(CT), magnetic resonance imaging (MRI), and three-dimensional studies of the upper airway using cone beam CT (CBCT) scans.[24-28] In addition, cephalometric analysis can be performed.[28-30,30a] More recently, computational models of the upper airway based on CT or MRI have been introduced to simulate the effects of upper airway manipulations and to predict success of various treatment options.[17,31-34]

The different techniques available for investigation of the upper airway all have their specific advantages and limitations.[20] Differences among the various techniques include aspects on invasiveness, exposure to radiation, costs related to the examination, and potential side effects.[20,22,35] In addition, a crucial question of whether the upper airway behaves differently during wakefulness versus during natural sleep remains unanswered to date.[36] Inasmuch as OSA occurs exclusively during sleep, it would be ideal to evaluate the upper airway during a full night of natural sleep; such investigation during natural sleep, however, is of limited feasibility, owing to the associated sleep disruption and the labor-intensive nature of such studies.

The technique of drug-induced sedation endoscopy (DISE), first described as "sleep nasendoscopy" by Croft and Pringle in 1991, has emerged as an alternative method to dynamically investigate the upper airway before non-CPAP treatment selection in patients with OSA.[13,36-38] Drugs typically used for DISE include propofol, midazolam, dexmedetomidine, and/or ketamine.[36,39] In a comparison of DISE with awake endoscopy, identical findings were observed in only 25% of the cases.[40] In this particular study reporting on 250 patients with OSA, the discrepancies between awake endoscopy and DISE involved the oropharynx in 33%, the hypopharynx in 50%, and the larynx (e.g., epiglottis) in 33% of the patients.[40] These findings have important implications for surgical treatment choices, especially with operations involving the tongue base.[41]

Recent studies indicate that both inter- and intra-rater reliability of DISE are reasonably good but that experience in performing DISE is needed in order to obtain reliable observations.[42-44] Much investigation, standardization, and optimization of DISE techniques are needed regarding factors such as method of sedation, depth of sedation, patient position, use of airway anaesthetics, duration of observation, and others.[36] In the literature, no consensus exists on a standard DISE classification system or quantification of degrees of collapse or obstruction; in Figure 149-2, a generic scoring form is depicted.[44]

Several studies confirm that the most frequent site of upper airway obstruction in patients with OSA is the palatal level[23,38,45]; however, a majority of patients with OSA have other sites of obstruction as well (multilevel collapse).[23,27] The probability of multilevel collapse increases with increasing OSA severity and with an increased level of overweight or obesity.[23] Logically, resolution of pharyngeal collapse at all levels involved in the upper airway collapse during sleep will be necessary to achieve successful management in the individual patient with OSA undergoing surgery.

Surgical Upper Airway Modifications

A schematic overview of several different site-specific techniques available for surgically modifying the upper airway in patients with OSA is provided in Table 149-2.

Nasal Surgery

Depending on the anatomic or functional abnormalities at the level of the septum, turbinates, and nasal valves, nasal surgery can be indicated to correct nasal obstruction. However, nasal surgery including septoplasty, septorhinoplasty, turbinate reduction, and nasal valve surgery usually is insufficient to treat OSA and cannot be recommended as a stand-alone procedure for the management of OSA in most patients.[46] On the other hand, nasal surgery might be performed in patients with nasal obstruction that experience problems with the use of CPAP or oral appliance therapy because of these nasal

complaints in order to improve adherence to treatment.[47] Successful nasal surgery may also be associated with a reduction in therapeutic CPAP pressure required to alleviate OSA.[48,49] Accordingly, a recent systematic review with meta-analysis of the existing literature on the relationship between nasal surgery and its effect on therapeutic CPAP pressure has been performed by Camacho et al.[50] The authors concluded that, indeed, isolated nasal surgery in patients with OSA associated with nasal obstruction reduces therapeutic CPAP pressures and that the data consistently suggest that isolated nasal surgery in these selected patients also increases CPAP use.[50]

Pharyngeal Surgery

The most commonly used surgical treatments for OSA are aimed at the pharyngeal airway where collapse and obstruction occur. It is important to recognize that an isolated single-level pharyngeal procedure would not be expected to solve multilevel obstruction. In cases of multilevel obstruction, isolated procedures might have a partial treatment effect or be one part of a multilevel treatment plan (e.g. staged surgery or multiple procedures). Adenotonsillar hypertrophy is the most common cause of OSA in children but a rare cause of OSA in adults.[46] As a consequence, adenotonsillectomy is the first-line therapy for nonobese children with OSA. In adult patients with OSA, (adeno)tonsillectomy can be recommended in the presence of (adeno)tonsillar hypertrophy with an expected reduction in sleep respiratory disturbances and improvement in architecture.[50a]

Uvulopalatopharyngoplasty (UPPP) is the most commonly performed pharyngeal surgical procedure for the treatment of OSA.[51] The classical UPPP procedure consists of partial excision and closure of the soft palate, uvula, and pharyngeal pillars, as well as tonsillectomy, if not previously performed[51] (Figure 149-3). A pooled data analysis of the literature (predominantly case series) published in 1996 revealed that UPPP had an overall success rate (i.e., reduction of AHI by more than 50%, with less than 20 events per hour of sleep, or reduction of apnea index by more than 50%, with less than 10 events per hour of sleep) of only 41% in unselected patients with OSA, but selecting patients with appropriate anatomy had an important impact on polysomnography outcomes.[18] When DISE is added to the diagnostic workup and preoperative evaluation for patient selection, it has been demonstrated that the success rate of UPPP increases over that for historical control data.[52] Recently, a randomized controlled trial comparing a modified UPPP with surgery delay showed a major reduction in OSA severity in the UPPP group compared with the control group (mean AHI reduction of 60%, versus 11%).[53] More important, UPPP improves clinical outcomes such as mortality risk, cardiovascular disease risk, motor vehicle crash risk, symptoms, and quality of life.[4,9,10,54-58]

The many variations of UPPP published in the literature aim to improve effectiveness, reduce surgical morbidity, and target specific patterns of collapse or obstruction. Examples are the uvulopalatal flap (UPF) technique, expansion sphincter pharyngoplasty, transpalatal advancement pharyngoplasty, and lateral pharyngoplasty.[59-61] The advantage of the UPF is that it is a potentially reversible flap that can be taken down if necessary to reduce the risk of nasopharyngeal incompetence; the technique comes with less postoperative side effects as there are no sutures and scar along the free edge of the palate[60] (Figure 149-4). The expansion sphincter pharyngoplasty (ESP) addresses lateral oropharyngeal or velopharyngeal collapse[62] (Figure 149-5). The early results with ESP are promising, and minimal complications have been reported with the procedure.[62] Transpalatal advancement pharyngoplasty is aimed at addressing anterior-posterior narrowing of the velopharynx, especially in concert with a long hard palate and vertically oriented soft palate.[59] The technical details and the wide array of UPPP variations are beyond the scope of this discussion.

Laser-assisted uvuloplasty (LAUP) is an office-based surgical procedure that progressively shortens and tightens the uvula and palate through a series of CO_2 laser incisions and vaporizations. This technique has not demonstrated consistent effect or benefit on OSA severity or symptoms or on quality of life measures and therefore, also in accordance with the practice parameters of the American Academy of Sleep Medicine (AASM), LAUP is not recommended for the management of OSA.[46,63]

Radiofrequency ablation (RFA) can be used to reduce or stiffen soft tissues. RFA of the palate is considered to be a minimally invasive surgical outpatient clinic procedure that decreases socially disturbing snoring as reported by the partner

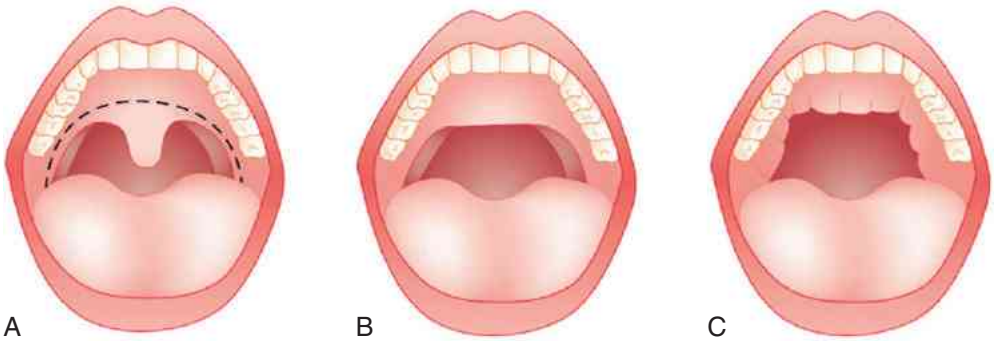

Figure 149-3 Classical uvulopalatopharyngoplasty technique. **A,** Redundant soft palate and pharyngeal pillar mucosa are outlined. **B,** Tonsils, pharyngeal pillar mucosa, uvula, and soft palate have been excised. The extent of soft palate excision is determined by placing traction on the uvula and noting the position of the mucosal crease. **C,** Mucosal flaps of the lateral pharyngeal wall and palatal muscle are advanced and closed with absorbable suture. (From Troell RJ, Strom CG. Surgical therapy for snoring. *Fed Pract* 1997;14:29–52.)

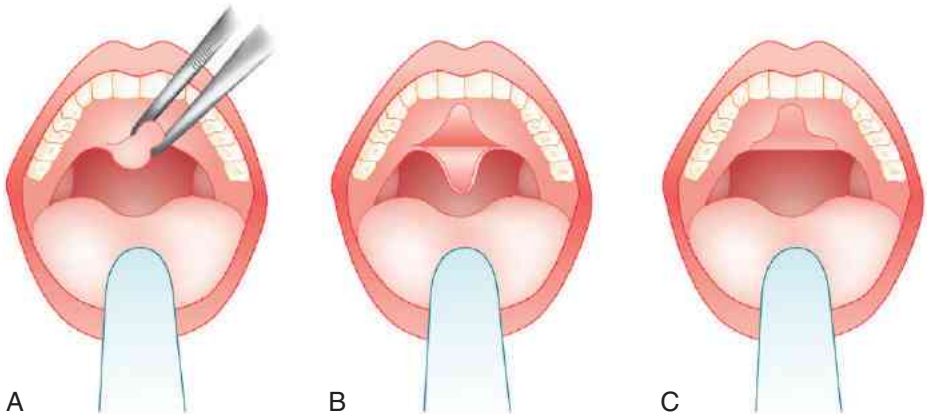

Figure 149-4 Uvulopalatal flap (UPF) technique. **A,** Uvula is reflected to identify mucosal crease of muscular sling. **B,** Knife removes mucosa on proposed flap site. **C,** Wound is closed with a half-buried suture of braided 3-0 Vicryl at the tip of the uvula and simple interrupted sutures along the mucosal closure. (From Troell RJ, Strom CG. Surgical therapy for snoring. *Fed Pract* 1997;14:29–52.)

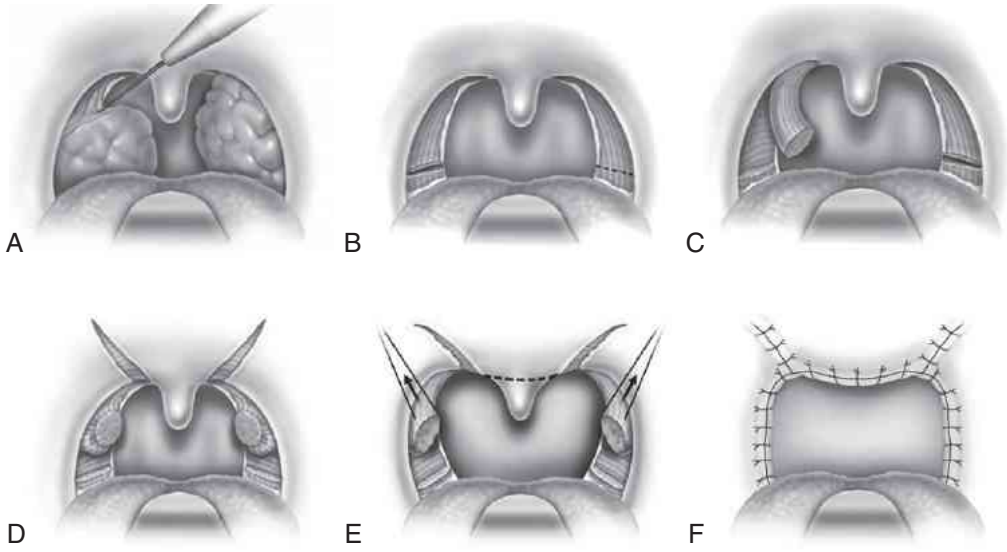

Figure 149-5 Expansion sphincter pharyngoplasty (ESP) technique. **A,** Tonsillectomy is performed. **B,** Horizontal incision made to divide the middle part of the palatopharyngeus muscle. **C,** The palatopharyngeus muscle is mobilized, although not completely, with care taken to leave its fascia attachments to the deeper horizontal constrictor muscles. **D,** Superolateral incision made on the soft palate, revealing the arching fibers of the palatini muscles. **E,** Vicryl sutures are used to hitch up the palatopharyngeus muscle to the soft palate muscles superolaterally. **F,** Closure of the palatal incisions. of the patient. RFA of the palate has minimal effect on OSA severity, however, so it is not recommended as a single-stage procedure for the management of OSA.[46,64-67]

Taken together, the available evidence on pharyngeal procedures that address the palatal level suggests that UPPP and its variations can be applied in well-selected patients, whereas both LAUP and RFA of the palate are not recommended for the management of OSA.[52,53,57,63,64]

RFA tongue reduction is a minimally invasive technique for decreasing tongue volume when tongue hypertrophy contributes to the OSA.[68] When combined with RFA of the palate in patients with mild to moderate OSA, the procedure had a significant effect on airway volume, apnea index, and quality of life in a randomized sham placebo-controlled trial.[69] However, the magnitude of treatment effect is modest, especially in patients who are obese or have more severe OSA.[70,71] Consequently, RFA tongue reduction usually is performed as a valuable adjunctive surgical procedure, and not a primary procedure, in the management of OSA.[72,73]

In patients with OSA primarily related to hypertrophy of the tongue base, various techniques of partial glossectomy have led to significant reduction in OSA severity. The original studies describing partial glossectomy for OSA used laser techniques.[74,75] More recently, investigators have obtained good success, with less patient morbidity, using an irrigating, suctioning bipolar device instead of the laser.[76-79,79a] Tongue

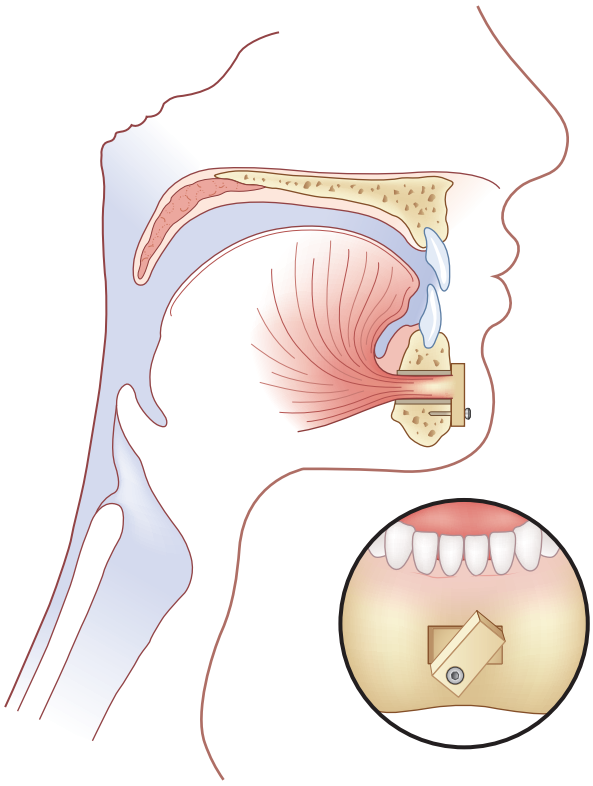

Figure 149-6 Genioglossus advancement. In this procedure, the tongue is placed under anterior traction by performing a limited mandibular osteotomy, with subsequent advancement of the genial tubercle–genioglossus muscle complex. After removal of the buccal cortex and medullary bone, the lingual cortex of the advanced bony segment including the genial tubercle is fixated in its new anterior position (*inset*). (From Riley RW, Powell NB, Guilleminault C. Obstructive sleep apnea and the hyoid: a revised surgical procedure. *Otolaryngol Head Neck Surg* 1994;111:717–21.)

