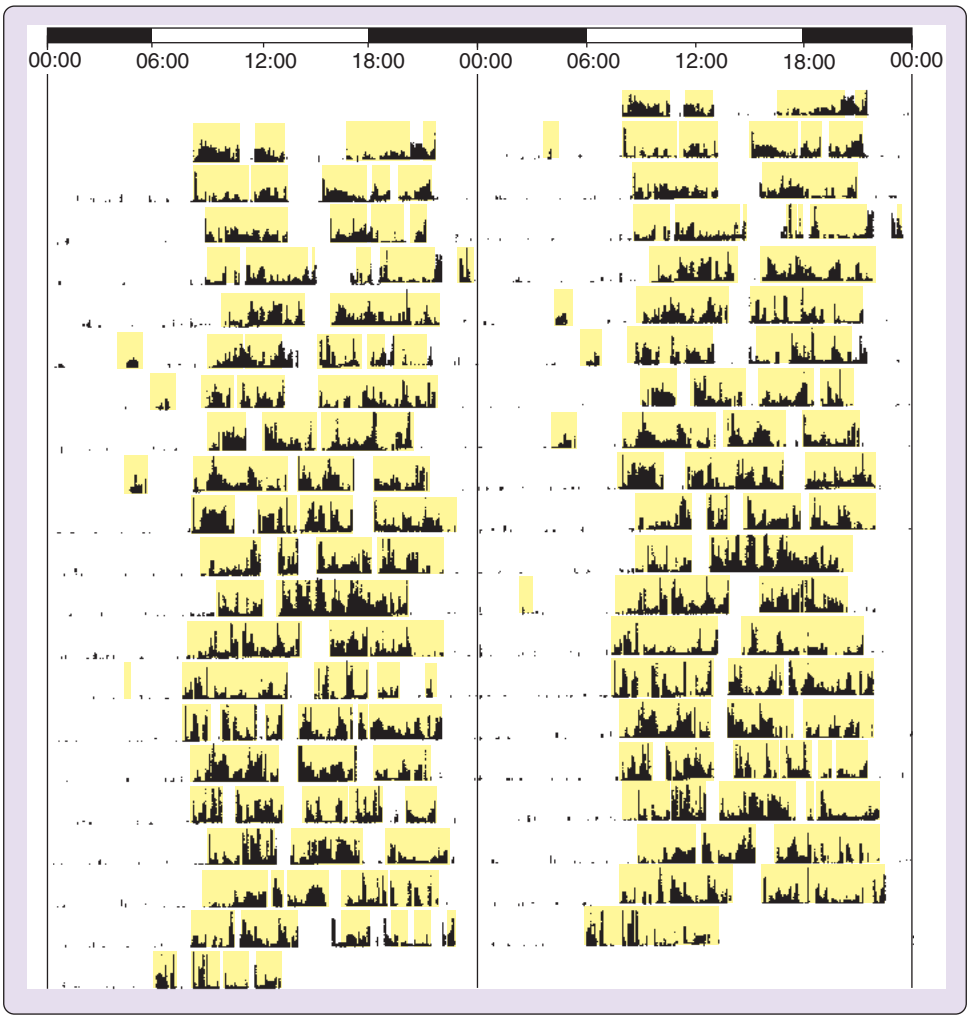

Figure 99-4 Actigraphy in a patient with posttraumatic pleiosomnia but without excessive daytime sleepiness. The actigraphy was performed 12 months after mild traumatic brain injury and demonstrated increased sleep amount per 24 hours (13 hours), with prolonged sleep times during the night and multiple rest periods during the day. Mean sleep latencies were 18 minutes on the Multiple Sleep Latency Test and 40 minutes on the Maintenance of Wakefulness Test.

persistent symptoms after TBI, and in a longitudinal study at 10 years post-injury, fatigue still emerged as the most frequent complaint (together with balance problems).[42-45] Among 22 adults with moderate to severe TBI, fatigue was more prominent than EDS 1 to 11 years after injury.[46] Posttraumatic fatigue is associated with limited daily functioning.[47] Higher levels of posttraumatic fatigue are associated with reduced quality of life.[48,49] The effect of posttraumatic fatigue on other symptoms is unclear. For instance, several groups report a correlation between posttraumatic fatigue and worse cognitive performance,[49,50] whereas other studies fail to detect any robust relationship.[51,52] Among many other causes, neuroendocrine abnormalities have been suggested to influence posttraumatic fatigue; in particular, lower basal cortisol levels have been correlated with higher fatigue scores.[53,54] Depression and anxiety are frequent after TBI, and an association with fatigue has been shown repeatedly.[21,49,55] However, a substantial proportion of patients with posttraumatic fatigue do not present mood disturbances, suggesting another cause and thereby illustrating the multifaceted etiology of this condition.

INSOMNIA AFTER TRAUMATIC BRAIN INJURY

Estimations of the prevalence of posttraumatic insomnia are varied mainly because of methodologic differences and inconsistent definitions. Most reports indicate that insomnia affects 30% to 70% of TBI patients,[22] but one prospective study using objective measures such as actigraphy and polysomnography found insomnia in only 5%.[19] In fact, some studies showed that TBI patients might overestimate insomnia symptoms. Compared with subjective, questionnaire-based measures of insomnia, two nights of polysomnography revealed lower frequencies of disrupted sleep.[56] In a prospective study using the Pittsburgh Sleep Quality Index, insomnia occurred in 30% of 50 consecutive TBI patients.[57] Among 116 consecutive patients with combat-related TBI, 55.2% had insomnia according to the *Diagnostic and Statistical* Manual *of Mental Disorders*, fourth edition criteria.[58] Pain is a common complication of TBI and a frequent cause of disturbed sleep.[59] In a retrospective study, 45% of 184 somnolent TBI survivors reported insomnia, and pain appeared as the predominant

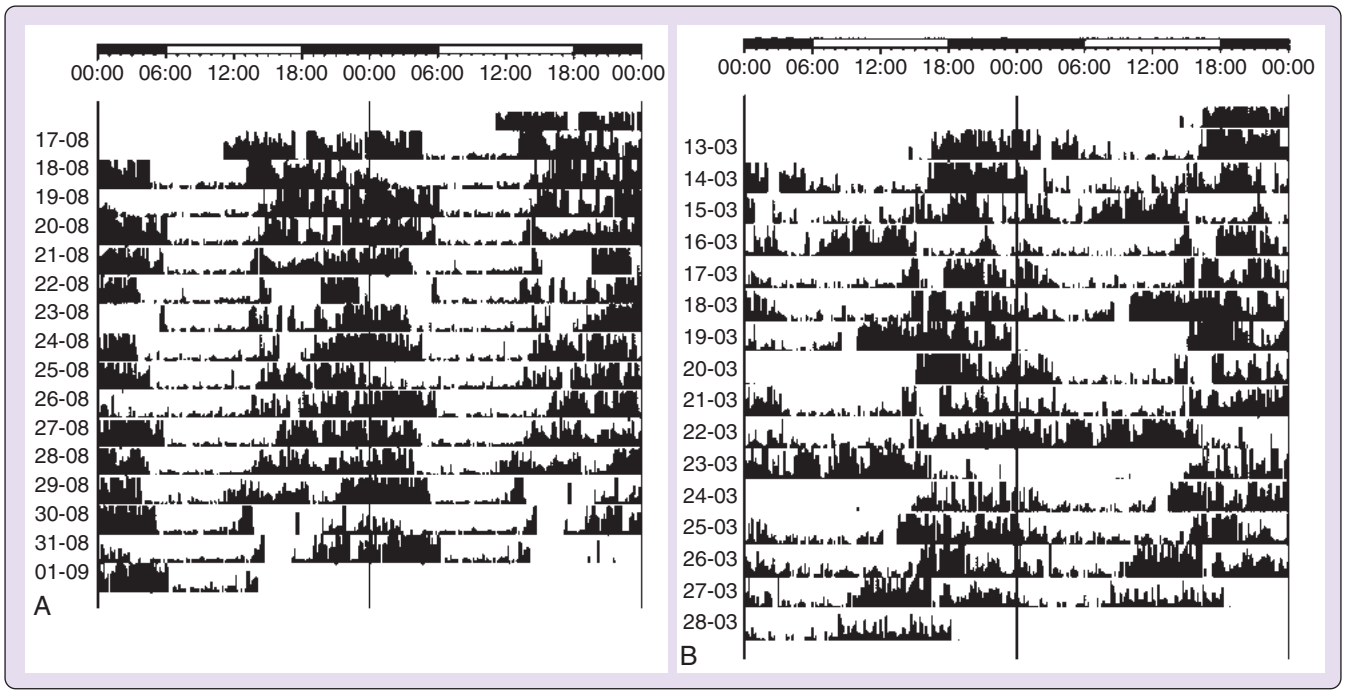

Figure 99-5 Actigraphy in two patients with different posttraumatic circadian sleep-wake disorders. The first patient **(A)** has delayed sleep phase syndrome. The second patient **(B)** has an irregular sleep-wake pattern. (From Ayalon L, Borodkin K, Dishon L, et al. Circadian rhythm sleep disorders following mild traumatic brain injury. *Neurology* 2007;68:1136–40.)

underlying feature.[28] Other contributing factors include dizziness, anxiety, and depression.[60] On the other hand, posttraumatic insomnia can interfere with rehabilitation because it often exacerbates other symptoms, including headache and emotional distress, and it may aggravate cognitive impairment.[61] Indeed, when comparing TBI patients with and without posttraumatic insomnia, sustained attention is significantly worse in the former group.[62]

Studies using polysomnography have revealed reduced sleep efficiency, increased sleep fragmentation, and increased sleep-onset latency among TBI patients.[56,63-65] Sleep fragmentation appears to be particularly pronounced in those patients with mild TBI, anxiety, and depression.[64] In fact, patients with a history of mild TBI more frequently report insomnia symptoms, together with higher levels of fatigue, depression, and pain.[61] On the other hand, repetitive TBI increases the severity of insomnia, as shown in 150 male military patients seen in a TBI clinic in Iraq.[66] Others have not found a correlation between injury variables and occurrence of insomnia.[67]

CIRCADIAN SLEEP-WAKE DISORDERS AFTER TRAUMATIC BRAIN INJURY

Few studies have described circadian sleep-wake disorders after TBI, perhaps because they lacked temperature and melatonin measurements.[14,19] However, posttraumatic circadian disturbances may be underestimated because problems such as initiating or maintaining sleep are easily confused with insomnia. One systematic study of 42 patients with insomnia complaints after mild TBI identified circadian rhythm sleep disorders in 36% of patients using actigraphy, saliva melatonin measurements, and body temperature measurement (Figure 99-5).[68] Other groups have confirmed a high prevalence of circadian rhythm disorders after TBI.[69-73] In addition, evening melatonin production is significantly lower in 23 TBI patients more than 1 year after injury than in 23 age- and sex-matched healthy controls.[74] This finding indicates that TBI may be associated with persistent circadian sleep-wake disorders and impaired melatonin synthesis.[74]

OTHER SLEEP-WAKE DISTURBANCES AFTER TRAUMATIC BRAIN INJURY

Narcolepsy

In the first decades of the 20th century, when the independency of narcolepsy as a nosological entity was still under debate, several reports on so-called posttraumatic narcolepsy emerged in the literature.[75-78] During the past 25 years, additional reports have appeared on this topic.[19,28,79-86]

The name *posttraumatic narcolepsy* suggests that TBI directly destroys the hypocretin-producing neurons in the posterior hypothalamus, thereby leading to narcolepsy symptoms, including EDS, cataplexy, hypnagogic hallucinations, and sleep paralysis. Indeed, acute TBI is associated with severe (but transient) hypocretin deficiency in the cerebrospinal fluid (CSF),[19,87] and postmortem studies of patients with severe TBI reveal mild damage to the hypocretin-producing neurons.[88,89] However, TBI also damages other sleep-wake regulating hypothalamic cell groups, including neurons producing melanin-concentrating hormone or histamine.[88,89] Thus the existence of true posttraumatic narcolepsy has to be questioned because, as opposed to the highly selective hypocretin deficiency in narcolepsy, TBI causes nonselective damage to the hypothalamus and other brain regions. This is

also reflected by the clinical characteristics; most patients with so-called posttraumatic narcolepsy do not have typical cataplexy but usually have hypersomnia (contrary to the normal amount of sleep per 24 hours in narcolepsy). Even in the presence of proven hypocretin CSF deficiency and a positive MSLT, the symptoms of such patients are best described as a *narcolepsy-like phenotype after TBI*. If TBI-induced brain injury damages the hypothalamus, the reported sleep-wake disturbance clearly goes beyond typical narcolepsy with cataplexy, as illustrated by the extensive literature on secondary narcolepsy.[90,91] A further limitation pertains to the low specificity of the MSLT-based diagnosis of narcolepsy without cataplexy, consisting of mean sleep latency lower than 5 minutes and multiple sleep-onset REM sleep periods.[92]

On the other hand, we found a history of TBI in 7 of 37 consecutive narcolepsy patients with clear-cut cataplexy, with proven CSF hypocretin deficiency and positive HLA DQB1*0602 haplotype.[86] The latency between TBI and narcolepsy onset was 2 years or less in all but 1 patient. This unexpectedly high prevalence of TBI (19%) among narcolepsy patients suggests some kind of causal relationship. Perhaps partial loss of the hypocretin neurons due to TBI triggers an autoimmune or neurodegenerative process, leading to overt narcolepsy in susceptible patients.[86]

Kleine-Levin Syndrome

Kleine-Levin syndrome (KLS) is a very rare sleep disorder of possible hypothalamic origin, characterized by recurrent episodes of extreme hypersomnia and behavioral disturbances such as hypersexuality and hyperphagia.[93] First described almost a century ago, the etiology of this disorder remains a mystery (see Chapter 100). Several researchers observed a temporal link between the onset of KLS and TBI.[94-98] Billiard and Podesta recently reviewed most of these cases and concluded that most patients present with genuine KLS, whereas in others the delay between TBI and occurrence of symptoms argues against a causal relationship between the two conditions.[99] The largest review on KLS included 186 patients, and in 9%, TBI was identified as a precipitating factor, compared with 38% of cases triggered by infections.[93]

Obstructive Sleep Apnea

In our prospective study of posttraumatic sleep-wake disturbances, only 11% of patients had OSA,[19] whereas other groups have reported higher frequencies ranging from 23% to 36%.[20,28,58,100] When extensively evaluating pre-TBI behavior, including bed partner interviews, OSA emerges in a large proportion of TBI survivors as a de novo posttraumatic feature.[28] Among 116 patients with combat-related TBI, multivariate analysis identified blunt trauma (as opposed to blast injury) as a significant predictor of OSA.[58]

The link between TBI and OSA is unclear. Preexisting EDS due to OSA increases the risk for TBI, especially while driving. Thus OSA might represent a risk factor for TBI in many patients, rather than a posttraumatic consequence. On the other hand, posttraumatic sequelae such as physical disability, depression, pain-related immobility, and pharmacologic treatment for posttraumatic epilepsy or mood disturbances, could cause weight gain and thus increase the risk for OSA.[59] Partial loss of neurons producing hypocretin in TBI patients might also trigger weight gain.[87-89] Furthermore, neuroendocrinologic disturbances are common after TBI.[101] The apolipoprotein E ε4 allele (ApoE-ε4) is associated with cognitive decline and development of dementia in both healthy subjects and TBI patients, and it seems to increase the risk for OSA in TBI patients.[102] Thus the combination of ApoE-ε4 and OSA may combine to impair cognition in TBI patients.

Recognition of OSA in TBI survivors is important because it is significantly associated with EDS and contributes to cognitive impairment.[33,103] Conversely, posttraumatic neuropsychiatric consequences such as PTSD may adversely affect adherence with continuous positive airway pressure therapy.[104]

PARASOMNIAS, SLEEP PARALYSIS, AND HYPNAGOGIC HALLUCINATIONS

Among 184 patients with head and neck trauma evaluated with interviews, questionnaires, and electrophysiologic examinations, as many as 53% reported hypnagogic hallucinations, 15% had sleep paralysis, and 9% had REM sleep behavior disorder.[28] Rodrigues and Silva reported on a 28-year-old man with severe TBI and slow recovery after an initial 2-month coma, who then developed a transient syndrome characterized by narcolepsy-like EDS, polysomnography-documented REM sleep behavior disorder, and periodic limb movements during sleep.[105] In another retrospective study on 60 TBI patients, one-fourth of all patients had various parasomnias, sometimes in combination, including acting out dreams (8.3%), nightmares (6.7%), sleepwalking (8.3%), sleep paralysis (5%), nocturnal enuresis (5%), cataplexy (3.3%), and nocturnal eating (3.3%).[100] Apparently, none of the patients had any sleep complaints before the TBI,[100] suggesting that trauma-induced damage to brain circuits that regulate sleep-wake behavior contributes to posttraumatic parasomnias. In our own study, we found a low incidence of sleep paralysis (5%) and hypnagogic hallucinations (5%), which was even lower than the prevalence of these features in the normal population.[19] Thus it remains unknown whether parasomnias in TBI survivors emerge as de novo symptoms or simply are undiagnosed before the TBI.

DISTURBED DREAMING

Dreaming can be altered in TBI patients depending on the time since TBI, the presence of other comorbidities, and memories concerning the moments immediately before the TBI. In the acute phase after TBI, dream recall seems decreased and may even be completely lost despite normal REM sleep.[17,106] During recovery, when TBI survivors tend to have longer and more consolidated sleep, dream recall is still reduced, and patients indicate less vivid dreams.[107,108] On the other hand, persistent nightmares with trauma-related content are highly prevalent in TBI survivors and may in turn worsen posttraumatic sleep-wake disturbances, in particular by interrupting sleep.[109,110] Guilleminault and colleagues reported nightmares in up to 41% of TBI patients.[28]

SLEEP-WAKE DISTURBANCES AFTER TRAUMATIC BRAIN INJURY IN CHILDREN

Although TBI is the most common cause of long-term disability in children, there is a striking paucity of data regarding posttraumatic sleep-wake disturbances in this age group.[111] In

light of the evidence that sleep is important for learning, memory, and neural plasticity, more studies on this topic are urgently needed.[112-114]

Among 19 adolescents with sleep disturbances 3 years after TBI, polysomnography and actigraphy revealed significantly lower sleep efficiency with more awakenings and more wake time than in controls.[115] Another prospective and longitudinal study confirmed the persistence of sleep disturbances up to 24 months after TBI.[116] The authors identified mild TBI, frequent pain, and psychosocial problems as risk factors for disturbed sleep. Conversely, sleep disturbances predict poorer functional outcome in children with moderate to severe TBI.[116] Acute TBI also alters sleep patterns in infants and young children.[117]

The few available studies on posttraumatic sleep-wake disturbances mostly focus on sleep problems and less on impaired daytime vigilance.[118-120] A prospective study compared the frequency of sleep problems between children aged 6 to 12 years with a history of moderate TBI ($n = 56$) or severe TBI ($n = 53$) and controls with only orthopedic injuries ($n = 80$) at 6, 12, and 48 months after TBI.[119] They found more sleep problems only in the severe TBI group, whereas children from the moderate TBI and orthopedic groups did not differ. In contrast, another study of children in the same age range considered also the parents' perspective and revealed greater parent reports of sleep disturbances 6 months after mild TBI compared with parent reports of children with only orthopedic injuries.[120] Of note, the affected children with mild TBI did not self-report greater sleep problems, thus indicating the importance of a rigorous search for sleep-wake disturbances in children with TBI. Likewise, using actigraphy and questionnaires in 15 children with moderate to severe TBI, poor sleep with prolonged sleep onset and impaired sleep maintenance was more common, notably without any evidence for circadian rhythm disorders or more frequent daytime napping.[121]

Diagnosis of Sleep-Wake Disturbances after Traumatic Brain Injury

The clinical manifestations of sleep-wake disturbances after TBI are pleomorphic, and the underlying causes are complex and differ from one patient to another. At the same time, sleep-wake disturbances may be obscured by other, more salient clinical consequences of TBI. Because sleep-wake disturbances can impair recovery from TBI, correct and timely recognition is important. In addition to sleep specialists and neurologists, awareness of posttraumatic sleep-wake disturbances is important for neurosurgeons, physicians working in intensive care units and rehabilitation centers, general practitioners, and psychiatrists. Currently there are no useful risk factors or biologic markers heralding the development of sleep-wake disturbances soon after TBI, except for intracranial hemorrhage, which is associated with posttraumatic hypersomnia.[36] Hence we should consider the possibility of sleep-wake disturbances in every TBI patient, and ideally, this screening should be repeated at several time points. A detailed overview on this topic has recently been published.[122]

Assessment of posttraumatic sleep-wake disturbances includes a structured interview, questionnaires for semiquantitative measurement and longitudinal monitoring, and sleep laboratory examinations such as whole-night polysomnography, MSLT, MWT, and actigraphy. Many self-report instruments are available to assess sleep-wake disturbances; most of them, however, have not been developed and validated specifically for TBI patients.[123]

A detailed history and self-report questionnaires are a crucial diagnostic aid, but many studies report a marked discrepancy between subjective estimates and the results of sleep laboratory examinations. In general, patients with moderate to severe TBI may underestimate their sleep-wake disturbances, whereas patients with mild TBI tend to overestimate. Table 99-1 presents an overview of studies reporting discrepant findings between subjective and objective measures of posttraumatic sleep-wake disturbances. Paradoxically, these underestimations and overestimations of sleep-wake disturbances by TBI patients are actually some of the most consistent findings across studies on posttraumatic sleep-wake disturbances.[19,32,38,42,56] The underlying mechanisms for this discrepancy are unknown, but potential explanations include distorted perception because of neurologic or neuropsychiatric comorbidities, deficits in frontal-executive functioning, and impaired self-awareness.[38,74,123-125] The Patient Competency Rating Scale is a common tool to assess self-awareness in TBI patients.[126] Comparing 30 TBI patients with high levels of self-awareness and 32 TBI patients with impaired self-awareness, appropriate perception of symptoms was associated with better neuropsychological function and higher functional independence.[124] The deleterious effects of impaired self-awareness after TBI may include poorer treatment outcome, longer hospital and rehabilitation stay, and poor compliance.[125]

In the diagnostic management of TBI patients, this peculiarity has to be considered. As a consequence, a high degree of clinical suspicion is crucial when searching for potential sleep-wake disturbances in TBI patients. Whenever possible, the clinician should obtain the perspectives and ratings of relatives and caregivers. Finally, the threshold to perform sleep laboratory examinations should be low.

Treatment of Sleep-Wake Disturbances after Traumatic Brain Injury

Sleep-wake disturbances after TBI often have multiple causes that should be considered by the treating physician. For instance, insomnia will likely persist despite successful treatment of sleep-disordered breathing if concomitant features such as pain and depression are not adequately addressed. This might explain why several treatment studies in TBI patients failed to obtain significant improvements of sleep-wake disturbances after TBI.[127,128] On the other hand, successful treatment of sleep-wake disturbances after TBI may improve pain, communication, cognition, and mood disturbances, thereby optimizing recovery and outcomes.[129] Currently, the number of inadequately treated TBI patients appears high. In one study, for instance, 60% of TBI patients with chronic and severe insomnia syndromes were not receiving any treatment.[61]

Treatment of sleep-wake disturbances after TBI includes pharmacologic and nonpharmacologic therapy. Good sleep hygiene should be encouraged in all TBI patients, although this approach alone failed to produce significant improvements in a recent study.[130] Cognitive-behavioral therapy may represent a promising approach in patients suffering from posttraumatic insomnia.[131,132] A randomized, placebo-controlled study revealed positive effects of blue light therapy

Table 99-1 Subjective Estimates and Objective Sleep Laboratory Findings Correlate Poorly in Patients with Traumatic Brain Injury

Type of Sleep-Wake Disturbance	Study	Study Design	Patients (age)	Injury Severity	Subjective Measurement	Objective Measurement	Outcome
Insomnia	Ouellet & Morin, 2006[56]	Prospective	14 TBI patients (30 ± 10 yr) 14 healthy good sleepers (30 ± 10 yr)	Mild: *n* = 4 Moderate: *n* = 5 Severe: *n* = 5	Insomnia Severity Index TBI: 18.3 ± 3.5 Controls: 1.7 ± 1.6	Sleep latency/ efficiency (PSG) TBI: 23 ± 21 min/ 87 ± 7% Controls: 20 ± 9 min/91 ± 3%	Despite showing similar PSG findings, TBI patients had significantly higher subjective insomnia measures.
Hypersomnia	Sommerauer et al., 2013[38]	Retrospective case-control	36 patients with pleiosomnia (36 ± 12 yr) 36 age-/sex-matched controls	Mild: *n* = 13 Moderate: *n* = 7 Severe: *n* = 16	Sleep logs TBI: 9.4 hr (6.8–15.0 hr) Controls: 7.5 hr (6.1–9.3 hr)	Actigraphy TBI: 10.8 hr (8.0–15.6 hr) Controls: 7.3 hr (5.7–9.2 hr)	TBI patients significantly underestimated their sleep need (*P* = .02). Conversely, controls showed good agreement between self-reported and actigraphically measured sleep need.
EDS	Baumann et al., 2007[19]	Prospective	65 patients (39 ± 17 yr), 6 mo post-TBI	Mild: *n* = 26 Moderate: *n* = 15 Severe: *n* = 24	Epworth Sleepiness Scale 7.5 (range, 2–20) ≥10 in 18 patients (28%)	MSLT Mean sleep latency: 9 ± 5 min, ≤5 min in 16 patients (25%)	The combined presence of both subjective and objective EDS was observed in 38%, but only in 9% did subjective and objective EDS concur. Likewise, ESS score and MSLT results did not correlate.
EDS	Masel et al., 2001[32]	Prospective	71 patients (32 ± 11 yr) 38 ± 60 mo after injury Patients with objective EDS (*n* = 33) compared with those without (*n* = 38)	Various head injuries (83% with accidental TBI)	Epworth Sleepiness Scale Without obj. EDS: 6.0 ± 5.3 With obj. EDS: 6.5 ± 4.3	MSLT Mean sleep latency: Without obj. EDS: 14.3 ± 2.4 min With obj. EDS: 6.4 ± 1.9 min	Patients with objective EDS (mean sleep latency on MSLT ≤10 min) estimated their sleepiness similarly to patients without EDS, indicating an inability to perceive posttraumatic EDS.
Amelioration of EDS with modafinil	Kaiser et al., 2010[134]	Double-blind, randomized, placebo-controlled	20 patients with EDS or fatigue (modafinil group: 37 ± 9 yr; placebo group: 43 ± 19 yr)	GCS: 7–8 2 yr after injury	Estimation on vigilance impairment amelioration with 100–200 mg modafinil or placebo	MWT (increase of mean sleep latency) Modafinil: 8.4 ± 9.6 min Placebo: 0.4 ± 6.2 min	Similar subjective estimation of vigilance improvement between modafinil and placebo groups but significantly improved ability to remain awake in the day (*P* = .005)

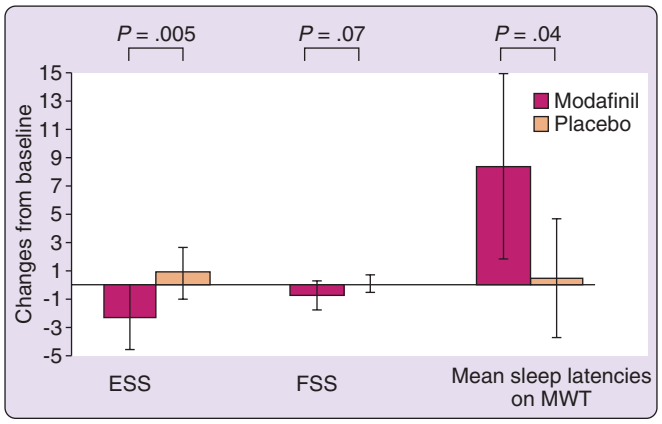

Figure 99-6 Effects of modafinil on posttraumatic excessive daytime sleepiness (EDS) and fatigue. Modafinil (100–200 mg each morning) improves subjective and objective posttraumatic EDS but not fatigue. ESS, Epworth Sleepiness Scale; FSS, Fatigue Severity Scale; MWT, Maintenance of Wakefulness Test. (From Kaiser PR, Valko PO, Werth E, et al. Modafinil ameliorates excessive daytime sleepiness after traumatic brain injury. *Neurology* 2010;75:1780–5.)

on posttraumatic fatigue and EDS.[133] In a double-blind, randomized, placebo-controlled study, 100 to 200 mg/day of modafinil significantly improved ESS scores and mean sleep latencies on MWT (Figure 99-6).[134] In addition, actigraphy suggested an increase in wakefulness of almost 2 hours per day, but without reaching statistical significance. Modafinil does not improve fatigue,[134] but fatigue may improve with treatment of associated pain or depression.

CLINICAL PEARLS

- Sleep-wake disturbances are common among TBI survivors but are often undiagnosed.
- After TBI, arousal disturbances, including hypersomnia, EDS, and fatigue, are the most common type of sleep-wake disturbances.
- PTSD nightmares and sleep disturbance and OSA may complicate the clinical picture.
- Recognition of these problems requires a high degree of clinical suspicion because they are often underreported by TBI patients.
- Untreated sleep-wake disturbances may negatively influence recovery and functional outcomes.

SUMMARY

During the past decade, a large body of studies has expanded our knowledge of the epidemiologic, clinical, and diagnostic aspects of sleep-wake disturbances after TBI. Disturbed arousal represents the most common sleep-wake disturbance after TBI and includes excessive daytime sleepiness, hypersomnia, and fatigue. Recognition of sleep-wake disturbances after TBI is often unsatisfactory because the treating physician either overlooks, underestimates, or incorrectly appreciates them. Sleep-wake disturbances may be obscured by other, more pressing clinical consequences of TBI, or the patients themselves may not adequately recognize their sleep-wake problems. Because sleep-wake disturbances can negatively affect recovery after TBI and significantly reduce quality of life, measures to quickly diagnose and treat the disorder are clearly warranted. In addition, more tailored therapeutics are needed for TBI survivors with sleep-wake disturbances.

Chapter 100

Kleine-Levin Syndrome

Isabelle Arnulf

Chapter Highlights

- Kleine-Levin syndrome (KLS) is a rare, relapsing-remitting disease affecting mostly adolescents. It is characterized by episodes of hypersomnia lasting one to several weeks, along with cognitive, behavioral, and psychiatric disturbances. Patients are normal between episodes.
- The sudden, severe (characterized by more than 18 hours of sleep per day), and recurrent hypersomnia helps differentiate KLS from other psychiatric mimics.
- Older case reports emphasized symptoms of hypersexuality, hyperphagia, male sex, and teenage onset, but recent large series now give a more precise and different picture.
- Derealization (a striking feeling of unreality), confusion, and apathy occur in all patients; disinhibited behavior is less frequent.
- Approximately one third of affected patients are female. KLS begins before the age of 12 years in approximately 10% of patients and after age 20 in 10%.
- Hypersomnia episodes usually become less severe and less frequent over time and eventually disappear with advancing age. Up to 28% of patients, however, experience prolonged episodes (lasting more than 30 days), and some 15% show no sign of recovery after more than 20 years of the disease.

Kleine-Levin syndrome (KLS) is a rare disease characterized by recurrent episodes of severe hypersomnia as well as cognitive, behavioral, and psychological disturbances.[1] The typical presentation is in an otherwise completely normal teenager, who suddenly (usually in a context of flu, alcohol use, or sleep deprivation) looks exhausted, needs to sleep 18 to 20 hours a day, becomes mute or answers just "yes" or "no" to questions, and reports feeling "unreal." The patient sleeps in a darkened room for 1 or 2 weeks, comes out only for brief meals and use of the toilet, and then immediately goes back to bed. The teen stops answering the cell phone and stops using social networks and computer games. After a couple of weeks in most cases, the episode ends with 1 or 2 days of insomnia. The teen then becomes more talkative and resumes normal sleep, cognition, and behavior for several weeks or months until a new episode appears.

Because the hypersomnia is prominent, KLS has been classified among the hypersomnias of central origin, but many symptoms are suggestive of a wider brain dysfunction, perhaps involving association cortex. These symptoms include exhaustion, severe apathy with loss of spontaneous autoactivation, and a striking derealization that is perceived by others as highly disagreeable. In some but not all patients, the behavioral and psychological changes include various forms of disinhibition similar to frontal lobe dysfunction, including rudeness, ravenous intake of certain foods, or inappropriate overt sexual offers. Blunted or sad mood (with a typically unexpressive face) and possibly hallucinations and paranoiac delusions are other, more psychiatric-related symptoms. Functional brain imaging is now a widely used research tool in KLS, both between and during episodes (which can be challenging), and shows persistent, reduced activity, mostly in the parietotemporal and mesiotemporal associative cortex.[2,3] The cause of KLS is unknown, but genetic factors may contribute, because multiplex families represent 2% to 5% of cases. In addition, metabolic and inflammatory or autoimmune origins are suspected.[4]

HISTORY

Reports suggestive of KLS are found in the nineteenth century literature[5] (Box 100-1). In 1925, Kleine described nine patients with periodic hypersomnia (two with increased food intake and one with menstruation-linked hypersomnia).[6] In 1936, Levin emphasized the association of periodic somnolence with morbid hunger in a single patient.[7] In 1942, Critchley coined the eponym Kleine-Levin syndrome. He claimed that male gender, onset in adolescence, periodic hypersomnia, compulsion to eat, and spontaneous remission were mandatory characteristics of KLS, dismissing as "doubtful" the previously reported female cases and the patients without hyperphagia.[8] His opinion prevailed[9] until a series of cases of KLS in women[10] as well as numerous patients without hyperphagia[11,12] were reported. After 2000, several large case series better characterized the spectrum of KLS,[3,11,13-17] finding that in addition to hypersomnia, slowed cognition, apathy, and

Box 100-1 THE FIRST REPORT OF PROBABLE KLEINE-LEVIN SYNDROME IN 1862*

Dr. Wilson, a physician in the Middlesex Hospital (United Kingdom), observed a very remarkable case of "double-mind" in a child. This patient was timorous, timid, and modest; he ate with moderation; in his usual state, he showed by his actions that he had an honest and scrupulous nature. As soon as the disease recurred, however, he lost all of these qualities. He slept a lot, was difficult to arouse, and as soon as he was awakened, he spontaneously sang, recited, and behaved with great ardor and aplomb. When he was not asleep, he ate ravenously. As soon as he got out of bed, he would approach another patient's sleeping area and then seize, without any hesitation, all the food he could find. Apart from this intriguing disease, he was intelligent and skillful.

Box 100-2 DIAGNOSTIC CRITERIA FOR KLEINE-LEVIN SYNDROME (ICSD-3)

A. The patient experiences at least two recurrent episodes of excessive sleepiness of 2 days to 5 weeks duration.
B. Episodes recur usually more than once a year and at least once every 18 months.
C. The patient exhibits normal alertness, cognitive function, behavior, and mood between episodes.
D. The patient must demonstrate at least one of the following during episodes: cognitive dysfunction, altered perception, eating disorder (anorexia or hyperphagia), disinhibited behavior (such as hypersexuality).
E. The hypersomnia and related symptoms are not better explained by other sleep disorders, other medical, neurologic, or psychiatric disorders (especially bipolar disorder), or use of drugs or medications.

ICSD-3, *International Classification of Sleep Disorders—Third Edition.*

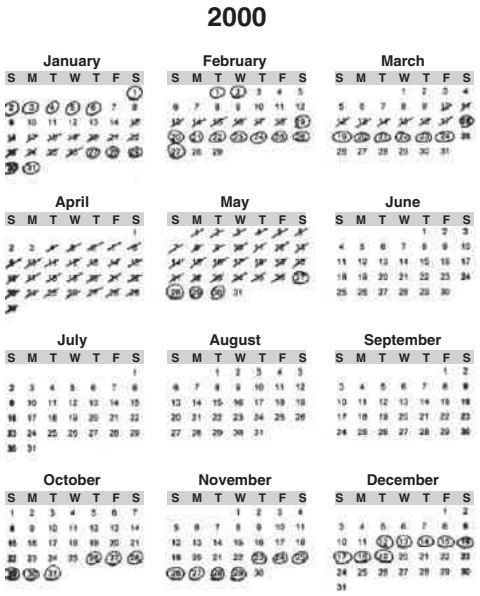

Figure 100-1 Calendar diary recording Kleine-Levin syndrome episodes during the first year of the disease in a 15-year-old girl as reported by her mother. *Circles* indicate the days with complete hypersomnia, whereas *slashes* indicate days marked by abnormal feelings (derealization, apathy, confusion) but no hypersomnia.

derealization were common, and only one third to half of patients had socially disruptive symptoms such as hypersexuality and hyperphagia, and not with each episode.[11,17] Much current KLS research focuses on functional brain imaging, genetics, and possible autoimmunity.

CLINICAL FEATURES

Episodes

The international criteria for diagnosing KLS are presented in Box 100-2.[1] The disease is typically relapsing-remitting (Figure 100-1). KLS episodes start abruptly (i.e., within a few hours) in half of the cases and progressively (within a few days) in the remainder.[11] When the end of an episode is sudden, patients frequently experience some insomnia and mild elation for up to three nights, although this is not the case when the end is gradual. Episodes last a median of 13 days, occurring every 3 months on average.[11,17] However, the clinical picture is highly variable, including short episodes (e.g., 7 days) occurring every month in young patients as well as prolonged episodes of 6 months or more with mostly apathy and altered cognition. Prolonged (lasting more than 1 month) episodes are observed in 28% of patients.[17] By contrast, some patients (mostly when treated) have mini-episodes of exhaustion and derealization lasting 1 day or even a few hours, which disappear after sleeping.[4] In most patients, the episodes are monophasic, with all symptoms always present during the full episode, whereas some rarer patients have biphasic episodes, consisting of a first phase of excitation, disinhibition, and sometimes insomnia for a few days, followed by a longer period of hypersomnia (in this order or in the reverse order). The frequency and duration of episodes are unpredictable. Patients with long episodes at KLS onset usually continue to have long episodes later, with longer disease duration.[17] In a recent series of 108 cases, patients averaged 19 episodes of 13 days duration.[11] The mean interval between episodes was 5.7 months, with a range of 0.5 to 66 months. Over the course of several years, the frequency and duration of episodes often lessen.[12,13]

Disease Duration

In large series, 80% of patients experienced their first episode between 13 and 19 years old, whereas 10% did so before the age of 13 years (childhood forms), and 10% (adult forms) started after the age of 20. The youngest age of disease onset is 4 years,[18] whereas the oldest is 82 years.[19] The episodes tend to be less frequent and then disappear with time. Indeed, most affected teenagers have no more episodes by their thirties.[12,13] The accurate disease duration can be evaluated only over long follow-up periods, especially because patients managed by pediatricians can be lost to follow-up in the transition to adulthood, and because patients may not inform the physician of late relapses (sometimes after 15 years of remission). If the end of the disease is defined as no more episodes after a period that is the double of the longest interval between episodes,

the disease duration was evaluated, using an actuarial curve, as a median of 13.6 ± 4.3 years in a recent series.[11] High episode frequency at the beginning of the disease was associated with a shorter course in a meta-analysis of 168 cases in the literature,[20] but this feature was not apparent in a recent single-center large study.[17] Male sex, onset before the age of 12 or after 20 years, and the presence of hypersexuality during episodes predicted longer disease duration.[11] Approximately 15% of patients (including more than half of those with adult onset) still have recurrent episodes after 25 years of disease.[11]

Triggering Events

Eighty-nine percent of patients remembered an event closely associated with disease onset, most often infections (72%, of whom one fourth had a coldlike syndrome with fever), alcohol use (23%), sleep deprivation (22%), unusual stress (20%), physical exertion (19%), traveling (10%), head trauma (9%), and marijuana use (6%). In infection-triggered KLS, symptoms of KLS occurred shortly (between 3 and 5 days) after the onset of fever. The agents responsible for the first infection included mostly viruses (e.g., Epstein-Barr virus, varicella-zoster virus,[11,21,22] Asian influenza virus,[23] H1N1 influenza virus,[17] enterovirus[24]) and *Salmonella yyphi*[25] and *Streptococcus*.[26,27] Rare postvaccine onset associations include combined typhoid and tetanus vaccine,[27] tuberculosis vaccine,[11] papillomavirus vaccine, and H1N1 vaccine.[17] Factors that trigger relapses are similar, although nothing can be identified in 15% to 20% recurrences. In a cohort of teenagers with KLS in Taiwan carefully followed for at least 2 years, the timing of disease onset and of recurrent episodes correlated significantly (the coefficient of correlation was between 0.45 and 0.55) with community outbreaks of upper respiratory infections such as acute bronchitis, bronchiolitis, and pharyngitis and nasopharyngitis.[15]

SYMPTOMS DURING EPISODES

Some core symptoms are almost always present, at least during the first years of the disease, including hypersomnia, cognitive impairment, derealization, apathy, and personality changes. The frequency of other symptoms such as hypersexuality, hyperphagia, hallucinations, delusions, and headache varies among patients and between episodes.[15]

Sleep Symptoms

All patients with KLS have hypersomnia, and this symptom is required for diagnosis. One of the major characteristics of hypersomnia during a KLS episode is the extremely prolonged duration of sleep (especially in teenagers), with a reported median 18 hours of sleep per day. In a recent series, sleep was enormously increased during episodes, averaging 18 ± 4 hours per 24-hour period. Most patients are difficult to awaken and report intense dreaming and frequent hypnagogic hallucinations during episodes. Sleep paralysis is uncommon, and cataplexy is absent. Patients, however, remain arousable, waking up spontaneously to void and eat, but are irritable or aggressive when awakened or prevented from sleeping. Sleep symptoms evolve from frank hypersomnia during the first episodes to a heavy fatigue accompanied by a feeling "as if in twilight between sleep and waking" during later episodes,[13] especially during episodes of increased duration. Most patients have a main, prolonged sleep episode during the night that ends around midday, followed by a nonrestorative long nap in the afternoon.

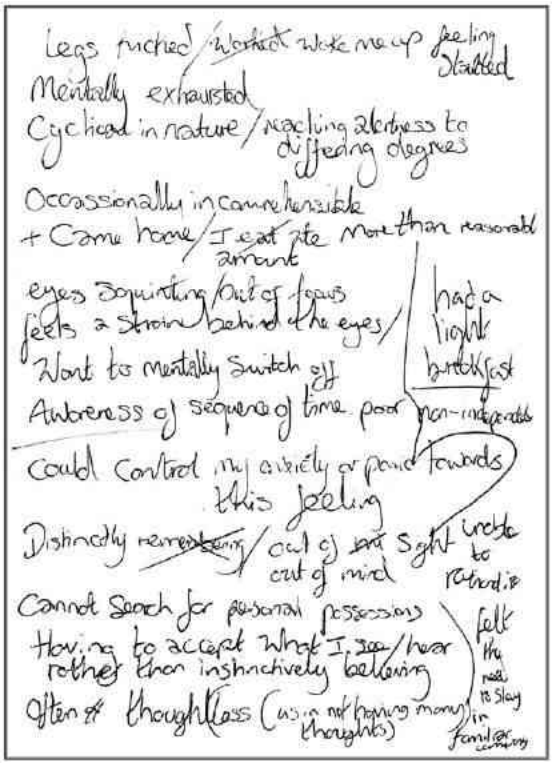

Figure 100-2 Symptom self-report of an 18-year-old boy with Kleine-Levin syndrome during an episode. Both the nature of the reported symptoms and the abnormal, sometimes incoherent writing serve to illustrate his cognitive problems.

Cognitive Symptoms

During an episode, the most obvious cognitive sign is bradyphrenia, or slow thinking. Patients look exhausted; they do not initiate conversation, are slow to answer, and answer with just "yes" or "no" (note examples in Videos 100-1 and 100-2). They frequently are disoriented in time and less often in space. Nevertheless, they can write, read, and calculate when asked and can distinguish left from right. If they write, the short messages they send are frequently confused (Figure 100-2). These confused communications can raise concern regarding alcohol or substance use. Anterograde amnesia is frequent. Some teenagers improperly sent to school during episodes were unable to follow the lessons and to complete examinations and had no memory of what they were taught. A mild apraxia is possible. Some patients report that they do not remember how to put on a T-shirt or how to use tools. The patients report that they do not "understand" the world around them. They can watch television without understanding what happens. Beyond this abnormal mental status, the remainder of the neurologic exam shows nothing out of the ordinary. These findings, together with the frank apathy and derealization, suggest dysfunction of association cortex during episodes. Altered cognition may persist during a few days or weeks after the end of an episode, especially with episodes that end gradually, so some caution is needed before sending a teenager back to school.

Derealization

Almost all (98% to 100%) patients report that the world around them seems unreal, as if they were "in a bubble" or "in a dream,"[28] feeling that their perceptions are unreal or altered in some way.[3] One patient described himself as living in a parallel world without being an actor in his life. Patients scored much higher during episodes compared with between episodes (70 ± 22 versus 13 ± 18) on the Depersonalization/Derealization Inventory.[3] Altered visual, auditory, tactile, temperature, and pain senses are common. Difficulty seeing space in three dimensions and discerning contours,[3] unusual food tastes, perception of abnormal smells, disturbed hearing (hypersensitivity to noise, voices seeming far away), increase in pain threshold, difficulty distinguishing cold from hot water, and dealing with cross-modal sensory stimulations are common. Taking a shower can be disagreeable because a patient may see water flowing on the body without feeling it at exactly the same time, in addition to difficulties evaluating its temperature. Some do not like looking at their face in the mirror, because they can have difficulty recognizing themselves.[3]

Apathy

Striking apathy affects almost all patients with KLS.[17] Patients do not seek novelty and stop their usually enjoyable activities, including reading, smoking, watching TV, playing video games, seeing friends, using social networks, and using cell phones and texting. They have a withdrawn attitude, and 80% of them neglect their hygiene. Typical examples are omission of brushing or styling the hair and not taking a shower for several days until pushed by their parents. The average apathy score on the Starskein Apathy Scale (range 0 to 40) was 30 ± 8 during symptomatic periods versus 9.5 ± 5 during asymptomatic periods.[3] Speaking often seems to require exceptional effort. Some patients remain able to perform their daily routine mechanically. A young patient, who is normally a talented skier, robotically skied after his brother during an episode, without taking any risk or initiative.[4] This complex inability to properly interpret novel environments makes patients unfit to drive during episodes. At the beginning of an episode, one of our patients drove behind his brother's car and followed the wrong vehicle for more than 600 km, crossed a national border, bought gas, and finished in a car crash with complete amnesia of the event.

Disinhibited Behavior

Hyperphagia and hypersexuality often are identified as characteristic or typical symptoms of KLS,[9,29] yet only 57% of patients experience hyperphagia and only 50% to 53% demonstrate hypersexuality, and these are features only in some but not all episodes.[11,15] Single case reports probably have overreported these symptoms,[9,29] because these were mandatory[30] for KLS diagnosis before the 2005 and 2013 international definitions.[1,31] Hyperphagia is different from bulimia in that it does not involve voluntary vomiting or attempts at controlling weight. Patients are disinhibited toward specific food and good manners, to the point of "stealing candies in their friend's bag" or "eating all available food."[5,32,33] Some patients report that they eat a large amount of food once a day and immediately resume sleep. Parents may find candies and cakes hidden under the patient's bed. On the other hand, 34% to 40% of patients actually eat less, sleeping all the time, and when they are called to the family dining table, they eat mechanically.[34,35]

Hypersexuality affects less than one half of patients with KLS during at least one episode, but it can be diagnostically useful because it is uncommon in other psychiatric syndromes. It is one of the most embarrassing symptoms in public and may lead to legal problems if not prevented. This mental, physical, and behavioral loss of sexual inhibition affects boys more often than girls (58% versus 35%), with increased masturbation ("to the point of bleeding"), increased demands on sexual partners, inappropriate sexual behaviors such as exposing or touching the genitals, masturbating in the presence of parents and physicians, swearing, asking overtly sexual questions of a teacher, touching a stranger's breast, and making sexually inappropriate proposals.[25,36] As an example, one of our patients mechanically accompanied his family to the beach during an episode. Once in his swimsuit on the beach, however, he started to masturbate openly in front of his grandmother, aunt, parents, and little sister. A 13-year-old patient entered the bathroom where his stepmother was taking a shower and proposed sexual relations to her. Plasma levels of sex hormones (testosterone, luteinizing hormone, follicle-stimulating hormone) were normal in 14 patients and mildly decreased in 2 patients.[20] Of importance, testosterone is not increased during KLS episodes.

Repetitive, compulsive behaviors also are common. One third of patients sing, pace (Videos 100-3 and 100-4), tap or snap their fingers, or repeatedly listen to the same music or watch the same video in a continuous loop.[11,15,37,38] Some patients exhibit regressive behaviors such as skipping or playing with their fingers,[39] speaking with a childish voice (as in Videos 100-1 and 100-2), using childish words, or asking their mother to sleep nearby.[11,35] Some parents qualify behaviors associated with each episode with a specific (low) mental age. Young patients have tantrums, especially when prevented from rest or sleep, or when brought to medical care.[40-43]

Psychotic, Mood and Anxiety Symptoms

Flattened affect and sad mood (with rare cases of suicidal attempts)[22,44] are observed in approximately half of patients[11,15] and are more prevalent in women than in men.[11] Decreased mood may last only one day (often close to the end of an episode), with teenagers crying and feeling that the disease "will never end." Some patients may ask if they could die from it or express the desire to die if it does not stop.[11] The abrupt termination of an episode commonly is characterized by a feeling of relief and elation lasting 1 to 3 days, with some logorrhea and a feverish desire to reclaim the missing time. When an episode ends slowly, the sad mood may persist. Anxiety can be high during episodes. Patients may fear being left alone at home and can be panicked when left alone in unusual environments such as a hospital, when going outside, or when meeting people.[35] Typically, patients stay in their room, refusing the visits of friends or relatives. During milder episodes, they are able to stay a few hours in the family room, and in rare cases they may accept to go out of the house, but mostly in noncrowded places. They often do not open the door for visitors.

One third of patients report short-lasting hallucinations (such as of a snake near the bed or a dangerous man with a bear in the hospital elevator) and delusions.[35] Most delusions

are mild, characterized by grandiosity, such as patients reporting being able to guess the identity of the caller when the phone rings, being able to pilot the plane they are in, or being able to stop the clock by thought.[45] Reported delusions include being in the movie that the person is watching, the belief that the patient's (still-alive) father is dead, or the feeling of being observed, filmed, or poisoned. Patients also may view themselves as God or hear voices telling them to kill their father. Ideas of reference (the feeling that people look specifically at them, usually with aggressive intent) are typical. Psychotic symptoms usually last only a few hours to a few days and stop spontaneously.

Autonomic Symptoms

Headache, photophobia, and phonophobia are frequent. Most patients remain lying in their room in the dark. In teenagers, during an episode, the face often has an exhausted look, a reduced facial expression, and an empty gaze. Patients may void less often (e.g., only once a day) and have, in rare cases, urinary retention. Orthostatic hypotension is common, especially if the patient has been spending much time in bed.[46,47] Other autonomic signs are rare, including high blood pressure,[34] bradycardia or tachycardia,[48] and ataxic or rapid ventilation.[49,50]

Asymptomatic Periods

During asymptomatic periods, patients generally have normal amounts of sleep and no psychiatric or cognitive symptoms (as evident in Videos 100-2 and 100-4) and normal anxiety, depression, and eating attitude test scores, with a normal[17] or somewhat increased[11] body mass index. The question of whether KLS promotes bipolar disease or psychosis in a subsample of patients cannot be easily answered. When contrasted with the high frequency of siblings affected in patients with bipolar disorder, a familial history of severe depression and bipolar disorder is rare in meta-analyses of cases[20] and was similar in frequency among control subjects in two large controlled studies.[11,17] However, subtle cognitive impairment (mostly affecting verbal memory and executive function) was reported in a few patients formally evaluated with neuropsychological testing.[16,28,51] One long-term follow-up study reported that 25 patients were in good health several years after the cessation of their KLS episodes, suggesting that complete recovery with a good prognosis is the rule for KLS.[13]

CLINICAL SUBTYPES OF THE DISEASE

KLS may be mild, moderate, or severe. In mild forms, teenagers experience 1-week symptomatic periods two or three times a year. In moderate forms (mostly observed in children and teenagers), patients may experience a 7- to 10-day episode every month,[52,53] Episodes lasting more than 1 month are observed in 28% of patients, often since disease onset. A recent study suggests that when KLS starts after the age of 20 years, lasting recovery is less common, with resolution in less than 50% of these patients after 25 years of disease.[11] This last result suggests that in some rare cases, especially those of adult onset, KLS never fully resolves.

Several multiplex KLS families have been reported, representing both horizontal transmission (in three monozygotic twin pairs,[54,55] two brothers,[11] two sisters,[17] and a brother and his sister[33]) and vertical transmission (in a mother and her son,[14] two fathers and their sons,[11] a father and five of his 10 children,[56] an uncle and one nephew,[57] and two uncles and their two nephews.[17,58] The clinical symptoms are similar to those in sporadic cases. Affected siblings do not necessarily experience the episodes at the same periods of the year.

Menstruation-Related Hypersomnia

When episodes are temporally related with menstruation (just before or at time of), the condition is named menstrual/menstruation-related hypersomnia[59] and has been reported in only 18 women worldwide.[9] Hypersomnia episodes in these cases are associated with compulsive eating in 65%, sexual disinhibition in 29%, and depressed mood in 35%.[9] Episodes last 3 to 15 days and recur less than three times a year. Of note, a boy with KLS had a sister affected by menstrual-related hypersomnia.[60] In addition, girls with typical KLS episodes mostly but not exclusively associated with menstruations have been described.[6,27] Because these symptoms are similar to those of KLS, menstrual-related hypersomnia is now considered a variant of KLS in the *International Classification of Sleep Disorders—Third Edition*. Improvement with contraceptive doses of estrogen and progesterone has been reported in rare cases.[61]

DIFFERENTIAL DIAGNOSIS

Because KLS is exceptionally rare, several more common diagnostic possibilities should be considered first. When brought to the emergency department during a first episode, most patients undergo a classic workup for acute confusion and sudden behavioral changes in teenagers: checking for alcohol, prescription drug, and illegal substance intake as well as magnetic resonance imaging (MRI) or other imaging studies to rule out a tumor, trauma, stroke, or inflammation such as that associated with multiple sclerosis. Tumors within the third ventricle (such as colloid cysts, pedunculated astrocytomas, or, in some cases, craniopharyngiomas) may produce intermittent obstructions of ventricular flow, leading to headaches, vomiting, and a paroxysmal impairment of alertness. An electroencephalogram (EEG) will help rule out complex partial seizures. A few, nonspecific sharp waves and localized or generalized slowing of EEG activity may be observed in up to 70% of KLS cases. In addition to basic laboratory tests, clinicians might consider checking serum ammonia to rule out hyperammonemic encephalopathy[62] as well as carnitine, folate, vitamin B_{12}, pyruvate, and lactate level determinations. Evaluation for possible endocrinopathies and autoimmune diseases, as well as tests for intermittent porphyria and Lyme disease, also may be useful. A lumbar puncture (especially in a context of fever) usually is advised to exclude encephalitis. Severe basilar migraine may mimic a KLS episode but typically is of shorter duration.

Recurrent episodes of sleepiness can occur with psychiatric disorders such as depression, bipolar disorder, seasonal affective disorder, and somatoform disorder. Disinhibition also may be prominent in some teenagers with attention deficit–hyperactivity disorder. Hallucinations and delusions in a previously normal teenager are evocative of brief psychosis episodes. As a consequence, some patients with KLS may be admitted to a psychiatric ward before the correct diagnosis is made. KLS with psychotic symptoms differs from psychotic

disorders in the sudden occurrence and disappearance of delusions and hallucinations in KLS, the absence of long-term adherence to delusional beliefs, the presence of associated symptoms (mainly hypersomnia, mental slowness, confusion, and amnesia), and the recurrence of symptoms. The difference between KLS with mood changes and a depressive disorder is in how suddenly the symptoms come and go in a previously happy teenager, and in the association with cognitive and behavioral symptoms. Sleepiness associated with chronic mood disorders typically alternates with periods of insomnia, whereas insomnia is very brief (2 to 3 days) in KLS and occurs only at the onset or cessation of episodes. Excessive sleepiness can occur with drug or substance use, obstructive sleep apnea, narcolepsy, idiopathic hypersomnia, or insufficient sleep. In these disorders, however, sleepiness occurs daily and usually is not recurrent; in idiopathic hypersomnia, the level of sleepiness may fluctuate with some "better" periods but sleep still remains prolonged (e.g., 12 to 14 hours/day). "Idiopathic" stupor is a rare and debated entity, occurring usually in middle-aged subjects, with stuporous episodes lasting no more than 48 hours, associated with benzodiazepine intoxication.[63]

DIAGNOSTIC TESTS

Polysomnography

The polysomnography results depend on whether sleep is monitored only for the night or for 24 hours, at the beginning or the end of episodes, or at onset of the disease or later in its course. Twenty-four hour polysomnography demonstrates prolonged total sleep time (12 to 14 hours),[12-14] up to 18 hours or more in some reports.[64] In a metanalysis, the mean total sleep time was 445 ± 122 minutes (sleep stage N1, 6%; N2, 56%; N3, 19%; REM sleep, 19%) during the night in 40 patients.[20] In 15 patients monitored for 24 hours, sleep time was 740 minutes. In a series of 14 patients in Israel, sleep efficiency was decreased, with frequent awakenings and excess stages N1 and N2.[13] Nocturnal sleep time increased from an average 384 minutes during asymptomatic periods to an average of 568 minutes during symptomatic periods.[13] In 17 children with KLS, nighttime slow wave sleep percentage was decreased during the first half and REM sleep decreased during the second half of episodes.[65]

The Multiple Sleep Latency Test (MSLT) is dependent on the subject's willingness to cooperate, and results may be either normal[65] or abnormal, with short latencies or multiple sleep-onset REM periods and a narcolepsy-like pattern in up to 21% of patients.[20] As the disease develops, patients may not sleep continuously but stay in bed with eyes closed. They report that this behavior is driven by heavy fatigue and reduces the feeling of being unreal.

Other Tests

Spinal fluid studies have shown no abnormalities in cells, protein, or oligoclonal bands. Cerebrospinal levels of hypocretin-1 were within normal range in 16 patients,[33,66-69] although they were slightly decreased during episodes compared with between episodes in some cases.[66,67] Computed tomography scans and MRI studies yield normal results or reveal incidental findings unrelated to the disease. The most interesting tests are brain functional imaging studies, which show abnormalities in most cases (see Pathogenesis section).

EPIDEMIOLOGY

The exact prevalence of KLS is unknown, but it is considered to be an extremely rare disease, with a prevalence of 1 to 2 cases per 1 million population.[11,13,15,17] It has, however, been described in all continents and most countries, including Israel.[70] KLS seems more common in Jewish populations in the United States, but not in France. Reported male-to-female ratios vary, ranging from 2:1 to 3:1. Birth and developmental problems are risk factors for developing the syndrome, with up to one third of patients in two large series having suffered from difficult delivery as an infant or demonstrating childhood developmental problems.[11,17]

PATHOGENESIS

Mechanism of Symptoms

Many KLS symptoms such as derealization, apathy, and disinhibition are suggestive of altered function in association cortex. Possibly, dysfunction of the thalamus, hypothalamus, and basal forebrain contributes to hypersomnia.[2] Functional brain imaging during episodes shows hypometabolism in the thalamus,[15] hypothalamus, mesial temporal lobe, and frontal lobe, persisting during asymptomatic periods in one half of the patients.[2,3,71] Single-photon emission computed tomography (SPECT) imaging in 41 patients during asymptomatic periods showed hypoperfusion in the hypothalamus, thalamus (mainly the right posterior part), the caudate nucleus, and cortical association areas (anterior cingulate, orbitofrontal,[1] and right superior temporal cortices) relative to that in control subjects[3] (Figure 100-3). Two additional hypoperfused areas emerged during symptomatic periods, located in the right dorsomedial prefrontal cortex (possibly underlying apathy) and the right parietotemporal junction (possibly underlying derealization). Patients with KLS performing a working memory task need to recruit a different network (including increased thalamic activity and decreased cingular activity and adjacent prefrontal cortex, as shown by functional MRI) to achieve performance levels similar to or lower than those in control subjects, suggesting a more effortful process and some compensation between episodes in patients.[51,72]

Mechanism of the Disease

The mechanism of KLS is unknown. Neuropathologic examination in four patients with KLS (two primary and two secondary cases) suggests mild localized encephalitis.[49,73-75] Three subjects showed perivascular lymphocytes in the hypothalamus, amygdala, and the gray matter of the temporal lobes, the thalamus, and the diencephalon and the midbrain. In the fourth case, a smaller locus coeruleus and decreased pigmentation in the substantia nigra were reported.

Several mechanisms have been hypothesized to cause KLS, including those with autoimmune, genetic, and metabolic aspects. An autoimmune basis for the disorder is suggested clinically by the onset during adolescence, often in conjunction with an infection, a traumatic head injury, or alcohol intake (which increases blood–brain barrier permeability and may promote the passage of antibodies)[76] and by the relapsing-remitting aspect and by recurrences. However, there is no evidence for systemic immune abnormalities.[76a] An association with HLA DQB1*02 (odds ratio, 2) in 30 European

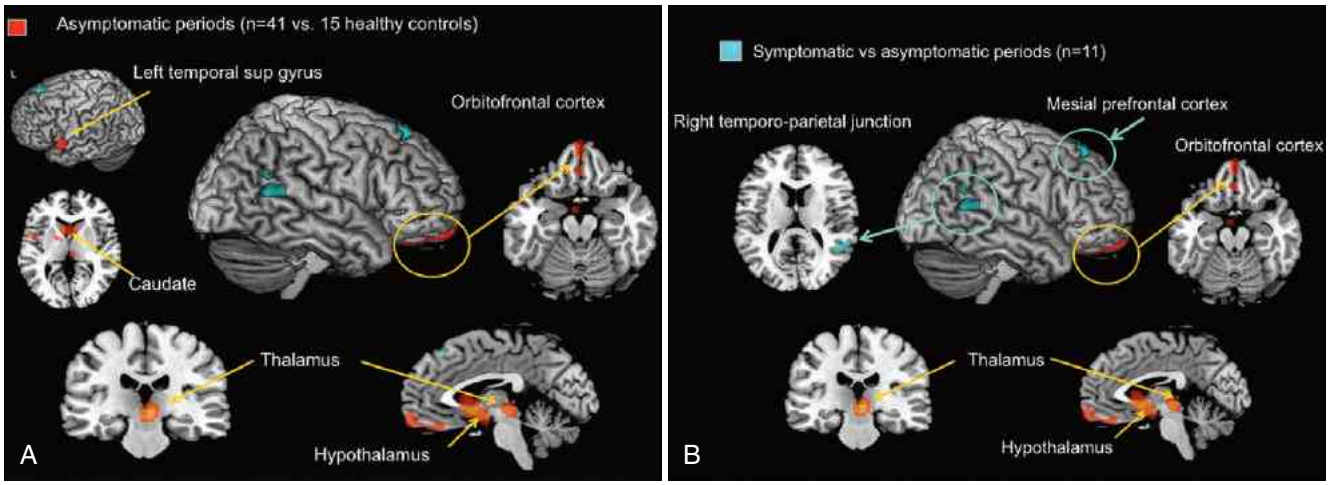

Figure 100-3 Single photon emission computed tomography (SPECT) imaging of brain in Kleine-Levin syndrome (KLS), between episodes (**A**) and during episodes (**B**). This group analysis in 41 patients with KLS shows decreased perfusion (*red*) during asymptomatic periods in the hypothalamus, thalamus, caudate nucleus, left temporal superior gyrus, and orbitofrontal cortex, when compared with healthy control subjects (**A**). During episodes, the right parietotemporal junction and the right dorsomedial prefrontal cortex show hypoperfusion (*green*) relative to the asymptomatic period (**B**). The right parietotemporal junction is more hypoactive in patients with more severe derealization. (From Kas A, Lavault S, Habert MO, Arnulf I. Feeling unreal: a functional imaging study in 41 patients with Kleine-Levin syndrome. *Brain* 2014;137:2077-87, with permission.)

patients[14] was not replicated in 108 American patients[11] or in 28 children in Taiwan.[15] Although familial risk is low (1% per first-degree relative), 5% of cases feature an affected family member, suggesting an 800- to 4000-fold increased risk in first-degree relatives.[11] KLS probably is not a form of epilepsy because epileptiform EEG activity is very rare,[77-79] and the symptoms are not relieved by administration of anticonvulsants during episodes.

TREATMENT

General Management

No formal, established treatment protocol for KLS has been recognized. Drug trials have been disappointing, and none has been performed in a placebo-controlled or blinded manner. Patients and families benefit from reassurance, simple hygiene rules, and home management. During the episodes, it is recommended to let the patient sleep at home in a familiar environment under family supervision, rather than resorting to hospitalization. This approach reduces anxiety related to novelty and the risk of embarrassing public behaviors and is safer for the patient. It is important to explain to the family that attempts to wake up or stimulate the patient are useless and painful. Driving should be firmly forbidden during episodes because sleepiness, automatic behavior, and altered perception increase the risk of a road accident. The family should regularly check during an episode that the patient drinks and eats enough (in case of reduced eating/drinking) or not too much (in case of hyperphagia), urinates at least once a day (in case of urine retention), and has no suicidal ideas. Between episodes, patients should keep a regular sleep-wake schedule (because sleep deprivation can trigger episodes), refrain from alcohol consumption, and avoid contact with others who may be infectious.

Medications during Episodes

Once an episode has started, there is no evidence that medications can stop its development. Still, we recommend trying amantadine (an antiviral and stimulant therapy) at least once, which may help abort episodes, as reported by 50% patients in a cross-sectional interview.[11] During episodes, stimulants (modafinil, methylphenidate, amphetamine) may partially improve alertness, but these medications have no effect on apathy, derealization, and confusion, as reported by 20% of patients[11] and by 40% of treating physicians.[20,22,73] When psychotic symptoms are prolonged and prominent, risperidone seems to be more helpful than other neuroleptics in retrospective and cross-sectional series.[11,20] In cases in which major anxiety occurs, a benzodiazepine can be of some help.

Drugs Preventing New Episodes

When episodes are frequent, disabling, or prolonged, preventive medications can be explored—notably, lithium.[14,20,52] The reported benefit of lithium in reducing the frequency and even stopping the disease varies, ranging from 25% to 80%.[11] In our experience, with serum lithium levels between 0.8 and 1.2 mmol/L,[80] episodes stopped completely in 35% of patients and were less frequent or less severe in another 45% of patients, with immediate relapses within 2 days when lithium was discontinued.[81] The potential risks of lithium therapy are thyroid and kidney insufficiency[82]—hence the importance of adequate hydration and regularly monitoring serum levels of lithium as well as thyroid-stimulating hormone and creatinine.[11,20] Lithium may be tapered after a few years of complete benefit or after the age of 30 years .

Antiepileptic mood stabilizers (e.g., valproate) seem less effective than lithium in our experience.[11,20] In women with menstrual-associated KLS, estrogen-progesterone may be tried,[59] although we have not seen any obvious benefit

(except from preventing undesired pregnancy with severe sexual disinhibition). Antidepressants appear to have no benefit in KLS.[11,20]

CLINICAL PEARLS

- The interview of the patient's family is the most important part of the diagnosis of KLS, because the patient's report often is blurred by amnesia and altered perceptions during episodes. Videos made by the family showing behavioral changes during episodes are very helpful. Sleep monitoring during episodes is too inconsistent to aid in diagnosis.
- It is mandatory to document clear-cut episodes (at least two) with altered sleep, cognition, and behavior, as well as clear-cut asymptomatic periods, at least during the first years of the disease. Parents should keep a calendar tracking episodes and "good" periods.
- The diagnosis is essentially clinical and retrospective—hence the importance of the history, focused on symptoms of apathy (e.g., patient not using the cell phone) and derealization (subjective feeling of being "in a dream" or feeling "unreal"). Functional brain imaging, which is easily feasible during asymptomatic periods, often (70%) shows mild hypoperfusion of the parietotemporal junction and of the mesiotemporal lobe, along with asymmetric perfusion of the thalamus.
- Longer (lasting more than 1 month) episodes affect 28% of patients. The prolonged duration may be a feature at disease onset and is associated with longer disease duration and larger impact on quality of life.

SUMMARY

KLS is a rare, relapsing-remitting disease of unknown origin. The disease usually starts during adolescence and has a male (66%) predominance; one third of patients have a history of birth or developmental problems. KLS is characterized by recurrent episodes of hypersomnia (more than 18 hours of sleep/day), lasting one to several weeks, associated with cognitive impairment, derealization, apathy, and behavioral changes. Less frequently, episodes include disinhibition with hyperphagia and hypersexuality, or depression, hallucinations, and delusions. Between episodes, patients have normal sleep, mood, cognition, and behavior for one to several months. Episodes may be triggered by infection, alcohol intake, or sleep deprivation. Episodes usually become less frequent and less severe by age 30. No diagnostic test for KLS is available, but results of functional brain imaging often are abnormal, both during and between episodes. Lithium therapy probably decreases the frequency of the episodes.

Parasomnias

Chapter 101

Parasomnias: Overview and Approach

Bradley Vaughn

Chapter Highlights

- Parasomnias are part of a larger group of disorders that produce nocturnal events.
- Parasomnias can be divided into those associated with non–rapid eye movement sleep, those associated with rapid eye movement sleep, and those associated with transitions or no specific sleep stage.
- The evaluation of parasomnias depends on an accurate history and clear description of the events.
- Key features in the history, physical examination, and polysomnography help distinguish the parasomnias.
- Parasomnias offer an opportunity to diagnose other potential sleep, medical, neurologic, or psychiatric disorders.

Parasomnias are part of a larger group of disorders that produce nocturnal events. Most of us envision these nocturnal events as part of entertaining stories from bed partners or roommates. Yet diligent clinicians understand that these events may result in injuries, sleep disruption, and psychosocial impairment and hold the opportunity to diagnose underlying sleep or medical disorders provoking the behavior.[1] Nocturnal events can be typically classified into parasomnias, sleep-related movements, or neurologic, medical, or psychiatric events.

Parasomnias are defined as undesirable physical events or sensory experiences that occur with entry into, during, or arousing from sleep. Many times these events may involve common and usual behaviors, but they also may include bizarre and unusual events like seemingly purposeful movements, perceptions, dreaming, and autonomic output. The *International Classification of Sleep Disorders*, third edition categorizes parasomnias into three major categories: non–rapid eye movement (NREM) sleep-related parasomnias, rapid eye movement (REM) sleep-related parasomnias, and other parasomnias[2] (Table 101-1). Beyond parasomnias some patients may have movement disorders that present in the transition period between wake and sleep or during sleep that can be confused with parasomnias but still represent a risk for harm.[3] Nocturnal events may also include events that go beyond the state of sleep and offer an opportunity to diagnose and potentially treat other medical, neurologic, or psychiatric events.[4] This section (Chapters 101 to 106) addresses the classic parasomnias of NREM and REM sleep–related events and reviews the expansion of other parasomnias and movement issues in sleep.

CLASSIFICATION OF PARASOMNIAS

The categorization of nocturnal events has progressed as our understanding of the mechanisms involved with sleep and wake and of these events has improved. Early classification and nomenclature used the nature of the behavior as the prominent distinguishing feature to categorize the events. Some remnants of this convention still exist in terms such as

Table 101-1 Parasomnia Classification

NREM Sleep–Related Parasomnias

Disorders of arousal (from NREM sleep)
- Confusional arousals
- Sleepwalking
- Sleep terrors

Sleep-related eating disorder

REM Sleep–Related Parasomnias

REM sleep behavior disorder
Recurrent isolated sleep paralysis
Nightmare disorder

Other Parasomnias

Exploding head syndrome
Sleep-related hallucinations
Sleep enuresis
Parasomnia due to a medical disorder
Parasomnia due to a medication or substance
Parasomnia, unspecified

sleepwalking, *sleep-related eating*, and *sexsomnia*. However, as we have developed further understanding of the neurologic drivers of sleep-wake states and the components of consciousness, we have grouped events toward the originating sleep-wake state and to some extent limited common pathology.[5] The brain's three distinct states allow us to understand that the starting physiologic state provides the substrate for which these parasomnias may exist and form the basis of parasomnias associated with NREM sleep, those associated with REM sleep, and those associated with transitions between wake and sleep. This classification scheme also allows us to move toward a classification structure more aligned with physiology and subsequently underlying pathology.

Some parasomnias may represent a mixture of states.[2] This model is best exemplified when considering the NREM sleep–related parasomnias or disorders of arousal (see Chapter 102). The disorders of arousal (sleep terrors, sleepwalking, and confusional arousals) are associated with mixture of NREM sleep and wake (see Table 101-1). These disorders are most likely not distinct but instead represent a continuum of behaviors that share components of NREM sleep associated with minimal cognitive functioning and amnesia for the events, with features of wake such as eyes open (Table 101-2).[1] These events are more likely to be triggered by stimuli, occur after sleep deprivation or psychosocial stressors, and involve a variety of nonstereotyped behaviors. Some patients report a memory of vague visual imagery and auditory impressions. Although no clear neuropathology has been uniformly identified, early studies suggest that these individuals may have compromised ability to inhibit or fully permit arousal from sleep.[6,7] Therefore these parasomnias may be an early indicator of other sleep disruption.

Of the REM sleep–associated parasomnias, recurrent isolated sleep paralysis may represent a mixture of wake and REM sleep (see Table 101-2 and Chapter 103). Although many times associated with narcolepsy, this disorder in isolation is characterized by the intrusion of REM sleep–related paralysis into wakefulness.[7,8] Other REM sleep parasomnias are confined to the state. Nightmare disorder is typically isolated to REM, but the distressing features carry over into wakefulness (see Chapter 104).[9,10] REM sleep behavior disorder is an example of neurologic impairment of the circuitry that produces the REM sleep–associated atonia.[11] This disorder is characterized by dream enactment, typically violent, and lack of the usual paralysis of REM sleep[11] (see Table 101-2). REM sleep behavior disorder has been associated with Parkinson disease, multiple system atrophy, and dementia with Lewy bodies and may predate other symptoms by decades.[12,13] This disorder represents an example of how sleep-dedicated neural circuitry may be uniquely more vulnerable to specific types of degeneration or injury.

Many of the disorders categorized as "other parasomnias" represent events that occur during the transition between wake and sleep (see Table 101-1 and Chapter 105). Some sensory events such as exploding head syndrome and sleep-related hallucinations are events that may occur as the patient enters light sleep but that also may occur on awakening.[14-16] Additionally in this group are parasomnias that occur across the spectrum of sleep states or represent a loss of sleep-wake state distinction, and some movements can be for parasomnias (see Chapter 106). Parasomnias can be initiated by medications or other neurologic, psychiatric, or medical disorders.[4,17-21] Some hypnotics with short half-lives have been implicated in initiating parasomnia behavior.[17,18] Medical issues that provoke arousals such as chronic obstructive pulmonary disease or renal disease have been reported to cause parasomnic behaviors. Parasomnias have been associated with other neurologic degenerative and autoimmune disorders.[19,22] Recent identification of a novel parasomnia disorder associated with antibodies directed toward IgLON5 raise a new pathophysiologic mechanism for nocturnal events.[22] Several researchers have postulated the existence of an overlap disorder in which patients lose the neurologic ability to express discrete sleep stages.[23]

Events can also occur during the night that may not be truly part of sleep. Approximately 20% of patients with known epilepsy have seizures occurring predominantly at night, and the behaviors may frequently overlap with those seen in parasomnias.[24,25] The key element is that these events have stereotypic behavior usually at the beginning of the event. Other neurologic disorders can present with nighttime events, such as confusion in association with encephalopathy or dementia.[26] Psychiatric disorders, such as panic attacks or dissociative events, may be predominantly expressed during the night hours as nocturnal events.[27,28] Other medical disorders can also evoke arousals with disturbed mentation. Hypoglycemia, from nocturnal insulin administration, can cause arousal with cognitive impairment typically in the early morning.[21] Similarly, cognitive depressant medications taken before bedtime may also impair cognition in individuals when waking at night.

APPROACH TO DISTINGUISHING NOCTURNAL EVENTS

The goal of any evaluation of a patient with nocturnal events is to prevent subsequent harm. The initial consultation should focus on the following questions: (1) Is the patient at risk for potential harm or causing harming to someone else? (2) What may be driving the appearance of these events? and (3) Are these events indicating another underlying disorder?

Table 101-2 Distinguishing Features of Nocturnal Events

Feature	Disorders of Arousal	Sleep-Related Eating Disorder	REM Behavior Disorder	Recurrent Isolated Sleep Paralysis	Exploding Head Syndrome	Psychogenic Events	Nocturnal Seizures
Behavior	Confused; semipurposeful movement with eyes open	Eating typically high-calorie foods; eyes open	Sometimes combative with eyes closed	Episodes of inability to move	Painless sensation of explosion inside the head	Variable	Dependent on the portion of brain involved
Age of onset	Childhood and adolescence	Variable	Older adult	Variable	Adult	Adolescence to adulthood	Variable
Time of occurrence	First third of night	First half of night	During REM	Typically on awakening	Usually near sleep onset but can be variable	Anytime	Anytime
Frequency of events	Less than one per night	Variable	Multiple per night	Variable less than weekly	Rare	Variable	Frontal seizures—multiple per night
Duration	Minutes	Minutes	Seconds to minute	Seconds to minutes	Seconds	Variable minutes or longer	Usually under 3 minutes
Memory of event	Usually none	Usually none or limited	Dream recall	Yes	Yes	None	Usually none
Stereotypical movements	No	No	No	No	Similar sensation	No	Yes
Polysomnogram findings	Arousals from slow wave sleep	Arousal from NREM sleep	Excessive electromyogram tone during REM sleep	Arousal from REM sleep	Usually occurs in light sleep	Occur from awake state	Potentially epileptiform activity

Table 101-3 Indications for Polysomnography in Patients with Nocturnal Events

Atypical presentation for a parasomnia (time of night, behavioral description)
Events injurious or with significant potential for injury
Significant disturbance to patient's home life
Unusual age of onset
Events stereotyped or repetitive
Unusual frequency of the events
Patient has excessive daytime sleepiness or complaints of insomnia
Complaints suggestive of sleep apnea, periodic limb movements, or other sleep disorders

In general, one can differentiate parasomnias by looking for key distinguishing features (see Table 101-2). The foundation of any evaluation of nocturnal events is a thorough history and physical examination. Although there are no absolutes, the underpinning of the evaluation is based on a clear description of the events from witnesses who can give an accurate testimony of the behaviors. Historical features such as time of night, duration, frequency of occurrence, behavioral characteristics with each event, eyes open or closed, memory recall, age of onset, and family history of nocturnal events may help differentiate these disorders.[2] The physician should also search for factors that precipitate parasomnias such as poor sleep environment, improper sleep hygiene, sleep deprivation, circadian rhythm abnormalities, other sleep disorders, medical issues, fever or other illnesses, emotional stress, medication use, and ingestion of alcohol or sedatives before sleep onset.[2,17,18,29,30] Additional search for other neurologic symptoms such as decreased sense of smell, constipation, or other autonomic issues may give clues to REM sleep behavior disorder.[31] Similarly, features suggesting cognitive decline in an adult may provide the opening for further investigation of encephalopathic processes or dementia.

Polysomnography can provide important information in determining the etiology of the nocturnal events, with the goals of capturing the physiology of each sleep state and evaluating the possibility of other contributing sleep disorders.[2] Overnight polysomnography is necessary if the history is atypical, sleepiness is significant, other sleep disorders are suspected, or the patient is at risk for self-harm or harming others (Table 101-3).[32] Studies should include complete respiratory monitoring, time-synchronized video monitoring, additional electromyographic recording from all four limbs, a complete set of cephalic electrodes, and ability to extensively review the electroencephalogram.[11,24,30] Incorporation of a full 10- to 20-electrode array and ability to view the tracing in 10-second windows are necessary in evaluating for seizures and the differentiation of the epileptiform discharges from potential normal variants or artifacts.[33]

CLINICAL PEARL

Disorders of arousal are more common in children but can also present in adults. When patients have a recurrence of somnambulism, sleep terrors, or confusional arousals, the clinician should ask about other features that may be causing arousals. Sleep-related events such as sleep apnea or periodic limb movements may provoke parasomnias for which the parasomnia is the sentinel symptom hallmarking the other sleep issue.

SUMMARY

Parasomnias as part of a greater group of nocturnal events allow us to examine the interaction of behaviors we associate with wakefulness during sleep. Although we recognize the three normal states of being as wakefulness, NREM, and REM sleep, we understand that these distinct states may not be as distinct as "a flick of a switch" phenomenon. Disruption of the neuronal processes determining a state of being can cause a mixture of these states. Thus behaviors normally accompanying one state may intrude into another.[2] The mechanisms determining the state distinction also may be impaired and allow the mixture these states, such as in disorders of arousal. This process of state change can be disrupted by disorders causing arousals such as sleep apnea or poor sleeping environment. Similarly, nocturnal events can be the manifestation of a vulnerability of a neuronal circuit to disease process, such as in REM sleep behavior disorder. In addition, sleep-related movements may be easily misinterpreted as part of a parasomnia, as may other medical, neurologic, or psychiatric disorders. A detailed history and clear description of the events may aid in establishing clues about the underlying etiology. The challenge for the clinician is to recognize the prospect of using these nocturnal events as the trigger to diagnose and treat other underlying issues.

Chapter 102

Non–Rapid Eye Movement Parasomnias: Clinical Spectrum, Diagnostic Features, and Management

Alon Y. Avidan

Chapter Highlights

- Non–rapid eye movement (NREM)–related parasomnias range from mild episodes that often do not disrupt the patient's sleep, such as mild confusion with sleep talking, to aggressive and potentially injurious motor disturbances such as sleepwalking and sleep terrors.
- NREM-related parasomnias generally occur as an incomplete transition from NREM deep sleep to wakefulness, typically with the patient appearing in a state of impaired arousal, lasting for a few seconds to minutes, and is associated with partial or complete amnesia.
- Essential physiologic drives, such as hunger, aggression, and sex, may be manifested by sleep-related eating behaviors, sleep-related violence, or sleep-related sexual behaviors.
- Despite their odd and peculiar clinical presentations, NREM parasomnias are readily explainable, diagnosable, and treatable.
- Other sleep disorders, such as sleep apnea, may cause arousals that provoke a NREM-related parasomnia.

Non–rapid eye movement (NREM)-related parasomnias are defined as *undesirable and often abnormal motor or subjective phenomena that arise during arousals from NREM sleep.*[1-5] The episodes may include abnormal movements, behaviors, emotions, and autonomic activity, most of which are explainable, diagnosable, and treatable.[3,5-10] These parasomnias may occur in response to internal factors, such as apneic episodes and fever, or may be triggered by external stimuli. The latest (third) edition of the *International Classification of Sleep Disorders* (ICSD3) defines NREM parasomnias to include the disorders of arousal (confusional arousals, sleepwalking, and sleep terrors) and sleep-related eating disorder (SRED). Sexsomnia is included as a behavior under confusional arousals and sleep walking, but some sleep specialists consider this as a distinct parasomnia.

CLINICAL FEATURES OF DISORDERS OF AROUSAL

The arousal disorders are classified as such on the basis of the following common characteristics: (1) pathophysiology involving impaired arousal from deep sleep, (2) genetic and familial patterns of inheritance, (3) predisposition secondary to sleep fragmentation, (4) impaired cognitive functioning during the event, and (5) universal amnesia after the event.[6] Although these parasomnias share these common characteristics, the events are phenomenologically distinguished by the clinical presentation and behaviors. Sleep terrors begin with a sudden explosion of sympathetic activity, distress, and expression of fear, which diminish over time, whereas confusional arousals and sleepwalking rarely begin with distress. Confusional arousals usually consist of normal arousal behaviors, with abnormal duration rarely manifesting in explosive distress or motor behavior. Similarly, somnambulistic behaviors consist of normal arousal behaviors at onset, proceeding to nonagitated motor behavior with lack of distress. Figure 102-1 extrapolates in a graphic format the spectrum of behavioral manifestations of the arousal disorders, the duration of the arousal episodes, the magnitude of displacement/ambulation, and the degree and intensity of distress as a function of time.[11] Occasionally, an admixture of two arousal disorders ("hybrid attacks/parasomnias"), comprising waxing and waning of the multiple behavior types, may occur. All events usually start in stage N3 NREM sleep and terminate either in wakefulness or during lighter NREM sleep. The episodes typically are brief (*solid lines* in Figure 102-1) but sometimes can be prolonged (*hatched lines*).

CLASSIFICATION OF THE DISORDERS OF AROUSAL

The ICSD3 diagnostic criteria for the disorders of arousal are outlined in Table 102-1. The behavioral episodes commonly begin as partial arousals from stage N3 slow wave sleep and typically are brief but can be protracted, lasting up to 30 minutes.

Other behavioral manifestations may be based on the following additional features[6]:

Inappropriate speech: Sleeptalking, utterance of random speech, or shouting may occur.

Confused demeanor and stare: During an episode, the eyes often are wide-open, with a confused "glassy" stare.

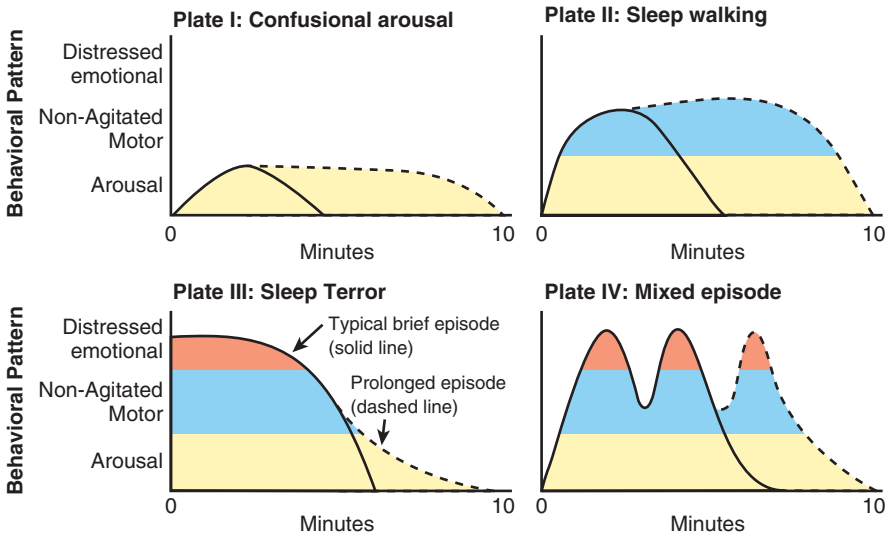

Figure 102-1 Semiology of Disorders of Arousal as a Function of Time. Diagrammatic representation of the common behavioral semiologic pattern as a function of time for the key disorders of arousal (NREM parasomnias). Depicted are hierarchical combinations of the three behavior states on the vertical axis (arousal → nonagitated motor → distressed state) as a function of time (1 to 10 minutes) on the horizontal axis. *Plate I* represents a typical confusional arousal spell. The parasomnia consists of normal arousal behaviors but of abnormal duration only. *Plate II* depicts a classic somnambulistic event comprising normal arousal behaviors at onset, proceeding to nonagitated motor behavior. *Plate III* illustrates a typical episode of sleep terrors, beginning with an intense autonomic discharge, appearance of distress, experience of predominantly negative emotional behavior typically of sudden onset; motor and normal arousal behaviors usually are also seen during these events, either at onset or thereafter. *Plate IV* is a mixed type, comprising two different arousal disorders, referred to hybrid attacks or hybrid parasomnias, with waxing and waning of the multiple behavior types. All events usually start in stage N3 NREM sleep and terminate either in wakefulness or in lighter NREM sleep. The episodes typically are brief (*solid lines*) but sometimes can be prolonged (*hatched lines*). Patients who start out with a confusional arousal who experience locomotion and displacement from the bed would be categorized as experiencing somnambulism. (Modified from Derry CP, Harvey AS, Walker MC, et al. NREM arousal parasomnias and their distinction from nocturnal frontal lobe epilepsy: a video EEG analysis. *Sleep* 2009;32:1637–44.)

Table 102-1 *International Classification of Sleep Disorders* Criteria* for the Disorders of Arousal

1. Repeated episodes of partial or incomplete awakening from NREM sleep
2. Inappropriate response, or failure to respond, to efforts of observers to intervene or redirect the affected person during the episode
3. Diminished to absent cognitive functioning or dream-like mentation or imagery after the event
4. Fragmented or no recollection for the episode
5. Absence of other primary sleep disorder, mental disorder, medical condition, medication, or substance use to help explain the disturbance

*Modified from the *International classification of sleep disorders—third edition* (ICSD-3). Darien (Ill.): American Academy of Sleep Medicine; 2014.

Absence of response to external stimuli: The patient with an arousal disorder may be very difficult to awaken and, even when the efforts succeed, the patient does not return readily to baseline function, remaining in a prolonged state of confusion and disorientation. This is termed *sleep inertia*.

Explosive onset: The patient with spells suggestive of an arousal disorder typically experiences a sudden, abrupt, and *explosive* onset associated with abnormal motor, behavioral, autonomic, or sensory symptoms.[12]

Universal amnesia: Children with disorders of arousal often have complete amnesia for these episodes, whereas adults may retain fragmentary recollection.

Dreaming mentation: Dreamlike mentation or similar altered state of consciousness has been reported occasionally after such arousal episodes.

Diminished cognition: Impairment in or absence of higher cognitive functioning is characteristic of disorders of arousal.

Arousals may be from any NREM sleep stage but primarily arise from stage N3 sleep and have a propensity to occur during the first third of the night. Disorders of arousal are common in children; in this age group, they typically are considered to be normal age-related sleep manifestations, generally not requiring specific interventions.[13,14] Predisposing factors include febrile illness, emotional stress, sleep deprivation, alcohol, a full bladder, and central nervous system (CNS)-acting medications.[15] In both adults and children, primary sleep disorders such sleep apnea and periodic limb movements also may provoke disorders of arousal.[16,17]

PATHOPHYSIOLOGY OF THE DISORDERS OF AROUSAL

Several physiologic mechanisms have been proposed to help explain the disorders of arousal, but a current prevailing theory postulates that they occur as a result of incomplete transition from one sleep state into another. Sleep stage

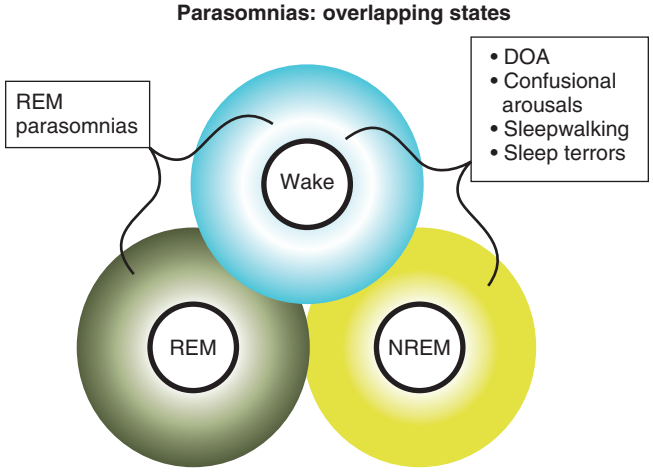

Figure 102-2 Parasomnias as State Dissociation Disorders. Under various conditions, abnormal admixtures of the three sleep-wake states—(1) NREM sleep, (2) REM sleep, and (3) wakefulness—may occur, with consequent overlap, giving rise to parasomnias. Wakefulness and sleep are not mutually exclusive states, and sleep-to-wake dissociation, incomplete transition, or oscillation from one sleep state to another leads to the parasomnias. Parasomnias are hypothesized to be due to changes in brain organization across multiple sleep-wake states: incursion of wakefulness into NREM sleep leads to the disorders of arousal, and intrusion of wakefulness into REM sleep produces REM sleep parasomnias, of which REM sleep behavior disorder (RBD) is the most dramatic and clinically important. (Modified from Mahowald MW, Schenck CH. Non-rapid eye movement sleep parasomnias. *Neurol Clin* 2005;23(4):1077–106, vii; and Avidan AY, Kaplish N. The parasomnias: epidemiology, clinical features, and diagnostic approach. *Clin Chest Med* 2010;31:353–70.)

progression entails coordination of several neuronal centers for an equivocal declaration of stage.[2,5] As illustrated in Figure 102-2, vulnerability to incomplete transition is at a maximum between NREM sleep and the awake state. During this period of sleep-stage admixture, the intrusion of one state into another may result in complex behaviors.[5,6,18,19] Some evidence for this admixture rests on studies showing that affected patients may have impaired awakening mechanisms. Additionally, the partial arousal state may activate central pattern generators in the neuroaxis, producing complex involuntary motor events such as walking.[2]

CLINICAL EVALUATION AND DIFFERENTIAL DIAGNOSIS OF DISORDERS OF AROUSAL

The clinical evaluation of patients suspected to have an arousal disorder should focus on the key items to aid in establishing the diagnosis. These key items rely heavily on historical features as well as a search for other associated features. In general, patients with NREM parasomnias require in-laboratory investigation if they are at risk for hurting themselves or are suspected of having another sleep or medical disorder, or if the events are disruptive to sleep or other functioning. The key elements of the clinical semiology—age at onset, frequency, and duration—are established in the initial evaluation. A clear description of the events, from either the patient or the bed partner, is essential to determine the underlying disorder, and the details of multiple occurrences will further clarify the etiology. In comparison with nocturnal seizures, the parasomnias are characterized by a variety of behaviors with a low frequency, as opposed to the stereotypical behavior and higher frequency of events in a given night with frontal lobe seizures.[20,21] Confusional arousals consist of episodes of abrupt awakening associated with confusion and disorientation. If displacement takes place out of bed, the event is categorized as sleepwalking and may include a range of behaviors from simple automatic non–goal-oriented behavior to more complex violent, inappropriate, agitated behavior. The hallmark of sleep terrors is a piercing scream signaling arousal, associated with increased sympathetic response and aggression. *Age at onset* for arousal disorders commonly is in childhood or the teens, generally after puberty. By contrast, nocturnal seizures, such as nocturnal frontal lobe epilepsy (NFLE), typically emerge between the ages of 10 and 20 years but may persist into young adulthood, and REM sleep behavior disorder (RBD) more typically affects older adults.[20,22] The *frequency* of events in disorders of arousal typically is only a few times per month or week, rarely with more than one event per night, and the arousals usually occur in the first half of the night. NFLE and RBD events may occur several times per night at any time during the night, with the latter more common in the second half of the night. The *duration* of events in disorders of arousal may be more prolonged, especially when sleep inertia is prolonged. NFLE and RBD typically are of brief duration. As a general rule, nocturnal seizures begin with stereotypical, sometimes bizarre semiology (or only minimal behavioral abnormalities), may be followed by postictal confusion, and can occur at any time of night and in any age group, whereas RBD is not characterized by stereotypy, and patients usually retain memory for the coinciding dream mentation[20,23,24] (Table 102-2). A recently described self-administered scale for arousal disorders, *Paris Arousal Disorders Severity Scale* (PADSS), may be useful in clinical practice to assess patients presenting with a history of abnormal or violent nocturnal behaviors. This scale has been found to have reasonably sound psychometric attributes.[25]

Confusional Arousals

Essential and Associated Characteristics

Confusional arousal, also referred to as a state of "sleep drunkenness" or an interval of "excessive sleep inertia," consists of a brief period of confusion and disorientation during and after arousal from slow wave sleep.[26-28] To an observer, patients appear to experience confused mentation, display inappropriate behaviors, and are slow or fail to respond to questioning. The timing of the episodes is most commonly during the first half of the night, in keeping with the higher propensity for arousal out of stage N3 sleep. Confusional arousals typically last a few minutes, are terminated by reinitiation of sleep, and are associated with retrograde and anterograde amnesia. Sexsomnias are considered a subtype of confusional arousals and consist of inappropriate amnestic sexual behaviors, sometimes triggered by primary sleep disorders.[29]

The proposed pathophysiology of confusional arousals is an incomplete awakening from slow wave sleep leading to intensification and prolongation of the normal period of sleep inertia.[30] Predisposing factors may include sleep deprivation and recovery from sleep curtailment, circadian rhythm sleep disorders (shift work disorder), fever, sleep-disordered breathing, CNS depressants (sedative-hypnotics and antihistamines), exposure to stimulants, or any factors that deepen sleep and impair ease of awakening.[31] Confusional arousals may be experimentally induced by attempts at forced arousal from

Table 102-2 Key Features and Treatment for Parasomnias

	Disorders of Arousal			REM Parasomnias		
Feature	**Confusional Arousal**	**Sleepwalking**	**Sleep Terrors**	**RBD**	**Nightmares**	**Nocturnal Seizures**
Timing at night and sleep stage specificity	Usually occurs in the first half of the night and typically out of stage N3 slow wave sleep			Begin out of REM sleep and typically occur in the last third of the night		At any time of night, but usually out of NREM sleep Favoring occurrence when EEG is synchronized
Family history	Frequently positive (in 62% to 96%)			No	May be positive	May be positive ~39% more likely, especially in nocturnal frontal lobe epilepsy (NFLE)
Behavior semiology	Sudden arousals followed by confusion, disorientation, and amnesia for the event	Abrupt arousal, potential for confusion/agitation if interrupted vigorously Amnestic on following day	Sudden arousal with intense screaming, inconsolable crying, agitation, and heightened autonomic discharge	Arousal followed by purposeful dream enactment, including yelling, punching, kicking, or fighting a supposed intruder/animal	Paroxysmal awakenings with anxiety and dream recall	Stereotypical, monomorphic paroxysmal events, often with dystonic limb posturing, vocalizations and confusions; may have partial recall/amnesia
Event duration	Few seconds to minutes	Usually 1–10 minutes	Few seconds to minutes	Usually less than 10 minutes	Few seconds to minutes	Few seconds to few minutes
Age at onset (years)	Typically <10			Typically >60	Typically <10	14 ± 10
Triggering factor(s)	Sleep deprivation, febrile illness, anxiety, stress, sleep apnea apnea, motor disorders of sleep			Medications (antidepressants), caffeine, alcohol	Yes: sleep deprivation, febrile illness	Not typical but may be precipitated by sleep deprivation
Frequency	Few times per month/week; very rarely >1 episode in a single night					Frequent: May occur multiple times in a night
Postspell behavior	Limited to no recall of the events with confusion			Recall is typical at times with vivid details. Patients with RBD often describe needing to protect themselves from an attacker (animal/intruder)		Complete/partial recall to amnesia and confusion
PSG changes	Abrupt arousal from slow wave sleep (stage N3) with expressions of confusion/ambulation/intense fright in all three arousal types, followed by return to sleep; increased cyclic alternating pattern (CAP)			Abnormal increased chin or limb EMG tone (atonia is noted during normal REM sleep)	Dense eye (phasic) movements during REM sleep	Epileptiform activity/muscle artifact/or normal EEG if limited montage
Treatment	Safety interventions/protect patients; remove sharp objects from bedroom, cover windows, barricade furniture, place door alarms Avoidance of precipitating factors, protecting sleep environment, improving sleep hygiene, avoidance of sleep deprivation Hypnosis, anticipatory awakenings are helpful If episodes are frequent, severe, and disruptive to sleep continuity, or result in daytime sleepiness or injury, consider pharmacotherapy			RBD: Level A: promote safety Level B: pharmacotherapy with melatonin or clonazepam Nightmares: Reassurance, avoid injury, treat precipitating factors		Antiepileptic drugs, carbamazepine most frequently used for normal seizures

EEG, Electroencephalogram; EMG, electromyogram; PSG, polysomnography; RBD, REM sleep behavior disorder; SRED, sleep-related eating disorder.

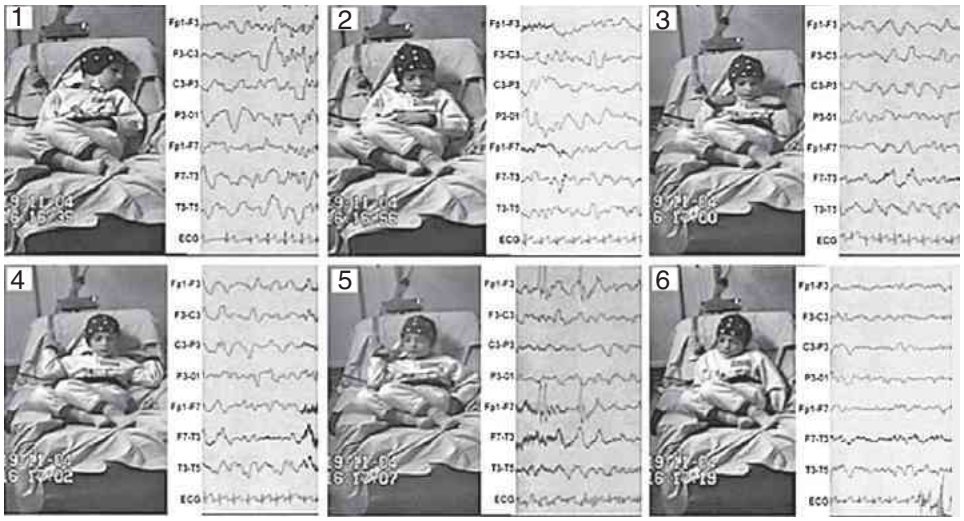

Figure 102-3 Confusional Arousals in a 7-Year-Old Boy. The parasomnia begins with the patient in stage N3 NREM sleep, depicted by delta activity in the right panel of the first fragment of the recorded polysomnogram (1). The episode progresses with the patient's raising the head (2) and placing his hands on the chest (3). The patient then raises his arms to touch the recliner back (4) and repositions his body (5 and 6). The total duration of the episode was longer than 30 seconds, but the electroencephalogram (EEG) remained characteristic of slow wave sleep, as exemplified by delta-to-theta range activity concurrent with motor behavior. Compared with patients with sleepwalking and sleep terrors, patients with confusional arousals present with less complex ambulatory events in bed but never with walking or terror-specific behavior. (From Tinuper P, Bisulli F, Provini F. The parasomnias: mechanisms and treatment. *Epilepsia* 2012;53[Suppl. 7]:12–9.)

slow wave sleep and, in adults, during recovery from sleep deprivation.

Demographic Features and Epidemiology

Confusional arousals are almost universal among children younger than 5 years of age and are less common in older childhood. The prevalence in the adult population is approximately 4%.[32] In a European study involving patients aged 15 or older, confusional arousals were reported by 2.9% of subjects in the sample.[33] In one recent cross-sectional study in the United States surveying 19,136 healthy adults older than 18 years of age, 15.2% of participants reported episodes of confusional arousals in the previous year. Of this sample, 8.6% described full or partial amnesia for the episodes and 14.8% had confusional arousals and nocturnal wandering episodes.[34] In adults, demographic assessment determined that populations at risk include those with an underlying psychiatric disorder. The overlap between confusional arousal and psychiatric comorbidity is significant: 51% of adult patients with confusional arousal reported concomitant symptoms of anxiety, 60% reported depressed mood, and 22% were diagnosed with bipolar disorder.[32,33] A similar epidemiologic study found that confusional arousals were associated with sleep and mental disorders (bipolar and panic disorders) or psychotropic drugs (especially antidepressants) in 84% of the cases, and underlying sleep disorders accounted for 70.8% of the confusional arousals.[34] Additional risk factors include circadian rhythm sleep disorder, sleep deprivation, and prolonged sleep duration of 9 hours or longer.[34]

Objective and Polysomnographic Features

Confusional arousals represent an admixture of wakefulness into non-REM sleep.[6-8,35] Patients awaken partially exhibiting marked confusion, slow mentation, disorientation, perceptual impairment, and errors of logic. Polysomnographic recordings during the episodes demonstrate arousals from deep slow wave associated with brief episodes of delta activity, stage N1 theta patterns, with repeated micro-sleeps, or a diffuse and poorly reactive alpha rhythm (Figure 102-3). The duration of the episode typically is between 30 seconds to several minutes, and the electroencephalogram (EEG) during the recordings depicts characteristics of stage N3 sleep, with delta-to-theta range activity.[15] Unlike in somnambulism and sleep terrors, motor events in confusional arousals are less complex and typically do not include any form of ambulation or sympathetic activation.[15]

Differential Diagnosis

Distinguishing confusional arousals from other paroxysmal disorders and normal arousals can present a diagnostic challenge. Confusional arousals are differentiated from other parasomnias, such as somnambulism, by the lack of displacement out of bed or walking. Confusional arousal episodes lack an acute fear component, intense screaming/crying, and increased autonomic hyperarousal, seen with sleep terrors, nor are there the complex dream enactment behaviors of RBD.[36] Unlike in RBD, confusional arousal episodes tend to occur in children, during delta sleep, and in the first half of the night. Amnesia for the event preceding the arousal is typical in confusional arousals. Complex partial nocturnal seizures of frontal lobe or inferomesial temporal origin may manifest with confusional amnestic semiology. Unlike confusional arousals, however, nocturnal seizures with ictal confusion episodes begin with more stereotypical behavior, have a variable frequency, and may be associated with EEG changes.[23,24]

Kleine-Levin syndrome (KLS), one of the periodic hypersomnolence disorders, is associated with sleep inertia and occasionally may be difficult to differentiate from confusional arousals. During the periods of prolonged sleep, patients with KLS experience the mental confusion and incoherent speech common to sleep inertia. KLS, however, has the additional distinctive features of prolonged periods of sleep and abnormal behaviors of irritability, hypersexuality, and hyperphagia during wakefulness.[37,38] KLS also may be associated with episodes of sleep eating and sleep sexual activity, which further blurs the clinical distinction.[39]

Epidemiologic data showed that 13.2% of patients with confusional arousals had obstructive sleep apnea, compared with 2% of those without such arousals.[33] Patients with sleep-related breathing disorders may engage in a variety of peculiar behaviors after an apneic episode. Figure 102-4 shows a diagnostic polysomnogram of a 54-year-old man who presented with a history of disruptive nighttime confusion and singing behaviors. During the recorded event, an arousal from slow wave sleep, the patient is seen with the arms abducted; he was then observed to "flap" his arms and was described by the technicians to be "quacking like a duck."[18] In the setting of sleep apnea, confusional arousals may result from associated hypoxemia, triggering an arousal during sleep, which in some cases provokes waking neurobehavioral deficits.[33]

Behavioral and Pharmacologic Treatment Options

Treatment is rarely indicated, because in most cases the disorder remits with age and episodes can be prevented or limited by avoidance of the facilitating factors (e.g., sleep deprivation, stimulants). Confusional arousals may be managed conservatively by avoiding sleep deprivation, preventing irregular sleep-wake schedule patterns, limiting exposure to CNS depressants, and managing coexisting sleep disorders. Pharmacologic management often is not necessary because the arousal episodes are self-limiting. In refractory cases, some patients respond to tricyclic antidepressants such as clomipramine (Table 102-3).

Confusional Arousals Subtype: Sexsomnias

Clinical Features and Typical Characteristics

One of the more bizarre and intriguing arousal disorders is a variant of confusional arousals known as *sexsomnia*, somnambulistic sexual behavior, or "sleepsex."[29,40,41] Sexsomnias consist of abrupt nocturnal episodes of often-inappropriate sexual

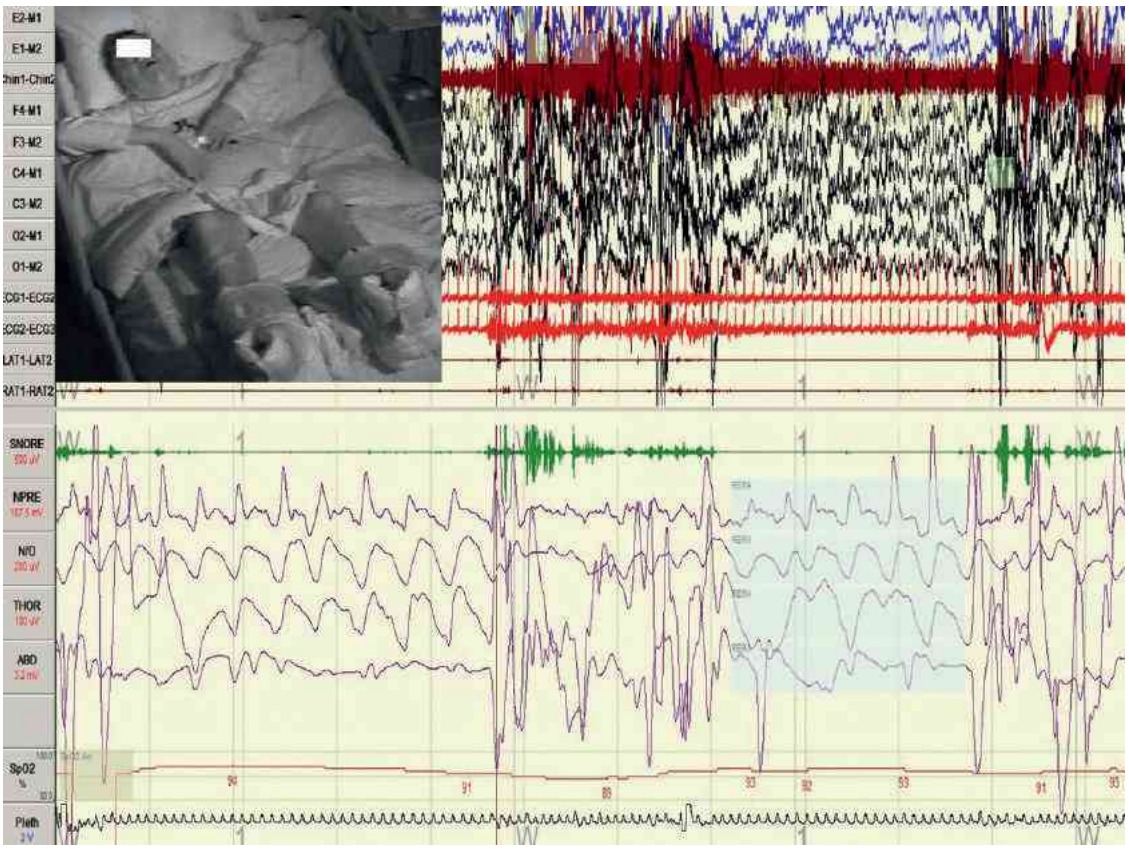

Figure 102-4 Confusional Arousal Secondary to Sleep-Disordered Breathing. A 120second epoch of a diagnostic polysomnogram (PSG) conducted to evaluate arousals with confusion and singing behavior in a 54-year-old man. A representative event for the patient is illustrated: an arousal from slow wave sleep, as demarcated by the *star,* with the patient's arms abducted (in "flapping" his arms; he also was described by the technicians to be "quacking like a duck"). Channels are as follows: electrooculogram (*left*: E1-M2; *right*: E2-M1), chin EMG (Chin1-chin2), EEG (*left*: frontal-F3, central-C3, occipital-O1, left mastoid-M1; *right*: frontal-F4, central-C4, occipital-O2, right mastoid-M2); two ECG, two-limb EMG (LAT, RAT), snore, nasal-oral airflow-N/O, nasal pressure signal-NPRE, respiratory effort (thoracic, abdominal), and oxygen saturation (Sa_{O_2}). ECG, Electrocardiogram; EEG, electroencephalogram; EMG, electromyogram; LAT, left anterior tibialis; RAT, right anterior tibialis. (Modified from Avidan AY,. Kaplish N. The parasomnias: epidemiology, clinical features, and diagnostic approach. *Clin Chest Med* 2010;31:353–70.)

Table 102-3 Treatment Options for Disorders of Arousal

Component	Confusional Arousal	Sexomnias	Somnambulism (Sleepwalking)	SRED	Sleep Terrors
Environmental safety	X	X	X	X	X
Scheduled anticipatory awakening	X		X		X
Behavioral management	Reassurance of benign nature Avoid precipitants: Sleep deprivation Alcohol CNS depressants	Enhancing sleep hygiene, ensuring optimal sleep duration Psychotherapy and stress management Comorbid mood disorder or anxiety[1]	Avoid precipitants: Sleep deprivation Lithium Nonbenzodiazepines receptor agonists		Reassurance of benign nature Relaxation therapy Hypnosis/autogenic training* Psychotherapy
Pharmacologic management	Imipramine Clomipramine Clonazepam	Benzodiazepines Clonazepam Antidepressants Sertraline GABAergic agents Lamotrigine Valproic acid Serotonin reuptake inhibitors	Benzodiazepines Clonazepam (0.5–1 mg) Diazepam (10 mg) Triazolam (0.25 mg) Imipramine (50–300 mg) Melatonin Paroxetine	Dopamine agonists, selective serotonin reuptake inhibitors, and topiramate[†]	Paroxetine (20 to 40 mg) Clonazepam (0.5–1 mg) Trazodone Hydroxytryptophan Imipramine/clomipramine

*Autogenic training is a special relaxation technique similar to meditation.
[†]Side effects include weight loss, cognitive impairment, paresthesias, visual symptoms, and less frequently, renal calculi.
CBT, Cognitive-behavioral therapy; CNS, central nervous system; GABAergic, gamma-aminobutyric acid–ergic; SRED, sleep-related eating disorder.

behaviors occurring with limited awareness during the act, relative unresponsiveness to the external environment, and amnesia for the event.[41]

Patients with sexsomnia engage in often inappropriate amnestic sexual behavior ranging from masturbation, attempting sexual activity with a partner cosleeping in the same bed, and may include attempted sex with a nonpartner with whom the patient does not share a bed or a room.[29] The consequences of sexsomnia can be serious, leading to marital distress and even forensic repercussions in aggressive, inappropriate cases or those involving minor children.[31] Although the underlying cause of sexsomnias is unknown, factors such as fatigue, stress, alcohol use, and substance abuse and physical contact with another person in the bed can precipitate the episodes.[42] The prevalence of sexsomnia is unknown, and the disorder probably is underreported. A recent review from Spain, behavioral semiology in the sexsomnias ranges from gentle and affectionate with the bed partners to violent explosive sexual acts, typically out of character for the afected person.[43] As with any behaviors, sexual behaviors can occur in a variety of disorders including as part of disorders of arousal, RBD, epileptic seizures, and psychiatric events.[42] These events can have significant forensic implications (Chapter 65). Anecdotal evidence suggests that successful amelioration of sexsomnia events entails the following approach: optimizing safety, enhancing sleep hygiene measures, ensuring optimal sleep duration, and, especially in patients with anxiety, psychotherapy and stress management techniques.[40,44,45] Benzodiazepines, particularly clonazepam, may be considered for first-line pharmacotherapy, with a recommended dosage ranging from 0.25 mg to 2 mg at bedtime (Table 102-3).[46]

Somnambulism

Essential Features and Associated Characteristics

Somnambulism, or sleepwalking, consists of complex behaviors that are initiated during slow wave sleep and result in walking during sleep. The episodes generally last from 1 to 5 minutes and may consist of a wide range of activities. Typical spells consist of complex behaviors ranging from simple and calmly sitting up in bed, simple walking to agitated walking, and rarely, in extreme cases, frantic efforts to escape a perceived threatening situation, sometimes accompanied by inappropriate behavior such as urinating.[47] Typical frequency ranges from several times a week to only when precipitating factors are present.[5,19] Somnambulism occasionally may result in falls and injuries incurred during attempts to "escape" or while walking.

Although most who experience sleepwalking are children, this usually benign and self-limiting condition can be associated with violent behaviors, injury to the sleepwalker or the bed partner, sleep disruption, hypersomnia, anxiety, psychological distress, and altered quality of life.[48] Precipitating factors include the use of sedatives, acute sleep deprivation, and specific causes of arousals such extrinsic stimuli (noise).[49] In addition, drugs with effects recognized as possible contributing factors include selective serotonin reuptake

inhibitors,[50,51] bupropion,[52] mirtazapine,[53] paroxetine,[54] and norepinephrine reuptake inhibitors.[49,55,56]

Other medical events and conditions such as fever, untreated sleep apnea, stress, and distended bladder may exacerbate the frequency of sleepwalking episodes. These occurrences demonstrate that sleep fragmentation and deprivation increase sleepwalking episodes and support the hypothesis that an impairment of either the sleep homeostatic mechanism or the arousal mechanism is at the root of these events.[49,50]

Demographic Features and Epidemiology

In a recent review of data for a large population of adults, the lifetime prevalence of nocturnal wandering with abnormal state of consciousness was 29.2%, whereas 3.6% of the sample subjects experienced more than one episode of nocturnal wandering in the previous year. The prevalence of sleepwalking in the general pediatric population is between 1% and 17% and approaches 4% in adults.[32,57] A large study involving more than 1000 children from Los Angeles reported a prevalence of 2.5% of sleepwalking,[58] whereas a study of Swedish schoolchildren revealed a prevalence of 7%,[59] peaking between the ages 4 and 8 years.[60,61] Male-to-female ratio is 1, and familial patterns are common.[3] Recently, a specific human leukocyte antigen gene (*DQB1*) was found to increase susceptibility to sleepwalking.[62]

Objective and Polysomnographic Features

The utility of formal polysomnography in the evaluation of somnambulism is mainly in the exclusion of potential mimics such as nocturnal seizures and RBD, and of other primary sleep disorders that may potentially contribute to this parasomnia. However, two fundamental difficulties impede the ability to accurately describe them: (1) Somnambulistic behaviors do not occur nightly, and (2) when the episodes do occur, they often are less dramatic or complex than previously described by the patient or family members. Polysomnographic findings in patients with sleepwalking episodes usually show frequent arousals from slow wave sleep, the emergence of hypersynchronous slow wave EEG just before and during arousals, and diminished delta activity. These findings may represent instability of slow wave sleep in the early portion of the sleep period[31,63,64] (Figure 102-5). However, these frequent polysomnographic variables are neither diagnostic of nor confirmatory for sleepwalking. The lack of specificity and sensitivity for these biomarkers degrades their usefulness as tools in the clinical or forensic confirmation of parasomnias.[63,65]

Differential Diagnosis

Considerations in the differential diagnosis for sleepwalking include other disorders of arousal, such as sleep terrors and confusional arousals, and RBD. Whereas in RBD, patients are in REM sleep and appear to be acting out a dream sequence, sleep terror and confusion arousals are more abrupt in onset, with the typical association of hypersynchronous and high-amplitude delta activity on polysomnography.[66] The first reports of sleep-related partial complex seizures with ambulatory automatisms appeared almost four decades ago, published by Pedley and Guilleminault,[73] who termed these events "episodic nocturnal wanderings," characterized by paroxysmal ambulation and bizarre behavioral manifestations during sleep.[49,67] Episodic nocturnal wandering episodes may represent complex partial seizures but also can be seen in alcohol intoxication (differentiated by drunken behavior while awake), dementia, and CNS drug–related effects.[49,68]

Behavioral and Pharmacologic Treatment Options

The cornerstone to managing sleepwalking and the other disorders of arousal is maximizing patient safety, achieved by avoiding the precipitating factors and ensuring a safe living environment by removal of sharp-edged furniture, covering windows, eliminating obstacles that may lead to injury during a sleepwalking episode, locking doors, using door alarms, and providing the safest possible sleeping area, on the ground floor rather than upstairs, or on the lower rather than an upper bunk bed.[44] Behavioral intervention of scheduled awakenings is successful in ameliorating sleepwalking episodes but, compared with pharmacologic treatment modalities, has the added advantage of avoidance of CNS-acting medications.[47] The technique calls for the parents to gently wake the patient approximately 15 to 30 minutes before the child typically experiences a sleepwalking episode.[69] Once the child responds, parents are instructed to allow the child to fall back asleep. Parents are instructed to continue the scheduled awakenings for 4 weeks and to log the frequency of the episodes during this period.[69] Although robust efficacy data currently are lacking, the theory behind the scheduled awakening tecchnique suggests that altering the patient's sleep patterns decreases the disruption in slow wave sleep.[70] Alternatively, the technique may condition the patient for self-arousal just before the arousal event, thereby avoiding it altogether, or may normalize the patient's total sleep time and improve sleep efficiency.[69] In adults with sleepwalking, sleep disorder–focused

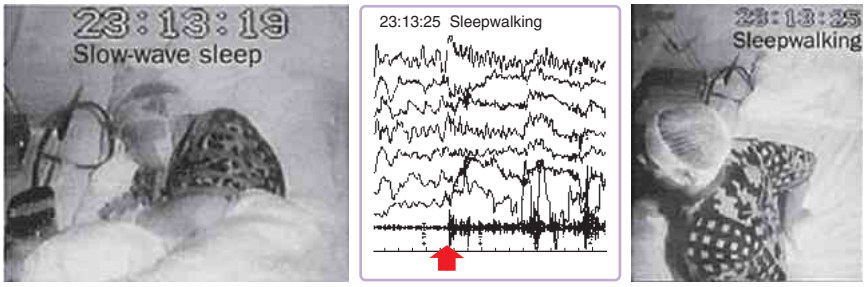

Figure 102-5 Polysomnography in Sleepwalking: Slow Wave Sleep Instability. Polysomnographic fragment highlights instability during stage N3 during sleepwalking episode (*arrow*), demarcated by sudden onset of a diffuse, high voltage rhythmic delta activity. The patient is ambulating and appears confused; the electroencephalogram (EEG) recorded concurrently shows a diffuse theta activity with intermixed alpha, beta, and delta activities. (Modified from Bassetti C, Vella S, Donati F, et al. SPECT during sleepwalking. *Lancet* 2000;356:484–5.)

psychotherapy and hypnosis constitute an alternative to pharmacotherapy.[71] Definitive pharmacotherapy with tricyclic antidepressants or benzodiazepines is necessary when the sleepwalking spells are frequent or severe or may possibly lead to injury.[3,72-84] Treatment of sleepwalking is summarized in Table 102-3.

Sleep Terrors

Essential Features and Associated Characteristics

Sleep terrors, also known as night terrors (pavor nocturnus), consist of a sudden arousal from deep sleep manifested by a piercing scream accompanied by significant autonomic arousal and behavioral manifestations of intense fear. This is the most dramatic of the arousal disorders. In addition to the characteristic sudden arousal plus the piercing scream, the patient often exhibits signs of intense fear, extreme panic, and confusion, associated with sympathetic activity manifested by tachycardia, tachypnea, reduced galvanic skin resistance reflecting diaphoresis, flushing of the skin, and mydriasis. The episodes typically are followed by amnesia and disorientation and occasionally prominent motor activity and displacement resulting in bodily injury.[5,35,85,86] Sleep terror episodes may become violent, potentially resulting in injury to the patient and bed partner, at times with forensic implications.[87-89] Sleep terrors reflect a state of cerebral hyperresponsiveness consisting of incoherent vocalizations, extreme agitation, escape behavior, and marked confusion.[3,90] The duration of the event usually is between 30 seconds to a few minutes. A universal feature is inconsolability, and attempts by the observer to interrupt the episode or soothe the patient may exacerbate, intensify, or prolong the episodes. The patient typically appears to be awake and may sometimes misperceives the nature of the environment or engages in automatic activity such as running for a door or window.[12]

Demographic Features and Epidemiology

Prevalence is approximately 1% to 6% among prepubertal children and 1% among adults. Males are more commonly affected than females, with a peak incidence between 5 and 7 years of age.[91] Episodes tend to decrease in frequency or cease during early adolescence. Psychopathology often is rare in affected children but may have a more significant role in adult sufferers.[92] As with sleepwalking, sleep terrors are much more prevalent in adults than has been generally acknowledged.[71]

Objective and Polysomnographic Features

Although sleep terrors usually are diagnosed on the basis of clinical criteria alone, video polysomnography, with multiple EEG channels included in the recording montage, may be performed for atypical episodes (i.e., repetitive episodes, occurrence several times per night, or a stereotypical behavior pattern) or in patients with possible underlying sleep disorders or neurologic or psychiatric issues.[63,93]

The onset of sleep terror episodes typically is within the first few hours of the night, during stage N3 sleep. Before a sleep terror spell, the EEG typically reveals high-voltage, symmetric, hypersynchronous slow wave activity. The characteristic polysomnogram during the sleep terror episode may reveal a sudden and incomplete arousal from slow wave sleep associated with a regular, rhythmic slow wave activity pattern, accompanied by a marked increase in muscle tone and change in respiratory and heart rates and sympathetic hyperactivation.[94-96] Although these changes may be difficult to appreciate consistently, the arousal from N3 sleep (as noted by the star in the figure), with inconsolable crying along with screaming, often is a unique feature that can be revealed with video monitoring (Figure 102-6).

In children with sleep-disordered breathing, periodic limb movements in sleep may precipitate sleepwalking or sleep terrors; improvement may be obtained after treatment of these primary sleep disorders.[16,97] When patients with arousal disorders undergo formal polysomnography, detailed examination of the nasal cannula/pressure transducer system and/or esophageal manometry is key to fully evaluating the possibility of respiratory events provoking the parasomnia.[16]

Differential Diagnosis

The differential diagnosis should include REM nightmares, nocturnal anxiety attack related to obstructive sleep apnea, nocturnal cardiac ischemia, and sleep-related epileptic seizures. Differentiation from nightmares is most important. Nightmares are distinguishable from sleep terrors in that the former often are associated with a vivid recall of the dream event during REM sleep, the clinical presentation is less dramatic, and many patients do not experience the typical autonomic hyperarousal that characterizes the latter[2,3,35] (Table 102-2). Sleep terrors preferentially occur during stage N3 slow wave sleep[95] and are universally characterized by amnesia, but fragmentary indistinct recollections of threats (spiders, monsters, snakes) from which patients have to defend themselves are sometimes reported.[16] Differentiating between sleep terrors and sleep-related epilepsy occasionally is difficult, and the use of electroencephalography is helpful in patients in whom the episodes are atypical, frequent, and less responsive to management. Nocturnal seizures, especially complex partial seizures, may have a major fear component and manifest with many of the characteristics found in sleep terrors including screaming, panic, fear, tachycardia, and vague frightening perceptions. For this reason, history and clinical semiology alone are not sufficient to conclusively differentiate sleep terrors from seizures. In these challenging cases, video polysomnographic recording with a full set of EEG electrodes is essential when the spells are frequent, repetitive, or refractory to conventional therapy or have atypical features.

Behavioral and Pharmacologic Treatment Options

Treatment often is unnecessary when episodes are rare but is essential when events are frequent, intense, or disruptive to the patient's sleep. The most essential first step is to facilitate safety measures, because these are paramount in protecting the patient from injury. As with sleepwalking, security and protection of the patient from harm in the external environment are prudent. Typical measures include (1) ensuring that the patient's sleeping area is on the ground floor, (2) avoiding the upper deck of a bunk bed, (3) removing sharp furniture close to the bed area, (4) barricading windows, (5) providing special bolts for windows and doors, and (6) using door alarms and bells to alert the family members should the child leave the room.[98] The parents and the patient need to be educated and reassured that these episodes are transient and self-limiting and typically will be outgrown with time. Additional measures should focus on maintaining a regular sleep-wake schedule, reducing or entirely eliminating caffeinated beverages. As with the other arousal disorders considered here, it is

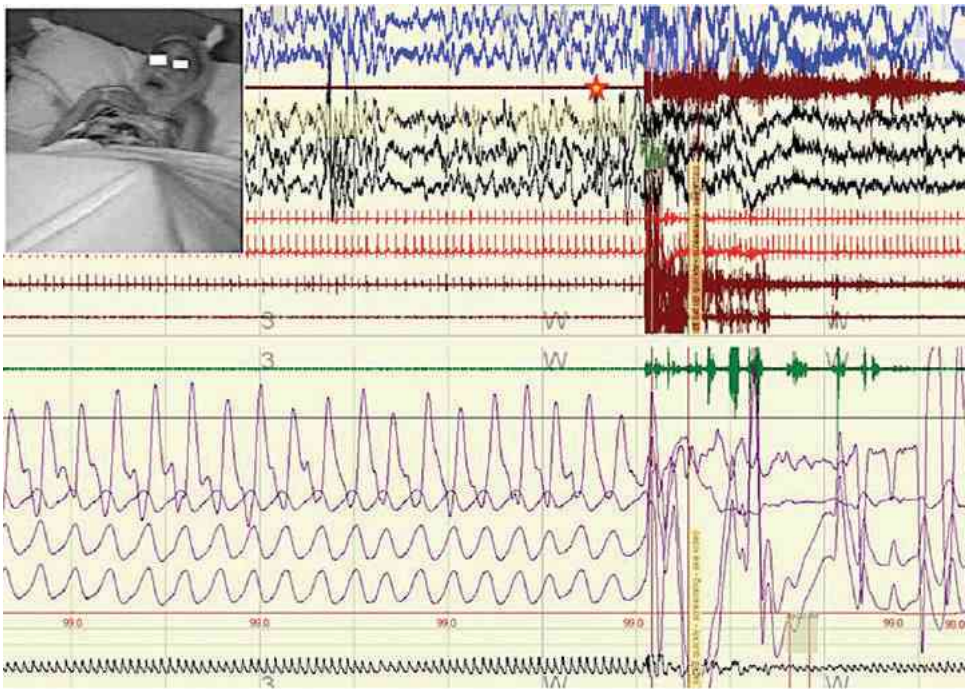

Figure 102-6 Two-minute epoch of a diagnostic polysomnogram performed to evaluate arousals associated with screaming and inconsolable crying in a 9-year-old boy. The recording was obtained during one of the patient's representative spells: an arousal out of slow wave sleep demarcated by the *star*, accompanied by screaming, with the patient's arms flexed and held close to the chest (as if afraid and protecting himself). Channels are as follows: electrooculogram (*left*: E1-M2, *right*: E2-M1), chin EMG (Chin1-chin2), EEG (*right*: frontal-F4, central-C4, occipital-O2, right mastoid-M2), two ECG, two-limb EMG (LAT, RAT), snore, nasal-oral airflow-N/O, nasal pressure signal-NPRE, respiratory effort (thoracic, abdominal), and oxygen saturation (SaO_2). ECG, Electrocardiogram; EEG, electroencephalogram; EMG, electromyogram; LAT, left anterior tibialis; RAT, right anterior tibialis. (Modified from Avidan AY, Kaplish N. The parasomnias: epidemiology, clinical features, and diagnostic approach. *Clin Chest Med* 2010;31:353–70. Polysomnogram slide courtesy Timothy Hoban, MD, Professor of Pediatrics and Neurology, University of Michigan, Ann Arbor, Michigan.)

best not to confront, restrain, or awaken the patient during the episodes, because such interventions may prolong and worsen the behavior.[98]

Scheduled or anticipatory awakenings several minutes before the time of the regular occurrence of episodes may be of considerable benefit. The technique is especially helpful when the sleep terror episodes occur at a consistent time. Hypnosis is another practical, inexpensive, and effective treatment, especially when posthypnotic suggestions are used to help decrease awareness of the unpleasant nocturnal sensory experience.[75,99-103] Adult sufferers with a history of a psychiatric disorder may benefit from psychotherapy and stress reduction as well as reassurance.[6,104-106] Pharmacotherapy should be reserved for patients with severe, frequent, and refractory sleep terror episodes. Treatment options consist of clonazepam and tricyclic antidepressants. Low-dose benzodiazepines (clonazepam, diazepam) may be effective when administered close to bedtime[107] (Table 102-3).

Sleep-Related Eating Disorder

Essential Features and Associated Characteristics

Sleep-related eating disorder (SRED) consists of episodes of amnestic nocturnal sleepwalking associated with compulsive eating behavior, occurring with fluctuating levels of impaired consciousness and sometimes associated exposure to psychotropic agents (e.g., zolpidem, olanzapine).[73-76] These events of eating occur after a partial arousal from sleep, and the patient may consume unusual food items, such as inedible substances (e.g., bar of soap) or cat food on a sandwich, or may display atypical eating (eating mayonnaise out of a jar, biting into a frozen pizza). The main concerns with SRED are related to the safety and welfare of the patient during the preparation of food (i.e., cutting and cooking) and the potential metabolic consequences (obesity, poor glucose control) of the compulsive eating.

A number of terms may be used to describe patients that experience abnormal eating behaviors at night.[77,78] SRED should not be confused with *evening hyperphagia* or *night eating syndrome* (NES). Evening hyperphagia describes excessive and unrestrained eating after the last meal and before falling asleep, while the patient is fully awake and cognizant. NES similarly indicates consciously eating greater than 50% of the daily calories in late evening and before bed or during full awakenings during the sleep period. This syndrome is associated with mood disturbances, obesity, and substance abuse but also may have links to a circadian delay in meal timing.

Demographic Features and Epidemiology

The precise prevalence of SRED is somewhat difficult to ascertain on account of misunderstanding and confusion regarding diagnostic criteria and a low awareness of SRED and NES.[77] Nevertheless, the current data indicate a prevalence of approximately 1.5% of NES in the adult

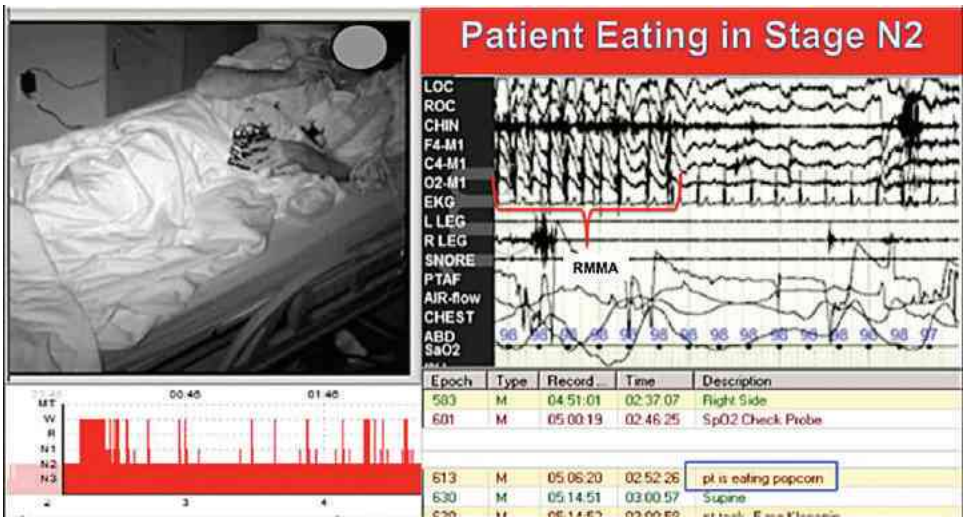

Figure 102-7 Characteristic behavior in a patient with known amnestic sleep-related eating disorder (SRED). A recording of arousal activity, obtained during NREM sleep, shows the patient eating popcorn, his favorite sleep-related eating food item, which he was instructed to bring with him to the sleep laboratory. The patient had no recollection of this activity on awakening in the morning. The repetitive chewing movements are evident as rhythmic masticatory muscle activity (RMMA) on the electromyogram tracings, as noted in the *bracketed* segment, associated with arousals during NREM sleep.

population.[80,92] The prevalence of SRED in a student population was 4.6%; an inpatient eating disorder sample reported more than triple (16.7%) and an outpatient eating disorder sample reported nearly double (8.7%) the prevalence for the healthy sample.[82]

Objective and Polysomnographic Features

Formal polysomnography may be indicated for the workup of SRED as it may be related to other comorbid sleep disorders, which predispose to arousal such as restless legs syndrome, periodic limb movements of sleep, or obstructive sleep apnea.[83,84,108-110] Patients should be invited to bring their habitually eaten nocturnal food items to the sleep laboratory for the study.[77] If the patient is observed to eat during the sleep study recording, the accompanying sleep-wake state is delineated and the sleep technologist is enlisted to assess and document the level of awareness of the event and ability to recall the eating episode in the morning.[77] Most of the SRED events occur out of NREM sleep, and patients are noted to have increased periodic limb movements.[83] Electromyographic findings may show repetitive chewing movements—rhythmic masticatory muscle activity (RMMA)—during the event (Figure 102-7). The specific pathophysiologic implication of the RMMA in SRED is unknown at present but may be related to dopaminergic mechanism.[83]

Recently, it has been shown that SRED is more common in patients with restless legs syndrome, potentially induced by hypnotics to help address the sleep-onset insomnia in this condition. This new finding broadens the clinical manifestations of restless legs syndrome to include nocturnal eating and validates that both NES and amnestic SRED may be relieved by dopaminergic therapy.[111]

Differential Diagnosis

SRED is distinct from NES, which is characterized by morning anorexia, evening hyperphagia (while awake), and insomnia and is associated with hypothalamic-pituitary axis abnormalities.[112-115] Both SRED and NES need to be differentiated from other conditions associated with nocturnal eating. In contrast with SRED, in KLS, Prader-Willi syndrome, and compulsive eating disorder, the compulsive eating occurs during waking periods.[116]

Behavioral and Pharmacologic Treatment Options

Treatment includes management of any underlying sleep disorder (such as obstructive sleep apnea). As with other disorders of arousal, safety measures are of upmost importance and include padding or removing sharp furniture, barricading windows, and using alarms to alert the household to safely guide the patient back to bed. If the patient has a history of SRED spells that involve food preparation, cabinets and drawers housing sharp utensils should be locked, and stove/oven knobs should be removed until the episodes resolve.

If the patient suffers from other disorders of arousal, recommended treatments for these conditions, such as benzodiazepines or tricyclic antidepressants, may help (Table 102-3). Dopamine agonists, selective serotonin reuptake inhibitors, and topiramate have all been reported to help improve symptoms, although lack the support from large trials is a limitation as in the other parasomnia categories.[117,118] Patients with restless legs syndrome who also have SRED often responds to therapy with a combination of a dopaminergic agonist as well as an opiate or topiramate.[108,119] A typical starting dose of topiramate is 25 mg near bedtime, and titrated to clinical efficacy at an increasing dose of 25 mg every week.[120]

CLINICAL PEARLS

Disorders of arousal may place patients at high risk for sleep-related injuries and can adversely affect quality of life. Accordingly, health care providers need to adequately screen for, correctly classify, and appropriately manage these disorders. Investigation of nocturnal events can be challenging to even

Continued

CLINICAL PEARLS—cont'd

the most ardent clinician and requires careful attention to detail. Essential to any degree of therapeutic success are identification and elimination/treatment of predisposing factors including environmental issues, provoking medications and other substances, and concomitant sleep disorders. Minimization of stimuli in the bedroom including extraneous sounds and lights may limit occurrence of events. Alcohol remains a known precipitant for some arousal disorders, but its role in provoking somnambulism is controversial. Formal evaluation and treatment of other sleep disorders are key to successful management.[121,122-126]

SUMMARY

The disorders of arousal are a unique group of sleep disorders that share similar characteristics and have a common underlying pathophysiology. Successful amelioration of disturbing arousals will depend on accurate diagnosis, focusing on key distinguishing features, and appropriate treatment strategies. Often reassurance, addressing safety issues, and education are important for the less dramatic parasomnias. Safety precautions and good general sleep hygiene measures are vital recommendations, because such disorders can be exacerbated by sleep deprivation and various other factors. When the nocturnal episodes are frequent or involve aggressive or dramatic behaviors, pharmacotherapy with a benzodiazepine, particularly clonazepam, at night is the preferred approach with most of the disorders of arousal. Other therapy relies on the use of short-acting benzodiazepines, such as diazepam and alprazolam, or tricyclic antidepressantss in the case of sleep terrors. Relaxation training and guided imagery may be helpful strategies for some patients, especially those with disorders of arousal.

Rapid Eye Movement Sleep Parasomnias

Michael H. Silber; Erik K. St. Louis; Bradley F. Boeve

Chapter 103

Chapter Highlights

- Rapid eye movement (REM) sleep behavior disorder (RBD) is a unique parasomnia characterized by loss of REM sleep atonia and dream enactment behavior. This chapter explores the epidemiology, clinical features, pathophysiology, diagnosis, and management of the condition.
- RBD is associated with the group of neurodegenerative disorders known as the synucleinopathies, including Parkinson disease, dementia with Lewy bodies, and multiple system atrophy. Robust evidence confirms that a majority of patients with idiopathic RBD also harbor synucleinopathy pathology. Other etiologic factors include the use of antidepressants and certain autoimmune disorders.
- RBD is diagnosed through clinical history and polysomnography. Quantitative assessments of muscle tone in REM sleep can result in greater diagnostic accuracy. Management includes addressing bedroom safety and the use of medications such as melatonin and clonazepam.
- Other REM sleep parasomnias include nightmare disorder, recurrent isolated sleep paralysis, and sleep-related painful erections. The epidemiology, clinical features, and management of the latter two conditions are discussed in this chapter.

RAPID EYE MOVEMENT SLEEP BEHAVIOR DISORDER

Overview

Rapid eye movement (REM) sleep comprises a complex combination of phasic and tonic phenomena, including desynchronized electroencephalographic activity, rapid eye movements, dreaming, and skeletal muscle atonia (Figure 103-1). In disorders such as narcolepsy, these phenomena can dissociate, resulting, for example, in intrusion of muscle paralysis during wakefulness (cataplexy and sleep paralysis). Conversely, muscle tone can be retained in REM sleep, a finding known as REM sleep without atonia (RSWA) (Figure 103-2). This allows dream enactment motor activity to occur in the condition known as REM sleep behavior disorder (RBD).

The first description of such a dissociated state was in experimental cats in which introduction of pontine lesions resulted in motor behaviors during REM sleep.[1] Retained muscle tone in REM sleep caused by clomipramine was described in human subjects in 1972.[2] Similar findings were reported in sleep during alcohol withdrawal, a state given the name "stage1-REM sleep."[3] The definitive descriptions of the disorder, as well as its name, are attributed to Carlos Schenck and Mark Mahowald, who published reports of 10 cases in 1986 and 1987, 3 associated with neurodegenerative disorders.[4,5] Extensive subsequent studies of the clinical features, pathophysiology, etiology, and management have led to a deeper understanding of the complexity and broad implications of this unique parasomnia.

Epidemiology

The prevalence of RBD is uncertain. In a Hong Kong community-based study of 1034 subjects 70 years of age or older, prevalence of RBD was estimated at 0.38%.[6] Telephone interviews of 19,961 European subjects suggested a prevalence of sleep-related violent behavior of 1.6%; the study authors estimated that less than 0.5% had RBD.[7] RBD becomes more frequent with increasing age. In population-based RBD prevalence studies, the age- and sex-adjusted estimate for polysomnography-confirmed RBD in a Korean population aged 60 years or older was 2.01%, and the idiopathic RBD (iRBD) prevalence estimate was 1.34%.[8] In Olmsted County, Minnesota, the prevalence of probable RBD symptoms reported by bed partners of persons aged 70 to 99 years was 8.9%.[9]

RBD occurs more frequently in men. Pooled data for 514 patients in six series from the United States, Europe, and China indicate a male predominance of 78%.[10-15] This difference is less marked in patients with RBD younger than 50 years of age (52% to 59% of affected men).[12,13,16] RBD commences most frequently in middle-aged to older persons; the mean age at onset of symptoms ranged between 45 and 61 years in several large series,[10-13] and the mean age at diagnosis, between 52 and 65 years.[10-13,15]

In a questionnaire series of 316 patients with iRBD, a proxy-reported family history of presumed RBD was found in 13.8% of cases, compared with 4.8% of control subjects.[17] An environmental risk factor study of 347 patients with iRBD

Figure 103-1 Normal REM Sleep Atonia. A 30-second polysomnogram epoch demonstrates normal REM sleep levels of atonia in submentalis, arm, and anterior tibialis leg leads on the electromyogram (EMG).

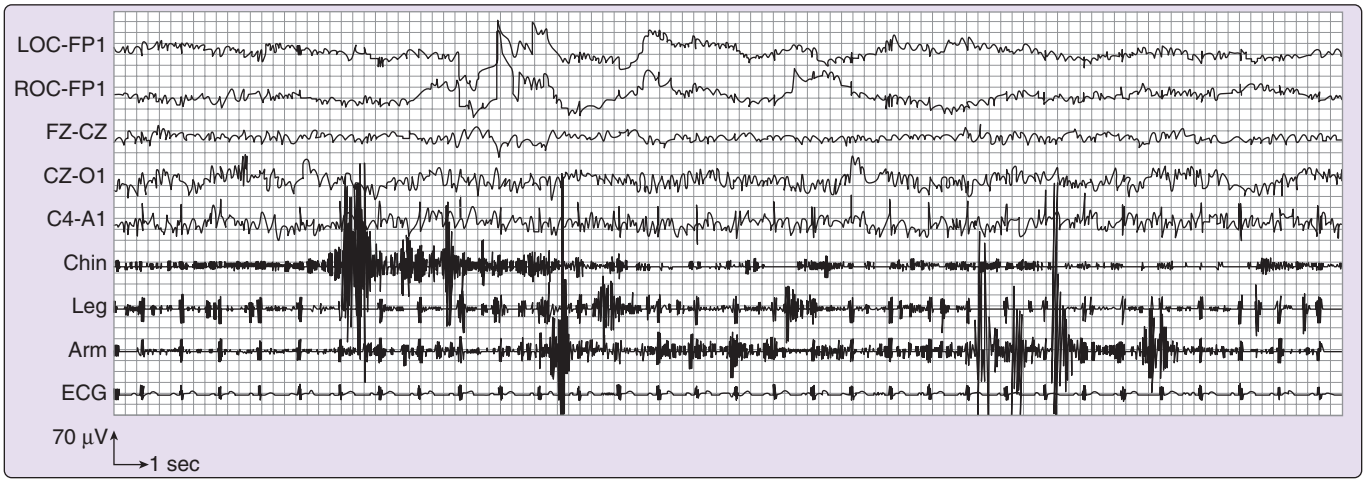

Figure 103-2 Abnormal REM Sleep without Atonia (RSWA). Increased phasic/transient muscle activity is shown in the submentalis, anterior tibialis, and arm electromyographic leads in this 30-second polysomnogram epoch. A more sustained lower-grade elevation of muscle tone lasting for longer than one half of the epoch represents abnormal tonic muscle activity, seen in the submentalis and arm channels of the electromyogram (EMG).

found cigarette smoking, previous head injuries, farming occupation, and pesticide exposure to be associated with RBD more frequently than in control subjects.[18] Although most of these factors also have been linked to Parkinson disease, smoking, by contrast, is associated with lower risk for Parkinson disease.[19]

Clinical Features

Patients with RBD exhibit abnormal motor behaviors during REM sleep, predominantly while in bed. These behaviors include talking, screaming, swearing, gesturing, arm flailing, punching, kicking, and leaping or falling off the bed.[11,20] Walking or running away from the bed occurs in 11% of patients, in addition to the more typical in-bed activities.[11] Although violent behaviors are most common, nonviolent activities such as laughing, whistling, singing, and masturbation occur at times in 18% of patients.[21] Self-injuries are reported in 32% to 76% of patients,[11,13,20,22] including lacerations, ecchymoses, limb fractures, and subdural hematomas[11,22,23] requiring medical attention in approximately 11% of the cases. Injuries occur when patients fall off the bed or strike the limbs against the wall, a headboard, or bedside furniture. Occasional patients have attempted to leap through a window.[11,24] Sixty-four percent of bed partners report being assaulted, and many have been injured.[11,22] Injurious behaviors include punching, slapping, kicking, pulling of hair, and attempted strangulation.[6,11,24,22] Periorbital hematomas and dental injuries have been reported.[5,11] Not understanding the organic nature of the disorder, patients and their partners often are mortified by the behaviors; some patients have built elaborate barriers in their beds or even slept in restraints to avoid injuring their spouse.[11,25] The frequency and severity of

behaviors are highly variable. In some patients with concomitant neurodegenerative disorders, the frequency of events appears to diminish over time, for uncertain reasons.[11,26]

Dream content changes in RBD and becomes more violent in nature in most cases. In a series of 93 cases, dreams involved defense of the sleeper against attack in 80% (65% human assailants and 35% animals), defense of relatives against attack in 7%, adventures in 9%, sporting activities in 2%, but aggression by the dreamer in only 2%.[11] In a study of 98 dreams reported by patients with RBD compared with 69 control dreamers, the RBD dreams featured a higher level of aggression and a higher frequency of animal characters.[27] Despite the aggressive nature of the dreams, daytime aggressiveness questionnaire scales have yielded findings in the normal range[28] or have even shown lower values on the physical aggressiveness subscale than for control data.[27]

Etiology and Associated Disorders

Association with Neurodegenerative Disorders

Synucleinopathies are a group of neurodegenerative disorders in which the protein alpha-synuclein accumulates abnormally to form inclusions in the cell bodies or axons of neurons or oligodendrocytes. The synucleinopathies include Lewy body disease—manifested as phenotypes of Parkinson disease, dementia with Lewy bodies, or pure autonomic failure—and multiple system atrophy. Associated RBD is very common in these disorders, and increasing evidence suggests that most cases of apparent iRBD are due to otherwise asymptomatic synucleinopathies.

Parkinson disease, characterized clinically by often asymmetric rest tremor, rigidity, bradykinesia, and postural instability responsive to levodopa, is associated on histopathologic examination with α-synuclein–containing intraneuronal Lewy bodies in substantia nigra and other structures, with resultant degeneration of the dopaminergic nigrostriatal pathway.[29] The reported frequency of RBD in Parkinson disease ranges between 15% and 65%.[30-34] Clinical features of Lewy body dementia differ from those of Alzheimer disease and may include impaired attention and visuospatial organization, fluctuating course, visual hallucinations, parkinsonism, delusions, and depression.[35] Lewy bodies are found in cortical, limbic, and substantia nigra neurons. When dementia develops later in the course of Parkinson disease, the designation Parkinson disease with dementia is used. Patients with dementia and RBD have clinical and psychometric features much more suggestive of Lewy body dementia than of Alzheimer disease.[36-38] The frequency of RBD in dementia with Lewy bodies is reported to be 68% to 80%.[39]

Multiple system atrophy is a neurodegenerative disorder with dysautonomia and variable combinations of parkinsonism (poorly responsive to levodopa) and dysfunction of the cerebellar and corticospinal systems.[40] Sleep-disordered breathing, including obstructive sleep apnea (OSA), central sleep apnea, and nocturnal stridor, is common. In contrast with Parkinson disease and dementia with Lewy bodies, alpha-synuclein is found in non–Lewy body inclusions in oligodendrocytes. RBD occurs in 60% to 90% of patients with multiple system atrophy, both the cerebellar and the parkinsonian phenotypes.[41,42]

Many cross-sectional studies have demonstrated that patients with the apparently idiopathic form of RBD have physiologic and imaging abnormalities suggestive of the prodromal phase of a synucleinopathy[43] (Table 103-1). Loss of olfactory function has been noted in 58% to 93% of patients with iRBD, significantly more than in control subjects[44-46] and similar to that in patients with Parkinson disease.[47] Similarly, abnormalities in color vision have been detected both in patients with iRBD and in those with Parkinson disease.[48] The presence of abnormalities of olfaction and color vision in patients with iRBD at baseline increases the risk of phenoconversion to parkinsonism or dementia over 5 years.[49] Autonomic symptoms[50,51] and abnormalities on tests of cardiovascular autonomic function[51-54] are more frequent in patients with iRBD than in control subjects. Subtle abnormalities in motor function, including altered gait and decreased hand dexterity, have been detected in patients with iRND.[51,55] Abnormalities in visuospatial abnormalities are evident on cognitive testing,[56] and electroencephalogram (EEG) spectral analysis has demonstrated increased theta power during wakefulness, decreased beta power during REM sleep,[57] and increased delta power in NREM sleep[56] compared with control data.

A range of advanced imaging studies have shown abnormalities in patients with iRBD, particularly in the nigrostriatal system implicated in parkinsonism (Table 103-1). Transcranial sonography has shown midbrain hyperechogenicity in 36% to 63% of patients with iRBD[45,47,57-59]—a finding also noted in patients with Parkinson disease. Single photon emission tomography (SPECT) scans with use of the tracer ^{123}I-fluoropropyl (FP)-CIT (2β-carbomethoxy-3β-[4-iodophenyl]-N-[3-fluoropropyl]-nortropane) or ^{123}I-IPT ([N]-[3-iodopropene-2-yl]-2beta-carbomethoxy-3beta-[4-chlorophenyl] tropane) have shown reduction of striatal dopamine transporters in 36% to 40% of patients with iRBD.[45,59,60] Reduced activity has been associated with progression to a

Table 103-1 Prodromal Features of Fully Expressed Synucleinopathies in Patients with Idiopathic Rapid Eye Movement Sleep Behavior Disorder (iRBD)

Physiologic Abnormalities
Reduced olfaction
Reduced color vision
Autonomic dysfunction (symptoms, cardiovascular tests, ^{123}I-MIBG myocardial scintigraphy)
Motor dysfunction
Cognitive dysfunction
EEG power abnormalities
Imaging Abnormalities
Midbrain—transcranial sonography
Striatal dopamine transporters—SPECT scans
Putaminal volume—MRI scans
Parkinson disease–related covariance pattern—PET and SPECT scans
Hyper- and hypoperfusion of various brain regions—SPECT scans
Pons and midbrain abnormalities—MRI diffusion tensor imaging
Hippocampal gray matter—voxel-based morphometry
Cerebellum and pontine tegmentum—voxel-based morphometry

EEG, Electroencephalogram; MIBG, metaiodobenzylguanidine; MRI, magnetic resonance imaging; PET, positron emission tomography; SPECT, single photon emission computed tomography.

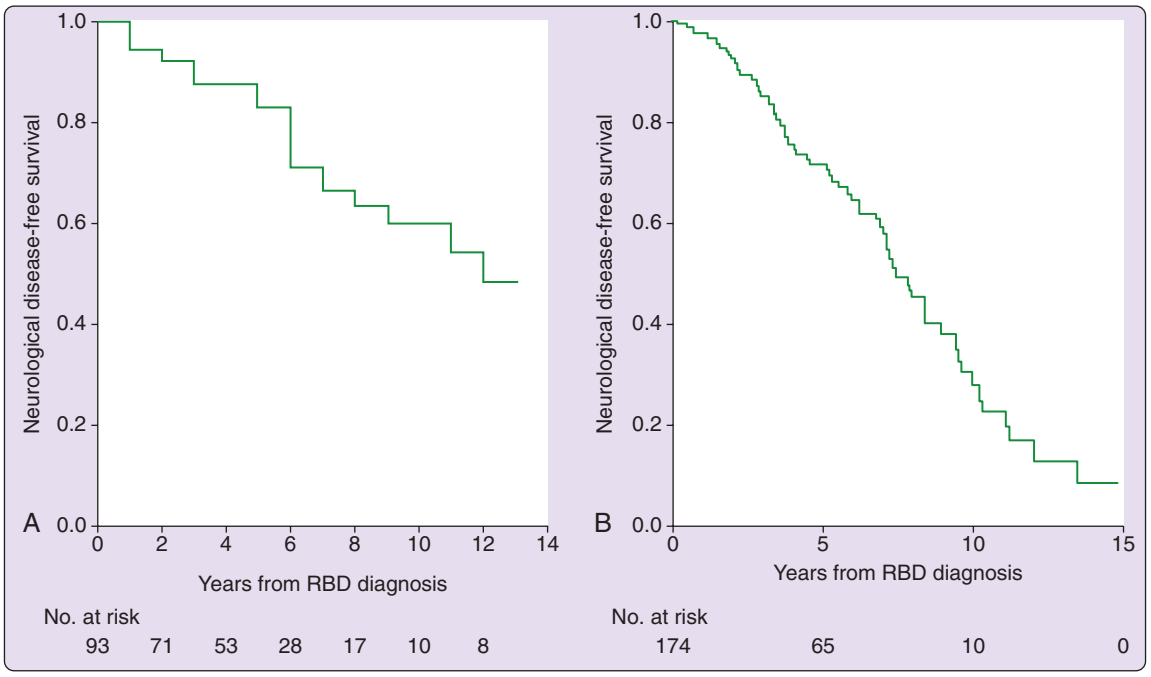

Figure 103-3 Progression from Idiopathic REM Sleep Behavior Disorder (RBD) to Fully Developed Synucleinopathies. Kaplan-Meier curves showing the rate of progression from idiopathic RBD to fully developed synucleinopathies in two studies. (**A,** Modified from Postuma RB, Gagnon JF, Vendette M, et al. Quantifying the risk of neurodegenerative disease in idiopathic REM sleep behavior disorder. *Neurology* 2009;72: 1296–1300, with permission.[72] **B,** Modified from Iranzo A, Fernandez-Arcos A, Tolosa E, et al. Neurodegenerative disorder risk in idiopathic REM sleep behavior disorder: study in 174 patients. *PLoS One* 2014;9:e89741, with permission.[74])

fully expressed synucleinopathy.[59,61] In volumetric measurements on 3T magnetic resonance imaging (MRI) scans, putaminal volumes were smaller in patients with iRBD than in control subjects.[62] ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET) and ethyl cysteinate dimer (ECD) SPECT scans assessing a brain network known to be abnormal in Parkinson disease (i.e., Parkinson disease–related covariance pattern) showed similar increased activity in patients with iRBD, and those exhibiting such abnormalities had a greater likelihood of subsequent phenoconversion to Parkinson disease or dementia with Lewy bodies.[63] SPECT scans with ^{99mc}Tc ECD in patients with iRBD have shown variable changes in multiple brain regions compared with control subjects.[64-66] MRI diffusion tensor imaging has shown abnormalities in the pons and midbrain of patients with iRBD,[67,68] and two studies of voxel-based morphometry have shown inconsistent changes in various brain regions.[67,69]

These data conclusively indicate that many patients with iRBD have abnormalities found in fully expressed synucleinopathies and that the presence of some of these changes predicts phenoconversion to parkinsonism or dementia. The rate of such conversion has been assessed in several prospective studies. A parkinsonian disorder emerged over a mean of 3.7 years in 38% of 29 men with iRBD diagnosed after the age of 50 years.[70] When the same cohort was reassessed 16 years later, parkinsonism or dementia had developed in 80.8%, with a mean of 14.2 years from iRBD onset to phenoconversion.[71] In a study of 93 patients (80% men) with iRBD, parkinsonism or dementia developed in 28% over a mean of 11.5 years from iRBD onset.[72] A survival analysis estimated the risk of phenoconversion at 10 years from polysomnographic diagnosis of RBD to be 40.6% and at 12 years from diagnosis, 52.4% (Figure 103-3, *A*). A similar survival analysis of a cohort of 44 patients with iRBD followed for a mean of 10.5 years since diagnosis estimated a 34.8% rate of conversion at 5 years, 73.4% at 10 years, and 92.5% at 14 years.[73] In a larger series of 174 patients with iRBD from the same center followed for a mean of 4 years from diagnosis, survival analysis predicted phenoconversion rates of 33.1% at 5 years, 75.7% at 10 years, and 90.9% at 14 years (Figure 103-3, *B*).[74] Thus it appears that parkinsonism or dementia will develop in most patients with iRBD if they live long enough. A significant conversion rate has been confirmed in the only community-based study of 44 neurologically normal subjects with iRBD aged 70 to 89 years. After a median of 3.8 years, mild cognitive impairment, generally a precursor of dementia, had developed in 14, and Parkinson disease in 1. Compared with that in control subjects, the risk of phenoconversion estimated by hazard ratio was 2.2 (range, 1.3 to 3.9).[75] The latency between the onset of iRBD and phenoconversion can be extremely prolonged. A retrospective study of 27 patients diagnosed with iRBD at least 15 years before development of a fully-expressed neurodegenerative syndrome found a median interval of 25 years and a maximum interval of 50 years.[76]

RBD occasionally has been reported in other neurodegenerative disorders that are not synucleinopathies. In a series of 45 patients with clinically diagnosed progressive supranuclear palsy (PSP), a disorder associated with tau protein inclusions, 13% were reported to have polysomnography-confirmed RBD, and another 14%, RSWA.[77] By contrast, none of the bed partners of nine patients with PSP, one with the diagnosis subsequently confirmed pathologically, reported the presence of dream enactment behavior.[78] In a series of 15 patients with clinically diagnosed Alzheimer disease, 1 patient (7%) had

polysomnography-confirmed RBD, and 27%, RSWA.[79] However, the pathologic changes of Lewy body dementia and Alzheimer disease often occur concurrently in patients with suspected Alzheimer disease, and this may not be diagnosable ante mortem. RBD also has been described in association with Huntington disease[80] and with Guadeloupean parkinsonism, another tauopathy.[81]

The association of RBD with synucleinopathies has been confirmed in an international study of 172 patients with RBD, diagnosed either clinically or by polysomnography, who subsequently underwent autopsy.[82] Synucleinopathies were found in 93% (95% of 82 patients with polysomnography-confirmed RBD). These included 82% with Lewy body pathology (34% with concomitant Alzheimer-type changes) and 11% with multiple system atrophy. In the group with polysomnographic confirmation, Alzheimer disease alone was found in only one patient, and PSP in another. In one patient with iRBD who died without the development of another overt neurologic disease, pathologic changes of Lewy body disease were found at autopsy, confirming an earlier reported similar case.[83] Whether a specific neurodegenerative disorder is associated with RBD appears to depend on the propensity for the disorder to involve pontomedullary neurons, and not on the chemistry of the accumulating protein. This issue is discussed further in the subsequent Pathophysiology section.