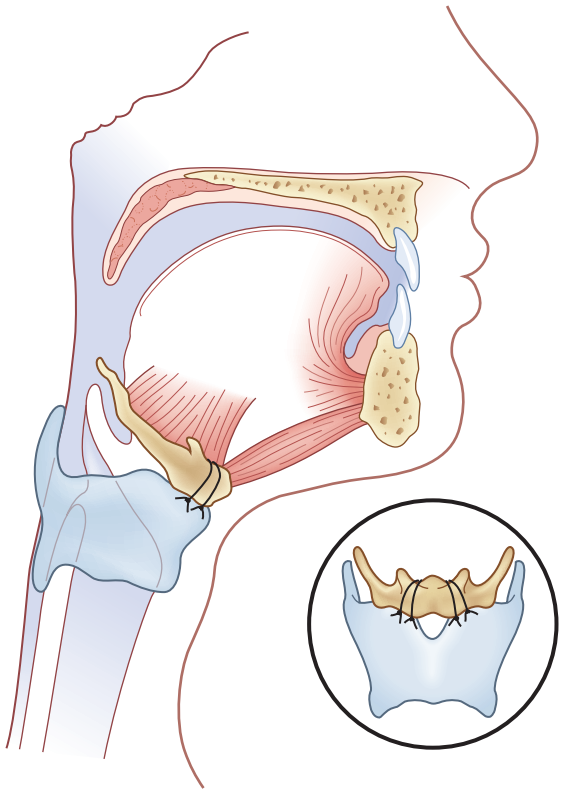

Figure 149-7 Modified hyoid myotomy and suspension (HMS) procedure. The hyoid bone is isolated, the inferior body is dissected clean, and the major portion of the suprahyoid musculature remains intact. The hyoid is advanced over the thyroid lamina and immobilized with sutures placed through the superior aspect of the thyroid cartilage (*inset*). (From Riley RW, Powell NB, Guilleminault C. Obstructive sleep apnea and the hyoid: a revised surgical procedure. *Otolaryngol Head Neck Surg* 1994;111:717–21.)

reduction achieved using transoral robotic surgery (TORS) techniques also has been proved to be feasible, low-risk, and well tolerated.[80-82] As with most surgical upper airway modification techniques, it has been shown that the preoperative BMI predicts treatment success using TORS for OSA management.[83]

Another treatment approach to manage tongue obstruction is to advance or stabilize the tongue using various techniques. Genioglossus advancement uses the forward placement of the geniotubercle to place sufficient tension on the tongue, preventing it from collapsing (Figure 149-6). Hyoid suspension or hyoidthyropexia for the treatment of OSA consists of securing the hyoid arch anteroinferiorly to the thyroid lamina, with or without hyoid myotomy (Figure 149-7). Alternatively, the hyoid bone can be suspended from the mandible using any of various methods. Genioglossus advancement and hyoid suspension are rarely performed in isolation, so assessment of isolated effectiveness is difficult. Suture-based tongue suspension procedures aim to tether the tongue to the mandible by means of sutures, ribbons, or barbs.[84] Adjustable tongue advancement, effected through placement of a tissue anchor in the tongue base and an adjustment spool at the mandible, and of a tetherline to suspend the tongue, was reported to be feasible and well tolerated, but further research is needed on the efficacy of this novel procedure.[85,86] Tongue suspension should be considered in patients with OSA who demonstrate tongue base obstruction. As a stand-alone procedure, its success rate is only 36.6%,[84] possibly related to the multilevel obstruction common in OSA. In addition, tongue suspension is effective and safe as part of a multilevel surgical approach for patients with OSA.[84]

Various case series have shown mixed results with the various hypopharyngeal procedures, but most demonstrate at least partial effectiveness.[84,87-89] As a result, consensus is lacking regarding which procedure is best used to address hypopharyngeal obstruction in OSA, because individual anatomy and obstruction patterns are indications for different types of procedures. For example, tongue hypertrophy might best be treated with tongue reduction (e.g., partial glossectomy), whereas tongue collapse might be more readily treated with tongue advancement or stabilization (e.g., genioglossus advancement, hyoid suspension, tongue suspension). The previously described surgical procedures are site-directed to specific areas of the upper airway. Often these procedures are combined in various ways to address multilevel obstruction. Other surgical procedures also have a multilevel effect on the airway and are indicated in specific circumstances. As described next, neuromuscular upper airway stimulation therapy, especially with electrical stimulation of the hypoglossal nerve, is a new multilevel treatment that activates pharyngeal airway dilator muscles to enlarge the lower pharynx and indirectly can stabilize the upper pharynx.[90-92] MMA, also described

further on, has a multilevel effect by enlarging the anterior-posterior dimensions of the upper and lower pharynx and stabilizing lateral wall collapse.[93]

Upper Airway Neurostimulation Therapy

Direct electrical stimulation of the hypoglossal nerve, which innervates the intrinsic and extrinsic muscles of the tongue, during sleep, to restore or maintain upper airway patency, is an experimental therapy for OSA with a history of 20 years of research and development.[90,94-98] From a pathophysiologic standpoint, selective stimulation of the hypoglossal nerve during sleep may provide an interesting approach to management of OSA based on the restoration or improvement of upper airway dilator muscle activity during sleep.[90,91]

The feasibility of and therapeutic potential for chronic hypoglossal nerve stimulation using a first-generation system (Inspire 1, Medtronic, Inc., Minneapolis, Minnesota) in patients with OSA were investigated in a multicenter study.[97] Eight patients with OSA received this first-generation, fully implantable pulse generator (IPG) triggered by a pressure sensor, located at the sternum, detecting respiratory effort. Electrical stimulation was sent from the IPG to the hypoglossal nerve by way of a stimulation lead containing a half-open cuff around the nerve.[97] Throughout the entire study, unilateral hypoglossal nerve stimulation decreased the severity of OSA. After a minimum follow-up period of 6 months, all patients tolerated long-term stimulation, and no adverse effects were noted.[97]

On the basis of this first experience, the safety and therapeutic feasibility as well as the efficacy of three different second-generation hypoglossal nerve stimulation devices have been explored in recent clinical studies. Three types of systems were analyzed in these studies: the HGNS (Hypoglossal Nerve Stimulation) system (Apnex Medical, Inc., St. Paul, Minnesota), the Aura6000 system (ImThera Medical, Inc., San Diego, California), and the Inspire II Upper Airway Stimulation (UAS) device (Inspire Medical Systems, Inc., Maple Grove, Minnesota). Early results of these studies have been published and confirm the safety and feasibility of the second-generation implantable systems for upper airway neurostimulation therapy for OSDB.[94,95,98] The primary component in all three systems is an IPG. Furthermore, the main difference between the three systems is that with the Aura6000 system, the stimulation onto the body of the proximal hypoglossal nerve from the multielectrode lead is continuous, obviating the need for respiration-sensing leads, whereas with the two other systems, the HGNS system and the Inspire II UAS device, the hypoglossal nerve stimulation will be intermittent and synchronized with the signal of the respiration-sensing leads that measure the respiratory cycle.[94,95,98] Among other differences, during the surgical technique for the Inspire II UAS system, the cuff section of the stimulation lead needs to be placed on the medial division of the distal hypoglossal nerve, thereby aiming at selective stimulation of the protrusor muscles of the tongue only.[90,92] Subsequently, appropriate placement of the stimulation lead needs to be confirmed by observing tongue protrusion during stimulation and by electromyographic monitoring during surgery.[90] The identification of patients with OSA who are more likely to benefit from upper airway neurostimulation therapy has been an important part of the research agenda.[98,99] Recent data suggest that responders to this therapy have a body mass index (BMI) of 32 kg/m^2 or less and AHI of 50 or below (i.e., fewer than 50 events per hour of sleep).[98] In addition, the absence of complete concentric collapse at the level of the palate as documented during DISE may predict therapeutic success with implanted upper airway neurostimulation therapy (Figure 149-8).[98,99] Therefore DISE can be recommended as a patient selection tool for use of implanted upper airway stimulation therapy for OSA.[99]

Although the early experience with stimulation is promising, the study results have been mixed. A prospective randomized trial of upper airway neurostimulation used the HGNS system, but the trial was discontinued in 2013 because the

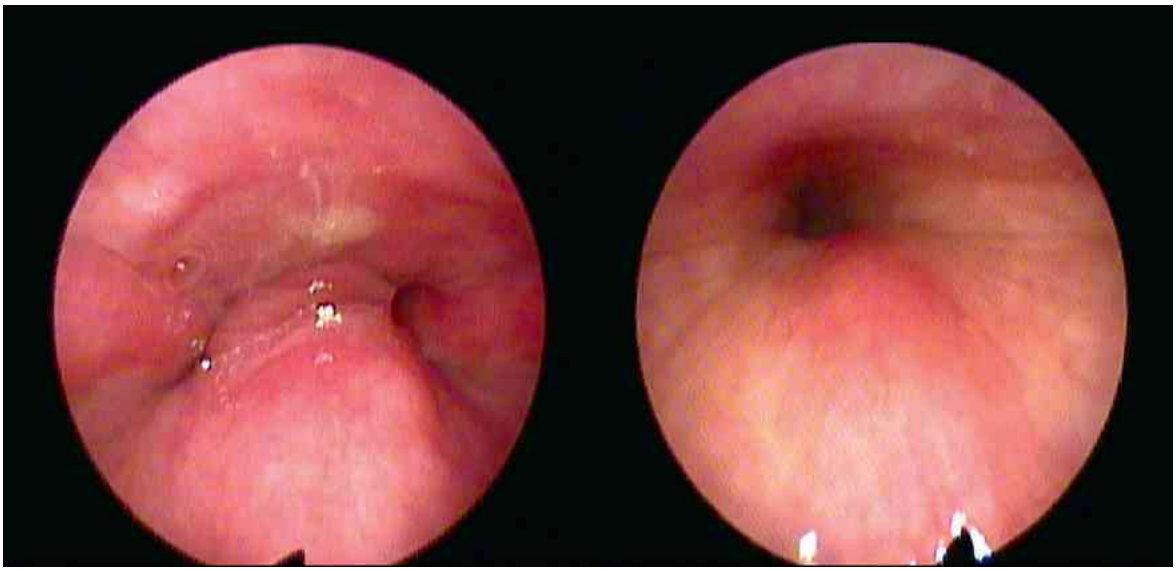

Figure 149-8 Example of anteroposterior (*left*) versus concentric (*right*) collapse at the palatal level during drug-induced sedation endoscopy (DISE). (From Vanderveken OM, Maurer JT, Hohenhorst W, et al. Evaluation of drug-induced sleep endoscopy as a patient selection tool for implanted upper airway stimulation for obstructive sleep apnea. *J Clin Sleep Med* 2013;9:433–8.)

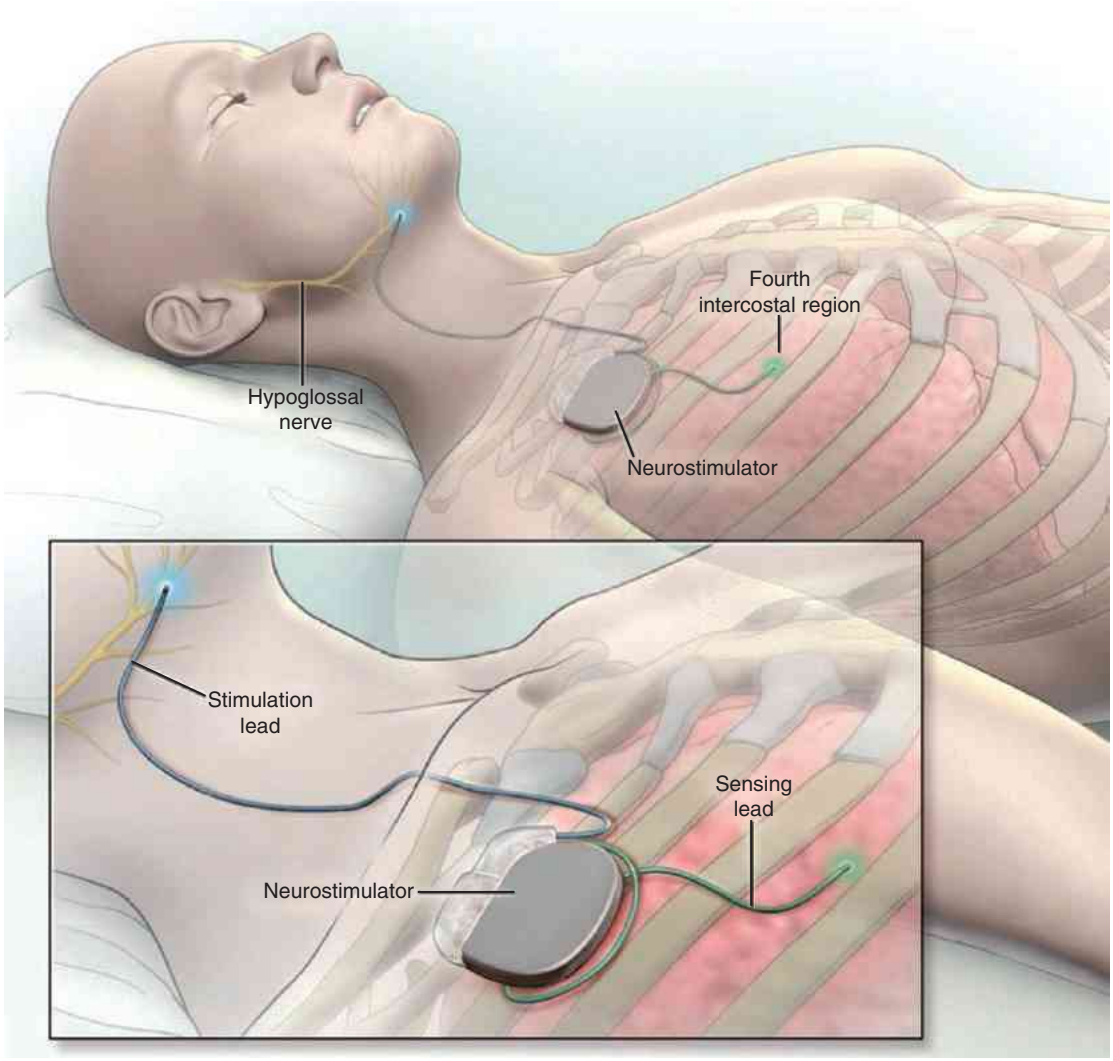

Figure 149-9 Upper airway stimulation using Inspire 2 implant (Inspire Medical Systems). The neurostimulator delivers electrical stimulating pulses to the protruding branches of the hypoglossal nerve through the stimulation lead; the stimulating pulses are synchronized with ventilation detected by the sensing lead. (From Strollo PJ Jr, Soose RJ, Maurer JT, et al. Upper-airway stimulation for obstructive sleep apnea. *N Engl J Med* 2014;370:139–49.)

interim analysis showed that it was unlikely to meet the primary efficacy end point. Apnex Medical, the producer of HGNS and the trial's sponsor, ceased its activity in 2013 because of the nonviable results of that trial (available at ClinicalTrials.gov—https://clinicaltrials.gov/ct2/show/NCT01446601).

More recently, a large multicenter, prospective case series assessed the safety and effectiveness of upper airway neurostimulation therapy using the Inspire II UAS device (Figure 149-9) in 126 well-selected patients with OSA.[90] The results of this pivotal study demonstrated that hypoglossal nerve stimulation led to significant improvements in polysomnographic parameters in 66% of patients, with associated improvements in sleepiness, snoring, and quality of life, in this sample.[90] Unfortunately, exploratory analysis did not yield predictors of failure in the 34% of nonresponders. Serious adverse events (e.g., reoperation) were uncommon, and the side effects, such as tongue irritation, were not bothersome or else resolved in most patients.[90] In a minority of patients, a tooth guard was needed to permit healing of tongue soreness or abrasion related to the overnight tongue protrusion induced by the stimulation.[90] In addition, the results of a randomized, 1-week therapy-withdrawal trial among a subset of responders showed that continuation of stimulation was necessary to maintain the effect (i.e., withdrawal of stimulation led to worsening OSA almost to pretreatment levels).[90] A randomized withdrawal trial in responders, however, should not be confused with a prospective randomized trial like the HGNS trial. The promising results of this multicenter case series assessing the Inspire II UAS device led the U.S. Food and Drug Administration (FDA) to approve the Inspire UAS device for treatment of selected patients with moderate to severe OSA.

The results of a recent systematic review and metaanalysis of the literature indicate that hypoglossal nerve stimulation for OSA is reported to carry low risk of serious complications.[91] The investigators concluded that the available data in literature show high rates of therapy adherence and stable outcome results over 12 months of follow-up in selected patients with OSA.[91,96] Endoscopic findings in a subset of

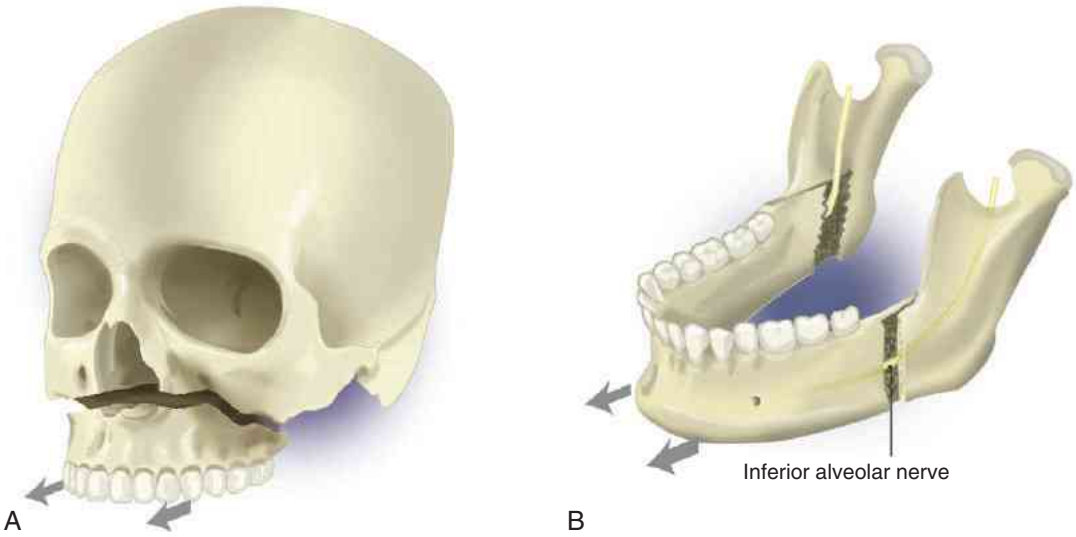

Figure 149-10 Maxillomandibular advancement (MMA) surgery for obstructive sleep apnea syndrome provides enlargement of the upper airway by means of a Le Fort I advancement osteotomy of the maxilla **(A)** and a bilateral sagittal split advancement osteotomy of the mandible **(B)**. (From Rosenberg AJ, Damen GW, Schreuder KE, Leverstein H. [Obstructive sleep-apnoea syndrome: good results with maxillo-mandibular osteotomy after failure of conservative therapy]. *Ned Tijdschr Geneeskd* 2005;149:1223–6.)

patients who underwent upper airway neurostimulation therapy using the Inspire II UAS device revealed that responders had greater retropalatal enlargement with stimulation than nonresponders, and that the neurostimulation increased both the retropalatal and retrolingual cross-sectional areas.[100] This observation of multilevel enlargement induced by upper airway neurostimulation therapy may explain the sustained reductions in OSA severity in two thirds of the selected patients receiving UAS therapy.[90,100] It is important to reiterate that patient selection appears to be critical, and even among carefully selected patients (e.g., BMI of less than 32 kg/m^2, no complete circumferential velopharyngeal collapse, and other criteria), the nonresponder rate is still significant, with no clear predictors.[96] Further research is ongoing and will be necessary to elucidate the optimal roles for this exciting therapy.

SKELETAL MODIFICATIONS

Orthognathic surgery for the treatment of OSA was first described when mandibular advancement surgery was reported to reverse the symptoms of sleep apnea.[101] In 1986, Riley and coworkers were the first to describe the combination of advancement of both maxilla and mandible to improve airway patency in patients with OSA.[102] Although trial-based evidence is still scarce, MMA currently is regarded as a highly effective and safe surgical modality for treatment of OSA.[93] MMA surgery in patients with OSA consists of a bilateral sagittal split osteotomy (BSSO) of the mandible with advancement and a Le Fort I osteotomy of the maxilla with advancement (Figure 149-10). In patients with OSA, MMA surgery generally requires a minimum advancement of the mandible by 10 mm to achieve optimal effectiveness.[103,104] As a consequence of the skeletal advancement, several upper airway muscles and ligaments are repositioned anteriorly,

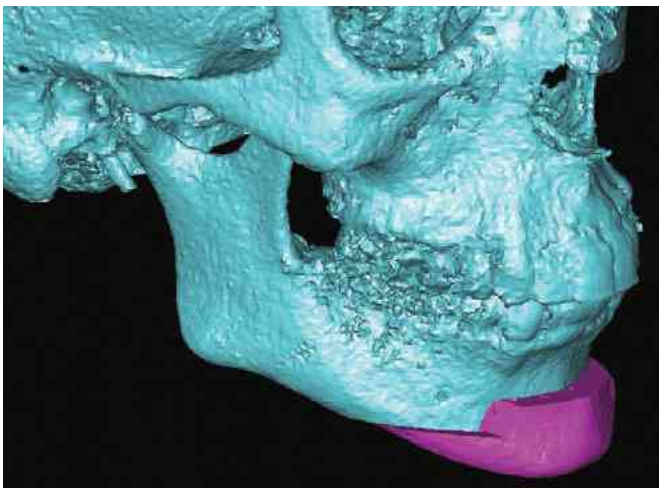

Figure 149-11 Modified genioplasty. In this procedure, the tongue is put under anterior traction by performing a trapezoid-shaped osteotomy with advancement of the chin (*purple*) and the genial tubercle–genioglossus muscle complex.

including the anterior belly of the digastric, mylohyoid, genioglossus, and geniohyoid muscles. The advancement of the maxilla pulls the soft tissue of the palate forward, tightens the palatoglossal and palatopharyngeal muscles, and increases tongue support. Moreover, adding the maxillary advancement also increases the amount of mandibular advancement that can be accomplished with surgery. To achieve additional improvements in oro- and hypopharyngeal airway patency, MMA surgery can be combined with a genioglossus advancement or a modified genioplasty[105,106] (Figure 149-11; see also Figure 149-6). To decrease the cervical fat mass, as appropriate, and to further improve airway patency, cervicomental liposuction may be added to the surgical plan in selected

cases.[106] MMA results in structural enlargement of the nasooropharyngeal airway and enhanced tension and decreased collapsibility of the pharyngeal airway. When these surgical techniques are applied only for OSA and not for dentofacial abnormalities per se, the procedure is referred to as "telegnathic surgery" instead of "orthognathic surgery." For parallel information on orthodontic therapy for management of OSA, see Chapter 143.

General Outcomes of Maxillomandibular Advancement Surgery for Obstructive Sleep Apnea

OSA management after MMA surgery generally is successful in a high proportion of patients. A recent metaanalysis of data for 627 patients from 22 studies demonstrated that the median rate of surgical success, defined by a postoperative AHI less than 20 (i.e., fewer than 20 events per hour of sleep), with greater than 50% reduction overall, is 86%.[93] Surgical cure, defined more stringently by a postoperative AHI less than 5, was observed in 43% of patients in this metaanalysis. After a mean follow-up period of 5 months, a statistically and clinically significant reduction in the mean AHI, from 63.9 to 9.5, has been observed.[93] Although the number of studies evaluating long-term outcomes of MMA surgery is still limited, long-term results appear to be relatively stable over follow-up periods exceeding 2 to 5 years.[103,104,107-109] In addition, several studies found statistically and clinically significant improvements in blood pressure after MMA surgery in patients with OSA.[110,111] Finally, evidence for the medium- to long-term stability of the mandibular or maxillary advancement with MMA surgery in patients with OSA has been corroborated by several cephalometric studies.[104,112-114]

In evaluations of subjective outcomes after MMA surgery for OSA, most patients report improvements in snoring, witnessed apneas, excessive daytime sleepiness and quality of life, morning headaches, memory loss, and impaired concentration.[93,110,115,116] In most cases, CPAP can be discontinued after MMA surgery, with patients overall reporting that treatment was worthwhile and recommendable to others.[115]

The specific effects of MMA surgery on upper airway dimensions and surrounding structures have been extensively studied using different techniques, including cephalometry (Figure 149-12) and three-dimensional CT studies (Figures 149-13 to 149-15).[30a,116-118] On the other hand, up to this date, the available data are insufficient to support a relationship between OSA improvements such as reductions in AHI and changes in the upper airway and its surrounding bony structures.[117]

Simultaneous advancement of the maxilla and mandible changes the skeletal framework of the face, thereby resulting in a possible rejuvenation of the middle and lower third of the face. This concept of a "reverse face lift," with positive effects on facial aesthetics, after MMA surgery in patients with OSA is observed in a majority of cases (Figure 149-16). One study found that at 6 months after surgery, 50% of patients reported a younger and 36% reported a more attractive facial appearance.[105,107] Of note, however, 9% of patients in this study reported a less attractive facial appearance after surgery. Conversely, in another study, patients with OSA indicated that they were not bothered by their appearance after MMA surgery.[119] Although patients seeking treatment for OSA generally do not desire an aesthetic facial improvement, it is mandatory to communicate the anticipated facial changes before surgery. Indeed, although 50% of patients undergoing MMA are satisfied with the aesthetic result after the surgery, 30% are indifferent to their postoperative appearance, whereas up to 13% and 5% are disappointed and unsatisfied,

respectively.[120] A surgical technique involving a so-called counterclockwise rotation of the occlusal plane, which previously has been used in correcting severe "bird-face" deformity, may be used both to achieve aesthetic goals and to fulfill the main objective in the treatment of patients with OSA—an optimal increase in airway patency.[121]

Major complications associated with MMA surgery in patients with OSA are rarely reported.[93] Individual and nonfatal cases of postoperative cardiac arrest or dysrhythmia have been reported.[122] One study described a case of a life-threatening airway obstruction after extubation that required reintubation.[123] However, no immediate postoperative deaths

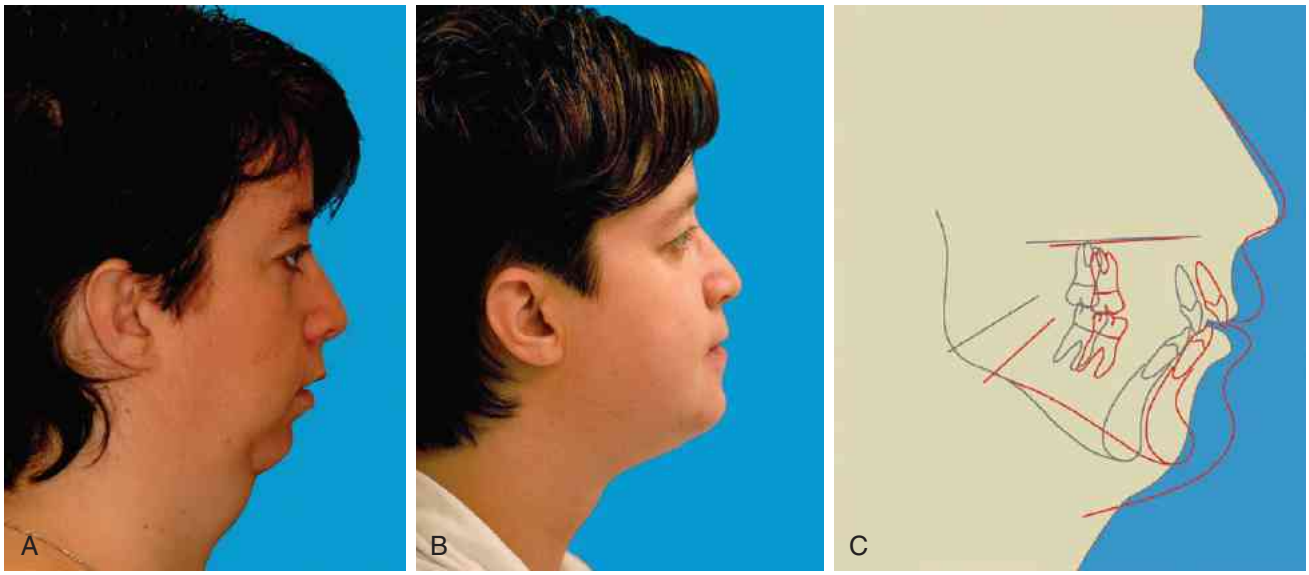

Figure 149-16 Effects on facial aesthetics of maxillomandibular advancement surgery. Preoperative **(A)** and postoperative **(B)** photographs illustrating the rejuvenation of the middle and lower thirds of the face after maxillomandibular advancement surgery combined with a modified genioplasty and cervicomental liposuction in a patient with severe obstructive sleep apnea syndrome. The effect on the patient's profile of profound advancement of the lower third of the face can be appreciated when the pre- and postsurgical cephalometric radiographs are superimposed **(C)**. (From Doff MH, Jansma J, Schepers RH, Hoekema A. have been reported after this type of surgery in patients with OSA.[93] (See also Chapters 121 and 148.)