Association with Other Neurologic Disorders

REM sleep motor dyscontrol is a common feature of narcolepsy.[xx] On the basis of data obtained in a questionnaire and telephone interview study, 35% of 55 narcoleptic patients were suspected of having RBD.[84] Polysomnography studies in narcoleptic patients have suggested frequencies of RBD from 36% to 43%.[85] RBD starts at a younger age than in patients without narcolepsy[86] and may be present at the start of the illness.[87]

RBD has been described in several rare paraneoplastic and autoimmune encephalopathies. Voltage-gated potassium channel complex antibodies are associated with limbic encephalitis and Morvan syndrome, a disorder characterized by profound insomnia, dysautonomia, and peripheral neuromuscular irritability, sometimes associated with tumors such as malignant thymoma. RBD has been described in patients with both phenotypes.[88,89] Ma1 and Ma2 autoantibody–related encephalopathies are associated with testicular and other cancers. The clinical phenotype may include narcolepsy and RBD.[90,91] A newly described autoantibody directed against IgLON5, a neuronal cell adhesion molecule, is associated with a distinctive neurologic syndrome characterized by progressive gait disturbances, bulbar symptoms, stridor, central hypoventilation, dysautonomia, and abnormal ocular movements.[92] All eight affected patients exhibited abnormal movements during REM and NREM sleep, with RBD being diagnosed in the four patients in whom REM sleep was recorded during polysomnography. In one series of patients with iRBD, systemic autoimmune disease seemed to be common in women with RBD.[93] However, a controlled study of 318 patients with iRBD did not reveal a higher frequency of autoimmune diseases in the RBD group.[94]

RBD also has been described in patients with a range of other neurologic disorders, including Machado-Joseph disease (spinocerebellar atrophy type 3),[95] adult-onset autosomal dominant leukodystrophy,[96] myotonic dystrophy type 2,[97] autism,[98] Tourette syndrome,[99] Möbius syndrome,[100,101] and Smith-Magenis syndrome.[101] Structural brainstem lesions occasionally may cause RBD, including multiple sclerosis,[102] astrocytomas,[101] acoustic neuroma,[103] vascular malformations,[104,105] central nervous system vasculitis,[106] and cerebral infarcts.[107,108]

Association with Antidepressants

RSWA[109,110] and RBD[12,111,112] have been related to antidepressant use. In comparison with patients with iRBD not taking antidepressants, RBD commenced earlier in patients in the antidepressant group, which also had a higher percentage of women.[113] In a study of early- versus late-onset RBD, the frequency of psychiatric diagnoses and antidepressant use was higher in the early-onset group.[16] A multicenter, controlled study that included 318 iRBD cases showed a higher percentage of depression and antidepressant use for the RBD group.[94] Various hypotheses have been suggested to explain this apparent association.[16,114] Antidepressants might cause RBD idiosyncratically in a minority of treated patients through a mechanism unrelated to synucleinopathies. Alternatively, antidepressants might unmask RBD in patients with otherwise subclinical synucleinopathies, resulting in an earlier presentation of RBD. Finally, antidepressant use may be a surrogate marker for depression, which is known to be an independent prodromal feature of synucleinopathies.[115] To address these possibilities, 100 patients with iRBD, 27 of whom were taking antidepressants, were followed for a mean of 4.5 years.[114] The groups with and without antidepressants showed the same frequency of abnormalities in olfactory, color vision, autonomic, and motor tests, suggesting that the antidepressant group patients were no more predisposed to development of a fully expressed synucleinopathy. However, the rate of phenoconversion to a diagnosis of a fully expressed synucleinopathy was slower in the antidepressant group, implying that RBD had emerged earlier than it would have if the patients were not taking antidepressants. By contrast, if depression were the initial manifestation of a synucleinopathy, one might have predicted phenoconversion to occur at least at the same rate as for the group not taking antidepressants, and perhaps faster.

Association with Other Drugs

An acute, transient form of RBD induced by withdrawal from barbiturates[116] and ethanol[117] has been described. Beta blockers[119] and caffeine abuse[120] also may possibly induce RBD.

Pathophysiology

The primary generator of REM sleep lies in the lateral pontine tegmentum in a small area ventral and slightly rostral to the locus coeruleus. Depending on researchers and species studied, the region has been termed the subcoeruleus nucleus, perilocus coeruleus alpha, sublateral dorsal tegmental nucleus, or nucleus reticularis pontis oralis.[118,119] Predominantly glutamatergic neurons in the vicinity of this nucleus are responsible for the atonia of REM sleep. These neurons project both directly to inhibitory interneurons in the ventral horn of the spinal cord and also to neurons in the ventromedial medulla, including the gigantocellular and magnocellular neuronal groups.[118,120] The spinal interneurons and ventromedial medullary neurons inhibit anterior horn cells in the ventral horn of the spinal cord by release of the inhibitory

neurotransmitters glycine and gamma-aminobutyric acid (GABA), resulting in skeletal muscle atonia.[118,119] Theoretically, then, RBD could arise from interruption of these pathways at pontine, medullary, or spinal cord levels.

Various animal models confirm these hypotheses, illustrated by the following examples.[121] Bilateral pontine tegmental lesions in cats cause loss of REM atonia and dream enactment behavior, depending on the exact site and extent of the lesions.[122] Loss of REM atonia and complex motor behavior in REM sleep are seen in rats with lesions in the sublateral dorsal nuclei in the pons.[123] Lesions of the medullary gigantocellular nuclei result in loss of REM atonia in cats.[124] Transgenic mice expressing reduced glycine and GABA inhibitory activity exhibit motor behaviors during REM sleep with loss of REM atonia.[125] In humans, rare cases of focal lesions in the pontine tegmentum have been reported to cause RBD.[102,104,106,126,127] In Parkinson disease, Lewy bodies are found in neurons in the subcoeruleus nuclei in the pons and magnocellular reticular formation in the medulla.[128] In an MRI study of 24 patients with Parkinson disease, 12 with RBD and 12 without, reduced signal intensity was seen in the locus coeruleus–subcoeruleus complex, more marked in the subgroup with RBD.[129] The degree of signal intensity reduction correlated with the percentage of abnormal muscle tone in REM sleep.

This model fits with the Braak staging scheme for the pathologic features of Parkinson disease.[130] In this scheme, pathologic changes of Lewy body disease develop first in the dorsal nucleus of the vagus in the medulla and the olfactory bulb—stage 1—and subsequently ascend to affect pontomedullary structures, including the magnocellular and sublateral dorsal nuclei—stages 2 and 3. Only in stage 4 is substantia nigra involved, resulting in overt parkinsonism, whereas mild cognitive impairment and dementia develop with cortical involvement in stages 5 and 6. This anatomic progression can explain the phenomenon of iRBD being in many cases a prodrome for the later development of Parkinson disease. Experimental evidence suggests that this relatively stereotypical progression of pathology may be explained by a prionlike mechanism whereby alpha-synuclein aggregates can be induced transneuronally and serve as templates for further misfolding of the protein and subsequent neurodegeneration.[131] Clearly the Braak staging scheme does not fit all cases of Lewy body disease. In some patients with Parkinson disease, RBD develops simultaneously with the onset of parkinsonism or thereafter,[11] whereas in Lewy body dementia, cognitive impairment precedes definite parkinsonism.[128] Further animal and human studies are needed to define more precisely the nature of progression in RBD-associated neurodegeneration.

Diagnosis

Diagnostic criteria for RBD include the presence of RSWA (Figure 103-2) on polysomnography, sleep-related injurious or potentially injurious disruptive behaviors by history, and/or abnormal REM sleep behaviors during polysomnography, absence of epileptiform activity during REM sleep (unless RBD can be clearly distinguished from any concurrent REM sleep–related seizure disorder), and no better alternative explanation for the sleep disturbance.[132] In view of the resource-intensive nature of confirmatory polysomnography, however, a designation of "probable RBD" can be applied to patients presenting with a clear-cut clinical history of dream enactment behaviors but lacking polysomnographic evidence for RSWA, either owing to unavailability of the test or on account of the failure of polysommnography to record REM sleep. Also, because dream enactment is only rarely captured during in-laboratory polysomnography, RBD diagnosis usually instead relies on the history of dream enactment behaviors, together with recording of RSWA.[132,133]

For use in epidemiologic research studies or clinical practices without readily accessible polysomnography, well-validated questionnaire screening instruments for probable RBD are available.[134-141] The REM Sleep Behavior Disorder Single-Question Screen (RBD1Q) poses a single "yes/no" question about dream enactment, providing 93.8% sensitivity and 87.2% specificity for RBD diagnosis in Parkinson disease in a large, multicenter validation study.[137] The Mayo Sleep Questionnaire (MSQ), a screening questionnaire that can be administered to either the patient or the bed partner, is another well-validated tool, with an Informant (Bedpartner) Version being particularly useful in older patients.[141,142] The MSQ-Informant (Bedpartner) Version is 100% sensitive and 95% specific[141] and the MSQ-Patient Version is 100% sensitive and 73% specific for RBD diagnosis.[143] The RBD-HK poses 13 questions about the frequency and severity of dream enactment behavior, with a cutoff score of 18 of 100 possible points yielding positive and negative predictive values greate than 80%.[135] The REM Sleep Behavior Disorder Screening Questionnaire (RBDSQ) is a 10-item questionnaire self-rated by the patient with scores ranging from 0 to 13 points, yielding average scores of 9.5 in patients with RBD and 4.6 in control subjects without RBD.[135] Despite the usefulness of these measures for screening purposes, excluding mimickers of RBD (e.g., OSA with atypical arousals during REM sleep, NREM sleep parasomnias, and nocturnal epilepsy) is difficult and usually requires confirmation of RSWA by polysomnography.[14,28,132,144-147]

Polysomnographic RSWA manifests in submentalis, anterior tibialis, and arm leads of the electromyogram (EMG), especially flexor digitorum superficialis (FDS) and biceps brachii.[132,148-150] An expanded EMG montage, including the FDS, biceps, and abductor pollicis brevis muscles, has been shown to be most sensitive for identifying RSWA.[149,150] The prevailing "gold standard" for RSWA determination is the use of visual scoring methods as first proposed in 1992,[151] with subsequent modifications.[132,149,150,152,153] RSWA is classified as either excessive phasic (transient) or tonic muscle activity (Figure 103-2). Phasic RSWA is scored when a 3-second "mini-epoch" (with each 30-second epoch containing 10 mini-epochs) contains phasic (transient) muscle activity bursts exceeding the REM background EMG amplitude by a factor of at least four, and lasting at least 0.1 second.[132,148,151,152] The American Academy of Sleep Medicine has defined abnormal RSWA as the presence of five or more 3-second mini-epochs containing excessive measured phasic (transient) muscle activity within a single 30-second REM epoch.[132] Tonic muscle activity is scored when the REM EMG background exceeds twice the background voltage amplitude and lasts longer than 15 seconds within a 30-second epoch.[132,148,152] The designation "any" referring to muscle activity percentage, which includes either phasic, tonic, or both activities present within a 3-second mini-epoch, is a more inclusive and more easily applied metric for clinical use.[152,153] Percentage muscle activity for phasic, tonic, and "any" muscle activity is then determined by dividing the total number of 3-second mini-epochs (for phasic and

"any") EMG activity and the number of 30-second tonic epochs by total REM time.[148,152,153] Many studies have shown clear elevations of phasic and tonic muscle activity in patients with RBD over that in control subjects without RBD, with diagnostic cutoffs determined for both individual and combined muscles.[148,152-155]

Various phasic, tonic, and "any" density cutoff values have been established for RBD diagnosis with 100% specificity. The SINBAR ("Sleep Innsbruck Barcelona") group of investigators has proposed a 31.9% "any" muscle activity cutoff for RBD diagnosis using combined submentalis and bilateral FDS EMG derivations.[152] A 43.4% "any" muscle activity diagnostic cutoff has been suggested for the commonly used combined submentalis and anterior tibialis EMG derivations from either split- or full-night polysomnograms in patients with RBD plus concomitant OSA.[153] Measuring the phasic muscle burst duration was found to further help distinguish patients with RBD from control subjects.[153]

Abnormal levels of RSWA also may be found incidentally during polysomnogram recordings in patients without dream enactment behavior, especially in patients taking antidepressants.[156,157] The significance of incidental RSWA for future development of dream enactment or neurodegeneration is unknown although anecdotal cases of progression to synucleinopathy have been reported.[136] RSWA without clinical dream enactment occurs frequently in Parkinson disease and other synucleinopathies, suggesting that additional lesions in other structures may be required to mediate full RBD.[31]

Considerable progress has been made in the development of computerized automated methods for RSWA analysis, including the REM Atonia Index,[154,155] an enveloping technique for mentalis short- and long-duration muscle activity measurement,[158] and an automated SINBAR method analyzing combined submentalis and FDS muscle activity.[159] Diagnostic yield comparable to that for visual RSWA scoring methods has been demonstrated for the REM Atonia Index[153,154,160] and automated SINBAR methods.[159] A disadvantage of the visual methods is their labor-intensiveness, but validation of automated RSWA methods for limb, as opposed to mentalis, muscles is limited.[159]

REM Sleep Behavior Disorder Variants

RBD has been described in association with three variant syndromes in which dream enactment and RSWA are associated with other parasomnias or disturbances of sleep architecture. Overlap parasomnia disorder is characterized by overlapping clinical features of both NREM disorder of arousal parasomnias (such as sleepwalking, night terrors, confusional arousals, or related events including sleep eating or sexsomnia behaviors) and RBD.[161,162] A recent review of 144 cases suggested that overlap parasomnia disorder is a distinct clinical entity. In 69% of patients with this disorder, the RBD plus parasomnia was idiopathic, with an earlier age at onset than for patients with typical RBD alone. Patients with overlap parasomnia exhibited more prominent NREM than REM parasomnia characteristics, with RBD either being mild or discovered incidentally.[163] The association of overlap parasomnia with synucleinopathies also appears to be less clear than for typical RBD, although overlap parasomnia has been described in Parkinson disease. Further research is necessary to clarify whether overlap parasomnia has a natural history different from that for typical RBD.[164]

Status dissociatus is a rare condition involving completely eroded wake and sleep state boundaries, with resultant disturbances in vigilance, cognitive functioning, and sleep motor control. Conventional sleep stage scoring during polysomnography is almost impossible owing to the characteristic admixture of neurophysiologic features of wake, NREM, and REM sleep states.[165,166] Agrypnia excitata is another rare, closely related condition with the distinctive features of inability to fall asleep coupled with excessive motor and autonomic hyperactivity. Polysomnography in agrypnia excitata shows absence of N3 sleep, spindles, and K complexes, with persisting N1 architecture and brief periods of REM sleep with loss of normal atonia.[167] Oneiric behaviors (complex motor acts resembling simple daytime activities and gestures, such as chewing, hair combing, or pointing) also are characteristic of agrypnia excitata.[168] Status dissociatus may be seen in certain pontomesencephalic brain lesions and late-stage neurodegenerative disorders, including multiple system atrophy and other synucleinopathies. Agrypnia excitata is thought to arise from thalamic-limbic dysfunction associated with delirium tremens, fatal familial insomnia, and certain autoimmune encephalopathies including voltage-gated potassium channel antibody (Morvan) syndrome.[169] Clonazepam has been reported to be effective in the treatment of status dissociatus[165]; treatment approaches for agrypnia excitata beyond supportive care have not been described.

Differential Diagnosis

Mimickers of RBD include nightmares, NREM parasomnias, nocturnal epilepsy, OSA with "pseudo-RBD"–type confusional arousals from REM sleep, and psychiatric disorders such as posttraumatic stress disorder (PTSD) or nocturnal panic disorder.[144,170,171] Patients with nightmare disorder may vocalize or move minimally during their dreams but dream enactment involving complex motor behaviors paralleling dream content usually is lacking. These patients do not exhibit RSWA during polysomnography. Nocturnal epilepsy, particularly frontal lobe or extratemporal seizures, may very closely mimic RBD in some cases, although nocturnal epilepsy usually is distinguished by relative stereotypy across events and lack of paralleling dream mentation.[170] Video EEG polysomnography, including a full EEG montage, is necessary in some cases to rule out nocturnal epilepsy with confidence. OSA may manifest with dream enactment behavior that subsides with successful nasal continuous positive airway pressure therapy, and in patients with OSA alone, without comorbid RBD, RSWA is not observed during polysomnography.[171] Psychiatric disorders such as PTSD and panic disorder are sometimes difficult to distinguish from RBD, although PTSD and panic disorder are not associated with RSWA. In keeping with the frequent association of RBD with comorbid depression, some patients may have both conditions. Confident RBD diagnosis requires a thorough clinical history and examination, as well as confirmation of RSWA by the "gold standard" of polysomnography.[14,132,144]

Management

The goals of RBD treatment are to reduce dream enactment behavior frequency and severity and to prevent injury. Bedroom safety principles should be advised for all patients, including removal or padding of bedside furniture with sharp corners, minimizing fall-related injury potential by

Table 103-2 Principal Treatments for Rapid Eye Movement Sleep Behavior Disorder (RBD)

Drug	Possible Mechanism of Action	Dose	Adverse Effect(s)
Clonazepam	$GABA_A$ receptor agonist	0.25–2 mg	Sedation, dizziness, sexual dysfunction, worsened sleep-disordered breathing
Melatonin	Unknown	3–15 mg	Sedation

$GABA_A$, Gamma-aminobutyric acid type A (receptor).

adding bed rails, lowering the mattress to floor level or placing cushions near the bed, erecting pillow barriers between the patient and the bed partner, and removing firearms from the bedroom.[136,144] A bed alarm system also may be useful to alert the patient or caregiver if the patient leaves the bed.[172]

Melatonin and clonazepam are the two mainstays of RBD pharmacologic treatment[11,173-176] and appear to be similarly effective in reducing dream enactment behaviors. However, although clonazepam and melatonin both effectively reduce RBD symptoms, these drugs only rarely actually stop the behaviors.[174] Consequently, the development of other novel agents to treat RBD is needed, including prospective comparative treatment trials.[177]

Clonazepam has been the traditional drug of choice for RBD, with a reported median effective dose between 0.25 and 2.0 mg at bedtime. Approximately 90% of subjects in open label studies reported a partial or complete response to the drug, but no controlled trials have been performed.[11,174-176,178] However, clonazepam has several adverse effects that may limit its application in most elderly patients, including worsened OSA, cognitive dysfunction, and dose-related adverse effects of sleepiness, dizziness, unsteadiness, and sexual dysfunction.[144,174] Both melatonin and clonazepam decrease polysomnographic motor activity during REM sleep.[151,175,176,179-182]

Several retrospective and small prospective studies support the use of melatonin treatment for RBD.[173,174,178,180,181,183-185] Melatonin may have a slightly more robust effect in reducing injuries, with fewer adverse effects,[174] although a prospective comparison with clonazepam has not been performed.[177] Melatonin may be more effective and tolerable in elderly patients, especially those with cognitive impairment or parkinsonism.[174] Adverse effects of melatonin include daytime sleepiness and dizziness, with headache and hallucinations occasionally reported.[173,174] Use of melatonin doses between 3 and 15 mg at bedtime (with occasional patients using doses up to 25 mg) has been reportedly effective, with a median dose of 6 mg[174] (Table 103-2).

Other drugs also have been reported to reduce RBD symptoms, including pramipexole,[186,187] zopiclone,[179] zonisamide,[188] donepezil,[189,190] ramelteon,[191] agomelatine,[192] memantine,[193] cannabidiol,[194] and the herbal supplement Yi-Gan San.[195]

OTHER RAPID EYE MOVEMENT SLEEP PARASOMNIAS

Nightmare Disorder

Nightmare disorder is discussed elsewhere in this book (see Chapters 53 and 104).

Recurrent Isolated Sleep Paralysis

Sleep paralysis has long been recognized in different cultures, often with postulation of a supernatural explanation.[196] It consists of an inability to move or speak at sleep onset, or on awakening from sleep, with at least partial preservation of consciousness. The trunk and all four limbs are affected.[197,198] The paralysis resolves after sensory stimulation, such as with someone touching the patient. At least initially, events usually are associated with severe anxiety.[197] Hypnagogic or hypnopompic hallucinations are experienced by 21% to 24% of patients with sleep paralysis.[199] Events occur more commonly on awakening than at sleep onset.[199] A large population-based European study suggested that sleep starts, sleep-related cramps, and sleeptalking were more common in patients with hypnagogic hallucinations than in control subjects.[199] Polysomnographic studies have suggested that sleep paralysis may occur during dissociated REM sleep, with persistence of consciousness and alpha activity intruding into the otherwise desynchronized REM sleep EEG.[196]

Sleep paralysis is common in narcolepsy but occurs frequently in isolation in the general population. Reported prevalence of sleep paralysis varies widely between studies, with higher rates reported in samples of students, patients with psychiatric illnesses, and patients with panic disorder.[200] The prevalence within a large population-based study of 8085 subjects was 6.2%.[199] Predictive variables for sleep paralysis included bipolar disorder and the use of anxiolytic medications. Sleep paralysis can start at any age, but onset may be most common during young adulthood and middle age.[199] A population study from Hong Kong suggested a bimodal age at onset, with peaks in adolescence and after age 60 years.[201] Familial sleep paralysis has been described, [197] with recognition of three- to four-generation families and a possible maternal inheritance pattern.[198]

Sleep paralysis should be considered a disorder only if it is recurrent and results in clinically significant distress including bedtime anxiety or difficulty initiating sleep.[132] Explanation and reassurance usually are sufficient to address the patient's concerns. Antidepressants occasionally have been tried, presumably to suppress REM sleep phenomena, but no adequately reported studies of pharmacologic interventions are available.

Sleep-Related Painful Erections

Sleep-related painful erections is a rare disorder of uncertain etiology. The mean age at diagnosis is 39.8 years, with symptoms present for a mean of 5.4 years.[202] Painful erections occur during REM sleep, usually nightly and sometimes several times a night.[203] Erections are painless during intercourse or

masturbation.[204] Structural abnormalities of the penis are not present. Polysomnography shows reduced sleep efficiency, increased wake time after sleep onset, and decreased percentage REM sleep compared with control data.[203] One study showed reduced vagal activity during sleep and a trend toward heart rate acceleration during spontaneous body movements.[203] Various medications have been reported to be effective for weeks to months in usually single-patient reports, including propranolol,[202] clozapine,[205] clonazepam,[206] baclofen,[206] and various antidepressants (amitriptyline,[206] paroxetine,[202] and venlafaxine[206]), but no controlled or systematic long-term study of management has been performed.

CLINICAL PEARLS

- RBD occurs predominantly in men (78% of patients), but this difference becomes less marked when the disorder commences before the age of 50 years.
- RBD can result in serious injuries to both patients and their bed partners, including fractures, subdural hematomas, ecchymoses, lacerations, and dental injuries.
- RBD is strongly associated with fully expressed synucleinopathies (Parkinson disease, dementia with Lewy bodies, and multiple system atrophy), and in most patients with idiopathic RBD, a fully expressed synucleinopathy will develop within 15 years of RBD diagnosis.
- Although both clonazepam and melatonin are effective in treating RBD, clonazepam has many side effects, especially in elderly and neurologically disabled persons, and melatonin should be the first drug tried in these patients.
- Recurrent isolated sleep paralysis may occur in 6% of the population but should be regarded as a disorder only if it results in significant distress including bedtime anxiety or difficulty initiating sleep.

SUMMARY

Dissociation of the phenomena characterizing the REM sleep state results in a number of disorders, with broad implications for elucidation of sleep and neurologic disease. Clinical and basic science research over the past 50 years has resulted in an understanding of RBD that exceeds that of any other parasomnia. It is an example of a sleep disorder in which the anatomic, physiologic, and pathologic substrate correlates closely with the clinical and polysomnographic manifestations. Increasingly sophisticated diagnostic tools are becoming available, and effective forms of management have emerged. RBD serves as a biomarker for the development of fully expressed synucleinopathies, and an important goal of future research will be finding therapeutic agents that may delay or prevent phenoconversion to overt neurodegenerative disorders. The contribution of antidepressants to the pathogenesis of RBD remains unsettled, and further studies are needed to determine definitively whether these drugs are primary etiologic agents or merely unmask an evolving synucleinopathy. Other REM parasomnias range from the very common (nightmares and sleep paralysis) to the rare (sleep-related painful erections). Further investigations of their pathophysiology and optimal management are needed.

Nightmares and Dream Disturbances

Isabelle Arnulf

Chapter Highlights

- Nightmares and nightmarish dreamlike content are not limited to rapid eye movement (REM) sleep.
- Most adults with arousal disorders occasionally remember dreamlike and nightmarish mental content associated and congruent with the motor episodes of sleepwalking or sleep terrors.
- Patients with REM sleep behavior disorders report enacted dreams containing more elements of aggression and animals, with behavior isomorphic to the dream content.
- In arousal disorders, patients often run out of the bed to avoid an imminent, life-threatening danger, whereas patients with REM sleep behavior disorders counterattack their dreamed attacker while staying recumbent in the bed.
- Patients with narcolepsy have long and intense dreams during sleep-onset REM periods (with pleasurable flying expeditions), with a high number of lucid dreams and nightmares. The multimodal hypnagogic hallucinations in narcolepsy suggest awake dreaming.

A 62-year-old patient experienced recurrent nightmares in which he was obliged to swallow several big, yellow snakes every night. As a consequence, he was scared of going to bed and delayed this moment every night. The patient interview revealed that he did not use any drug capable of producing these dreams and did not have posttraumatic stress disorder (PTSD), previous experience with snakes, sleep terrors, rapid eye movement (REM) sleep behavior disorder (RBD), or general nightmare disorder. However, with information provided by video polysomnography (PSG) and Multiple Sleep Latency Tests, the patient was discovered to suffer from hypnagogic hallucinations linked with a long-lasting form of narcolepsy. This case illustrates that patients complaining of nightmares or disturbed dreaming may not use the word "nightmare" as a sleep specialist would (i.e., restricting this word to REM sleep-associated nightmares). Patients use this word in various situations, including the classic REM sleep nightmare disorders, poststress disorders, distressing dreams linked with psychiatric conditions, and disturbed dreaming associated with drugs and substances, neurologic diseases or conditions (including hypnagogic hallucinations), sleep terrors, RBD, status dissociatus, and epic dreaming. The sensorial characteristics of their mental experience; its construction, timing, duration, and context; their associated behaviors, autonomic signs, ability to recognize the unreal nature of the experience, and associated disorders; and aspects and timing of PSG help to determine a diagnosis (Table 104-1). In terms of mechanisms, recent insights have shown that most of these disturbed mental experiences associated with neurologic diseases result from a dissociated sleep-wake state.

NIGHTMARE DISORDER

Diagnosis

Nightmare disorder is characterized by recurrent episodes of intense dysphoric dreaming (involving feelings of threat, anxiety, fear or terror, anger, rage, embarrassment, and disgust) that arise primarily during REM sleep and that often result in awakening. The episodes tend to occur during the second half of the major sleep episode when the REM pressure is most pronounced. Nightmare content most often focuses on imminent physical danger to the individual but may also involve other distressing themes. Most patients are able to detail the nightmare's contents on awakening. Nightmares are distinct from anxiety dreams, which are frightening dream experiences remembered only after waking in the morning. Nightmare disorder can lead to sleep avoidance and deprivation and thereby to more intense nightmares, which can produce insomnia. The disorder is distinguished from parasomnia-associated nightmares by the absence of enacted dreaming.

Epidemiology

Occasional nightmares are frequent in children (60% to 75%, beginning as young as 2.5 years old and peaking between 6 and 10 years old). Nightmares are repeated more than once a week in only 2% to 8% of children, but they often persist in adulthood. Girls and boys are equally affected until late adolescence, when girls are more affected than boys. About 4% of adults suffer from a nightmare disorder. The nightmare frequency is higher in psychiatric disorders, including PTSD, substance abuse, stress and anxiety, borderline personality, and other psychiatric illnesses, including schizophrenia spectrum disorders. Nightmares particularly occur immediately after a traumatic stress. Nightmares beginning within 3 months of a trauma are present in up to 80% of patients with PTSD. Approximately 50% of PTSD cases resolve within 3 months, but posttraumatic nightmares may persist throughout life. Recurrent nightmares may also be a deleterious effect of various drugs,[1] including antidepressants, antihypertensives (beta blockers, α-adrenergic receptor agonists, enalapril, losartan, verapamil), dopamine receptor agonists, cholinesterase blockers (donepezil, rivastigmine, tacrine), varenicline (a

Table 104-1 Causes and Semiology of the Complaints of "Nightmares" and Disturbed Dreaming in Neurologic Diseases

	Aspects	Associated Disorders
Vivid dreaming	Dreams of flight, nightmares Fights with animals, aggression	Narcolepsy Parkinson disease Dementia with Lewy bodies
	Associated with autonomic dysfunction and status dissociatus	Guillain-Barré syndrome
Hypnagogic hallucinations	Multimodal, frightening Often associated with sleep paralysis and REM sleep behavior disorder	Narcolepsy
	Presence, passage, visual hallucinations of humans and animals Visual, spatial tilt, auditory Associated with autonomic dysfunction and status dissociatus	Parkinson disease Dementia with Lewy bodies Guillain-Barré syndrome
NREM parasomnia	Associated with screams, tachycardia, sudden arousal, escaping from the bed; mostly misfortunes (buried alive, collapsing ceiling, life-threatening danger)	Sleep terrors Confusional arousals
REM parasomnia	Enacted dreams with aggression by humans or animals, kicking, boxing, shouting, swearing	REM sleep behavior disorder (idiopathic, parkinsonism, dementia, narcolepsy)
Status dissociatus	Continuously enacted dreams with visual hallucinations (patients may seem awake)	Guillain-Barré syndrome Delirium tremens Fatal familial insomnia Morvan chorea Neurodegenerative diseases

nicotinic acetylcholine blocker), and ganciclovir. Also, the withdrawal of REM sleep–suppressive agents (antidepressants, benzodiazepine, barbiturate, ethanol) or the end-of-night REM sleep rebound after using short-acting hypnotics such as zolpidem can promote nightmares.

Criteria

Patients with nightmare disorders should meet the following criteria: (1) repeated occurrences of extended, extremely dysphoric, and well-remembered dreams that usually involve threats to survival, security, or physical integrity; (2) rapidly becoming oriented and alert on awakening from the dysphoric dreams; and (3) clinically significant distress or impairment in social, occupational, or other important areas of functioning that is caused by the dream experience or the sleep disturbance produced by awakening from it.[2] The impairment may be demonstrated in a variety of ways, including mood disturbance, resistance or anxiety about sleep, cognitive impairments, behavioral problems, negative impact on family functioning, daytime sleepiness or fatigue, and impaired occupational, education, and social function.

Evaluation

Overnight PSG is not routinely used to assess nightmare disorder but may be appropriately performed to exclude other parasomnias or sleep-disordered breathing. Sleep recordings during actual nightmares occasionally show abrupt awakenings from REM sleep preceded by accelerated heart and respiratory rates. Of note, posttraumatic nightmares emerge both from REM (sometimes just after less than 1 minute of REM sleep) and non–rapid eye movement (NREM) sleep (including sleep onset). Highly disturbing dream content frequently contrasts strikingly with relatively minor autonomic changes (e.g., no visible tears) and no acting out of the nightmare (no shouting, no attempt to suddenly escape the bed), which constitute the main differences with sleep terrors (which happen only on emerging from N3 sleep). RBD appears in middle age and is characterized by enacted dreams of defense against aggressions (often with injuries). Hallucinations and sleep paralysis may be described as "nightmares," but they specifically occur at sleep onset and offset, and the paralysis affects the whole body and induces a dyspnea. Nocturnal panic attacks are not associated with a detailed mental imagery. Severe sleep apnea may be associated with disagreeable sleep-associated perceptions or images that resolve with the treatment of apnea.

Treatment

The best-established treatment of idiopathic nightmare disorder is image rehearsal therapy, whereas systematic desensitization and progressive deep muscle relaxation training are suggested.[3] There is lower grade evidence for using lucid dreaming therapy and self-exposure therapy. Among the treatment of PTSD-associated nightmares, prazosin carries a level A recommendation, whereas clonidine benefit is less clear. Treatments with lower grade evidence include several drugs (trazodone, atypical antipsychotic medications, topiramate, low-dose cortisol, fluvoxamine, triazolam and nitrazepam, phenelzine, gabapentin, cyproheptadine, and tricyclic antidepressants) and behavioral therapies (exposure, relaxation, rescripting therapy, sleep dynamic therapy, hypnosis, eye-movement desensitization and reprocessing, and the testimony method).

DREAMLIKE AND NIGHTMARISH MENTATIONS DURING NREM PARASOMNIAS

General Context

Sleepwalking and sleep terrors consist of a series of abnormal mental experiences and complex behaviors associated with

sudden adrenergic discharges that occur during partial awakening from slow wave sleep—hence their name *arousal disorders*.[2] Most motor episodes begin with raising the head, opening the eyes, and looking about in a confused manner, sometimes with verbal utterances, a condition referred to as *confusional arousals*.[4] Following this common pattern of behavior, sleepwalkers sit up in bed, stand up, and walk, usually in a quiet but confused manner, whereas patients with sleep terrors scream or display the behavioral and autonomic signs of intense fear, escape the bed as if to avoid imminent danger, or defenestrate. Sleepwalking and sleep terrors show considerable overlaps, including difficult arousal, mental confusion when awakened from an episode, complete or partial amnesia for the episode, and dangerous behaviors during the episode. Both disorders arise from slow wave sleep, frequently co-occur in the same family or patient, and have a strong genetic background.[5] An inventory of behaviors assessing their severity has been recently developed for sleepwalking and sleep terrors with good psychometric properties.[6]

Sleepwalking– and Sleep Terror–Associated Mentations

Contrary to common belief, most adults with sleepwalking or sleep terrors occasionally remember the mental content (which they frequently identify as a dream or a nightmare) associated with their abnormal motor behavior.[7] Some isolated case reports first mentioned this association. A young patient rushed into the room where his parents were sitting and threw the butter dish out of the window, believing it to be a bomb.[8] A sleepwalker threw his wife on the floor, ran to his two children, took them into his arms, and ran outside. He afterward said he believed that the house was on fire.[9] Three patient series confirmed these clinical impressions. In 12 patients with sleep terrors who underwent electroencephalography (EEG) and heart rate monitoring for several nights, 58% recalled their mental content after spontaneous arousal from slow wave sleep associated with heart rate acceleration (but not necessarily with a scream).[10] In a series of 43 adults with sleepwalking or sleep terrors, 71% reported at least one dream associated with a nocturnal motor episode.[7] The dreams were mostly short, visual, and unpleasant. There was no major difference regarding the frequency and nature of the dream content in sleepwalking compared with sleep terrors. In another series of 73 adults with sleepwalking or sleep terrors, 53% reported nightmarish mental content combined with the sensation of a vital threat and the need to escape danger during the motor episodes, including the feeling of a dangerous intruder (sometimes a murderer) trespassing the room ($n = 6$); collapsing walls, ceilings, or houses or being buried alive ($n = 5$); crocodiles, bugs, and spiders ($n = 3$); choking ($n = 5$); the urgent need to flee or being chased ($n = 3$); a baby falling out of the bed or suffocating ($n = 1$); or being in a running car or a falling lift without brakes ($n = 1$).[6]

Two case series addressed the characteristics of these dreamlike mentations through content analysis. Using the categorization method developed by Hall and Van Castle, 39% of patients with sleepwalking or sleep terrors described the presence of at least one person in the enacted dream, mostly unknown to the dreamer, whereas only 33% were relatives of the dreamer. Eleven percent of patients saw animals, which were generally aggressive or frightening, during the episode. Most (80%) mentations were negative, associated with aggression (26% of the total dreamlike mentations) and misfortune (54%, vs. no case of good fortune), and 84% were apprehensive. In the case of aggressive mentations, the patient was not the primary aggressor. In addition, 12% of the dreamlike mentation reports contained at least one act of friendliness. In all cases, the patient befriended someone and attempted to protect them (generally a relative) from danger.[7] In another series of 32 patients with sleepwalking or sleep terrors, as many as 70% of the 74 enacted dreams contained threats, which were more commonly misfortunes and disasters than aggressions. As a response to these threats, the sleepwalkers mostly fled from the disasters (25% fought back when attacked). The scenario included their bedroom in nearly half of the sleepwalkers' dreams.[11] The projection of the mental images on the room background (suggesting activation of mental images and real images seen through the eyes of the sleepwalker) is illustrated by Figure 104-1. During this episode, a sleepwalker showed some abnormal images in the sleeping room to her husband.[12] A few case reports confirmed the mind-body isomorphism using a video or video PSG of the event, followed by a detailed report of a dream coherent with the previously observed behavior.[13] The following video clips, obtained in our patients, illustrate this isomorphism: a woman protected her head from a moving, heavy boom as she dreamed of sailing with the wing astern (Video 104-1); a patient ran out of bed and cried for help as he saw a truck swooping down on him (Video 104-2); and a patient dreamed of trying to remove an insect trapped in her nose (Video 104-3).

Mechanisms

There have been several hypotheses regarding the mechanisms of these abnormal dream mentations. The brief scenes may be hypnagogic hallucinations emerging from slow wave sleep rather than more classic dreams; alternatively, they could be the terminal part of a longer dream partially forgotten at the time of arousal,[7] or a phasic, short mental creation elicited before or just at the time of arousal by ambient noises or physical contacts.[12,14] The negative emotions associated with the mentations parallel the activation of the amygdala-temporoinsular areas disengaged from the control of the prefrontal cortex (motor and emotional activation, such as fear and wandering) observed in functional imaging and deep EEG during sleepwalking.[15,16] The emotional and motor features of parasomnias could be interpreted as a release of inhibition of the subcortical central pattern generators, which regulate innate behavioral automatisms and survival behaviors.[17] The relatively consistent mental contents during sleep terrors across individuals (ceiling collapse, being buried alive, and escaping a life-threatening event) followed by a common flight response supports this concept,[11] as predicted by the Threat Simulation Theory of dreams.[18] These mental contents may also be biased toward unpleasant experiences in clinical series because these patients would more frequently seek medical advice.

The source of the abnormal mental experiences is sometimes obvious to the patients. In the series of 73 adults with sleepwalking or sleep terrors, four patients replayed a recent event that had happened during daytime, in real life or on TV, during the motor episode.[6] The history of sleepwalkers being able to replay (at least partially) a recent daytime event was

Figure 104-1 A 33-year-old woman with sleepwalking dreamed that her baby was about to fall from her cradle. **A,** She suddenly stood up, caught the baby, and brought her cautiously (with slightly folded knees) onto her bed, illustrating the isomorphism between dream content during sleepwalking and real behavior (from infrared video clip). **B** and **C,** During several episodes, the patient stared and pointed with her finger toward an invisible person, trying to convince her husband of the apparition, as if she were hallucinating, illustrating how the dreamed images are projected on the real bedroom scene.

further substantiated by a cognitive experiment performed on 19 sleepwalkers.[19] In the evening, the sleepwalkers were intensively trained on a sequence of large movements (learned during a variant of the serial reaction time task), resulting in a hands' choreography. During the nighttime, one sleepwalker reenacted a fragment of the recently trained motor behavior during a sleepwalking episode (with a concomitant delta and theta EEG background). This study provided the first evidence for the temporally structured replay of a learned behavior during sleep in humans.

Distressing mentations and nightmares during sleepwalking or sleep terrors are suggestive of abnormal emotion processing during sleep. Psychological trauma has been reported to influence the content of the sleepwalking or sleep terrors episode.[20] Additionally, recent stressful events may trigger abnormal nocturnal episodes and have even been replayed during episodes. Compared with sleepwalkers, higher levels of anxiety, obsessive-compulsive traits, phobias, and depression have been found in adult patients with sleep terrors in one study.[21] However, most studies showed no psychiatric disorders in these patients. Patients with sleepwalking or sleep terrors scored slightly higher than healthy controls on depression and anxiety scales,[22] but their scores did not differ from those of patients with RBD.[11] In addition, they had normal daytime aggression scores.[11] Another study of 105 sleepwalkers showed they scored on depression and anxiety scales similar to those of the general adult population.[23] The presence of psychopathology in sleepwalkers was associated with a higher frequency of nightmares and with potentially injurious behaviors. The successful treatment of a comorbid depressive disorder in 100 adults with sleepwalking or sleep terrors had no effects on the course of parasomnias, suggesting that the concurrent psychopathology did not play an essential role.[24]

Treatment

If sleepwalking or sleep terrors are causing distress or danger despite safety measures (avoiding sleep deprivation and other priming factors, such as alcohol, heavy meals, hyperthermia or daytime stress; quietly guiding back the patient to bed; closing windows and doors), behavioral (relaxation training, hypnosis) or medical (benzodiazepines, antidepressants, carbamazepine, melatonin; these drugs must be given at least 1 hour before going to bed to guarantee an effect as soon as 30 minutes after sleep onset) therapies are indicated. None of these therapies, however, has been tested with randomized trials. In our experience, the treatment of patients with sleepwalking or sleep terrors typically improves the dreams as well.

DISTURBED DREAMING IN REM SLEEP BEHAVIOR DISORDER

Dreams and Nightmares

Patients with RBD enact violent dreams during REM sleep in the absence of normal muscle atonia.[2] This disorder is frequent in patients with synucleinopathies (including dementia with Lewy bodies, Parkinson disease, and multiple sleep atrophy) and rare in patients with other neurodegenerative disorders (see Chapter 103). The dreams associated with RBD are usually different from those experienced by patients before RBD onset. The patients report enacted dreams containing more elements of aggression and animals than control subjects when they are asked about the dreams they remember in the last month.[25] This is also true for the dreams of patients with Parkinson disease, with or without RBD.[26] When dream reports are collected daily over several weeks in patients with treated RBD and controls, there are no differences in the content of the dreams, suggesting either a bias of

recall shifted toward selectively remembering the enacted violent dreams or a benefit of clonazepam on the abnormal dreaming process itself.[27] One may note, however, that the dream content of patients with Parkinson disease (whether they have RBD or not) includes heightened aggressiveness and an increased presence of animals compared with those of normal subjects.[28]

RBDs constitute a unique window to study the dreaming process from a point of view external to the dreamer. Behaviors, facial expressions, and verbal utterances are concordant with the dream reports obtained on awakening. In addition, some dream-enacted behaviors can be prolonged and scenic and may be more prolonged than the sleepwalking or sleep terrors behaviors. They include gesturing, reaching, grabbing, arm flailing, slapping, punching, kicking, sitting up, and leaping from bed. A demonstrative example of a patient with Parkinson disease using his pillow to defend himself against pterodactyls in his dream is shown in Video 104-4. In contrast to sleepwalking, only a minority of patients with RBD (3%) occasionally stand, and most have their eyes closed. Most descriptions emphasize the forceful and violent aspect of these motor behaviors, which are usually associated with vivid, unpleasant, and active dreams.[29] In 58 patients with Parkinson disease and RBD, the most commonly associated dream is fighting in response to danger (91%), whereas pleasant activity is reported in 20% of patients and daily activity in 22% of patients.[30] Nonviolent elaborate behaviors, however, occur in 18% of patients with Parkinson disease (coexisting in this case with violent behaviors within the same or other nights), as well as in patients with idiopathic RBD and RBD associated with other diseases.[31] They include eating and smoking (in the absence of real food or cigarettes); picking apples; dancing; teaching; gesturing thumbs up; kissing; giving a lecture; selling textiles; clapping at a show; sorting buttons; displaying pelvic, coitus-like thrusting; masturbating; urinating (while dreaming of urinating in a river as a child); scoring a goal; bicycling; greeting; flying; building a staircase; getting dressed and inspecting the army; and searching for treasure. Most behaviors are learned behaviors in accordance with the cultural and social context of the patient. Patients display various types of vocalizations, such as mumbling, talking, shouting, swearing profanities, laughing, and crying.[29] However, most patients mumble or speak during RBD, sometimes quite easily, and they speak with appropriate prosody, gestures, fluency, and syntax.[31] Singing and whistling are possible with correct musicality, and the local dialect is maintained (Video 104-5).[31]

Mechanisms of Abnormal Dreaming

RBDs are strongly linked to brainstem focal or neurodegenerative lesions within the system causing muscle atonia during REM sleep.[32,33] In this case, the motor correlates of dreams should be rendered visible for observers, whether these dreams are agreeable or not. In animal models with focal brainstem lesions that cause RBD, the RBD behaviors also contain a majority of violent behaviors (chasing or fighting) and a minority of nonviolent behaviors (licking or grooming).[34] In human RBDs, 80% of RBD-associated dreams are violent or unpleasant. The aggressive dream content correlates with more severe frontal dysfunction in Parkinson disease, regardless of whether RBD is present.[28] In this case, disturbed dreaming in RBD may be a consequence of the frontal dysfunction rather than of a brainstem lesion. In addition, the intense apparent emotions observed in RBD patients suggest an increased activation of the amygdala, as shown in normal REM sleep. Another mechanism could be related to the general function of dreams, as suggested by the Threat Simulation Theory.[18] This theory suggests that the function of dreaming is to simulate threatening events in a virtual environment and to rehearse threat perception and threat avoidance for the evolutionary purpose of increased survival. If true, this threat simulation would be exacerbated in the dreams of patients with Parkinson disease (and even more in cases of associated RBD), possibly linked with the frontal dysfunction. These dreams of fighting wild animals and aggressors are not a consequence of personality changes because they contrast with the placid personality and absence of aggressiveness during the daytime in RBD patients.[11,25]

Treatment

Several large series show the benefit of melatonin (3 to 12 mg before sleeping; one study was double blinded and placebo controlled[35]) and clonazepam (0.5 to 2 mg before sleeping)[29] on nightmares and the corresponding behaviors during RBD.[36] A few recent observations suggest that zopiclone and cholinesterase inhibitors (rivastigmine, donepezil) may also help.[37] In contrast, the effects of pramipexole are debated. Two open series reported alleviation of events in RBD, but a double-blind trial failed to show benefit.[38] Whether these drugs attenuate the negative emotions in dreams or just reduce the motor expression of dreams is yet incompletely determined.

DISTURBED DREAMING, NIGHTMARES, AND HALLUCINATIONS IN NARCOLEPSY

Dreams

Patients with narcolepsy often report frequent and intense dreaming (Figure 104-2, *left*). In a controlled series of 53 patients, narcoleptics remembered, on average, 49 dreams/month, compared with 15 dreams/month in controls, including more frequent dreams of false awakening.[39] The intense characteristics of dreaming activity are more obvious during sleep onset in REM periods,[40] with reports containing longer and a more complex organization.[41] Narcoleptic patients experienced more negative emotional tone and stronger positive emotions of dreams than healthy controls.[42] Narcoleptic patients also experienced more recurrent dreams than controls[39] or insomniacs.[43] The level of consciousness during dreams was also increased,[40] with narcoleptic patients having much more lucid dreams than controls.[39] As many as 85% of narcoleptics also experienced "dream delusion," or difficulty distinguishing between dream and reality, and mistook the memory of a vivid dream for a real experience.[44] One man, after dreaming that a young girl had drowned in a nearby lake, asked his wife to turn on the local news in full expectation that the event would be covered. Another patient experienced sexual dreams of being unfaithful to her husband. She believed this had actually happened and felt guilty about it.

Nightmares

Between 33% and 83% of narcoleptic patients report nightmares (Figure 104-2, *right*),[39,45,46] more often[39] or as frequently[46] in narcolepsy with than without cataplexy and more frequently than in controls[39] and in insomniacs.[43] Whether

Figure 104-2 Vivid dreams painted by their author, a 19-year-old patient with narcolepsy; "We were on field trip with my class, traveling in a giant ball silently floating over a desert. Suddenly, we saw a large building with a moving surface. As we approached, we discovered that the moving surface was composed of thousands of Spidermen. We leant with interest" (*left*). "In this nightmare, I was obliged to kill my whole family in a tube placed in the backyard. I had to kill them with a ballroom shoe, which was a long, tedious and horrible experience" (*right*).

the nightmares result from an overactive REM system, sleep onset in REM periods with more perceived sleep paralysis, fragmented REM sleep, abnormal amygdala activation in narcolepsy, overall higher daytime stress, or side effects of antidepressants and stimulants is yet undetermined. In a series of 54 narcoleptic patients, the occurrence of nightmares was higher in patients with RBD.[46] Narcoleptic patients with nightmares had longer wakefulness time and higher percentages of N1 stage sleep, suggesting either that nightmares disrupted sleep or that superficial sleep promoted their onset.[46] Lucid dreaming, which is easily achieved by three fourths of narcoleptic patients, may be used to turn recurrent nightmares into agreeable dreams,[39] as illustrated in the following examples: "I was chased by an aggressor and had to kill myself by throwing myself onto an electrified fence to avoid the aggressor and wake up"; "I was chased by soldiers and chose to fly to escape them"; "I built a panic room in myself where I mentally went during my nightmare to escape dangerous people"; "I was seeing my family tortured to death and decided that it was not true, because we were rehearsing a play or a movie. I was behind the camera"; and "I built myself a suit of armor made of lightning that protected me from my enemies."[39] A small (11%, 6 of 54 patients) proportion of patients reported that nightmares had been eliminated by narcolepsy medications, mostly anticataplectic drugs.[46]

Hallucinations

Hallucinations are experienced by 45% to 80% of narcoleptic patients with cataplexy[47-49] and by 29% of narcoleptic patients without cataplexy.[49] The formed hallucinations are multimodal, with visual, auditory, olfactory, sexual, tactile, and motor perceptions. The visual hallucinations are the most frequent, including human or fantastic characters that are complete or incomplete (subjects standing still or moving, transparent bodies, isolated head moving, Picasso-like faces, vampires, decapitated heads, or a rare guardian angel; Figure 104-3, *A*) and animals (Figure 104-3, *B*).[49] Auditory hallucinations come second in terms of frequency, with nonverbal (footsteps, doors opening, alarm clock, music box, singing sparrows, bells, gun detonation, and broken china) and verbal (hearing one's own first name is the most frequent, bits of conversations, but with no imperative voice or replacement of will as in schizophrenia). Motor (or kinetic) hallucinations include the sensation of laterally moving the body, being sucked into the bed, flying, levitating, and having out-of-body experiences (Figure 104-3, *C*). Tactile hallucinations include feelings of blowing fresh air, a smooth touch, drops of water, burning body sensations, and being bitten, trampled, strangled, or sexually abused.[48,49] Multimodal hallucinations may be experienced together as a holistic, real phenomenon, often referred to by patients as "waking dreams." Hallucinations are frightening in 80% patients,[50] and their major impact is anxiety.[48] As a consequence, some patients close their door or sleep with weapons on their bed table. They can be associated with sleep paralysis, which is, with RBD, their major determinant (Figure 104-3, *D*).[49] Hallucinations typically occur at sleep onset and offset, but they also occur under fully awake conditions in 40% of patients.[48,49] They begin at about 20 years of age. Because hallucinations can be pervasive, some narcolepsy patients have even been misdiagnosed as having schizophrenia.[51] This misdiagnosis is rare, however,[52] because narcoleptic hallucinations differ from schizophrenic hallucinations by their major association with sleep, more frequent visual and multimodal hallucinations, and exceptional delusional thinking.[48,49,53] Hallucinations may be phasic elements of sleep (possibly abnormal ponto-geniculo-occipital wave

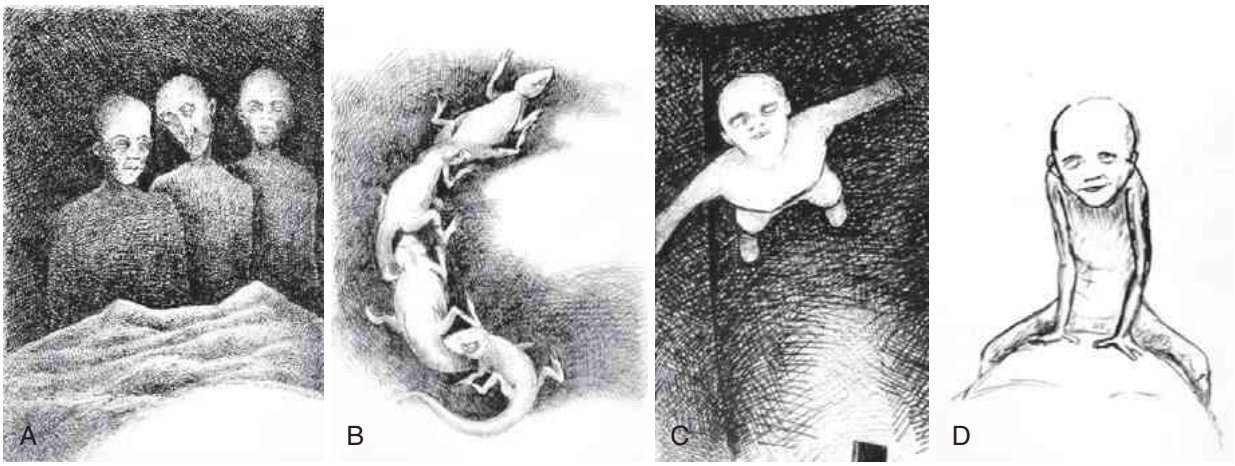

Figure 104-3 Hypnagogic hallucinations drawn by a 45-year-old man with narcolepsy. **A,** The patient experienced recurrent hallucinations of "friends" around his bed at sleep onset or offset. They were not identifiable but perceived as friendly. **B,** Another recurrent hallucination was a salamander crawling on the bed. **C,** Additionally, the patient had an out-of-body experience (but no heautoscopy), then floated in the corner or just below the ceiling of the room. **D,** Eventually, he felt a small, malicious child sitting on his chest and pressing it, inducing dyspnea and the feeling that it was impossible to move (sleep paralysis and hallucination).

activities) occurring during the wake state. They are usually reduced by anticataplectic drugs.

DREAM DISTURBANCES AND HYPNAGOGIC HALLUCINATIONS IN OTHER NEUROLOGIC DISEASES

Parkinson Disease

Compared with normal controls, the dreaming activity changes in Parkinson disease. As many as 46% of patients report altered dream phenomena,[54,55] with a high frequency of nightmares and violent or unpleasant dreams in Parkinson disease patients, especially when levodopa therapy is introduced.[54-56] In early Parkinson disease stages, patients' dreams differ from those of the control group in features related to aggressive actions (in which they frequently had a passive role), the presence of animals, a relatively higher frequency of friendly acts toward other characters, and a lower frequency of bodily misfortunes.[28] Because the altered dreaming is related to frontal cognitive impairment and not to RBD, the authors speculate that the higher level of aggression reflects intensification of the limbic preponderance during sleep owing to a loss of the prefrontal regulatory influence. In contrast, Borek and colleagues found a relatively higher frequency of aggressive features in PD patients with than without RBD (with no further difference in men vs. women with RBD), although dreams were less aggressive in women with Parkinson disease than in men.[26] The altered dreaming activity was associated with more frequent awakenings and illusions or hallucinations, but not with specific (levodopa, dopamine agonist) medications.[56] A "kindling" phenomenon starts from altered dreaming and evolves toward illusions, then hallucinations of minor then major severity; eventually, psychosis is suspected.[54] The presence of vivid dreams and nightmares correlated with concurrent hallucinations, but did not predict the future development of hallucinations when they occurred in nonhallucinators in a 10-year prospective study.[57] The interest in vivid dreams and nightmares as a step toward psychosis, however, did not include RBD, which was not identified as a disorder at the time of the study.[54] When RBD was examined at cohorts' entry into the study, it proved to be a major determinant for concurrent and incident hallucinations, as well as later development of psychosis and dementia.[57,58]

In addition to altered dreaming, visual hallucinations are experienced by an average of one third of patients with Parkinson disease. They consist of visions of human figures or faces, or animals, sometimes in miniature, or scenery of outstanding beauty.[49,59,60] In addition to older age and longer disease course, several risk factors have been associated with the occurrence of hallucinations, including dopaminergic and anticholinergic therapy, cognitive impairment, visual deficits, excessive daytime sleepiness, and sleep disturbances.[59-63] It is likely that hallucinations in Parkinson disease are better explained by state dissociation and intrusion of dreamlike phenomena into wakefulness (as in primary narcolepsy) than by "psychosis" of cortical origin. Evidence for this mechanism consists of the frequent association of hallucinations with RBDs[64] and with excessive daytime sleepiness,[59] as well as their timely occurrence at the end of nighttime and daytime REM sleep episodes (Figure 104-4).[65] This narcolepsy-like mechanism was also postulated in patients with excessive daytime sleepiness.[66] Eventually, a brain examination showed numerous Lewy bodies within the subcoeruleus nucleus but not in the cortex in a patient with visual hallucinations plus RBD.[65] Eventually, a loss of hypocretin neurons, which can contribute to the sleepiness and hallucinations in patients with Parkinson disease, was demonstrated.[67,68] These results supported a brainstem-hypothalamus origin for visual hallucination in Parkinson disease, rather than a cortical origin (and onset of dementia with Lewy bodies), as thought before. The treatment of nightmares and hallucinations in Parkinson disease and other neurodegenerative diseases usually requires decreasing or stopping the provocative drugs (usually dopamine agonists and antidepressants) to assess for RBD (and treat adequately with melatonin or clonazepam) and, if severe, use of atypical neuroleptics such as quetiapine or clozapine.

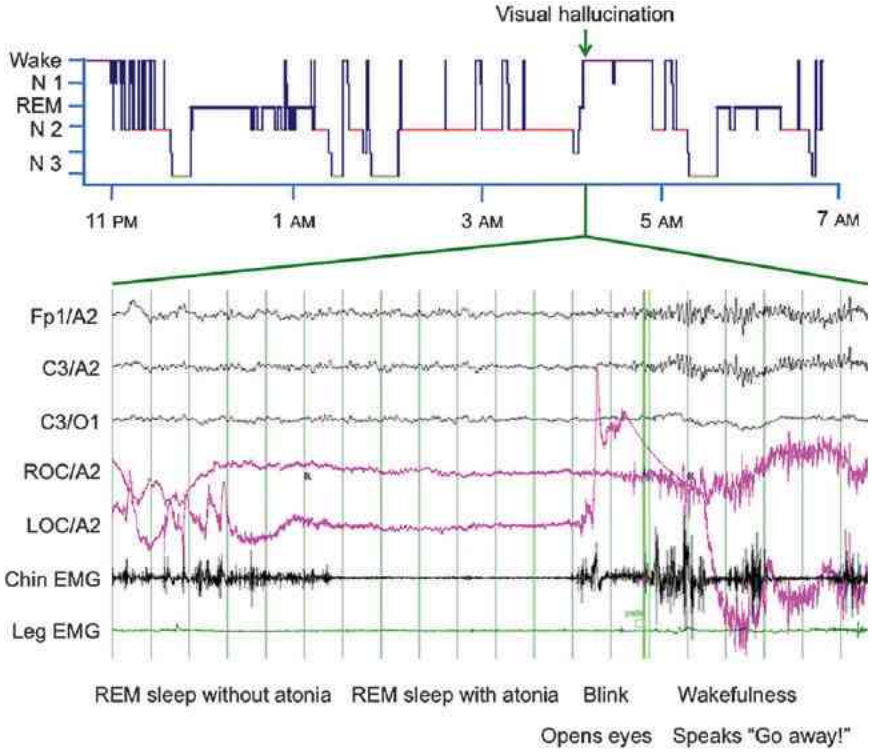

Figure 104-4 Visual hallucination experienced by a patient with Parkinson disease on emergence from REM sleep. On the hypnogram (*upper panel*), the visual hallucination emerges from a short REM sleep episode and triggers a prolonged awakening. The electroencephalogram shows REM sleep without atonia followed by REM sleep with atonia, then a blink, followed by a sudden awakening. On the video clip, the patient opens the eyes (blink) and speaks, saying "Go away!" to her hallucination. She later reported to the nurse that she saw her grandchildren around her in the bedroom.

Guillain-Barré Syndrome

Guillain-Barré syndrome is a rare, acute, and severe polyradiculopathy, probably of autoimmune origin. Although it mostly affects the peripheral nervous system, signs of central nervous dysfunction, such as RBD,[69] sleepiness, hallucinations, abnormal antidiuretic hormone secretion, and low cerebrospinal fluid levels of hypocretin are noted.[70] In a consecutive series of 139 patients with Guillain-Barré syndrome without any psychotropics and opiates, we found that patients frequently reported vivid dreams (19%), illusions (30%, including an illusory body tilt), hallucinations (60%, mainly visual), and delusions (70%, mostly paranoid).[71] Examples include a dream of floating over the streets of New York early in the morning and seeing people taking out their garbage (a vivid dream that the patient remembered several years afterward); an intravenous bag mistaken for a banana tree (visual illusions); the bed feeling as if it were vertical, with the nurses walking on the walls (spatial illusions); and animals or painted deceased relatives raising their arms through the frame (visual hallucinations). A patient believed that he was a prisoner of the Germans during World War II trying to cross a border and was continually asking the nurses for his passport (a brief psychosis). In patients monitored during the hallucinatory period, the PSG showed a status dissociatus characterized by major insomnia; REM sleep without atonia during 92% of the REM sleep time in all hallucinators (RBD could not be assessed because patients were totally paralyzed by the Guillain-Barré syndrome process); bursts of rapid eye movements during stage N2 sleep; sleep onset in REM periods; and continuous, rapid switching between waking, N1 sleep, and REM sleep stages across day and night. In addition, there were signs of dysautonomia. The status progressively disappeared when hallucinations subsided. In this case, status dissociatus (rather than "isolated" RBD) was associated with disturbed dreaming and hallucinations.

Delirium Tremens, Fatal Familial Insomnia, and Morvan Chorea: Agrypnia Excitata

Notably, some forms of status dissociatus include continuous dreaming and hallucinations, motor activity, and a complete loss of wake-sleep boundaries, with patients fluctuating continuously between N1/REM sleep and wakefulness.[72] Such status dissociatus is observed in Parkinson disease, dementia with Lewy bodies, Guillain-Barré syndrome, alcohol withdrawal syndrome (delirium tremens),[73] fatal familial insomnia, and Morvan chorea. This phenomenon has been named *agrypnia excitata* by the Bologna group and is sometimes called *oneirism* in French groups, but these names refer to the same observation of severe visual hallucinations and enacted dreams (resembling a continuous RBD, but with open eyes). Two specific variants of status dissociatus included a case of frontal dementia of unknown origin with continuous dreamlike activity across all sleep stages, bursts of rapid eye movements during NREM sleep, and RBD,[74] as well as eight patients with a tauopathy and abnormal antibodies plus obstructive sleep apnea, stridor, abnormal sleep architecture with undifferentiated NREM sleep or poorly structured stage N2 sleep with

simple movements and finalistic behaviors, normalization of NREM sleep by the end of the night, and RBD.[75]

CLINICAL PEARLS

The clinician should realize that some patients use the words "disturbed dreaming" and "nightmares" not only for indicating the classic REM sleep nightmare disorder, PTSD, and distressing dreams associated with psychiatric conditions, drugs, and substances but also for reporting the mental experiences associated with hypnagogic hallucinations, sleep terrors, RBDs, and status dissociatus. The characteristics (type, construction, timing, duration, and context) of their mental experience, along with associated behaviors, autonomic signs, and associated disorders, and aspects and timing on PSG are crucial for making a diagnosis.

SUMMARY

Most adult patients with arousal disorders remember a mental content timely associated with sleepwalking and sleep terrors, mostly a brief visual scene including misfortune, apprehension, and life-threatening, imminent dangers that they must flee. The observed behaviors and speeches are congruent with the mental content. During RBDs, patients mostly enact violent dreams in which they are aggressed by humans and animals and counterattack, despite their placid personality when awake. About 20% of the behaviors and dreaming are elaborated, nonviolent content, including laughing, performing their job, or speaking with people. Narcolepsy patients have longer, more intense and lucid dreams than controls, with more frequent nightmares that are associated with time of sleep onset in REM periods. Vivid dreams, illusions, hallucinations, and psychosis in several neurologic diseases caused by neurodegeneration (mostly synucleinopathies, including Parkinson disease, dementia with Lewy bodies), autoimmunity (primary narcolepsy, Guillain-Barré syndrome, Morvan chorea), and alcohol withdrawal (delirium tremens) seem linked to abnormal REM sleep and status dissociatus.

Chapter 105

Other Parasomnias

Alex Iranzo

Chapter Highlights

- The heterogeneous group of other parasomnias includes sleep-related hallucinations, exploding head syndrome, sleep enuresis, and sleeptalking.
- Other parasomnias are very frequent, transient, and usually benign in nature, but some rare disorders can be progressive and devastating.
- Patients' education and reassurance that they are harmless conditions is necessary. Therapy is rarely warranted but could be considered when experiences are bothersome, unpleasant, terrifying, or very frequent and causing sleep difficulties.
- Although most cases are benign and idiopathic, some are associated with serious conditions such as narcolepsy in patients with hypnagogic hallucinations, brainstem stroke in subjects with complex nocturnal visual hallucinations, and obstructive sleep apnea and recurrent urinary tract infections in children with sleep enuresis.

Parasomnias are undesirable physical events or experiences that occur during entry into sleep, within sleep, or during arousal from sleep.[1] The *International Classification of Sleep Disorders,* third edition (ICSD3) classifies "other parasomnias" to include a miscellaneous group of phenomena not linked to a specific sleep stage such as sleep-related hallucinations, exploding head syndrome (EHS), sleep enuresis, the normal variant sleeptalking, and parasomnias secondary to a medical disorder and to a medication or substance.[1] This chapter describes the conditions listed in the other parasomnias category and will discuss the possible epidemiology, pathophysiologic consequences, and clinical approach.[1]

SLEEP-RELATED HALLUCINATIONS

Definition, Diagnostic Criteria, and Classification

Hallucinations are sensory experiences that are perceived in the absence of environmental stimuli. Consciousness is preserved, and subjects can describe in detail their perceptions with or without insight into their unreality. Hallucinations should be distinguished from illusions, which correspond to misperceptions or distorted perceptions of real external stimuli. They also should not be mistaken for dreams, which are experiences that occur when the individual is asleep and are recalled on awakening.[2] Hallucinations are the result of an abnormal neuronal sensory processing in the setting of the wake-sleep transition (e.g., hypnagogic hallucinations, hypnopompic hallucinations), sensory deprivation (e.g., severe vision loss in the Charles Bonnet syndrome), structural brain lesions (e.g., stroke), neurologic diseases (e.g., Parkinson disease), psychiatric diseases (e.g., schizophrenia), metabolic diseases (e.g., hypoxic encephalopathy), and the use or withdrawal of a medication (e.g., dopaminergic agents).

Although hallucinations can occur during daytime wakefulness, at sleep onset, and on awakening from sleep, daytime hallucinations are more frequent than sleep-related hallucinations.[2] According to the ICSD3, diagnostic criteria of sleep-related hallucinations include (1) a complaint of recurrent hallucinations that are experienced just before sleep or on awakening during the night or in the morning, (2) hallucinations that are predominantly visual, and (3) disturbance that is not better explained by another sleep disorder (especially narcolepsy), mental disorder, medical disorder, medication, or substance use.[1]

Sleep-related hallucinations may be classified into two different forms according their time of occurrence, clinical characteristics, and underlying substrate: (1) hypnagogic (those that occur at sleep onset) and hypnopompic (those that occur upon awakening) hallucinations, which are experiences that are either idiopathic or related to other conditions, particularly narcolepsy; and (2) complex nocturnal visual hallucinations (CNVHs), which occur after sudden awakening during the night, are not simple experiences, and are almost always linked to an underlying pathology, usually neurologic, psychiatric, metabolic, and ophthalmic in nature.[2]

Hypnagogic and Hypnopompic Hallucinations

Clinical Findings. Hypnagogic hallucinations (HHs) and hypnopompic hallucinations (HPHs) are visual (e.g., feeling someone or something present in the room; simple elementary forms such as sparks, lines, flashes, confetti, and shadows; complex forms like waterfalls, cucumbers, animals, known or unknown people or faces, dwarfs, thieves, firemen, and lifelike scenes), auditory (e.g., footsteps, explosions, shots, a beep from a cell phone, voices of known or unknown people, familiar or unfamiliar songs), tactile (e.g., someone grabbing the subject, bugs crawling on the skin, tingling, pain), gustatory (e.g., metallic taste), olfactory (e.g., perfume, cologne, feces, smoke), and kinetic (e.g., floating, flying, jumping, falling, out-of-body experiences, levitation). Most of the people who experience HH and HPH know that the perceptions are not true and do not exist. Despite this, some hallucinations, such as seeing and hearing persons, are very vivid and real and may be experienced as unpleasant, frightening, and hard to

distinguish from true events.[3] Kinetic hallucinations are so bizarre they may lead to paranormal beliefs or be mistaken for delusional psychosis.

Epidemiology. Epidemiologic studies are scarce and give different estimations of prevalence because of methodologic differences in the definition of hallucination and the accuracy of how data were obtained (telephone interviews, questionnaires). HHs are more common than HPHs. In a community sample of 49,772 people from the United Kingdom aged 15 to 100 years, who were interviewed by telephone, 37% reported HH and 12.5% HPH.[4] In an observational study involving 134 healthy medical students from Spain with a mean age of 22 years, 13% reported sleep-related hallucinations.[5]

Associations. There is no known familial or genetic predisposition. The most important precipitant in predisposed individuals is sleep deprivation leading to HH or HPH during daytime naps or during the night. Many drugs and psychoactive substances have been related to HH and HPH, such as hashish, opiates, amphetamines, cocaine, hypnotics, and zopiclone.[3] Simultaneous occurrence of HH or HPH with sleep paralysis is common in healthy people and in narcoleptics.

In *narcolepsy*, HHs are more frequent than HPHs. In one study hallucinations occurred in 59% of patients with cataplexy and in 28% without cataplexy.[6] They were experienced in the context of sleep onset (55%), sleep offset (3%), and onset-offset (42%). Hallucinations were visual in 95% of the patients, auditory in 75%, kinetic in 55%, and tactile in 33%, and 10% experienced passage or presence of a real person. Olfactory and gustatory hallucinations were not reported. When narcoleptic patients experience sleep paralysis, the most common simultaneous hallucinations are tactile (e.g., a frightening pressure on the chest) and visual (e.g., feeling the presence of someone or a shadow). Events can be so vivid that some undiagnosed narcoleptic patients may be convinced that they are experiencing paranormal events.[7] In narcolepsy, HH and HPH occur predominantly in the supine position.[8]

Etiology. HH and HPH are thought to be intrusions of the characteristic dreamlike phenomena of rapid eye movement (REM) sleep into wakefulness.

Management. When HH and HPH are idiopathic, patients need to be assured that they correspond to a very frequent and almost normal phenomenon that occurs in healthy people and not a sign of psychosis, narcolepsy, or a paranormal experience. Patients with narcolepsy need to be informed that hallucinations are part of the disease. When treatment is needed because hallucinations are frequent or bothersome, clomipramine 10 to 75 mg at bed time may be effective, particularly in those associated with sleep paralysis. Sodium oxybate may not help diminish events in patients with narcolepsy.[9,10]

Complex Nocturnal Visual Hallucinations

Clinical Findings. CNVHs occur following a sudden awakening. They may be primary or much more frequently secondary to an underlying condition. Despite the variety and large number of conditions that may cause CNVH, the type of visual hallucinations are very similar among them. CNVHs are complex, vivid, detailed, relatively stereotyped, static or mobile, colorful images of people, animals, and elaborated scenes resembling a dream. They can be brief, lasting a few seconds, or prolonged, lasting several hours. They usually disappear if the eyes are opened or if the lights of the room are switched on. Sometimes the images are distorted in shape or size, such as those seen in the Alice in Wonderland syndrome. In rare cases, visual hallucinations can be associated with auditory hallucinations (e.g., a song, a crowd of people talking or chanting) or tactile (e.g., tingling, pain). Insight regarding the hallucinations is more reduced than in HH and HPH, and subjects may believe they are true and leave the bed to investigate whether the images are real or not. In other patients, insight is preserved but hallucinations are perceived as bothersome and distressing. CNVH may co-occur with HH and HPH. The secondary, but not the primary, form of CNVH may coexist with hallucinations during wakefulness.[1,11,12]

Associations. Precipitants of CNVH depend on the nature of the underlying condition and include sleep deprivation, fever, trauma, electrolyte disturbances, changes in medication, poor vision, and low ambient illumination. In contrast to HH and HPH, CNVHs are secondary to a large number of conditions of different origin (Table 105-1).[11-27]

In *Parkinson disease* hallucinations occur in about 25% of patients.[13] Risk factors are older age, long disease duration,

Table 105-1 Conditions Associated with Sleep-Related Hallucinations

Hypnagogic and Hypnopompic Hallucinations
Sleep deprivation[1]
Narcolepsy[6,7]
Complex Nocturnal Visual Hallucinations
Parkinson disease[6,11,13-16]
Dementia with Lewy bodies[17,18]
Peduncular hallucinosis[11,19,21,22]
Charles Bonnet syndrome[11,23]
Schizophrenia[11]
Metabolic encephalopathy[11]
Posterior cerebral artery infarction[11]
Delirium tremens[11]
Migraine[11]
Focal epilepsy[11]
Guillain-Barré syndrome[26]
Sleepwalking[1,2,27]
Night terrors[1,2]
Idiopathic hypersomnia[12]
Anxiety disorder[12]
Acute alcohol withdrawal[12]
Acute barbiturate withdrawal[12]
Acute benzodiazepine withdrawal[12]
Lipophilic beta blockers[1,2]
Dopaminergic agents[1,2]
Substances with hallucinogenic properties like mescaline, LSD, amphetamine, and cocaine[1,2]

increased motor disability, depression, cognitive impairment, hypersomnia, REM sleep behavior disorder (RBD), and the use of dopaminergic agonists and anticholinergics.[6,13] Hallucinations are mostly visual, recurrent, static or mobile, stereotyped, vivid, involving shadows, silent moving animals and people, and the presence or passage of a quiet known person or pet. They appear mostly in dim surroundings or at night. Tactile, auditory, and kinetic hallucinations are rare. Although the etiology of these hallucinations in Parkinson disease is unclear, the connection to REM sleep intrusions into wakefulness or perceptual disturbance is debated.[6-16]

Dementia with Lewy bodies is dependent on visual hallucinations as one of the major diagnostic criteria.[17] In one study, a patient with dementia with Lewy bodies experienced an episode of CNVH, and polysomnography showed that it resulted from an awakening arising from N2 sleep stage.[18] Patients with dementia with Lewy bodies or other forms of dementia may find it difficult to distinguish CNVH from dreams.

Peduncular hallucinosis is characterized by CNVH in the setting of pontine, midbrain, or thalamic damage.[11,19] The most common etiology is vascular, but tumors and inflammatory processes have also been described.[20] These stereotypic events are usually self-limited, starting a few days after the stroke and commonly associated with hypersomnia. CNVHs occur in the evening, last several minutes or hours, and disappear when the eyes are open.[11] Patients may lack insight and may interact with the hallucinations, performing pseudopurposeful activities (e.g., using a screwdriver, putting on trousers, or talking). Polysomnographic studies have shown that the hallucinations occur during wake-sleep transitions with preserved occipital alpha activity.[21,22]

Charles Bonnet syndrome is characterized by CNVH in elderly subjects with severe visual loss secondary to bilateral ocular pathology (e.g., macular degeneration, cataracts, glaucoma). The syndrome may be caused by any lesion affecting the visual pathway, including the optic nerve, optic chiasm, and temporal and occipital lobes. For these patients CNVH occurs in the evening and night when the patient is drowsy but the eyes are still open. Patients usually have insight into the nature of their perceptions. The course and treatment depends on the underlying pathology. Symptomatic therapy with atypical antipsychotics such as olanzapine may be effective.[11,23]

Polysomnography. The few studies that have described the polysomnographic pattern of CNVH have shown that CNVHs arise from N2 and N3 sleep and not from REM sleep. During the events, electroencephalography shows occipital alpha rhythm without epileptic activity, indicating that the subject is awake.[12,24] CNVHs experienced by Parkinson disease patients may arise from four distinct circumstances: (1) during REM sleep without atonia, (2) on arousal from non–rapid eye movement (NREM) sleep, (3) in the daytime during drowsiness within the wake-NREM sleep transition, and (4) during wakeful state.[25]

Etiology. The anatomic substrate of CNHV shares a final common pathway where the occipital visual cortex generates false images from reduced sensory inputs. Input reduction may arise from the occipital cortex itself (e.g., in dementia with Lewy bodies) or its afferents from the thalamus (e.g., peduncular hallucinosis), the brainstem (e.g., Parkinson disease), and the retina (e.g., Charles Bonnet syndrome).[11]

Management. In most cases reassurance is sufficient. Adequate treatment of the underlying condition may eliminate the CNVH. Withdrawal of the offensive agent (e.g., β-adrenergic antagonist, dopaminergic agents, anticholinergics) often results in resolution of CNVH.[12] In cases in which therapy is warranted, antidopaminergic psychotics (e.g., risperidone, quetiapine, olanzapine, and clozapine) or anticholinesterase inhibitors (e.g., rivastigmine) may be effective.

EXPLODING HEAD SYNDROME

Definition and Diagnostic Criteria

EHS is characterized by a sense of a loud explosion in the head that awakens the individual.[28] Diagnostic criteria of the ICSD3 include (1) a complaint of a sudden noise or sense of explosion in the head either at the wake-sleep transition or on awakening in the night; (2) abrupt arousal following the event, often with a sense of fright; and (3) experience not associated with significant complaints of pain.[1]

Clinical Findings

Patients are abruptly woken by an imagined, sudden, violent, and frightening sensation of explosion deep in center or back of the head or near them.[29] Patients have a clear recollection of the events without any postictal confusion. Episodes last between a split second and a few seconds and disappear completely the moment the subject is awakened. The noise is perceived over both ears,[30] although a few subjects describe hearing the sound in only one ear.[31,32] Patients report noise, not pain, and describe the experience in many ways, such as "sudden bang in the head,"[29] "thunderclap,"[29] "shouts,"[30] "shotgun,"[33] "loud metallic noise,"[33] "clash of cymbals,"[33] "door slamming,"[33] "the earth moved,"[33] "electric shocks,"[33] "bomb like explosion,"[33] "electrical current running,"[34] "a beep,"[35] and "a buzzing noise."[36] Some patients are so alarmed by its violence that think that it is a symptom of a stroke or a brain tumor.[30] The explosive noise may occasionally be accompanied by a simultaneous flash of light in front of the eyes,[30,33] hypnic jerks of the whole body[30] or one limb,[36,37] and the sensations of fear, difficult breathing, palpitations, and sweating on awakening.[33] In one case, EHS was followed by episodes of sleep paralysis.[35] Attacks occur exclusively during sleep, during the transition from wakefulness to sleep, or less often on awakening from sleep, particularly during the nighttime. In a few cases the attacks only appear on awakening from nighttime sleep[31,37] or during daytime naps.[37]

Epidemiology

There are no epidemiologic studies focused on EHS, and less than 100 cases are reported in the medical literature, but it is suspected to be much more common.[29] In fact, a recent study found that recurrent EHS occurred in 16% of college students.[37a] Onset is usually after the age of 50 years, but it may start in childhood and adolescence. There is a slight predominance in females.

Natural Course

The frequency and course of episodes are highly variable, ranging from two or three spells in a lifetime up to several per

night for several weeks. Some patients have clusters lasting weeks to a few months separated by prolonged periods of remission. The condition improves and resolves spontaneously.[28]

Laboratory Investigations

Neurologic examination, brain magnetic resonance imaging, angiography, electroencephalography, and interictal polysomnography are normal. Sleep studies reveal that the attacks may either evolve at the transition from wakefulness to N1,[30,38] and from N2,[32,38] or in the transition from N1 to wakefulness.[36] No epileptic activity, apneic events, or electrocardiographic abnormalities are seen in the episodes.

Associations

Family history of EHS may occur, but it is very uncommon.[36] There are no identifiable precipitants, although a few patients state that attacks tend to occur when they are under stress or very tired. Events are not associated with any type of headache disorder or neurologic, psychiatric, or auditory diseases.

Etiology

The etiology of the EHS is unknown. It is an abnormal sensory phenomenon occurring at the transition from wakefulness to sleep. The events may represent an auditory sleep-related hallucination or a sensory variant of hypnic jerks.[2] Some investigators suggest events may be related to abnormalities in the brainstem reticular formation,[37] an acoustic migraine aura,[38] or middle-ear eustachian tube dysfunction.[31]

Management

Treatment is generally not required because EHS is a benign disorder that remits with time. Education and reassurance that EHS is a harmless condition can be necessary to reduce fear and anxiety. A medication can be tried when episodes interfere with sleep or cause stress. Anecdotal reports suggest benefit with clomipramine,[30] topiramate,[36] flunarizine,[37] nifedipine,[39] or clonazepam.[40]

SLEEP ENURESIS

Definition

Sleep enuresis (SE), also called bedwetting and nocturnal enuresis, is defined as involuntary recurrent micturition during sleep in subjects older than 5 years at least twice a week for more than 3 months.[1]

Classification

SE is classified into a primary and a secondary form depending on whether the patient has been dry during sleep for at least 6 months. This distinction is made because primary and secondary forms have different etiologies despite the same symptoms. Primary SE is more frequent than secondary SE.[1]

Primary Sleep Enuresis

Diagnostic Criteria. According to ICSD3, diagnostic criteria include the following: (1) the patient is older than 5 years; (2) the patient exhibits recurrent involuntary voiding during sleep, occurring at least twice a week; (3) the condition has been present for at least 3 months; and (4) the patient has never been consistently dry during sleep for at least 6 months.[1]

Epidemiology. SE affects approximately 4% to 16% of school-aged children.[41-43] A study on the development of parasomnias from childhood to early adolescence showed that enuresis occurred in 16% of 1353 children and persisted in adolescence in 12% of these cases.[43] The prevalence of SE decreases with time, being present in about 10% of 6-year-olds and 3% of 12-years-olds.[43] Adult enuresis is rare, occurring in about 0.5% to 3% of the population, and is usually linked to an underlying condition. In children, primary SE is more common in boys than in girls. In adults it is more frequent in women.[1]

Polysomnography. Sleep studies show that the episodes of SE occur from wakefulness and any sleep stage. During sleep, 39% of episodes occur in N2, 20% in N3, and 9% in REM sleep. Most of the events occur in the first third of the night. Polysomnography studies show an increased number of arousals.[44] Obstructive sleep apnea occurs in 8% to 47% children with SE.[45]

Associations. About two thirds of cases of primary SE are familial, and one third are sporadic. SE occurs in 77% of children when both parents had SE, and in 44% when one of the parents had a history of SE.[46] There is a higher concordance rate for monozygotic twins than in dizygotic twins.[47] Models of heritance can be either autosomal dominant or autosomal recessive.[47] Linkage studies have demonstrated associations with chromosomes 4, 8, 12, 13, and 22.[47] Primary SE is usually not associated with involuntary voiding during wakefulness. SE may cause embarrassment and low self-esteem, causing psychosocial stress for the patient.

Etiology. The etiology of primary SE is unknown, but several mechanisms are implicated in its pathophysiology: polyuria leading to nocturia, reduced bladder functional capacity (the volume at which the bladder empties itself is reduced), increased nocturnal bladder activity, decreased nocturnal secretion of vasopressin (the antidiuretic hormone), and central difficulty of arousing from sleep. The latter may be the most important factor in primary SE due to a delayed development of the central nervous system leading to a failure in the arousal system in response to the sensation of a full bladder. Enuretic boys are found to be more difficult to arouse from sleep than age-matched controls,[48,49] and a small proportion of children with primary SE have reduced vasopressin levels during sleep, resulting into high urinary volume.[50]

Management. Parent and child involvement, motivation, and cooperation are crucial. To avoid embarrassment and low self-esteem causing the patient psychosocial stress, parents must be supportive of the child and use positive reinforcement for desired behaviors. Fluid restriction in the evenings and forced awakenings in the middle of the night to urinate are not usually effective. Treatment includes behavioral therapy with daytime bladder control training,[51] alarm systems as a conditioning therapy,[52,53] and drugs such as imipramine, oxybutynin, and desmopressin.[54]

Secondary Enuresis

Diagnostic Criteria. According to the ICSD3, diagnostic criteria include the following: (1) the patient is older than 5 years; (2) the patient exhibits recurrent involuntary

voiding during sleep, occurring at least twice a week; (3) the condition has been present for at least 3 months; and (4) the patient has been consistently dry during sleep for at least 6 months.[1]

Associations. Secondary SE is the result of an acquired factor such as excessive liquid intake, diabetes mellitus, diabetes insipidus, malformations of the genitourinary tract, recurrent urinary tract infections, chronic constipation and encopresis producing an extrinsic pressure on the bladder, significant psychosocial stress, attention-deficit hyperactivity disorder, developmental disorders in children with intellectual disability, obstructive sleep apnea, congestive sleep heart failure, nocturnal epilepsy, stroke, Parkinson disease, dementia of any type, neurogenic bladder in spinal cord lesions and multiple sclerosis, and the use of diuretics.[1]

Etiology. Etiology depends on the underlying condition. Overall, pathophysiology of secondary SE includes an inability to concentrate urine, increased urinary production, hyperactivity of the bladder, and genitourinary tract malformations. Failure of arousal from sleep when the bladder is full of urine may also occur in a few cases with secondary SE, but this is a factor mostly associated with primary SE.

Management. The underlying cause should be treated first (urinary infection, urinary malformation, sleep apnea, diabetes mellitus, diabetes insipidus) before symptomatic therapy. In children, specific therapy for primary SE should be tried in secondary SE.

SLEEPTALKING

Definition and Classification

Sleeptalking, also known as somniloquy, consists of talking while the individual is asleep. This should be distinguished from periods of talking during nocturnal awakenings. Sleeptalking may not be mistaken for other sounds occurring in sleep, such as catathrenia, snoring, stridor, choking, and coughing. There are two forms of sleeptalking: a primary form in which sleeptalking is an isolated manifestation, and a secondary form in which it is one the clinical features of a different underlying condition, such as confusional arousals and RBD.

Isolated Sleeptalking

Clinical Findings. Sleeptalking is a normal sleep variant, a benign phenomenon in which the individual remains immobile (except for the act of talking) and usually does not remember the event the next morning on awakening. In most instances, the spells do not cause an awakening and are noticed by the bed partner or household members who report them.[55] In most cases, the episodes are sporadic, self-limited, and brief, usually lasting less than 1 minute. Sometimes the events may occur nightly in clusters, particularly when the subject is under emotional stress. Episodes may range from speaking a single word or a sentence to a long elaborated dialogue. Content may be either meaningful or nonsense. Sleeptalkers seem to be either talking to themselves or having a dialogue. The voice can be the same or different as in the waking state. Sometimes sleeptalking may be accompanied by other sounds and vocalizations, such as whispering, muttering, humming, moaning, weeping, giggling, and shouting. It is rarely accompanied by crying, laughing, and singing.[55] In a study performed in the Basque country, a region in northern Spain in which two completely different official languages are spoken (Euskera and Spanish), most children used their dominant (native) language during sleeptalking, and less than 4% used their nondominant language.[56]

Epidemiology. Sleeptalking is very common in the general population. About half of children present somniloquy at least once a year, but less than 10% present it every day.[56,57] Sleeptalking in children decreases with time and is slightly more common in boys (53%) than in girls (47%).[43]

Natural Course. Onset is usually between the ages of 3 and 10 years, but it may start in adolescence and even in early adulthood. The course is variable because it may be present for a few days only, recur in clusters, or last for several months or many years. In children, sleeptalking usually resolves spontaneously during adolescence or adulthood.

Polysomnography. There are few formal studies assessing isolated sleeptalking with polysomnography. These have shown that sleeptalking occurs in all sleep stages; 50% to 60% of cases are associated with N1 and N2 sleep, 20% to 25% with N3 sleep, and 20% to 25% with REM sleep.[58] Some subjects only experience sleeptalking during NREM sleep, others exclusively in REM sleep, and the majority in both NREM and REM sleep.[58] When a person is experiencing sleeptalking and is experimentally awakened, dream recall occurs in 79% of the episodes arising from REM sleep, in 46% of the events arising from N2 sleep, and in 20% of the spells arising from N3 sleep. Sleeptalking episodes related to REM sleep are longer and clearer than those occurring in N2 and N3 sleep.[58] In REM sleep, episodes of sleeptalking are characterized by sustained alpha electroencephalographic trains.[59]

Associations. Most cases of sleeptalking are not associated with a medical illness or psychopathologic conditions. Predisposing factors include anxiety, sleep deprivation, and fever. Children are more likely to experience recurrent sleeptalking if parents had sleep talking during childhood.[60]

Etiology. The etiology is unknown. Some cases may have a clear familial predisposition suggesting a genetic background.[61]

Management. Isolated sleeptalking is benign and an uncommon reason for consultation in a sleep center. However, it may become disturbing for both the sleeptalker and the bed partner if it is frequent and excessively long or loud and if the content includes obscenities and discusses intimate experiences. Isolated sleeptalking has no specific medical treatment, but adequate sleep hygiene and reduction of emotional stress may help.

Secondary Sleeptalking

Sleeptalking may occur as one of the clinical manifestations of several disorders (Table 105-2) that are covered in other chapters of this book.

Table 105-2 Conditions Associated with Secondary Sleeptalking

Confusional arousals[88]
Night terrors[88]
Sleepwalking[88]
Sleep-related eating syndrome[66]
Sexsomnia[63]
REM sleep behavior disorder[74,89-91]
Status dissociatus[68]
Parasomnia overlap disorder[69]
Agrypnia excitata[92]
IgLON5 parasomnia[73]
Nocturnal frontal lobe epilepsy[1]
Periodic limb movement disorder[93]
Obstructive sleep apnea[94]
Nocturnal panic attacks[1]
Sleep-related dissociative disorder[1]

PARASOMNIA DUE TO A MEDICAL DISORDER

Parasomnia due to a medical disorder consists on the presence of a parasomnia that is attributable to an underlying neurologic disorder or medical condition.[1] Secondary NREM sleep and REM sleep parasomnias are covered in Chapters 102 and 103, respectively.

NREM Sleep Parasomnias

Confusional arousals, night terrors, and sleepwalking are idiopathic disorders of arousal that are not linked to any specific psychiatric, psychological, neurologic, or medical disorder. Patients with disorders of arousal do not develop a neurodegenerative disease with time. Episodes of disorders of arousal can be precipitated by sleep deprivation, night shifts, fever, alcohol, noise, touch, psychological stress, and anxiety.[62] Coexistent obstructive sleep apnea and periodic leg movements in sleep may provoke partial arousals, resulting in episodes of disorders of arousal and sleepwalking variants (sleep-related eating disorder, sleep driving, and sexsomnia) in predisposed individuals.

Sleep-related eating disorder is associated with sleepwalking, sleep smoking, sexsomnia,[63] narcolepsy with cataplexy,[64] restless legs syndrome,[65] nocturnal eating syndrome,[65] and depression.[66,67]

Combined NREM and REM Sleep Parasomnias

Parasomnia Overlap Disorder

Parasomnia overlap disorder is the coexistence of a disorder of arousal (NREM parasomnia) and RBD (REM parasomnia) in the same patient. This entity mainly affects young subjects in whom NREM sleep clinical and polysomnographic features of the parasomnia predominate over RBD. Two thirds of these patients have an idiopathic form,[68-70] and the remaining third have a form linked to several heterogeneous disorders, such as Mobius syndrome,[68] narcolepsy,[68] multiple sclerosis,[68] removal of fourth ventricle astrocytoma,[68] head trauma,[68] atrial fibrillation during sleep,[68] posttraumatic stress disorder,[68] ethanol abuse,[68] harlequin syndrome,[71] and brainstem structural lesions.[72] On the other hand, the link between NREM sleep parasomnia and RBD can be by chance in an older subject who has had a disorder of arousal since childhood that persists and who decades later develops RBD. In some cases, this may explain the fact that a few subjects with idiopathic RBD who are older than 60 years report that their abnormal behaviors started 30 to 50 years earlier. In more severe cases of overlap disorder, patients have degradation of sleep and wake features and behaviors to point of the being indistinguishable in status dissociates.

IgLON5 Parasomnia

The recently described IgLON5 parasomnia[73] is a novel neurologic disorder initially described in eight unrelated adults in whom subacute (two cases) and chronic (six cases) presentations were noted. Patients presented clinically with witnessed apneic events, stridor, abnormal sleep behaviors, and additional waking neurologic symptoms such as gait instability, dysarthria, dysphagia, chorea, and mild dysautonomia. Patients had no previous history of disorders of arousal, they denied insomnia, and they were unaware of their sleep behaviors that were only noted by the bed partner. Video polysomnography showed a complex, distinct pattern characterized by (1) normal occipital alpha rhythm during wakefulness; (2) mild to moderate reduction of total sleep time and sleep efficiency; (3) a distinctive temporal sequence of sleep stages and behaviors taking place, from most abnormal at the beginning of the night to more normal at the end; (4) initiation of sleep and reentering of sleep after awakenings characterized by prolonged periods of theta activity with motor activation and rapid repetitive leg movements that do not fit criteria periodic leg movements in sleep; (5) reduced amount of normal N2 sleep; (6) periods of diffuse delta activity, typical of normal N3 sleep, mixed with spindles; (7) poorly structured stage N2 sleep characterized by clear spindles and K-complexes with frequent vocalizations (e.g., talking, laughing, crying) and simple (e.g., raising the arm, punching) and finalistic (e.g., goal-directed behaviors like sucking the thumbs while apparently eating, manipulating wires) behaviors; (8) RBD characterized by limb and body jerks but no violent or finalistic behaviors; and (9) obstructive sleep apnea and inspiratory stridor secondary to vocal cord palsy, particularly intense during normal N3 stage (Figures 105-1 and 105-2). Longitudinal follow-up by polysomnography showed no deterioration of these features with time.

Autoantibodies against IgLON5, a neuronal cell adhesion protein, were identified in all patients. The haplotypes DQB1*0501 and DRB1*1001 were detected in all four patients tested. Most of the patients died suddenly during wakefulness or in sleep. Neuropathology performed in two patients showed a tauopathy mainly involving the tegmentum of the brainstem and the hypothalamus, making the underlying pathophysiologic process unclear. To date (September 2015) two additional cases with the same HLA haplotype have been published where insomnia, hypersomnia, chorea, and dementia were part of the clinical spectrum.[73a,73b]

REM Sleep Parasomnias

As pointed out in the ICSD3, when diagnostic criteria for RBD are met, the more specific diagnosis of RBD should be

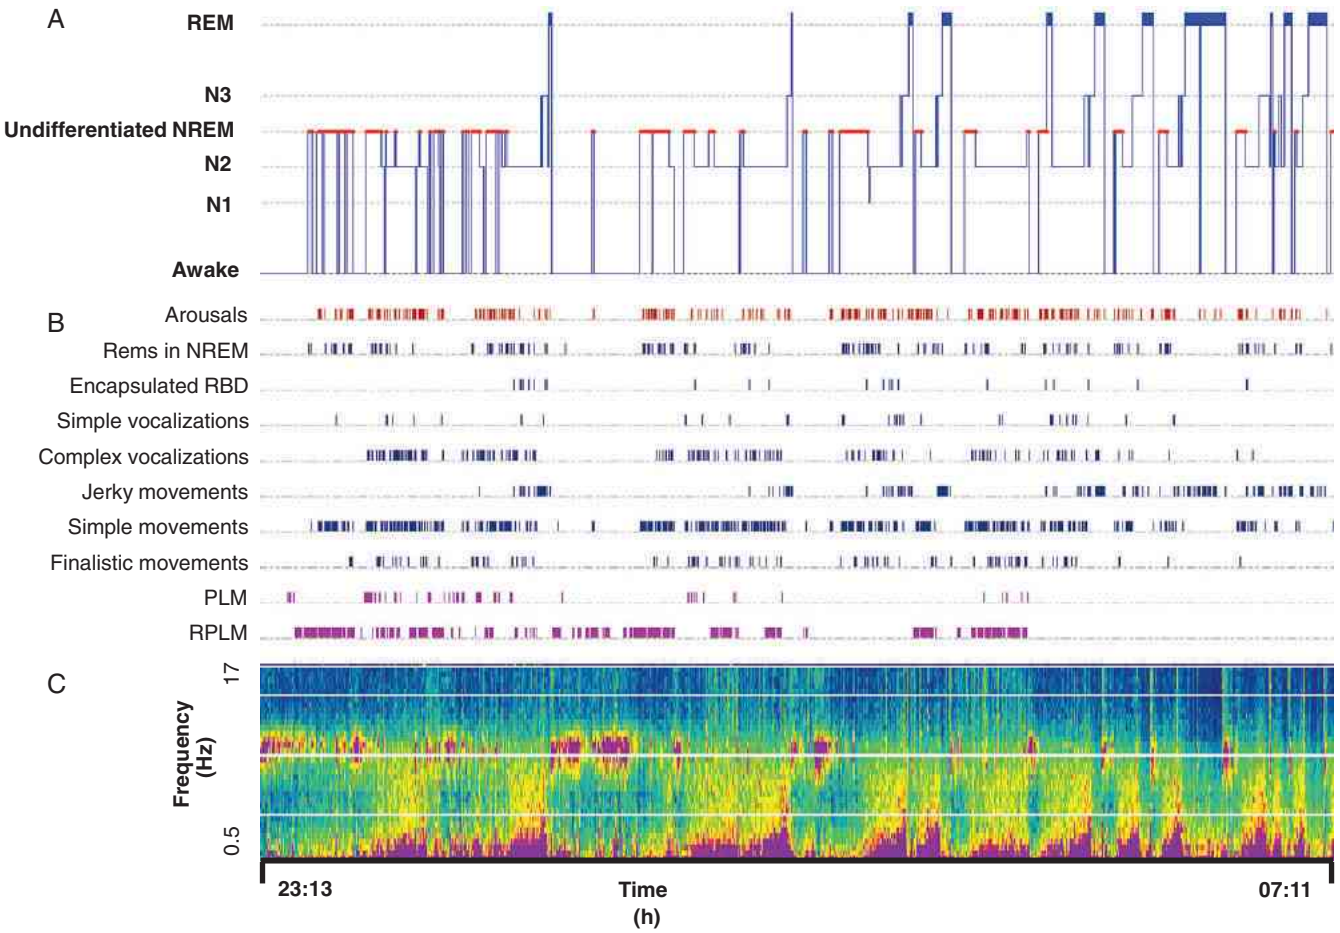

Figure 105-1 Sleep recording with continuous positive airway pressure in a patient with IgLON5 parasomnia. **A,** Hypnogram. **B,** Arousals, dissociations, and abnormal movements. **C,** Density spectral array showing the power spectrum of electroencephalographic frequencies (0–17 Hz) in electrode C3 referenced to electrode O2. *Warmer colors* indicate more dominant frequencies. made, as with the other parasomnias.[1] In some instances, RBD may be an important clinical feature, and in others it is not clinically significant and is overlooked by other symptoms and signs (e.g., dementia, confusion, seizures). RBD is frequent among 25% to 58% patients with Parkinson disease,[74-78] 70% to 80% with dementia with Lewy bodies,[74,75,79] and 90% to 100% with multiple-system atrophy[74,75,80] as well as other neurodegenerative diseases, autoimmune diseases like narcolepsy, and structural brainstem lesions (see Chapter 103).[74]

PARASOMNIA DUE TO A MEDICATION OR SUBSTANCE

The assumption of drug-induced parasomnia is based on the temporal association between the introduction of the drug and the onset of the abnormal sleep behaviors and their cessation after the drug is stopped. The emergent parasomnia can be de novo parasomnia, the aggravation of a chronic intermittent parasomnia, or the reactivation of a previous parasomnia.[1]

NREM Sleep Parasomnias

The most common drugs inducing NREM sleep parasomnias are zolpidem (used at therapeutic doses for insomnia)[81] and less frequently sodium oxybate (at high doses within the normal range for narcolepsy).[82] Both medications can cause sleepwalking, sleep-related eating disorder, sleep driving, and sleep sex.[81,82] There is no strong evidence that alcohol causes sleepwalking or other NREM parasomnias, but alcohol could increase sleep apnea evoking a parasomnia event.[1]

REM Sleep Parasomnias

Antidepressants, including tricyclics, selective serotonin reuptake inhibitors, and selective noradrenaline reuptake inhibitors, have been described to trigger or aggravate RBD. They include clomipramine, imipramine, nortriptyline, mirtazapine, fluoxetine, venlafaxine, paroxetine, sertraline, citalopram, and escitalopram.[74,83,84]

The introduction of lipophilic beta blockers such as bisoprolol can also induce RBD parasomnias.[85] There are also reports of RBD induced by withdrawal from meprobamate and alcohol.[86] Suvorexant may induce sleep paralysis.[87]

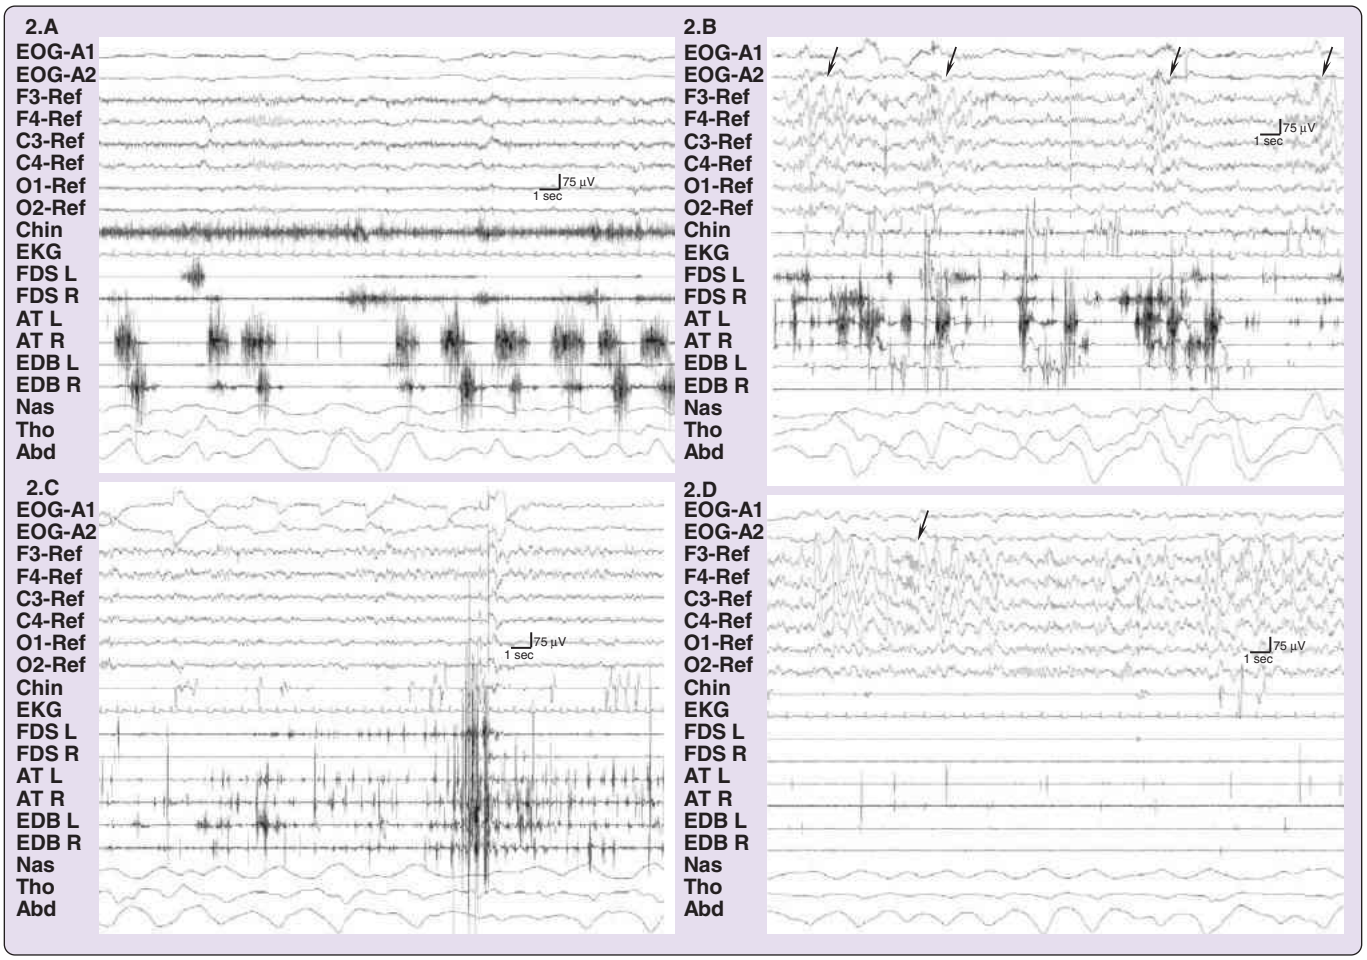

Figure 105-2 Polysomnographic epochs illustrative of each sleep state in a patient with IgLON5 parasomnia. **A,** Sleep onset characterized by undifferentiated NREM sleep with diffuse theta activity and rapid periodic leg movements particularly prominent at the right anterior tibialis electromyographic channel. **B,** N2 sleep with chains of two or three consecutive K-complexes (*arrows*) with frequent muscular phasic activity in electromyogram (EMG) surface of the limbs that correlate with finalistic movements. **C,** REM sleep with typical rapid eye movements and electroencephalogram (EEG) features with excessive phasic muscular activity and limb jerks indicative of REM sleep behavior disorder. **D,** N3 with diffuse delta activity mixed with well-defined sleep spindles at 13 Hz (*arrows*) without vocalizations nor movements. Note the calibration mark for time/EEG voltage.

CLINICAL PEARL

When facing a patient who seeks medical advice for abnormal behaviors or experiences during sleep, clinicians should be aware that, in addition to NREM sleep parasomnias, REM sleep parasomnias, and sleep-related movement disorders, there still remains a group of other parasomnias that include sleep-related hallucinations, exploding head syndrome, sleep enuresis, and sleeptalking.

SUMMARY

This chapter describes a miscellaneous group of parasomnias that are included in the ICSD3 under the category "other parasomnias." Sleep-related hallucinations are experiences perceived in the wake-sleep transition or on awakening during the night or in the morning. Hypnagogic and hypnopompic hallucinations are common in the general population and in narcolepsy, whereas complex nocturnal visual hallucinations are usually linked to an underlying pathologic condition such as Parkinson disease, brainstem structural lesions, and severe vision loss. EHS is possibly a type of auditory hallucination characterized by a benign sense of a loud explosion in the head that awakens the individual. SE is characterized by recurrent involuntary voiding during sleep in subjects older than 5 years. SE is usually idiopathic and transient, but other conditions such as obstructive sleep apnea and genitourinary tract malformations may be associated. Isolated sleeptalking is a very common normal sleep variant that consists of talking while the individual is asleep. However, sleeptalking also occurs in the setting of the NREM- and REM-related parasomnias. RBD is associated with neurodegenerative diseases, autoimmune diseases, structural brainstem lesions, and medications such as antidepressants. All types of NREM-related

parasomnias may be induced by medications, particularly by zolpidem. The recently described IgLON5 parasomnia is characterized by obstructive sleep apnea, abnormal sleep architecture, and abnormal behaviors during both NREM and REM sleep in subjects with a brainstem and hypothalamic tauopathy and antibodies against the protein IgLON5.

Sleep-Related Movement Disorders and Their Unique Motor Manifestations

Rachel E. Salas; Seema Gulyani; Anthony B. Kwan; Charlene E. Gamaldo

Chapter Highlights

- The *International Classification of Sleep Disorders*, 3rd edition, currently recognizes 10 sleep-related movement disorders and 4 isolated sleep-related movements that are generally characterized as simple and stereotyped movements primarily affecting sleep initiation, maintenance, or quality.
- To be classified as a disorder, these movements must be associated with a functional complaint (e.g., daytime sleepiness).
- Sleep clinicians should have a familiarity with all sleep-related movement disorders to distinguish them from other more clinically significant medical and neurodegenerative disorders with which they may share some overlapping clinical features.

A variety of simple and complex movements can occur during sleep. Many movements are considered part of the normal sleep-wake state or may be normal variants, whereas others may be more disturbing. The third edition of the *International Classification of Sleep Disorders* (ICSD3)[1] currently lists 10 sleep-related movement disorders (SRMDs) and 4 isolated sleep-related movements that are relatively simple, stereotyped movements disturbing to sleep or sleep onset.[1] SRMDs are important to recognize and to differentiate from normal physiologic movements during sleep and other more serious movements that occur during sleep in medical disorders, such as nocturnal seizures and parasomnias. The presence of significant clinical consequences, such as interference with sleep quality, daytime dysfunction, or body injury requiring medical treatment, is what differentiates sleep-related rhythmic movement disorder from normal sleep-related movements.[2] In the case of sleep-related rhythmic movement disorder, timely recognition is necessary because it often warrants further evaluation or treatment. This chapter provides a discussion of the movements commonly observed during sleep (Figure 106-1), focusing primarily on the sleep-related movements (both physiologic and pathologic) that are not specifically covered in designated chapters elsewhere within this textbook. These movements of sleep are divided into three groups: (1) normal physiologic movements typically observed in sleep, (2) isolated sleep-related movements and normal variants, and (3) SRMDs. Normal physiologic movements typically observed in sleep, movements classified as isolated sleep-related movements, and normal sleep-related movement variants are important events to recognize as benign and not indicators of other possible pathologic processes. SRMDs include a range of simple and repetitive movements that may be associated with downstream clinical symptoms. Some features are useful clues to distinguish normal movements from more clinically significant events during sleep. Key elements in the history, such as a clear description of the events, specific region of the body, time of occurrence, age at onset, and findings on polysomnography (PSG), are helpful for determining the etiology.

NORMAL PHYSIOLOGIC MOVEMENTS OF SLEEP

Phasic Twitches During REM Sleep

Twitches during rapid eye movement (REM) sleep are sudden, brief physiologic movements. These twitches typically occur during the phasic periods of REM sleep and can usually be observed in the context of visible eye movements. The movements are seen in the leg electromyography leads and take on a short (usually <0.10 second) repetitive burst pattern that is superimposed on the suppressed "atonic" background electromyographic (EMG) baseline (Figure 106-2). These twitches usually involve small distal muscle groups and as a result are not usually manifested as an overt segmental body movement.

Major Body Movements

The American Academy of Sleep Medicine (AASM) scoring manual currently recognizes the phenomenon of major body movements as a normal manifestation of body movements due to individuals' moving or shifting position during a sleep period.[2] These movements can be scored as contiguous with the sleep stage that occurred before and after the major body movement epoch if the preceding epoch does not demonstrate overwhelming evidence of prolonged arousal or awakening (e.g., slow eye movements). If evidence suggests prolonged arousal or awakening within the epoch following the major body movement, the major body movement epoch is considered a wake state; if the body movement occurs contiguous

with two definitive wake epochs of wakefulness, it is also considered a wake epoch.

ISOLATED SLEEP-RELATED MOVEMENTS AND NORMAL VARIANTS

Periodic Limb Movements in Sleep

Polysomnography Scoring Criteria and Motor Features

Periodic limb movements in sleep (PLMS) in isolation (i.e., not associated with another sleep or medical disorder) are benign, sporadic episodes of involuntary leg movements that occur during sleep. PLMS typically involve extension of the big toe in combination with partial flexion of the ankle, the knee, and sometimes even the hip.[1] Although these movements predominantly occur in the legs, they may occur in the upper extremities as well. According to the AASM scoring criteria, PLMS must consist of a series of four or more consecutive movements, each lasting 0.5 to 10 seconds with intermovement intervals of 5 to 90 seconds and an amplitude greater than 8 mV above the resting baseline EMG signal (Figure 106-2). The PLMS index is defined as the number of PLMS divided by the observation time in hours. In general, a PLMS index is considered abnormal if it is more than 5 per hour in children and more than 15 per hour in adults.[1] Five percent to 6% of all asymptomatic adults have been reported to demonstrate PLMS on PSG, and in these cases they are considered benign epiphenomena. For this reason, PLMS is included in this chapter as a clinical consideration under the category of a normal variant. Figure 106-2 provides unique physiologic features to distinguish PLMS from other isolated sleep movements and normal variants that can be mistaken for PLMS on PSG, and Table 106-1 offers some of the pathological associations with periodic limb movements. In the context of coexisting clinical or functional symptoms, further clinical evaluation is recommended. The reader is referred to Chapter 95 for discussion of PLMS as it relates to periodic limb movement disorder, restless legs syndrome, and other sleep disorders.

Excessive Fragmentary Myoclonus

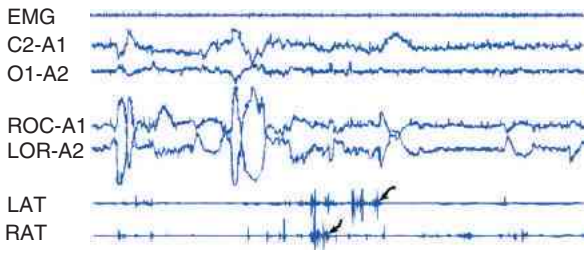
Excessive fragmentary myoclonus (EFM) is characterized by very small (often nonvisible to the blind eye) movements of the corners of the mouth, fingers, or toes. EFM is usually noted as an incidental EMG finding and to date has not been associated with any negative clinical sequelae. EFM is usually seen during non-REM (NREM) sleep. Morphologically, the EMG bursts seen in EFM occur for at least 20 minutes during NREM sleep with at least 5 bursts per minute, each with a duration of approximately 150 milliseconds (see Figure 106-2).[2] EFM activity typically occurs without evidence of alterations in the electroencephalogram (suggesting an associated arousal). However, in the case of relatively high altitude EFM bursts, associated K-complexes or shifts to faster electroencephalographic (EEG) frequencies may be observed.[3] EFM predominantly occurs in adult men. On rare occasions, EFM may result in sleep fragmentation and may be associated with obstructive sleep apnea (OSA), central sleep apnea, sleep-related hypoxemic/hypoventilation syndromes, narcolepsy, periodic limb movement disorder, and various causes of insomnia.[1]

Alternating Leg Muscle Activation

Alternating leg muscle activation (ALMA) was first coined by Chervin et al[4] to describe alternating EMG bursts in the legs during sleep. Much shorter in duration than PLMS, ALMA is defined by a duration of 100 to 500 milliseconds with a frequency range for the EMG bursts that alternate between the legs of 0.5 to 3.0 Hz (see Figure 106-2). A single ALMA episode represents at least four movements that alternate between the legs. Although the pathophysiologic mechanism of ALMA is currently unknown, researchers suspect a relation between ALMA and serotoninergic and dopaminergic pathways in the spinal network. Although ALMA does not require treatment in most cases, a sleep specialist may consider treatment in select patients who also exhibit sleep disruption. In fact, treatment of ALMA with pramipexole, a

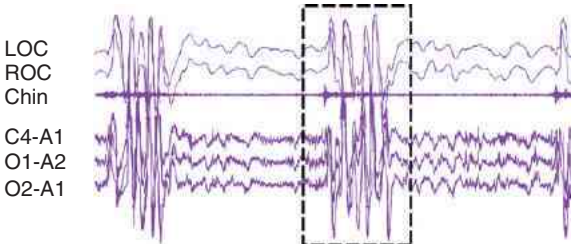
Disorders with their Distinct Features

REM twitches



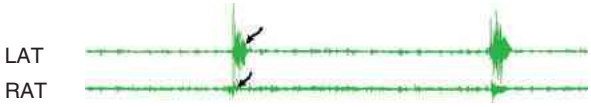
- Occur during phasic periods of REM sleep and often seen along with visible eye movements
- Leg movements are typically short (usually <.10 sec) repetitive burst pattern superimposed on the suppressed "atonic" background EMG baseline
- Twitches usually involve small distal muscle groups and as a result do not usually manifest as an overt segmental body movement

RMD



- Repetitive, stereotypes, and rhythmic motor behaviors involving large muscle groups (e.g. body rocking or head banging)

PLMS

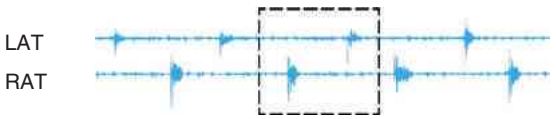


- Typically involve extension of the big toe, along with partial flexion of the ankle, the knee and rarely hip
- Consist of a series of > 4 movements, 0.5 - 10 seconds and 5 to 90 seconds between movements and an amplitude > 8 mV above the resting baseline EMG signal

EFM

- Very small to no visible movement (e.g. minor movement or twitching of the fingers, toes or corners of the mouth)
- Persists in all stages of sleep (at least 20 mins of NREM sleep with EFM must be recorded)

ALMA

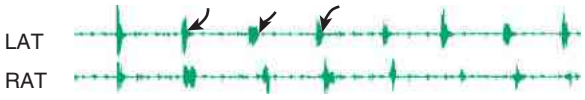


- Alternating contractions between legs
- Usual range of duration is 100-500 msec

HFT

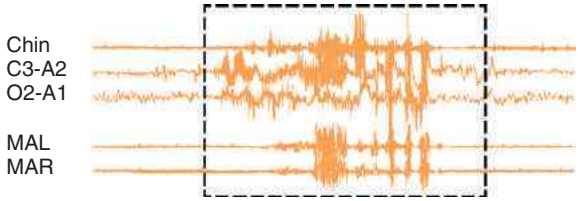
- Rhythmic foot movements in one or both feet
- Occurs at the transition between wake and sleep or during light sleep (N1 and N2)
- Usual range of duration is 250-1000 msec

Leg Cramps



- Non-period bursts of gastrocnemius EMG activity rarely associated with any other physiological changes during sleep (i.e. arousal heart rate increase etc.)
- Can be observed in all sleep stages and wake

Bruxism



- May consist of either brief/phasic or sustained/tonic elevations of EMG activity

Denotes an individual movement Highlights a movement cluster

Table 106-1 Occurrence of Periodic Limb Movements in Sleep due to Medical Disorders or Medication or Substance

Sleep Disorders	Medical Disorders Not Primarily Affecting Sleep	Medications
Restless legs syndrome (Willis Ekbom Disease)	Severe congestive heart failure	Clomipramine
Periodic limb movement disorder	Hypertension	Lithium
Narcolepsy	Tourette syndrome	Fluoxetine
Obstructive sleep apnea	End-stage renal disease	Venlafaxine
REM sleep behavior disorder	Syringomyelia Juvenile fibromyalgia Systemic sclerosis (scleroderma) Spinal cord injury Morbus Parkinson Multiple system atrophy Posttraumatic stress disorder	Selective serotonin reuptake inhibitors Bupropion Doxepin

dopamine agonist, may be considered because it has been shown to significantly reduce the occurrence of ALMA, insomnia, and daytime sleepiness.[5]

Hypnagogic Foot Tremor

Hypnagogic foot tremor (HFT) is categorized as a rhythmic movement of the feet or toes that occurs at the transition between wake and sleep or during light sleep.[6] To be designated an HFT, at least four EMG bursts, 250 to 1000 milliseconds in duration, must occur in a frequency range series between 0.3 and 4.0 Hz (see Figure 106-2). HFT appears as trains of recurrent EMG potentials or movements in either one or both legs, whereas ALMA appears as a brief activation in the anterior tibialis of one leg alternating with the other leg. PLMS, in contrast, have a longer interval between the movements. Whereas PLMS have a minimum interval of 5 seconds, the interval is 0.25 second for HFT and 0.3 second for ALMA. Currently, no clinical consequences of HFT have been reported; thus, treatment outside of patient education on the diagnosis and the benign nature of this movement disorder during sleep is typically all that is warranted. HFT appears to be a fairly common disorder. In 2001, Wichniak et al[6] looked at the prevalence of this disorder in 375 consecutive patients with sleep disorders and found a prevalence of 7.5%.

Sleep Starts (Hypnic Jerks)

Sleep starts, also known as hypnic jerks, are sudden, brief, simultaneous contractions of the body or one or more body segments occurring at sleep onset. Sleep starts occur at the wake-sleep transition and are usually not repetitive.[1] Sleep starts (hypnic jerks) usually consist of a single contraction that often affects the body asymmetrically. The jerks may be either spontaneous or induced by stimuli. PSG recordings show that hypnic jerks generally occur during transitions from wakefulness to sleep, mainly at the beginning of the sleep episode. Superficial EMG recordings of the involved muscles show brief (generally 75- to 250-milliseconds) high-amplitude potentials, either singly or in succession. The electroencephalogram typically shows drowsiness or stage N1 sleep during these movements. The motor activity is often associated with sensory (e.g., a feeling of falling, pain, tingling), auditory (e.g., banging, snapping, or crackling noises), or visual (e.g., flashing lights, hypnagogic hallucination) sensations. Interestingly, a sharp cry may even occur with the movement. The patient may not recall these often "dramatic" movements if they do not result in an awakening. When sleep starts are frequent, intense, or repetitive, they could potentially result in insomnia. The prevalence for sleep starts may be as high as 60% to 70%.[1] Sleep starts affect all ages and both sexes. Patient education on the diagnosis and the benign nature of these phenomena should be pursued. Excessive caffeine or other stimulant intake, prior intense physical work or exercise, sleep deprivation, and emotional stress all can increase the frequency and severity of sleep starts and should be a point of discussion with patients presenting for evaluation.

SLEEP-RELATED MOVEMENT DISORDERS

SRMDs encompass a broad range of simple and typically stereotyped movements that are rarely associated with clinical dysfunction (e.g., poor sleep quality, nonrestorative sleep, fatigue). These phenomenologic features are helpful clues in distinguishing SRMDs from the more complex and clinically significant movements observed during sleep (e.g., in the case of parasomnias, which can involve behaviors and movements that may result in injuries, sleep disruption, adverse health effects, and unpleasant psychosocial effects). In this section, we discuss the following disorders: sleep-related leg cramps, bruxism, sleep-related rhythmic movement disorder, benign sleep myoclonus of infancy, and propriospinal myoclonus at sleep onset. These are all conditions currently classified in the ICSD3 under the SRMD category. The diagnoses of SRMD due to medical disorder, SRMD due to medication or substance, and SRMD unspecified are not covered in detail in this chapter. Differentiating between the SRMDs can be accomplished by recognizing features that are unique to their respective presentations, including the specific body regions affected, age at onset, and unique polysomnographic features. Detailed discussion of these characteristic features is presented in the following section.

Sleep-Related Leg Cramps

Clinical Features

Sleep-related leg cramps are painful sensations usually in the calf or small muscles of the foot and are caused by sudden and intense involuntary contractions during which there is muscle

spasm and hardness for several seconds.[1] In addition, the diagnosis requires that the painful muscle contractions occur during the sleep period and that the pain is relieved by forcefully stretching the affected muscle. Although the sleep-related leg cramps normally begin suddenly, they may also begin slowly with less painful warning signs.[7] These cramps can last for a few seconds up to several minutes. They may also occur as rarely as once per year in some individuals, whereas others can have many cramps every night, potentially resulting in insomnia. Individuals with sleep-related leg cramps report, in general, more sleep disturbances, snoring, less adequate sleep, and excessive daytime sleepiness.[8] In addition, individuals who experience leg cramps tend to have a lower quality of life.[8] Although generally considered to be an idiopathic condition, sleep-related leg cramps have been reported to be associated with vascular disease, lumbar canal stenosis, cirrhosis, hemodialysis, pregnancy, neuromuscular disorders, and other medical conditions (e.g., metabolic disorders). Moreover, certain medications may also result in sleep-related leg cramps.

Differential Diagnosis

Sleep-related leg cramps are often cited as a condition easily confused with the leg discomfort experienced in those individuals with restless legs syndrome (RLS; Willis Ekbom Disease [WED]). The leg discomfort of RLS, however, does not typically involve cramps that can be resolved by stretching. Because both disorders are characterized by leg discomfort and RLS patients may report cramping sensations, careful clinical history and examination are needed to distinguish between these disorders. The critical differentiating feature of sleep-related leg cramps is the actual spasm or hardening of the muscle that occurs during the leg pain, which is not seen in RLS. Furthermore, leg cramp events tend to be much briefer compared with the typical symptoms of RLS, which can persist for hours. Nocturnal leg cramps can also be confused with epilepsy, particularly in infants. Features to help distinguish between the two include the fact that sleep-related cramps last less than a second, whereas epileptic movement is more rhythmic and lasts longer and is typically associated with other features suggestive of seizure. Sleep-related leg cramps can also be confused with various other disorders, such as chronic myelopathy, peripheral neuropathy, and muscular pain fasciculation syndrome, so it is important to distinguish sleep-related leg cramps by clinical history and physical examination. Unlike nocturnal cramps, peripheral neuropathy tends to be associated with sensory or motor findings.[9] Focal dystonias of the feet can be distinguished electrophysiologically from leg cramps by demonstration of ongoing co-contraction of agonist and antagonist muscles. Whereas the history and physical examination are necessary in distinguishing sleep-related leg cramps from other medical conditions, laboratory studies and other more specialized testing (e.g., electromyography, nerve conduction studies) are typically unnecessary to make the diagnosis.

Polysomnography Scoring Criteria and Motor Features

Individuals who experience chronic sleep-related leg cramps often also report insomnia. Sleep-related leg cramps reveal nonperiodic bursts of gastrocnemius EMG activity that arise without any specific preceding physiologic changes during sleep.[1] Sleep-related leg cramps may also be observed throughout all sleep stages, which further demonstrates that they cannot be attributed to physiologic changes during particular stages.

Pathophysiology

The pathophysiologic mechanism of sleep-related leg cramps is still uncertain. These muscle cramps occur when sustained recruitment of motor units causes the leg muscles to contract. Based on electrophysiologic recordings, leg muscle contractions are associated with high-frequency and high-voltage discharges after spontaneous firing of anterior horn cells, which suggests abnormal excitability in the spinal cord.[9] Other mechanisms that may contribute to leg cramps include spinal disinhibition, abnormal terminal motor nerve excitability, and enhanced muscle contraction propagation through cross-activation of adjacent neurons.[10] Pain experienced in leg cramps may result from local ischemia or from local metabolite accumulations.

Prevalence and At-Risk Groups

Although these nocturnal leg cramps generally occur in older adults, leg cramp disturbances may occur at any age. Sleep-related leg cramps occur in about 7% of children and adolescents (typically not occurring before the age of 8 years), 33% of adults older than 60 years, and 50% of adults older than 80 years, with both older groups reporting a symptom frequency of at least once every 2 months. Pregnancy has also been associated with sleep-related leg cramps; about 33% to 50% of pregnant women experience leg cramps that also tend to become worse as pregnancy progresses but tend to go away after delivery. Vigorous exercise, use of certain medications (e.g., naproxen, intravenous iron sucrose, conjugated estrogens, and teriparatide), dehydration, fluid and electrolyte disturbances, and disorders that reduce mobilization in individuals can trigger nocturnal cramps. In addition, individuals with certain medical disorders, such as diabetes, sleep apnea,[11] blood vessel disease, metabolic disorders, and nerve or muscle diseases, may be more likely to have sleep-related cramps.

Treatment

Treatment of leg cramps includes frequent stretching or massaging of the affected muscle, application of heat, and movement of the affected limbs. In one report, quinine was considered to be an effective option, but the benefits may be modest (about 20% to 25% reduction in the number of cramps).[12] In another study, quinine (300 to 500 mg) did show clinically significant improvement of leg cramps.[13] Limitations of quinine also relate to severe side effects (e.g., thrombocytopenia and cardiac arrhythmias) that, for most clinicians, are thought to outweigh the potential benefits.[12] Although diltiazem has been shown to be effective, supporting data are limited.[12] Anticonvulsants, such as gabapentin and levetiracetam, have not been adequately assessed. Studies have also suggested that vitamin E may be an effective treatment. Recently published case series reported almost complete resolution of leg cramps with the use of continuous positive airway pressure in patients with moderate to severe sleep apnea.[11] Magnesium supplements are marketed for the prophylaxis of cramps, but systematic review reported that it is unlikely that magnesium supplementation provides clinically meaningful cramp prophylaxis to older adults experiencing skeletal muscle cramps.[14]

Sleep-Related Bruxism

Clinical Features

The repetitive jaw muscle activity characterized by clenching or grinding of the teeth and by bracing or thrusting of the mandible is referred to as bruxism, the Greek word for "gnashing of teeth." The clinical diagnosis of sleep-related bruxism, which is described in much more detail in Chapter 144, can be made when an individual demonstrates or reports regular or frequent tooth grinding sounds during sleep and one or more of the following: abnormal tooth wear consistent with the reports of tooth grinding during sleep, transient morning jaw muscle pain or fatigue, temporal headache, and jaw locking on awakening consistent with reports of tooth grinding during sleep.[1] The intensity and duration of sleep-related bruxism are variable, but it often occurs hundreds of times during a sleep period. Although there is likely to be a relationship between bruxism and stress or anxiety, this has not been adequately supported.

Prevalence and At-Risk Groups

Sleep-related bruxism tends to occur in families; approximately 20% to 50% of affected individuals have at least one direct family member with a history of tooth grinding, and childhood sleep-related bruxism appears to persist into adulthood in two thirds of reported cases. Despite this, no genetic variants or genetic inheritance patterns have been identified with sleep-related bruxism. Bruxism is more common during childhood. Prevalence is approximately 8% in middle-aged adults and 3% in older adults, which may be explained by edentulism, use of dentures, and changes in sleeping behaviors (i.e., no bed partner) likely influencing reporting.[1] There is no gender difference for sleep-related bruxism. Curiously, individuals who are highly motivated or characteristically maintain high vigilance may have an increased prevalence of sleep-related bruxism.[1] Precipitating factors can include anxiety related to current life events, tasks requiring high levels of performance, and repetitive tasks with short deadlines.[1] The use of cigarettes or caffeine in the hours before sleep also can contribute to the occurrence of sleep-related bruxism (probably because of the increased arousals and sleep instability).

Differential Diagnosis

Sleep-related bruxism needs to be differentiated from other faciomandibular activities occurring during sleep, such as faciomandibular myoclonus, REM sleep behavior disorder, abnormal swallowing, gastroesophageal reflux, night terrors, confusional arousals, dyskinetic jaw movements persisting in sleep (dystonia, tremor, chorea, dyskinesia), and, rarely, sleep-related epilepsy.

Unpleasant muscle and tooth sensations, limitation of jaw movements, orofacial pain, temporal or tension headaches, tooth wear, fractured teeth, and buccal lacerations may result from excessive bruxism.[1] Headaches, frequently reported by both adults and children, typically involve the temporal regions and tend to be reported either in the morning (with sleep bruxism) or during the day (with wake bruxism). Sleep-related bruxism can be so loud that it can be disruptive to the affected person's bed partner and to those sleeping nearby.

Polysomnography Scoring Criteria and Motor Features

PSG is not required to make the diagnosis, but bruxism can be recorded with EMG activity on the PSG study.[2] PSG may be indicated to evaluate for associated respiratory disturbances, gastroesophageal reflux, REM sleep behavior disorder, night terrors, faciomandibular myoclonus, or epilepsy.[1] The muscle potential increase, as recorded on the polysomnogram, must be differentiated from simple body or head movements; myoclonus, which is periodic short muscle contractions during sleep; head banging, rhythmic movements of the head occasionally occurring at a frequency of about 1 Hz, which is within the frequency of bruxism; and other rhythmic oromandibular activities (e.g., sleep chewing automatism). To detect and to study sleep bruxism, standard PSG has to include additional EMG derivations; surface electrodes are placed over bilateral masseter and temporal muscles, sometimes even on the frontal muscles; audio-video recordings help confirm the nature of the sounds (e.g., grinding, snoring) and the type of movements (e.g., sigh, swallowing, coughing, myoclonus, body rocking). The electrographic picture of a bruxism episode can vary from a sustained tonic contraction to a phasic burst, with an increase in muscle potential (more than 20% of the maximal voluntary activity awake) lasting 0.5 second or more with an intermovement interval of more than 3 seconds.[15] These increases in muscle potential, to be clearly identified as bruxism, have to be correlated to the loud "grinding sounds" as noted online by a vigilant technician or recorded for later analysis. There are no standard criteria for reports of bruxism episodes; usually indices are used to give the total number of episodes per hour of sleep.

There are distinct morphologic features of bruxism on PSG that include brief (phasic) or sustained (tonic) elevations of chin EMG activity that are at least twice the amplitude of background EMG activity. Phasic elevations occur in a regular sequence at least three times with each elevation and about 0.25 to 2 seconds in duration (Figure 106-2). For tonic elevations, EMG activity must occur for more than 2 seconds to be scored as bruxism. New episodes of bruxism are scored after a period of at least 3 seconds of stable background chin EMG activity has occurred. The sensitivity of PSG in detecting sleep-related bruxism in severe cases is moderate to high, whereas it is low in mild cases because of the night-to-night variability. Interestingly, bruxism has been found to be associated with cyclic alternating pattern[16-18] preceding EEG activity in the alpha range as well as tachycardia.[19,20] Ambulatory home monitoring may be used for screening, diagnosis, and treatment outcome assessment by studying the individual in his or her native environment, but it is characterized by lower diagnostic specificity.[1]

Pathophysiology

Sleep-related bruxism can be primary or idiopathic when there is no identified cause, whereas secondary sleep-related bruxism may result from the use of medications or recreational drugs or a variety of medical disorders (e.g., Parkinson disease, REM sleep behavior disorder, Down syndrome).[1] Interestingly, catecholamines (e.g., norepinephrine and dopamine) have been potentially implicated as having a role in the pathophysiologic process of bruxism.[21-23] Sleep-related bruxism may occur in those with cerebral palsy and mental retardation and

in adult patients with abnormal movements, such as oromandibular myoclonus/faciomandibular myoclonus, or with sleep-related breathing disorders, such as sleep apnea.[1]

Treatment

Sleep specialists should evaluate for secondary causes of bruxism, such as undiagnosed and untreated sleep apnea, epilepsy, tics, and medication-induced dyskinesias or dystonias. Bruxism typically involves a constellation of stereotypical somatic complaints, such as dental attrition, tooth pain, temporomandibular joint dysfunction, and headaches, whereas other disorders within the differential, such as sleep apnea, epilepsy, tics, and medication-induced dyskinesias, typically do not.[24] In addition, sleep apnea is often associated with snoring and witnessed apneas and excessive daytime sleepiness, whereas tics tend to occur during the day and not during sleep. Medication-induced dyskinesias and dystonias (e.g., oromandibular dystonia and orofacial dyskinesia) are temporally related to an onset associated with the initiation or use of particular medications. The utility of dental splints and mouth guards may be helpful in many cases in the appropriate patient. In severe cases, medications such as anxiolytics and muscle relaxants may be considered. Behavioral modifications can also be helpful. Consider referral to a dentist or sleep behavioral psychologist for a team-based approach in patients who appear to have severe bruxism or are experiencing reduced quality of life.

Sleep-Related Rhythmic Movement Disorder

Clinical Features

Sleep-related rhythmic movement disorder (RMD) is characterized by repetitive, stereotyped, and rhythmic motor behaviors. It is a clinical diagnosis based entirely on the patient's history and neurologic examination. Subtypes of RMD include body rocking, head banging, head rolling (side-to-side movements of the head), and a combined type involving two or more of the individual types. Whereas other movements, such as body rolling, leg banging, and leg rolling, may also be noted, movements such as hand banging are less common. Interestingly, different types of RMD may sometimes occur in the same individual during the same night.[25-27]

The episodes usually last less than 15 minutes, but the duration may vary from a few minutes to an hour, with a frequency of 0.5 to 2 per second. Rhythmic humming may be heard along with the movements.[1] The movements and the associated sounds may be quite loud. Environmental noise or distractions during the movements may lead to cessation of the event. Whereas RMD was thought to occur mostly during transitions between sleep and wakefulness, these movements may occur during any stage of sleep[28,29] and during quiet wakeful activities, such as listening to music or riding in a vehicle.[1] Children with RMD are otherwise normal but may experience insomnia, parasomnia (e.g., sleepwalking), and daytime sleepiness.[30] Significant daytime sleepiness may also be observed in adults.[31] RMD in infants and toddlers is typically not associated with significant risk of injury. Some patients may develop a soft tissue swelling over the forehead known as "head banger tumor." On rare occasions, enlargement of the diploic space in the parietal and occipital bones with loss of adjacent gray matter on magnetic resonance imaging in head bangers has been reported.[32]

In adults, RMD is more likely to be reported in association with other primary sleep disorders, such as OSA, narcolepsy, REM sleep behavior disorder, and attention-deficit/hyperactivity disorder, which may be of potential therapeutic benefit.[33] For instance, RMD such as body rocking, head banging, and head rolling may be noted in severe RLS.[34] Furthermore, RMD during sleep onset for an individual with RLS may even be used as a strategy to relieve internal dysesthesia symptoms of RLS. Interestingly, OSA-associated RMD often improves with positive airway pressure when patients are treated for OSA. Curiously, individuals with narcolepsy may demonstrate rhythmic movements that result in the termination of episodes of sleep paralysis.[35] These movements are usually more concerning and bothersome for the bed partner than for the patient. Patients with RMD may experience insomnia, but it is not clear whether sleep difficulties are evoked by the movements or simply accompany them.[12]

Differential Diagnosis

The diagnosis of RMD is one of exclusion. Diagnosis of RMD can typically be established by clinical history or video recordings provided by the patient. PSG is indicated when the clinical history alone is insufficient to provide diagnostic certainty or when the movements are atypical or particularly violent. Seizure is in the differential if movements are associated with other clinical evidence suggestive of a seizure (e.g., bowel or bladder incontinence, tongue biting, foaming at the mouth) or supported by the patient's history (i.e., seizure risk). In cases in which there is a concern for seizure, full electroencephalography should be considered. Other conditions to consider in the differential diagnosis for RMD include parasomnias such as REM sleep behavior disorder (which tend to be complex and "goal directed," but in the context of inappropriate behavior, whereas RMD is more monophasic and not goal directed). Other conditions in the differential diagnosis include sleep myoclonus (which occurs in all stages of NREM and REM sleep) and bruxism. RMD is specifically distinguished from tremor, another common neurologic disorder in the differential, as it is defined as a rhythmic and involuntary movement of any body part. The neurologic and medical history often elucidates the underlying cause of tremor, particularly when it is temporally associated with a specific event (e.g., stroke or head injury) or disease manifestation or progression (e.g., multiple sclerosis). On the other hand, RMD is classified as a disorder only if the behaviors interfere with normal sleep and cause impairment in daytime function.

Polysomnography Scoring Criteria and Motor Features

The AASM scoring manual currently defines RMD as a minimum of four stereotypical movements occurring in a cluster pattern at a frequency of 0.5 to 2.0 Hz (Figure 106-2). RMD can be witnessed during quiet wakeful activities or during sleep initiation, presumably as a potential self-soothing ritual. Video-PSG studies have shown that nearly half of all rhythmic movements occur during stages N1 or N2 exclusively, with approximately one third occurring throughout both NREM and REM sleep and one quarter occurring exclusively during REM sleep. Interestingly, the rhythmic movements exclusive to REM occur more frequently in adults.

Prevalence and At-Risk Groups

Although it is seen in adults, RMD is an SRMD primarily observed in children. At 9 months of age, 59% of all infants have been reported to exhibit one or more sleep-related rhythmic movements; the overall prevalence has been reported to decline to 33% by 18 months and to only 5% by 5 years.[1] Temper tantrums and attention-deficit disorder[36-39] and high levels of general distress and generalized anxiety disorder[40] may be associated with RMD. Attention-deficit/hyperactivity disorder, RLS, and sleep apnea[33,34,41,42] have also been associated with RMD. REM sleep behavior disorder has also been reported to be associated with RMD.[43,44]

Pathophysiology

The neurobiologic mechanisms underlying RMD remain uncertain. Because these movements are common in infants and young children, some believe that the cause is related to the soothing effect of vestibular stimulation by the rhythmic movements. The absence of organic causes in the majority of cases has led to behavioral and psychological theories[45] proposing that perhaps RMD is linked to fluctuations in arousal that are mediated through central motor pattern generators of the brainstem.

Treatment

There are no proven therapies for RMD. On the occasion when treatment is required (i.e., concerns about self-injury), safety precautions are typically emphasized (i.e., protective head gear), followed by the use of clonazepam and imipramine based on a limited amount of efficacy data.[46] Other treatments that have been used include antidepressants,[47,48] behavioral interventions,[49] hypnosis,[50] and sleep restriction.[51] RMD requires specific treatment only if risk of body injury or severe disruption to the sleep of a bed partner is present.[12] Subsequently, induced sleep disorders such as insomnia can be independently evaluated and addressed.

Benign Sleep Myoclonus of Infancy

Clinical Features

Benign sleep myoclonus of infancy (BSMI) is the myoclonic jerking movement of the elbow, fingers, toes, and face during sleep in infants. The diagnosis can be made when there is observation of repetitive myoclonic jerks involving the limbs, trunk, or whole body in an infant (e.g., birth to 6 months of age).[1] The movements tend to be bilateral and massive, involving large muscle groups, and can occur in the whole body or only in the limbs, the trunk, or rarely the face. Symptoms may be present for only a few days or may last for several months. These movements occur during sleep only and stop when the infant is aroused. Diagnosis of BSMI can be made if the infant has all the aforementioned criteria and symptoms cannot be better explained by the use of a medication or by another sleep, medical, or neurologic disorder.[1]

Differential Diagnosis

BSMI is considered benign and rare, but it is often confused with epilepsy, particularly myoclonic seizures and myoclonic encephalopathy. An EEG recording during episodes of myoclonus will not show parallel seizure activity in the brain. Neurologic examination findings are usually normal for patients with BSMI, although some may exhibit nonspecific neurologic signs or expressive language delays. Workup may include electroencephalography, a metabolic panel, and screening for toxins in the case of equivocal clinical presentations.[52] Provocative maneuvers, such as gently rocking the child's crib, have been shown to induce a BSMI event and may be useful with EEG monitoring to help differentiate BSMI from seizures. Other key features to distinguish BSMI from other neurologic disorders are listed in Table 106-2.

Table 106-2 Common Mimics of Benign Sleep Myoclonus of Infancy (BSMI)

Mimics	Distinguishing Features
Myoclonic seizures	Can occur while infants are awake, whereas BSMI will stop abruptly and consistently when infants are aroused Often associated with perinatal disorders (i.e., hypoxic-ischemic encephalopathy, infection, or metabolic abnormalities), whereas BSMI is typically manifested in neurologically normal infants
Infantile spasms (West syndrome)	Often seen after the first month of life but may occur earlier Manifested by sudden head flexion with arm extension and lower extremity flexion Usually associated with hypsarrhythmia electroencephalographic pattern
Pyridoxine-dependency seizures	Responsive to vitamin B_6 treatment
Myoclonic encephalopathies	Can occur while infants are awake, whereas BSMI will stop abruptly and consistently when infants are aroused
Hyperekplexia (startle disease)	Can occur while infants are awake, whereas BSMI will stop abruptly and consistently when infants are aroused Generalized stiffness while awake Exaggerated startle reflex
Jitteriness	Typical movements occur as an excessive response to stimulation, such as touch or loud noise

Polysomnography Scoring Criteria and Motor Features

On PSG, a BSMI event generally demonstrates paroxysmal body jerks that typically occur in clusters of four or five in number that are usually 40 to 300 milliseconds in duration. Once the BSMI episode has ensued, the paroxysmal body jerks can be repeated for several minutes in most cases but rarely continue past an hour. The video monitoring and EEG channels, during an episode of BSMI, will not demonstrate concurrent arousals, awakening, or (as noted before) ictal or interictal activity, which helps differentiate BSMI from seizures.

Pathophysiology

The pathophysiologic mechanism of BSMI remains unknown. It has been proposed that BSMI may be due to the inability of an immature (and unmyelinated) central nervous system's descending pathway to sufficiently inhibit the underlying movements generated from the cervical spinal cord.[1]

Prevalence and At-Risk Groups

The prevalence for BSMI is unknown, and the incidence has been estimated at 0.8 to 3 per 1000 live births.[54] Interestingly, boys are affected more than girls. Whereas BSMI has been reported in a case of opioid withdrawal syndrome, the majority of infants are neurologically normal and born to mothers with no history of illicit drug use.[53]

Treatment

No specific therapeutic intervention is necessary, except parental education on the disorder and reassurance. Recognition of this condition is important, especially to avoid potentially harmful and certainly unwarranted antiepileptic treatment. Workup may include electroencephalography, a metabolic panel, and screening for toxins.[52]

Propriospinal Myoclonus at Sleep Onset

Clinical Features

Propriospinal myoclonus at sleep onset (i.e., spinal myoclonus, plurisegmental myoclonus, intersegmental myoclonus, axial myoclonus) is a rare disorder characterized by jerks involving the abdominal and truncal muscles occurring at the transition from wakefulness to sleep.[1] The diagnosis can be made when a patient reports sudden jerks, mainly of the abdomen, trunk, and neck, during relaxed wakefulness and drowsiness as the patient attempts to fall asleep. The jerks disappear with sleep onset and are not observed during sleep.

These movements directly result in complaints of sleep disruption and insomnia not otherwise explained by another cause. Movements are typically spontaneous but can be evoked by external stimulations. The movements disappear with mental activation and with the onset of a stable sleep stage. Propriospinal myoclonus can have a negative impact on quality of life and is described as a chronic, unremitting condition that may result in injury to the patient or the bed partner.

Differential Diagnosis

Because of the stereotyped and rhythmic pattern of the often "full body jerking" appearance of these movements, they can easily be confused with seizures. In the case of propriospinal myoclonus at sleep onset, EEG signal will be normal during the event. Because of its temporal relation to sleep onset, observers may also confuse it with movements triggered by the dysesthesias of RLS since these dysesthesias can also be triggered with relaxed wakefulness in the recumbent position. A simple clinical history will help distinguish the voluntary movements to relieve RLS dysesthesias compared with the involuntary movements seen with propriospinal myoclonus of sleep onset.

Polysomnography Scoring Criteria and Motor Features

PSG confirms that the myoclonic activity is restricted to the wakefulness period preceding sleep onset or falling to sleep and is manifested as trunk flexion or, less frequently, extension.

Table 106-3 Common Mimics of Propriospinal Myoclonus

Sleep starts
Phasic REM twitches
Fragmentary myoclonus
Epileptic myoclonus
Periodic limb movements in sleep
Psychogenic myoclonus

During relaxed wakefulness, the myoclonic activity appears when the EEG alpha rhythm spreads from the occipital to the frontal leads or as the alpha rhythm drops out. Isolated or repetitive jerks may occur. The EMG discharges last typically 100 to 300 milliseconds but sometimes longer, with both reciprocal and co-contracting agonist-antagonist activity.

During relaxed wakefulness, the myoclonic activity appears when the EEG alpha rhythm spreads from the posterior to the anterior cortical areas or when it drops out. The jerks disappear with sleep onset and are not observed during sleep. Jerks may recur at quasi-periodic intervals (every 5 to 40 seconds), and this pattern may repeat itself more than a hundred times with consequent delayed sleep onset and sleep fragmentation.[45] No EEG abnormalities in the routine recording have been reported. Similar to RLS, these movements appear to be related to the recumbent position and a state of relaxed wakefulness. Table 106-3 highlights some of the mimics for propriospinal myoclonus.

Pathophysiology

Although the pathophysiologic mechanism for propriospinal myoclonus remains unknown, it is believed to involve the spinal cord serving as the underlying generator for the movement. Interestingly, persistent propriospinal myoclonus occurring during the day has been linked to structural spinal cord disease, whereas propriospinal myoclonus during sleep onset at this point in time has not.[1]

Prevalence and At-Risk Groups

It is likely that propriospinal myoclonus is a rare condition. The disorder has been reported to affect adults and to be more common in men, but it has not been reported to affect children.[1]

Treatment

As with most SRMDs, education is recommended for treatment after a thorough evaluation to rule out more serious disorders. Some patients may respond to clonazepam.

CLINICAL PEARL

Key features to help distinguish SRMDs from other movements observed during the night typically include the following: normal physical and neurologic examination findings, absence of comorbid neurologic conditions, absence of abnormal neurophysiologic findings (e.g., normal sleep and wake EEG findings), and presence of simple and stereotyped movements (as

CLINICAL PEARL—cont'd

opposed to the more complex movements and behaviors seen with parasomnias or seizures). Because of the simple and stereotypical appearance of SRMDs, each individual type can be differentiated by the characteristic age at onset, characteristic timing at which it occurs during the night, body region affected, and unique polysomnographic characteristics.

SUMMARY

The ICSD3 currently recognizes 10 different SRMDs and 4 isolated sleep-related movements. Although most SRMDs are considered benign, they can often result in sleep disruption and reduced quality of life. Thus, because of the relatively high prevalence of SRMDs and the phenomenologic overlap with other neurodegenerative or medical conditions, sleep health care providers and scientists should be familiar with this class of sleep conditions.

ACKNOWLEDGMENT

The authors wish to acknowledge Mr. Anthony Kwan for his original work on Figure 106-1 and Ms. Seulah Choi for her original work on Figure 106-2.

Section
14 Sleep Breathing Disorders

Chapter
107 Sleep Related Breathing Disorders: Classification

Richard B. Berry

Chapter Highlights

- This chapter presents a classification and clinical overview of sleep breathing disorders based on the recently published *International Classification of Sleep Disorders*, third edition (ICSD3).
- Diagnostic criteria for sleep related breathing disorders in adults, including the obstructive sleep apnea disorder, central sleep apnea disorders, and sleep-related hypoventilation disorders, are provided based on the ICSD3.
- New additions to the ICSD3 classification of sleep related breathing disorders include diagnostic criteria for the obesity hypoventilation syndrome and treatment-emergent central sleep apnea.
- Out-of-center sleep testing (home sleep apnea testing) is now included in the diagnostic criteria for obstructive sleep apnea disorder in adults.
- Central sleep apnea with Cheyne-Stokes breathing is uniquely defined in the ICSD3 based on symptoms and comorbid conditions as well as polysomnographic findings.
- Areas of controversy and unresolved issues relating to the ICSD3 diagnostic classification of sleep related breathing disorders are discussed.

Box 107-1 ADULT SLEEP RELATED BREATHING DISORDERS IN THE ICSD3 (ICD-9) [ICD-10]

Obstructive Sleep Apnea Disorders

Obstructive Sleep Apnea, Adult (327.23) [G47.33]

Central Sleep Apnea Disorders*

Central Sleep Apnea with Cheyne-Stokes Breathing (786.04) [R06.3]
Central Sleep Apnea Due to a Medical Disorder without Cheyne-Stokes Breathing (327.27) [G47.37]
Central Sleep Apnea Due to High Altitude Periodic Breathing (327.22) [G47.32]

Sleep Related Hypoxemia Disorders

Sleep-Related Hypoxemia (327.26) [G47.36]

*In ICSD3, Central Sleep Apnea Syndromes (here, "disorders" is used for consistency).

ICD-9, *International Classification of Diseases*, 9th revision; ICD-10, *International Classification of Diseases*, 10th revision; ICSD3, *International Classification of Sleep Disorders*, 3rd edition.

This chapter presents a classification and clinical overview of sleep breathing disorders based on the recently published *International Classification of Sleep Disorders*, third edition (ICSD3).[1] The term *Sleep Related Breathing Disorders* is used throughout the text and tables of this chapter to conform to the ICSD3 terminology. The goal is to provide a summary of diagnostic criteria for the major disorders, with brief illustrative clinical cases for selected disorders. Box 107-1 lists the ICSD3 sleep related breathing disorder classification in adults; the *International Classification of Diseases*, 9th (ICD-9) and 10th (ICD-10) revisions' codes for each diagnosis are also listed. The ICSD3 provides a timely update of diagnostic criteria for sleep related breathing disorders because the ICSD2 (second edition) was published in 2005. Where appropriate, areas of controversy and unresolved issues are discussed.

Of note, the ICSD3 does not itself define sleep-related respiratory events, but instead refers to the most recent version of the *American Academy of Sleep Medicine (AASM) Manual for the Scoring of Sleep and Associated Events* (hereafter referred to as the AASM scoring manual).[2] Where relevant for understanding diagnostic criteria, the definition of selected respiratory events is reviewed. The fact that patients may fit into more than one diagnostic category of sleep-related breathing disorders is emphasized in the ICSD3.

The ICSD3 often uses the term *disorder* rather than *syndrome*. A disorder usually refers to a disease process for which a cause is known. In contrast, a syndrome is a constellation of symptoms. In general, use of disorder versus syndrome is somewhat arbitrary and often variable in the medical literature. For example, the term *congenital central hypoventilation syndrome* continues to be used in the literature although the genetic cause has been identified (mutation in *PHOX2B* gene).

OBSTRUCTIVE SLEEP APNEA DISORDERS

In the ICSD3, obstructive sleep apnea (OSA) disorders are classified separately as adult and pediatric. However, this chapter refers solely to adult disorders. OSA is classified as a disorder in the ICSD3. One could argue that OSA is better described as a syndrome because the pathophysiology may be structural in one patient and due to unstable respiratory control in another patient.[3] It is to be noted that the term *obstructive sleep apnea syndrome* is frequently used in the literature.

The adult OSA diagnostic criteria currently include a provision for use of both in-center polysomnography (PSG) and out-of-center sleep testing (OCST), in which sleep is usually not recorded. OCST has also been termed *portable monitoring*, *home sleep testing*, and *home sleep apnea testing*. Obstructive respiratory events in sleep that account for the diagnosis of adult OSA include obstructive and mixed apneas, hypopneas, and respiratory effort–related arousals (RERAs). The ICSD3 does not provide a definition for these events. A summary of such respiratory event definitions as defined by the AASM scoring manual is provided in Box 107-2. There are currently two hypopnea definitions in the manual ("recommended" and "acceptable"). Of note, if sleep is not recorded, hypopneas must be scored based on airflow attenuation and arterial oxygen desaturation criteria alone because there is an inability to score arousals from sleep without documentation of sleep.

The most recent version of the AASM scoring manual defines the apnea-hypopnea index (AHI) as the number of apneas and hypopneas per hour of sleep; the respiratory disturbance index is defined as the AHI plus the number of RERAs per hour of sleep. If OCST is performed, sleep is usually not recorded, and the diagnostic metric is the number of apneas and hypopneas per hour of monitoring time (sometimes called the *respiratory event index*). The ICSD3 does not define the terms AHI, RDI, or respiratory event index.

Diagnostic criteria for OSA (Box 107-3) require either 15 or more obstructive respiratory events per hour of sleep using PSG (or per hour of monitoring using OCST) *or* a combination of symptoms, manifestations, and comorbidities (see later) and at least 5 but less than 15 obstructive respiratory events per hour of sleep (PSG) or per hour of monitoring if OCST is used. The rationale is that patients with 15 or more obstructive respiratory events per hour are thought to have a clinically significant disorder even if symptoms are absent. The best evidence for increased risk for cardiovascular morbidity is in patients with more than 30 obstructive respiratory events per hours of sleep.[4] In the case of at least 5 but less than 15 obstructive respiratory events per hour, the clinician may be concerned about overdiagnosis in an asymptomatic patient without a significant clinical disorder. The requirement of symptoms in the milder range of an increased AHI (or RDI) will exclude asymptomatic patients. The clinical significance of an AHI (or respiratory disturbance index [RDI]) in the mild range must be evaluated by the clinician,

Box 107-2 ADULT RESPIRATORY EVENT DEFINITIONS

Apnea

1. Score a respiratory event as an apnea when *both* of the following criteria are met:
   a. There is a drop in the peak signal excursion by ≥90% of pre-event baseline using an oronasal thermal sensor (diagnostic study), positive airway pressure (PAP) device flow (titration study), or alternative apnea sensor (diagnostic study).
   b. The duration of the ≥90% drop in sensor signal is ≥10 seconds.
2. Score an apnea as obstructive if it meets apnea criteria and is associated with continued or increased inspiratory effort throughout the entire period of absent airflow.
3. Score an apnea as central if it meets apnea criteria and is associated with absent inspiratory effort throughout the entire period of absent airflow.
4. Score an apnea as mixed if it meets apnea criteria and is associated with absent inspiratory effort in the initial portion of the event, followed by resumption of inspiratory effort in the second portion of the event.

Hypopnea

1A. Score a respiratory event as a hypopnea if *all* of the following criteria are met (**RECOMMENDED**):
   a. The peak signal excursions drop by ≥30% of preevent baseline using nasal pressure (diagnostic study), PAP device flow (titration study), or an alternative hypopnea sensor (diagnostic study).
   b. The duration of the ≥30% drop in signal excursion is ≥10 seconds.
   c. There is ≥3% oxygen desaturation from preevent baseline, or the event is associated with an arousal.

1B. Score a respiratory event as a hypopnea if *all* of the following criteria are met (**ACCEPTABLE**):
   a. The peak signal excursions drop by ≥30% of preevent baseline using nasal pressure (diagnostic study), PAP device flow (titration study), or an alternative hypopnea sensor (diagnostic study).
   b. The duration of the ≥30% drop in signal excursion is ≥10 seconds.
   c. There is a ≥4% oxygen desaturation from preevent baseline.

Respiratory Effort–Related Arousal

Score a respiratory event as a respiratory effort-related arousal (RERA) if there is a sequence of breaths lasting ≥10 seconds characterized by increasing respiratory effort or by flattening of the inspiratory portion of the nasal pressure (diagnostic study) or PAP device flow (titration study) waveform leading to arousal from sleep when the sequence of breaths *does not meet criteria for an apnea or hypopnea.*

Adapted from Berry RB, Brooks R, Gamaldo CE, et al, for the American Academy of Sleep Medicine. *The AASM manual for the scoring of sleep and associated events: rules, terminology and technical specifications*. Version 2.2. www.aasmnet.org. Darien, Illinois: American Academy of Sleep Medicine, 2015.

taking into account symptoms as well as comorbid cardiovascular conditions. Certainly, symptomatic patients with an AHI (RDI) in the mild range may experience benefit from treatment of OSA.[4]

Identification of RERAs is adjudicated based on associated arousal rather than oxygen desaturation and therefore requires the recording of sleep (i.e., PSG). Hypopneas are included as OSA respiratory events without specific determination as to whether they are obstructive or nonobstructive (i.e., central). It is emphasized that symptoms and comorbid conditions thought to be associated with or adversely affected by the presence of OSA are required for the diagnosis if the index of obstructive events is equal to or greater than 5 per hour but less than 15 per hour (see Box 107-3). Such comorbid conditions qualifying a patient for a diagnosis of OSA include systemic hypertension, a mood disorder, cognitive dysfunction, coronary artery disease, stroke, congestive heart failure, atrial fibrillation, type 2 diabetes mellitus, nocturia, and erectile dysfunction.

Although a major study published in 1993 found OSA prevalence (defined as symptoms *and* AHI ≥5 per hour) to be 2% in women and 4% in adult men,[5] the current prevalence of OSA is believed to be much higher, likely because of increased prevalence of obesity.[6] The prevalence of OSA in fact varies with the characteristics of the population studied and respiratory event definitions.[4] Note that although patients with obesity-hypoventilation syndrome are currently classified under the sleep-related hypoventilation disorders (see later), 80% to 90% of patients so classified also meet diagnostic criteria for OSA.

There is continuing controversy concerning the most appropriate definition of hypopnea.[4] The current AASM scoring manual *acceptable* definition of hypopnea, a 30% or greater drop in airflow plus 4% or greater arterial oxygen desaturation (see Box 107-2), is consistent with that accepted by the Centers for Medicare and Medicaid Services. The recommended definition of hypopnea is based on a lesser degree of oxygen desaturation (≥3%) or the presence of an associated arousal, or both. The AHI-acceptable and AHI-recommended terminology will be used here to denote the AHI determined using either the acceptable hypopnea (H-acceptable) or recommended hypopnea (H-recommended) definition. Note that, because RERAs by definition do not meet diagnostic criteria for hypopnea,[2] classification of a given event as RERA versus hypopnea often depends on the definition of hypopnea that is used to score events. For example, an event characterized by flattening of the airflow profile with a 30% reduction in flow for 15 seconds followed by a 2% arterial oxygen desaturation and an arousal would meet diagnostic criteria for H-recommended but not H-acceptable. If hypopneas are scored based on criteria for H-acceptable, the event would meet criteria for RERA. If one uses the ICSD3 criteria, which include the RERA index as part of the diagnostic metric (e.g., AHI-acceptable + RERA index), a wider spectrum of patients will be diagnosed as having OSA than using AHI-acceptable. The addition of the RERA index will diagnose patients often labeled as having the upper airway resistance syndrome as having OSA. These patients report symptoms due to respiratory arousals but do not have significant arterial oxygen desaturation.[4] Of note, upper airway resistance syndrome is not included in the ICSD3 diagnostic criteria; such patients are thought to have a variant of OSA (see Chapter 112, Snoring and Pathologic Upper Airway Resistance Syndromes). If the H-recommended definition is used, most events scored as

Box 107-3 ICSD3 DIAGNOSTIC CRITERIA: OBSTRUCTIVE SLEEP APNEA, ADULT

(A and B) or C satisfy the criteria.