Minor complication rate has been reported to be approximately 3%.[93] Minor complications include hemorrhage or local infections that generally are cured with either antibiotics or surgical drainage. The presence of postoperative malocclusions or facial paresthesia is not included in this minor complication rate. Facial paresthesia is present in almost all patients after surgery, but resolution has been reported in approximately 85% of patients at the 1-year follow-up evaluation.[93] By contrast, some studies indicate that one half of the patients treated report a persistence of facial paresthesia.[120] Although malocclusions may be seen in up to 44% of patients, they generally can be resolved with (prosthetic) dental treatment or equilibration of the dental occlusion.[122] However, when patients are orthodontically prepared for MMA surgery, malocclusions generally pose no long-term problem with postoperative orthodontics. Some studies report a trend for poor bone healing and increased foreign body reactions after MMA surgery in patients with OSA.[124]

At 3.5 days, average hospital stay is slightly longer after MMA surgery in patients with OSA than in "conventional" orthognathic patients.[93] Most patients with OSA are able to return to full-time work within 2 to 10 weeks after their surgery.[110,125]

The most relevant patient characteristics and clinical factors predictive of a favorable outcome after MMA surgery in patients with OSA include younger age, lower preoperative BMI, and less severe OSA.[93] Moreover, an increased postoperative posterior airway space, determined from lateral cephalometric radiographs, appears to be the only relevant cephalometric variable of predictive value for a successful outcome of MMA surgery.[93] In addition, the amount of advancement of the maxilla appears to correlate with the degree of reduction in AHI.[93,116]

Preoperative Evaluation for Maxillomandibular Advancement

In general, prerequisites for MMA surgery include clinically "significant" OSA that is not amenable to conservative management (e.g., CPAP), a medically and psychologically stable condition, and the patient's desire for surgery and informed consent before the procedure.[126] A lateral cephalometric head film is mandatory to plan MMA surgery, as well as a preoperative polysomnographic recording. Surgery also may be planned using three-dimensional imaging techniques such as (cone beam) CT. Subsequently, virtual surgical planning can be conducted, which offers the surgeon valuable information on the anticipated skeletal, airway, and facial aesthetic changes (Figure 149-17).[127] Fiberoptic nasopharyngoscopy also is recommended before surgery. This imaging procedure can further help to identify nasal, retropalatal, or tongue base pathology that may affect the outcome of MMA surgery (e.g., lingual tonsillar hypertrophy).

Finally, the response to an oral appliance also may be used to select suitable candidates for MMA surgery.[128] Patients demonstrating a substantial reduction in baseline AHI (i.e., to less than 50%) with oral appliance therapy appear to be especially good candidates for MMA surgery.[128] Despite the variety of treatment protocols, a precise treatment algorithm for choosing MMA surgery in OSA management has yet to be established, and the decision depends in large measure on patient's preference.

Postoperative Management after Maxillomandibular Advancement

Medical surgical management of the postsurgical patient with OSA is more complicated than with conventional orthognathic patients, despite the profound and immediate postsurgical improvement in pharyngeal airway patency. If recovery is sufficient, discharge is up to the surgeon and patient but requires proper pain control and capability of oral intake. Because younger patients tend to recover more quickly, discharge usually is earlier in this patient category.

Follow-up evaluation depends on the surgeon's individual protocol and the specific patient characteristics. Of note, postoperative edema usually is maximal 72 hours after surgery. Frequent postoperative follow-up visits are recommended until full recovery has been achieved. A polysomnographic follow-up study at 6 months or later after MMA is recommended.[129] As with all other surgical options for OSA treatment, it should be stressed to the patient that weight loss is an important part of the pre- and posttreatment OSA management, because even modest weight change will affect the outcome.

Upper Airway Bypass: Tracheostomy

Tracheostomy remains an important treatment option for OSA even though it is used by only a small minority of patients. The tracheostomy provides an alternative airway that bypasses the upper airway obstruction, and it is highly effective for controlling the OSA.[25] It becomes an important treatment option in patients with severe OSA and serious comorbid illnesses that render other surgical treatments too risky.

Tracheostomy has several important advantages. The surgery is relatively simple and short compared to what would otherwise typically be required to address severe OSA. The major treatment effect is immediate. Patients function normally with eating and speaking by capping the tracheostomy cannula during waking hours and then simply uncap the cannula for sleep. A tracheostomy is reversible in case it is somehow intolerable to the patient, which is unlike almost every other surgical treatment of OSA. Patients typically become very skillful with management of the tracheostomy cannula. Specific disadvantages of a tracheostomy have been recognized. The cannula requires daily maintenance with cleaning and/or changes, although this process is simple. Some patients are self-conscious about the visible cannula. The stoma can accumulate granulation tissue or scar tissue that may require intermittent procedures to clear. Local infections can occur, requiring antibiotics or topical stoma treatment. Cannula dislodgement can be problematic in rare cases, and even life-threatening if the cannula dislodges from the the normal stoma position into the trachea. In addition, patients must avoid submerging the neck under water lest water aspiration occur, even if the cannula is capped.

Bariatric Surgery

Bariatric surgery is indicated in morbidly obese patients (BMI of 40 kg/m^2 or greater) with OSA in whom significant weight loss cannot be achieved through conservative measures such as hypocaloric diet and exercise training[46] (see also Chapter 121). In case of significant obesity-related comorbidity such as hypertension or diabetes, bariatric surgery should be considered starting from BMI of 35 kg/m^2 or greater. It has been clearly demonstrated that the surgical weight loss induced by bariatric surgery can result in significant decrease in OSA severity.[130,131] However, OSA of considerable degree can persist in some patients even after substantial weight loss.[130,132,133] Therefore, a follow-up sleep study is recommended after bariatric surgery to check for residual OSA, especially in patients with low minimum SaO_2 levels and high supine AHI preoperatively.[130,131] If necessary, retitration of CPAP settings may be scheduled, which may lead to higher treatment compliance afterward.[131] CPAP optimization and vigilance may be necessary to treat residual OSA when present and to help maintain weight loss, because there are limited data to suggest an association between postoperative CPAP use and weight loss outcomes.[133]

Combination Therapy Including Multilevel Surgery

To reach the therapeutic target, preferably an alleviation of the disease, it may be necessary to prescribe two or more therapies, with adjunctive modalities used as needed to supplement the primary treatment options.[14] In the management of OSA, however, combining treatment options has been somewhat undervalued. A combination approach is especially appropriate in this setting because as described earlier in the chapter and elsewhere in this book, no single therapy (surgical or nonsurgical) is universally effective. Many of the surgical treatments are site-specific, so combinations of procedures may be necessary to address all sites of obstruction.

Concerning the nonsurgical treatment options for OSA, several possible combinations have been reported, such as combining oral appliance therapy with sleep positioning therapy (SPT) or the combination of CPAP with oral appliance therapy (see Chapters 116, 147 and 150).[134-136] In addition, positional therapy may also be an adjunctive treatment in patients on CPAP who require high pressure levels in the supine position to improve adherence to the CPAP regimen.[46] The addition of oral appliance therapy has been shown to be an effective mode of combination therapy to control OSA after UPPP failure.[137] The combination of positional therapy and surgical upper airway modifications can result in a significant decrease in OSA severity in patients in whom surgery converted non-positional OSA into positional OSA.[138,139] Similarly, the combination of two or more surgical techniques, performed either simultaneously or staged, or so-called *multilevel surgery*, can be regarded as combination therapy for OSA. For example, combining UPPP (or anatomically-directed variants) with hypopharyngeal procedures results in a significant decrease in OSA severity, a significant improvement in daytime sleepiness, and a high degree of patient satisfaction, with an acceptable complication rate.[140,141,142,143] With currently available upper airway surgery protocols to address all relevant areas of obstruction can achieve clinical outcomes (e.g., reduction in symptoms and improvement in quality of life) comparable to CPAP therapy.[144]

CLINICAL PEARLS

- CPAP remains the standard modality to treat OSA. The clinical effectiveness of CPAP treatment, however, often is limited by poor patient (and partner) acceptance, leading to suboptimal adherence. Consequently, an urgent need for non-CPAP treatment options is well recognized.
- To move away from a "trial and error" empirical clinical paradigm, there has been increasing interest in drug-induced sedation endoscopy (DISE), as part of the therapeutic decision-making process regarding upper airway surgery.
- Many surgical options are available, and each has its indications. Nasal airway surgery complements most other surgical and nonsurgical treatments when the nose is obstructed. Site-directed upper airway procedures can be very effective, when combined appropriately, for addressing many combinations of obstruction. Upper airway neurostimulation appears promising for selected patients with multilevel soft tissue collapse and possibly in patients with particularly collapsible tissue (as opposed to structural abnormalities). MMA is an especially useful option in patients with malocclusion, which can be addressed simultaneously, or with facial skeletal compromise. Tracheostomy is an important option for patients with severe comorbid illnesses who cannot tolerate CPAP or more extensive surgery. Bariatric surgery can allow weight loss for significant clinical improvement in patients presenting with severe obesity associated with OSA or other obesity-related comorbidity.

SUMMARY

OSA has major socioeconomic consequences and should be approached as a chronic disease requiring long-term, multidisciplinary management. Although CPAP is overall the most successful treatment for moderate to severe OSA when used properly and consistently, its clinical effectiveness often is limited by poor patient and partner acceptance, which leads to suboptimal adherence. Because many patients with OSA remain inadequately treated owing to inconsistent levels of adherence to CPAP, and because mild OSA deserves treatment in those with problematic symptoms, there is a genuine need for non-CPAP treatment options (Table 149-1). Additionally, it may be necessary to combine two or more of the available treatment options to achieve a successful outcome targeting disease alleviation.

The spectrum of OSA is quite diverse in terms of nature and severity, so the selection of the right treatment regimen for each individual patient will be of utmost importance. Among the different techniques that can be used for the preoperative upper airway assessment, DISE is increasingly performed for dynamic upper airway evaluation to select the proper non-CPAP treatment for patients with OSA.

Surgical treatment of upper airway abnormalities, craniofacial deformations, or obesity may be applied in selected patients with OSA. In general, sleep surgery procedures are directed at specific collapsible upper airway structures, so preoperative upper airway investigation may add to proper selection of a specific surgical procedure for an individual patient. Taking into account that in a majority of patients with OSA, a multilevel collapse is observed within the upper airway, the treatment plan should aim at resolution of the anatomic compromise at all levels involved in the obstructions occurring during sleep.

The results of upper airway neurostimulation therapy in carefully selected patients with OSA are promising. Its safety, combined with associated high rates of therapy adherence and sustained reductions in OSA severity, should sustain further effectiveness research in this particular area.

MMA surgery plays an important role in the correction of OSA that is refractory to noninvasive therapies. MMA surgery in patients with OSA generally is more complex than "conventional" orthognathic surgery because OSA patients require large advancements, are usually older, and often have other comorbidities. With proper precautions, however, it is a safe and highly effective treatment modality for OSA. MMA surgery probably is the most effective surgical intervention besides tracheostomy in patients who are skeletally compromised (e.g., retrognathia or bimaxillary retrusion). These patients should therefore be informed about MMA surgery as one of the primary treatment modalities.

Tracheostomy remains an important treatment option for patients with severe OSA and serious comorbid conditions that might limit the other surgical treatment options. Bariatric

surgery is a valuable treatment option to treat obesity-related OSA and other obesity-related diseases and conditions in patients who are unable to lose sufficient weight by conservative measures.

Finally, combining different treatment options for the alleviation of OSA is undervalued and underinvestigated. Further research on the possible combinations is strongly needed, because no single treatment can adequately manage all patients with OSA.

Pharmacotherapy, Complementary, and Alternative Medicine for Sleep Bruxism

Ephraim Winocur; Luis Buenaver; Susheel P. Patil; Michael T. Smith

Chapter Highlights

- Sleep bruxism and obstructive sleep apnea are two common disorders involving oral and/or oropharyngeal dysfunction that (1) can be independent or concomitant and (2) can be difficult to successfully manage by means of mainstream, conventional medical approaches.
- Although conventional management approaches are efficacious, such as with dental appliances to prevent tooth wear from repeated bruxism, they often are poorly tolerated, and alternative pharmacologic and complementary approaches frequently are sought by the patient.
- This chapter reviews emerging pharmacotherapies, behavioral, and complementary and alternative medicine approaches for the management of sleep bruxism.
- Also given appropriate consideration are issues of importance regarding clinical application of these approaches: the preliminary nature of the evidence base, the need for systematic investigation of promising interventions, and potential side effects and the minimal or modest efficacy of many of these approaches that limit their use at this time.

This chapter reviews the evidence supporting the use of pharmacologic therapies, psychological/behavioral interventions, and complementary and alternative medicine (CAM) to manage sleep bruxism (SB). Orthodontic, oral appliance, and surgical treatments for sleep-disordered breathing (SDB) are covered in Chapters 143, 147, and 149, respectively. Detailed information on SB definition, prevalence, etiology, and differential diagnosis is specifically found in Chapters 144 and 145.

SLEEP BRUXISM

Bruxism is a repetitive jaw-muscle activity characterized by clenching or grinding of the teeth and/or by bracing or thrusting of the mandible. Bruxism has two distinct circadian manifestations: It can occur either during sleep—*sleep bruxism*(SB)—or during wakefulness—*awake bruxism* (AB).[1] This distinction between AB and SB is made because the etiologies are increasingly believed to be distinct and the interrelationships between the two entities are unclear.[2]

SB is broadly conceptualized as a sleep-related movement disorder, but its etiology remains poorly understood. As opposed to earlier conceptualizations of SB, which had little empirical support and emphasized the role of malocclusion and peripheral nervous system mechanisms, modern evidence-based theories emphasize central nervous system dysfunction and autonomic arousal as primary to the pathophysiology of SB. Multiple intrinsic factors, including genetics, aberrant autonomic sympathetic-cardiac activation, and neurotransmitter system dysfunction, have been implicated in the disorder.[3] Extrinsic factors such as medication side effects and tobacco use also may induce and/or exacerbate AB and/or SB.[4] In view of the lack of clear understanding of SB and the likelihood of a heterogeneity of pathophysiologic mechanisms, it is not surprising that a definitive cure for SB is lacking.

Current conventional treatments focus on managing the harmful consequences of SB and protecting orofacial structures. The most frequently used interventions are based on use of dental appliances to prevent tooth wear. These approaches, however, do not treat the underlying pathophysiology, and the devices often are poorly tolerated by the patient.[5] Medications, behavioral interventions, and CAM approaches for treatment of SB have received some preliminary research attention, but decisions to intervene with these approaches must be considered carefully, owing to reported side effects, relatively sparse scientific evidence regarding their use, and a potentially unfavorable cost-benefit ratio. Presented next is an overview of pharmacologic approaches, behavioral interventions, and CAM for SB management.

EMERGING AND ALTERNATIVE APPROACHES TO MANAGEMENT OF SLEEP BRUXISM

Beyond conventional medical treatments, additional management strategies for use in SB fall into three categories: (1) pharmacotherapies, (2) behavioral interventions, and (3) CAM. Of note, the studies reviewed in the subsequent discussions of these categories are not intended to exhaustively represent these three modalities. The emphasis is on empirical studies published in the English language, specific to subjects diagnosed with SB. Also mentioned are some

approaches that may be widely used but have minimal empirical support.

Pharmacotherapies for Sleep Bruxism

Because SB is widely believed to be centrally mediated, ideal treatments presumably would be neurotropic medications that may regulate cerebral and autonomic hyperarousal (which can be a state of sustained hypervigilance and/or repetitive physiologic reactivity). A critical review intended to assess the exacerbating and ameliorating effect of medication on bruxism in humans, however, found relatively more drugs that cause or aggravate SB than drugs that effectively reduce bruxism.[6] At present, strong evidence–based data from which to draw firm clinical conclusions concerning the effects of medication on SB are lacking.[7] The literature remains controversial and is based largely on anecdotal case reports or experimental studies targeting SB mechanisms.[6] Accordingly, owing to lack of efficacy and efficiency data, no definitive recommendations can be made about the pharmacologic treatment of SB. Table 150-1 summarizes selected studies from the relevant literature.

Sedative, Anxiolytic, and Antidepressant Drugs

Psychosocial stress and psychopathologic conditions, particularly anxiety, have traditionally been conceptualized as playing a pathophysiologic role in SB, although this perspective has

Table 150-1 Drug Therapies for Sleep Bruxism

Reporting Study	Study Design	Drug (Generic Name)	Influence on Sleep Bruxism Muscle Activity Index	Comments
Saletu et al. 2010[9]	Single-blind, placebo-controlled, nonrandomized, cross-over. (polysomnographic study)	Clonazepam	↓	Possible serious adverse side effects

SB, Sleep bruxism; ↓, ameliorate; ↔, no effect; ↑, exacerbate.

been questioned owing to a lack of clear evidence linking these phenomena specifically to SB. AB has been more clearly linked with anxiety and psychosocial stress.[8] Nevertheless, benzodiazepines have been used clinically for SB because of their anxiolytic, muscle relaxant, and hypnotic properties. A placebo-controlled polysomnographic study found clonazepam to significantly improve both the SB index and subjective sleep quality[9]; diazepam has been reported (only in an abstract format) to significantly reduce nocturnal masseter electromyogram (EMG) activity in patients suffering from clinical symptoms of masticatory hyperactivity.[10] Caution is warranted in prescribing benzodiazepines, especially for long periods, because of the potential for various adverse side effects, including respiratory depression, tolerance, dependency, abuse, seizures on abrupt withdrawal, somnolence, and occasionally muscular hypotonia and coordination disturbances. Respiratory depression is a particular concern in patients with comorbid sleep apnea. Dependency and abuse are among risk factors that prevent general use of clonazepam for SB management.

Buspirone, an atypical anxiolytic, has been reported to relieve selective serotonin reuptake inhibitor–induced bruxism ("secondary bruxism") in some patients, to have no such effect in others, and to possibly cause bruxism in another study.[10] It is not a medication likely to be selected for primary SB management.

Use of sedating tricyclic antidepressants such as amitriptyline has been suggested as a treatment for SB, on the basis of presumed associations between depression and SB. However, negative findings have been reported (i.e., no reduction in SB motor index), and insufficient evidence-based data have been accumulated to support the foregoin assumption.[6,11] Moreover, a recent comparative study that aimed to investigate the short-term effects of occlusal splint therapy versus tricyclic antidepressants (amitriptyline) found that occlusal splint therapy may be more effective than these drugs in the management of bruxism.[12] In general, available evidence suggests that drugs prescribed to treat anxiety and depression are relatively poor candidates for SB management—particularly selective serotonin and serotonin-norepinephrine reuptake inhibitors, which in turn also can exacerbate AB and/or SB.[13]

GABAergic Medication

Baclofen,[14] a gamma aminobutyric acid (GABA) agonist, and tiagabine,[15] a GABA reuptake inhibitor, were found to effectively decrease SB. These studies suggest that SB, which has been categorized since 2005 by the *International Classification of Sleep Disorders* (ICSD2)[16] as a movement disorder, might be successfully treated with the inhibitory neurotransmitter GABA, as with other sleep movement disorders such as restless legs syndrome and periodic limb movement disorder. This assumption regarding pathophysiology requires further investigation in well-designed studies to support such medication use in SB management.

Antihistaminic Medication

A recent, randomized placebo-controlled clinical trial investigated the efficacy of hydroxyzine for treating parent-reported SB in 30 children.[17] Hydroxyzine is a histamine H_1 receptor antagonist with sedating properties that typically is used to treat pruritus (itching) and anxiety in children. Compared with placebo, hydroxyzine decreased the parental self-reported bruxism score without serious adverse effects. Although the mechanism of action is not known, the investigators speculated that the effects may be due to increased sleep depth, decreased anxiety, and muscle relaxation. More research with objective measures on SB muscle index (as described in Chapters 144 and 145) and assessing side effects (such as school-time sleepiness in children) is warranted before following such avenues of investigation in SB management.

Sympatholytic Medications

Sympatholytic medications have been suggested as having the potential to reduce SB by dampening sympathetic nervous system arousal during sleep. A promising experimental randomized control study of sleep bruxers found that clonidine, an $\alpha 2$ adrenergic agonist, but not propranolol, an β_2-adrenergic receptor antagonist, reduced SB activity by decreasing sympathetic tone in the 60-second period preceding the onset of SB events. The investigators concluded that the diminution of paroxysmal sympathetic activation, which typically is observed before an SB event, was associated with reduced subsequent motor activation during SB.[10] Caution is indicated, however, in prescribing clonidine for SB because of its reported serious adverse side effects, including hypotension, syncope, bradycardia, atrioventricular block, somnolence and fatigue, headache, sexual dysfunction, and others. Coordinated collaboration with the patient's primary physician is especially important in prescribing these medications, at the lowest dose as possible. It is not yet a safe route for managing SB in the general population.

Dopamine-Related Agents

A relationship between dopamine, the immediate precursor of norepinephrine, and SB has been hypothesized on the basis of the role of dopamine in movement disorders such as Parkinson disease. An early neuroimaging study explored possible functional abnormalities of the central dopaminergic system in humans with SB.[3] This double-blind, placebo/experimentalcontrolled trial investigated the effects of bromocriptine, a dopamine agonist, on SB. Unfortunately, four of six subjects discontinued participation owing due to severe adverse side effects. The two participants who completed the trial, however, demonstrated a 20% and 30% reduction, respectively, in number of bruxism episodes per hour (rhythmic masticatory muscle activity [RMMA]) of polysomnographically measured sleep compared with a placebo.[18] A subsequent study by the same group[11] and an investigation by another group,[19] however, failed to demonstrate any significant effects of bromocriptine on SB. Furthermore, an experimental controlled trial showed a mild beneficial effect of L-dopa, a catecholamine precursor, on RMMA (20% to 30% reduction of SB as reported by Lobbezoo and coworkers[6]).

The literature on the effects of dopamine antagonists on SB in humans also is mixed. Some studies report exacerbating effects of haloperidol and other antagonists, one study reported no impact, and at least one study found that risperidone was associated with clinical improvement in patients with SB.[6] Thus the effect of dopamine-related medications on bruxism remains unclear. More controlled, evidence-based research that identifies potential subgroups of responders and those at risk for dopamine\-related exacerbation is needed.

Botulinum Toxin Injections

Botulinum toxin (BT) injections commonly are used to treat cervical dystonia, blepharospasm, hemifacial spasm, tardive

dyskinesia and sometimes in dentistry for severe oromandibular dystonias, including bruxism. BT is a neurotoxin produced by the anaerobic bacterium clostridium botulinum, which prevents the release of acetylcholine from presynaptic vesicles at the neuromuscular junctions, resulting in the blockade of motor fibers. Clinical effects are a temporary muscle contraction weakness, typically lasting 3-4 months.[13] Studies of BT injections for SB are limited, including a handful of case reports, two open-label prospective studies, and at least one small-sample-size randomized, controlled clinical trial.

In the first open-label study, 18 subjects diagnosed with severe bruxism were treated with a mean dose of approximately 62 mouse units (MU) per masseter muscle over a 3-year period.[20] Eighty-nine percent of the patients in this self-report study indicated a marked relief of self-awarenss of tooth grinding (a debated marker if based on self-report) and functional improvement in chewing, swallowing, and/or speaking. The investigators concluded that subjects required BT injections approximately every 5 months for effective, sustained relief. A lack of placebo control and objective EMG measurement, however, limits conclusions that can be drawn from this study.[20]

In a small-sample-size randomized, placebo-controlled trial (n = 12), 80 MU of botulinum toxin A (Dysport; Ipsen Ltd., Wrexham, United Kingdom) diluted in 0.8 mL of saline significantly reduced EMG-measured SB compared with placebo saline injections at 4, 8, and 12 weeks. No subjects withdrew from the study, and no adverse events were reported.[21]

A more recent open-label study of patients with SB (n = 20) whose bruxism was refractory to oral splint treatment evaluated the effects of bilateral BT injections to either the masseter or the masseter plus temporalis muscles.[22] A comprehensive PSG assessment of SB activity conducted 4 weeks later demonstrated that participants in both treatment groups exhibited significant reductions in the peak amplitude of rhythmic masticatory muscle activity but no differences in the frequency, number, or duration of bursts.[22] A majority of the patients also reported a significant reduction in morning jaw muscle stiffness. Of note, 70% of subjects reported localized discomfort associated with a decrease in the sensation of masticatory force, but this generally was well tolerated over the 4 weeks. Fifteen percent of the affected subjects, however, complained that muscle weakness contributed to masticatory difficulties.

Although the available data suggest that BT injections may be an efficient treatment for severe oromandibular dystonias, the long term consequence and risk of BT in SB patients need to be balanced with SB severity. Furthermore, the small number of studies and unresolved issues including occasional complications related to local muscle weakness and the high cost of treatment indicate that BT injections should be reserved for extreme cases of SB in which all other therapies have failed and the adverse clinical consequences of SB, including significant tooth wear, interference with dental rehabilitation, jaw muscles and/or temporomandibular joint pain, headaches, and social /marital conflicts, are evident. In the presence of secondary AB or SB due to psychotic medication for mental health disorders, BT use is to be recommended with caution, because BT action is temporary (i.e., it lasts only a few months).

Behavioral Interventions for Sleep Bruxism

The studies on behavioral interventions for SB reviewed here derive from mainstream psychological theories and practice, some of which are more relevant to AB and were conducted when the distinction between AB and SB was not well established or made. AB and SB can overlap in a significant number of subjects but with a different time course over the lifespan.

Massed Practice Therapy and Habit Reversal for Bruxism

Massed negative practice and habit reversal are related behavioral therapies developed to reduce unwanted daytime behaviors, habits, compulsions, and tics. Early clinical approaches to bruxism failed to appreciate that sleep and wake bruxism might be different problems requiring unique treatments. Both forms of bruxism were conceptualized as a ticlike habit,[23] which potentially could be reduced or even extinguished by enhancing the noxious aspects of the behavior through conscious repetition of "bruxing" (voluntary repetitive rapid and brief contraction) or clenching (voluntary sustained contraction) to induce muscle fatigue.[24] One early study that compared such massed negative practice with relaxation training found that neither approach significantly reduced bruxism.[25] Some case reports, however, suggest a possible benefit of massed practice for AB.[23,26,27]

Habit reversal is a related behavioral strategy designed to decrease maladaptive behaviors by increasing awareness of grinding and clenching and substituting a competing behavior such as jaw muscle relaxation, which is subsequently reinforced. Habit reversal was developed by Azrin and Nunn in 1973[28] and has been effective in treating motor disorders (e.g., thumb sucking, nervous tics, nail biting), many of which are oral in nature (as reviewed by Miltenberger and associates).[29] A handful of studies of temporomandibular joint disorder (TMD) have found that habit reversal reduces facial pain[30-34] and associated maladaptive oral habits, which include AB and clenching.[30,32] There is minimal evidence, however, documenting that either massed practice or habit reversal interventions practiced during the daytime can generalize to or be effective for SB.

Arousal with Overcorrection

We are aware of at least one study that combined an arousal procedure with a behavioral intervention known as *overcorrection* to reduce SB behavior.[35] Overcorrection involves repeated practice of a positive substitute behavior (e.g., massage, teeth brushing, flossing, mouth rinsing, and so on) after punishment (awakening) when the targeted behavior is expressed. Arousal with overcorrection is an intervention based on *operant conditioning,* a principle positing that behavior is largely controlled by contingencies; punishment (i.e., the arousal) and reinforcement (i.e., the positive behavior). Arousal with overcorrection has been successfully used to treat nocturnal enuresis.[36]

In an early application of arousal with overcorrection for SB (n = 2),[35] each subject completed multiple baselines over time, alternated by two experimental conditions: (1) arousal alone (spouses awakened patient for 15 to 120 seconds during an SB episode) and (2) arousals with overcorrection. In the overcorrection condition, patients were awakened and instructed to complete a 10-minute procedure that included face and hand washing, brushing and flossing teeth, rinsing

the mouth with water, then use of mouthwash, and repeating. The arousal with overcorrection condition was moderately effective in reducing the number of sleep bruxing episodes (lasting 15 seconds or longer) as observed and recorded by the subject's spouse during the 2-hour period immediately after sleep onset. Similar to other aversive conditioning studies, SB activity returned to baseline levels following cessation of treatment. Limitations of this study include requiring implementation with a partner, the lack of objective measures, and the ability to target only audible bruxing. Although the approach is promising, replication is needed with better objective measures and larger sample sizes, before the efficacy of overcorrection for SB can be determined.