A. The presence of one or more of the following:
   1. The patient complains of sleepiness, nonrestorative sleep, fatigue, or insomnia symptoms.
   2. The patient wakes with breath holding, gasping, or choking.
   3. The bed partner or other observer reports habitual snoring, breathing interruptions, or both during the patient's sleep.
   4. The patient has been diagnosed with hypertension, a mood disorder, cognitive dysfunction, coronary heart disease, stroke, congestive heart failure, atrial fibrillation, or type 2 diabetes mellitus.

B. Polysomnography (PSG) or out-of-center sleep testing (OCST*) demonstrates:
   1. Five or more obstructive respiratory events† (i.e., obstructive or mixed apneas, hypopneas, or respiratory effort–related arousals [RERAs])‡ per hour of sleep during PSG or per hour of monitoring (OCST*)

   or

C. PSG or OCST* demonstrates:
   1. Fifteen or more obstructive respiratory events† (i.e., obstructive or mixed apneas, hypopneas, or RERAs)‡ per hour of sleep during PSG or per hour of monitoring (OCST*)

*OCST may underestimate the true number of obstructive respiratory events per hour because actual sleep is not usually recorded.

†Respiratory events defined according the latest version of the *AASM Manual for the Scoring of Sleep and Associated Events*.

‡RERAs cannot be scored using OCST because arousals cannot be identified.

RERAs when using H-acceptable would meet criteria for H-recommended such that AHI-acceptable + RERA index ≈ AHI-recommended.[4] Data indicate that using a diagnostic metric including RERAs or an AHI-recommended will identify an increased percentage of individuals studied as having OSA.

The following clinical case illustrates the hypopnea definition issue. A thin 30-year-old man reported loud snoring and daytime sleepiness. A diagnostic PSG recorded 420 minutes of sleep, during which there were 10 obstructive apneas, 10 hypopneas (H-acceptable definition) and 40 RERAs. The AHI was therefore 2.8/hour, and the RDI was 8.6 per hour. Many of the events scored as RERAs were associated with a 1% or 2% drop in the oxygen saturation. Using the AHI-acceptable as a diagnostic metric, the patient does not have the OSA disorder. If the same sleep study were scored using the recommended rather than the acceptable hypopnea definition, 10 obstructive apneas, 45 hypopneas, and 5 RERAs would be scored, and the AHI would be 7.8 per hour (the RDI would have continued to be 8.6 per hour). A diagnosis of OSA would then be possible (if associated with symptoms/comorbidity). This assumes that 35 of the 40 RERA events were associated with a 30% or greater drop in flow as well as inspiratory flattening for at least 10 seconds.

CENTRAL SLEEP APNEA DISORDERS

Patients with the central sleep apnea (CSA) disorders are a diverse group with a wide spectrum of etiologies.[7,8] Many of the diagnostic entities associated with CSA are associated with either unknown or multiple etiologies. The common finding is absence of airflow and respiratory effort (central apnea) or reduced airflow and respiratory effort without clear evidence of partially obstructed breathing (e.g., inspiratory airflow signal flattening or paradoxic thoracoabdominal respiratory effort [central hypopnea], or both). In the AASM scoring manual,[2] scoring hypopneas as central or obstructive is noted as an option, with the following specifications: hypopnea is scored as obstructive if any of the following are present: there is snoring during the event; there is increased inspiratory flattening of the nasal pressure or positive airway pressure (PAP) device flow signal compared with baseline breathing; or there is an associated thoracoabdominal paradox that occurs during the event but not during preevent breathing. A hypopnea is scored as central if none of these are present. The option for scoring hypopneas as central was added because some patients with CSA have a significant proportion of events that are central hypopneas.[4,9,10] Further, a number of large clinical trials of patients with CSA have included central hypopneas in the inclusion criteria.[9,10]

Some clinicians have proposed that the CSA disorders can be categorized on the basis of the disorder being associated with awake- or sleep-associated hypocapnia (i.e., high ventilatory drive) and normocapnia or hypercapnia (i.e., normal or low ventilatory drive).[7] Primary CSA, CSA with Cheyne-Stokes breathing (CSB), CSA due to high-altitude periodic breathing, and treatment emergent CSA are thought to occur because the sleeping arterial partial pressure of carbon dioxide ($Paco_2$) is below the apneic threshold (AT)—the $Paco_2$ value below which there is no ventilatory effort.[7] High hypercapnic ventilatory drive (both awake and during sleep) characterizes such patients and is associated with a small difference between the sleeping $Paco_2$ and the AT (delta $Paco_2$). While awake, such patients have a normal or low $Paco_2$. The low awake or sleeping $Paco_2$ does not cause the small delta $Paco_2$ but rather is a marker of high ventilatory drive. CSA due to a medical disorder without CSB and CSA due to a medication or substance are thought to be associated with normal or low ventilatory drive.

Central Sleep Apnea with Cheyne-Stokes Breathing

In the ICSD2,[11] this entity was listed as CSB pattern without a requirement for symptoms or associated conditions. One could argue that diagnostic criteria for a breathing *pattern* would be more appropriately defined in the scoring manual rather than in the classification of sleep disorders. As defined in the ICSD3, central sleep apnea with Cheyne-Stokes breathing (CSA-CSB) is a clinical disorder rather than simply a PSG finding (Box 107-4),[1] with the main rationale being that the identification of patients with CSA-CSB, which is a very common disorder, has clinical implications, including etiology (most have congestive heart failure) and prognosis.[12] Thus symptoms (sleepiness, insomnia, awakening short of breath, snoring, witnessed apneas) or the presence of comorbid conditions (atrial fibrillation, congestive heart failure, or a neurologic disorder), or both, are required in the ICSD3 for a diagnosis of CSA-CSB. CSA-CSB is common in patients with both stable and decompensated congestive heart failure[13] and can occur following a cerebrovascular accident.[14-16] Renal failure has also been associated with CSA-CSB, although such documentation in the literature is very

Box 107-4 ICSD3 DIAGNOSTIC CRITERIA: CENTRAL SLEEP APNEA WITH CHEYNE-STOKES BREATHING

(A or B) + C + D satisfy the criteria.

A. The presence of one or more of the following:
   1. Sleepiness
   2. Difficulty initiating or maintaining sleep, frequent awakenings, or nonrestorative sleep
   3. Awakening short of breath
   4. Snoring
   5. Witnessed apneas

B. The presence of atrial fibrillation/flutter, congestive heart failure, or a neurologic disorder

C. Polysomnography (PSG) (during diagnostic or positive airway pressure titration) shows all of the following:
   1. Five or more central apneas or central hypopneas per hour of sleep
   2. The total number of central apneas and/or central hypopneas is >50% of the total number of apneas and hypopneas
   3. The pattern of ventilation meets criteria for Cheyne-Stokes breathing

D. The disorder is not better explained by another current sleep disorder, medication use (e.g. narcotics), or substance use disorder

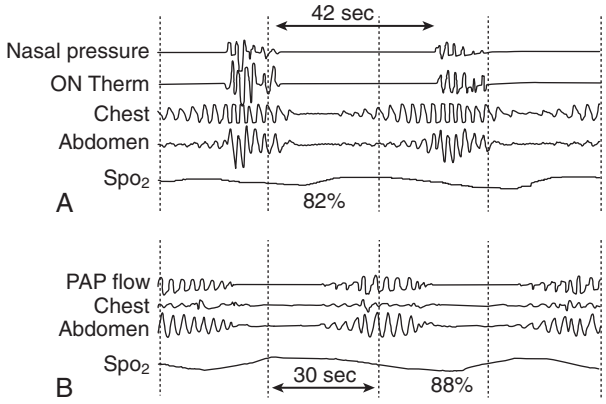

Figure 107-1 Respiratory events during a diagnostic **(A)** and positive airway pressure sleep study **(B).** The middle event in the top tracing is a "mixed" apnea; the flanking events are "obstructive" apneas. Central apneas with Cheyne-Stokes breathing are shown in the lower tracing. The patient was on continuous positive airway pressure of 12 cm H_2O. ON Therm, Oronasal thermal flow sensor; PAP, positive airway pressure.

limited.[17] Patients with idiopathic CSA-CSB have also been reported.[18]

In the current AASM scoring manual,[2] CSA-CSB (the respiratory event, not the clinical disorder) is scored when both of the following criteria are met:

1. Three or more consecutive central apneas or central hypopneas, or both, separated by a crescendo and decrescendo change in breathing amplitude with a cycle length of at least 40 seconds
2. Five or more central apneas or central hypopneas, or both, per hour of sleep associated with the crescendo and decrescendo breathing pattern recorded over at least 2 hours of monitoring.

The ICSD3 criteria for CSA-CSB are listed in Box 107-4. If central apneas of CSB morphology as defined previously are *not* frequent enough to be more than 50% of the total respiratory events, CSB is simply listed as a PSG finding. Note that CSA-CSB and OSA diagnoses may coexist in a patient who meets PSG and clinical criteria for both. Further, as per the ICSD3, diagnostic criteria for CSA-CSB may be met during *either a diagnostic PSG or PAP titration*. Many patients with CSA-CSB associated with heart failure have a significant number of both obstructive and central apneas,[13] and the predominance of obstructive versus central events may vary over time or during the night[19] in a given patient. If a patient with a mixture of obstructive and central events is placed on continuous positive airway pressure (CPAP), with titration specifically for the OSA, central events, including outright CSA-CSB, may persist after obstructive events have resolved.

A typical clinical example is the following. A 50-year-old man with a history of witnessed apnea, snoring, atrial fibrillation, and congestive heart failure underwent diagnostic and therapeutic PSG. During the diagnostic portion of the study, 120 minutes of sleep were recorded. The AHI was 30/hour with 40 obstructive apneas, 10 mixed apneas, and 10 central apneas. Typical obstructive and mixed events in this patient are shown in Figure 107-1, *A*. During the CPAP titration portion of the PSG, 300 minutes of sleep were recorded, with an AHI of 15/hour, 15 obstructive apneas, 50 central apneas, and 10 hypopneas (adjudicated as obstructive). The central AHI was 10/hour, and central events composed more than 50% of the respiratory events on CPAP. A typical period of central apnea, in fact central apnea with CSB, in this patient is shown in Figure 107-1, *B*. This patient meets diagnostic criteria for OSA (diagnostic portion) and CSA-CSB (the CPAP titration portion). The clinical implications of such results remain to be defined; presumably, the patient continues to carry the cardiovascular morbidity and mortality associations of CSA-CSB in this setting.

Central Sleep Apnea Due to a Medical Disorder without Cheyne-Stokes Breathing

CSA that is attributed to a medical disorder, but does not have the characteristic periodic breathing pattern of CSB, is classified as CSA due to a medical disorder without Cheyne-Stokes breathing (Box 107-5). Here the term *medical disorder* is used as an all-inclusive nomenclature that includes cardiovascular, respiratory, and neurologic conditions; however, most of these patients have brainstem lesions of developmental, vascular, neoplastic, degenerative, demyelinating, or traumatic origin. Examples of such neurologic conditions that are typically associated with CSA without CSB include prior cerebrovascular accident (CVA),[14-16] Chiari malformation,[20] brainstem neoplasms, and multiple system atrophy.[21] A predominance of OSA versus CSA is more common after a CVA.[15] However, many post-CVA patients have a mixture of OSA and CSA; CSA following CVA can be present with and without a pattern of CSB.

Patients classified in the diagnostic category of CSA without CSB may have awake or sleep-related hypoventilation, or both. Further, in such patients, if diagnostic criteria for CSA and sleep-related hypoventilation are met (see later), both diagnoses are made (i.e., CSA *and* sleep–related hypoventilation).

Box 107-5 ICSD3 DIAGNOSTIC CRITERIA: CENTRAL APNEA DUE TO MEDICAL DISORDER WITHOUT CHEYNE-STOKES BREATHING

Criteria A to C must be met:
A. The presence of one or more of the following:
   1. Sleepiness
   2. Difficulty initiating or maintaining sleep, frequent awakenings, or nonrestorative sleep
   3. Awakening short of breath
   4. Snoring
   5. Witnessed apneas
B. Polysomnography (PSG) shows all of the following:
   1. Five or more central apneas and/or or central hypopneas per hour of sleep
   2. The number of central apneas and/or central hypopneas is >50% of the total number of apneas and hypopneas
   3. Absence of Cheyne-Stokes breathing
C. The disorder occurs as a consequence of a medical or neurologic disorder but is not due to medication use or substance use.

Box 107-6 ICSD3 DIAGNOSTIC CRITERIA: CENTRAL SLEEP APNEA DUE TO HIGH-ALTITUDE PERIODIC BREATHING

Criteria A to D must be met:
A. Recent ascent to high altitude*
B. The presence of one or more of the following:
   1. Sleepiness
   2. Difficulty initiating or maintaining sleep, frequent awakenings, or nonrestorative sleep
   3. Awakening with shortness of breath or morning headache
   4. Witnessed apnea
C. The symptoms are clinically attributable to high-altitude periodic breathing, or polysomnography, if performed, demonstrates recurrent central apneas or hypopneas primarily during non–rapid eye movement sleep at a frequency of ≥5/hour.
D. The disorder is not better explained by another current sleep disorder, medical or neurologic disorder, medication use (e.g., narcotics), or substance use disorders.

*Typically at least 2500 meters (8202 feet), although some individuals may exhibit the disorder at altitudes as low as 1500 meters.

Box 107-7 ICSD3 DIAGNOSTIC CRITERIA: CENTRAL SLEEP APNEA DUE TO A MEDICATION OR SUBSTANCE

Criteria A to E must be met:
A. The patient is taking an opioid or other respiratory depressant.
B. The presence of one or more of the following:
   1. Sleepiness
   2. Difficulty initiating or maintaining sleep, frequent awakenings, or nonrestorative sleep
   3. Awakening short of breath
   4. Snoring
   5. Witnessed apneas
C. Polysomnography (PSG; diagnostic or on positive airway pressure) shows all of the following:
   1. Five or more central apneas and/or central hypopneas per hour of sleep (PSG)
   2. The number of central apneas and/or central hypopneas is >50% of the total number of apneas and hypopneas
   3. Absence of Cheyne-Stokes breathing
D. The disorder occurs as a consequence of an opioid or other respiratory depressant.
E. The disorder is not better explained by another current sleep disorder.

Central Sleep Apnea Due to High-Altitude Periodic Breathing

Periodic breathing during sleep is a common response to altitude. Typically, an altitude of at least 2500 meters (8202 feet) is required for such periodic breathing to be present. However, some individuals may exhibit the disorder at altitudes as low as 1500 meters. There are no specified levels of central AHI (central apneas or central hypopneas per hour) nor frequency of episodes of periodicity of breathing that clinically separate a normal from an abnormal response to altitude. The ICSD3 diagnostic criteria require 5 or more central events per hour of sleep *and* associated symptoms to make the diagnosis of CSA due to high-altitude periodic breathing (Box 107-6). The cycle length of this periodic breathing is commonly less than 40 seconds and often as short as 12 to 20 seconds.[22,23] The periodic breathing present at altitude does *not* specifically meet the criteria for CSB as defined earlier. A diagnosis of CSA due to high-altitude period breathing may be made concomitantly with a diagnosis of OSA if criteria for each of these are clearly present. A study by Pagel and colleagues[24] of sleep study results at three sleep centers at progressively higher altitudes found that central apnea becomes significantly more common at increasing altitude in both the diagnostic and treatment portions of PSG in patients with OSA, with an apparent exponential increase in the percentage of OSA patients with a central apnea index greater than 5 occurring with increasing altitude.

Central Sleep Apnea Due to a Medication or Substance

Patients with this diagnosis have CSA adjudicated as secondary to an opioid medication or other respiratory depressant (Box 107-7). The condition has been described in patients taking methadone and long-acting forms of morphine or oxycodone as well as individuals being treated with fentanyl patches or continuous narcotic infusions.[25] Suboxone (a combination of buprenorphine and naloxone) is often used for treatment of patients with narcotic dependence and pain and can also be associated with central apnea. Patients taking these medications can also manifest OSA and ataxic breathing. In addition, some patients may exhibit mostly obstructive respiratory events during a diagnostic study but mainly central events on positive airway pressure, and the required frequency of central events to meet diagnostic criteria for this entity may be present on either a diagnostic or PAP PSG. Although most patients with this disorder have normal or only mildly elevated awake values of $Paco_2$, some manifest sleep-related

Box 107-8 ICSD3 DIAGNOSTIC CRITERIA: PRIMARY CENTRAL SLEEP APNEA

Criteria A to D must be met:

A. The presence of at least one of the following:
   1. Sleepiness
   2. Difficulty initiating or maintaining sleep, frequent awakenings, or nonrestorative sleep
   3. Awakening short of breath
   4. Snoring
   5. Witnessed apneas

B. Polysomnography demonstrates all of the following:
   1. Five or more central apneas or central hypopneas per hour of sleep
   2. The total number of central apneas and/or central hypopneas is >50% of the total number of apneas and hypopneas
   3. Absence of Cheyne-Stokes breathing

C. There is no evidence of daytime or nocturnal hypoventilation.

D. The disorder is not better explained by another current sleep disorder, medical or neurologic disorder, medication use, or substance use disorder.

hypoventilation (see later) as well as central apneas. If sleep-related hypoventilation is present, a diagnosis of sleep-related hypoventilation due to a medication or substance is made *in addition to* a diagnosis of CSA due to a medication or substance.

Primary Central Sleep Apnea

Primary CSA, which has also been referred to as idiopathic CSA, is a disorder of unknown etiology and is characterized by recurrent central apneas that do not have CSB morphology (Box 107-8) or a specific known etiology. Primary CSA is believed to occur because the sleeping arterial $Paco_2$ is below the AT,[26,27] as discussed previously. High hypercapnic ventilatory drive (both awake and during sleep) characterizes such patients; while awake, they therefore have a normal or low $Paco_2$. The reason for the high ventilatory drive in patients with primary CSA is unknown.

Clinical manifestations of primary CSA typically include daytime sleepiness, insomnia, awakening short of breath, and witnessed apneas. PSG diagnostic criteria include the requirement that there must be 5 or more central apneas or central hypopneas per hour of sleep and that central, rather than obstructive, events make up greater than 50% of the total number of scored respiratory events. Further, the central apneas or hypopneas cannot, by definition, occur with the periodic breathing morphology of CSB. If the central apnea is believed to be due to a medical or neurologic condition or to a medication, then a diagnosis of primary CSA is not made. Primary CSA is a diagnosis based on *exclusion of identifiable causes of this pattern of breathing*. Clinical implications regarding etiology and sequelae of this disorder are not clear.

A typical clinical example is the following. A 30-year-old man underwent a PSG to evaluate complaints of snoring, witnessed breathing pauses, and mild daytime sleepiness. The PSG showed a total sleep time of 420 minutes and an AHI of 15/hour. There were 20 obstructive apneas and 85 central apneas. The central apneas did not have a Cheyne-Stokes morphology, although runs of central apneas did occur, most commonly associated with stages 1 and 2 non–rapid eye movement sleep (Figure 107-2). The patient was taking no medications and was otherwise healthy. Magnetic resonance imaging revealed no structural lesion of the brainstem (note that such a lesion would define the disorder as CSA due to a medical disorder without CSB).

Treatment-Emergent Central Sleep Apnea

Treatment-emergent CSA as defined in the ICSD3 is similar to a phenomenon described in the medical literature as complex sleep apnea. In this situation a patient with predominantly obstructive respiratory events (obstructive and mixed apneas or hypopneas) during a diagnostic PSG manifests predominantly central respiratory events (persistent or emergent) on PAP treatment (CPAP, or bilevel PAP without a backup rate) after the obstructive events have resolved.[28] This remains an area of controversy[29] because some clinicians consider all patients manifesting the pattern described previously as having complex sleep apnea (or TE-CSA), whereas others reserve the diagnosis of TE-CSA for patients in whom a clear diathesis for CSA is not present. A diagnosis of treatment emergent CSA as defined in ICSD3 (Box 107-9) is more specific than the typically applied terminology of complex sleep apnea because it requires that the CSA present during a PAP sleep study *not be* better explained by another CSA disorder or diathesis (e.g., CSA-CSB or CSA due to a medication or substance). Perhaps a more accurate term would be *idiopathic treatment emergent CSA*, when a reason or even risk for the phenomenon is unclear; in any event, the current term has clinical importance and specificity in that CSA has been reported to be present in 2% to 20% of patients in whom PAP is initiated,[28-29] whereas the TE-CSA as defined by the ICSD3 is believed to resolve with chronic PAP treatment in most patients.

In contrast, patients with complex sleep apnea associated with opioids and patients with CSB-CSA and heart failure each are less likely to experience resolution of CSA with chronic CPAP.[30,31,32] Although about 50% of patients with CSA-CSB due to heart failure will respond to the first night of exposure to CPAP, after 3 months about 43% still have an AHI greater than 15/hour.[30] However, the long-term morbidity associated with the diagnosis of treatment emergent CSA (ICSD3 criteria) and the pathophysiology have not been defined. Patients with persistent CSA on chronic CPAP treatment may not experience benefit from PAP treatment and may fail to be adherent to CPAP.

An illustrative clinical example of treatment emergent CSA is follows. A 50-year-old man underwent a PSG to evaluate complaints of snoring, daytime sleepiness, and witnessed apnea. He was being treated for systemic hypertension, had no history of heart failure, and was not taking opioid medications. During the diagnostic portion of the PSG, 120 minutes of sleep were recorded, with an AHI of 40/hour, including 55 obstructive apneas, 5 central apneas, and 20 hypopneas. During the CPAP titration, 300 minutes of sleep were recorded, with a final overall AHI of 20/hour. Respiratory events consisted of 10 obstructive apneas, 10 hypopneas (uncharacterized as central or obstructive), and 80 central apneas. The central apneas did not have Cheyne-Stokes morphology. A diagnosis of OSA and treatment emergent CSA was made.

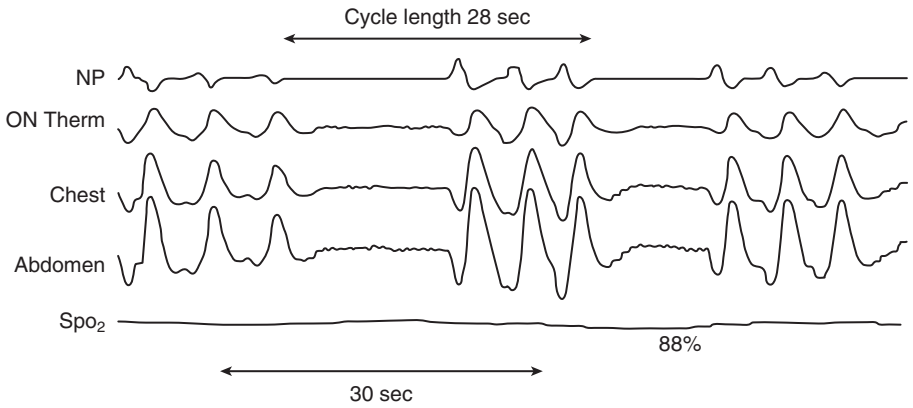

Figure 107-2 Central apneas in a patient without an apparent cause of central apnea. Note that the cycle length of the central events is less than 30 seconds. NP, Nasal pressure; ON Therm, oronasal thermal flow sensor.

Box 107-9 ICSD3 DIAGNOSTIC CRITERIA: TREATMENT EMERGENT CENTRAL SLEEP APNEA

Criteria A to C must be met:

A. Diagnostic polysomnography (PSG) shows five or more predominantly obstructive respiratory events (obstructive or mixed apneas, hypopneas, or respiration effort–related arousals [RERAs]) per hour of sleep.
B. PSG during use of positive airway pressure without a backup rate shows significant resolution of obstructive events and emergence or persistence of central apnea or central hypopnea with all of the following:
   i. Central apnea–central hypopnea index [CAHI] ≥5/hour
   ii. Number of central apneas and central hypopneas is ≥50% of total number of apneas and hypopneas
C. The central sleep apnea (CSA) is not better explained by another CSA disorder (e.g., CSA with Cheyne-Stokes breathing or CSA due to a medication or substance).

Box 107-10 ICSD3 DIAGNOSTIC CRITERIA: OBESITY-HYPOVENTILATION SYNDROME

Criteria A to C must be met:

A. Presence of hypoventilation during wakefulness (Pa_{CO_2} >45 mm Hg) as measured by arterial P_{CO_2}, end-tidal P_{CO_2}, or transcutaneous P_{CO_2}.
B. Presence of obesity (body mass index >30 kg/m^2; >95th percentile for age and sex for children).
C. Hypoventilation is not primarily due to lung parenchymal or airway disease, pulmonary vascular pathology, chest wall disorder (other than mass loading from obesity), medication use, neurologic disorder, muscle weakness, or a known congenital or idiopathic central alveolar hypoventilation syndrome.

SLEEP-RELATED HYPOVENTILATON DISORDERS

The sleep-related hypoventilation disorders are listed in Box 107-1. The current criteria for scoring hypoventilation during sleep for adults are addressed by the most recent version of the *AASM Manual for the Scoring of Sleep and Associated Events*,[2] as follows:

1. Score hypoventilation during sleep if *either* of the following occur:
   a. Increase in the arterial P_{CO_2} (or surrogate) to a value >55 mm Hg for ≥10 minutes
   b. Increase of ≥10 mmHg in arterial P_{CO_2} (or surrogate) during sleep (in comparison to an awake supine value) to a value exceeding 50 mm Hg for ≥10 minutes

Because monitoring of arterial P_{CO_2} during sleep is not practical and is not widely done during PSG, acceptable surrogates include end-tidal P_{CO_2} and transcutaneous P_{CO_2}. Arterial oxygen desaturation is often present but is not required for the diagnosis.

The rationale for the previous definition of sleep-related hypoventilation is discussed in a review paper[4] and is based on limited "consensus" evidence. A normal increase in Pa_{CO_2} during sleep compared with awake has been described, with a range of about 2 to 8 mm Hg. The criteria attempt to define both an abnormal increase in Pa_{CO_2} and an absolute Pa_{CO_2} level considered to represent hypoventilation. Note that criterion 1a, although stated as an increase, in fact represents an absolute value during sleep rather than a comparison to awake and therefore not necessarily an effect of sleep in a person with awake hypoventilation. On the other hand the arterial P_{CO_2} invariably increases during sleep, irrespective of the presence or absence of daytime hypoventilation. The ICSD3 diagnostic criteria for sleep-related hypoventilation are simply those as defined in the AASM scoring manual.

Obesity-Hypoventilation Syndrome

The obesity-hypoventilation syndrome (OHS) is the only sleep-related hypoventilation disorder that requires documentation of awake hypoventilation (Pa_{CO_2} >45 mm Hg) (Box 107-10). In the other ICSD3 defined sleep-related hypoventilation disorders, awake hypoventilation may or may not be present.

During PSG, if a noninvasive estimate of the Pa_{CO_2} is measured in OHS patients, sleep-related hypoventilation is invariably present (i.e., criterion 1a for scoring hypoventilation during sleep), with increases in the Pa_{CO_2} from awake to sleep typical (i.e., criterion 1b for scoring hypoventilation during sleep). Arterial oxygen desaturation in usually present during sleep and may be present during wakefulness, but neither is required for a diagnosis of OHS. In 80% to 90% of

Box 107-11 ICSD3 DIAGNOSTIC CRITERIA: IDIOPATHIC CENTRAL ALVEOLAR HYPOVENTILATION

Criteria A and B must be met:
A. Sleep-related hypoventilation is present.
B. Hypoventilation is not primarily due to lung parenchymal or airway disease, pulmonary vascular pathology, chest wall disorder, medication use, neurologic disorder, muscle weakness, or obesity or congenital hypoventilation syndromes.

Box 107-12 ICSD3 DIAGNOSTIC CRITERIA: SLEEP-RELATED HYPOVENTILATION DUE TO A MEDICATION OR SUBSTANCE

Criteria A to C must be met:
A. Sleep-related hypoventilation is present.
B. A medication or substance known to inhibit respiration and/or ventilatory drive is believed to be the primary cause of sleep-related hypoventilation.
C. Hypoventilation is not primarily due to lung parenchymal or airway disease, pulmonary vascular pathology, chest wall disorder, neurologic disorder, muscle weakness, obesity-hypoventilation syndrome, or a known congenital central alveolar hypoventilation syndrome.

Box 107-13 ICSD3 DIAGNOSTIC CRITERIA: SLEEP-RELATED HYPOVENTILATION DUE TO A MEDICAL DISORDER

Criteria A to C must be met:
A. Sleep-related hypoventilation is present.
B. A lung parenchymal or airway disease, pulmonary vascular pathology, chest wall disorder, neurologic disorder, or muscle weakness is believed to be the primary cause of hypoventilation.
C. Hypoventilation is not primarily due to obesity-hypoventilation syndrome, medication use, or a known congenital central alveolar hypoventilation syndrome.

OHS patients, a diagnosis of OSA can also be made.[33] The other 10% to 20% manifest awake hypoventilation that worsens during sleep in association with reduced tidal volume. In OHS, by definition, the etiology of the hypoventilation is not primarily due to lung parenchymal or airway disease, pulmonary vascular pathology, chest wall disorder (other than mass loading from obesity), medication use, neurologic disorder, muscle weakness, or a documented congenital or idiopathic central alveolar hypoventilation syndrome.

The etiology of OHS also likely varies among individuals. In clinical practice there is often uncertainty concerning the most appropriate diagnosis in an obese individual with OSA, obstructive lung disease, and awake hypoventilation; for example, does the patient have OHS or the "overlap syndrome" (OSA + chronic obstructive pulmonary disease [COPD])? Such clinical considerations affect the optimal treatment of the awake- and sleep-related hypoventilation disorder. If a patient diagnosed with OHS undergoes CPAP treatment for the OSA component, normalization of the awake $Paco_2$ can occur; similarly, treatment of the OSA in the overlap syndrome can favorably affect both OSA and COPD outcomes. An unresolved issue concerning the nosology is the recommended exclusion of a diagnosis of OHS in the presence of "a known idiopathic central hypoventilation syndrome" (see later); such a diagnosis in an obese patient would require that the clinician affirm that the hypoventilation developed before obesity or persisted after resolution of obesity, an unlikely clinical possibility.

Idiopathic Central Alveolar Hypoventilation

In this disorder, the cause of sleep-related alveolar hypoventilation is unknown (Box 107-11). It is a diagnosis of exclusion, and the disorder appears to be rare. By definition, the hypoventilation is *not* primarily due to an identifiable cause of hypoventilation such as lung parenchymal or airway disease, pulmonary vascular pathology, chest wall disorder, medication use, neurologic disorder, muscle weakness, obesity, or congenital hypoventilation syndromes. The congenital central hypoventilation syndrome usually manifests at birth, but late-onset cases have been described. The definitive diagnosis of congenital central hypoventilation syndrome requires demonstration of a mutation in the *PHOX2B* gene.[34]

Sleep-Related Hypoventilation Due to a Medication or Substance

In this disorder the sleep- related hypoventilation is due to a medication or substance that inhibits ventilatory drive (Box 107-12). Hypoventilation may be present during wakefulness but is not required for the diagnosis. The medications associated with the closely related diagnosis of CSA due to medication or substance (see earlier) may also be associated with sleep-related hypoventilation. Hypoventilation is not primarily due to another identifiable cause of hypoventilation, such as lung parenchymal or airway disease, pulmonary vascular pathology, chest wall disorder, neurologic disorder, muscle weakness, OHS, or a known congenital central alveolar hypoventilation syndrome. Although obstructive and central apneas may be present, the predominant respiratory pattern is usually one of reduced tidal volume or ataxic breathing and associated arterial oxygen desaturation. However, some patients may manifest frequent central apneas and also meet the criteria for sleep-related hypoventilation. When relevant criteria are met, as defined above, a diagnosis of OSA or CSA, or both, due to a medication or substance, as well as sleep-related hypoventilation due to a medication or substance, may be made.

Sleep-Related Hypoventilation Due to a Medical Disorder

In this disorder of breathing during sleep, sleep-related hypoventilation is believed to be due to a defined medical disorder (Box 107-13). Here the term "medical disorder" is inclusive and includes disorders of the lung parenchyma, airways, or pulmonary vasculature; chest wall disorders (other than mass loading for obesity); neurologic disorders such as neuromuscular disorders (disorders of the brain, spinal cord, or phrenic nerve); and myopathies.[35,36] By definition, hypoventilation is *not* associated with OHS or a central alveolar

Box 107-14 ICSD3 DIAGNOSTIC CRITERIA: SLEEP-RELATED HYPOXEMIA

Criteria A and B must be met:

A. Polysomnography, out-of-center sleep testing, or nocturnal oximetry shows the arterial oxygen saturation (Spo_2) during sleep of ≤88% in adults or ≤90% in children for ≥5 minutes.
B. Sleep-related hypoventilation is not documented.

hypoventilation syndrome. Although awake hypoventilation may be present, this is not required for this diagnosis. The predominant respiratory pattern is one of reduced tidal volume or ataxic breathing and associated arterial oxygen desaturation, rather than a predominant pattern of central or obstructive apnea. However, if appropriate criteria are met, as defined previously, a diagnosis of OSA or CSA, or both, due to a medical or neurologic condition, as well as sleep-related hypoventilation due to a medical disorder, may be made.

SLEEP-RELATED HYPOXEMIA DISORDER

This disorder has also been referred to as *nocturnal oxygen desaturation* and is based on either PSG, OCST, or oximetry findings (Box 107-14). Note that a diagnosis of sleep-related hypoventilation with such hypoxemia cannot be made if Pco_2 is not measured during sleep or, if measured, remains within normal limits. Conversely, if sleep-related hypoventilation is documented (as measured by arterial blood gas, transcutaneous Pco_2, or end-tidal CO_2 sensors), the disorder is classified as sleep-related hypoventilation rather than sleep-related hypoxemia disorder. OSA or CSA may be present, but such events are not directly associated with the majority of the sleep time spent with hypoxemia. Physiologic causes, if known, should be indicated (e.g., shunt, ventilation-perfusion [V/Q] mismatch, low mixed venous oxygen, and low partial pressure of inspired O_2, as with high altitude). In the ICSD3, sleep-related hypoxemic disorder is listed separately from the sleep-related hypoventilation disorders. Note, however, that most disorders associated with a diagnosis of sleep-related hypoventilation due to a medical disorder will be classified as sleep-related hypoxemia disorder if the sleeping $Paco_2$ or a surrogate has not been measured, or if such a measure does not meet criteria for sleep-related hypoventilation. For example, a patient with COPD (whether or not awake $Paco_2$ is elevated) undergoing nocturnal oximetry without a CO_2 measure may show significant nocturnal arterial oxygen desaturation; such a patient would fit criteria for sleep-related hypoxemia disorder. One could argue that this diagnostic category should be combined with the sleep-related hypoventilation disorders. In fact, the ICD-9 (International Classification of Diseases) diagnostic code 327.26 denotes sleep-related hypoxemia or hypercapnia associated with a condition classified elsewhere. Further, such hypoxemia during sleep may also be associated with sleep-related hypoventilation not clearly documented by a CO_2 sensor because of limitations in the technology of CO_2 sensors, which typically substitute for direct arterial blood gas measurement.

OTHER SLEEP RELATED BREATHING DISORDERS

As may be expected, a number of sleep related breathing disorders do not fit easily into the previous diagnostic categories. Many types of lung disease, including COPD, cystic fibrosis, asthma, interstitial lung disease, and pulmonary vascular disease (often with pulmonary arterial hypertension), may result in hypoxemia during sleep with or without documented awake or sleep-related hypoventilation. If sleep-related hypoventilation is not documented but nocturnal hypoxemia is present, a diagnosis of sleep-related hypoxemic disorder is made. Further, many of these clinical entities may "overlap" with either CSA or OSA. The most classically described overlap syndrome,[37] consisting of the combination of OSA and COPD, is a common condition that clearly does not fit easily into a diagnostic category. These patients may have episodes of obstructive events (apnea, hypopnea, or both) superimposed on a low baseline sleeping arterial oxygen saturation. Patients with the overlap syndrome would by definition meet diagnostic criteria for OSA, but the recognition of the role of COPD is important because patients benefit from treatment of both components. It has also been increasingly shown that treatment of the OSA component when present in combination with the previously noted pulmonary and pulmonary vascular disorders may also be necessary for optimal treatment of each entity.

CLINICAL PEARL

Sleep related breathing disorders encompass a wide and clinically important spectrum of disordered breathing and related medical morbidities, which often overlap. The ICSD3 has published new diagnostic criteria for sleep related breathing disorders. Separate diagnostic criteria are now available for CSA with CSB, OHS, and treatment emergent CSA. Definitions of specific respiratory events are not provided in the ICSD3, and the clinician must use the *AASM Manual for the Scoring of Sleep and Associated Events: Rules, Terminology and Technical Specifications* for such definitions. A diagnosis of treatment emergent CSA requires that the CSA during positive-pressure initiation is *not* better explained by another CSA disorder. In this sense, *treatment emergent CSA* is more specific than the widely used term *complex sleep apnea*. A diagnosis of sleep-related hypoventilation disorders requires measurement of $Paco_2$ or a surrogate of $Paco_2$ during sleep.

SUMMARY

A diagnosis of OSA in adults requires either 15 or more obstructive events (obstructive or mixed apneas, hypopneas, and RERAs) per hour or the combination of symptoms or comorbid conditions and 5 or more obstructive events per hour. The diagnoses of CSA with CSB, CSA due to a medical disorder without CSB, CSA due to a medication or substance, and primary CSA all require 5 or more central apneas or central hypopneas per hour of sleep, with at least 50% of the total number of respiratory events present during sleep being central apneas or central hypopneas. A diagnosis of sleep-related hypoventilation disorders requires demonstration of hypoventilation during sleep (in practice, usually assessed by a surrogate measure of arterial Pco_2 such as end-tidal Pco_2 or

transcutaneous Pco_2 monitoring). OHS requires demonstration of awake hypoventilation; most of these patients also have OSA. In the other sleep-related hypoventilation disorders, daytime hypoventilation may or may not be present. A diagnosis of sleep-related hypoventilation due to a medical disorder requires that hypoventilation is primarily due to a disorder of the lung parenchyma, airways, or pulmonary vasculature; chest wall disorders (other than mass loading for obesity); neurologic disorders (disorders of the brain, spinal cord, or phrenic nerve); or myopathy.

Sleep Breathing Disorders: Clinical Overview

Reena Mehra; Douglas E. Moul; Kingman P. Strohl

Chapter 108

Chapter Highlights

- Sleep breathing disorders (SBDs) is an umbrella term used to describe a range of breathing disorders of sleep that include obstructive sleep apnea, central sleep apnea, periodic breathing, and sleep-related hypoventilation.
- Overall, SBDs are highly prevalent in adults, with each type of disturbance having distinct pathophysiologic and clinical features. The widespread prevalence and scope of SBDs, afflicting more than 50 million Americans alone, along with the compounding adverse effects on medical, mental health, quality-of-life, and productivity outcomes, provides compelling motivation to design and engage in strategies to optimize their diagnosis and management.
- SBDs uniquely intersect with a host of medical, surgical, and neurologic comorbid conditions and directly affect health outcomes. Optimal management strategies for SBDs therefore must involve not only multidisciplinary expertise but also a team-based approach incorporating efforts from primary care physicians, medical and surgical subspecialists, and sleep specialists.
- Novel therapeutics will likely be forthcoming based on addressing the specific pathophysiologic attributes of SBDs, including critical closing pressure of the upper airway, upper airway muscle recruitment, arousal threshold, and loop gain.
- From a holistic standpoint, it is imperative to take into account the health status and life course of the patient when tailoring treatment strategies for an SBD such that these are effectively incorporated in the patient's personal life narrative.

The broad impact of disorders of respiration in sleep on human health and disease has spurred the development of major new conceptual frameworks and treatments over the past 50 years.[1] We now know in much greater detail how sleep is a critical biologic function for brain development and maintenance, behavioral vigilance, memory, and general well-being. Respiratory disturbances during sleep dramatically interfere with not only brain but also other organ functions, resulting in accompanying cardiovascular, endocrine, neurologic, and psychiatric disorders. The functional benefits of sleep reside in the amount and continuity of sleep and its various stages, effects that are inevitably disrupted in those with sleep breathing disorders (SBDs).

The purpose of this overview to the section on SBDs is to orient and represent a broad view of pulmonary-related sleep medicine and to provide a framework for consideration of the SBDs in a clinical preventative paradigm. More detailed and annotated work on each aspect of what we will cover will be found in the subsequent chapters of this section.

HISTORICAL PERSPECTIVE

SBD is an umbrella term used to describe a range of sleep-related breathing disorders that includes obstructive sleep apnea (OSA), central sleep apnea (CSA), periodic breathing (including Cheyne-Stokes breathing), and sleep-related hypoventilation (see Chapter 107). Historically, recurrent central or nonobstructive events (airflow and effort absent) were clinically identified as part of the pathobiology of congestive heart failure and central nervous system disorders, including stroke. Now OSA (airflow absent but efforts persist) is considered more prevalent, with each apnea type exhibiting somewhat different clinical presentations

OSA as a clinical entity began to be recognized in the 1960s when several groups in Europe reported observations on sleep in patients with excessive daytime sleepiness.[2] Suspecting upper airway obstruction as the cause for disturbed sleep, several groups took a radical step by performing tracheostomy as treatment. This regularized breathing during sleep, with the signs and symptoms of awake-time sleepiness[3] and cardiopulmonary disease resolving.[4] Other centers soon used the same diagnostic and therapeutic approach, confirming the disease ("upper airway apnea") in adults and children. In the 1970s, case series of OSA were reported, and the term *polysomnography* became widely used to describe the process of monitoring sleep and its associated movements and cardiopulmonary functions. Motta and colleagues in 1978 reported success with tracheostomy for OSA in a large case series.[5] In the 1980s there was an emphasis on the neurophysiology of respiratory control and the anatomic features of a vulnerable upper airway, the interactions of which created recurrent nonobstructive and obstructive apneas and hypopneas,

respectively.[6] OSA was still considered a rare and curious disease, to be considered when other causes for polycythemia, pulmonary hypertension, or extreme inability to stay awake were excluded. OSA treatments first described in 1981 included positive airway pressure (PAP)[7] and uvulopalatopharyngoplasty surgery[8] directed at abnormalities of the size and compliance of the nasopharynx and oropharynx.

In 1993, the first organized epidemiologic investigation published the figure of a 2% to 4% prevalence of OSA syndrome (elevated apnea-hypopnea index [AHI] with symptoms) in adults, placing OSA in the United States among common chronic medical conditions such as asthma and diabetes.[9] Since then, established clinical pathways for management have been developed in addition to improved methods of positive-pressure therapy delivery and to the alternative of oral appliance therapy. Outcomes of both the untreated and the treated state of OSA have been described in enough detail to articulate general thresholds for OSA severity: mild (AHI, 5 to 15), moderate (AHI, 15 to 30), and severe (AHI, >30).

Central sleep apnea and Hunter-Cheyne-Stokes breathing are among the SBDs that received initial attention in the early nineteenth century. Although these disorders are less prevalent than OSA, the symptom-based characteristics and physiologic perturbations are perhaps more readily apparent. In 1818, John Cheyne, a physician in Dublin, was one of the first to describe the disorder in a 60-year-old patient with breathing oscillations that he observed during sleep in the latter phases of the patient's illness. On postmortem examination, Cheyne discovered that the patient's heart was enlarged with fatty tissue invasion of the cardiac muscle.[10] In 1854 another physician from Dublin, William Stokes, went further and attributed the abnormal breathing pattern to a "weakened state of the heart."[11] For the purposes of historical accuracy, it should be noted that 37 years before Cheyne's report, John Hunter, an English surgeon, was the first to describe the classic crescendo-decrescendo breathing pattern: "The patient's respiration was extraordinary. He ceased to breathe for twenty or thirty seconds and then started breathing again. First faintly, and then with increasing force until the climax, after which his breathing again weakened until it disappeared completely."[12] Treatment options for CSA associated with Hunter-Cheyne-Stokes breathing initially included stabilization of the underlying contributing condition (e.g., optimizing heart failure management) and some drugs. More advanced technologies are currently available, including novel PAP approaches.

OVERVIEW OF THE PATHOPHYSIOLOGIC BASIS OF SLEEP BREATHING DISORDERS INFORMING THE TREATMENT APPROACH

Our review in 1987 described the clinical understanding of sleep apnea and the intent of different therapies to address suspected anatomic and neural factors in SBDs and the elements of clinical risk gleaned in the examination of the patient.[6,13] Although long-term prognostic generalizability has leapt forward in the past 25 years regarding SBDs more generally, the fine-grained understanding about findings on sleep studies still has areas of substantial ambiguity, particularly when patient-specific findings and preferences need to be incorporated into treatment planning. For example, two clinically salient domains of ambiguity concern treatment emergent CSA and residual sleepiness in the OSA patient who is fully compliant with continuous positive airway pressure (CPAP). Accordingly, the field has moved to more fundamental issues,[14-16] including the development of a process of separating and measuring features during sleep that correlate with the expression of recurrent apneas in an individual patient.[17,18] These features include (1) the pharyngeal critical closing pressure (Pcrit), (2) the recruitment (or "gain") function of muscles that keep the airway patent, (3) the threshold for arousal from sleep, and (4) the tendency for a disturbance to "set up" the person for a subsequent apnea ("loop gain") (see Chapters 109 and 122).

The pressure at which the compliant upper airway closes can be measured during sleep and calculated as the Pcrit. A positive pressure needed to keep the airway open is called a positive Pcrit and is the principle for using CPAP; if closing requires a negative pressure (as in a healthy person or in those with nonobstructive apneas or hypopneas), it is a negative Pcrit. Moving Pcrit to a more negative level is therefore beneficial in terms of treating OSA. Upper airway muscles can keep an airway open through brainstem activation using reflex mechanisms and direct actions on size or stiffness of the airway wall. Sleep reduces both activation and reflex recruitment, and in severe OSA there are additional reductions in reflex activations.[19-21] Another factor is the inherent gain of recruitment with the increasing chemoreceptor stimulation.[22] Furthermore, muscle efferent output must be translated into mechanical changes in the airway, which may be more difficult in the presence of edema.[23]

Arousal thresholds operate in SBDs in two ways.[24,25] Arousals are a mechanism that not only shorten events but also rapidly increase ventilation for any given carbon dioxide level. However, a longer time to arousal is thought to increase the chance for a person to increase drive to upper airway muscles, improve ventilation, maintain oxygenation, and reduce arousals during sleep,[24,26] permitting muscle activation to rise up to open the airway.

The fourth mechanism to discuss is loop gain, which is the propensity of the respiratory feedback control system to oscillate in response to a perturbation like a nonobstructive or obstructive apnea. A high loop gain indicates a relative inability for a person's control system to return to steady breathing after a disturbance such as an apnea, and a number of studies indicate that high loop gain is a factor in OSA and in the recurrent nonobstructive apneas of Cheyne-Stokes breathing. One major aspect of this control system relates to the effectors for ventilation (nerves, muscles, chest wall); another is related to the response organized by the brainstem to the disturbance. Oxygen administration can decrease loop gain and reduce OSA in some patients who have a high loop gain,[27] and indomethacin can increase loop gain and increase the tendency for apneas to reoccur.[28] CPAP itself will lower loop gain,[29] as the ventilatory response to CO_2 decreases (i.e., ventilation becomes less oscillatory) following treatment with CPAP.[22,30] Thus an individuality of and change in loop gain could be a mechanism of the appearance of emergent nonobstructive apnea, the variability among individuals in drug trials, the success of oxygen therapy, and obstructive and nonobstructive tendencies in disease presentation.

In summary, the anatomy of an apnea in sleep is determined in the following manner. There is a reduction in global respiratory muscle drive to create opportunity for an apnea. The nonobstructive apnea occurs when the upper airway has

a negative Pcrit, whereas the obstructive apnea occurs when there is a mechanical collapse with a reduction in drive to upper airway dilator muscles. In the middle of the apnea, drive increases to one degree or another, with both negative pressure and chemoreflex stimulus, until there occurs either an arousal or sufficient muscle activation to reopen the airway. The degree of overshoot in ventilation sets up the opportunity for a reduction in drive to set up the next apneas. Less well known are the factors that lead to the length of an apnea, the interapneic interval, and the cycle length between the onset of one apnea and the onset of the next.

All of these four factors contribute alone and in combination to the development and level of severity of both nonobstructive and obstructive apneas and will affect the response to therapy. There is some prospect that these elements will be ultimately measurable using a CPAP interface to clamp the airway pressure and initiate interventions to collect values related to muscle recruitment, arousals, and loop gain.[26] Currently, longitudinal studies of these factors and how they influence the development of sleep apneas over time are absent, and the collected traits at presentation are more epidemiologically oriented (e.g., obesity, hypertension) than based on data on causes (e.g., Pcrit, loop gain). In addition to the functional factors just discussed, some supportive evidence for risks associated with molecular markers associated with sympathetic activity, oxidative stress, and inflammation are present in some but not all cross-sectional studies in the presence of hypoxia-reoxygenation with recurrent obstructive and nonobstructive apneas.[31] Genetic and epigenetic factors will undoubtedly emerge, but currently the genetic studies are underpowered for common alleles and inconclusive for rare alleles sought in family studies.[32] Although some causal generalizability has arisen epidemiologically about the effects of SBDs, and etiologic frameworks have undergone robust clarifications, the current level of knowledge leaves the sleep clinician with limited guidance, relying mainly on modification of an abnormal Pcrit, and clinical management is based on algorithms rather than measures of the four pathophysiologic causes.

CLINICAL ASSESSMENTS AND DECISION MAKING

Detection of SBDs is at a historical inflection point. Rather than "rare, curious, or untreatable," SBDs are inevitably present in any clinical cohort. Treating SBDs improves quality of life and reduces cardiovascular risks. SBDs are common, treatable, and likely to some extent preventable. Because OSA is itself as common as asthma or diabetes, the sleep medicine specialist cannot take care of all SBD patients. The role of the specialist, like that of the diabetes or asthma specialist, is to assist in diagnosis and treatment of more complex cases and, in the future, to institute care paths to serve as a guide for the primary care physician or subspecialist for informed management of SBDs.

The prevalence and scope of SBDs, afflicting more 50 million Americans alone, along with its compounding effects on adverse medical, mental health, behavioral, and quality-of-life outcomes, as well as loss of productivity,[33] provides compelling motivation to engage in strategies to optimize the diagnosis and management of these conditions. SBDs have been notably underrecognized, with 85% to 90% of cases estimated to be undiagnosed.[34] This is partly attributable to limited awareness and understanding of the relevance of SBDs and to suboptimal guides and tools available for practitioners to efficiently diagnose and treat SBDs. A challenge facing many primary care physicians, our first-line "gatekeepers," is to choose which health problem to address for each patient, given clinical time constraints and patients' own health care preferences. In contrast, subspecialists face the challenges of addressing focused domains of care in a targeted and comprehensive manner, but not necessarily the composite of a patient's comorbidities. In the middle zone, treatment of SBDs encompasses somewhat specialized aspects of respiratory care but, owing to the prevalence and protean effects of untreated SBDs, necessitates the involvement of a wide range of medical specialties.

Hence there exist multiple opportunities to identify SBDs not only in everyday settings of health maintenance and disease prevention but also along the patient's trajectory through acute inpatient settings and subsequent outpatient follow-up. For example, while addressing a variety of common medical issues such as blood pressure and diabetes control, the patient and clinician may not prioritize or view SBD symptoms (e.g., snoring, daytime sleepiness) as clinically relevant or important. Nonetheless, a systematic approach for identifying and managing respiratory and nonrespiratory sleep disorders can have strategic importance for the effective longitudinal control of cardiovascular and cardiometabolic health consequences. Treatment of SBDs is part of a holistic approach of medical management and optimization of health care.

The clinical evaluation of a person suspected of having an SBD or being assessed after initiation of treatment requires a multisystem assessment. Because sleep patterns and preferences are determined by embodiments of personal, occupational, and social goals, effective care of SBDs can take on a complexity and richness not often needed for other organ-specific specialty assessments. Certain instruments, such as the Berlin Questionnaire and the STOP-BANG questionnaire, are designed to provide risk factor analysis as well as a psychometrically valid, generalizable suspicion of OSA. The Berlin Questionnaire is geared toward recognition of OSA in the primary care office, and it best considered for its negative predictive value, rather than as a predictor of severity of disease.[35] The STOP-BANG was developed for preoperative screening for general anesthesia in a population particularly at risk for OSA because of many chronic illnesses,[36] and it is gaining increasing use primarily because of ease of implementation; note, however, that the original STOP-BANG includes neck size measurement, which is often overlooked. These instruments highlight that the clinical skill set for the sleep specialist has come to include understanding of self-report scales and their utility, appropriate context, and limitations, especially in regard to determining the need for clinical management. Similarly, assessments of diagnostic tests such as polysomnography require a skill set in evaluating the plausibility of the test compared with pretest probability, the risk and difficulty of testing, the ability to initiate a treatment decision based on its result, and patient collaboration. Interpreting information, scales, and tests related to SBDs requires topic-related skills in identifying a study question, interpreting study design, and data analysis. Insurance providers and patients are asking tough questions about process and value. Sleep medicine specialists have to acquire these skills in communication, but translating some of these issues to other specialties remains a challenge for sleep clinicians.

Growing attention has been paid to research in health services and quality improvement in the treatment of SBDs. This trend has engaged funding agencies, health care delivery systems, and the government, and each has increasingly emphasized this as an area of focus as population-level health impacts become better known. Such research will increasingly shape the financing and administration of SBD-associated health care. As the volume of systematic research studies increases, assessing the nature and quality of the studies, particularly when they suggest contrasting findings, is essential for the development of wise clinical practices. Meta-analyses and systematic reviews can be helpful to integrate findings from several studies and appraise biases. Cost-effectiveness and comparative effectiveness analyses attempt to scale the real-world benefit of new interventions to current standards of care while simultaneously evaluating associated costs.

Incorporating proven state-of-the-art innovations at the bedside will continue to be an ethical priority in evaluating and treating SBDs in a clinical system that embraces continuous quality improvement. Important outcomes commonly evaluated include reduction of cost, reduction of morbidity and mortality, and improvement in patient satisfaction. A vital part of quality improvement is sustainability—creating systems to ensure the desired outcomes are regularly achieved. Accordingly, SBD specialists will need to oversee quality improvement projects to better understand how the process works, how to improve individual practice, and how to sustain successful practice in the changing health care environment.

SLEEP BREATHING DISORDERS IN DISEASE-SPECIFIC POPULATIONS

SBDs are uniquely comorbid with a whole host of major, common clinical conditions and medical settings, spanning, but not limited to, cardiac disease, obstructive and restrictive pulmonary disease, neurologic conditions, kidney disease, and the perioperative and anesthesia setting. The common clinical scenarios discussed in this section and highlighted in Table 108-1 provide a sense of the need for high-level awareness of SBDs and a low threshold for testing for, and managing, associated SBDs in such conditions and settings because an SBD often represents a modifiable risk factor for adverse health outcomes related to these.

Cardiovascular Disease

SBDs and cardiac disease have clear bidirectional relationships. As an example, a family medicine practitioner evaluates a patient with recalcitrant hypertension who meets the criteria for resistant hypertension. The practitioner notes that the patient snores and has a history of witnessed apneas. In this clinical scenario, it must be considered that concomitant and sustained increases in blood pressure are observed in OSA, likely through pathways involving hypoxia as a potent stimulus for sympathetic activation, hypercapnia, reductions in baroreflex sensitivity, and direct increases in sympathetic nervous system activation.[37,38] OSA-induced increases in activation of the renin-angiotensin-aldosterone system may in particular play a role in resistant hypertension. Results pooled across many randomized controlled trials designed to examine the effect of OSA reversal with CPAP on blood pressure outcomes consistently demonstrate statistically significant and clinically meaningful reductions in office systolic and diastolic blood pressure levels.[39] In fact, the Joint National Committee has recognized OSA as a secondary contributor to hypertension.[40] OSA has also been associated with nocturnal nondipping patterns[41,42] (i.e., does not undergo a standard dipping pattern of blood pressure reduction of at least 10% of the wake value), which is predictive of future cardiovascular risk.[43-45] Furthermore, resistant hypertension (approximately 15% of the hypertensive population[46]), which involves blood pressure above goal despite at least three antihypertensive medications,[47] is an entity in which OSA represents an important promulgating contributor. In fact, a large randomized clinical trial has demonstrated 3-month improvement in mean and diastolic blood pressure in those with resistant hypertension and OSA treated with CPAP versus no therapy.[48]

As another example, an internist admits a patient for management of acute non-ST elevation myocardial infarction; the patient undergoes coronary catheterization. Phenotypic characterization in this case most likely involves a background risk for dyslipidemia, hypertension, and diabetes mellitus. In terms of how undiagnosed SBD fits into this clinical paradigm, it should be recognized that SBD prevalence is greater than 70% in acute coronary syndrome and appears to be characterized by mainly obstructive respiratory physiology.[49] Furthermore, compared with patients without OSA, those with OSA and coronary artery disease have a higher degree of late lumen loss,[50] a marker for coronary restenosis after percutaneous coronary intervention, and there is evidence that OSA inflicts direct cardiac injury.[51] The prevalence of OSA exceeds that of other known risk factors for coronary artery disease on those who are revascularized and therefore represents a key modifiable therapeutic target to consider after coronary intervention.[52] Untreated severe OSA also predicts increased mortality and subsequent myocardial infarction in patients who have experienced an ST elevation myocardial infarction.[53] Similarly, CPAP treatment in those with cardiovascular risk appears to reduce cardiac event risk[54] and minimizes need for revascularization.[55] The treating physician also needs to consider the benefits of SBD treatment on cardiovascular risk factors (e.g., hypertension) to mitigate future adverse cardiovascular events.

Down the hall from the catheterization laboratory, in the heart failure unit, a cardiologist is managing a patient with acutely decompensated reduced ejection fraction heart failure (left ventricular ejection fraction of 30%) with diuresis and afterload reduction pharmacologic therapy. A high index of suspicion for SBD in systolic heart failure should be in place given the known high prevalence in this setting (ranging from 50% to 75%[56,57]), and a combination of OSA and CSA with Cheyne-Stokes breathing is typically represented. Symptom-based screening for SBDs in heart failure patients poses a challenge because standard symptoms of SBD such as excessive daytime sleepiness are often not present. This is likely because of the overall enhanced sympathetic nervous system state inherent in heart failure. Moreover, symptoms of nocturnal awakenings due to shortness of breath and nocturia may be attributed to heart failure rather than an SBD, potentially leading to underdiagnosis of an SBD. Hypoxia-induced impairments in myocardial oxygen delivery and increased cardiac strain from sympathetic activation are likely factors in the initiation and progression of SBD-related heart failure. The dire importance of the detection and treatment of an SBD in those admitted with acute decompensated heart

Table 108-1 Key Considerations in Specific Clinical Conditions and Settings

Clinical Condition	Key Considerations
Hypertension	• Sleep breathing disorder prevalence of 50% to 60% is driven predominantly by obstructive sleep apnea.[40] • Elevation in blood pressure in obstructive sleep apnea occurs both awake and in the sleep period. • Nondipping blood pressure patterns are observed in obstructive sleep apnea, which is predictive of adverse cardiovascular sequelae.[43-45] • More than 15 randomized controlled trials have demonstrated improvement in blood pressure profiles with continuous positive airway pressure.[39] • The Joint National Committee recognizes obstructive sleep apnea as a secondary contributor to systemic hypertension.[40]
Resistant hypertension	• Obstructive sleep apnea is associated with resistant hypertension (prevalence of 60% to 90%)[86] and biologic plausibility for modulation by a hyperaldosteronism state. • Interventional trial data support blood pressure improvement with treatment of obstructive sleep apnea with continuous positive airway pressure in resistant hypertension.[48]
Coronary artery disease	• The prevalence of sleep breathing disorders is approximately 70%, and they primarily involve obstructive physiology.[49] • Obstructive sleep apnea is associated with late lumen loss (marker for restenosis) after coronary intervention[50] and appears to inflict direct myocardial injury (i.e., increased troponin-I levels).[51] • The prevalence of obstructive sleep apnea as a risk factor in coronary artery disease exceeds that of other traditional risk factors such as hypertension and diabetes mellitus.[52] • Untreated severe obstructive sleep apnea is associated with increased cardiovascular-specific mortality in several large scale epidemiologic studies.[87,88]
Heart failure	• Sleep breathing disorder prevalence of 50% to 75% is characteristic; a combination of obstructive sleep apnea, central sleep apnea, and Cheyne-Stokes breathing is represented.[56,57] • Clinical presentation is a challenge because typical symptoms of excessive daytime sleepiness are not present (presumably owing to sympathetic nervous system activation) and symptoms of sleep-related nocturnal dyspnea overlap with symptoms characteristic of fluid overload and paroxysmal nocturnal dyspnea characteristic of heart failure. • Sleep breathing disorders in acute decompensated heart failure are associated with a 50% to 60% increase in mortality after discharge and increased hospital readmissions.[58] • The effect of improvement of sleep breathing disorders with adaptive servoventilation in heart failure on mortality and other outcomes is biologically tenable and is currently the focus of study in large multicenter interventional trials.
Atrial fibrillation	• The prevalence of sleep breathing disorders in atrial fibrillation is estimated to be approximately 50%, with a stronger magnitude of association with central than with obstructive sleep apnea.[63] • Autonomic nervous system fluctuations are strongly implicated in atrial arrhythmogenesis based on experimental data, as are the mechanisms of intermittent hypoxia, the resolution phase of hypercarbia, and intrathoracic pressure alterations resulting in direct mechanical effects on the thin-walled atria. • Several retrospective studies have demonstrated a significant decrease in atrial fibrillation recurrence after ablation or cardioversion with the treatment of sleep breathing disorders compared with no treatment.[60,61]
Chronic obstructive pulmonary disease	• The presence of concomitant chronic obstructive pulmonary disease and obstructive sleep apnea has been termed overlap syndrome. • Patients with overlap syndrome experience more profound hypoxia and pulmonary vasoconstriction compared with either disorder in isolation. • REM sleep likely represents a particular state of vulnerability for obstructive lung disease given enhanced cholinergic mediated bronchoconstriction and further blunting of the hypoxic and hypercapnic ventilatory drives. • Continuous positive airway pressure and bronchodilators should be used along with supplemental oxygen in overlap syndrome because this strategy appears to confer a survival advantage.[67]
Obesity-hypoventilation syndrome	• This is defined by obesity (body mass index >30 kg/m^2), resting hypercapnia, and is characteristically associated with sleep-related hypoventilation in the presence or absence of obstructive sleep apnea. • Obesity-hypoventilation syndrome is important to recognize because it is associated with right-sided heart failure and increased mortality compared with obstructive sleep apnea alone.[68]

Continued

Table 108-1 Key Considerations in Specific Clinical Conditions and Settings—cont'd

Clinical Condition	Key Considerations
Stroke	• The prevalence of sleep breathing disorders is approximately 50% to 70% in the setting of acute ischemic stroke, with representation by both obstructive and central sleep apnea.[69,70] • Sleep breathing disorders tend to improve over time after stroke; however, half of these individuals continue to have sleep breathing disorders 3 months after stroke.[69,70] • Moderate to severe sleep breathing disorders in stroke that remain untreated may hinder the poststroke recovery process and also impair cognitive function and have an association with depression, with apparent improvement with continuous positive airway pressure use.[76]
Renal insufficiency	• Sleep breathing disorder–related intermittent hypoxia contributes to activation of the systemic and renal-specific renin-angiotensin-aldosterone system. • Recognition of sleep breathing disorders in renal insufficiency remains a diagnostic challenge because of the often atypical presentation of symptoms. • The prevalence of sleep breathing disorders is approximately 50%, with obstructive and central disordered breathing contributions.[78] • In end-stage renal disease, there is evidence that nocturnal hemodialysis is more effective than traditional hemodialysis in the improvement of sleep breathing disorder parameters.[80]
Perioperative anesthesia	• Anesthetics may result in a particular disadvantage to a vulnerable upper airway in patients with obstructive sleep apnea owing to effects of anesthesia in terms of blunting the hypoxic and hypercapnic ventilatory drives and also reducing upper airway muscle tone.[81] • Data are accruing that suggest the importance of identifying sleep breathing disorders preoperatively in an effort to improve outcomes, including perioperative and postoperative morbidity and mortality, and of enhancing anesthesiology preparedness for handling a compromised upper airway and blunted ventilatory drive during intubation and anesthesia administration.

failure is underscored by a large study noting a 50% to 60% increase in postdischarge mortality in those with an SBD compared with those without.[58] Although treatment of SBDs in patients with heart failure has not unequivocally demonstrated mortality benefit,[59] existing data are limited given suboptimal reversibility of Cheyne-Stokes breathing pathophysiology in response to CPAP. On the other hand, improvement in secondary outcomes, including left ventricular function and exertional capacity, has been observed with CPAP, with potential advantages in terms of mitigating heart failure progression. Larger ongoing clinical trials using more sophisticated treatment modalities such as adaptive servoventilation (using variable pressure support delivery to stabilize oscillatory breathing patterns) in patients with CSA and Cheyne-Stokes breathing are underway to address this question more definitively.

Meanwhile, in the electrophysiology laboratory, an electrophysiologist prepares to perform pulmonary vein isolation ablation in a patient with atrial fibrillation. In addressing the important issue of sustainability of normal sinus rhythm after such ablation in a patient with a predisposed substrate, the possibility of an SBD should be strongly considered given numerous data that have accrued supporting reduced recurrence of atrial fibrillation with SBD treatment.[60,61] Albeit, to date, these data are based on retrospectively designed studies, the consistency and reproducibility of these findings are sufficiently compelling to lead the clinician here to assess and investigate the possibility of an SBD. Epidemiologic data indicate a stronger association of CSA compared with OSA as the SBD related to atrial fibrillation, independent of underlying self-reported heart failure,[62] with an overall prevalence of about 50%.[63] Autonomic nervous system fluctuations have a strong biologic basis in terms of arrhythmogenic propensity[64] and have been implicated in experimental models of obstructive apneas and also appear to exert effects in central apnea physiology given the accompanying sympathetic excitation observed.

Pulmonary Disease

A pulmonologist treating a patient with chronic obstructive pulmonary disease (COPD) also needs to be cognizant of the potential for a concomitant SBD, that is, the "overlap syndrome" (see Chapter 119), so coined given the prevalent merging of these two common pulmonary disorders and the distinctness of the pathophysiology occurring as a result of this overlap above and beyond each disorder alone.[65] Patients with overlap syndrome have more profound hypoxia and resultant nocturnal oxygen desaturation than those with either disorder alone and thereby theoretically have higher risk for pulmonary vasoconstriction and pulmonary hypertension. A modest degree of pulmonary hypertension in general has been observed in OSA, with immediate temporal influences of apneic events resulting in acute rises in pulmonary artery pressure from initiation to termination of the apneic event.[66] Rapid eye movement (REM) sleep, characterized by predominance during the latter part of the sleep cycle, in particular represents a state of vulnerability given the physiology of REM-related reduction in hypoxic and hypercapnic ventilatory drive, reduced muscle tone, and enhanced likelihood for bronchoconstriction due to REM-related parasympathetic tone. Consideration of nocturnal bronchodilators for the COPD and CPAP therapy for the OSA is warranted in light of data demonstrating that these modalities when used together confer a survival advantage compared with supplemental oxygen (long-term oxygen therapy) alone.[67]

Obesity-hypoventilation syndrome (OHS; see Chapter 120) is characterized by morbid obesity and awake resting hypercapnia accompanied by sleep-related hypoventilation with or without the presence of OSA. Importance of recognition of an SBD in OHS lies in its association with right-sided

heart failure and, if left untreated, increased mortality risk.[68] The degree of hypoxia is more profound and extensive in OHS with OSA than in OSA alone.

Other Comorbid States

A neurologist evaluates a middle-aged woman in the office subsequent to the patient suffering right-sided lacunar stroke with failure of improvement in functional outcome and depressed mood. An SBD (primarily OSA and/or CSA) in this setting is not only an independent predictor of ischemic stroke but also highly prevalent after stroke and accompanied by worse post-stroke outcomes. An SBD is common after ischemic stroke, affecting 50% to 70% of patients, and although over time the degree of SBD may improve, at least half of patients will have an SBD 3 months after the stroke.[69,70] Although both OSA and CSA may occur after a stroke, improvement over time is more pronounced for CSA than for OSA.[71] CSA represents a negative prognostic indicator after stroke[71] and is related to stroke severity as well as topography.[72,73] Although some epidemiologic data support a stronger association of SBDs and incident ischemic stroke in men,[74] other data in an Asian population suggest that younger women may be at higher stroke risk.[75] When of moderate or severe degree, SBDs can hinder the recovery and rehabilitation process. Identification and treatment of an SBD are important given associations of SBDs with depressed mood, cognitive dysfunction, and impairment of the ability to perform activities of daily living. Data suggest that treatment of SBDs may thwart compromise of neurologic and cognitive function in the stable poststroke phase.[76] Interestingly, stroke etiology subtypes, including cardioembolic, large artery, and small artery strokes, are not variable in terms of association with SBDs or their severity.[77]

Similarly, an elderly man with daytime sleepiness and snoring in the setting of chronic renal insufficiency is being seen by a nephrologist in clinic. Although sleep symptoms are common among patients with chronic renal insufficiency, there are challenges in terms of specificity of these symptoms in the detection of SBDs in this setting. It also appears that there are a fair number of patients with an SBD and chronic renal insufficiency who do not have standard symptoms but do have an SBD. Insults to the kidney occur because of SBD-related intermittent hypoxia, which activates not only the systemic but also the renal-specific renin-angiotensin system, resulting in progression of renal disease and thereby underscoring the importance of the detection and treatment of SBDs. In end-stage renal disease, an estimated 50% of patients are afflicted with an SBD.[78] In end-stage renal disease, both OSA and CSA are observed, with a prevalence apparently concordant to that observed in the setting of heart failure[79] and with a potential overlap in pathophysiology in terms of contribution of rostral neck edema. Nocturnal versus conventional hemodialysis has been demonstrated to improve both OSA and CSA physiology.[80]

A middle-aged obese man with hypertension and a neck circumference of 18 inches is being prepared to undergo an appendectomy under general anesthesia. He undergoes standard preoperative anesthesia testing. Per the STOP-BANG screening questionnaire, he meets high pretest probability for OSA (more than three items positive). Patients with OSA may exhibit anesthesia medication–related reduction in hypoxic and hypercapnic ventilatory, with increased sensitivity to sedatives and opioids. A detailed airway assessment should be performed in these cases, with preparedness tactics in place, including airway adjuncts such as oral, nasal, and laryngeal mask airways as well as use of the ramped-up position, which enhances visualization of the glottic aperture during intubation. Attention to postoperative management is also of critical importance; descriptive data indicate elevated residual neuromuscular blockade effect, postoperative hypoxia, and increased length of stay in patients at high risk for OSA compared with those without high pretest probability for OSA.[81]

ECOLOGIC FEATURES

Holistically speaking, SBDs will have a bearing on one's health status and life course. In relation to the project of understanding patients' personal narratives and reactions concerning SBDs and their treatment, it is evident that generalizing about the life course narratives of persons with SBDs is epidemiologically not feasible. Treating SBDs will always remain a practical art.

Patients individually fit suspected or diagnosed SBDs into personal narratives. On the population-level of understanding the effects of SBDs, one may certainly appreciate how compliance with treatment may be partially determined by social or cultural contexts, to yield different rates for morbidities and mortality across groups.

In considering the course of OSA and its treatment, for example, it is essential to appreciate that although the cardiovascular and cerebrovascular outcomes are typically "hard" (i.e., not subject to reappraisal),[82] the decision to accept an identity (here the issue is having an SBD) or a treatment (such as CPAP) is "soft" (i.e., continually subject to reevaluation).

There are many patients who have sleep studies, and who even go on to use CPAP (or other non-PAP therapies) for a period of time, but then stop using treatment, only to come back to consider treatment years later. The implication is that the goal for the clinician need not exclusively be immediate treatment compliance (although this is certainly a main issue for insurers and a worthy goal for a practitioner), but instead to place some credence on identifying with the patient's personal narrative as the patient confronts the diagnosis of an SBD. For many days' clinical work, doing the medical art well is measure enough, irrespective of the patient's decision or indecision. This is the approach taken with motivational interviewing,[83] which, curiously, turns out to be highly effective in interacting with patients across a broad range of clinical presentations, severity, and response to treatment suggestions.

It should also be appreciated that the chronic sleep deprivation and neurocognitive sequelae associated with chronic OSA have an effect on patients' comprehension and treatment compliance. The frontal lobes are the most affected by sleep deprivation. In clinical practice, lowering of frontal functioning from chronic sleep deprivation has been observed to degrade a patient's capacity for maintaining personal morale, regulating affect in response to daily events, thinking more reflectively, remembering well, and relating to others. Anecdotally, some SBD patients can thus present as having psychiatric or personality disorders in clinical encounters, leading to a delayed or missed diagnosis of an SBD. Many presenting patients have impaired comprehension of health care information and physician recommendations. Additionally, it has been long known that for some patients, sleep deprivation may increase anxiety. This anxiety might be generalized or conditioned to nighttime and sleep stimuli; for example, for OSA

patients, each breath could be a choking experience. The sleepy patient may not have sufficient judgment and free will when making health care decisions about OSA treatments. Yet, for some who are diagnosed and treated, the mental health symptoms will be substantially improved and occasionally cured, owing to the benefits of getting uninterrupted wholesome sleep and reduced oxidative stress.

The clinician should also consider that comorbid disorders may disturb sleep to such an extent that compliance with treatment for an SBD becomes difficult if not impossible. This may arise, for example, if the patient has comorbid insomnia. However, other comorbidities can likewise provide the context for impairing good sleep. These include psychiatric conditions, cardiorespiratory conditions, pain, aging, and the use of particular medications such as alerting agents (e.g., stimulants, with some such as pseudoephedrine even available over the counter), anticholinergics, corticosteroids, and adrenergic inhalers.

The aging process presents interesting clinical issues regarding the SBDs. As middle age advances into older age, populations become increasingly biologically and clinically diverse throughout this span of time in relation to the burden of comorbidities, including those that an SBD might affect. Additionally, there is the consideration that the major measure of the sleep apneas, the AHI, may have normative ranges that increase with aging in adults. Reynolds and colleagues noted that in a cohort of patients advancing though the age span from 50 to 80 years, the AHI according to 1980s scoring rules increased per decade to a plateau at about 70 years of age.[84] These studies of recruited samples of healthy aging would give the impression that aging populations have AHIs that are biologically normal for their age although elevated for younger age groups. Indeed, there is debate about the optimal approach to treatment of SBDs, particularly OSA, in aging populations, including whether there might be an acceptable AHI level, perhaps 15 events per hour, which could be medically insignificant in older patients. However, although in practice it seems likely that some increase in AHI might be overall benign in some patients; aging patients should be considered to require the same attention to clinical symptoms and the comorbid milieu as younger populations in considering the diagnosis and treatment of the various SBDs. The recent literature on reduced sleep, SBDs, and hypoxemia playing an initiating or amplifying role in the development of Alzheimer disease and other dementias (including ischemia-related stroke)[85] reinforces such a clinical strategy.

CLINICAL PEARLS

- SBDs are a modifiable risk to be considered in numerous cardiologic settings, including treatment of resistant hypertension, minimization of risk for restenosis after percutaneous coronary intervention, mitigation of progression of heart failure and its adverse outcomes, and reduction in atrial fibrillation recurrence after intervention.
- SBDs also contribute to morbidity accompanying pulmonary disorders, including COPD, pulmonary hypertension, and OHS.
- SBDs are increasingly recognized as not only an independent predictor of acute stroke but also an obstacle in the poststroke recovery and rehabilitation process.
- Assessment of an SBD in the preoperative anesthesia setting is imperative to ensure implementation of optimal preparedness strategies for the perioperative and postoperative settings, including providing availability of adjunct airways and postoperative respiratory monitoring.
- Upper airway and central physiologic characteristics that predispose to the propagation of apneas and hypopneas in OSA include the critical closing pressure of the upper airway, upper airway muscle recruitment, arousal thresholds, and loop gain.

SUMMARY

In the past 20 years, treating the SBDs has developed from a medical curiosity to an epidemiologic mandate. Such a mandate for sleep medicine encompasses not only OSA but also other numerous forms of sleep-related respiratory disturbances (see Chapter 107). Despite the evidence base, however, patients and many medical professionals still have a dim appreciation of current knowledge about SBDs, their recognition, and their response to therapy. Even as physiologic knowledge of SBDs advances, there remains a continuing need for the expansion of public and medical education about SBDs and a continuing need for developing decision supports about SBDs for nonsleep clinicians as well as sleep specialists. That said, there is every reason to be confident that the physiologies of SBDs will continue to be explored in ever-increasing depth and sophistication. The four-factor functional model for OSA as discussed earlier will motivate attempts to apply a causal, systematic analysis of SBDs, based on measurable physiologic variables. Biochemical, genetic, and epigenetic variables related to the SBDs will also need to be explored more broadly, particularly those that have tie-ins to other highly prevalent cardiovascular, respiratory, and metabolic health conditions.

Chapter 109

Central Sleep Apnea: Definitions, Pathophysiology, Genetics, and Epidemiology

Madalina Macrea; Eliot S. Katz; Atul Malhotra

Chapter Highlights

- The various clinical entities comprising sleep breathing disorders are the result of pathophysiologic mechanisms that frequently overlap. Defining the types of central sleep apnea (CSA) within the sleep breathing disorder spectrum is essential for a common language among clinicians, educators, and researchers.
- CSA includes several heterogeneous syndromes, many heavily represented in day-to-day medical practice. Recent scientific evidence allows a more comprehensive understanding of CSA epidemiology, genetics, pathophysiology, and associated morbidity and mortality.
- Several mechanisms participate in the control of breathing. Chemical, mechanical, and neural pathophysiology involved in CSA, and their clinical implications, are detailed.
- Considerable progress has been made in our understanding of control of breathing related to CSA, with major implications of these new findings for patient care. Only by further mechanistic research are new therapeutic strategies likely to emerge.

Sleep breathing disorders (SBDs) is characterized by repetitive periods of cessation in breathing (i.e., apneas) or reductions in breathing (i.e., hypopneas) that occur during sleep. The various clinical entities belonging to SBDs are the result of pathophysiologic mechanisms that frequently overlap; centrally driven events are primarily due to a temporary loss of output from the pontomedullary pacemaker that generates breathing rhythm, resulting in loss of the respiratory pump muscles (diaphragm, thorax, abdomen). Alternatively, obstructive events are primarily due to inward collapse of the oropharynx when the pharyngeal dilator muscles are relaxed, resulting in loss of airflow because of upper airway narrowing.[1] Both obstructive and central respiratory events converge in their symptoms of frequent nocturnal awakenings and excessive daytime sleepiness.

Defining the end points of SBDs polysomnographically (i.e., central sleep apnea [CSA] and obstructive sleep apnea [OSA]), is often a straightforward process. In CSA, both oronasal flow and thoracoabdominal excursions are absent; that is, there is an absence of respiratory effort during the cessation of airflow, whereas in OSA, there are ongoing respiratory efforts during the absence of oronasal flow. In contrast, differentiating rigorously between events within the SBD spectrum (i.e., "central" and "obstructive" hypopnea) is difficult without quantification of respiratory effort as recorded by esophageal pressure monitoring. Because esophageal manometry is mildly invasive and rarely employed clinically, thoracic and abdominal excursions assessed by respiratory inductance plethysmography are widely used to detect asynchrony of these excursions during hypopnea (consistent with obstruction) or in-phase breathing (consistent with decreased central drive). Thus, central hypopnea is characterized by a proportional and synchronous decrease in thoracic and abdominal excursions, whereas obstructive hypopnea is characterized by paradoxical inward rib cage movement or asynchronous decrease in the thoracic and abdominal excursions (Figure 109-1). Nasal pressure recordings are sometimes used as a surrogate for upper airway narrowing because inspiratory flattening has been shown to correspond with inspiratory flow limitation. Additionally, obstructive and central apneas may overlap within the same event: such "mixed" apneas have features of both conditions, when an apnea begins with loss of central drive to breathe ("central" apnea) but then proceeds with increasing effort against an occluded upper airway ("obstructive" apnea).