Nocturnal Biofeedback and Aversive Conditioning

Aversive conditioning is a type of behavioral conditioning in which a noxious stimulus is repeatedly paired with a maladaptive behavior targeted for extinction. EMG activity–activated alarms have been investigated as a form of aversive conditioning to treat SB. Typically, an audible tone is triggered during sleep "bruxing" episodes with the purpose of waking a subject from sleep. Under this paradigm, for patients to avoid the noxious feedback and achieve consolidated sleep, they must learn to sleep without bruxing. Early studies using masseter and/or temporalis EMG activity thresholds to induce arousals consistently demonstrated reductions in SB duration, but not in frequency.[37,38] Moreover, most studies found that SB activity returns to baseline or is increased on discontinuation of biofeedback.[39,40]

Investigators seeking sustained treatment effects upon discontinuation of EMG feedback have increased the aversive nature of the intervention by requiring that subjects become fully awake after an alarm. Two small (n = 6 and n = 10) studies employed an arousal task—one requiring subjects to perform a 3- to 5-minute task and the other requiring subjects to get out of bed, cross the room, and record the time and sleep quality—after auditory feedback. Both studies found significant reductions in SB lasting for up to 2 weeks on discontinuation of the feedback.[41] A more recent single case study reported that reductions in bruxism frequency were maintained 6 months after cessation of treatment.[42] Several additional one- and two-subject case studies of EMG feedback plus arousal, however, have yielded mixed results.[43-46]

More contemporary approaches have sought improve biofeedback approaches by (1) delivering a stimulus that does not disrupt sleep and (2) improve upon SB detection algorithms to differentiate true bruxism episodes from benign parafunctional activities. A five-night study (n = 7) explored afferent stimulation of the maxillary division of the trigeminal nerve using mild electrical stimulation of the lip during SB episodes.[47] The investigators found significant reductions in SB event duration but not in event frequency. Subjects did not report being awakened by the stimuli. Four small studies (sample sizes ranging from 11 to 19 subjects) have attempted to classically condition electrical stimulation to grinding and clenching behavior in order to extinguish SB. These studies, termed *contingent electrical stimulation* (CES), used a portable EMG device with advance signal processing features designed to differentiate grinding and clenching activity from other benign oral motor movements.[48-51] Patients precalibrate the device while awake by engaging in a variety of oral motor activities (e.g., grimacing, swallowing) and are able to adjust the level of the electrical stimulation so that it does not induce frank awakenings. Only one of the studies, however, used PSG to demonstrate that CES had no apparent effects on sleep architecture or continuity.[49] These studies suggested that the device could discriminate between common parafunctional jaw muscle activity and SB and that feedback significantly reduced the number of SB episodes per hour. A recent systematic review of biofeedback treatments for SB, however, concluded that much of the literature is of poor quality and subject to bias.[52] This report also found that the pooled CES outcomes data did not show improvement in EMG measures of SB episodes compared with control conditions. At this time, it is unclear whether CES is effective for SB and even less clear whether the effects persist on discontinuation of the device. Newer biofeedback approaches appear to have potential but require larger and well-designed studies.

Complementary and Alternative Medicine Approaches

Hypnotherapy

Although several of the studies and case reports just described are inconclusive, preliminary explorations with varying degrees of promise, they are all grounded in well-established behavioral learning theories, typically considered outside the realm of CAM. Hypnotherapy might arguably be better characterized as a form of CAM. Hypnosis has been described as a state of focused attention involving concentration and inner absorption with a relative suspension of peripheral awareness.[53] The intervention often involves facilitating the patient's tendency to become engrossed in a perceptual or creative experience, the promotion of dissociation (i.e., mental separation of elements of experiences that typically would be processed together), and suggestibility (i.e., responsiveness to social cues, leading to a greater likelihood to comply with hypnotic suggestions).[53] Hypnotic techniques often are used in pain management, the treatment of phobias, and depression, with some empirical support

There are a handful of published papers investigating the use of hypnosis in treating SB.[54-57] Most are case studies that used unstandardized and poorly defined methodology, self-report measures, and combined hypnotherapy with other intervention elements, preventing conclusions regarding efficacy to be drawn. One uncontrolled study in eight subjects, however, incorporated EMG monitoring and found that SB activity was significantly reduced after a suggestive hypnotherapy intervention.[56] EMG data were not collected at follow-up assessments, so it is unclear whether the effects had any durability. Overall, owing to the lack of methodologic rigor, standardization, and objective measurement, the efficacy of hypnotherapy for SB is unclear.

Acupuncture

Acupuncture often is mentioned as a treatment approach for bruxism. Acupuncture has been used to treat and ameliorate chronic facial pain related to TMD and mandibular dysfunction,[58-64] but the available evidence evaluating or demonstrating an effect of acupuncture on SB is minimal.

Nutritional Supplements

Studies investigating the efficacy of certain nutritional supplements (i.e., magnesium, calcium, potassium, and vitamins) are lacking and of insufficient scientific quality to support their use in SB management at this time.

Conclusion

At this time, except for oral appliances, few treatments for SB have been adequately studied to accumulate a scientific knowledge base supporting their use.[65] See selected readings for more information.

CLINICAL PEARLS

- In general, there is insufficient evidence supporting any pharmocotherapy for SB, but some medications, such as GABAergic agents, α2 adrenergic agonists (e.g., clonidine) and antihistamines warrant further research to assess efficacy and safety.
- If used in patients with SB, clonidine and clonazepam should be prescribed in low doses, in exceptional and rare circumstances, for short periods with medical supervision, owing to side effects including hypotension or other cardiovascular problems for clonidine, and to the risk of dependency and abuse or adverse effect on sleep breathing for clonazepam.
- The available evidence suggests that drugs prescribed to treat anxiety and depression are relatively poor candidates for treating SB, particularly selective serotonin and serotonin-norepinephrine reuptake inhibitors, which typically can exacerbate SB.
- BT injections may be efficacious for some cases of SB (for reduced amplitude of muscle activity, but not its frequency or duration). However, this approach should be reserved only for severe cases in which all other therapies have failed and when the harmful consequences of SB outweigh the risks of BT adverse effects.
- Many behavioral/psychosocial treatment approaches to SB are based on outdated conceptualizations of the pathophysiology of SB and generally lack strong support for their efficacy. However, because SB etiopathophysiologic mechanisms can be multiple and are not fully known, treatment planning should not automatically exclude behavioral/psychosocial treatment in the era of personalized medicine.
- Integrated medicine requires further development for managing SB.
- Studies on other CAM approaches to management of SB, such as hypnotherapy, acupuncture, and nutritional supplements in particular, are of limited and insufficient scientific quality to support their use.
- Currently, EMG biofeedback devices to manage SB vary in quality and capability. Some studies, however, support the efficacy of some specific biofeedback devices, with or without arousal procedures. There is an obvious need for larger randomized controlled trials and for effectiveness ("real-world") clinical studies using standardized outcome measures before final conclusions and recommendations can be given.

SUMMARY

In light of the fact that the existing mechanical treatment modalities for SB often are associated with poor adherence rates and/or are lacking in long-term outcomes data, more effort should be made by the biobehavioral and integrative medical communities to develop and test new pharmacologic, behavioral, and CAM treatments for SB. Unfortunately, the evidence base for these approaches remains relatively weak and underdeveloped. None of the reported modalities can be fully recommended at this time. Some approaches, however are quite promising and may have benefit as adjuvants to conventional treatments. As the pysiologic, behavioral, and psychological factors of these diseases become better understood, novel pharmacologic, behavioral, and CAM interventions can be expected to be more readily developed and rigorously tested.

Psychiatric and Medical Comorbidities and Effects of Medications in Older Adults

Steven R. Barczi; Mihai C. Teodorescu

Chapter Highlights

- Insomnia in older adults fits the typical profile of a "geriatric syndrome" as characterized by high prevalence, multifactorial etiology, frequent involvement of multiple organ systems, and ultimately, adverse effects on the older person's quality of life.
- Late-life insomnia frequently coexists with other health problems that may disturb sleep, with a preferred nosology of comorbid insomnia. Because these syndromes cross organ systems and transcend discipline-based boundaries, they challenge traditional ways of planning and delivering care.
- Management of comorbid insomnia requires a multifaceted approach that addresses the associated medical and psychiatric conditions, optimizes medications, intervenes on concurrent primary sleep disorders, and also targets perpetuating factors that may reinforce poor sleep behaviors during and/or after the initial physiologic insult.

SLEEP DISTURBANCES IN THE OLDER ADULT

Epidemiology

The number of Americans older than 65 years of age has been steadily increasing, reaching approximately 40 million people at present.[1] It is estimated that by 2050, the U.S. population will more than double (to 89 million). The prevalence of sleep difficulties rises with increasing age. Sleep is considered to be reflective of overall health and is susceptible to the influence of many endogenous and exogenous factors. Changes in sleep in older adults appear to be more strongly associated with psychosocial and health factors than with aging itself.[2,3] In a cohort of more than 300 community-dwelling subjects with a mean age of 72 years, followed for 3 years, sleep disturbances appeared to be related to physical, environmental, and health factors rather than to age-dependent sleep changes.[4]

Health problems appear to have additive effects with respect to the likelihood of concomitant sleep complaints. The 2003 "Sleep and Aging" survey (part of the "Sleep in America" poll) reported that 36% of people 65 years of age and older without comorbid illnesses had sleep problems, 52% with one to three comorbid conditions had sleep disturbances, and 69% of those with four or more comorbid illnesses had disturbed sleep.[2] In addition, an inverse proportion was noted between the self-perceived quality of the respondents' sleep and the number of their comorbid conditions.[2]

Approximately two thirds of aged Medicare beneficiaries have multiple chronic conditions.[3] The simultaneous occurrence of several medical conditions in the same person constitutes the concept of *multimorbidity*. The prevalence of multimorbidity increases significantly with age in both men and women. The specific prevalence of individual conditions varies depending on the age group, gender, and population

sampled (e.g., community-based versus clinic cohort). Most commonly defined chronic conditions in people 70 years or older include osteoarthritis, hypertension, heart disease, diabetes, obstructive lung disease, and cancer in approximate descending order of frequency, from 55% to 10%.[5,6] In a community-based longitudinal study of more than 1200 elderly persons followed for 2 years, the baseline number of physical disorders was associated with prevalence, incidence, and persistence of insomnia. Insomnia also was associated with incident depression and an increase in reported physical disorders.[7]

Population-based surveys reported that between 89% and 94% of those older than 65 years of age take prescription medications, with nearly 40% taking more than 5 medications and 12% taking more than 10 medications.[8,9] *Polypharmacy* generally is defined as taking more than 5 medications, with incremental increases corresponding to the number of coexisting age-associated diseases.[9] Existing practice guidelines recommend use of multiple medications for a number of chronic diseases (e.g., congestive heart failure [CHF], diabetes). Consequences of polypharmacy include adverse drug effects, drug-drug interactions, and medication cascade effects.[9] The *cascade effect* refers to the use of medications to treat the side effects of other medications.

Nosology

In older adults with chronic illnesses, the terms *primary insomnia* and *secondary insomnia* do not adequately represent the complex interplay of cause and effect in determining etiology (Figure 151-1). Sleep difficulties in older persons can be conceptualized as a geriatric syndrome, because they are attributable to multiple and interdependent predisposing, precipitating, and perpetuating factors.[10] Medical or psychiatric conditions may manifest with precipitating events that produce symptoms of discomfort and emotional distress, potentially leading to increased sympathetic drive, hypothalamic-pituitary-adrenal axis activation, and, ultimately, recruitment of neural systems to produce arousal.[11,12] In acute situations, pathophysiologic changes such as hypoxemia, metabolic derangements, fever, or systemic inflammatory responses also can lead to delirium with characteristic alterations in sleep-wake patterns.[12] Psychological factors of hyperarousal, stress response, predisposing personality traits, and maladaptive attitudes can perpetuate sleep changes seen during illness in later life.[13] In many situations, the interplay between underlying illnesses and their treatments, sleep hygiene, medications, and the sleep environment all are contributing to the problem. The precise relationship between an illness and the neurophysiologic, biochemical, and hormonal sequelae that contribute to sleep disruption remains uncertain in most cases of insomnia in older adults. For these reasons, establishing a clear, consequential relationship becomes a clinical challenge. Therefore the term *comorbid* is believed to more adequately describe insomnia. The 2005 National Institutes of Health State-of-the-Science Conference on Insomnia proposed using the diagnosis of "comorbid insomnia" when an illness coexists with sleep changes but the dynamics of cause and effect are not proved.[11]

Management

The approach to the management of comorbid insomnia is evolving. Historically, if a sleep problem was attributed to an associated physical or mental illness, then the primary focus was on optimizing treatment of that underlying health concern. Intervention consisted of correction of neurochemical, metabolic, and physiologic derangements in illness with the hope that sleep would improve. More recently, a series of controlled trials have demonstrated the efficacy of cognitive-behavioral therapy (CBT) in managing insomnia complaints in a variety of different illnesses. On these grounds, a growing trend is for all comorbid or secondary insomnia to be treated the same as for primary insomnia—with CBT and, when indicated, adjunctive hypnotic therapy.[14] This approach is supported by a study of CBT for insomnia in older adults with osteoarthritis, coronary artery disease, or pulmonary disease. Ninety-two participants (with a mean age of 69 years) were randomly assigned to receive classroom CBT or stress management and wellness training (placebo condition). CBT participants demonstrated larger improvements on 8 of 10 self-report measures of sleep; the type of chronic disease had no impact on these outcomes. These results challenge the clinical distinction between primary and secondary insomnia and suggest that psychological factors are likely to be involved in insomnias that are presumed to be secondary to medical conditions.[15] Although more data are needed to determine the most effective approach, a multifaceted intervention appears to be most logical, including optimization of comorbid health issues and treatment of insomnia using CBT and/or pharmacotherapy.

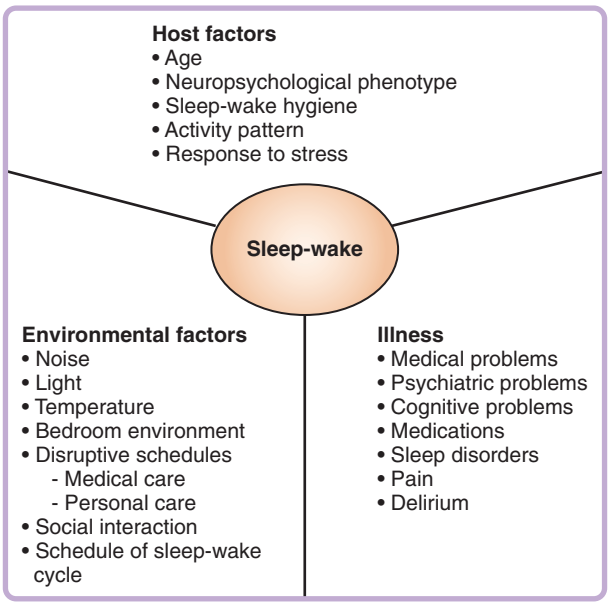

Figure 151-1 Sleep-wake symptomatic status depicted as a syndrome that results from dynamic interactions among genetic and phenotypic characteristics, illness as a function of comorbid conditions and polypharmacy, and environment, to include modulating nociceptive interactions with disruptors and zeitgeber qualities. This model could further identify predisposing, precipitating, and perpetuating factors, but it underscores the limited ability to establish a clear, consequential relationship in the context of the ever-changing interplay of these factors.

PSYCHIATRIC CONDITIONS AND SLEEP IN THE OLDER ADULT

Mental health conditions are prevalent in the geriatric population and often are associated with complaints of difficulties

related to sleep. Indeed, sleep disruption is a part of the diagnostic criteria of many psychiatric disorders. Therefore, to be an independent diagnosis, insomnia has to constitute a distinct complaint and be more prominent than that typically associated with mental disorders.[16] Psychiatric and somatic symptoms, as well as the level of physical activity, significantly and independently increase the risk of insomnia in older clinic patients.[17] Acutely ill psychiatric patients show reduced sleep efficiency, prolonged sleep latency, decreased total night sleep, and increased arousals.[18] Conversely, sleep difficulties in the general population are associated with a higher prevalence of psychiatric disorders and symptoms than in persons without sleep complaints.[19-21] Part of this clinical correlation may reflect the high degree of overlap of medical conditions with psychiatric conditions.

Depressive Disorders

Depression is associated with sleep disturbances in both elderly general populations[22] and clinical populations, with insomnia in the primary care setting showing a stronger association with depression than with any other medical disorder.[23] In a large cross-sectional study (comprising more than 700 subjects, with a mean age of 80 years), approximately one third of participants experiencing depression symptoms (Geriatric Depression Scale score greater than 5) reported moderate to severe sleep onset or sleep maintenance difficulties, whereas almost another third reported mild sleep problems.[24] Older adults with a history of depression show impairments in sleep quality and lower levels of health functioning; these impairments were on a gradient, with declines in those with current depression.[25]

Sleep complaints also foreshadow the onset of depression in older adults, with insomnia a strong risk factor for future depression in elderly patients not currently depressed.[26] Insomnia reported at baseline and 1 year later increased the risk of development of depression eightfold[27] in one elderly cohort. Clinical sleep disturbance, defined as a Pittsburgh Sleep Quality Index (PSQI) score higher than 5, was found to be a powerful predictor of depression recurrence (adjusted hazard ratio, nearly 5) in a 2-year longitudinal study of community-dwelling older adults.[28]

Objective and subjective sleep findings in depression often have different implications and may not always correlate with each other.[29,30] From 60% to 80% of depressed adults and older adults complain of difficulty falling or staying asleep, or being tired in the day.[31,32] These subjective sleep complaints may persist beyond the resolution of depressive symptoms.[33] Prevalence of symptoms is comparable between genders.[34] An apparent association has been noted between greater level of depressive symptoms and worse subjective sleep quality and more subjective daytime sleepiness, as well as objectively measured wake (time) after sleep onset (WASO) and wake episodes longer than 5 minutes.[35]

Objective sleep findings in older adults with depression include prolonged time to sleep onset, decreased sleep efficiency, poor sleep continuity, and increased early-morning awakening. Additionally, total sleep time is reduced, with relative increases in stage 1 and stage 2 sleep and corresponding decreases in slow wave sleep. Other findings include shortened rapid eye movement (REM) sleep latency, a longer first REM sleep period, and increased total REM sleep and density of the rapid eye movements.[18,36,37] Although these patterns of sleep change are well described in depressed persons, no single sleep variable currently is specific enough to distinguish depression from other psychiatric disorders.[18] Furthermore, longitudinal studies of EEG sleep profiles in depression show state and trait characteristics, meaning that some of these characteristics can change over time.[38] Such differentiation may play a role in identifying persons at high risk for depression and in predicting future episodes of depression, as well as in assessing the response to pharmacologic and behavioral treatments.

Bipolar Affective Disorder

Only limited data are available with regard to sleep in older adults with bipolar affective disorder. Overall, compared with normal subjects, patients with bipolar spectrum disorders experience significantly more sleep loss and social rhythm disruption after both minor and major life events, leading to disrupted biologic rhythms and affective symptoms.[39] Manic episodes usually involve a prolonged period of increased activity with minimal sleep. Insomnia can precede manic episodes as a first symptom in up to 77% of cases.[40] Although first-onset mania can occur in elderly persons, this feature warrants suspicion for medical illness or drug effects as contributors. Of people with initial onset of mania in later life, many have a history of depression.[41] Moreover, sleep loss may trigger manic episodes, emphasizing a need to clinically monitor sleep changes and to address sleep-disrupting factors in an attempt to decrease such exacerbations.[40]

Bereavement and Grief

A systematic review looking at late-life spousal bereavement found a strong relationship between bereavement and nutritional risk with involuntary weight loss, and between evidence for impaired sleep quality and increased alcohol consumption.[42] Levels of grief usually are highest within the first 4 months of bereavement, with recovery periods varying with the stress of the bereavement or coping skills and extending to 2 to 3 years. In 38 bereaved seniors assessed at more than 2 months after the event, questionnaire- and diary-based measures of sleep correlated with the level of depressive symptomatology. Sleep duration correlated with the level of grief severity, although no sleep measure correlated with days since loss.[43] In a cross-sectional survey of 170 women (mean age, 66 years) assessed at an average of 26 months from the loss event, insomnia was reported by 13% of subjects. Other sleep-related symptoms included an irregular sleep pattern, nightmares, and sleeping excessively.[44]

Sleeping 6.5 to 9 hours per night at baseline predicted better social functioning, better emotional health, and more energy in older persons who have suffered bereavement.[45] Baseline complicated grief scores of recently widowed elderly persons were significantly associated with sleep difficulties at an 18-month follow-up evaluation.[46] In a study of 28 spousally bereaved older adults assessed at 4 months from the loss event or later, polysomnographic data demonstrated mildly prolonged latency to sleep and REM sleep and mildly reduced sleep time and sleep efficiency. More profound grief tended to be associated with less time spent asleep and reduced alertness at 8 PM.[47] In summary, problems with sleep during bereavement may predict current and future depression and offer a potential target for treatment.

Anxiety Disorders

Common anxiety conditions in older adults include generalized anxiety disorder (GAD) and panic disorder. Most anxiety conditions in the elderly are continued disorders from earlier in their life, with the exception of some increased agoraphobia. Although they cannot be said to suffer from a specific anxiety disorder, many older adults can experience increased anxiety when faced with chronic health conditions, functional limitations, or concerns about issues such as safety or finances, which in addition to the effects of certain medications used to treat other conditions may contribute to neurochemical changes and/or increased adrenergic drive. This association is reflected in the finding that even subclinical anxiety symptoms are associated with higher levels of wake after initial sleep onset as measured by actigraphy and sleep log.[44]

GAD, a condition of overall hyperarousal, is the most prevalent condition among subjects complaining of insomnia who have a mental health diagnosis in the adult population.[48] Sleep disturbance is a core symptom in the diagnosis of GAD and is reported by appproximately two thirds of patients with this diagnosis.[43] In a cross-sectional sample derived from the Einstein Aging Study (comprising 702 participants with an average age of 80), approximately 30% of subjects scoring in the anxiety range (Beck Anxiety Inventory score greater than 11) indicated moderate to severe sleep onset or sleep maintenance difficulties, whereas approximately 50% reported mild difficulties.[24] Objective findings include more awakenings, longer time to fall asleep, and decreased sleep efficiency and total sleep time, with less consistent findings of more stage 2 and decreased slow wave sleep.[18,49]

Approximately 80% of older adults with GAD also have a depressive disorder, making specific objective sleep findings difficult to interpret. Anxiety symptoms, however, were associated with poor sleep efficiency and more time spent awake after sleep onset (i.e., sleep fragmentation) in a population of elderly women, even after accounting for significant depressive symptoms.[50] These findings suggest that untreated anxiety symptoms might account for poor sleep quality in older women that persists even after treatment of depressive symptoms.

Panic disorder also is associated with sleep complaints, including trouble falling sleep and disturbed and restless sleep, as well as nocturnal panic attacks. Nearly one fourth of patients with panic disorder report either severe sleep restriction (to 5 hours or less) or increases in sleep duration (to 9 hours or longer).[51] Nocturnal panic attacks occur at least weekly in 18% to 45% of affected patients.[52,53] These attacks are characterized by similar symptom severity and duration of daytime attacks and occur usually in the first few hours of sleep in transition from stage 2 to slow wave sleep.[54] People with nocturnal panic attacks have higher rates of insomnia and depression than people with panic disorder without nighttime episodes.[55,56] Sleep panic attacks can manifest with aspects of the clinical history similar to that for sleep apnea, parasomnias, gastroesophageal reflux disease (GERD), and posttraumatic stress disorder (PTSD)—a consideration during the workup for sleep complaints.

In older adults with PTSD, many had symptoms for years, with this condition continuing in later life. It appears that although the severity of PTSD seems similar in younger and in older adults, the elderly report less reexperiencing but more symptoms of hyperarousal compared with younger people.[57] Sleep disturbance is common in PTSD, with reported rates of 44% to 91%, including insomnia and nightmares.[58] The most specific findings in PTSD are recurrent awakenings and excessive body movement.[59] A meta-analysis of 20 polysomnographic studies comparing sleep in people with and without PTSD reported more stage 1 sleep, less slow wave sleep, and greater density of rapid eye movements; older patients with PTSD had less slow wave sleep and more REM sleep than age-matched control participants, with possible confounding by the time elapsed since traumatic experiences.[60]

Elderly persons also may be more predisposed to exacerbations or new onset of symptoms in the context of worsening health conditions or on being confronted with the death of friends or spouses, as well as their own mortality. In addition, previous mechanisms for coping may now be affected by physical (e.g., as in a man who habitually works himself to fatigue, or runs to relieve tension, but now has retired or has pain that limits his exercise ability) or cognitive limitations (e.g., regular inhibition of intrusive thoughts leading to more effective coping may be compromised in a person with executive dysfunction such as mild cognitive impairment), which are more likely to occur with increased age.

MEDICAL CONDITIONS AND SLEEP IN THE OLDER ADULT

A specific medical illness may have several mechanisms that interfere with sleep, and different effects on sleep architecture may be seen in its acute versus its chronic state. The immediate physiologic derangements or distress attributable to an illness may transiently disturb sleep. Chronic pain, cardiovascular disease, pulmonary disease, chronic kidney disease, gastrointestinal conditions, and endocrine and genitourinary conditions all have been associated with poor sleep. Sleep disturbance may worsen symptoms in these disorders or even worsen the prognosis.

Pain

Pain is a common contributor to comorbid insomnia. The relationship between pain and sleep is complex: Pain can disrupt sleep, and poor sleep may increase perceived pain intensity.[61] Studies suggest that 25% to 50% of community-dwelling older persons have important pain problems.[62] In a population of adults aged 55 to 84, 19% reported that pain disrupted their sleep at least a few nights per week, and 12% reported almost nightly sleep fragmentation due to pain.[2] In referral populations of patients with chronic pain, prevalence rates of insomnia can range between 50% and 70%.[63] In a polysomnographic study of older adults with chronic pain, afflicted persons spent significantly longer time in bed and had worse sleep onset latency, sleep latency to N2, sleep efficiency, wake time after sleep onset, and number of awakenings compared with control group subjects; sleep duration and time spent in each sleep stage did not differ between the two groups. Investigators also found that older people with chronic pain had lower intensity in the delta frequencies (0.5 to 1.99 Hz and 2 to 4 Hz) throughout the night, especially in the first 6 hours.[64] Actigraphy recordings and sleep diary data seem to confirm these findings and showed subjects with

chronic pain spending significantly more time in bed, with consequent lower sleep efficiency.[65]

Arthritis

As a condition producing pain and disability, arthritis increases with advancing age.[66] Evidence suggests that as many as 60% of those with arthritis experience pain during the night, mediating a substantial amount of the relationship between arthritis and sleep problems. Adults older than 65 with knee arthritis have been observed to have problems initiating sleep (31%), problems maintaining sleep (81%), and a tendency to awaken early in the morning (51%).[67] In a sample of approximately 600 older adults with osteoarthritis (with a mean age of 78), correlates of poor sleep were greater arthritis severity, presence of three or more comorbid conditions, depressed mood, and restless legs symptoms; poor sleep was significantly associated with greater fatigue.[68]

Patients with self-reported arthritis-related sleep disruption are more likely than those without sleep disturbance to pursue multiple sources of self-care and medical care.[69] Cognitive-behavioral approaches demonstrated efficacy in improving self-reported measures of sleep.[15] At least one third of respondents in a recent survey had clinically moderate to severe levels of pain and sleep symptoms, significant enough to lead almost half of the affected patients to ultimately participate in a randomized trial comparing three group-format behavioral interventions.[70]

Gastroesophageal Reflux Disease

Insomnia frequently is associated with GERD.[71] Up to 70% to 90% of persons with GERD report nighttime symptoms and sleep disruption.[72,73]

The prevalence of daily reflux symptoms among those older than 50 years has been reported at 10%.[74] A survey including more than 14,000 respondents reported a higher prevalence of heartburn in elderly persons (approximately 62%) than in younger adults (59%), and the prevalence of frequent symptoms (more often than twice per week) also was higher among elderly subjects (approximately 31%).[75] Sleep disturbance was present in 29% of the older adults, compared with 19% of younger ones. The relationship between disturbed sleep and GERD is likely to be bidirectional: Sleeping increases the likelihood of reflux, and reflux episodes often awaken the patient.[76,77]

Patients with nighttime acid reflux may underestimate the degree of sleep disruption that occurs when objective measurements of pH and electroencephalogram (EEG)-confirmed arousal are compared against patient recollection the next morning.[76] On ambulatory 24-hour esophageal pH monitoring in 54 of 313 consecutive patients (older than 62 years of age) from a primary care setting, 20% (11 of 54) of this subgroup demonstrated increased acid contact time; only 6 patients (11%) exhibited both symptomatic and objective indications of acid reflux.[78] A pilot study enrolling 16 subjects with chronic insomnia found silent reflux in 4 (25%), as evidenced by abnormal results on 24-hour pH testing. Aggressive treatment for reflux resulted in normalizaton of sleep efficiency in 3 of the 4 affected subjects.[79]

Reviewing the clinical history for nocturnal cough or wheezing as a surrogate for reflux also is important, because not all patients with overnight reflux will experience classic chest pain, but their sleep may be disrupted nevertheless. Published evidence demonstrates that acid suppression therapy helps control nighttime heartburn symptoms, reduces the number of GERD-associated sleep disturbances, and improves subjective sleep quality and next-day work performance.[80] Finally, a mechanical link between the phrenoesophageal ligament and the lower esophageal sphincter may explain the coexistence of sleep apnea and reflux.[77,81]

Heart Disease

Coronary artery disease and CHF together constitute a leading cause of morbidity and mortality in older adults. Many relationships exist between cardiac disease and sleep. Nocturnal ischemia, nighttime arrhythmias, and sleep-disordered breathing all are linked to altered sleep in underlying heart disease. A well-described circadian pattern of myocardial ischemia or infarction occurs in early to mid-morning and is ascribed to the catecholamine surge that accompanies awakening and upright status. In a retrospective analysis of data on more than 3300 adults presenting with acute coronary syndrome (ACS), 26% of the subjects were awakened from sleep[82]; older age and lower left ventricular ejection fraction were independent predictors of nocturnal ACS in this cohort. Chronic problems with sleep initiation correlate with an increased risk of death from coronary artery disease in male patients.[83] In study of more than 1200 women experiencing initial myocardial infarction, one half reported new onset of or worsening sleep disturbance before myocardial infarction, with similar prevalence rates across racial groups. Women reporting prodromal sleep disturbance were more likely to be older, to be heavier, and to report cognitive changes, new or increasing anxiety, and unusual fatigue.[84]

Moderate or severe insomnia was reported by 37% of patients experiencing an ACS during hospitalization and was associated with 76 minutes more awake time after initial sleep onset as measured by home polysomnography (PSG). Although depression and insomnia were strongly associated, approximately 1 in 4 patients with insomnia did not report significant depressive symptoms.[85]

Finally, coronary artery bypass surgery is associated with protracted sleep disturbance up to 2 years after the procedure.[86] The mechanism for this sequela is unclear, with occult heart failure, secondary mood issues, or brain microvascular ischemic changes as possibilities.