DEFINITIONS

As defined by the *International Classification of Sleep Disorders*, third edition (ICSD3), CSA includes six heterogeneous adult syndromes (Box 109-1).[2,3] Several of these have in common a waxing and waning ventilatory pattern.

1. *Cheyne-Stokes breathing* (CSB) is an abnormal pattern of breathing characterized by oscillations of tidal volume between apnea or hypopnea at the nadir of ventilation and hyperpnea at the height of ventilation, with a spindle-like crescendo-decrescendo pattern in the depth of breathing.[4] According to the American Academy of Sleep Medicine

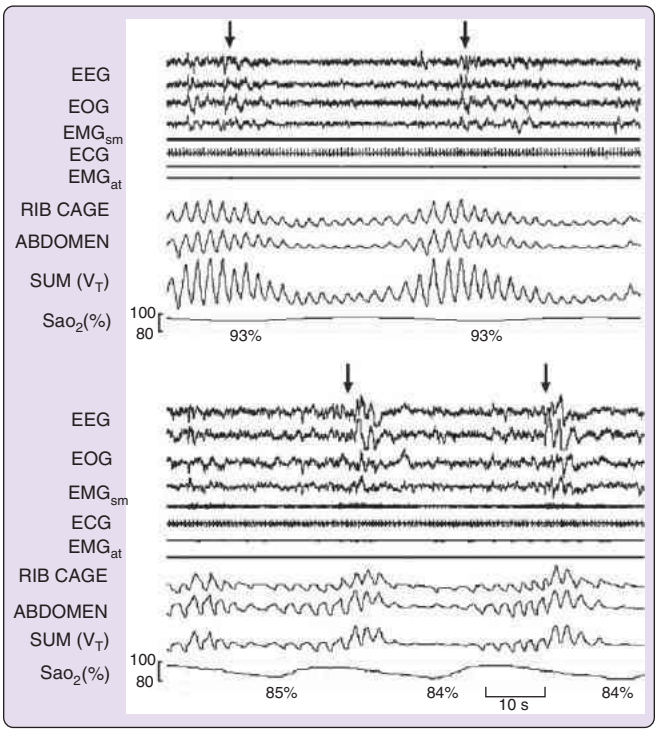

Figure 109-1 Polysomnographic recordings of central and obstructive hypopneas from patients with heart failure with use of respiratory inductance plethysmography. The *upper panel* shows a central hypopnea during stage 2 NREM sleep in a patient who has central sleep apnea with Cheyne-Stokes breathing. Note in-phase gradual waxing and waning of tidal volume during hyperpnea and only minimal O_2 desaturation during hypopnea. Arousal occurs several breaths after termination of the hypopnea. The *lower panel* shows an obstructive hypopnea in a patient with obstructive sleep apnea. Note that in contrast to central hypopnea, rib cage and abdominal motion are out-of-phase and O_2 desaturation is greater during hypopnea, and the rise in ventilation following its termination is more abrupt and hyperpneas are shorter. In addition, arousals occur earlier at hypopnea termination. ECG, Electrocardiogram; EEG, electroencephalogram; EMG_{sm}, submental electromyogram; EMG_{at}, anterior tibial EMG; EOG, electrooculogram. Arrows (↓) indicate arousals. (From Central Sleep Apnea and Cheyne-Stokes Respiration, Volume 5, Issue 2, The Proceedings of the American Thoracic Society.)

Box 109-1 HETEROGENEOUS ADULT SYNDROMES OF CENTRAL SLEEP APNEA

Central sleep apnea with Cheyne-Stokes breathing

Central sleep apnea due to high-altitude periodic breathing
Central sleep apnea due to a medication or substance
Primary central sleep apnea
Treatment emergent central sleep apnea

(AASM),[5] CSB in adults is scored when both of the following are met: (1) there are episodes of three or more consecutive central apneas or central hypopneas, or both, separated by a crescendo and decrescendo change in breathing amplitude with a cycle length of at least 40 seconds (typically 45 to 90 seconds), and (2) there are five or more central apneas or central hypopneas, or both, per hour associated with the crescendo and decrescendo breathing pattern recorded over a minimum of 2 hours of monitoring. In terms of nocturnal oxygen desaturation, there is generally less desaturation during central apnea and hypopnea than during obstructive events in patients with heart failure.[6]

2. *Primary CSA* resembles CSA-CSB except that the cycle duration is shorter, arousals occur earlier (at the termination of apnea versus during or near the peak ventilatory effort), and resumption of breathing is more abrupt and not crescendo, typically with a large-volume breath. The patient must not be hypercapnic while awake ($Paco_2$ greater than 45 mm Hg). The diagnostic polysomnography (PSG) shows five or more apneic episodes per hour of sleep, the number of central apneas or central hypopneas more than 50% of the total number of apneas and hypopneas, and absence of CSB.
3. *High-altitude periodic breathing* is seen in normal persons at elevations greater than 7600 meters and in some at lower altitudes (see Chapter 122). This ventilatory pattern is characterized by periods of alternating hyperpnea and apnea,[7] the cycle length typically being between 12 and 34 seconds. PSG, if performed, demonstrates recurrent central apneas or hypopneas primarily during NREM sleep at a frequency of five or more per hour.
4. *CSA due to a medical condition, without CSB* is encountered in individuals with cardiac, renal, and neuromuscular disease who have CSA without the CSB.
5. *Central sleep apnea due to a medication or substance* is commonly seen in patients with long-term opioid use that causes respiratory depression by acting on the μ receptors of the ventral medulla. PSG demonstrates lack of CSB and five or more central apneas or central hypopneas, or both,[1] per hour of sleep, with the number of central apneas or central hypopneas, or both, greater than the total number of apneas and hypopneas.
6. *Treatment emergent central apnea* (or "complex" sleep apnea) is included in the ICSD3 and refers to CSA not explained by another CSA disorder (e.g., CSA with CSB or CSA due to a medication or substance). The diagnostic PSG shows five or more predominantly obstructive respiratory events per hour of sleep. The titration PSG without a backup rate shows resolution of obstructive events and emergence or persistence of central apnea or central hypopnea with both a central apnea-central hypopnea index (CAHI) of five or more per hour and number of central apneas and central hypopneas 50% or greater than total number of apneas and hypopneas.

PATHOPHYSIOLOGY

As Cherniack[8] noted in the early 1980s, breathing in an awake healthy person involves a smooth and regularly recurring sequence of inspiration and expiration without pauses. The rate and depth of breathing are regulated by a negative-feedback control system aimed at maintaining arterial partial pressures of carbon dioxide ($Paco_2$) and oxygen (Pao_2) at relatively constant levels. When diseases of the lung or chest wall produce hypoxemia and hypocapnia or hypercapnia, they usually do so without affecting the regularity of breathing. Several mechanisms and their corresponding controls influence the rhythmicity of breathing. A synopsis of the following

roadmap we used in the discussion of CSA pathophysiology and its clinical translation is detailed in Tables 109-1 and 109-2.

Mechanisms

Several types of receptors and their associated afferent and efferent pathways are involved in maintaining the regular normal breathing.

Chemical Aspects of Ventilation

Ventilatory responses vary widely between the awake and asleep state, as well as between rapid eye movement (REM) and non–rapid eye movement (NREM) sleep. Ventilation during sleep is largely regulated by the same mechanisms that drive breathing while awake,[9] except that behavioral influences[10] become suppressed in transition to, and during, sleep. Therefore central apneic events are rarely present during the awake state[11,12] or REM sleep.[13] During NREM sleep, however, changes in the respiratory pattern are primarily controlled chemically, being the result of a fine balance among a critical $Paco_2$ level, below which there is a central cessation of breathing (i.e., apneic threshold); its triggering factors (mainly hypocapnia); and respondent receptors (i.e., central and peripheral chemoreceptors). Additionally, the level of ventilation in respiratory dysrhythmias is augmented by arousals from sleep, resulting in transient hyperventilation with hypocapnia below the apneic threshold[14] and therefore initiation of central apneic events, primarily during NREM sleep.

Table 109-1 Common Non-cardiac Conditions Associated with Central Sleep Apnea Events

Medical Condition	Prevalence (%)	Authors

Hypoxic Stimulus and Peripheral and Central Chemoreceptors. The chemoreceptors involved in the ventilatory response are both peripheral and central, each of them responding to changes in arterial Po_2 *and* Pco_2 in a complex, interactive manner. In mammals, the peripheral chemoreceptors are represented by the aortic and carotid bodies. The carotid bodies represent the main drive of the ventilatory stimulation due to acute, chronic,[15,16] and intermittent[17] hypoxia and contain the glomus cells that respond to the changes in the arterial blood oxygen concentration through several neurotransmitters, such as acetylcholine, substance P, and adenosine triphosphate.[18] The aortic bodies, on the other hand, likely become upregulated only if the carotid bodies are chronically absent, and then respond to changes in the arterial Po_2[19] through mechanisms that are less known. Notably, studies in patients with long-standing OSA demonstrated the possibility of the carotid bodies becoming desensitized with extended exposure to intermittent hypoxia.[20-22] In comparison with the peripheral chemoreceptors, the central chemoreceptors have a wide anatomic distribution in the brainstem (especially in nucleus tractus solitarius [NTS], locus coeruleus, raphe nuclei, and the retrotrapezoid nucleus [RTN]) and respond to central nervous system–specific hypoxia by augmentation of alveolar ventilation during both wakefulness[23] and sleep.[24]

Hypercapnic Stimulus and Peripheral and Central Chemoreceptors. In addition to responding to hypoxia, the carotid bodies also act as a sensitive detector of the adequacy of alveolar ventilation,[25] as seen in the prompt ventilatory response to small increases in arterial Pco_2 and insensitive feedback to decreasing arterial Po_2 until it reaches the critical value of 50 to 60 mm Hg.[26] Quantitatively, assuming a purely additive model, Forster estimated that 40% of the steady-state ventilatory CO_2 response belongs to the carotid body and 60% to the central chemoreceptors, the carotid body providing its response prompter.[27,28] In the absence of an exact biologic definition for the central chemoreceptors, most consideration is given to the possibility that these cells are glial or vascular cells that regulate the activity of surrounding neurons through paracrine mechanisms and respond promptly to the changes of the local neuronal pH.[29,30] Anatomically, the RTN is considered to be the predominant location of integration of the central chemoreceptor drive.[31]

Apneic Threshold and Implications for Central Sleep Apnea. During NREM sleep, motor output to respiratory muscles is dramatically reduced compared with wakefulness, causing mild to moderate sustained hypoventilation in all healthy subjects (+2 to +8 mm Hg $Paco_2$). If relative hyperpnea occurs and $Paco_2$ falls below a characteristic value for each individual (the apneic threshold), a central apnea occurs (see Fig. 109-2).[32] The hypocapnia-induced apneic threshold is not a constant value but usually occurs at a level very close to the eupneic $Paco_2$ present during wakefulness following a very small reduction in $Paco_2$, from 2 to 5 mm.

Mechanistically, to reach the apneic threshold, transient ventilatory overshoots are necessary, commonly provided by transient arousals with consequent brief hyperpnea with hypocapnia. Alternatively, to overcome the apneic threshold

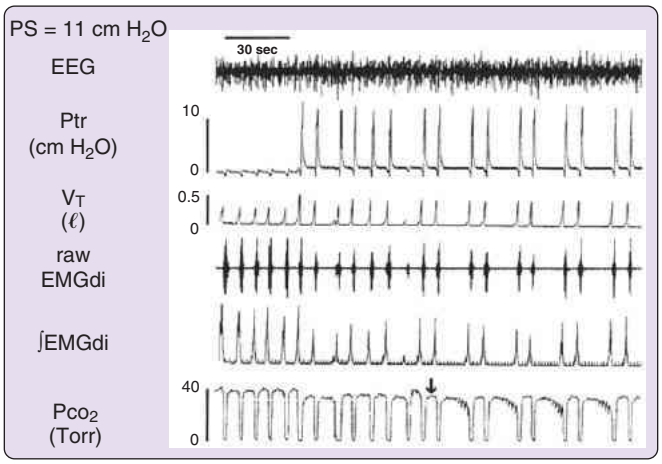

Figure 109-2 Polygraph record of one pressure support (PS) trial (11 cm H_2O) in which ventilatory instability was achieved in dogs. A reduced diaphragmatic EMG (EMGdi) and inspiratory effort on the seventh ventilator cycle was insufficient to trigger a ventilator breath. Clear periodicity developed after the ninth ventilator cycle. The *arrow* marks the petCO2 considered to be the apneic threshold. Ptr, Tracheal pressure. (Modified from Nakayama H, Smith CA, Rodman JR, et al. Effect of ventilatory drive on carbon dioxide sensitivity below eupnea during sleep. *Am J Respir Crit Care Med* 2002;165:1251–61.)

and therefore reinitiate the breathing rhythm, a $Paco_2$ higher by 1 to 4 mm Hg than the apneic threshold is needed; this difference reflects a postapneic control system termed *inertia*, aimed at enhancing the chemoreceptor stimulus after the ventilatory overshoot.

Interactions between the Central and Peripheral Chemoreceptors. Several anatomic and functional connections (e.g., the RTN receives direct input from the NTS and, thus, the carotid body)[33] serve a dual chemotactic role (peripheral and central), raising the question of interdependence between the two types of chemoreceptors. Failing to demonstrate unequivocally the existence of only one model because of variations in the experimental protocol, the literature describes three possible interactions: additive (the two responses simply sum), hyperadditive (the two responses multiply), or hypoadditive (the sum of each response is less than their mathematical sum). Regardless of the specifics of the final augmentative response, it is postulated that carotid chemoreceptors act as the immediate hypocapnic sensors,[34] given the lack of short-term response of the central chemoreceptors to systemic hypocapnia when normocapnia and normoxia are maintained at the level of the carotid bodies.[35] However, peripheral receptors do not primarily induce hypocapnic apnea by themselves, as demonstrated by experimental models involving isolated carotid body hypocapnia that fails to result in apnea.[36] Therefore it appears that both central and peripheral chemoreceptors must interact and respond to hypocapnia for the ventilatory overshoot to induce central apnea during sleep.

Mechanical Aspects of Ventilation

Dysfunction of upper airway mechanics represents the basis of OSA pathophysiology. Such dysfunction, however, is also observed in CSA because of upper airway collapsibility resulting in ventilatory instability.

The two primary collapsing forces of the upper airway are intraluminal negative pressure (generated by the diaphragm during inspiration) and extraluminal soft tissues (e.g., generated by fat deposition within bony structures surrounding the airway). These forces are opposed primarily by the pharyngeal dilator muscles, whose activity either varies from breath to breath (phasic respiratory muscles such as genioglossus) or stays similar throughout the respiratory cycle (tonic muscle, such as the tensor palatini). Additionally, activity of these muscles is dependent on mechanoreceptor and chemoreceptive influences. Studies in animals have shown that chemoreceptor activation resulted in an augmented depolarization of the inspiratory and expiratory hypoglossal motoneurons, thus providing evidence for the arterial chemoreceptors' contribution to maintaining upper airway patency throughout the respiratory cycle.[37] Additionally, the activity of the most important pharyngeal dilator muscle, the genioglossus, is accentuated by hypoxia and abolished by hyperoxia.[38] Alternatively, hypercapnia at the level of peripheral and central chemoreceptors leads to increased afferents to hypoglossal motoneurons and decreased threshold of the genioglossus activation. Comparing the quantitative participation of mechanoreceptors with chemoreceptors as modulators of upper airway activation, it has been suggested that chemoreceptors are stronger, although the two stimuli in combination may interactively augment upper airway muscle activity more than either stimulus alone.[39] Besides the upper airway muscles, the fluctuations in chemical stimuli also affect the diaphragm. Animal studies demonstrate a linear chemoreceptor-driven recruitment of the diaphragm electromyogram.[40] Endoscopy performed during both induced and naturally occurring central apnea demonstrated that upper airway obstruction occurs without evidence of an inspiratory effort in the first 10 seconds of a CSA episode.[41] Consequently, neuromuscular respiratory pathology overlaps in these different types of SBDs, making a clear adjudication between obstructive and central events difficult in many cases.

Neural Aspects of Ventilation

The respiratory neurons are divided into two groups, inspiratory and expiratory. The former belong to the dorsal respiratory group localized in the area of the NTS; the latter belong to the ventral respiratory group localized adjacent to the nucleus ambiguous.[42] Although the hypoxic and hypercapnic afferent responses of the peripheral and central chemoreceptors activate certain populations of respiratory neurons, the details of such intricate processes are still missing; likewise, the relative contribution of each neuronal population to central apnea pathogenesis is also unknown.[43] Studies of several congenital disorders have provided information on the central apnea neuronal ventilatory impairment and helped in understanding better the sudden infant death syndrome. Such rare congenital diseases include Leigh syndrome, a mitochondrial encephalopathy whose manifestations include frequent post-sigh apneic episodes due to lung stretch receptors ending their vagal afferents into abnormal NTS[44]; and Fukuyama-type congenital muscular dystrophy, in which sudden death is commonly encountered as a result of migration defects of the brainstem structures involving pathology of the arcuate nucleus that acts as a central chemoreceptor sensitive to hypercapnia.[45]

As Harper and colleagues[46] reviewed recently, however, CSB with or without CSA affects the brain structure and function beyond the rhythmicity of breathing and includes

hormonal, autonomic, and behavioral (affect, memory, and cognition) functions. Neural injuries of the ventrolateral and dorsal medullary areas are common in heart failure patients who demonstrate CSB patterns with or without CSA, affecting the final pathway of sympathetic outflow and sympathetic tone regulation.[47] Congenital central alveolar hypoventilation syndrome (CCAHS) neuropathology also involves the ventrolateral medulla, with subsequent dysfunction of the respiratory phase switch.[48] Neurotransmitter system injuries have been also recognized in CCAHS, in the raphe system, locus coeruleus (noradrenergic neurons), ventral midbrain, hypothalamus, and basal ganglia (dopaminergic fibers).[49] The cerebral cortex is not spared in either of these conditions; ischemic damage to the right insula is significantly accentuated in heart failure patients who have a high prevalence of OSA and CSB.[50] Essentially, because of hippocampal injury, short-term memory and cognitive impairments are also common in CCAHS.

Ventilatory Control in Central Sleep Apnea

Metabolic Control of Ventilation

Normal respiratory rhythmicity during sleep is maintained by a complex feedback mechanism best described by the concept of "loop gain," with CO_2 responsiveness between the eupnea and apneic threshold contributing.[51] *Loop gain* is an engineering term that describes the dynamic feedback of several stabilizing ventilatory mechanisms composed of three elements: (1) the controller gain (chemoresponsiveness, including ventilatory response to Pao_2 and $Paco_2$ above and below eupnea); (2) the plant gain (effectiveness of CO_2 excretion from such ventilatory response); and (3) mixing gain (e.g., from circulation delay between the lungs and the peripheral and central chemoreceptors). Simplistically, the loop gain could be defined as the ratio of the amplitude of the ventilatory response to a ventilatory disturbance. A loop gain of less than 1 accompanies a stable ventilatory system with low respiratory variability because disturbances lead to smaller responses, assuring a rapid return to a stable pattern. On the contrary, a loop gain of greater than 1 accompanies an unstable ventilatory system with high respiratory variability, in which disturbances lead to disproportionately large responses, resulting in a perpetual waxing and waning pattern. The ventilatory control system is dynamic, with both chemical and nonchemical inputs contributing to the breath-by-breath variability, as detailed by Khoo[52] (Figure 109-3).

Ventilatory variability is due to the feedback instability of the hypoxic and hypercapnic chemosensitivities. For example, a transient episode of hyperpnea leads to an eventual decrease in ventilation, but given the lag in the chemical response due to the circulation time, the initial correcting ventilatory response occurs well into the hyperpneic episode. This brief episode of hypopnea or apnea elicits a similarly delayed response, resulting in an ongoing oscillatory pattern of hyperpnea-hypopnea, whose magnitude and duration depends heavily on the *net effects* of the ventilatory control system. Several factors influence each of the gains: (1) the controller gain is affected by the sensitivity of the peripheral chemoreceptors to changes in gas partial pressure, sensitivity of central centers to peripheral chemoreceptors, and the excitability and integrity of the lower motor neurons supplying the respiratory muscle; (2) the plant gain is determined by the respiratory cycle frequency, $Paco_2$, Pao_2, ventilation-perfusion matching,

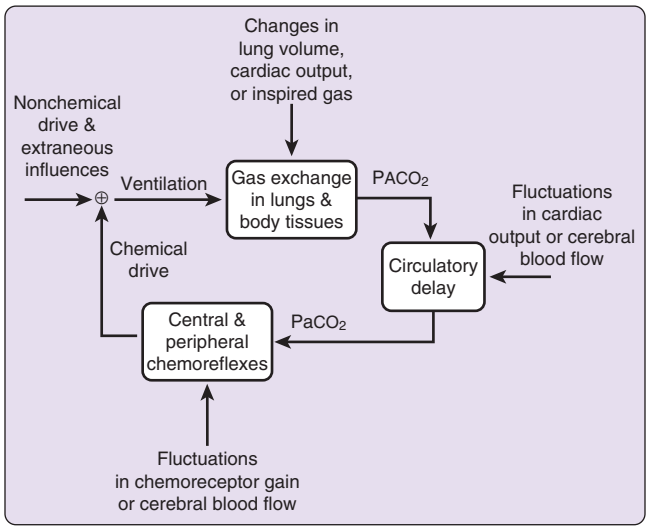

Figure 109-3 Chemical and nonchemical inputs contributing to the breath-by-breath variability.

and dead-space ventilation[53]; (3) the mixing gain is dependent on the circulatory delay time, thoracic blood volume, and brain extracellular fluid volume. In addition to the loop gain, another factor affecting ventilatory stability is the $Paco_2$ reserve, that is, the difference between the eupneic $Paco_2$ and the $Paco_2$ at the apneic threshold. The lower the $Paco_2$ reserve, the smaller the increase in the ventilation required for reaching the apneic threshold and developing central apnea. Conversely, when the apneic threshold for $Paco_2$ is far away from the eucapnic $Paco_2$, large ventilatory changes are necessary to lower the $Paco_2$ below the apneic threshold, decreasing the likelihood of developing central apnea.

The theoretical applications of the concepts of ventilatory instability and loop gain have been translated clinically by several clinical experiments. Common to all of them is the pathophysiologic relationship between alveolar ventilation (V_A) and alveolar Pco_2 described best by several authors[54-56]; a compiled explanation is given by Dempsey and colleagues[51] and depicted in Figure 109-4.

In hypoxic and normoxic acetazolamide-induced metabolic acidosis, the accompanying hyperventilation results in an increase in the V_A required to reduce the $Paco_2$ to the apneic threshold, protecting against apnea and respiratory instability. Despite a similar conceptual pathway of *reduced plant gain* for both hypoxic and normoxic hyperventilation, in hypoxia the slope of the ventilatory response increases and therefore the CO_2 reserve below eupnea is decreased, predisposing to ventilatory instability compared with nonhypoxic hyperventilation (Figure 109-5).[54]

Ventilatory instability is also promoted by *increasing plant gain,* such as is seen with $NaHCO_3$-induced metabolic alkalosis that narrows the CO_2 reserve without a change in the slope of the CO_2 response below eupnea.[58] For the controller gain, both increased and decreased controller gain have been demonstrated using pharmacologic manipulations of the peripheral chemoreceptor sensitivity; intravenous administration of dopamine resulted in a fall in ventilation and reduced O_2 sensitivity[59] (i.e., *reduced controller gain*), whereas administration of the dopamine D_2-receptor antagonist domperidone

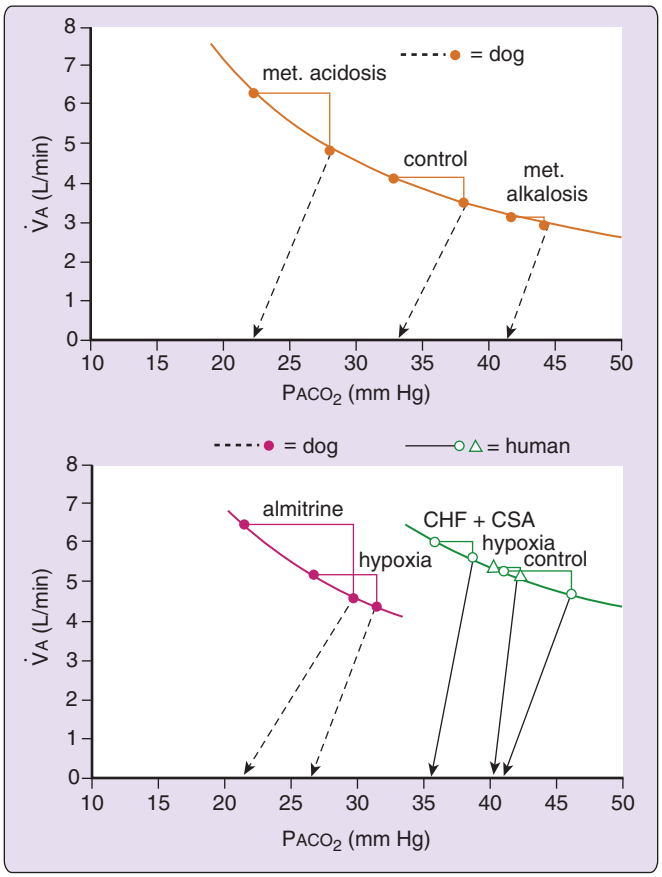

Figure 109-4 The effects of changing background ventilatory drive on the gain of the ventilatory responsiveness to CO_2 below eupnoea, on "plant gain," and on the CO_2 reserve (ΔP_{ETCO_2} eupnoea – apnea) in sleeping dogs and humans. Data are plotted on separate isometabolic lines for dogs [CO_2 flow ($\dot{V}_{CO_2}$) = 150 mL/min^{-1}] and for humans ($\dot{V}_{CO_2}$ = 250 mL/min^{-1}). The *diagonal dashed* or *continuous lines* join eupneic and apneic points, and their slopes indicate the gain below eupnoea of the ventilatory response to hypocapnia in each condition. The height of the *vertical bar* above the isometabolic line indicates the increase in $\dot{V}_A$ required to reduce the P_{aCO_2} to the apneic threshold (i.e., the inverse of plant gain). The CO_2 reserve is the difference in P_{ACO_2} between eupnoea and the apneic threshold. CHF, Congestive heart failure; CSA, central sleep apnea.

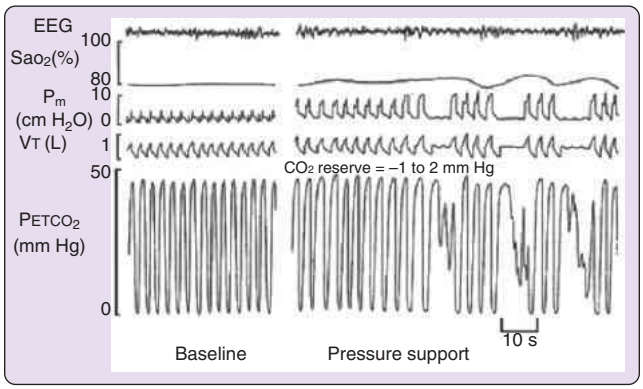

Figure 109-5 Hypoxia reduces the CO_2 reserve. A healthy human is exposed to moderate hypoxia (Pa_{O_2} 80%) for 15 to 20 minutes during NREM sleep, causing mild hyperventilation. When pressure support ventilation is subsequently applied, note that a transient reduction of only 1 or 2 mm Hg in P_{ACO_2} is required to cause apnea and periodic breathing. This effect contrasts with the 3- to 5-mm Hg ΔP_{ACO_2} required in the normoxic control condition. The CO_2 reserve is markedly reduced in hypoxia despite the reduced P_{ACO_2} and plant gain because the slope of the $\Delta\dot{V}_A$–ΔP_{ACO_2} relationship below eupnoea is significantly increased. EEG, Electroencephalogram; P_m, Mean airway pressure. (From Braley TJ, Segal BM, Chervin RD. Sleep-disordered breathing in multiple sclerosis. *Neurology* 2012;28:929–36.)

resulted in increased carotid body sensitivity to O_2 (i.e., *increased controller gain*).[60] As detailed in Figure 109-5, the steeper the slope of the V_{ACO_2}–P_{ACO_2} relationship, the smaller the change in P_{aCO_2} required to reach the apneic threshold, and therefore the higher the controller gain. Numerous clinical entities are associated with one or more abnormalities of loop gain, as summarized in Table 109-3.

Neural Control of Ventilation

Neural mechanisms of ventilatory control in central apnea are likely as important as the metabolic pathways, dictating behavior during wakefulness, affecting airway patency, and controlling respiratory plasticity. The wakefulness stimuli to breathe include tonic excitatory inputs from the so-called reticular formation, brainstem aminergic systems, and hypothalamic orexin neurons.[61] Younes,[62] using correlational analysis, demonstrated that an effective neural control of the upper airway and chest wall respiratory muscles was more important than the inherent passive collapsibility of the airway.

Respiratory plasticity translates into *long-term facilitation* (LTF), a term used to describe the increase in the respiratory activity that persists after the conclusion of an acute episode of intermittent hypoxia.[63] Mediated through several receptors, including serotonergic and *N*-methyl-D-aspartate, this response in sleeping humans is aimed at stabilizing ventilation through increased minute ventilation (i.e., ventilatory LTF),[64] decreased inspiratory upper airway resistance,[65] and increased genioglossus electromyographic activity (i.e., upper airway LTF).[66] However, concentrating on central apnea pathophysiology, Chowdhuri and colleagues[67] demonstrated that, in healthy participants undergoing nasal noninvasive ventilation for promoting hypocapnic central apnea, the increase in the hypocapnic ventilatory response resulted in a significant decrease in the CO_2 reserve, thus offsetting the protective effect of LTF.

Examples of Pathophysiologic to Clinical Applications

Cheyne-Stokes Breathing with or without Central Sleep Apnea

CSB is characterized by a destabilizing interplay of several gains: specifically, controller and plant, with CSA presenting when this destabilization is most accentuated. A *high controller gain* is due to a hypersensitive ventilatory chemoreflex response to CO_2. Although the exact mechanism for this increase in chemosensitivity is not yet known, both congestive (i.e., pulmonary edema[68] and left atrial stretch[69]) and noncongestive factors (reduced carotid arterial blood flow[70]) result in vagal afferents that stimulate central respiratory control centers and fail to allow the P_{aCO_2} to increase at sleep onset.[71] Ventilatory control is also affected in congestive heart failure (CHF) patients because of an attenuated cerebrovascular reactivity to the changes in P_{aCO_2} levels.[72] *The mixing gain* is a concept sometimes used to define how a delay in the circulation can be destabilizing for ventilation. The fact that the chemoreceptors are in the carotid bodies and brainstem rather than in the lung is one factor that can

Table 109-3 Loop Gain Abnormalities in Clinical Disorders

Increased Plant Gain	Decreased Plant Gain	Increased Controller Gain	Decreased Controller Gain	Increased Mixing Gain
Obesity-hypoventilation syndrome (OHS)	Congenital central hypoventilation syndrome	Cheyne-Stokes breathing (CSB)	OHS	CSB
Neuromuscular weakness	Hypercapnic chronic obstructive pulmonary disease	High-altitude periodic breathing Treatment emergent central apnea		Idiopathic pulmonary hypertension

contribute to instability because periodic breathing would be unlikely if chemoreceptors were in the lung. Circulatory delay was induced in classic experiments by Guyton and colleagues,[73] who showed that delays of several minutes (beyond what could occur clinically) were sometimes required to induce periodic breathing in animals. Subsequent studies suggested that circulatory delay was similar in patients with CSB with CHF compared with patients without CSB matched for the severity of heart failure. However, some studies have shown that improvements in circulatory delay are associated with improvement in loop gain (and hence improved AHI). Thus, in aggregate, the data suggest that circulatory delay is necessary but not sufficient to destabilize ventilation in most cases. Therefore the overall response in CSB is that of an increased loop gain manifesting as increased ventilatory instability.

CSB with CSA had been also noted in individuals with cerebrovascular accident (CVA) and chronic renal failure. Among patients with CVA and CSA, the presence of CSB with long hyperpnea and cycle durations, and a gradual rise to peak tidal volume during hyperpnea, was associated with left ventricular systolic dysfunction, but was not related to the location or type of stroke. The authors indicated that the presence of CSA with CSB was more closely associated with left ventricular systolic dysfunction than it was with the stroke itself.[74] Similarly, Yamamoto and Mohri,[75] studying the influence of chronic renal insufficiency on SBDs in patients with symptomatic chronic heart failure, found that most of these patients had unspecified central events, with estimated glomerular filtration rate comparable between non-SBD and SBD groups. The authors suggested that renal dysfunction played a relatively minor role in determining breathing abnormalities in chronic heart failure.[75]

High-Altitude Periodic Breathing

High-altitude periodic breathing is another example of ventilatory instability that occurs during sleep in individuals during ascent to moderate and high altitude (see Chapter 122). Individual susceptibility to high-altitude periodic breathing is driven by multiple genetic factors; polymorphisms in numerous genes, including the hypoxia-responsive transcription factor subunit EPAS1/HIF2α and additional genes in the HIF pathway linked to hemoglobin level, have been associated with differences in susceptibility to or severity of acute mountain sickness associated conditions.[76,77] In this case, high-altitude periodic breathing is the result of ambient hypoxia inducing hyperventilation (*increased controller gain*), which further leads to hypocapnia and consequently to *decreased plant gain*. Overall, however, the controller gain dominates the decreased plant gain, resulting in periodic breathing.[78]

Treatment Emergent Central Sleep Apnea

Treatment emergent central sleep apnea develops in some patients both during titration and after continuous positive airway pressure (CPAP) therapy initiation. This phenomenon is associated with *increased controller gain* due to lowering upper airway resistance with perhaps a contribution of the air leak washing out the anatomic dead space.[79] It usually resolves spontaneously with ongoing CPAP therapy. As in a pilot study, loop gain was higher in patients with treatment emergent sleep apnea in whom central apneas persisted after 1 month of CPAP therapy; loop gain measurement in these patients may enable an a priori determination of those who need alternative modes of PAP.[79a]

Obesity-Hypoventilation Syndrome

Obesity-hypoventilation syndrome (OHS) is characterized by a combination of obesity (body mass index >30 kg/m^2) and arterial hypercapnia during wakefulness ($Paco_2$ >45 mm Hg) (see Chapter 120). OHS is the result of an interplay between respiratory mechanics and ventilatory drive, with leptin, a circulating protein produced mainly by adipose tissue, playing a role. A deficiency of this adipokine, as seen in the leptin-deficient *ob/ob* mouse mode, results in impaired respiratory mechanics, depressed ventilatory responsiveness, and awake hypercapnia.[80] Because leptin replacement in these mice reverses their OHS, recent work has focused on the potential role of leptin in individuals with OHS. It is presumed that the development of central leptin resistance or relative leptin deficiency in OHS could contribute to the development of awake hypoventilation by altering respiratory drive output as well, affecting the mechanical properties of the lungs and chest wall and attenuating the normal compensatory mechanisms used by individuals to cope with obesity-related respiratory loads.[81] These patients have decreased ventilatory responsiveness to hypoxia and hypercapnia compared with similarly obese non-OHS patients and also respond with large increases in $Paco_2$ to small decreases in ventilation (*increased plant gain*), increasing overall the probability of developing central apneic events.[82]

Congenital Central Alveolar Hypoventilation Syndrome

CCAHS is a rare congenital disease caused by mutation in *PHOX2B* gene leading to lack of central drive and decreased

ventilatory response to $Paco_2$ (decreased controller gain) despite normal lungs and respiratory muscle function.

Hypercapnic Chronic Obstructive Pulmonary Disease

Although not characterized by frank central sleep apneas or as a CSA disorder, advanced chronic obstructive pulmonary disease (COPD) is associated with progressive hypercapnia due to impaired lung mechanics, with renal compensation toward a physiologic pH (by increasing serum bicarbonate). Prognosis in individuals with advanced COPD has been reported to be negatively affected by hypercapnia,[83,84] and degree of hypercapnia is not correlated with survival after hypercapnia has developed.[85] The long-term optimal management of the hypercapnia in these patients remains unclear. Recent data by Köhnlein and colleagues demonstrated that the addition of long-term noninvasive positive pressure ventilation to standard treatment improved 1 year survival of patients with hypercapnic, stable COPD when noninvasive positive pressure ventilation was targeted to reduce hypercapnia.[86] Patients with COPD and concomitant OSA may be referred to as having "overlap syndrome" (see Chapter 119), and large series have shown that patients with overlap syndrome who did not receive treatment with nocturnal CPAP had a lower survival rate than patients who suffered from either COPD[87] or OSA[88] alone. However, data regarding optimal management of overlap syndrome are lacking.

Opioid-Induced Central Sleep Apnea

The exact pathophysiologic mechanism of opioid-induced apnea remains poorly understood but is likely related to opioid-induced suppression of inspiration generated by the pre-Bötzinger complex in the brainstem.[89] Both a periodic, non-waxing waning breathing pattern, and a cluster-type breathing pattern, each with central apneas, have been reported during NREM sleep in individuals receiving chronic opiates.[90] Chronic opioid use is a risk factor for the development of central sleep apnea and ataxic breathing,[91] but it is only rarely associated with daytime hypercapnia.[92]

GENETICS

Congenital Central Alveolar Hypoventilation Syndrome

Most CSA disorders in adults have not been linked to specific genotypes. The one clear exception is CCAHS, which is a monogenetic disorder of central respiratory control associated with diffuse autonomic dysregulation[93] and, at times, Hirschsprung disease and tumors of neural crest origin.[94] CCAHS is characterized by a specific facial phenotype, such as boxy facies and an inferior inflection of the lateral segment of vermillion border on the upper lip.[95] CCAHS has a familial presentation, and the *PHOX2B* mutation located on chromosome 4p12 has been identified and confirmed as the disease-defining gene.[96-99] CCAHS, a lifelong disease, is diagnosed in the absence of other systemic pathology and a positive *PHOX2B* screening test or whole-gene *PHOX2B* sequencing test.[100] Clinically, CCAHS is defined by an inability to adapt appropriately to needed ventilatory changes; these patients have altered or absent perception of shortness of breath when awake and profound and life-threatening hypoventilation during sleep.[101] Patients with CCAHS develop apnea or severe bradypnea during NREM sleep. However, expression of the disease is highly variable, with some patients presenting as neonates and others presenting in adulthood, largely depending on the genotype. Approximately 90% of mutations involve excessive polyalanine repeats of the *PHOX2B* gene beyond the normal 20/20 pattern observed in the normal population. Polyalanine repeat patterns of 20/25 to 20/33 typically present at birth with hypoventilation. By contrast, people with a 20/24 pattern may present after the neonatal period, including as adults. Approximately 10% of CCHAS patients have nonpolyalanine repeat mutations (frameshift, missense, or nonsense), and they are typically affected at birth with hypoventilation during wakefulness and sleep. Therapeutically, CCAHS patients require intratracheal or noninvasive positive pressure ventilation during sleep, and about one third also require additional ventilator support during wakefulness, including positive pressure ventilation or diaphragmatic pacing.[102] Generally, adults present with the 20/24 CCAHS genotype, which typically involves only mild hypoventilation that can be managed with noninvasive ventilation during sleep only.

EPIDEMIOLOGY

Risk Factors

Several independent risk factors have been established for CSA-CSB. In patients with CHF and reduced left ventricular ejection fraction, risk factors for CSA-CSB include age older than 60 years, male gender, presence of atrial fibrillation, and hypocapnia.[103-105] For patients with treatment emergent CSA, a high baseline AHI or arousal index, hypertension, opioid use, coronary artery disease, stroke, and CHF all appear to be risk factors.[106]

Prevalence

CSA is estimated to account for 5% to 10% of patients with SBDs that, according to ICSD3, includes OSA, sleep-related hypoventilation disorders, and sleep-related hypoxemia disorder.[107] Additionally, variations in the hemodynamic profile of CHF patients predispose them to alterations day to day and sometimes within the same night of the predominant type of apnea—from OSA to CSA, and vice versa.[108,109]

Cheyne-Stokes Breathing

CSA-CSB is highly prevalent in patients with left ventricular dysfunction regardless of the etiology (ischemic vs. idiopathic), type (preserved or low ejection fraction), New York Heart Association (NYHA) class, and acuity of event (acute or chronic heart failure).[110] CSA-CSB can present during both sleep and wakefulness. Nocturnal CSA-CSB has been studied mostly in stable compensated heart failure and is present in up to 44% of patients who have heart failure with a reduced ejection fraction (HFREF)[111,112] and in up to 27% of patients who have heart failure with a preserved ejection fraction (HFPEF).[113] CSA-CSB during wakefulness is less common, occurring in 16%[114] of patients with HFREF NYHA class II or III; however, because it emerges in the early afternoon and evening and evidence of nocturnal CSA-CSB correlates only weakly with its presence, its reported prevalence could be underestimated. CSA-CSB has been demonstrated after myocardial infarction and unstable angina; in both situations, it is a common occurrence, being present in more than 60%[115] of these patients.

Primary Central Sleep Apnea

Primary CSA, formerly categorized as "idiopathic" CSA, is uncommon. The general population prevalence of primary CSA is not known. However, within the sleep center population, the prevalence has been reported to be 4% to 7%. A higher prevalence of idiopathic CSA has been reported in older patient populations.[116] These individuals usually complain of excessive daytime sleepiness, insomnia, or difficulty breathing during sleep.[117]

High-Altitude Periodic Breathing

Despite considerable heterogeneity in the susceptibility to altitude illness, periodic breathing in the form of cyclic central apneas and hypopneas occurs in almost all individuals at a sufficiently high altitude.[118]

Treatment Emergent Central Sleep Apnea

When treatment emergent CSA (or "complex" CSA) is simply defined as the emergence of central apneas and hypopnea both during and after the application of PAP therapy in patients with OSA, its estimated prevalence in the general sleep center patient population is between 10% and 15%.[119] Treatment emergent CSA is a dynamic process, and its prevalence decreases with ongoing PAP therapy within 2 to 3 months in most patients.[120]

Central Sleep Apnea Due to a Medical Disorder

A synopsis of several common noncardiac medical conditions associated with CSA events is described in Table 109-1. In cardiac conditions not related to left heart disease, CSA events were identified by PSG in 10.6%[121] of a cohort of such patients who developed NYHA class II or III disease due to variety of conditions such as idiopathic pulmonary hypertension, chronic thromboembolic disease with pulmonary hypertension, COPD, and interstitial lung disease. PSG and ambulatory cardiorespiratory sleep studies documented concomitant CSA in up to 39% of patients with idiopathic pulmonary hypertension and NYHA class II to IV chronic thromboembolic disease with pulmonary hypertension[122] and in up to 20% of patients with hypertrophic cardiomyopathy.[123]

Central Sleep Apnea Due to a Medication or Substance

Opioid-induced CSA has only been recognized since about 2000,[124] with a reported prevalence, for example, of 30% of patients in a methadone pain program.[125] Given the progressive increase in opioid use for symptom management in both neoplastic and chronic diseases, it is expected that such CSA will be increasingly identified in clinical sleep practice.

Age

In both general and heart failure populations, CSA-CSB seems to be more commonly encountered in patients of advanced age. In children with CHF, CSA-CSB is quite rare,[126] whereas in a random sample of men aged 20 to 100 years, using sleep laboratory evaluation subsequent to a telephonic survey, Bixler and colleagues[127] noted CSA in 0.4% of those 45 to 64 years old and in 1.1% for those 65 to 100 years old. Others[128] have reported an even higher occurrence of 17% in a population aged 71 years and older.

Gender

Among healthy middle-aged adults, CSA syndromes are overall much more common in men (7.8%) than in women (0.3%).[129] For example, a study including a large proportion of women with stable HF reported unspecified CSA in only 0.05% of those with HF and in none of those with preserved ejection fraction heart failure.[130] Although OSA is increasingly recognized in postmenopausal women, similar consistent data for CSA are lacking.

Race

No data are available on the racial distribution of CSA syndromes to our knowledge.

Morbidity

Central Sleep Apnea and Cardiac Hemodynamics

In CSA-CSB, intermittent surges in blood pressure and heart rate occur in association with oscillations in ventilation. Such surges can be precipitated by cyclic increases in sympathetic nervous system activity targeting the heart and peripheral vasculature.[131,132] Studies concentrating on these hemodynamic responses have confirmed that the frequency and peaks of heart rate and blood pressure oscillations are dependent primarily on periodic oscillations in ventilation.[133] The clinical significance of this finding is not certain, but surges in blood pressure during hyperpnea may be one factor related to the poorer prognosis in patients with heart failure with CSB compared with those without it.[134] More recently, Yumino and colleagues[135] assessed the beat-to-beat stroke volume from before until the end of central respiratory events during sleep in patients with HFREF and demonstrated an increase in stroke volume by a mean of 2.6% (P <.001 for the difference).

Central Sleep Apnea and Cardiac-Related Hospital Readmission

The only study to date[136] that prospectively evaluated cardiac readmission associated with SBD in a cohort of hospitalized patients with acutely decompensated HFREF demonstrated CSA-CSB to be a predictor of both 1-month and 6-month readmission (univariable rate ratios of 1.5 and 1.63, respectively). Ongoing studies are evaluating whether treating CSA-CSB prevents such readmission.

Central Sleep Apnea and Cerebrovascular Accident

Using near-infrared spectroscopy in individuals with acute and subacute CVA, Pizza and colleagues documented asymmetrical patterns of cerebral hypoxia during unspecified CSA events, with significantly larger changes on the unaffected compared with the affected hemisphere.[137]

Mortality

As the oxyhemoglobin desaturations, arousals, increased sympathetic output, and negative intrathoracic pressure (during hyperpnea that follows central apnea in CSA-CSB) contribute to myocardial ischemia, CSA-CSB could contribute to excess mortality in patients with heart failure. Relatively large studies looking specifically at the mortality associated with unspecified CSA and CSA-CSB have provided divergent results, some likely deriving from the lack of a strict definition for CSA or for CSA-CSB. Javaheri and associates[138] evaluated

survival in HFREF (ejection fraction <45%) over a period of 51 months and demonstrated that patients with unspecified CSA had half the survival time of those without such CSA, 45 and 90 months, respectively (P = .01), independent of systolic function, NYHA functional class, heart rate, serum digoxin and sodium concentrations, hemoglobin, and age. In contrast, Andreas and colleagues[139] noted that, in patients with HFREF, nocturnal CSA-CSB had no prognostic impact. Both Andreas and colleagues[139] and Lange and Hecht[140] reported that awake CSA-CSB was associated with a high likelihood of death within 1 to 24 months. Roebuck and associates[141] noted that systolic heart failure patients with unspecified CSA had decreased survival at 500 days but similar long-term survival compared with those without such CSA. Luo and colleagues[142] demonstrated that unspecified CSA had no effect on the prognosis of middle-aged patients with CHF, whereas Bakker and associates[143] provided contrasting evidence by demonstrating a significantly lower survival rate in patients with heart failure and unspecified CSA compared with both heart failure and OSA (mean survival time difference, 3.8 years; P = .005) and those with heart failure only (mean survival time difference, 4 years; P = .01). Additionally, within the group of patients with HFREF and unspecified CSA, mortality is reported to be significantly higher in the "severe" (AHI >22.5/hour) unspecified CSA group compared with the "mild" unspecified CSA group (AHI <22.5/hour; 38% vs. 16%; unadjusted P = .002 and adjusted for the confounders age and NYHA class P = .035).[144] Notably, all of these studies have focused on understanding mortality in untreated patients with heart failure and CSA with or without CSB, and definitive outcome data on the impact of PAP therapy on the natural progression of unspecified CSA and CSA-CSB in patients with heart failure are still lacking. To date, the largest randomized controlled multicenter trial, the Canadian Continuous Positive Airway Pressure for Patients with Central Sleep Apnea and Heart Failure Trial (CANPAP)[145] and its post hoc analysis,[146] showed that death and heart transplantation events did not differ between the control group and the CPAP group. The post hoc analysis showed improved survival without heart transplantation in the CANPAP group when CPAP therapy was associated with a reduced frequency of CSA-CSB events to fewer than 15 events per hour.

CLINICAL PEARLS

- Centrally driven respiratory events are primarily due to a temporary loss of output from the pontomedullary pacemaker that generates breathing rhythm, resulting in loss of diaphragmatic activity.
- CSA with CSB is a form of periodic breathing, commonly observed in patients with heart failure, in which central apneas alternate with hyperpneas that have a waxing-waning pattern of tidal volume.
- Nocturnal CSB has been studied mostly in stable compensated heart failure and is present in up to 44% of patients with low ejection fraction and in up to 27% of patients with preserved ejection fraction. However, variations in the hemodynamic profile of heart failure patients predispose them to day-to-day and sometimes within-night alterations of the predominant type of apnea—OSA to CSA, and vice versa.
- Ventilatory control in CSA is largely chemically driven, especially during NREM, and is the result of a fine balance between a critical $PaCO_2$ level, below which there is a central cessation of breathing (i.e., apneic threshold); its ventilatory triggering factors (mainly hypocapnia); and respondent receptors (i.e., central and peripheral chemoreceptors). This complex feedback mechanism is best described by the concept of loop gain.
- CSA-CSB is likely an independent risk for increased mortality or cardiac transplantation in patients with heart failure.
- Definitive outcome data on the effect of PAP therapy on the natural progression of CSA and CSA-CSB in patients with heart failure are still lacking.

SUMMARY

In CSA, both oronasal flow and thoracoabdominal excursions are absent; that is, there is an absence of respiratory effort during the cessation of airflow. CSB and treatment emergent (or "complex") CSA are the most common clinical CSA patterns. CSA with CSB is characterized by oscillations of ventilation between apnea and tachypnea, with a waxing and waning crescendo-decrescendo pattern in the depth of respirations, and is highly prevalent in patients with heart failure. Treatment emergent CSA most commonly refers to the development of CSA with the application of CPAP in patients with OSA; in most cases, this breathing pattern resolves spontaneously with ongoing therapy. CSA-CSB is likely associated with increased mortality in treated patients with systolic heart failure. It remains unclear whether improving the frequency of CSA-CSB in sleep improves clinical outcomes in this setting or, conversely, resolution of the CSA-CSB is simply a marker of a good prognosis.

Chapter 110

Chapter Highlights

- Pathologically enhanced respiratory chemoreflexes result in a spectrum of polysomnographic breathing patterns and disorders, including central sleep apnea (CSA), periodic breathing/Cheyne-Stokes breathing, high-altitude sleep apnea, and treatment emergent CSA.
- A pathologically decreased chemoreflex can result in hypercapnic CSA.
- Opiate use causes a disintegrative CSA disorder with relatively unique polysomnographic features.
- Conventional polysomnography has limitations in accurate phenotyping the sleep apneas; thus, the true prevalence of various forms of central apnea syndromes is uncertain.
- Evidence suggests that about one third of those with obstructive sleep apnea have respiratory control as a key mediator of disease. Predominance of events in non–rapid eye movement sleep and persistent or enhanced respiratory instability during treatment with continuous positive airway pressure are key features that are readily recognized in clinical settings.
- Adaptive ventilation is a major advance in noninvasive ventilatory therapy of CSA syndromes. However, benefits in outcomes in heart failure patients are not proven, and there is potential for harm. Several other off-label approaches can be considered as primary or adjunctive therapy.
- Volume-assured positive pressure ventilation can improve oxygenation and ventilation in hypercapnic CSA and hypoventilation syndromes but may cause sleep fragmentation if pressure fluctuations are excessive.
- Residual disease during treatment is common in CSA syndromes. The long-term persistence of the residual central apnea depends on etiology and associated disorders.

The term central sleep apnea (CSA) describes both the pattern of an individual respiratory event and the clinical syndrome characterized by repeated episodes of apneas during sleep caused by an impaired respiratory drive system.[1,2] This is in contrast to obstructive apneas, in which respiratory drive remains active during the apnea, associated with upper airway occlusion (Figure 110-1).

Although central apneas are less frequent than obstructive, they present in ways and settings that are diverse. CSA breathing patterns can vary from the rhythmic sequences of apnea and recovery breaths in congestive heart failure (CHF) to the ataxic respiratory patterns in patients with opioid use.[3,4] Most humans exhibit central apneas during transitions into sleep, and they appear in travelers to high altitude. CSA patterns are associated with a range of medical conditions, from end-stage renal disease to multiple system atrophy and from opioid dependence to the central congenital hypoventilation syndrome.[5-9] CSA is important to recognize because of complications ranging from frequent nighttime awakenings and excessive sleepiness to adverse cardiovascular outcomes and mortality.[10-12]

Central respiratory events in sleep rarely occur in isolation, and many patients with sleep apnea appear to live on a phenotypic spectrum between the obstructive and central apneas. In heart failure and opioid-induced sleep apnea, central and obstructive apneas often coexist.[8,13] In treatment emergent CSA, alleviation of obstructive apneas with positive airway pressure (PAP) amplifies or unmasks a sensitive chemoreflex with resultant centrally mediated apneas and periodic breathing.[14] Identifying where the patient is on the obstructive-to-central spectrum and focusing on the factors responsible for this physiology are critical for accurate diagnosis of CSA and its management.

DEFINITIONS

Current definitions for central apnea and hypopnea are based on polygraphic data and are reviewed in Chapter 109 as well as the American Academy of Sleep Medicine (AASM) scoring manual.[15] A CSA syndrome is defined when five or more central apneas *and/or* central hypopneas are present per hour; that is, a central apnea-hypopnea index (CAHI) of greater than 5, with CAHI comprising more than 50% of all respiratory events.[16] For the various CSA syndromes, additional criteria related to signs and symptoms and specific etiologic entity are required.[16]

These diagnostic criteria can pose a challenge to investigators and clinicians alike because reliably differentiating hypopneas as central versus obstructive is difficult. Evidence of upper airway obstruction on polysomnography, including flow-limitation, does not rule out central apneas/hypopneas,[16a,16b] and esophageal manometry is rarely used in practice. Unclassified hypopneas are

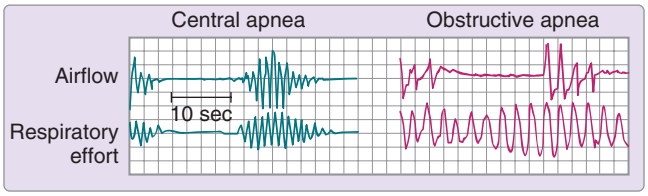

Figure 110-1 Central and obstructive sleep apnea. The relationship between airflow and respiratory effort in central and obstructive apnea. During central apnea, cessation of airflow occurs without associated ventilatory effort. Respiratory effort is present during an obstructive apnea. (From Wellman A, White DP. Central sleep apnea and periodic breathing. In: Kryger M, Dement W, editors. *Principles and Practice of Sleep Medicine*, fifth edition. Saunders: Philadelphia; 2011. p. 1140-1152.)

thus summed into the overall apnea hypopnea index (AHI), not the specific CAHI, biasing towards obstructive SDB.[16c,16d,16e] Accurately classifying SDB disorder as predominantly central or obstructive has implications for treatment.

Integrated analysis of polysomnography (PSG) features can improve identification of central hypopneas.[17] Predominance during non–rapid eye movement (NREM) rather than rapid eye movement (REM) sleep, lack of inspiratory airflow curve flattening or thoracoabdominal paradoxical breathing (chest wall moving inward with inspiration) during hypopnea, and arousal after[18] and gradual flow restoration pattern at hypopnea termination can help classify hypopneas as central.[17] Automation of hypopnea phenotyping (obstructive vs. central)[19] is possible, but accuracy in comparison to electromyography is limited (69%).

CLASSIFICATION OF CENTRAL SLEEP APNEA SYNDROMES

The *International Classification of Sleep Disorders*, third edition (ICSD3) group provides one framework for classifying CSA "syndromes"[16] (see Chapters 107 and 109). The approach in this chapter (Table 110-1) aims to demarcate physiologic and pathologic states in which CSA occurs and link mechanisms of CSA with therapies for each group. For example, it incorporates respiratory chemoreflex phenotyping based on PSG morphology or computational signal analysis. Thus "high chemosensitivity" suggests itself as a clinical category, the patterns of which could include central apneas, periodic breathing, or PAP-induced respiratory instability, signifying the need to consider chemoreflex stabilization in treatment. Our approach thus differs in some cases from the ICSD3 classification and should be considered complementary. For instance, sleep-related hypoventilation syndromes (e.g., obesity-hypoventilation syndrome [OHS]), a separate category in ICSD3, are included under the umbrella of CSA in this chapter under the hypercapnic category. Our aim is to emphasize the role impaired respiratory drive plays in the pathophysiology of these conditions and how treatment can be selected to address this impairment (e.g., bilevel ventilation with backup rate).

PATHOPHYSIOLOGY OF CENTRAL SLEEP APNEA SYNDROMES THAT AFFECT DIAGNOSIS AND TREATMENT

Pathophysiology of CSA is discussed in detail in Chapter 109, including the chemical, mechanical, and neural aspects of respiratory control; the feedback loop between the sensors and the respiratory center; the loop gain (measure of respiratory system stability) and its components (controller, plant, mixing); and other important features. Figure 110-2 summarizes the interplay between ventilatory drive (controller) and the lung's ability to excrete CO_2 (plant) in relation to normal (eupnea) and cessation (apnea) of breathing. In this section we highlight the physiologic concepts important for our approach to diagnosis and treatment and discuss them in the context of specific CSA syndromes.

Table 110-1 Pathophysiologic Classification of Central Sleep Apneas

Physiologic	Pathologic

• Sleep transition
• Phasic REM
	Nonhypercapnic
	• Medical condition related
	  • Congestive heart failure
	  • Poststroke
	  • ESRD
	  • PAH
	  • Atrial fibrillation
	• High altitude
	• Idiopathic
	Hypercapnic
	• Congenital central hypoventilation syndrome
	• Primary chronic alveolar hypoventilation syndromes
	• Other CNS disorders associated with CSA
	  • Encephalitis, tumors, strokes
	  • Anatomic abnormalities
	  • Neurodegenerative disorders
	• Muscular and PNS disorders associated with CSA (selected examples)
	  • Muscular dystrophies
	  • Acid maltase deficiency
	  • Charcot-Marie-Tooth disease and other neuropathies
	  • Postpolio syndrome
	  • Myasthenia gravis
	Disintegrative (e.g., brainstem injury, opioid induced)
	CSA with OSA or upper airway disorders (including treatment emergent CSA)

CNS, Central nervous system; CSA, central sleep apnea; ESRD, end-stage renal disease; OSA, obstructive sleep apnea; PAH, pulmonary arterial hypertension, PNS, peripheral nervous system; REM, rapid eye movements.

Pathophysiologic Changes that Lead to Central Sleep Apneas and Periodic Breathing

Interactions of three factors predispose an individual to ventilatory instability and central apneas-hypopneas during sleep[2,20]: low CO_2 reserve (CO_2 reserve = $Paco_2$ eupneic – $Paco_2$ apneic), abnormally high *or* low loop gain (a product of controller, plant, and mixing gains), and sleep state and stage instability.

CO_2 reserve is affected by changes in plant and controller gains. For example, CO_2 reserve is decreased in metabolic alkalosis (increased plant gain; see Figure 110-2), promoting the risk for central apneas and ventilatory instability, whereas it is increased with metabolic acidosis (decreased plant gain),[21]

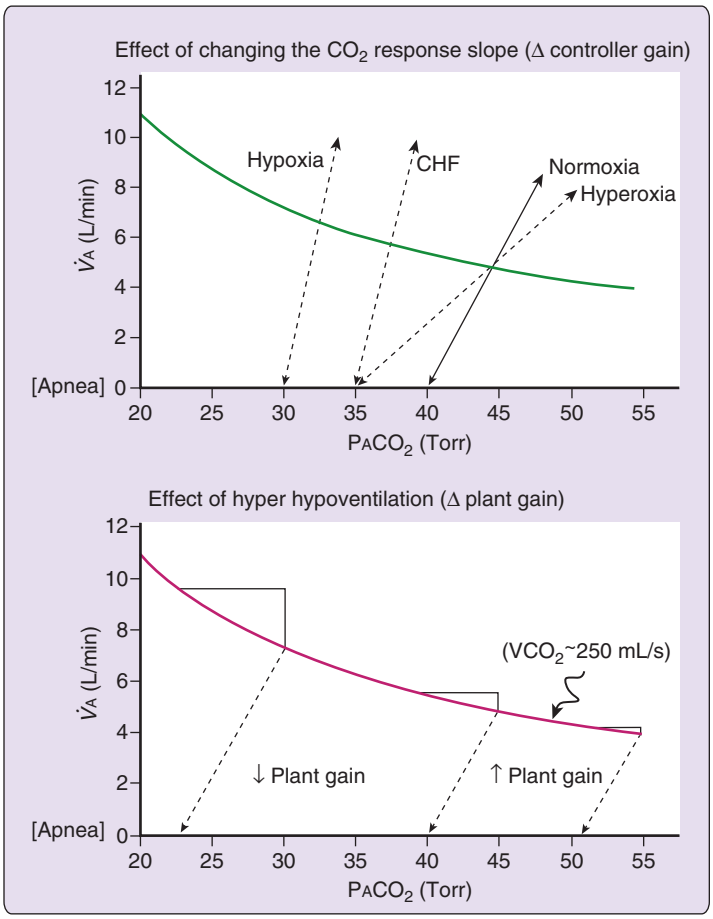

Figure 110-2 Changing plant gain (*bottom*) and controller gain (*top*) influences on CO_2 reserve. Diagrammatic representation of the steady-state relationship between alveolar ventilation and alveolar P_ACO_2 ($PaCO_2$) at a fixed resting CO_2 production (of 250 mL/min). The schematic figure shows how changing plant gain or controller gain will influence the "CO_2 reserve" or Δ $PaCO_2$ between eupnea and apnea. *Top,* Changing the background drive to breathe without changing the slope of the $\Delta\dot{V}_A$ versus Δ P_ACO_2 relationship (controller gain) above or below eupnea. For example, background hyperventilation (via metabolic acidosis or specific carotid body stimulation with almitrine) raises $\dot{V}_A$ and lowers P_ACO_2 along the isometabolic hyperbola (decreased plant gain). This means that a greater transient increase in $\dot{V}_A$ and reduction in P_ACO_2 is required to reach the apneic threshold than it would be under control, normocapnic conditions. The reverse is true for conditions that reduce the background drive to breathe and cause hypoventilation (e.g., metabolic alkalosis). *Bottom,* At any given level of background P_ACO_2, changing the slope (or responsiveness) of the relationship below eupnea would alter the CO_2 reserve or the amount of reduction in P_ACO_2 required to cause apnea. Changing the slope of the ventilatory response to CO_2 above eupnea would alter the susceptibility for transient ventilatory overshoots. Often both plant and controller gains may change together; note the reduced plant gains and increased controller gain, with hypoxia or with congestive heart failure patients. The increased controller gain dominates, and the net effect is a decreased CO_2 reserve and instability. (Modified with permission from Javaheri S, Dempsey JA. Central sleep apnea. *Compr Physiol* 2013;3[1]:141–63.)

which is protective against central apneas (see Figure 110-2). Administration of oxygen (which reduces hypoxic stimulus to breathing) has been shown to decrease ventilation and responsiveness to $Paco_2$ during sleep.[22] This stabilizes breathing through reduction in controller gain and increase in $Paco_2$ reserve, whereas hypoxia leads to opposite effects (see Figure 110-2). In addition, inherent delays in the negative feedback loop controlling ventilation (mixing gain) increase loop gain. This delayed recognition of blood gases by the controller (as in those with systolic CHF) predisposes to unstable and periodic breathing.

Transitions into and out of sleep, and between sleep stages, are inherently unstable in terms of respiratory control.[5] Brief central apneas and hypopneas occur during this time in normal individuals because of "unmasking" of the sleep apneic threshold that is very close to the wake eupneic threshold. In addition, upper airway and diaphragmatic muscle tone is reduced, with the associated increase in upper airway resistance and decreased inspiratory force, resulting in hypoventilation.[23,24] Then, as $Paco_2$ rises above the apneic threshold, rhythmic breathing is maintained.

During sleep, brief and abrupt transitions to wakefulness, termed *arousals*, can result in ventilatory instability, with level of ventilatory response and arousal threshold playing important roles. With a sudden arousal, the sleep eupneic $Paco_2$ (normally about 5 mm Hg higher than awake $Paco_2$) is detected as hypercapnic by the aroused respiratory control center. This signal to increase ventilatory drive, combined with the removal of the upper airway resistance induced by sleep, results in increased ventilatory response and reduction in $Paco_2$.[25,26] When sleep resumes, the current $Paco_2$ is considered to be hypocapnic for the sleeping brain, that is, below the apneic threshold, resulting in central apnea. Thus any process that leads to frequent sleep-wake transitions, such as sleep maintenance insomnia, sleep apnea, maladaptation to continuous positive airway pressure (CPAP), or periodic limb movement disorder, can increase the propensity to ventilatory overshoots, periodic breathing, and CSAs, especially in a setting of high chemosensitivity.[25,27-29]

Pathophysiologic Changes in Specific Central Sleep Apnea Syndromes

Nonhypercapnic Central Sleep Apnea

Disorders manifesting as nonhypercapnic (eupneic or hypocapnic) CSA have two physiologic phenomena in common: (1) normal or slightly low awake steady-state $Paco_2$, and (2) increased ventilatory responsiveness to $Paco_2$ or hypoxemia (increased loop gain). In the setting of arousals, CSAs are perpetuated owing to the so-called "inertial" effect (see Chapter 109).

Central Sleep Apnea and Periodic Breathing of Heart Failure. Heart failure is associated with Cheyne-Stokes breathing (CSB), which is seen at times during wakefulness and frequently during sleep. CSB is characterized by a crescendo-decrescendo pattern of tidal volumes with central apnea or hypopnea occurring at the nadir of the cycle (typically 60 to 90 seconds; Figure 110-3). It is in part a consequence of increased loop gain due to a heightened chemoreflex (sensitive controller)[30,31] and lack of the "normal" increase in $Paco_2$ with sleep onset (decreased CO_2 reserve).[32] These are superimposed on prolonged circulation time (increased mixing gain) resulting in cyclical ventilatory instability.[33]

Periodic breathing of shorter cycles occurs in other settings and conditions with "hyperactive" chemoreflex (as described later). Although ICSD3 defines CSB with specific cycle lengths and intervening apneas, we feel CSB represents one end of the chemoreflex activation severity spectrum, whereas at the other end of the clinical spectrum, although poorly recognized in practice, is nonapneic short cycle (≤30 seconds) periodic breathing.

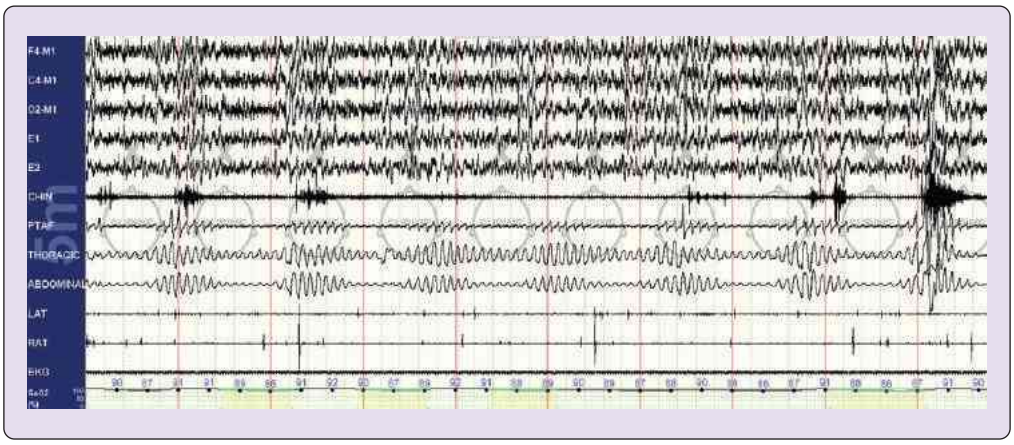

Figure 110-3 **Relatively long cycle periodic breathing and Cheyne-Stokes respiration.** Ten-minute screen compression, each vertical line is 30 seconds. A patient with congestive heart failure in NREM sleep. Note the symmetrical, concordant, waxing and waning flow and effort. Cycle lengths are about 45 to 50 seconds.

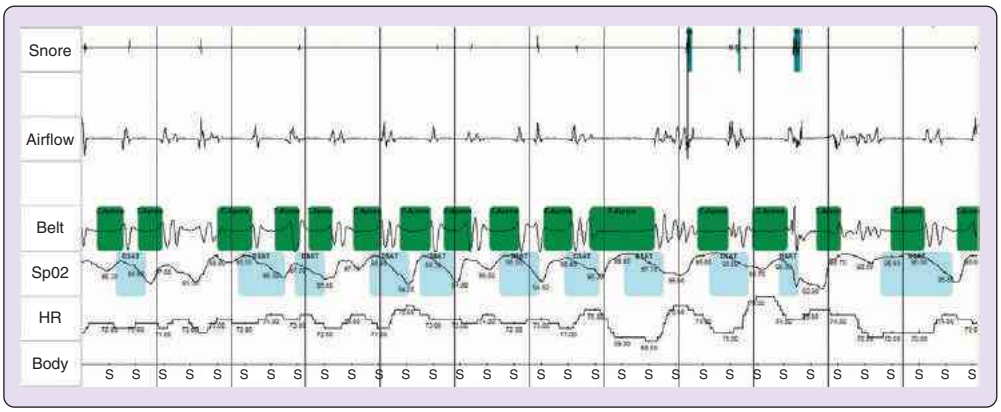

Figure 110-4 **Idiopathic sleep apnea.** A home sleep study on a medication-free 27-year-old nonobese man presenting with mild daytime sleepiness (Epworth Sleepiness Scale score of 9/24), nocturnal awakenings, and unrefreshing sleep. Note the short cycles (about 20 seconds) of pure central respiratory events.

Central Sleep Apnea Due to High-Altitude Periodic Breathing. In contrast to CSB in heart failure, the cycle time of periodic breathing at high altitude is short (probably owing to elimination of the mixing gain defect). The mechanism involves exposure to hypoxemia with resultant chemoreceptor-mediated hyperventilation during NREM and REM sleep. After approximately 10 minutes of hypoxia in a sleeping human, tidal volumes oscillate in a waxing and waning pattern. The oscillations increase in magnitude as hypoxia is maintained and $Paco_2$ falls further to the level of apneic threshold.[34] When that is reached, overt periodic breathing occurs with cycle times of 15 to 25 seconds (two to five large tidal volume breath clusters followed by apneas of 5 to 15 seconds).[2,35-37] There is wide variation in O_2 during this time. The predominant mechanism is increased loop gain manifested as a reduced $Paco_2$ reserve (1 to 2 mmHg) and increased chemosensitivity (see Figure 110-2).[21,38] The marked increase in arousals and decrease in slow wave sleep potentiate respiratory instability. Attesting to the key role for hypocapnia in this disorder of central apnea and periodic breathing, the breathing disorder can be improved with administration of small amounts of CO_2 (increase in $Paco_2$ reserve),[39] increasing dead space (increase in $Paco_2$ reserve),[40] and acetazolamide (reduction in plant gain and increase in $Paco_2$ reserve).[21] Patients with obstructive sleep apnea (OSA) and high loop gain have PSG features mimicking high-altitude periodic breathing, including NREM dominance and short cycle periodic breathing.

Primary Central Sleep Apnea. Primary (idiopathic) CSA is a rare disorder characterized by repetitive episodes of central apneas in NREM sleep, which are short and irregular (rather than periodic) and terminate with an abrupt, large breath (Figure 110-4), in contrast to what is characteristically seen in CHF. The most clearly demonstrated pathophysiology is an increased hypercapnic ventilatory response during wakefulness.[29,41] In addition, impairment of switching between expiration and inspiration has also been found in these patients.[42] It has been speculated that the long expiratory pause that typically occurs with these CSA events may be attributable to this impairment.

Other Nonhypercapnic Central Sleep Apnea Syndromes and Their Associated Medical Conditions. Common chronic medical conditions such as end-stage renal disease (ESRD), cerebrovascular accident (CVA), and pulmonary hypertension have been associated with nonhypercapnic CSA. In patients with ESRD, the central apnea index (i.e., frequency of central

apneas) inversely correlates with $Paco_2$ and cardiac silhouette enlargement,[6] and ultrafiltration increases $Paco_2$ with associated decline in the CAHI by 55%.[43] These findings suggest that a similar link may be present between volume overload and the CSA-CSB of CHF.

CSB occurs in a minority of patients (~7%) after CVA.[44] Although in many cases post CVA the CSB is associated with left ventricular dysfunction and hypocapnia,[45] some authors note an increased prevalence of CSB in patients with lacunar strokes (~20%) and without left ventricular dysfunction.[46] CSB has been reported in patients with idiopathic pulmonary arterial hypertension (PAH). The postulated mechanisms include decreased stroke volume and increased mixing gain,[2] although, as in case of CVA, no PAH-specific studies have been done.

Hypercapnic Central Sleep Apnea

Hypoventilation due to a failed or failing automatic control (and effector) system is the pathophysiologic hallmark of disorders that manifest with hypercapnic CSA. They can be broadly approached as disorders of impaired central drive ("won't breathe") or impaired respiratory muscle control ("can't breathe"). In general, the former category is due to processes involving the brainstem respiratory centers (e.g., congenital central alveolar hypoventilation syndrome), whereas the latter is due to neuromuscular weakness disorders (e.g., amyotrophic lateral sclerosis). Most of the above disorders are associated with pathologically *low* loop gain (either because of controller or plant components) and worsening of hypoventilation and apneas during REM sleep (in contrast to hypocapnic CSA, which is NREM dominant). The latter occurs primarily because of intercostal muscle atonia during REM. Most of these conditions are classified under the sleep-related hypoventilation disorders in the ICSD3 (see Chapter 107).

Congenital Central Alveolar Hypoventilation Syndrome and Idiopathic Central Alveolar Hypoventilation. Congenital alveolar central hypoventilation syndrome (CCHS, or "Ondine's curse") is a rare disorder of respiratory control and autonomic systems, first reported by Mellins in the 1970s.[47] Small tidal volumes and monotonous respiratory rates result in hypoventilation while the wakefulness and behavioral stimuli supply the respiratory drive. With sleep onset, worsened hypoventilation, hypercapnia, and hypoxemia ensue due to the impaired automatic control system. In many cases, if not identified early, this leads to asphyxia and death.[48] Mutations of the *PHOX2B* gene are disease defining.[49] This gene encodes a transcription factor responsible for the fate of early autonomic nervous system cells, including those in the respiratory control centers.[48]

Obesity-Hypoventilation Syndrome ("Pickwickian Syndrome"). "Joe was a wonderfully fat boy, standing upright with his eyes closed." This is the first depiction of OHS, found in Charles Dickens' book, *The Posthumous Papers of the Pickwick Club*. Today's medical literature requires that obesity and awake hypoventilation ($Paco_2$ >45 mm Hg) be present (without other causes for the latter) for the diagnosis of OHS.[50] Abnormalities include progressive hypoventilation and hypoxemia during NREM sleep with further impairment in REM sleep,[51] and OSA (nearly universal in OHS[52]). Pathogenetic mechanisms are complex and insufficiently investigated, even in face of the obesity epidemic. They include ventilatory abnormalities of OSA, increased work of breathing,[53] and blunted chemosensitivity (decreased loop gain).[54-56] There is a suggestion that resistance to leptin, a hormone produced by adipocytes that normally augments ventilatory response to $Paco_2$, is a possible mechanism for reduced controller gain in OHS.[57-59]

Other Central Nervous System–Related Disorders. Central neurologic processes that cause impairment of the brainstem respiratory centers, such as compression, edema, ischemia, infarct, tumor, encephalitis, and Arnold-Chiari malformations, have been associated with breathing dysrhythmias and CSA.[60-69] The specific manifestations depend on the location and the type of the insult. For instance, automatic failure of breathing control ensues following cervical cordotomy.[70] Damage to areas other than the brainstem (thalamus, basal ganglia, centrum semiovale) can lead to CSA, suggesting the importance of the descending signals for generation of the automatic breathing stimulus.[46]

Peripheral Nerve and Muscle Disorders. Neuromuscular diseases, such as muscular dystrophy, myasthenia gravis, Guillain-Barré syndrome, amyotrophic lateral sclerosis, postpolio syndrome, and Charcot-Marie-Tooth disease, can lead to awake alveolar hypoventilation, with worsening hypoventilation during sleep. This is occasionally associated with central apneas, although sleep-related hypoventilation without outright central apnea is the more prominent feature. Ventilation during sleep in patients with respiratory muscle disease often deteriorates well before awake ventilation is affected.

Disintegrative Central Sleep Apnea and Hypoventilation Associated with Opiates. Although the respiratory depressant effects of opioids are well known,[71,72] the effects of opiates on sleep are widespread and complex and affect many patients.[73] With chronic use, hypoventilation and obstructive and central apneas can occur in a single patient, fulfilling diagnostic criteria for several disorders under the ICSD3 classification. In patients with daytime hypercapnia, nocturnal hypoventilation can be profound. Two unique patterns of breathing tend to occur in patients taking chronic opioids: (1) cluster breathing characterized by cycles of deep breaths with relatively stable tidal volumes with interspersed central apneas of variable duration and (2) Biot breathing (ataxic breathing) with variable tidal volumes and rates.[2] In addition, patients taking chronic opioids with nearly pure OSA on initial PSG evaluation can develop treatment emergent central apnea.[74] In chronic opioid use, there is also a high prevalence of obstructive events.

Of the various opioid receptors, stimulation of μ and κ receptors tends to drive respiratory depression[8] primarily in the pre-Bötzinger complex.[75,76] At low doses, tidal volumes decline,[77] whereas at higher doses, respiratory rate and rhythm generation are suppressed.[8] Morphine given to normal human subjects acutely decreases hypercapnic and hypoxic controller gain[78]; however, chronic administration results in decreased hypercapnic but increased hypoxemic chemosensitivity.[79] Mechanisms of ataxic breathing (Figure 110-5), common among those taking chronic opioids (nearly 70%) and those taking higher doses (>200 mg of morphine,[4]), have not been elucidated. Similar features could occur with injury to the

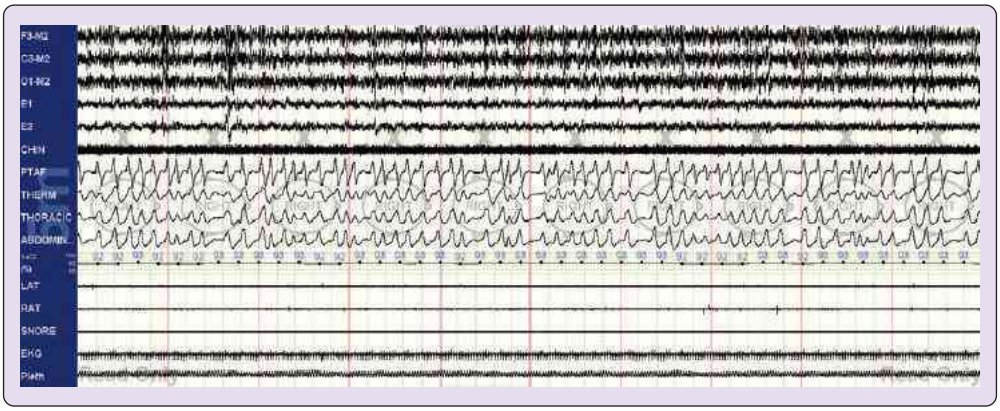

Figure 110-5 **Opiate-induced central sleep apnea and ataxic breathing.** Ten-minute screen compression; each vertical line is 30 seconds. In this methadone-treated 56-year-old woman, the most characteristic feature of opiate-related disease is the variability in expiratory duration, although tidal volumes also vary. These polysomnographic features are readily recognizable and occur in NREM sleep.

Figure 110-6 **Central sleep apnea associated with head and neck chemoradiation.** Ten-minute screen compression; each vertical line is 30 seconds. A 71-year-old man treated with radiation and platinum-based chemotherapy for laryngeal cancer. He presented with severe insomnia, multiple nocturnal arousals, and daytime fatigue. Note the variable-duration central apneas, mixed features, and sleep fragmentation.

carotid bodies, such as following head and neck chemoradiation (Figure 110-6).

Disordered Interplay Among Upper Airway Obstruction, Breathing Control, and Sleep-Arousal Propensity: Treatment Emergent Central Sleep Apnea ("Complex Sleep Apnea"). The $Paco_2$ reserve is labile during NREM sleep,[80] and arousals due to maladaptation to PAP can occur and drive instability.[14] Upper airway collapsibility as measured by Pcrit (pressure at which passive critical closing of the upper airway occurs) shows overlap between patients with OSA and controls.[81] Variations in Pcrit alone account for only a portion of variations in the apnea-hypopnea index (AHI)[82] or differences between those with pure OSA (100% of apneas obstructive) and predominant OSA (coexisting with CSA and mixed apneas).[83]

In some patients with OSA, central apneas and periodic breathing "emerge" during initiation of CPAP. This phenomenon is termed *treatment emergent CSA* in ICSD3[15] and is defined when there are five or more central apneas or hypopneas per hour of sleep, making up greater than 50% of all respiratory events during titration of CPAP in those fulfilling OSA criteria during diagnostic PSG. The existence of treatment emergent CSA (previously known as *complex sleep apnea*) as a unique entity has been controversial in the sleep world.[84] The original description noted a set of relatively unique features on *diagnostic* PSG and an incomplete treatment response that included induction of central apneas or persistent periodic breathing when CPAP was applied. The key feature is NREM-dominant central hypopneas or periodic breathing with obstruction (Figure 110-7), resolving spontaneously during REM sleep. That is, induction of central apneas was not required. However, the NREM dominance may be readily seen during positive pressure titration (Figure 110-8). A subsequent publication "defined" complex apnea, proposing the current ICSD criteria,[84] which also became the criteria used by medical insurance to qualify patients for the more expensive adaptive ventilators. The ICSD3 allows for the coexistence of periodic breathing and OSA (a "splitting" approach). The term *complex apnea* (a "lumping" approach) may have clinical utility in that a single term captures a number of ICSD categories with a common pathogenesis and identical responses to therapy. Central hypopneas are rarely scored in clinical practice, and thus reports of complex apnea or treatment-emergent sleep apnea, especially if using the ICSD3 treatment-emergent category and criteria, likely include only patients far on the spectrum of chemoreflex-driven instability than the middle ground, where a substantial minority of

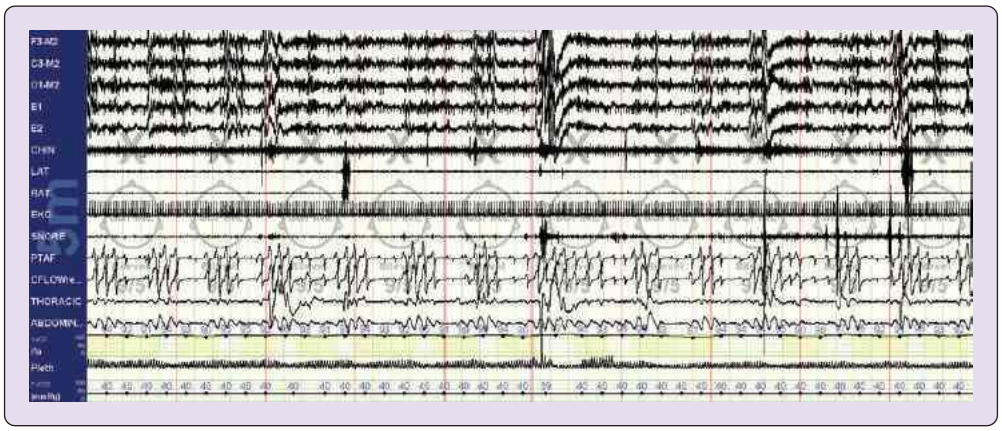

Figure 110-7 Key feature of NREM-dominant apnea. Ten-minute screen compression; each vertical line is 30 seconds. Periodic breathing with short cycles (30 seconds or less) and variable degrees of obstruction. Conventional scoring typically identifies these events as obstructive. Flow limitation is often seen, but the waxing-waning characteristic is usually evident.

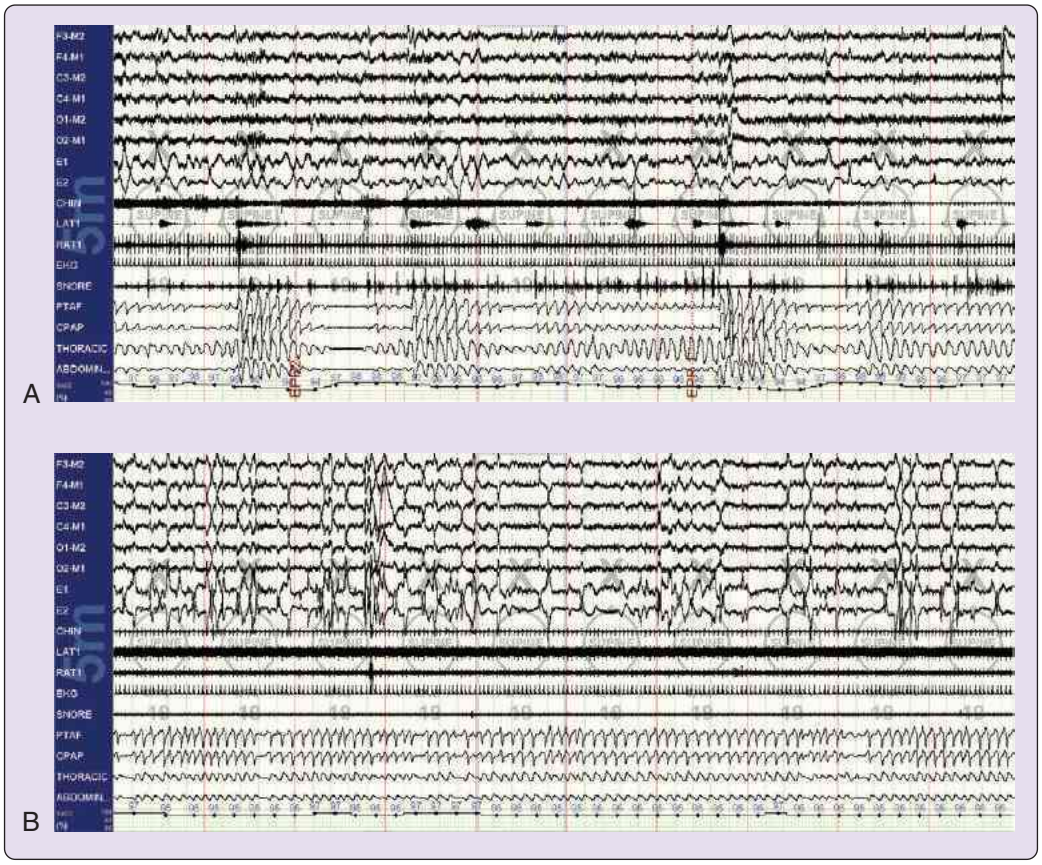

Figure 110-8 NREM-dominant sleep apnea. **A,** NREM-dominant sleep apnea, with continuous positive airway pressure (CPAP) during NREM sleep. Ten-minute screen compression; each vertical line is 30 seconds. Unresolved respiratory events occur across a range of CPAP pressures (5 to 19 cm) with long cycle events, some periodic breathing features, and clear obstructive features. **B,** NREM-dominant sleep apnea during REM sleep. Ten-minute screen compression; each vertical line is 30 seconds. The same subject as in **A** with spontaneous transition to REM sleep showing resolution of all abnormality. The CPAP pressures were progressively reduced to 10 cm with continued maintenance of stable breathing in REM sleep.

patients could fall. In these patients, short cycle (≤30 seconds) periodic breathing, with features of admixed obstruction, is highly reminiscent of high-altitude periodic breathing and was part of the original description.[80] It is possible that long cycles (≥60 seconds) may be caused by subclinical (or even subechocardiographic) cardiac diastolic dysfunction, but data are lacking on cardiac function differences between patients demonstrating purely long- versus short-cycle events.

A consistent feature of patients with treatment emergent or complex sleep apnea, documented in most publications

describing this phenomenon, is sleep fragmentation, which often persists despite reasonable respiration-targeted therapy. Because arousals amplify hypocapnic instability, inadequate cohesion of the NREM sleep–related network activity seems to be core pathology in some of these patients. This phenomenon is reminiscent of reports of CHF patients, in whom sleep fragmentation persists beyond that attributable to respiratory events.[85]

A pertinent question is whether the findings of the treatment emergent sleep apnea phenotype persist with continuous use of CPAP. Because central hypopneas or periodic breathing were not quantified in most studies, underestimation is probable and of uncertain degree. Lack of persistence may imply that it is simply a marker of the severity of OSA and dynamics of its improvement, or it may reflect an artifact of scoring approaches that ignore or misidentify central hypopneas. Some studies report resolution in 78% to 86% of patients[86,87] with 2 to 12 months of CPAP treatment, whereas others note treatment success rates of about 50%.[88] A prospective study by Cassel and colleagues,[89] who followed 675 patients with OSA with PSG at 0 and 3 months. At time zero, 12% had treatment emergent CSA, which resolved in 74% of the cases by 3 months; however, 7% of the original cohort without treatment emergent CSA were noted to have it on the 3-month study. One approach to quantifying the persistence of treatment emergent CSA is to measure residual respiratory events after several months of CPAP, using the flow data available in current generation devices. In a study (unpublished) of 217 patients after more than 6 months of therapy, the manually scored AHI_{FLOW} of 10/hour or greater was seen in 23%, and the central apnea index at the baseline sleep study was the only predictor of residual disease.

The predominant role of the CO_2 control instability in pathogenesis of treatment emergent or complex sleep apnea is supported by resolution with small increases of inhaled CO_2.[90,91] The mechanisms for improvement in chemoreflex events after prolonged use of CPAP include reduction in controller gain and increase in $Paco_2$ reserve.[92] Stabilizing central respiratory motor output through prevention of transient hypocapnia prevents most OSA in selected patients with a high chemosensitivity and a collapsible upper airway, whereas increasing respiratory motor output through moderate hypercapnia eliminates "obstructive" apnea in most patients with a wider range of chemosensitivity and CO_2 reserve.[93] Reducing chemosensitivity through hyperoxia has a limited and unpredictable effect on OSA.[93]

EPIDEMIOLOGY OF CENTRAL SLEEP APNEA AND ITS SUBTYPES

This topic is discussed in detail in Chapter 109. The epidemiology data for CSA are largely based on standard AASM definitions of respiratory events in sleep[94] and may underestimate the prevalence of CSA. This is largely due to the inability to effectively distinguish central from obstructive hypopneas without esophageal manometry, leading to classification bias toward obstructive sleep-disordered breathing (SDB; see Definitions section).

As alternate measures for detecting centrally mediated SDB are developed and automated, CSA prevalence may rise. For example, central apneas, periodic breathing, and CSB are patterns that suggest chemoreflex-mediated respiratory control dysfunction.[95] A biomarker of heightened chemoreflex activity (narrow-band elevated low-frequency coupling [$e\text{-}LFC_{NB}$]) has been described using an electrocardiogram-based analysis of heart rate variability and heart rate–respiratory coupling. This metric quantifies the metronomic self-similar oscillations that characterize nonhypercapnic CSA and periodic breathing.[96] One third of a large, community-based patient cohort with SDB (the Sleep Heart Health Study) exhibited the $e\text{-}LFC_{NB}$, which is associated with CSA and periodic breathing.[97] This proportion is roughly in keeping with detailed phenotyping experiments performed over the years.[81,98]

CLINICAL FEATURES AND DIAGNOSIS OF CENTRAL SLEEP APNEA AND ITS SUBTYPES

Clinical Presentation

The clinical presentation of patients with CSA varies by the etiology and subtype (Table 110-2). Symptoms and signs are not specific to CSA and often overlap with those of OSA as well as the underlying conditions leading to CSA (e.g., dyspnea on awakening in heart failure patients[99]). The following sections describe the PSG characteristics important in CSA, including the differences between nonhypercapnic and hypercapnic subtypes and finally the unique features of CSA associated with specific disorders.

Polysomnographic Features Important in Central Sleep Apnea

Diagnosis of CSA syndromes generally requires a full-night recording of standard PSG with special attention to inspiratory effort, to differentiate central (no inspiratory effort throughout event) versus obstructive apneas. Although this differentiation is simple for apneas, for hypopneas it requires esophageal manometry.[100,101] Respiratory inductance plethysmography excursions are present in both central and obstructive hypopneas, and determining whether decreases in effort and flow are proportionate can be arbitrary and difficult to operationalize.[102] Alternative strategies using PSG-based algorithms have been developed but show marginal accuracy compared with esophageal manometry (68% in one study).[17]

Table 110-2 Clinical Characteristics of Patients with Sleep Apnea

Central		Obstructive
Nonhypercapnic	Hypercapnic	
Insomnia	Daytime sleepiness Morning headache	Daytime sleepiness
Mild intermittent snoring	Snoring	Prominent snoring
Awakenings (choking, dyspnea)	Respiratory failure	Witnessed apneas, gasping
Normal body habitus	Normal or obese Polycythemia Cor pulmonale	Commonly obese Upper airway narrowing

Finally, cardiopulmonary coupling signal analysis as described previously may also be used to differentiate central predominant (chemoreflex-driven) versus obstructive SDB phenotypes[95] but has not been validated using esophageal manometry.

A consistent feature of nonhypercapnic, heightened chemoreflex-mediated central apnea is predominance of events during NREM sleep, especially during non–slow wave stages.[22,103-108] A metronomic self-similar appearance is typical, in contrast to opiate-induced CSA, in which variability of expiratory phase is characteristic. Additional features of chemoreflex modulation during sleep are noted in Table 110-3. In contrast, in many cases of hypercapnic CSA (and in OSA), the severity of SDB worsens markedly during REM sleep, especially if the motor neurons of the diaphragm are involved.[2,104] Notable exceptions are CCHS and opioid-induced CSA, in which SDB worsens in NREM sleep. Finally, objective measures of hypoventilation are needed, such as arterial, transcutaneous, or end-tidal P_{CO_2} (P_{ETCO_2}) to confirm hypercapnia in sleep.[15]

Propensity for sleep fragmentation and upper airway collapsibility can both worsen CSA and have specific treatment implications (see Treatment of Central Sleep Apnea). A sleep fragmentation phenotype on PSG can be suggested by prolonged sleep-wake transitional instability (>10 minutes), low sleep efficiency (<70%), persistently high N1 stage during PAP titration (>15%), and poor evolution of slow wave sleep (<1 Hz).[103] Upper airway collapsibility can be measured through the Pcrit, derived from relationships between maximal inspiratory airflow and nasal or mask pressure in OSA patients.[81,109]

Because of the challenges in diagnosing CSA without esophageal manometry, we recommend taking into account an array of the PSG features to distinguish between central and obstructive phenotypes as described previously (and in Table 110-3). Such an approach, combined with complementary measures of chemoreflex hyperactivity (e.g., cardiopulmonary coupling analysis) and identification of propensity for sleep fragmentation and airway collapsibility, can augment recognition of and treatment of CSA.

Unique Features of the Disorders

Nonhypercapnic Central Sleep Apnea

Central Sleep Apnea at High Altitude. Travelers to high altitudes often experience restlessness, frequent brief arousals, and unrefreshing sleep,[35] at least in part due to periodic breathing and CSA (see Chapter 122). Men are twice as likely to be affected as women, and at altitudes above 5000 feet it is nearly universal. PSG features are discussed in the section on Pathophysiology of Central Sleep Apnea Syndromes that Affect Diagnosis and Treatment.

Primary Central Sleep Apnea. Patients with primary CSA often present with insomnia or frequent awakenings during the night, rather than daytime sleepiness as seen in OSA.[110,111] Cycles of central apneas in idiopathic CSA are shorter (20 to 40 seconds) and not as gradual as in central sleep apnea with Cheyne-Stokes breathing (CSA-CSB) (see Pathophysiology of Central Sleep Apnea Syndromes that Affect Diagnosis and Treatment). Underlying medical conditions must be ruled out before diagnosis.

Heart Failure and Central Sleep Apnea. Clinical features, implications, and treatment of central apneas in CHF are discussed in detail in Chapters 109 and 129. In brief, age older than 60 years, male sex, and atrial fibrillation appear to be risk factors for CSA among those with CHF.[112] Patients generally present with CHF symptoms, fatigue, and weakness rather than sleepiness.[99,113-115] Symptoms and apneas improve with position changes, including lateral positioning, and are independent of the postural effects on the upper airway[116] suggesting that J-receptor activation or oxygen stores play a role in the pathogenesis of CSA-CSB. Arousals occur midcycle at the peak of the recovery.[117]

Other Medical Conditions Associated with Central Sleep Apnea. CSA is also found in patients with ESRD, CVA, PAH, and atrial fibrillation. There are no particular clinical features with high predictive value for CSA among these

Table 110-3 Recognition of Strong Chemoreflex Modulation of Sleep Breathing

Polysomnographic Feature	Relatively Pure Obstructive Sleep Apnea	Chemoreflex-Modulated Sleep Apnea
Periodic breathing, Cheyne-Stokes breathing	Rare	Typical (often short cycle, <30 sec in absence of CHF)
Respiratory event timing	Variable (each event tends to have different durations)	Self-similar, metronomic
Severity during sleep state	Greater severity in REM	Minimal severity in REM
Effort signal morphology	Well maintained during obstructed breath	Complete or partial loss between recovery breaths
Flow-effort relationship	Discordant: flow is reduced disproportionately to reduction in effort	Concordant: flow and effort follow each other in amplitude
Arousal timing	Early part of event termination	Crests event, often in the center of the sequence of recovery breaths
Oxygen desaturation	Irregular, progressive drops, V-shaped contour	Smooth, symmetrical, progressive drops rare

CHF, Congestive heart failure; REM, rapid eye movements.
From Thomas RJ. Alternative approaches to treatment of Central Sleep Apnea. *Sleep Med Clin* 2014;9(1):87–104.

patients (hypocapnia may be a clue), thus diagnosis requires heightened clinical suspicion and PSG.

Patients with ESRD and CSA (concomitant obstructive and mixed apneas are common) are generally male, older, and more frequently volume overloaded.[118,119] Ultrafiltration improves $Paco_2$ and CAHI,[43] suggesting initial avenue for management of CSA in ESRD. Higher suspicion for CSA is also warranted in those with larger territory and more severe CVAs.[46,120] Patterns of CSA include CSB with long cycle times in CVA patients with left ventricular dysfunction and periodic breathing with shorter cycle lengths in those without left ventricular dysfunction.[121-123] Central apneas improve with oxygen[121] and tend to resolve as patients recover from their stroke.[124,125] In patients with PAH, older age and sleepiness (Epworth Sleepiness Scale score of >10) are predictive of SDB,[126] and CSB is the predominant CSA pattern with cycle of about 45 seconds. Presence of atrial fibrillation should raise suspicion for CSA, and vice versa.[127-130] Among community-dwelling men, increasing central apnea index correlates with increasing prevalence of atrial fibrillation, and presence of CSA-CSB is associated with odds ratio of 4.5 for atrial fibrillation, even when controlled for cardiac comorbidities, including CHF.[128]

Hypercapnic Central Sleep Apnea

Hypercapnic CSA and hypoventilation should be considered if a condition associated with them (see Table 110-1) or certain clinical features (see Table 110-3) are present. A PSG and an assessment of sleep hypoventilation through nocturnal $Paco_2$ (or surrogate) are recommended. In cases in which hypercapnic CSA and hypoventilation are discovered during a PSG obtained for another indication (e.g., OSA), a careful clinical approach to identify the underlying cause is warranted. Our initial assessment is based on locating the lesion along an anatomic pathway that could result in hypoventilation: corticobulbar tracts, brainstem, bulbospinal tracts to cervical spinal cord, anterior horn cells, lower motor neurons, neuromuscular junction, and intercostal and diaphragmatic muscles. Lung and chest wall abnormalities are generally apparent on examination and basic diagnostic studies and can help identify the underlying medical disorder (e.g., chronic obstructive pulmonary disease) in those with hypercapnic CSA and hypoventilation. Selected conditions are discussed next.

Central Congenital Alveolar Hypoventilation Syndrome. The classic feature of presentation for CCHS is mild awake and marked sleep-related alveolar hypoventilation with hypercapnia and hypoxemia (Figure 110-9). Although classically diagnosed at birth, owing to variable penetrance of the *PHOX2B* mutations (polyalanine repeat mutations [PARMs]), some patients can present as late onset in childhood or even in adulthood.[131-135] In these individuals, alveolar hypoventilation can be unmasked by administration of CNS depressants and anesthetics, recent severe pulmonary infections, or in the setting of treatment for OSA, and CCHS should be considered in those without another explanation for hypoventilation. Clinical associations that should raise suspicion for CCHS include Hirschsprung disease, tumors of neural crest origin, autonomic dysfunction, facial dysmorphology, and dermatographism.[49,136,137] The ventilatory response and sensation of dyspnea are greatly diminished or absent in children with CCHS.[138] The respiratory pattern during sleep is characterized by markedly diminished tidal volumes and inappropriately constant respiratory rate in the face of hypercapnia and hypoxemia.[9,139] Ventilation is more stable during REM versus NREM sleep. There are variations in clinical phenotype with PARM genotype. For example, individuals with 20/25 (normal alanine repeat genotype being designated as 20/20) rarely require 24-hour ventilatory support, whereas for genotypes 20/27 to 20/33, continuous ventilatory support is needed.[140-142] Care for patients with CCHS should be provided through centers with extensive expertise in the condition.[12]

Obesity-Hypoventilation Syndrome. OHS should be suspected in an obese individual with daytime sleepiness.[143] Relative to the average OSA patient, those with OHS have a higher central fat distribution, are more likely to complain of dyspnea, and present with signs of cor pulmonale.[144-146] The diagnosis hinges on increased awake $Paco_2$ (>45 mm Hg) in the absence of other known causes of hypoventilation (e.g., chronic obstructive pulmonary disease, restrictive lung disease) and obesity (body mass index >30 kg/m^2). Serum bicarbonate and resting pulse oximetry can be used as simple screening tools for further testing. A bicarbonate level of 27 mEq/L or greater has 92% sensitivity for $Paco_2$ greater than 45 mm Hg (specificity of 50%[147]) among those with OSA. Rest O_2 saturation of less than 94% while breathing ambient air also suggests a need for blood gas measurement.[50,148] Up to 40% of patients with OHS continue to have persistent sleep-related O_2 desaturation despite elimination of upper airway obstruction, and hypoventilation can persist on autoadjusting PAP.[148] Hypercapnia may be more important than hypoxemia in mediating cognitive impairment individuals.[149,150] A recent study showed that although both CPAP and noninvasive ventilation improved $Paco_2$, sleep architecture, and SDB severity compared with lifestyle modification, with noninvasive ventilation, the decrease in $Paco_2$ was greater and was associated with improved 6-minute walk distance, spirometry, and some quality of life measures.[151]

Neurodegenerative Disorders. CSA and hypoventilation should be suspected in patients with neurodegenerative disorders. They are most common in multiple sclerosis (MS) and multiple system atrophy (MSA).[7] MS patients with brainstem involvement manifest with central apneas in contrast to those with nonbrainstem lesions and controls.[152] In MSA, central apneas, CSB, and apneustic breathing have all been reported.[153-155] CSA is uncommon in Alzheimer disease and Parkinson disease.[7,156-159] In amyotrophic lateral sclerosis, hypoventilation is the most common presenting feature of SDB, with nocturnal symptoms preceding daytime ventilatory failure.

Muscular and Peripheral Nervous System Disorders Associated with Central Sleep Apnea. In patients with muscular disorders, in addition to degeneration of the myocytes, impaired respiratory drive can contribute to hypoventilation. This abnormality was found in 20% of a myotonic dystrophy cohort.[160] In a recent study of 85 patients with myotonic dystrophy, 11% and 15% were found to have CSA and mixed sleep apneas, respectively, with 39% having OSA.[161] These patients were not sleepy but noted poor sleep quality as the most common symptom. The CAHI in this group correlated with slow oral swallowing time.[161,162]

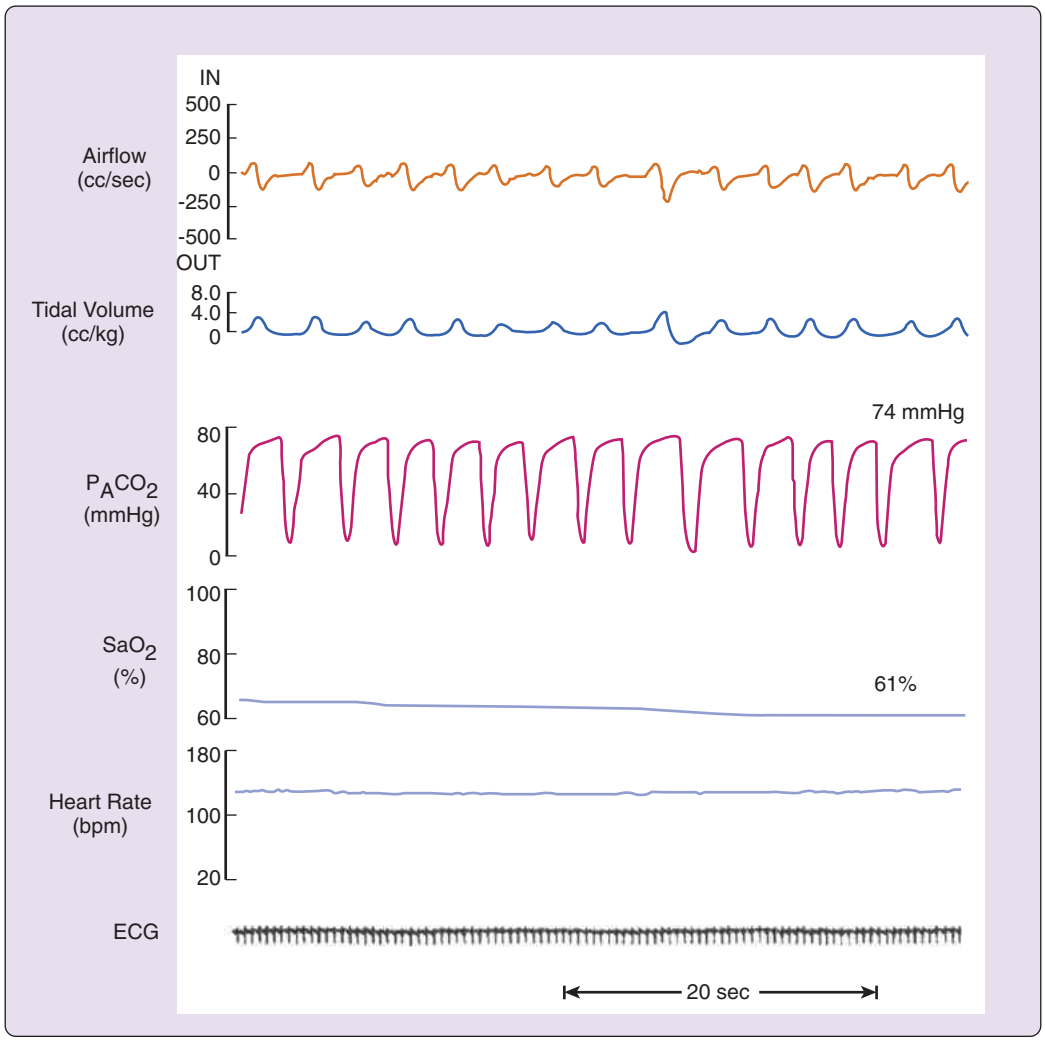

Figure 110-9 Central congenital hypoventilation. Polygraph tracing from 28-month-old girl, demonstrating typical breathing pattern during NREM sleep in congenital alveolar central hypoventilation syndrome. Note inappropriately regular (20 breaths/min), shallow breathing (tidal volumes averaging 3.5 mL/kg). Progressive hypercapnia and hypoxemia did not stimulate ventilation, arousal, or beat-to-beat heart rate variability. (Adapted with permission from Weese-Mayer et al.[9])

Disorders affecting the diaphragm or its nerve supply (Charcot-Marie-Tooth disease and other neuropathies, myasthenia gravis, and other neuromuscular junction disorders) present predominantly with sleep-related alveolar hypoventilation.

Opiate-Induced Central Apneas and Hypoventilation (Disintegrative Central Sleep Apnea). CSA should be considered in most patients on chronic opioid therapy (COT) with symptoms of disturbed sleep. Although most extensively studied among patients taking pure opioid receptor agonists (e.g., methadone, oxycodone), recent data reveal that combinations of partial agonists and antagonists (buprenorphine and naloxone)[163] also result in significant SDB, both central and obstructive. In those with CSA, case series suggest that there is increased sleep fragmentation, increased stage 2 sleep, and decreased REM and slow wave sleep,[164] consistent with NREM predominance of central events. On PSG, patients on COT can show predominantly OSA, CSA, or mixed phenotypes. CSA in COT can present during the initial polysomnogram or emerge after treatment of predominantly obstructive disease (treatment emergent CSA).[74] There is some consistency in published reports that decreased tolerance, efficacy (high residual sleep apnea), and compliance with CPAP are present in this setting of CSA (see Treatment of Central Sleep Apnea section later). Disintegrative CSA patterns may also be seen in patients with brainstem injury such as with stroke and MS. Finally, hypoventilation is not unique to use of opioids and can be seen with anesthetics, sedatives, and muscle relaxants.

Treatment-Emergent Central Sleep Apnea. Clinical features and diagnosis of treatment emergent CSA are discussed in detail under Pathophysiology of Central Sleep Apnea Syndromes that Affect Diagnosis and Treatment above. In brief, this entity is typically recognized by the appearance of central apneas, hypopneas, and periodic breathing when continuous or nonadaptive bilevel PAP is increased to control airway obstruction in patients diagnosed with OSA.[165] The most characteristic feature of such chemoreflex-driven respiration

is not the morphology of individual events but rather is the NREM sleep dominance and the timing and morphology of the sequential events (nearly identical) in a consecutive series of events.[14,95,103]

Various techniques may be used to identify patients with heightened chemoreflex and reduced CO_2 reserve. Times series analysis of electrocardiogram, described in earlier sections, can provide a map of state sleep oscillations with e-LFC_{NB} as a marker of central apneas and periodic breathing in those with treatment emergent CSA.[95] Loop gain, along with other phenotypic traits in OSA (genioglossus muscle responsiveness, arousal threshold, and Pcrit) can be assessed using dynamic flow and pressure responses to positive pressure dial-down.[81,98] In one study[81] of OSA patients, 19% had a relatively noncollapsible upper airway similar to controls, and in these patients, loop gain was almost twice as high as in patients with a collapsible airway, despite comparable AHIs, suggesting that treatment approaches other than upper airway stabilization maybe useful in these patients (see Treatment of Central Sleep Apnea). Other methods used to quantify loop gain and predict CPAP responsiveness among those with CSA-CSB are referenced for the interested reader.[30,166-168] If confirmed, respiratory chemoreflex phenotyping may become a common clinical reality.

TREATMENT OF CENTRAL SLEEP APNEA

Positive pressure, including "enhanced" positive pressure (see later) and non–positive pressure approaches, is available for the treatment of both hypocapnic and hypercapnic CSA syndromes, including idiopathic, treatment emergent or complex, periodic breathing, hypercapnic of various etiologies, and opiate-induced CSA. All these phenotypes, which may coexist and exhibit within-night and night-to-night dynamism, require an exact application of a multimode core therapeutic approach, including upper airway support, respiratory rhythm and drive modulation, and enhanced sleep consolidation as core approaches.[103]

Positive Pressure–Based Therapy

CPAP is a recommended initial option for CSA, based on the premise that upper airway obstruction is relevant for hypercapnic and nonhypercapnic types of CSA, a position endorsed by AASM guidelines.[169] However, there are now enough data to demonstrate that CPAP alone is poorly effective and tolerated in nonhypercapnic CSA syndromes, whereas adaptive servo ventilation (ASV) and enhanced CPAP (used with respiratory stabilization approaches that include hypocapnia minimization, sedatives, carbonic anhydrase inhibition, and oxygen) are superior treatment approaches for efficacious suppression of central apneas and periodic breathing patterns on the polysomnogram. Nonadaptive (fixed pressure) bilevel positive pressure ventilation alone is also suboptimal: this tends to exaggerate CSA and periodic breathing. Although using a backup rate with fixed bilevel positive pressure ventilation can reduce central apneas as the machine-delivered mandatory breaths substitute for lack of patient-derived respiratory effort, comparative studies with ASV show the latter to achieve superior elimination of central apneas. Nonrandomized evaluations show these devices to be about as effective as each other.[170] Because individual adaptive ventilator algorithms are substantially different, specific patient subsets may have differential responses (e.g., short vs. long cycle periodic breathing). Such individual differences in responses are currently not predictable through PSG features.

ASV devices provide expiratory support, inspiratory pressure support, and backup supportive responses guided by measures of ventilation or flow averaged over several minutes. These devices are primarily designed for patients with elevated loop gain and thus nonhypercapnic CSA but can be beneficial when hypoventilation is not the primary and sole abnormality, such as opiate-induced CSA. When used for CSA in patients with treatment emergent CSA and heart failure, central apneas are decreased in frequency, and numerous neurohumoral and cardiac function parameters are improved in heart failure patients.[171,172] Muscle sympathetic activity is reduced by adaptive ventilation but not CPAP in patients with CHF and CSA-CSB.[173] Treatment with ASV is better tolerated than CPAP and is effective in suppressing central apneas and improving oxygenation regardless of the presence of heart failure. Positive effects on sleep architecture are less impressive. The criteria for success and the respiratory event scoring criteria (often 4% desaturation association for hypopneas) can overestimate effectiveness. A randomized prospective trial of CPAP versus ASV used a success threshold of suppressing central AHI (essentially central apneas) below 10/hour of sleep as a criterion for success.[174] ASV was superior to CPAP in suppressing respiratory events, but sleep quality, sleepiness, and quality of life were not different between groups, raising the question of the best approach to quantify effectiveness beyond merely apnea suppression. Alternative indexes such as time in periodic breathing or stable breathing may provide useful efficacy information. However, in the intention-to-treat analysis, success (AHI <10/hour) at 90 days of therapy was achieved in 89.7% versus 64.5% of participants treated with ASV and CPAP.[174] The results also show how difficult it is to bring sleep and breathing back close to normal in these patients, even with optimal treatment of the CSA. Residual sleepiness in patients with CSA can be improved over auto-CPAP.[175] Similarly, opiate-induced CSA is difficult to treat with PAP, but ASV is superior to CPAP.[176] These patients do not have classic periodic breathing or metronomic central apneas and are characterized by ataxic breathing and central apneas of variable lengths. ASV devices can impose a rhythm in these conditions but can also induce patient-ventilator asynchrony and therefore need to be carefully titrated.

General Principles Regarding the Use of Adaptive Servo Ventilation Devices

All ASVs provide fixed or automatic expiratory airway support, adjustable minimal and maximal pressure support, and different options for backup rates (user specified, device algorithm estimated, or none). Volume and flow targets are used, and the sampling-averaging window extends over 3 to 4 minutes. Thus ASV devices track long-range respiratory patterns and make adjustments in the parameters to maintain the target within a prespecified range. Detection of apneic obstructive events results in expiratory pressure increases, whereas the difference between minimal and maximal allowable pressure support is the "adaptive space." The devices may be used with tight or relatively wide open user constraints depending on the preference of the physician and pressure tolerance of the patient. Cycle lengths likely influence

outcomes, and it is our observation that ASVs are less effective in patients with short cycle (≤30 seconds) periodic breathing. A subset of patients demonstrate immediate ASV intolerance and desynchrony, and this effect does not resolve with added time. Patients with prolonged sleep-wake transitional instability can have the pathology markedly amplified by an ASV. The normal fluctuations of respiration during REM sleep can inappropriately trigger the adaptive algorithms of ASVs and cause arousals, but this seems rare in clinical practice.

Recognition of Efficacy and Scoring of Respiratory Events During Adaptive Servo Ventilation Use

Scoring respiratory events during adaptive ventilation should use the pressure output signal from the ventilator. This is roughly equal and opposite to the patient's respiratory output. The flow and effort signals combine patient and ventilator contributions and give a false sense of success. See Figure 110-10 for excessive "pressure cycling," which is a response of an adaptive ventilator to ongoing periodic breathing. When pressure cycling persists, sleep fragmentation can be severe even if respiration is "improved." This pattern means than periodic breathing pathology is ongoing, necessitating the continued pressure response. When the ventilator enables stable respiration, cycling between the minimal and maximal pressure support zones is minimal. Further details on algorithms and titration strategies may be obtained from recent comprehensive reviews.[177,178] Bench testing of ASV algorithms show device-specific response characteristics, but stable breathing does not readily occur across a range of simulated central apnea patterns.[179]

ASVs are powerful devices, and if there is patient-ventilatory asynchrony, they can induce hypocapnia, excessive cycling of pressures, arousals, distorted flow patterns, and physical discomfort. Increased mortality through sudden cardiac death, and no benefits including quality of life, were reported in the Treatment of Predominant Central Sleep Apnoea by Adaptive Servo Ventilation in Patients with Heart Failure (SERVE-HF) study,[179a] which showed increased mortality with an ASV in patients with systolic heart failure (ejection fraction ≤45%) and AHI greater than 15/hour with 50% or more central events and a central AHI of 10/hour or greater. Hypocapnia, metabolic alkalosis, hemodynamic perturbations, and excessive sympathetic driving associated with excessive pressure cycling are speculative mechanisms of adverse outcomes.[180] The general consensus is that ASVs should be avoided in heart failure with reduced ejection fraction and CSA. Caution is recommended in the use of these devices in other vulnerable populations, such as patients with stroke or heart failure without reduced ejection fraction. Tracking of device data such as tidal volume stability, degree of pressure cycling, and surrogate signs of patient-ventilator asynchrony (e.g., wide variations in expiratory durations), regardless of underlying disease state, and not relying on manufacturer derived AHIs alone are prudent.

Considerations for the Treatment of Hypercapnic Central Sleep Apnea

Management of the sleep related breathing disorders of the hypoventilation syndromes is a complex process; a few key points are noted here.[181] Respiratory support may be provided by bilevel ventilation with a backup rate, volume target pressure-support ventilation, or invasive volume ventilation through a tracheostomy. These modes are also readily available on several home ventilators.

Volume-assured pressure support (VAPS) is an advance in management of hypoventilation syndromes and hypercapnic CSA. Besides expiratory, minimal, and maximal inspiratory support, backup rates, and various breath modulations such as inspiratory time and trigger and cycle sensitivity, a tidal volume target may be set. VAPS is most effective if there is hypoventilation without CSA, but it can provide benefits if used cautiously in hypercapnic CSA.

Sufficient expiratory pressure support to prevent major obstructive events is critical. REM sleep can demonstrate greater severity than NREM sleep and typically requires greater ventilation than NREM sleep. However, NREM dominance may also be seen, as in opiate-induced CSA. An autoexpiratory pressure function can aid in managing patients with markedly higher REM sleep settings. The backup rate is usually set slightly below the patient's native rate. However, if

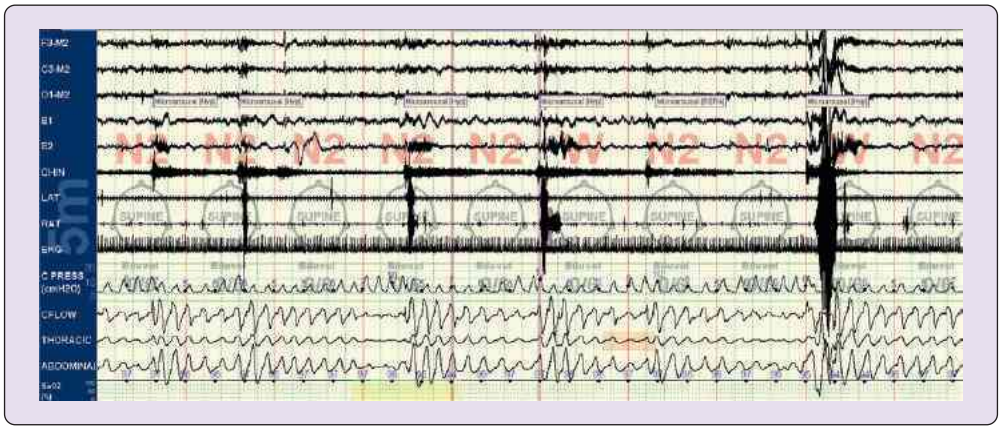

Figure 110-10 Pressure cycling during adaptive ventilation treatment. Five-minute compression snapshot; each vertical line is 30 seconds. The C-PRESS channel is the pressure output from the adaptive ventilator (Adapt SV). This 56-year-old man had predominantly central apneas, which were eliminated. However, respiratory instability, repetitive arousals, and pressure cycling continued without resolution, despite adjustments of pressure support. Persistent pressure cycling is readily recognized during home use by generating expanded night data using the device software, with attention to tidal volume and pressure traces. The device may not automatically detect respiratory events during such periods.

there is bradypnea (e.g., respiratory rate below 6 breaths/minute) or tachypnea (e.g., rate above 20 breaths/minute), entraining the patient to a different rate may be difficult and result in patient-ventilator desynchrony. Substantial inspiratory support (e.g., 25 cm H_2O) may be required to enable optimal ventilation.

Positive pressure ventilation therapy for hypercapnic CSA poses the specific challenge of inducing relative hypocapnia and respiratory instability and associated sleep fragmentation by overly aggressive ventilation.[182] There is a tradeoff between improving ventilation and oxygenation versus sleep quality because excessive volume targets and the associated pressure rises can induce sleep fragmentation. The rate of change in pressure support can be prescribed in these devices, providing one form of "brake" to prevent pressure-related sleep fragmentation. In the absence of PSG titration, when sleep versus wake and NREM versus REM sleep treatment requirements are not estimated, treatment may be less precise than possible. An iterative approach of two or three PSG titrations separated by a few months can result in greater precision of therapy and sleep quality, allowing resetting of the respiratory controller. Although empirical home ventilation can be obtained under specific diagnostic conditions (such as amyotrophic lateral sclerosis) and severities based on pulmonary function tests, PSG titration with transcutaneous CO_2 monitoring can improve precision of care.

Alternative Approaches to Positive Pressure Therapy

Minimization of Hypocapnia

That CO_2 can stabilize respiration has been known for decades, and prevention of hypocapnia is a critical stabilizing factor in sleep respiratory control. However, high concentrations of CO_2 fragment sleep by inducing arousals secondary to respiratory stimulation and sympathoexcitation.[183,184] The challenge has been delivery of CO_2 in a clinically adequate, tolerated, and precise manner. Holding the CO_2 steady and just above the NREM sleep CO_2 threshold can protect the CO_2 reserve while maintaining sleep consolidation.

In a study manipulating inhaled CO_2 in OSA patients but directly relevant to CSA treatment,[93] 26 patients with OSA (AHI 42 ± 5 events/hour with 92% of apneas obstructive) were treated with O_2 supplementation, an isocapnic rebreathing system in which CO_2 was added only during hyperpnea to prevent transient hypocapnia, and a continuous rebreathing system. With isocapnic rebreathing, 14 of 26 reduced their AHI to 31% ± 6% of control ($P < .01$) (responders); 12 of 26 did not show significant change (nonresponders). The responders versus nonresponders had a greater controller gain, a smaller CO_2 reserve, but no differences in Pcrit. Hypercapnic rebreathing (+4.2 ± 1 mm Hg P_{ETCO_2}) reduced AHI to 15 ± 4 of control ($P < .001$) in 17 of 21 subjects with a wide range of CO_2 reserve. Hyperoxia (SaO_2 ~95% to 98%) reduced AHI to 36% ± 11% of control in 7 of 19 OSA patients tested. Addition of a closed volume (dead space) to exhale increases rebreathing of exhaled air and results in a rapid increase in CO_2 levels and an increased tidal volume and respiratory rate. The concept has been used in mechanical ventilation to reduce hypocapnia for several years and more recently has been successfully used to treat CSA-CSB in heart failure.[184] Combining hypocapnia minimization with positive pressure is logical, and we have shown that keeping CO_2 above the apnea threshold with the use of enhanced expiratory rebreathing space (EERS) is an effective adjunct to PAP therapy[90]; EERS is the dead space concept applied to pressure ventilation and may be used with continuous or adaptive pressure support (Figure 110-11). There is no or a minimal increase in inspiratory CO_2 because of the positive pressure–induced washout. The physiologic target for titrations with EERS is to maintain end-tidal CO_2 ($ETCO_2$) at the low-normal range for sleep, that is, an increase of 2 to 8 mm Hg in $ETCO_2$. CO_2 manipulation can also be done by bleeding CO_2 into the circuit by a more precisely controlled flow-independent method. Successful treatment of mixed OSA and CSA using a proprietary device, the positive airway pressure gas modulator (PAPGAM), has been reported. This device delivers precisely controlled concentrations of CO_2. In a small case series, 6 patients with an average mixed apnea AHI of 43/hour on CPAP improved, with reduction of AHI to 4.5/hour and addition of 0.5% to 1% using PAPGAM.[91] Dynamic CO_2 manipulation (delivery restricted to a specific phase of the respiratory cycle) may, in future studies, improve the stabilizing effects of CO_2.[185]

Oxygen

Nasal O_2 has a long history of use to treat CSA and periodic breathing without CSA.[186,187] Effectiveness is typically partial, and residual sleep apnea and sleep fragmentation are common. High loop gain that is not primarily driven by hypoxia may not respond to O_2 at clinically safe doses, an escape from suppression of carotid body firing. Adding oxygen to CPAP may benefit CSA and treatment emergent CSA with a reduction in responsiveness of peripheral chemoreceptors and loop gain.[188,189] A study in a U.S. veterans population showed benefit in a predominantly CSA population, but the PSG changes were delayed by as much as an hour or more.[190] Respiratory event cycles can lengthen with the use of O_2. Such a change may "reduce" the respiratory event index but not imply a true stabilization of respiration. Use of O_2 also negates use of a desaturation parameter to score hypopneas. Beneficial effects of oxygen for CSA are not limited to those with oxygen saturations below thresholds used for long-term nasal oxygen therapy (e.g., ≤88%). Use of O_2 is off-label for CSA syndromes. The limitations include the long-term cost and difficulty with reimbursement in nonhypoxic patients.

Enhancing Sleep Consolidation

Arousals from sleep have a role in sleep apnea pathophysiology.[28] Sedatives can probably be used safely in minimally nonhypercapnic hypoxic CSA and NREM-dominant apnea in general because arousals further destabilize sleep and worsen sleep apnea severity For example, eszopiclone has been shown to reduce the AHI in patients with obstructive apnea with a low arousal threshold.[191] Likely mechanisms of benefit of sedatives in nonhypercapnic CSA include reduction of arousal-induced hypocapnia and increasing the proportion of NREM sleep spent in stable breathing. Triazolam, temazepam, zolpidem, and clonazepam have all been shown to reduce periodic breathing and CSA.[192-195]

Opioid-Induced Central Sleep Apnea

CSA is commonly associated with chronic opiate use and is dose related with substantial individual differences. PSG features of opiate effects may be more common than clinical symptoms, and the impact, on health, of CSA exclusively due to opiate use remains to be defined. Decreasing the dose of

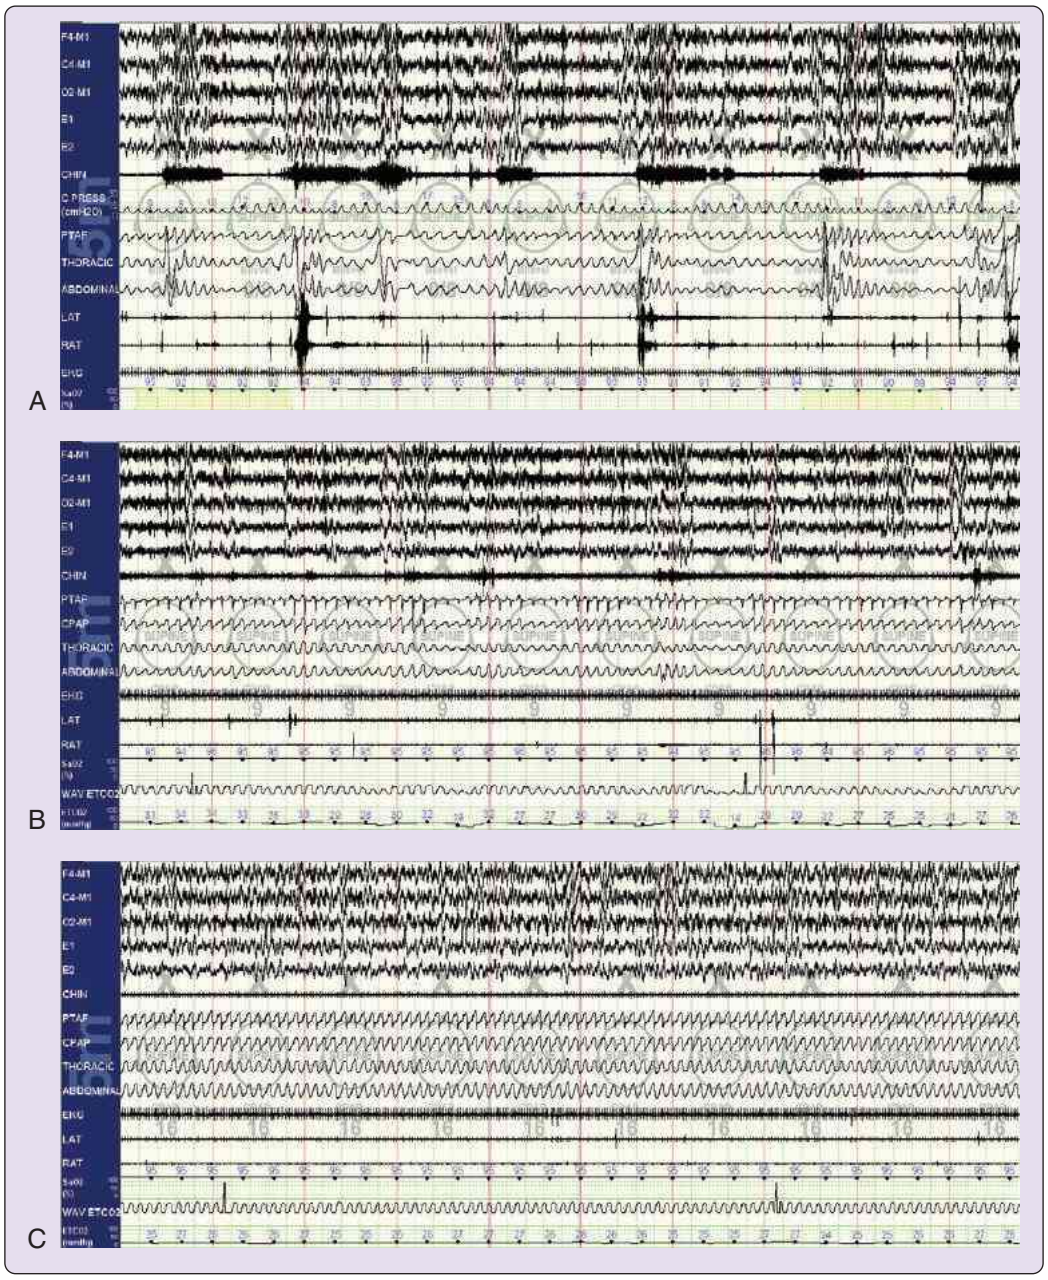

Figure 110-11 **Efficacy of CO_2 manipulation for stabilizing respiration.** A 72-year-old man with congestive heart failure (same patient as in Figure 110-3). *Top,* Adaptive servoventilation failure; note excessive cycling of pressure (the CPRESS channel) and the associated arousals. *Middle,* After addition of 50 mL enhanced expiratory rebreathing space (EERS), note stabilization of respiratory rhythm but residual flow limitation and mild residual periodic breathing. *Bottom,* With 100 mL EERS; note normalization of sleep and respiration. The end-tidal CO_2 ($ETCO_2$) signal plateau is slightly blunted and thus the CO_2 measured is falsely low. However, the resting wake $ETCO_2$ of this patient was 30 mm Hg, a level that can be readily seen in patients with congestive heart failure.

opiates may help reduce the frequency of central apneas[4] and should be routinely considered within the constraints of the disorder for which it was prescribed. In many patients, however, stopping opiates entirely may not be possible. CPAP alone will rarely be effective therapy. Opiate-induced ataxic breathing is quite sensitive to CO_2 levels—with ready induction of central apnea and worsening of dysrhythmic breathing on continuous or nonadaptive bilevel positive pressure ventilation. Although these patients tend to show mild hypercapnia, with $ETCO_2$ in the high 40- to low 50-mm Hg range, using a nonvented mask and EERS as needed to hold CO_2 in the mid 40-mm Hg range (thus preventing destabilizing degrees of hypocapnia despite supporting the upper airway) can be helpful regardless of the positive pressure mode used. We have found the use of acetazolamide to be of consistent benefit. Adaptive ventilation is a double-edged sword in these patients, being able to both enable stable breathing and markedly destabilize breathing.[176,196,197]

Carbonic Anhydrase Inhibition

Acetazolamide, a diuretic and carbonic anhydrase inhibitor, diminishes the ventilatory response of the peripheral chemoreceptors to hypoxia, decreases loop gain, and reduces the ventilatory response to arousals.[198-201] In animal models, it has been shown to lower the P_{ETCO_2} apnea threshold and widen the difference between the eupneic and P_{ETCO_2} thresholds.[21] Acetazolamide has been used in treating nonhypercapnic CSA or CSB, in patients with and without heart failure.[202] Although such results may be statistically significant, the degree of residual sleep apnea is unacceptable as sole long-term therapy. The drug may convert those with mixed OSA and CSA to mostly obstructive (the reverse of CPAP-induced CSA). Those with short cycle (≤30 seconds) periodic breathing not responding to EERS or adaptive ventilation are the best candidates. Acetazolamide has been successfully used as CPAP adjuncts at high altitude.[203,204] Zonisamide[205] and topiramate[206] have carbonic anhydrase inhibitory effects and could in theory be used in the place of acetazolamide. Acetazolamide can aid the treatment of hypercapnic CSA by reducing the propensity for worsening of respiratory instability, which pressure support ventilation can induce. The drug may have a special role in those with coexisting CSA in NREM sleep (requiring low levels of PAP) and OSA in REM sleep (requiring higher pressures that could exacerbate CSA in NREM sleep).

Other Drugs with Possible Benefits in Nonhypercapnic Central Sleep Apnea

Clonidine[207] and the 5-α reductase inhibitor finasteride[208] have been shown to improve breathing stability. Inhibition of H_2S (gaseous signal transmitted in carotid body) in a rodent model of CHF nearly normalized chemosensitivity and breathing instability, and may serve as a new therapeutic target.[209] A case report of unilateral carotid body denervation in a man with systolic heart failure and moderate CSA showed that chemosensitivity and sleep apnea severity were reduced and shifted to an obstructive phenotype 2 months after treatment, accompanied by an improvement in quality of life.[210] A recently completed trial of carotid body denervation in systolic heart failure patients may provide key risk-benefit information (ClinicalTrials.gov Identifier: NCT01653821) on pharmacologic targeting of carotid body function.

Other Treatment Options

Phrenic nerve stimulation[211,212] is an investigational approach that can improve the CAHI in heart failure patients with CSA-CSB. Sleep quality may not improve proportionately, and there is a concern that suppression of central apneas without enabling stable breathing or targeting the core pathophysiology of high loop gain may not provide long-term benefits, similar to the SERVE-HF study. A subset of CSA and treatment emergent CSA patients appear very supine position dependent, and avoidance of the supine position can markedly improve treatment efficacy.[116,213] An additional effect of body position, this time from vertical to horizontal, is on fluid redistribution from the caudal to cranial parts of the body.[214-218] The effect is rapid and is associated with increased neck circumference and hypocapnia from increased lung water in patients with central apnea. Therapeutic manipulation could include careful diuresis, a wedge pillow, or sleeping in a recliner.

CLINICAL PEARLS

- Sleep apnea caused by a pathologically activated respiratory chemoreflex results in a wide PSG spectrum of disease, with variable features of upper airway obstruction mixed with more traditionally accepted central patterns.
- Pathophysiology guides treatment. Treatment end points should aim to normalize sleep and sleep-breathing biology, not merely suppression of scored events to an arbitrary threshold.
- It is useful to consider CSA as taking hypercapnic and nonhypercapnic forms. Accurate phenotyping of sleep apnea is increasingly important because several on-label and off-label therapies, singly or in combination, have improved therapeutic options for CSA syndromes.
- Recognizing NREM sleep dominance of disease in nonhypercapnic CSA and minimizing the importance of concomitant upper airway flow limitation when identifying otherwise typical periodic breathing are applicable in clinical and research assessments. Hypercapnic CSA may be REM dominant, with the exception of opiate-induced CSA, and require ventilatory support for management. Unlike OSA, CSA is relatively difficult to treat and increases the risk for poor compliance, residual symptoms, ongoing sleep fragmentation, and high residual respiratory events despite therapy.

SUMMARY

CSA caused by pathologic activation of the respiratory chemoreflex includes idiopathic CSA, periodic breathing, high-altitude sleep apnea, and treatment emergent or complex sleep apnea. A narrow NREM sleep CO_2 reserve and propensity for arousal and sleep fragmentation are key pathophysiologic drivers. A unifying theme for nonhypercapnic CSA is predominance in NREM sleep and a metronomic appearance; cycle times, the duration of the respiratory event from peak to peak or trough to trough, can be short (≤30 seconds). Sleep fragmentation is often severe, but hypoxia is relatively moderate in nonhypercapnic CSA. The prevalence and evolution of residual CSA phenotypes with treatment remains to be accurately estimated owing to limitations of current approaches to PSG scoring; new methods need to be validated to outcomes. Non-invasive adaptive ventilation provides pressure support approximately equal and opposite to patient-generated ventilation, with substantial differences in individual device algorithms. Off-label approaches may be considered as adjuncts to improve therapeutic efficacy, including minimization of hypocapnia with dead space adapted to PAP, acetazolamide, and sedatives to reduce the arousal threshold.

Hypercapnic CSA is associated with pathologically reduced activation of the respiratory chemoreflex and may be seen in association with hypoventilation syndromes and neurologic disorders. Disease severity can be maximal in REM sleep, although successful ventilation (and reduction in hypercapnia) may result in respiratory instability in NREM sleep owing to relative hypocapnia. Non-invasive bilevel ventilation with a backup rate and volume-assured ventilation are primary therapeutic options; acetazolamide may improve respiratory drive and reduce NREM-related instability.

Anatomy and Physiology of Upper Airway Obstruction

James A. Rowley; M. Safwan Badr

Chapter Highlights

- Upper airway patency is determined by craniofacial structure, surrounding tissues, intrinsic properties of the upper airway, and the neuromuscular function of the upper airway.
- With sleep, the loss of the wakefulness drive to breathe is associated with decreased neuromuscular activity of the upper airway, and in particular decreased afferent reflexes, and is further modified by such factors as lung volume, hypercapnia, and age. Upper airway caliber decreases, with a resultant increase in upper airway resistance and compliance and upper airway collapsibility.
- In patients with obstructive sleep apnea (OSA), there is evidence of histologic changes to upper airway tissues, which may explain abnormalities in sensorimotor and reflex activity in the upper airway in patients with OSA.
- This chapter describes and discusses the factors that influence the determinants of upper airway obstruction in humans. However, further research is needed to understand how these determinants interact to maintain upper airway patency.

Although investigations into the pathogenesis of obstructive sleep apnea (OSA) have been underway since the disorder was first described, the mechanisms underlying an increased propensity to sleep-related upper airway obstruction in some individuals are not well understood. This chapter reviews the anatomy and physiology of the upper airway as they relate to upper airway patency and propensity to obstruct during sleep. The occurrence of collapse during sleep and not wakefulness implicates the removal of the wakefulness drive to breathe as a key factor underlying sleep-related upper airway obstruction. The determinants of upper airway patency—upper airway neuromuscular activity and nonneuromuscular factors including craniofacial structure, surrounding tissues, and intrinsic properties of the upper airway itself—are discussed.

This chapter additionally reviews the effect of sleep on upper airway properties such as patency, resistance, compliance, and collapsibility. Within each area, the factors that influence these properties, including host factors (e.g., gender and body mass index [BMI]), disease (e.g., tonsillar hypertrophy, fluid overload), and OSA, are examined.

BASELINE DETERMINANTS OF UPPER AIRWAY PATENCY

Upper Airway Function and Structure

The human upper airway is unique in that it serves as a multipurpose passage. It both transmits air to the lungs (through the nose and mouth) and liquids and solids to the esophagus (through the mouth). The upper airway, particularly the nose, also serves as a heat exchanger. In humans, the upper airway, particularly the larynx and lips, is important for vocalization. However, because it serves multiple purposes, portions of the upper airway lack rigid support, and hence are prone to collapse.

The upper airway is classically divided into five regions based on anatomic structures (see Figure 111-1, *A*). Each of these regions is either rigid and resistant to collapse or semirigid and susceptible to collapse. Whether rigid or semirigid, however, each region can become occluded because of other anatomic variants or abnormalities. Although the nose is a rigid section of the upper airway because of its bony components, it can become obstructed owing to nasal congestion and polyps, altering upper airway mechanics. The nasopharynx is defined as the area from the posterior aspect of the nasal turbinates to the horizontal plane of the soft palate. Thus the proximal portion of the nasopharynx tends to be rigid, but the distal region is semirigid. Nasopharyngeal patency can be compromised by local mass lesions and palatal and uvular hypertrophy or edema. The oropharynx is defined as the area from the soft palate to the base of the tongue and is semirigid. It can be further divided into an area posterior to the soft palate (retropalatal) and tongue (retroglossal). Oropharyngeal patency is generally compromised from tonsil hypertrophy, palatal or uvular enlargement, or macroglossia. Because the nasopharynx and oropharynx are semirigid, these two areas are the site of collapse in most patients with OSA. The hypopharynx extends from the base of the tongue to the larynx and is relatively rigid and resistant to collapse. Finally, the larynx, the most distal portion of the upper airway, is rigid, composed of both cartilage and muscle.

Upper airway caliber can be measured by a variety of methods, including computed tomography (CT) scanning, magnetic resonance imaging (MRI), nasopharyngoscopy, and acoustic imaging. These methods allow researchers to measure

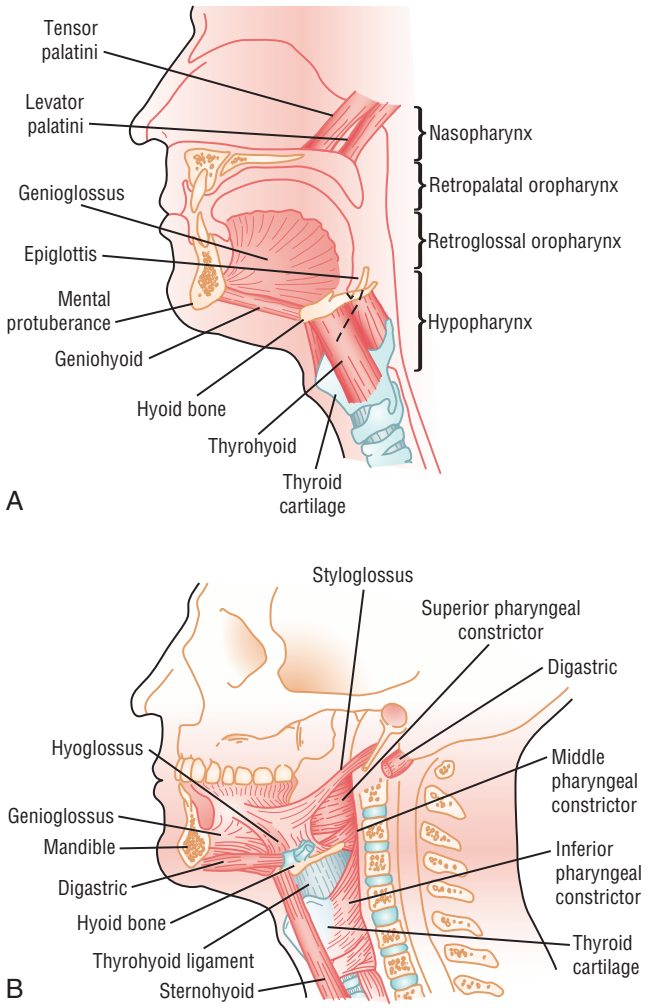

Figure 111-1 A, Schematic diagram of upper airway anatomy showing the classic divisions of the pharynx and key upper airway muscles. **B,** Schematic diagram of upper airway muscles and other key landmarks such as the hyoid.

upper airway caliber either at one point in the respiratory cycle (a static measurement) or dynamically throughout the respiratory cycle.

Neuromuscular Function of the Upper Airway

The upper airway musculature consists of 24 pairs of striated skeletal muscles extending from the nares to the larynx (see Figure 111-1, *B* for major anatomic landmarks and muscles).[1,2] These pharyngeal muscles have complex anatomic relationships but can generally be classified into groups that regulate the position of the soft palate, tongue, hyoid bone, and pharyngeal walls. The muscles are generally activated in groups to control the major functions of the upper airway such as phonation and swallowing.

There are two general patterns of electrical discharge from upper airway muscles when these are studied with multiunit electromyograms (EMGs): tonic (constant) activity, independent of phase of respiration; and phasic activity, occurring during one part of the respiratory cycle. There are at least 10 upper airway muscles that may be classified as pharyngeal "dilators," innervated by multiple cranial nerves. Some, such as the genioglossus, are classified as dilators by virtue of their phasic inspiratory activity. Others, such as the tensor palatini, do not clearly have a dilating effect but demonstrate activity throughout the respiratory cycle (tonic activity) and are presumed to "stiffen" the upper airway wall and decrease pharyngeal collapsibility. It is widely accepted that upper airway dilators play a critical role in preserving pharyngeal patency.[3] There is evidence from EMG studies that activity of upper airway dilators begins about 200 milliseconds before onset of thoracic pump activity in normal subjects.[4,5]

Upper airway narrowing or obstruction during sleep is associated with a sleep-related decrease in upper airway muscle activity. The effect of non–rapid eye movement (NREM) sleep on upper airway muscle function is complex and difficult to study because of the challenges in isolating the many other influences on upper airway muscle activity, such as changes in air flow, magnitude of negative pressure in the pharyngeal airway, and lung volume. Available evidence indicates that NREM sleep is associated with a reduction in tonic or phasic EMG activity in numerous upper airway muscles,[2] including the levator palatini,[6] tensor palatini,[7] palatoglossus,[6] and geniohyoid.[8] Studies measuring single motor unit activity of the genioglossus muscle also noted decreased activity of the phasic inspiratory motor units at sleep onset[9] and NREM stage 2 sleep with increased discharge frequencies and duration in NREM stage 3 sleep.[10] The EMG changes are accompanied by upper airway narrowing and increased upper airway resistance.

The effect of rapid eye movement (REM) sleep on upper airway muscle activity is more clearly documented. Activity of antigravity muscles is reduced during REM sleep, and there is strong evidence that activity of phasic upper airway dilating muscles, such as the genioglossus, is greatly attenuated during REM sleep,[11,12] particularly during periods of phasic rapid eye movements.[13,14] Reduced activity has also been shown for the alae nasi[13] and geniohyoid muscles.[8] Similar findings have been reported for single motor unit activity of the genioglossus.[15] In summary, the sleep state is associated with decreased upper airway muscle activity.

The response of upper airway muscles to chemical and mechanical perturbations during sleep may be relevant physiologically and clinically to such reduced activity. Negative pressure applied to the upper airway results in a brisk reflex response in upper airway muscle activity. This reflex is attenuated with application of topical lidocaine, indicating mediation through local mechanoreceptors.[16] Studies of reflex activity in the genioglossus, palatoglossus, and tensor palatini muscles show that this negative pressure reflex response is attenuated during NREM[17-19] and REM sleep[20] compared with wakefulness. Similarly, responsiveness of the genioglossus muscle to hypercapnia is attenuated during sleep.[21] This reflex response has also been shown to be attenuated with aging during both wakefulness and sleep.[22] These data suggest that upper airway dilator muscles are less able to maintain upper airway patency in the face of chemical or mechanical perturbations. Furthermore, there is evidence that lung volumes alter genioglossus muscle activity during NREM sleep, with decreases in end-expiratory lung volume being associated with increased genioglossus activity above baseline.[23]

The large number of upper airway muscles and their complex interactions mandate caution in extrapolating findings from studies focusing on the genioglossus or hypoglossal nerve activity alone, particularly because measurement of electrical activity of the muscle is not necessarily an appropriate

surrogate for muscle fiber shortening or indeed for upper airway dilation. In fact, there is evidence that upper airway muscle activation is not necessarily sufficient to dilate the upper airway under either physiologic or loading conditions, including resistive loading due to airway resistance[24] or elastic loading due to either increased soft or fat tissue[25-27] or small mandibular enclosure.[28] Nor may such activation be necessary; for example, in sleeping humans, increased end-expiratory lung volume has been found to result in decreased upper airway resistance and increased retropalatal cross-sectional area in association with *reduced* EMG activity of the genioglossus.[29] In patients with OSA, increased lung volume causes a substantial decrease in sleep-disordered breathing during NREM sleep,[30] and an inverse correlation between continuous positive airway pressure (CPAP) requirements and lung volume in patients with OSA has been found.[31]

It is also unclear whether complete atonia of the pharyngeal muscles increases upper airway collapsibility. For example, the pharyngeal airway becomes more collapsible in dead infants,[32,33] but not in paralyzed animal preparations.[34,35] In addition, REM sleep, associated with decreased neuromuscular stimulation, is not associated with changes in upper airway compliance or collapsibility in human studies of upper airway physiology.[36,37] Likewise, increased pharyngeal compliance in patients with sleep apnea cannot be attributed to decreased upper airway dilating muscle activity per se because patients with OSA show increased activity of the genioglossus muscle during wakefulness[38] and sleep,[39] perhaps as a compensation for anatomically reduced caliber. Similarly, when the pharyngeal airway is narrowed during hypocapnic central apnea,[40] more pronounced narrowing (or even closure) occurs in patients with OSA relative to normal control subjects despite complete inhibition of upper airway dilating muscle activity in both groups.

A related question is the role of upper airway dilating muscles in stabilizing the upper airway and therefore preventing upper airway obstruction, apart from activity that is directly associated with increased or decreased upper airway patency. There is evidence, for example, that stimulation of the hypoglossal nerve results in decreased collapsibility (i.e., a stiffer airway) and decrease surrounding pressure in animal models.[41,42] Existing studies indicate that supraphysiologic electrical stimulation of the hypoglossal nerve using a surgically implanted upper airway stimulation device in patients with OSA lead to significant improvements in the severity of the sleep-disordered breathing in a select group of patients.[43,44]

Nonneuromuscular Factors Contributing to Upper Airway Patency and Obstruction

Upper Airway Muscle Histology

There is a large body of research examining upper airway muscle histology in patients with OSA, based on the hypothesis that pathologic changes in upper airway muscle histology may promote upper airway obstruction by increasing propensity to upper airway muscle fatigue or delay reopening through impairment of sensorimotor function. Studies have shown a variety of histologic changes, including edema and mucosal gland hypertrophy,[45] neurogenic injury,[46] changes in muscle enzyme activity,[47,48] and leukocytic inflammation.[49,50] A consistent finding across studies is an increase in type 2 fast-twitch fibers in the genioglossus muscle of patients with OSA.[46,51-53] Because type 2 fibers are more likely to fatigue than type 1 fibers, these studies suggest that upper airway muscles in OSA patients are more susceptible to fatigue than in normal subjects. In contrast, there is no consistent finding for differences in tongue protrusive force[54,55] in patients with OSA compared with normal subjects.

Changes in sensorimotor activity of the upper airway in OSA patients have been studied based on evidence that upper airway sensory receptors contribute to apnea-terminal arousal and that topical anesthesia impairs these responses. In patients with OSA, changes in two-point discrimination, vibratory sensation, upper airway muscle reflex response to short air pulses, and sensory perception to varying air flow rates have been observed.[56-58] These changes may explain the observation that inspiratory load sensation is decreased in patients with OSA.[59,60] Such impairment of upper airway sensorimotor function may contribute to decreased upper airway muscle activity in response to upper airway obstruction, loading, or collapse.

Although the previous studies indicate changes in upper airway neuromuscular histology and sensorimotor function in patients with OSA, there is only minimal evidence linking specific histologic changes or sensorimotor changes to changes in upper airway mechanics or propensity of the upper airway to collapse. In fact, the noted histologic changes, if secondary to recurrent airway collapse, may not be contributing to an increased propensity to collapse. For instance, treatment with nasal CPAP has been associated with improvement in genioglossus muscle force production[52] and vibratory thresholds.[56] Thus further investigation is necessary to determine to what extent changes in upper airway histology and function seen in patients with OSA are primary or secondary and whether and how such changes, primary or secondary, contribute to the noted increased propensity to collapse in sleep in patients with OSA.

Craniofacial Structure

Craniofacial structure is an important determinant of upper airway patency. This is most evident in children with craniofacial abnormalities such as Pierre Robin sequence and Treacher Collins syndrome, each of which are associated with an increased prevalence of OSA.[61] In adults, several anatomic abnormalities have been associated with OSA, including retrognathia, micrognathia, overjet, and a high arched palate.[62-64]

Several investigations have used lateral cephalometry to analyze the contribution of craniofacial structure to the development of OSA (Figure 111-2).[65-73] These studies vary widely in methodology, sample size, gender ratios, and the presence and degree of obesity. In these studies, common craniofacial abnormalities that have been associated with increased severity of sleep apnea include (1) smaller airway dimensions, particularly those involving the maxilla and mandible; (2) mandibular retrognathia; (3) decreased posterior airspace; (4) an inferiorly placed hyoid bone; and (5) increased soft palate dimensions and length. These abnormalities decrease the dimensions of the nasopharynx and oropharynx, likely increasing the risk for upper airway obstruction. In one study in 57 male patients with OSA, airway collapsibility[74] was correlated with soft palate length, hyoid bone distance, and an inferiorly placed hyoid bone.

MRI has also been used to compare upper airway craniofacial structure and soft tissue between subjects with and

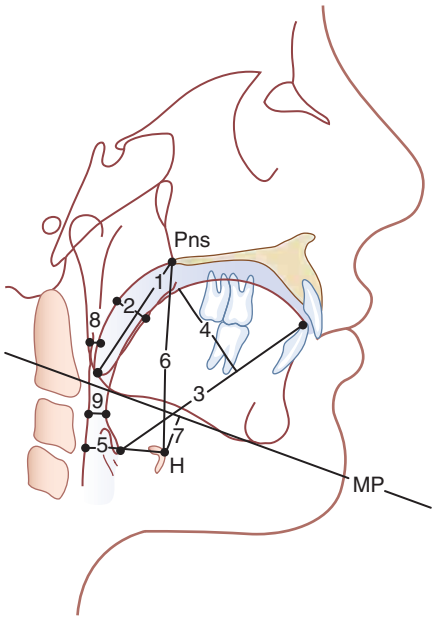

Figure 111-2 Cephalometric landmarks and soft tissue, hyoid position, and airway size variables frequently used in cephalometric studies. Landmarks: Pns, posterior nasal spine; H, hyoid bone; MP, mandibular plane (tangent line from the symphysis to the inferior border of the mandibular angle). Variables: (1) SPl, the length of the soft palate; (2) Spw, the width of the soft palate; (3) Tl, the length of the base of the tongue; (4) Tw, the width of the tongue; (5) H-Ph, the distance from the hyoid bone to the posterior wall of the pharynx; (6) H-Pns, the distance from the hyoid bone to Pns; (7) H-MP, the distance from the hyoid bone to the mandibular plane; (8) SPAS, the upper posterior pharyngeal space; (9) IPAS, the lower posterior pharyngeal space. In one study, critical closing pressure was predicted by the length of the soft palate (1), distance from hyoid bone to posterior wall of the pharynx (5), and the distance from the hyoid bone for the posterior nasal spine (6). (From Sforza E, Bacon W, Weiss T, et al. Upper airway collapsibility and cephalometric variables in patients with obstructive sleep apnea. *Am J Respir Crit Care Med* 2000;161[2 Pt. 1]:347–352.)

without OSA (Figure 111-3). Important differences have been found in men and include a wider mandibular divergence, smaller mandibular length, and smaller area at the mandibular plane being associated with OSA.[75,76] Although the hyoid bone was inferiorly placed in these studies in subjects with OSA, it was not a primary determinant of upper airway obstruction.

Craniofacial indexes derived from both cephalometric and MRI data have been used to compare OSA susceptibility between races. Redline and colleagues found that bony and soft tissue factors and brachycephaly were associated with OSA in whites, whereas only soft tissue factors were similarly associated in African Americans.[66,77] In contrast, Polynesian men with OSA were shown to have more mandibular retrognathia and larger nasal aperture width than white men, whereas neck circumference, tongue, and soft palate dimensions were associated with the respiratory disturbance index in the white subjects.[78] Finally, Japanese subjects with OSA have upper airway bony dimensions, whereas obesity and upper airway soft tissue and volume are less important.[76,78a] Taken together, these data indicate that race-specific craniofacial and neck structural factors contribute to the likelihood of having OSA.

Only one study has specifically compared gender differences in craniofacial and structural factors that could contribute to a propensity for OSA. Using MRI, Malhotra and colleagues[79] found that men had increases in airway length, soft palate cross-sectional area, and airway volume, presumably contributing to a diathesis for upper airway obstruction.

It should be noted that in many of these craniofacial studies, obesity remained the predominant etiologic factor for OSA, with abnormal craniofacial structure most important in nonobese patients with OSA. However, in a recent study in a large sample of men, obesity alone explained only 26% of the variance in the apnea-hypopnea index (AHI), and obese patients with unfavorable airway dimensions were susceptible to larger increases in OSA severity.[67]

Surrounding Tissues and Pressures

A collapsing upper airway transmural pressure can be generated either by a negative intraluminal pressure or a collapsing surrounding pressure. The role of negative intraluminal pressure in the pathogenesis of upper airway obstruction is widely hypothesized,[3] whereby a subatmospheric intraluminal pressure generated by the thoracic pump muscles causes upper airway collapse by "sucking" the hypotonic upper airway. However, there are no data showing that such subatmospheric intraluminal pressure causes upper airway obstruction in sleeping humans. In addition, upper airway narrowing and obstruction do not appear to require negative pressure. For example, studies using fiberoptic nasopharyngoscopy have shown that the upper airway narrows during hypocapnia mediated central inhibition.[40,80] Isono and colleagues[81] compared the mechanics of the pharynx in anesthetized and paralyzed normal subjects and in patients with OSA. The pharynx was patent at atmospheric intraluminal pressure in normal subjects and required negative intraluminal pressure for closure. In contrast, patients with OSA had a positive closing pressure; that is, the pharynx was occluded at atmospheric intraluminal pressure. Similarly, the critical closing pressure in patients with OSA has been generally found to be positive, as opposed to the negative critical closing pressure in normal subjects.[82, 83]

The disconnect between the occurrence of upper airway obstruction and of negative intraluminal pressure supports the possibility that upper airway patency is, in part, determined by the extrinsic or surrounding pressure contributed to by properties of soft tissue structures of the upper airway. Using MRI technology, three factors have been found to be most significantly associated with an increased risk for OSA: increased tongue size, increased size of lateral pharyngeal walls, and increased total soft tissue volume (Figure 111-4).[84] The association of increased tongue and lateral pharyngeal wall size with OSA has also been noted in CT and cephalometric studies of the upper airway[65,85] as well as in clinical studies.[62] Subsequent work has shown that these same factors show familial aggregation, even after correction for confounding factors such as gender and age.[86] Thus the known familial predisposition to OSA[87] may be in part explained by heritable soft tissue factors.

Enlarged tonsils have also been shown to be associated with an increased risk of OSA even after correction for BMI and neck circumference.[62] Enlarged tonsils are particularly noted as a causative factor in children and thin adults, who may have resolution of OSA after tonsillectomy.[88]

CT and MRI of the upper airway have also demonstrated evidence of increased soft tissue volume and pharyngeal fat at

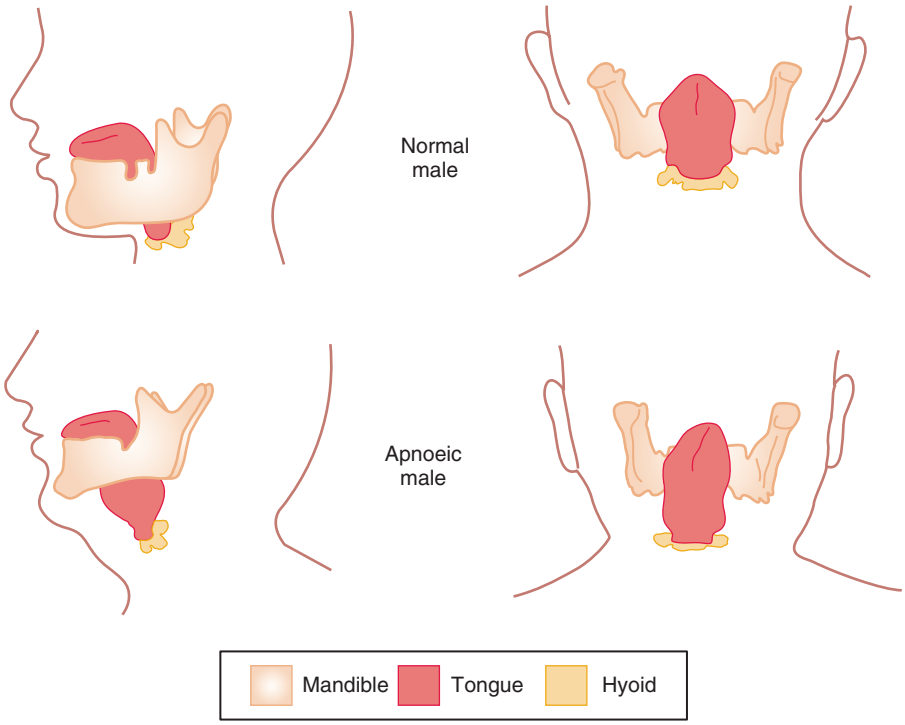

Figure 111-3 Three-dimensional reconstruction of hyoid, tongue, and mandible in a patient with obstructive sleep apnea (*bottom:* male, apnea-hypopnea index [AHI] 86 events/hr; body mass index [BMI] 31 kg/m^2; 49 years of age) and a normal subject (*top:* male, AHI 5 events/hr; BMI 25 kg/m^2; 44 years of age) illustrating the inferior-posterior positioning of hyoid and enlarged tongue volume. Note that the hyoid is more inferior-posteriorly positioned in the apneic subject than in the normal subject; tongue volume is greater in the apneic subject than in the normal subject. (From Chi L, Comyn FL, Mitra N, et al. Identification of craniofacial risk factors for obstructive sleep apnoea using three-dimensional MRI. *Eur Respir J* 2011;38[2]:348–58.)

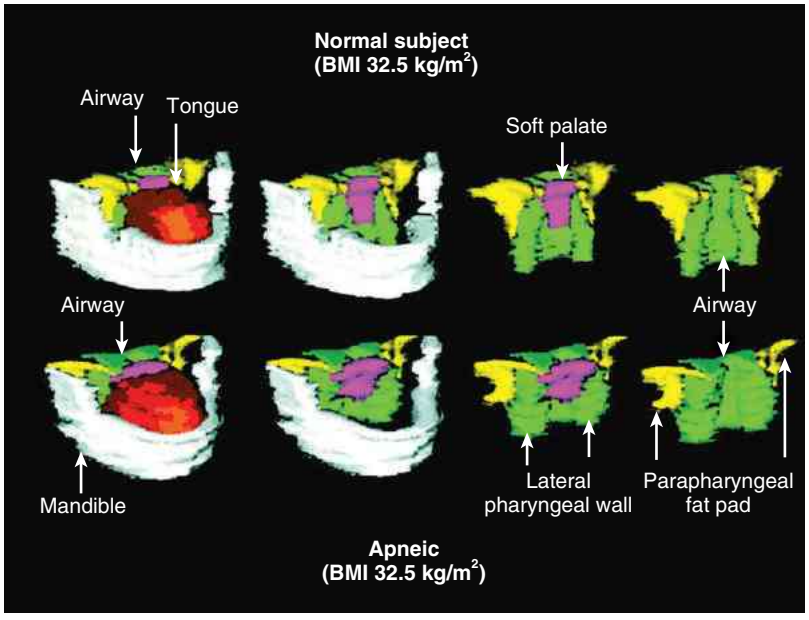

Figure 111-4 Volumetric reconstruction of axial magnetic resonance images in a normal subject and a patient with sleep apnea, both with an elevated body mass index of 32.5 kg/m^2. The mandible is depicted as *gray*, tongue as *orange/rust*, soft palate as *purple*, lateral parapharyngeal fat pads as *yellow*, and lateral/posterior pharyngeal walls as *green*. Note that the airway is larger in the normal subject than in the apneic subject. The tongue, soft palate, and lateral pharyngeal walls are larger in the patient with sleep apnea. (From Schwab RJ, Pasirstein M, Pierson R, et al. Identification of upper airway anatomic risk factors for obstructive sleep apnea with volumetric magnetic resonance imaging. *Am J Respir Crit Care Med* 2003;168[5]:522–30.)

the level of the nasopharynx in males,[89] which could explain, in part, their higher prevalence of OSA. Pharyngeal fat volume was found to correlate with the AHI in one study,[27] but not in other studies.[84,85] Further investigations are needed to better determine the role of pharyngeal fat volume in particular, and extrinsic tissue volume and pressures overall, in the generation of a collapsing transmural pressure and the pathogenesis of upper airway obstruction in sleeping humans.

Intrinsic Properties of the Upper Airway

The collapsing effect of transmural pressure on upper airway patency is subject to modification by the intrinsic compliance of the pharyngeal wall. In addition to the Isono and colleagues[81] data noted previously, it has been shown that, in the isolated upper airway model of collapsibility, critical closing pressure is negative during complete paralysis, indicating that at normal atmospheric pressure, the normal upper airway remains open.[90,91] These studies suggest that the pharyngeal wall has an intrinsic "stiffness" or resistance to collapse. The determinants of such intrinsic stiffness have not been fully elucidated but likely involve complex interactions among many of the pharyngeal components already discussed, including muscles (which may have different properties in a passive state compared with a stimulated state), bony structures (particularly in the nasopharynx), soft tissues, and vascular properties, with such interactions affecting pressure and cross-sectional area relationships.

In the passive or paralyzed nasopharynx, the relationship between pharyngeal transmural pressure and cross-sectional area is curvilinear, implying that the airway becomes more compliant as the cross-sectional area decreases, that is, the "tube law" (Figure 111-5). Therefore baseline decreased airway cross-sectional area is likely a determinant of diathesis for upper airway obstruction, supported by evidence that the pharyngeal airway is smaller during wakefulness in patients with OSA relative to that of normal subjects.[92-94] However, it has been shown that under the dynamic conditions of inspiratory flow limitation, airway compliance decreases at more negative driving pressures (associated with a smaller cross-sectional area), indicating that static airway properties may not be as physiologically or clinically relevant during dynamic conditions.[94a]

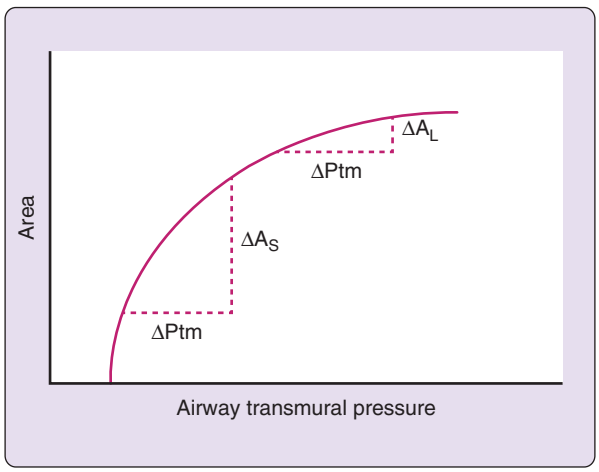

Figure 111-5 Illustration of the tube law of the pharynx. As transmural pressure (P_{tm}) increases, so does cross-sectional area (A). The slope of the tube law represents compliance of the pharynx. Note that compliance decreases as the area of the pharynx increases.

In association with such intrinsic properties of the upper airway, increased inspiratory lung volume is associated with increased upper airway caliber and decreased collapsibility. Potential mechanisms through which the increased caudal traction works include increased longitudinal tension, increased subatmospheric pressure through the trachea, and decreased transmural pressure.[42,95-97] Therefore caudal traction appears to influence upper airway collapsibility by both dilating and stiffening the pharyngeal airway as well as decreasing extramural tissue pressure. It is likely that patients with OSA are more dependent on such increased lung volume–associated dilatation or stiffening because of their relatively compliant upper airway.[81,98,99]

Vascular perfusion of the upper airway is also a potential determinant of intrinsic pharyngeal wall stiffness. Vasoconstriction and vasodilation have been shown to cause a decrease and increase in upper airway resistance, respectively.[100-102] More recently, a series of experiments have investigated the relationship between rostral fluid shifts and upper airway properties, demonstrating an association between reduction in leg fluid volume and increased neck circumference. In awake subjects, such rostral body fluid shift is associated with increased pharyngeal resistance,[103] decreased upper airway cross-sectional area,[104] and increased upper airway collapsibility.[105,106] Similar results have been found in patients with drug-resistant hypertension[107] and end-stage renal dialysis,[108,109] two groups in which there is evidence of an increased prevalence of OSA.[110] Interestingly, despite similar changes in leg total fluid volume and neck circumference with lower body positive pressure, men have a larger increase in collapsibility than women,[106] suggesting that a differential response to fluid shifts between men and women could contribute to the difference in gender prevalence in OSA.

When upper airway closure occurs, surface mucosal forces may impede subsequent upper airway opening.[35] In awake humans, surfactant and other topical lubricants have been shown to decrease the opening and closing pressures of the upper airway and to decrease upper airway resistance in sleeping normal subjects.[111,112] Mucosal lining forces may be particularly important in patients with OSA with mucosal inflammation from repeated trauma,[111] in whom the AHI in sleep decreases with the use of such soft tissue lubrication.[112,113]

In summary, upper airway patency is determined by multiple factors that are present during wakefulness and sleep, all typically further compromised during sleep compared with awake, leading to changes in upper airway function that contribute to sleep-related upper airway obstruction. The four primary factors include neuromuscular activity of the upper airway, craniofacial structure, tissues surrounding the upper airway, and the intrinsic properties of the airway (Figure 111-6). The following section reviews the sleep-specific effects on these factors and associated upper airway resistance and patency.

SLEEP EFFECTS ON UPPER AIRWAY PATENCY AND COLLAPSIBLITY

The sleep state is a challenge, rather than a period of rest, for the ventilatory system. In addition to the reduced activity

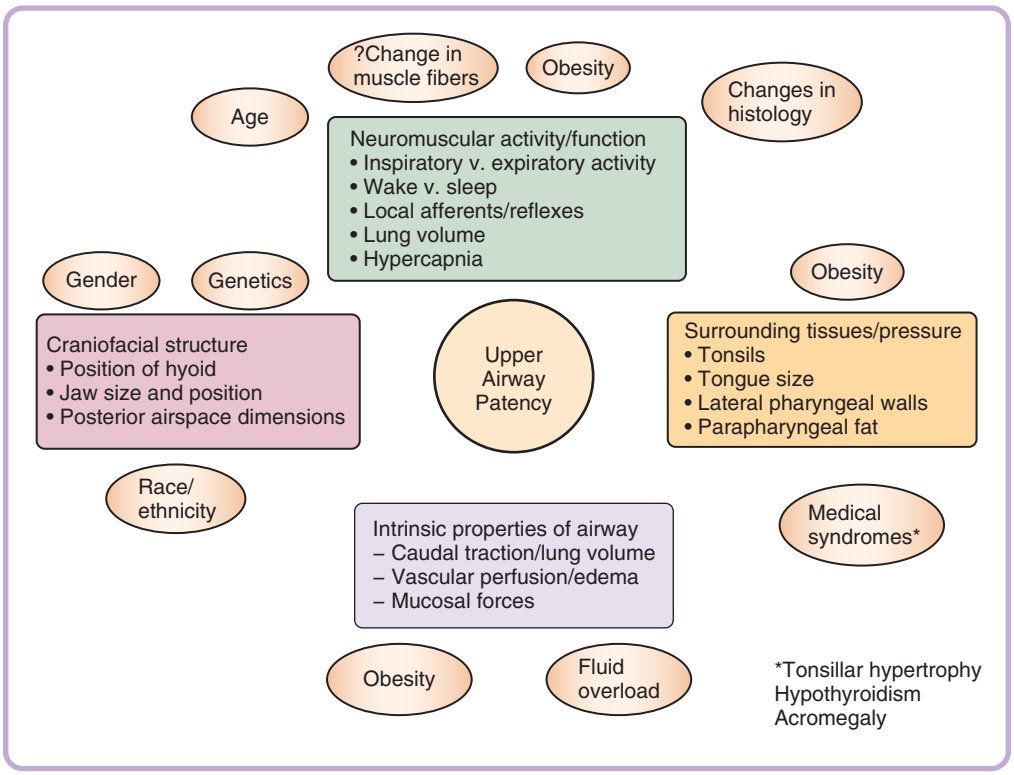

Figure 111-6 Summary showing the major determinants of upper airway patency and other factors that modify these main determinants.

of upper airway dilators discussed previously, consequences of the loss of wakefulness on the upper airway include reduced upper airway caliber, increased upper airway resistance, increased pharyngeal compliance, and collapsibility. Ultimately, these changes lead to reduced tidal volume and hypoventilation.

Upper Airway Caliber and Resistance

The sleep state is associated with upper airway narrowing and a corresponding increase in upper airway resistance. Using nasopharyngoscopy during sleep in normal subjects, Rowley and colleagues[46,126] have shown that, during NREM sleep, both retropalatal and retroglossal cross-sectional area decreases to approximately 70% of awake cross-sectional area, with further narrowing of the retroglossal airway during REM sleep. Decreased cross-sectional area corresponds with the pattern of decreased upper airway dilator muscle activity during NREM sleep and further reduction of the genioglossus during REM sleep. In REM sleep, retroglossal but not retropalatal cross-sectional area decreases further compared with NREM sleep.[36,114]

The evidence for increased upper airway resistance during sleep is compelling, even in normal subjects.[36,114-116] In fact, increased upper airway resistance occurs as early as sleep onset and continues to increase, reaching highest values in slow wave sleep. Most evidence indicates that there are no further increases in upper airway resistance during REM sleep compared with NREM sleep in normal humans.[36,114,117] In summary, the sleep state is associated with upper airway narrowing, which manifests as increased upper airway resistance and decreased pharyngeal caliber.

It is important to note that upper airway resistance is not an independent measure of the dynamic behavior of the pharyngeal airway during sleep. Many subjects exhibit inspiratory flow limitation, in which the pressure-flow graph demonstrates a changing relationship between driving pressure and inspiratory flow, culminating in complete dissociation between pressure and flow; that is, pressure continues to decrease with no further increase in flow (Figure 111-7, *A*). Thus the optimal physiologically meaningful measurement of upper airway resistance is the slope of the linear portion of the pressure-flow loop, which likely reflects upper airway caliber at the narrowest point in the upper airway at the beginning of inspiration (Figure 111-7, *B*).

Measurements and Meanings of Compliance and Collapsibility

The walls of the pharyngeal airway consist of compliant soft tissue structures, amenable to changes in pressure during the respiratory cycle. During wakefulness, upper airway caliber is constant during inspiration, with a decreased caliber during expiration, returning to inspiratory values at end-expiration. This finding has been observed in both normal subjects[92,118] and in patients with OSA[118] using either CT scanning or nasopharyngoscopy. Using nasopharyngoscopy, NREM sleep has been observed to be associated with significant dynamic within-breath changes in cross-sectional area, reaching a nadir at mid-inspiration,[118] with a rapid increase in cross-sectional area during expiration (Figure 111-8).[40] In addition, in subjects with OSA, there is progressive upper airway narrowing before the onset of apnea, which is primarily seen during expiration.[119] BMI appears to be a determinant of the degree

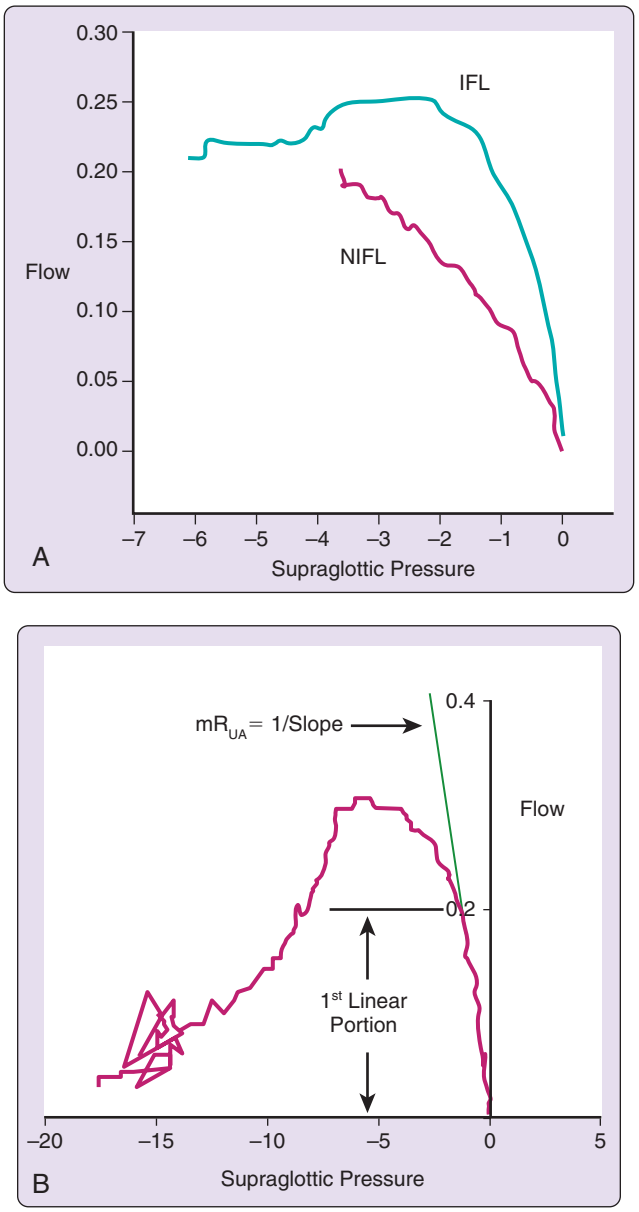

Figure 111-7 A, Pressure-flow loops illustrating a non–flow-limited (NIFL) and a flow-limited (IFL) breath. **B,** Illustration of a flow-limited breath and measurement of resistance along the first linear portion of the pressure-flow loop.

Expiratory pharyngeal narrowing during central hypocapnic hypopnea. *Am J Respir Crit Care Med* 2009;179:313–9.)

of airway narrowing seen in these studies.[40,118] The sleep reversal in the pattern of change in upper airway cross-sectional area is thought to be due to sleep-related increase in upper airway compliance, a decrease in pharyngeal caliber, and subsequently, decreased (more negative) inspiratory intraluminal pressure.

The changes in upper airway patency during sleep can be investigated using compliance as a measurement. Compliance of the pharyngeal wall is an important modulator of the effect of pressure changes on upper airway patency. The occurrence of pharyngeal narrowing and flow limitation suggests, although does not prove, increased pharyngeal compliance during sleep. Using a methodology that measures changes in cross-sectional area at different levels of applied pressure, it has been demonstrated that compliance is increased as the pharyngeal caliber decreases[81,120,121] and that the upper airway of patients with OSA is more compliant than that of normal subjects,[81,98,121,122] consistent with an increased propensity to collapse. Using a methodology that combines measurement of cross-sectional area using fiberoptic nasopharyngoscopy and measurement of intraluminal pressure at the same level in normal subjects has confirmed that retropalatal compliance is increased during NREM sleep compared with wakefulness, with no difference between REM sleep and wakefulness.[36] At the retroglossal level, however, compliance is not increased during either NREM or REM sleep compared with wakefulness.[114] The dissociation between compliance and reported muscle activity in these studies is consistent with studies in patients with OSA demonstrating that increased pharyngeal compliance occurs despite an increased activity of the genioglossus muscle during wakefulness[38] and sleep,[39] perhaps as a compensation for anatomically reduced caliber. This finding again suggests a major role for nonneuromuscular factors, as referred to previously, as determinants of pharyngeal compliance.

Collapsibility, which is the propensity of the upper airway to collapse or obstruct under certain conditions, increases during sleep compared with awake, likely owing to many of the factors discussed previously. Upper airway collapsibility has been primarily measured using the critical closing pressure, Pcrit, which is based on the concept of the Starling resistor,[123] whereby maximal flow through the resistor is dependent on the resistance of the upstream segment and the pressure surrounding the collapsible segment (Figure 111-9). In humans, the critical closing pressure can be partitioned between its passive mechanical properties (passive Pcrit) and active dynamic responses (active Pcrit).[124,125] Applying this model to humans, it has been shown that across the spectrum of obstructive sleep-disordered breathing, active Pcrit correlates with propensity for airway collapse.[82,83,126] For instance, Pcrit in normal subjects is generally less than 10 cm H_2O, whereas in patients with predominant hypopneas, it is between zero and −5 cm H_2O, and in patients with predominant apneas, it is more than zero cm H_2O. Although both active and passive Pcrit are increased in patients with OSA compared with control subjects, the difference between active and passive Pcrit is greater in non-OSA controls compared with those with OSA, likely associated with the greater ability of normal subjects to maintain airway patency.

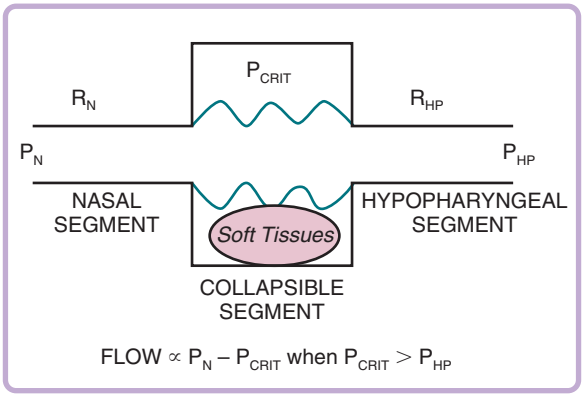

Figure 111-9 Starling resistor model of the upper airway. In this model, flow is proportion to the difference between P_N and Pcrit, with Pcrit greater than P_{HP}. P_N, Nasal (upstream) pressure; P_{HP}, hypopharyngeal (downstream) pressure; R_N, resistance in the nasal segment; R_{HP}, resistance in the hypopharyngeal segment.

The roles of mechanical loads and compensatory responses related to Pcrit are summarized in Figure 111-10. As shown in the left-hand bar with graded shading, approximate levels of Pcrit measurements define a continuum of upper airway collapsibility from health to disease. A Pcrit of approximately −5 cm H_2O represents the level above which obstructive hypopneas and apneas will occur. Structural characteristics of the upper airway impose mechanical loads and increase Pcrit, predisposing the upper airway toward collapse. Intact dynamic neuromuscular responses decrease Pcrit and maintain upper airway patency. In contrast, blunted neuromuscular responses increase Pcrit and predispose the upper airway toward obstruction.

Phase of the Respiratory Cycle: Inspiratory Versus Expiratory Narrowing

Upper airway obstruction during sleep is characteristically attributed to inspiratory narrowing owing to a collapsing subatmospheric pressure against a hypotonic pharyngeal airway. However, several lines of evidence implicate expiratory narrowing as a possible mechanism of the initial narrowing. First, ventilatory motor output is an important determinant of upper airway patency. Oscillation of ventilatory motor output, during the characteristic periodic breathing of OSA, is associated with pharyngeal narrowing or obstruction at the nadir of the motor output, especially in individuals with a highly

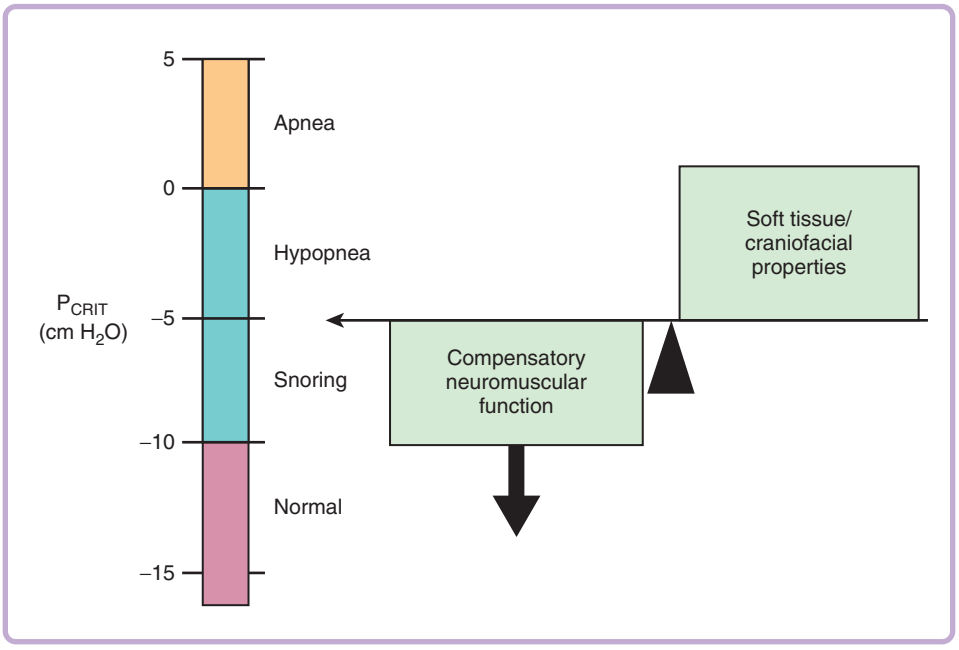

Figure 111-10 Role of mechanical loads and compensatory neuromuscular responses in the context of critical pressure measurements. See text for explanation. Figure 111-11 **A,** A recording of air flow (flow; inspiration positive), esophageal pressure (Pes), and rib cage and abdominal movements. Tracings show four breaths leading to an obstructive apnea (breaths -4, -3, -2, and -1). During the apnea, respiratory effort is indicated by the negative swings in the esophageal pressure and paradoxical rib cage and abdominal movements. **B,** Fiberoptic images of the retropalatal airway during the four breaths shown in **A** where breath-1 is the breath immediately preceding the apnea and breath-4 is the breath farthest away from the apnea. Within each breath the images selected correspond to the smallest cross-sectional area (CSA) that occurred during inspiration (Nadir Insp), the largest CSA during expiration (Peak Exp), and the CSA at end-expiration (End Exp). Note that progressive narrowing is occurring in both inspiration and expiration. Within each image the *dark area* is the airway lumen, the *lighter horseshoe shape* is the epiglottis, and the *white triangular shape* in the *bottom left corner* is the esophageal pressure catheter. (From Morrell MJ, Arabi Y, Zahn B, Badr MS. Progressive retropalatal narrowing preceding obstructive apnea. *Am J Respir Crit Care Med* 1998;158[6]:1974–81.)

collapsible airway.[127] Second, an obstructive apnea is often preceded by expiratory narrowing of the upper airway as evidenced by increased expiratory resistance[128] or progressive expiratory narrowing, detected by fiberoptic imaging (Figure 111-11).[119] Finally, although upper airway narrowing or occlusion occurs during a spontaneous or induced hypocapnic central apnea[80] or induced hypocapnic hypopnea,[40] pharyngeal narrowing during central hypopnea occurs during the expiratory phase only and is associated with increased expiratory upper airway compliance. Therefore upper airway obstruction may occur in either inspiration or expiration (Figure 111-12). Individuals with a high surrounding tissue pressure may be particularly susceptible to expiratory pharyngeal narrowing during such low ventilatory motor output and driving pressure.

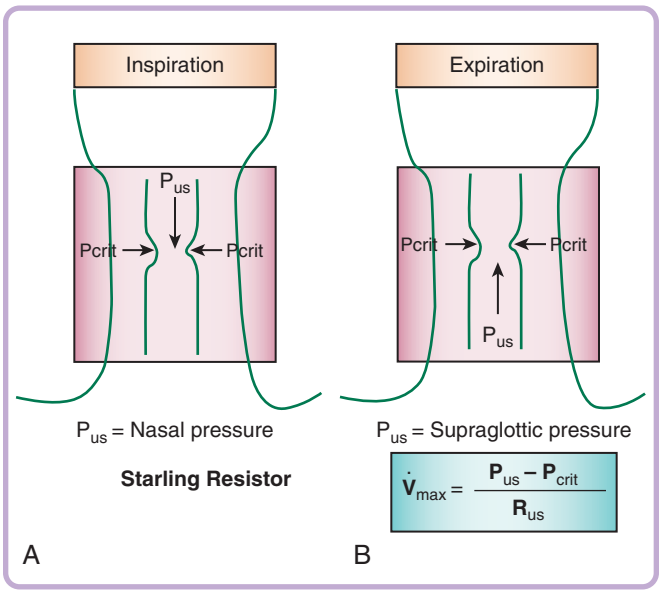

Figure 111-12 Schematic illustration for the collapsible segment of upper airway during hypocapnic hypopnea as a Starling resistor. In this model, flow is determined by the gradient between the upstream segment and critical closing pressure (Pcrit). During inspiration **(A)**, when upstream pressure (P_{us}) (i.e., nasal pressure) is below the Pcrit, the collapsible segment is closed, and no flow occurs. During expiration **(B)**, when P_{us} in the supraglottic area is below the Pcrit, the collapsible segment is closed, and no flow occurs. During hypocapnic hypopnea, expiratory flow is limited, correlating with the gradient between the supraglottic pressure and Pcrit. Hence this pressure gradient is an important determinant of pharyngeal narrowing. R_{us}, Upstream resistance; $\dot{V}_{max}$, maximal flow. (From Sankri-Tarbichi AG, Rowley JA, Badr MS. Expiratory pharyngeal narrowing during central hypocapnic hypopnea. *Am J Respir Crit Care Med* 2009;179[4]:313–9.)

Gender, Body Mass Index, and Weight Effects on Upper Airway Structure and Function

Potential determinants of upper airway mechanics during sleep include many variables known to be associated with an increased prevalence of OSA, such as gender, BMI, and age.

Most studies indicate no consistent difference in upper airway caliber, or compliance, between men and women without OSA. Upper airway resistance during NREM sleep is also similar in both genders,[117,129] although one study[130] demonstrated higher upper airway resistance in men during slow wave NREM sleep. REM sleep has not been similarly studied. Likewise, studies during wakefulness demonstrate no significant difference in upper airway cross-sectional area or smaller airway in women.[92,131-133] In addition, sleep-related narrowing is similar in men and in women (approximately a 40% decrease in cross-sectional area for both genders) from wakefulness to NREM sleep.[134] However, it appears that men have increased retropalatal compliance compared with women[134] because of gender difference in neck circumference, again indicating that factors other than gender are important in explaining such gender differences in upper airway function. Finally, there is no demonstrated gender difference in Pcrit under active conditions.[129] Thus the available studies taken together do not suggest a gender difference alone in upper airway mechanics during wakefulness or sleep, except for higher retropalatal compliance in men compared with women, in subjects without OSA. However, gender has been found to modulate the effect of BMI on Pcrit, and thus upper airway collapsibility, with men, with or without OSA,

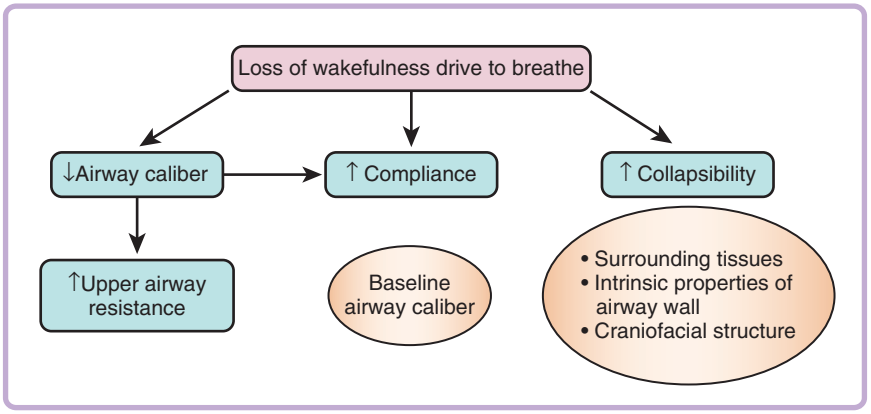

Figure 111-13 Effect of the loss of wakefulness drive to breathe on the upper airway.

increasing passive Pcrit in relation to increasing BMI more than women.[124]

The effect of age on upper airway resistance during sleep is variable across different studies. Browne and colleagues[135] and Thurnheer and associates[117] found no difference in upper airway resistance between young (<40 years) and older (>40 years) subjects. In contrast, in a group of 60 subjects without OSA, Rowley and colleagues found age to be the only independent predictor of upper airway resistance, with increased age associated with increased upper airway resistance. BMI was not a predictor of resistance.[129] More recently, however, increasing age was associated with increased upper airway resistance during sleep in a linear fashion.[136] Overall, it appears that aging is associated with increased upper airway resistance, and thus possibly increased diathesis for pharyngeal narrowing, during sleep. However, because age does not appear to be a predictor of Pcrit,[124] the significance of age-related increased upper airway resistance is unclear.

Hormonal Activity and Upper Airway Activity

There is also evidence that upper airway collapsibility can be influenced by hormonal activity, particularly leptin activity, in humans. For example, Shapiro and colleagues found in obese subjects that, although leptin levels were not associated with passive Pcrit or the severity of sleep apnea (presumably OSA), increased leptin levels were associated with an increased difference between active and passive Pcrit, independent of BMI and neck circumference.[137] Thus leptin appears to be associated with a decreased propensity to upper airway collapse.

In summary, upper airway patency during sleep is compromised by the loss of wakefulness drive of breathing (Figure 111-13). The loss of the wakefulness drive to breathe results in decreased upper airway neuromuscular activity and reflex activity, leading to decreased upper airway caliber and increased in upper airway resistance. The loss of wakefulness drive to breathe also results in increased airway compliance and collapsibility.

CLINICAL PEARL

The upper airway may be compromised and an individual put at an increased risk for OSA because of enlargement of soft tissue structures such as the tonsils, tongue, and lateral pharyngeal walls as a result of disease or obesity. Craniofacial structure, which is determined by genetics, race, and ethnicity, is an important determinant of upper airway patency; clinically significant changes can include micrognathia and retrognathia, overjet, and a high arched palate. Obesity, through a decrease in lung volume (particularly functional residual capacity), and fluid overload can each lead to changes in the intrinsic properties of the upper airway, increasing propensity to collapse. These factors, in association with sleep-related alterations in both neural control of the upper airway and central neural control of breathing, increase the propensity to upper airway obstruction or collapse in sleep in some individuals, leading to the clinical disorder of OSA.

SUMMARY

Upper airway patency is determined by multiple factors that are present during wakefulness and sleep, with sleep generally associated with compromise of these factors, leading to changes in upper airway function that contribute to upper airway obstruction. The four major determinants of upper airway patency are neuromuscular activity, craniofacial structure, tissues surrounding the upper airway, and the intrinsic properties of the airway. These determinants are modified by other factors, including age, obesity, gender, ethnicity, fluid overload, and other medical disorders, such as tonsillar hypertrophy (see Figure 111-6). During sleep, the loss of the wakefulness drive to breathing results in decreased upper airway neuromuscular activity and reflex activity, leading to decreased upper airway caliber and increased upper airway resistance (Figure 111-13). In addition, there is associated increased airway compliance and increased collapsibility, both of which are influenced by factors that determine baseline upper airway caliber, such as surrounding tissues, craniofacial structure, and the intrinsic properties of the upper airway.

This chapter has discussed the important structural aspects of upper airway structure, function, and patency. However, it is important to note that, although the upper airway narrows in humans during sleep, whether any given individual develops sufficient obstruction to develop the clinical disorder of OSA is likely an interplay between both upper airway structure and function and neural control of breathing during sleep.

Snoring and Pathologic Upper Airway Resistance Syndromes

Riccardo Stoohs; Avram R. Gold

Chapter Highlights

- Over the past two decades, knowledge of pathologic pharyngeal collapse during sleep has expanded from apnea and hypopnea to include even the mildest, silent inspiratory airflow limitation (IFL) during sleep. Both the clinical researcher and the sleep medicine practitioner of today must be able to recognize the mildest IFL on a polysomnogram and its clinical implications. This chapter discusses the physiologic and clinical features of IFL during sleep.
- Although habitual snoring is very common, the prevalence of isolated snoring (snoring in the absence of apnea and hypopnea, oxygen desaturations, arousals from sleep, and symptoms of obstructive sleep apnea) is unknown. Recent clinical investigation has led to uncertainty about whether such snoring can be considered benign. This chapter presents the issues involved in the diagnosis and management of isolated snoring.
- The paradigm of IFL during sleep leading to recurrent respiratory effort–related arousals is inadequate to explain the varied signs and symptoms of upper airway resistance syndrome (UARS) that have been recognized during the past decade or to distinguish between UARS patients and asymptomatic, healthy individuals whose polysomnograms are remarkably similar. This chapter discusses the evolving paradigm of UARS.

Snoring and upper airway resistance syndrome (UARS) represent obstructed breathing during sleep too mild to cause more than slight sleep fragmentation but with potential pathologic significance. In the past, the chief question to be answered was whether snoring, in the absence of obstructive sleep apnea (OSA), causes hypersomnolence, metabolic disorders, or cardiovascular disease. Currently there is growing evidence that mild inspiratory airflow limitation (IFL) during sleep, even in the absence of audible snoring or increased sleep fragmentation, may have a causative role in a variety of disabling somatic and affective disorders whose available treatment options are of limited benefit. After providing some background on the terms used in this chapter, we will first cover the physiology, recognition, and definition of IFL during sleep, the phenomenon known as increased *upper airway resistance*. We will next present the clinical manifestations of increased upper airway resistance, snoring, and UARS, attempting to organize the growing body of knowledge into a plausible pathophysiology and clinical paradigm of increased upper airway resistance in sleep.

BACKGROUND

Glossary of Terms Central to This Chapter

The terms defined below are described in detail and in context in this chapter:

Inspiratory airflow limitation. IFL describes a state of the upper airway (the pharynx) during sleep in which inspiratory airflow plateaus at a maximal level despite a continued increase in the pressure gradient between the nostrils and the hypopharynx. The failure of inspiratory airflow to increase despite the continued increase in the pressure gradient across the upper airway is caused by fluttering of the upper airway that prevents further increase in airflow. IFL can be divided into two subgroups based on whether or not it is *audible:* (1) *snoring* and (2) *silent IFL.* In this chapter, *snoring* is further divided into two subgroups: (a) *habitual snoring* and (b) *isolated snoring*

Snoring or inspiratory snoring. Audible inspiratory fluttering of the upper airway. It can occur during obstructive hypopnea when hypopnea is associated with a decrease in inspiratory airflow by 30% lasting at least 10 seconds accompanied by either an arousal from sleep or a 3% decrease in oxygen saturation. Alternatively it can occur in the absence of the above criteria for hypopnea, with higher levels of airflow, or with shorter duration or absence of arousals or oxygen desaturation. The presence of inspiratory snoring *always indicates the presence of IFL.* Although expiratory snoring exists (and will be discussed later in this chapter), the term *snoring* used without a modifier in this chapter refers to inspiratory snoring.

Habitual snoring: This term describes an observation (often a complaint) by a bed partner or roommate that a person consistently snores when asleep.

Isolated snoring: Following polysomnography, if an otherwise healthy, asymptomatic habitual snorer does not meet the current third *International Classification of Sleep Disorders*, third edition[1] (ICSD3) criteria for OSA, the patient is described as having *isolated snoring*.

Specific criteria for being "otherwise healthy" in the context of being a habitual snorer are described later in this chapter.

Silent inspiratory airflow limitation. Silent IFL is defined, and characterized by, the same *fluttering* of the upper airway that characterizes snoring; however, the frequency of the fluttering during silent IFL is, by definition, inaudible by humans.

Respiratory effort–related arousal (RERA): RERAs are transient arousals from sleep that follow a period of nonhypopneic IFL (either snoring or silent IFL) and are presumed to be caused by the inspiratory effort required to move air across a fluttering airway. As the name suggests, RERAs are *not* respiratory events per se, as are apneas and hypopneas. Whether an arousal following a period of IFL is in fact caused by the IFL cannot be definitively ascertained during clinical polysomnography; it is a presumption. To label an arousal a RERA, the authors of ICSD3 require 10 seconds of recognizable IFL preceding the arousal. A standard time requirement for IFL preceding an RERA, however, is not a feature of RERAs in the medical literature; a single flow-limited inspiration before arousal is the definition in some research.

Respiratory disturbance index (RDI): ICSD3 has replaced the apnea-hypopnea index (AHI) as a measure of the severity of OSA with the frequency of apneas, hypopneas, and RERAs. In this chapter, this new measure of the severity of OSA will be termed the RDI.

Upper airway resistance syndrome: The UARS does not exist in the ICSD3. It should be thought of as a syndrome coined by Dr. Christian Guilleminault and used by researchers who have broken away from the paradigm that hypersomnolence in patients with sleep-disordered breathing requires the presence of sleep fragmentation by apneas and hypopneas. In this chapter, UARS is defined as the symptom of either hypersomnolence or fatigue together with the presence of IFL during sleep adjudicated by polysomnography (as per the definition of IFL given previously) and an AHI of less than 5 per hour; the latter is the threshold of an OSA diagnosis in the ICSD2. In this chapter, symptoms and signs of UARS will be introduced to differentiate between UARS, OSA, and isolated snoring.

Upper Airway Resistance Versus Pharyngeal Collapse

Two terms used to describe the behavior of the upper airway (or pharynx) during sleep among snorers and patients with UARS are increased upper airway *resistance* and upper airway *collapse*. Many sleep researchers consider IFL during sleep to result from narrowing of the pharyngeal airway and increased resistance caused by the relaxation of pharyngeal dilator muscles, together with subatmospheric upper airway pressures during inspiration. As they measure increasingly negative esophageal or supraglottic pressures during inspiratory snoring, they think of upper airway *resistance* increasing. From this reasoning the clinical term *upper airway resistance syndrome* (UARS) was derived (as discussed later).

In contrast to this intuitive model of increasing upper airway resistance during sleep is the experimentally validated Starling resistor model of IFL[2] (see Chapter 17). The Starling resistor model postulates that the pharyngeal airway during sleep is a collapsible tube that will in fact collapse whenever the pressure within falls below a critical level, the pharyngeal "critical pressure" (Pcrit). It has been shown experimentally that as the severity of sleep-disordered breathing increases from isolated snoring to severe OSA, the pharyngeal Pcrit progressively increases from negative (subatmospheric) levels to positive levels.[3,4] Collapse of the pharynx, however, is not synonymous with apnea. When the pharynx collapses during sleep, one might experience either persistent apnea (no inspiratory airflow) or IFL (inspiratory airflow that has reached its maximum). When the pressure at the *upstream* end of the pharynx (the nares during inspiration) falls below Pcrit, the pharynx collapses, with resulting persistent apnea. When the pressure at the nares is above Pcrit, but the pressure at the downstream end of the pharynx (supraglottic pressure during inspiration) falls below Pcrit, as in a snorer, the pharynx also collapses. Because pharyngeal collapse leads to cessation of inspiratory airflow, pharyngeal pressure immediately equilibrates with nasal pressure opening the airway, with resumption of inspiratory airflow. The result is cyclical collapse and opening (fluttering) of the pharyngeal airway *limiting* inspiratory airflow to a fixed, maximal level (with the driving pressure fixed at nasal pressure minus Pcrit, no matter how low supraglottic pressure descends). Therefore, according to the Starling resistor model, the upper airway does not experience increased *resistance* during sleep, but a *fixed driving pressure* that limits airflow to a maximal level.

The language subsuming upper airway resistance and upper airway collapse therefore is derived from two different models of IFL. In this chapter, we will allude to *pharyngeal collapse* in the section that follows describing the polysomnographic appearance of IFL but use the term *upper airway resistance* for the remainder of this chapter, which does not require modeling of IFL.

Upper Airway Resistance Syndrome

As introduced in the glossary, we use the term UARS in this chapter, and it is found as a diagnosis in the current medical literature. However, the ICSD3[4] does not include UARS in its classification of sleep related breathing disorders but rather incorporates the polysomnographic manifestations of UARS into OSA. A brief discussion of the history of UARS will help the reader understand this dichotomy.

UARS came to public attention following the publication of a case series in 1993 by Dr. Christian Guilleminault and associates.[5] From among 48 patients with a diagnosis of idiopathic hypersomnolence, they selected 15 with the following characteristics:

- Intermittent or continuous snoring during sleep at home
- An AHI below the threshold for OSA by in-laboratory polysomnography (5/hour at Stanford University)
- More than 10 arousals per hour of sleep (a threshold they chose, attempting to limit their selected patients to those with an *increased* frequency of arousals)
- The presence of *upper airway resistive events* associated with arousals. These events were associated with reductions in airflow below the threshold to qualify as hypopnea and were identified using a pneumotachograph measurement of airflow and esophageal manometry to quantify effort.

Treatment of these 15 patients with nasal continuous positive airway pressure (CPAP) eliminated their resistive events and their associated arousals and relieved the patients' hypersomnolence (measured objectively by multiple sleep

latency testing). Because the patients did not meet diagnostic criteria for OSA (their resistive events were not hypopneas), the investigators designated a new syndrome: UARS. They hypothesized that UARS is a disorder of hypersomnolence related to sleep fragmentation by upper airway resistive events too mild to meet the diagnostic criteria of hypopnea. They further hypothesized that UARS patients have increased sensitivity to the respiratory effort related to these resistive events, giving rise to repetitive arousals (compared with OSA patients who typically arouse in response to higher degrees of obstruction: i.e., apneas and hypopneas). The hypothesis that UARS patients exhibit increased sensitivity to respiratory effort during sleep led to their arousals being termed RERAs.

Almost from the start, the establishment of a new syndrome of sleep-disordered breathing based on sleep fragmentation by RERAs created controversy.[6,7] Many believed that RERAs and hypopneas were essentially the same phenomenon and that both OSA and UARS described sleep fragmentation caused by upper airway resistive events giving rise to hypersomnolence. To eliminate the need for an additional syndrome of sleep-disordered breathing based on sleep fragmentation by RERAs, the authors of ICSD3 incorporated RERAs into the diagnostic criteria for OSA, creating diagnostic thresholds for OSA based on the combined frequency of obstructive events: apneas, hypopneas, and RERAs—the RDI. Therefore, by the clinical criteria of ICSD3, UARS has been "absorbed" into OSA.

The significance of UARS, however, does not end with its *absorption* into OSA. Since first being described by Guilleminault and associates as a syndrome of sleep fragmentation leading to hypersomnolence,[5] the paradigm of UARS has evolved. Investigators have observed that the sleep of UARS patients is characterized not only by the presence of RERAs but also by electroencephalographic differences and differences in sleep architecture that distinguish it from the sleep of healthy individuals. These *qualitative* differences in the sleep of UARS patients resolve with treatments that eliminate IFL during sleep and the hypersomnolence of UARS patients. Therefore, although the ICSD3 clinical criteria for OSA will result in many patients being treated for OSA who previously were diagnosed with UARS, it is not established that these former UARS patients are hypersomnolent because of sleep fragmentation by RERAs. Consequently, UARS continues on as a syndrome being studied by researchers examining alternatives to the OSA pathophysiologic paradigm of sleep fragmentation by apneas, hypopneas, and RERAs.

In our discussion of UARS later in this chapter, we will describe more fully the clinical presentation of UARS and the findings of investigators that have led them away from a sleep fragmentation paradigm of this disorder. We will also consider the alternative pathophysiologic paradigms of UARS that continue to evolve.

Inspiratory Airflow Limitation

Classically, the term *snoring*, the audible fluttering of the pharynx during inspiration, has been used to describe IFL during sleep. The term *snoring*, however, implies that pharyngeal fluttering is present only when it can be heard by a listener (the word *snore* itself resembles the sound of snoring). Hearing, however, is an insensitive means of detecting inspiratory fluttering of the pharyngeal airway during sleep. Because using the term *snoring* may lead one to believe that IFL is only present when audible, which is not the case, we have chosen to describe the characteristic inspiratory airflow through a fluttering upper airway during sleep as a state of *inspiratory airflow limitation* (as defined in the glossary above). The term IFL was first used by Schwartz and associates in their study of pharyngeal collapsibility during sleep in healthy humans[8] and was derived from the parallel term *expiratory airflow limitation*, used to describe expiratory airflow from the lungs of patients with asthma, chronic obstructive bronchitis, and emphysema whose bronchi flutter on expiration, limiting airflow.[9]

Recognizing Inspiratory Airflow Limitation with Physiologic Testing

With the incorporation of RERAs into the diagnostic criteria for OSA, recognizing the presence of IFL preceding an arousal and differentiating its appearance from that of non-flow-limited breathing during polysomnography is an important skill for practitioners of sleep medicine to develop. Similarly, for clinicians and polysomnographic technologists involved in titrating nasal CPAP to treat OSA, recognizing IFL during sleep is an important aspect of polysomnography to understand. In this section we begin by illustrating the appearance of IFL using airflow and supraglottic pressure tracings. We then demonstrate how IFL is recognized using the airflow and effort tracings available during clinical polysomnography.

Figure 112-1 illustrates five breaths during continuous non–rapid eye movement stage (NREM) 2 (N2) sleep at atmospheric pressure, all characterized by IFL. The individual being monitored is a 24 year-old woman with a body mass index of 19.9 kg/m^2 who does not snore audibly and has an AHI of 0.3/hour. Because Figure 112-1 has both an airflow tracing and a supraglottic pressure tracing, it precisely demonstrates the presence of IFL. Specifically, it shows that inspiratory airflow is limited to a maximal level (intersected by the vertical lines) despite the observation that the pressure gradient across the pharyngeal airway (atmospheric pressure minus supraglottic pressure) continues to increase (atmospheric pressure remains the same while supraglottic pressure continues to decrease beyond the vertical line). This defines IFL.

Figure 112-2 demonstrates both IFL and non-flow-limited inspiration in the same individual diagnosed with UARS during nasal CPAP titration. Although the left panel of the figure clearly demonstrates IFL at atmospheric pressure similar to that observed in Figure 112-1, the right panel, recorded at the therapeutic nasal CPAP level of 4 cm H_2O, presents airflow and supraglottic pressure tracings that parallel each other through four inspiratory cycles. The parallel tracings demonstrate that inspiratory airflow is continuously proportional to the driving pressure, 4 cm H_2O minus supraglottic pressure, and thus, according to the above definition of IFL, is not flow limited.

Figures 112-1 and 112-2 illustrate that, when one is provided with both an airflow signal and a supraglottic pressure signal, recognizing IFL is not difficult. It is emphasized that IFL is not defined by any specific decrease in inspiratory airflow (e.g., a 30% or 50% decrease in airflow) relative to *non*-flow-limited inspiration. Rather, IFL is defined by a specific relationship of airflow to driving pressure (nasal pressure minus supraglottic pressure). IFL can be more difficult to recognize in the absence of a supraglottic pressure signal

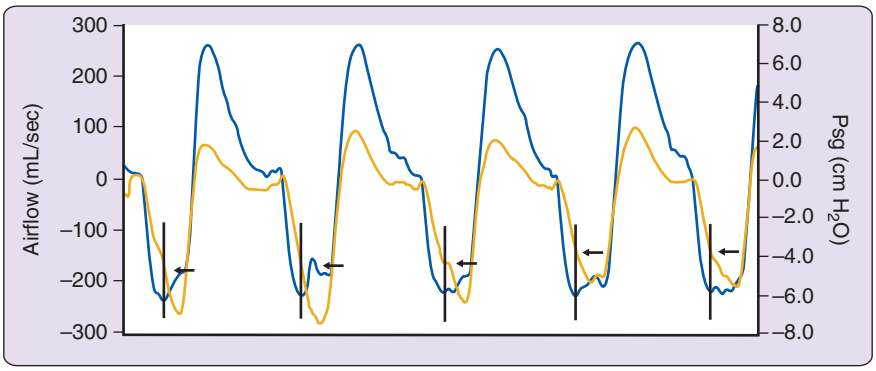

Figure 112-1 This figure illustrates inspiratory airflow limitation (IFL) in a sleeping research participant wearing a nasal mask attached to a pneumotachograph measuring airflow, with a pressure catheter placed through her nose to just above her vocal cords measuring supraglottic pressure (Psg). Airflow is the *blue tracing* with the units indicated on the left axis (inspiration is downgoing). Effort, represented by Psg, is the *yellow tracing* with the units indicated on the right axis. For each inspiration, a plateau in airflow during early inspiration is intersected by a *vertical line*. Beyond the line, there is no further increase in inspiratory airflow despite the continued decrease in Psg and a continued increase in the inspiratory pressure gradient Patm—Psg. Indeed, not only does the inspiratory airflow not increase, but also in the first four breaths it appears to decrease, a phenomenon known as *negative effort dependence* of airflow. IFL occurs when Psg decreases below this participant's pharyngeal Pcrit. The *horizontal arrows* mark the Psg at the onset of maximal flow (intersected by the *vertical line*) and suggest that this participant's pharyngeal Pcrit is approximately −4 cm H_2O, a common value for primary snorers or individuals who have upper airway resistance syndrome.[3]

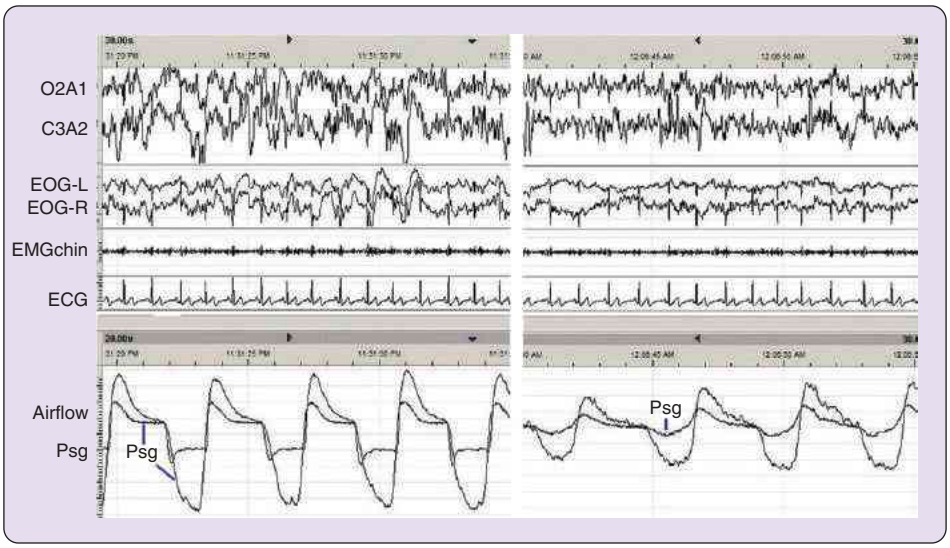

Figure 112-2 This figure demonstrates both inspiratory airflow limitation (IFL) and *non*-flow-limited inspiration in the same individual during nasal continuous positive airway pressure (CPAP) titration. The two polysomnographic tracings are obtained in stage N2 sleep, ½ hour apart. Below the sleep monitoring channels recording electroencephalograms (O2A1, C3A2), electrooculograms (EOG-L & R), superficial electromyograms of the chin (EMGchin), and electrocardiogram (ECG) are recordings of airflow (a pneumotachograph tracing) and supraglottic pressure (Psg). The *left panel* demonstrates four breaths at atmospheric pressure, whereas the *right panel* demonstrates four breaths with nasal CPAP at 4 cm H_2O. In each panel, airflow (*black tracing*) and Psg (*blue tracing*) are superimposed. The *left panel* demonstrates the plateau of inspiratory airflow (downgoing) at a maximal level occurring as Psg continues to decrease, which defines IFL. In the *right panel*, because pharyngeal pressure and Psg do not fall much below 4 cm H_2O (the CPAP applied to the nasal mask), Psg always remains above pharyngeal Pcrit, and the airflow and pressure tracings parallel each other (airflow is always determined by the pressure gradient: 4 minus Psg).

because one is then missing driving pressure; indeed, the presence of IFL can only be *assumed* in the absence of a supraglottic pressure tracing). To enable clinicians to recognize IFL during clinical polysomnography without the recording of supraglottic pressure, researchers have investigated the possibility of identifying IFL from the airflow signal alone.

In 1998, two studies evaluated the utility of a plateau of inspiratory airflow measured as a nasal pressure signal (pressure transducer airflow [PTAF]) to identify IFL.[10,11] Hosselet and associates[10] studied more than 47,000 breaths during polysomnography in 10 symptomatic OSA patients and 4 asymptomatic individuals without OSA, classifying the shape

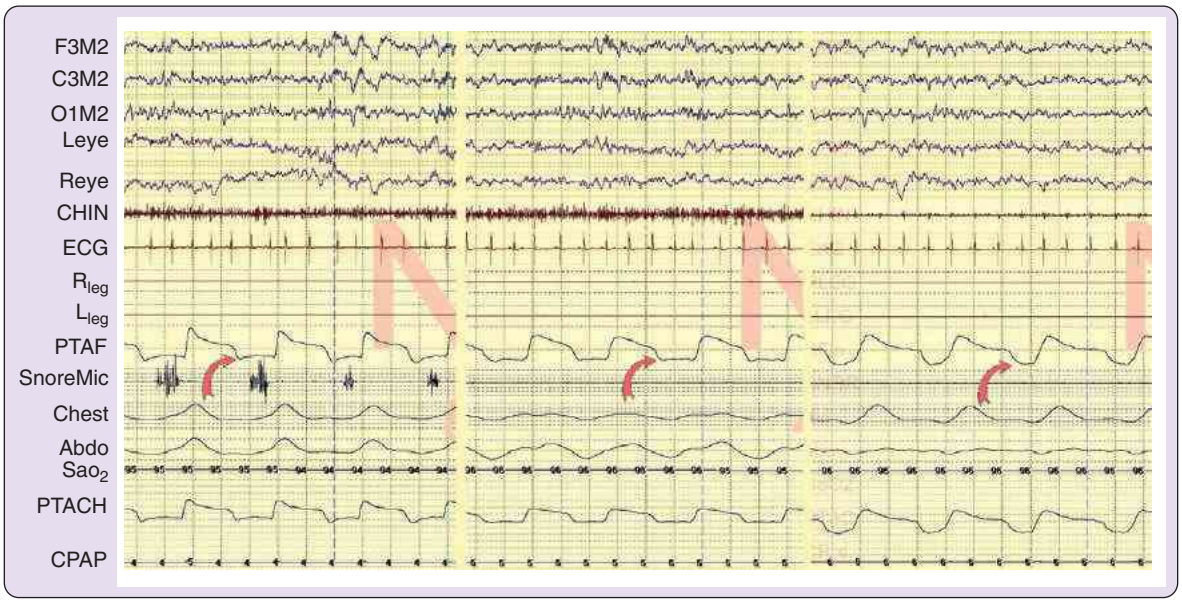

Figure 112-3 This figure's three panels, from left to right, represent three 12-second intervals at nasal continuous positive airway pressure (CPAP) levels of 4 cm H_2O, 5 cm H_2O, and 6 cm H_2O. Below the sleep monitoring channels recording electroencephalograms (F3M2, C3M2, O1M2), electrooculograms (L & Reye), superficial electromyograms of the chin (CHIN), and right and left tibialis anterior (R & L_{leg}) and ECG are several channels recording respiratory parameters. The respiratory channels include a pressure transducer-generated airflow signal (PTAF), a microphone placed on the neck to record snoring (SnoreMic), impedance plethysmography of the chest and abdomen (Chest and Abdo; movement), oxyhemoglobin saturation (SaO_2), a pneumotachograph airflow signal (PTACH), and a pressure transducer-recorded CPAP level (CPAP). At 4 cm H_2O, the *left panel*, the patient's inspirations all demonstrate IFL with audible snoring. Inspiratory airflow (downgoing) is seen to increase rapidly and then to plateau with a prolonged time spent at maximal inspiratory airflow (highlighted by the *arrow*). At 5 cm H_2O, IFL persists without audible snoring. Inspiratory airflow, again, increases rapidly and then demonstrates a prolonged plateau at maximal flow (highlighted by the *arrow*). At 6 cm H_2O, the airflow tracing no longer demonstrates inspiratory airflow limitation. Inspiratory airflow increases to its maximum more gradually and then immediately decreases, spending only a short time at maximal airflow. Expiratory time is prolonged relative to flow-limited conditions (the two *left panels*), and inspiration is a smaller percentage of the respiratory cycle.

of each breath's PTAF signal while also recording a pneumotachograph and supraglottic pressure signal (a gold standard assessment of airflow vs. driving pressure). They used a computer algorithm to classify each PTAF inspiration as non-flow-limited (sinusoidal in shape and resembling the airflow signal in the right panel of Figure 112-2), flow-limited (having a clear plateau and resembling the airflow signal in Figure 112-1 and the left panel of Figure 112-2), or intermediate (not sinusoidal but not fulfilling their program's criteria for an inspiratory plateau). The PTAF signal clearly separated their asymptomatic controls without OSA from their OSA patients, with the former having fewer flow-limited events. In a similar study of seven habitual snorers, Clark and associates[11] found that an inspiratory airflow plateau determined by PTAF identified flow-limited inspirations with a sensitivity and specificity of approximately 80%. Thus PTAF evidence of a clear inspiratory airflow plateau is a reasonably reliable method for identifying IFL during clinical polysomnography.

The ability to recognize IFL during diagnostic polysomnography, whether in-laboratory or during out-of-center sleep testing (OCST), can also be aided by the findings of Schneider and associates: During IFL, the ratio of the inspiratory time to the time of the entire respiratory cycle (i.e., the "duty cycle") is prolonged.[12] This distinction is illustrated in Figure 112-2, where four flow-limited inspirations (left panel) take up a larger portion of the respiratory cycle time than the non-flow-limited inspirations (right panel), where expiratory time is more prolonged. During IFL, the inspiratory airflow increases rapidly and remains near maximum throughout most of inspiration (left panel), maximizing the tidal volume under the flow-limited conditions. During the *non*-flow-limited breaths (right panel), the increase in inspiratory airflow is more gradual, and airflow remains near maximal for a shorter portion of inspiration.

Figure 112-3 represents both IFL and *non*-flow-limited breathing in a single patient with UARS undergoing nasal CPAP titration. In the absence of a supraglottic pressure signal, IFL can be recognized by the change in the airflow tracing between the two left panels recorded at CPAP levels of 4 and 5 cm H_2O demonstrating IFL, and the right panel recorded at a CPAP of 6 cm H_2O illustrating non-flow-limited airflow at therapeutic CPAP. At 4 and 5 cm H_2O, the flow-limited inspiratory airflow tracing is characterized by a rapid increase in airflow to a maximum followed by a prolonged plateau at maximal flow. At 6 cm H_2O, the non-flow-limited inspiratory airflow increases more gradually without a subsequent plateau, but a rapid decrease of airflow and a shorter ratio of inspiratory time to respiratory cycle time (exhalation is prolonged relative to flow-limited conditions). Thus, in the absence of a supraglottic pressure signal, both the shape and the relative duration of the inspiratory airflow tracing provide evidence for the presence of IFL.

Figure 112-4, a 30-second epoch of sleep from a patient with UARS, provides examples of overt IFL, more subtle IFL,

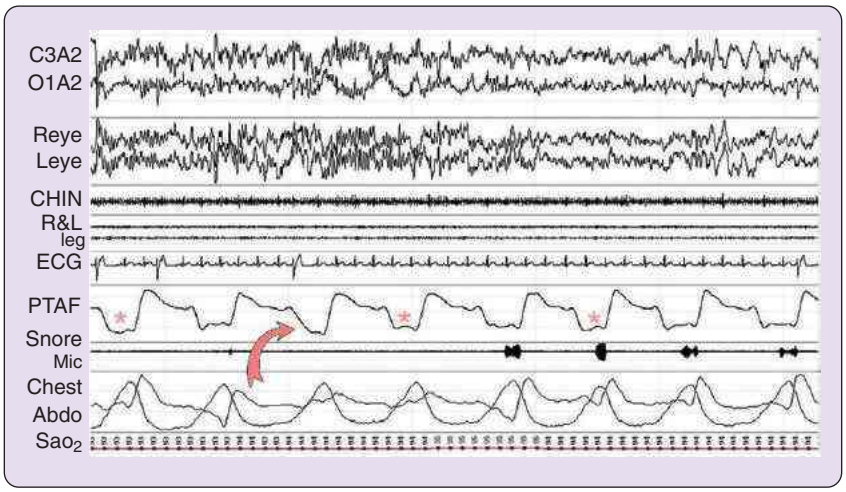

Figure 112-4 This figure demonstrates a 30-second epoch of NREM stage 2 (N2) sleep containing eight consecutive breaths representing both overt and subtle (*asterisks*) inspiratory airflow limitation and a *non*-flow-limited breath (*arrow*). The sleep parameters recorded include electroencephalograms (EEGs; C3A2, O1A2), electrooculograms (EOGs; Reye & Leye), superficial electromyogram of the chin (CHIN), superficial electromyograms of the right and left tibialis anterior (R & L_{leg}), and ECG. The respiratory parameters recorded are labeled similarly to those in Figure 112-3. Refer to the text for a complete characterization of the breathing.

and *non*-flow-limited breathing. Although several breaths in Figure 112-5 demonstrate the rapid increase in inspiratory airflow and long inspiratory airflow plateau of IFL, several (marked by an asterisk) demonstrate a less prolonged plateau of inspiratory airflow. The presence in these breaths, however, of a rapid increase in inspiratory airflow followed by a short plateau, as well as the accompanying snoring (recorded by microphone) for one of the breaths, can be used to identify all of these as examples of subtle IFL compared with the one *non*-flow-limited inspiration (marked by an arrow). Viewed from the perspective of respiratory cycle time, one can also appreciate that the *non*-flow-limited breath is preceded by the longest expiration and the ratio of inspiratory time to respiratory cycle time for the breath is lower than for the flow-limited breaths in the figure.

To summarize, in the absence of a supraglottic pressure catheter, IFL can be recognized, using a nasal pressure signal, as a plateau in inspiratory airflow and a prolongation of inspiratory time relative to total respiratory cycle time. Inspiratory airflow can be observed to rise rapidly to a maximum and to remain there for most of inspiration. From the figures provided, it can also be inferred that snoring, the audible manifestation of the fluttering pharyngeal airway characterizing IFL, is not as sensitive an indicator of IFL as the combined airflow and driving pressure criteria (Figures 112-1 and 112-2) or the airflow tracing alone. Figure 112-1, which in fact is a tracing of a lean female with no history of snoring, demonstrates definitive evidence of IFL determined by her airflow and supraglottic pressure recordings. In Figure 112-3, nasal CPAP of 5 cm H_2O resolves the patient's snoring before the airflow tracing demonstrates resolution of IFL at 6 cm H_2O. Figure 112-4 demonstrates five breaths clearly characterized by the airflow plateau associated with IFL, only four of which demonstrate snoring. For this reason, the presence of snoring should not be relied on to determine whether a patient with sleepiness or fatigue has sleep-disordered breathing. Even in the absence of apneas and hypopneas, silent IFL (defined in the glossary) associated with arousals (RERAs) may be prevalent enough to establish a diagnosis of OSA when using ICSD3 criteria, or UARS, using the criteria of sleepiness or fatigue in the presence of IFL as presented in the glossary. Similarly, the absence of snoring should not be relied on to determine whether a nasal CPAP level is therapeutic (i.e., has eliminated IFL). Rather, the polysomnographer, sleep medicine physician, and polysomnographic technologist should differentiate IFL during sleep from non-flow-limited inspiration using an airflow signal generated by either a pneumotachograph or a PTAF signal and determine therapeutic nasal CPAP as the pressure that eliminates IFL (as demonstrated in Figures 112-2 and 112-3). A CPAP level that eliminates IFL will, of necessity, eliminate all apneas, hypopneas, and RERAs.

PATHOLOGIC UPPER AIRWAY RESISTANCE SYNDROMES: CLINICAL ASPECTS

Snoring

Habitual snoring, as described early in the glossary, can be observed in patients with OSA complaining of daytime sleepiness, fatigue, and insomnia. Habitual snoring may also occur in the absence of symptoms and signs of OSA and without an RDI (a frequency of apneas, hypopneas, and RERAs) adequate to establish a diagnosis of OSA in the absence of symptoms—that is, an RDI of 15 per hour. In the latter instance, according to the ICSD3, it is regarded as "isolated snoring," listed in the category of sleep-related breathing disorders. This isolated snoring was previously referred to as habitual, simple, or primary snoring in the category of other parasomnias in the ICSD2.

As already noted, snoring is a sleep-related sound caused by vibration of soft tissue in the upper airway under conditions of IFL. In most individuals with isolated snoring, the snoring is limited to inspiration, although early expiratory snoring or snoring throughout expiration can occur.[13] Whether occurring during inspiration or expiration, snoring is generated by high-frequency opening and closing (fluttering) of

upper airway structures, including the tongue base and soft palate, aided by the adhesive properties of mucosal secretions. Acoustic studies have shown that the major frequency content of snoring is below 2000 Hz, with peak power below 500 Hz[14] (thus in the frequency range able to be heard by humans). Snorers experience increased total pulmonary resistance during sleep related to reduced upper airway muscle tone causing IFL and leading to increased inspiratory effort.[15]

There is, understandably, considerable variation in the prevalence figures reported for habitual snoring. Studies differ in how the study population is selected, with some determining a prevalence of isolated snoring and others including habitual snorers with OSA. Studies also differ in how snoring is assessed. S*ubjective* assessment has been conducted using the report of bed partners, but clinical experience indicates that a few snorers hear their own snoring, especially during sleep-wake transitions. *Objective* measurement relies on the use of calibrated monitoring devices either during polysomnography or in a setting outside a sleep disorders center. Patients also document their own snoring using recording applications for smart devices such as cellular phones. In addition to differences in methodology regarding diagnoses and snoring assessment, differences in gender and obesity distribution between studies may affect snoring prevalence significantly. Both gender and obesity can affect upper airway resistance (alternatively, collapsibility, assessed as the pharyngeal Pcrit) either by structural changes or neuromuscular mechanisms. Therefore the variability of study design is one reason for the varied prevalence figures for habitual snoring seen in the literature.

Further complicating a determination of the prevalence of snoring is the observation that, within individual patients, the severity of subjective snoring reported by the bed partner does not correspond with either objectively assessed snoring or the subjective assessment of the sleep technician monitoring the patient.[16] Data from Somnolab Sleep Disorders Center in Dortmund, Germany show that 28% of individuals reporting habitual snoring at home fail to present significant snoring during in-laboratory polysomnographic recordings (unpublished data). This may, in part, be due to considerable night-to-night variability of snoring intensity. Interventional studies have demonstrated that time spent snoring and snoring volume within one individual can vary from night to night depending on factors such as sleeping position, medications, alcohol intake, and cumulative or acute sleep debt. Alternatively, the discrepancy observed between a bed partner's report of snoring severity and that observed during in-laboratory polysomnography could be due to allergens in the home environment altering upper airway pressure-flow relationships. Also, discrepancies between snoring reported by a bed partner and that measured during polysomnography can be observed in patients who have had a recent change in bed partner, suggesting either differences among bed partners in sensitivity to the noise or in willingness to complain.[17]

As discussed earlier, prevalence data for snoring often come from study samples containing both individuals with isolated snoring and those with OSA. The 2011 Centers for Disease Control and Prevention report on unhealthy sleep behaviors, one such study, reports a snoring prevalence of 48% based on a telephone survey.[18] The report does not indicate how many of the snorers in this survey complained of hypersomnolence or other symptoms of OSA. Furthermore, the report does not specify the snoring severity of those individuals labeled as snorers: intermittent versus habitual. Based on data from the Sleep Heart Health Study, a sample of 5615 community-dwelling adults between the ages of 40 and 98 years, 13% of the participants had an AHI of less than 5/hour and reported *habitual* snoring (3 to 7 nights/week).[19] These data estimate a prevalence of habitual snoring without OSA of less than 15% in a community sample. Symptom data, however, are not provided and so one cannot determine a prevalence of isolated snoring. Of note, 29% of the 5615 men and women did not know whether they snored (perhaps because of absence of bed partner). Although the previous two examples illustrate the difficulty investigators have in determining the prevalence of habitual and isolated snoring, it remains clear that snoring is a common phenomenon that frequently prompts a referral for a sleep evaluation to establish a diagnosis of OSA.

When a habitual snorer presents for a sleep evaluation, polysomnography is warranted if witnessed apnea, hypersomnolence, fatigue, insomnia, somatic syndromes typically described among UARS patients (discussed in the next section), or comorbidities such as metabolic syndrome, cardiac dysrhythmia, or atrial fibrillation are present. In this case, polysomnography may lead to treatment of OSA when the ICSD3 diagnostic criteria for OSA are met. Habitual snoring in the absence of witnessed apnea, symptoms or syndromes, or comorbidities (after appropriate screening for comorbidities) does not automatically warrant a polysomnogram. Habitual snoring is a common occurrence among middle-aged, overweight men, and polysomnographic evaluations of *all* habitual snorers carries a very high cost-to-benefit ratio. A more practical approach would be to monitor asymptomatic, healthy habitual snorers over time for the development of signs and symptoms that would support obtaining polysomnography. Alternatively, OCST can be used to rule out moderate to severe OSA in asymptomatic, healthy habitual snorers in need of reassurance.

The rationale for not obtaining polysomnography in asymptomatic, healthy habitual snorers extends beyond the issue of costs, to a consideration of benefit. Specifically, even if such an individual fulfills ICSD3 criteria for OSA, the question is whether such an asymptomatic, healthy individual is in fact in need of treatment. To the contrary, cross-sectional polysomnographic data from an investigation by Pavlova and associates[20] of 163 asymptomatic, nonobese individuals screened for the absence of metabolic syndrome and cardiovascular disease (25% reporting "some" snoring) demonstrate that many such individuals have RDIs above 15/hour, fulfilling ICSD3 criteria for OSA. Indeed, the mean RDI for individuals older than 65 years was 22 per hour in Pavlova's study.[20] Similar data exist in three studies comparing inspiratory airflow dynamics during sleep between patients with somatic syndromes[21,22] and UARS[23] with those of rigorously screened healthy controls. For the three studies, 4 (11%) of 35 healthy controls (14 men and 21 women) met the ICSD3 threshold for OSA that would justify their treatment without symptoms or comorbidities (RDI ≥15/hour). Another 4 of the healthy controls had values of RDI between 10/hour and 15/hour, approximating the threshold for treatment. Thus, in the absence of data demonstrating a health risk from habitual snoring alone, a prudent approach to polysomnographic evaluation can be justified.

Before leaving the subject of whether to treat asymptomatic, habitual snorers without comorbidities, a word of caution is appropriate. In 110 overweight volunteers with snoring and mild OSA (27% smokers, 27% with hypertension, and 69% with hyperlipidemia), Lee and associates[24] demonstrated that the amount of time spent snoring was correlated with the extent of asymptomatic carotid artery stenosis independent of AHI and histories of other comorbidities. These findings suggest that in individuals predisposed to atherosclerosis (by smoking, hypertension, or hyperlipidemia), habitual snoring may be an *additional* risk factor for developing carotid artery atherosclerosis. On the other hand, data from a recently published study with a 17-year follow-up of 380 community-dwelling adults failed to document a significant relationship between objectively measured nocturnal time spent snoring and all-cause mortality from cardiovascular disease.[25] In the absence of certainty about the effects of habitual snoring, one should evaluate (beginning with noninvasive methods) an asymptomatic, habitual snorer without metabolic syndrome or atrial fibrillation for evidence of atherosclerosis before deciding that the patient is not in need of treatment and can be followed over time.

Asymptomatic, healthy individuals seeking treatment for habitual snoring or isolated snoring (following polysomnography because of reports of witnessed, or patient-perceived, apnea) will usually do so because they are concerned about the disruption of their bed partner's sleep. Any treatment that will lower the pharyngeal Pcrit, reducing the occurrence of IFL, will also have a beneficial effect on audible snoring. A wide variety of over-the-counter remedies are available for snoring, but they are of limited efficacy. A report of the American Academy of Sleep Medicine Clinical Practice Review Committee published in 2003 summarizes the absent or limited benefits of products such as nasal dilators, lubricants, oral dietary supplements, and magnetic pillows and mattresses.[26] In contrast to these ineffective treatments, any effective treatment used for OSA will be effective for asymptomatic snoring. Among these treatments, few isolated snorers choose nasal CPAP, considering it a burden to use and to maintain.

Successful or partially successful treatment of isolated snoring has been reported using lifestyle modifications. A lifestyle modification like weight reduction (by diet or bariatric surgery) can be an effective treatment for snoring because it can substantially lower pharyngeal Pcrit.[27] Because there are no "dose-response" data concerning the effect of weight loss on snoring intensity (loudness), the weight loss target should be based on factors like the pretreatment body mass index and the weight loss needed to obtain other expected health benefits. Although weight loss can effectively decrease the intensity of snoring, long-term maintenance of reduced weight is often unsatisfactory. For this reason, weight loss in combination with increased physical activity may be a more desirable approach. There is an independent, beneficial effect of physical activity on self-reported snoring in obese women.[28] Another lifestyle alteration that can decrease the intensity of snoring is avoiding alcohol consumption before going to bed. In a small group of otherwise asymptomatic snorers, Riemann and colleagues demonstrated that presleep alcohol ingestion increased the objectively measured incidence and loudness of snoring in a dose-dependent manner.[29] Other lifestyle modifications that can reduce snoring include avoiding sleep deprivation and the use of sedative-hypnotic medications.

Oral mandibular advancement appliances have been used successfully for the treatment of mild to moderate OSA and asymptomatic snoring in patients with a healthy dentition. Good results can be achieved with 50% to 75% of maximal voluntary protrusion. For patients with an insufficient number of healthy teeth, a tongue-retaining device may be a good alternative. Patients should be advised that snoring may not be completely abolished, but significant reductions in the time spent snoring and snoring intensity can be obtained.

Surgery can be performed for isolated snoring to decrease its occurrence and intensity. Surgical targets include the nasal turbinates and septum, the nasopharynx, oropharynx, tongue base, and hypopharynx. Sleep nasendoscopy with a flexible endoscope is increasingly used to perform a preoperative assessment of possible surgical targets. For this procedure, anesthesia is used to simulate sleep. At this time the data regarding the value of nasendoscopy before surgical treatment of snoring are indeterminate. The surgical method depends on the surgeon's preference and the availability of equipment, but procedures are performed using a scalpel, radiofrequency ablation, and YAG laser. Studies assessing the efficacy of these procedures have typically shown good immediate and short-term results. However, many of these studies have relied only on subjective assessments of snoring. A study on the subjective versus the objective improvement of snoring following palatal surgery published in 1994 did not find any objective improvement in snoring despite a subjective improvement in more than 75% of the participants.[30] In a more recent study, palatal surgery for isolated snoring improved subjective (questionnaire) and objective (sound analysis of 100 supine snorers before and after surgery) evaluations of snoring. However, the objective improvement was short-lived and correlated poorly with the subjective improvement on an individual basis.[31] A recent, long-term study evaluating patients treated with palatal surgery between 1985 and 1991 found a substantial rebound of snoring even in the absence of weight gain. In addition, 38% of the patients continued to experience surgical side effects (swallowing dysfunction, altered voice, and pain) that left them dissatisfied with the decision to have palatal surgery.[32]

Surgery intended to relieve nasal obstruction alone does not produce a significant improvement of objectively assessed snoring intensity and snoring time, nor does it decrease the AHI, despite improvement in nasal resistance.[33]