With increasing average life span and improvements in the management of acute coronary ischemia, it is projected that the incidence and prevalence of CHF will continue to rise. In a cross-sectional study of 223 elderly patients with New York Heart Association class II to IV heart failure, consistent difficulties maintaining sleep were reported by 23% of men and 20% of women, and 25% of the subjects were awake 1 to 3 hours per night.[87] In a study of more than 600 older adults (mean age, 78), cardiopulmonary symptoms (i.e., dyspnea and nighttime palpitations) and pain led to significant direct associations with sleep disturbances.[88] Presence or absence of heart failure did not alter this association. In a multisite randomized, controlled trial including subjects with a heart failure–related hospitalization (in the previous 6 weeks), 45% of participants reported poor sleep (PSQI of 5 or higher).[89] Compared with that in control subjects, the PSQI global score improved with twice-weekly structured exercise training. Improved sleep quality correlated with improved exercise capacity and reduced depressive

symptoms, but not with changes in body mass index or resting heart rate.

The classic sleep maintenance disturbance associated with CHF includes orthopnea, paroxysmal nocturnal dyspnea, nocturia, and sleep-disordered breathing. More than 50% of patients with moderate to severe CHF experience periodic breathing or Cheyne-Stokes respiration. The altered breathing may lead to increased sleep fragmentation, with consequent increase in daytime sleepiness.[90,91] Comorbid depression also was identified as a factor that increasingly contributes to sleep disturbance in elderly patients with CHF.[92]

Nocturia is common and often severe in patients with stable CHF. In a cross-sectional observational study of 173 patients (with a mean age of 60 years and a left ventricular ejection fraction of 32%) with stable chronic heart failure, a third of patients awakened three or more times per night to void.[93] This group exhibited a nearly sevenfold increase in the frequency of reported insomnia symptoms. Other findings included decreases in sleep duration and efficiency, REM and stage 3 sleep duration, and physical function and increases in the percentage of wake time after sleep onset, insomnia symptoms, fatigue, and sleepiness across levels of nocturia severity.

Chronic Lung Disease

Chronic obstructive pulmonary disease (COPD) contributes to poor sleep continuity as well as to increased daytime sleepiness.[94] In a study of correlates of insomnia in 142 Chinese patients with COPD aged 60 years of age or older, compared with sex- and age-matched control subjects, frequency of insomnia was 47.2% in the patient group and 25.7% in the control group, with higher rates in frequency of early, middle, and late insomnia.[95] Another study of 183 patients with COPD showed higher likelihood of insomnia in current tobacco users (odds ratio [OR], 2.13) and in those with frequent sadness or anxiety (OR, 3.57); oxygen use was associated with lower risk of insomnia (OR, 0.35).[96]

Reported sleep changes in COPD include increases in sleep stage shifts, decreased total sleep time, and increased number of arousals.[97] Even persons with mild to moderate COPD have lower sleep efficiency, a lower total sleep time, and lower mean overnight oxygen saturation compared with control subjects.[98] The sleep disturbance frequently is related to nocturnal cough, wheezing, and shortness of breath due to worsening of pulmonary mechanics and gas exchange during sleep. Hypoxemia, which is common in COPD during REM sleep, correlates with an increase in arousal and excessive daytime sleepiness. Although the use of oxygen therapy frequently corrects the underlying hypoxemia, it does not appear to improve sleep quality.[97] Use of inhaled ipratropium bromide improves sleep quality and duration, presumably through improved airflow.[99] However, use of a long-acting bronchodilator, such as formoterol, although overall beneficial for the lung process, may result in insomnia.[100]

The prevalence of insomnia symptoms in a sample of more than 1800 subjects with asthma, part of a 25,000-subject questionnaire, was significantly higher among asthmatics than nonasthmatics (47% versus 37%).[101] In the subgroup reporting asthma and nasal congestion, 56% had insomnia symptoms. The risk of insomnia increased with the severity of asthma; nasal congestion (OR, 1.50), obesity (OR, 1.54), and smoking (OR, 1.71) were other factors associated with increased risk. Nocturnal asthma symptoms resulting in nighttime awakenings may occur in more than 70% of persons with asthma. Other reported sleep symptoms include difficulty falling asleep, difficulty maintaining sleep, early-morning awakenings, and daytime sleepiness. Asthma control correlates with quality of sleep.[102]

Diabetes and Endocrine Disorders

Diabetic patients may have disrupted sleep as a consequence of advanced age, obesity, and treatments for and complications of common comorbid diseases (e.g., depression, cardiovascular disease). Diabetes-specific complications, such as neuropathy, may directly interfere with sleep or contribute to restless legs symptoms and nocturnal leg cramps. In almost 10,000 adults participating in the National Health and Nutrition Examination Survey in the period 2005 to 2008, diabetes was associated with increased risk of inadequate sleep, frequent daytime sleepiness, restless legs symptoms, sleep apnea, and nocturia.[103] All of these showed higher risk with increasing severity in graded fashion. Diabetes duration was significantly associated with the same problems: Risk increased 20% to 30% per 10 years since diagnosis.

In a large study of more than 13,000 adults with diabetes mellitus, 24% reported insomnia.[104] In the more than 200 subjects older than 60 years of age, evaluated at less than 2 years before death, the prevalence was approximately 36%. Nonetheless, insomnia was more prevalent in younger (i.e., younger than 60 years of age) subjects surviving more than 24 months (compared with those 60 years of age or older).

A growing body of literature indicates a link between sleep and glycemic control. Thirty percent of diabetic patients demonstrate sleep maintenance disturbances, with the severity of disruption correlating with the degree of hyperglycemia.[105,106] Of interest, the likelihood of being insulin resistant increases linearly with concurrent sleep complaints.[107] Consequently, high HbA1c was found to be associated with difficulty in maintaining sleep but also early-morning awakenings.[108] In an ancillary study to the Coronary Artery Risk Development in Young Adults, among the 40 subjects with diabetes, 10% higher sleep fragmentation was associated with a 9% higher fasting glucose level, a 30% higher fasting insulin level, and a 43% higher insulin resistance estimated using the homeostatic model assessment method. Insomnia was associated with a 23% higher fasting glucose level, a 48% higher fasting insulin level, and an 82% higher homeostatic model assessment insulin resistance level.[109]

One third of patients with diabetes have problems with sleep fragmentation, with nocturia, leg cramps, leg pain, and cough as contributing factors. Likewise, patients with diabetes have an increased prevalence of both restless legs syndrome (RLS) and periodic limb movements of sleep.[110] A growing body of epidemiologic and experimental evidence links sleep apnea and disorders of glucose metabolism; however the cause and effect relationship remains to be determined.[111]

Thyroid disease also may influence sleep architecture. Among 6000 subjects (older than 65 years) participating in the Osteoporotic Fractures in Men study, no difference in sleep quality was found between subclinically hypothyroid and euthyroid men.[112] Compared with euthyroid men, subclinically hyperthyroid men had lower mean actigraphic total sleep time, lower mean sleep efficiency, higher mean

wake time after sleep onset, and increased risk of sleep latency of 60 minutes or longer.

Renal and Urologic Diseases

Sleep disruption is common in patients with urologic and kidney disease. Benign prostatic hyperplasia and prostate cancer typically are diseases of the aging male, steeply increasing in frequency with age. Overactive bladder is characterized by urinary urgency, frequency, nocturia, and sometimes incontinence. It increases markedly with advancing age in both men and women.[113]

Nocturia is a well-recognized etiologic factor in sleep maintenance disturbance in later life, and nighttime urination often is associated with poor quality of sleep and increased fatigue in the daytime.[114] It is reported to be an independent predictor both of self-reported insomnia (75% increased risk) and reduced sleep quality (71% increased risk) based on a survey of more than 1400 elderly persons.[115] In approximately 16,000 participants in the Third National Health and Nutrition Examination Survey, prevalence of nocturia, defined as two or more voiding episodes nightly, was approximately 16% for men and 21% for women. This study showed that nocturia is a strong predictor of mortality, with a dose-response pattern in increased mortality risk with increasing number of voiding episodes nightly.[116] The severity of nocturia increased with advancing age. Urinary incontinence, recurrent cystitis, and diabetes mellitus were the strongest associated factors for nocturia of any degree.[117] Other etiologic factors include polyuria, low bladder capacity, sleep apnea, excessive fluid intake before bedtime, alcohol, caffeine, diuretics, medical disorders such as hypertension, CHF, and prostatic disease. The *nocturnal polyuria syndrome* is characterized by an inappropriate nocturnal urine output, often an undetectable plasma ADH during the night, and increased thirst, particularly at night[118]; 24-hour urine output is normal or only moderately increased. In older adults with concurrent insomnia and nocturia, brief behavioral treatment for insomnia (consisting of instructions on reducing time in bed and setting a regular sleep schedule) also may produce symptomatic improvement in patients with self-reported nocturia.[119]

Approximately 40% of community-dwelling older adults report sporadic or chronic urinary incontinence,[120] with the most common cause documented as the overactive bladder syndrome. Urine loss is considered a geriatric syndrome in that it leads to a spectrum of physical, psychological, and social consequences that can be a detriment to the older person's function and quality of life. The effects of incontinence on sleep are best studied in the nursing home population with both polysomnographic and actigraphy samples demonstrating sleep disruption with nocturnal wetting episodes. Of interest, 51% of these episodes occurred during or within 60 seconds of an abnormal sleep breathing event.[121] In people who are chronically incontinent, the relationship between urine loss and awakening is not as tightly linked.[122]

Rates of chronic kidney disease (CKD) and end-stage renal disease show a steady increase beyond the age of 60, with a striking rise in prevalence after age 75.[123] Fifty-seven percent of patients with end-stage renal disease report sleep maintenance problems, and 55% report early-morning awakening. There are marked abnormalities seen on the sleep EEGs of patients with CKD, including overall reduction in total sleep time, decreased sleep efficiency due to wakefulness after sleep onset, and reduced total REM sleep.[124] Overall prevalence of insomnia in patients managed with hemodialysis (HD) was described to be between 45% and 86%.[125] In a longitudinal study (up to 2 years) of patients with CKD not on dialysis and those on HD, disruption of sleep was independent of several risk factors.[126] Among the patients on HD, sleep disruption was of much greater severity than among those with CKD not on dialysis. Missing a dialysis session or shortening the prescribed duration of dialysis appeared to be associated with greater severity of sleep disturbance.

Patients on HD have a 50% to 80% rate of sleep-wake complaints and a higher prevalence of OSA (which lessens in severity after dialysis), RLS, periodic limb movements of sleep (PLMS), early insomnia, and excessive daytime sleepiness.[124,127,128] Quality of sleep was associated with hemoglobin level, serum albumin, and depression in 89 patients on HD with a mean age of 60 years. In a study involving patients on HD with a mean age of 65 years, treatment of kidney disease with erythropoietin improved sleep quality by polysomnographic and subjective measures and reduced the number of periodic limb movements.[129] More than 50% of patients on HD report chronic pain, and this complaint is thought to be significantly associated with insomnia and depression in this condition.[130]

Cancer

Cancer frequently is a disease of older persons, with greater than 60% of all cancers diagnosed after the age of 65 years. The prevalence of sleep problems in persons with cancer is difficult to determine with wide variance based upon type and stage of cancer. Large epidemiologic studies suggest that sleep problems are very common, affecting 55% to 87% of patients[131,132]; approximately one half of the patients reported onset within the period 6 months before diagnosis to 18 months after diagnosis.[133] In a study of 867 older adults (46% of whom were women) who were newly diagnosed with breast, colorectal, lung, or prostate cancer and followed at four points during the year after diagnosis, insomnia remained present in 23.2% of patients 1 year after their cancer diagnosis. The study authors reported a lessening of reports of pain, fatigue, and insomnia over time; however, a high attrition rate was noted.[134]

Persons with cancer may have a baseline history of insomnia or a primary sleep disorder, or they may have sleep effects from the cancer, its treatment, or the psychological response to the diagnosis.[132] In a meta-analysis of sleep across chemotherapy treatment regimens, subjective and objective sleep quality was found to be poor, with a high frequency of nocturnal awakenings. Daytime sleepiness increases in the active phase of chemotherapy, and insomnia symptoms are common before and after chemotherapy sessions. In women with recurrent or metastatic breast cancer, difficulty falling asleep, nocturnal awakenings, difficulty awakening, and daytime sleepiness are problematic at different points in the course of chemotherapy.[135]

Most of the studies reported in the literature report on sleep changes in early-stage cancer.[133] Forty-four percent of hospitalized cancer patients are prescribed hypnotic therapy.[136]

In a large sample of approximately 2000 cancer patients, approximately 23% reported taking hypnotic medications. Factors associated with a greater utilization of hypnotic

medication were older age, greater difficulties initiating sleep, more stressful life events experienced in the past 6 months, higher levels of anxiety, past or current psychological difficulties, greater use of opioids, and past or current chemotherapy treatments.[137]

Trials of CBT in cancer patients suggest significant improvement in their sleep with this therapy.[131] In a recent study of 111 cancer subjects with insomnia, although mindfulness-based stress reduction protocols produced a clinically significant change in sleep and psychological outcomes, CBT for insomnia (CBT-I) was associated with rapid and durable improvement and is still regarded as the best choice for nonpharmacologic treatment of insomnia.[138]

MEDICATIONS IN OLDER ADULTS AND IMPACT ON SLEEP

The use of prescription drugs and over-the-counter (OTC) drugs is common in older persons. A multitude of both OTC and prescription medications are known to influence the sleep-wake cycle and to produce comorbid insomnia. Their adverse effects are diverse but can be broadly categorized as those that produce drowsiness or daytime somnolence, those that are activating or stimulating to the brain, those that interfere with sleep by indirect mechanisms, those that may directly exacerbate primary sleep disorders, and those that influence sleep architecture through other effects. Adverse side effects and drug-drug or drug-disease interactions are more likely to occur in older adults. These effects can then lead to direct or indirect effects on overnight sleep quality and quantity. Many of these drugs can alter patterns of sleep and wakefulness both during periods of administration as well as during withdrawal. It is especially important to avoid using hypnotics or stimulants as agents in the cascade effect (use of medications to treat sleep-related side effects of other medications) unless all other attempts at medication adjustment have been considered.

Medications that Promote Daytime Sleepiness

Drowsiness is an extremely common drug side effect, with close to 600 medications cited as causing drowsiness in the side effects index of the *Physicians' Desk Reference*.[139] Excessive daytime sleepiness is a frequent sleep complaint in the elderly population, with a baseline tendency among older adults to have shorter sleep latency during the day.[140] Many medications have the capacity to interfere with acetylcholine or histamine, both regulatory neurotransmitters for wakefulness. These anticholinergic agents are known to have somnogenic effects—drowsiness while awake—as well as negative cognitive, affective, and quality-of-life outcomes in older adults.[141] Antihistaminergic drugs have variable central nervous system (CNS) penetration and binding. Histamine H_1 receptor antagonists such as diphenhydramine are much more likely to produce sedation and cognitive impairment than tertiary antihistamines.[142] General classes of agents with these effects are antihistamines, antispasmodics, antipsychotics, antiemetics, and antiparkinsonian drugs. Notable specific examples include tricyclic antidepressants such as amitriptyline, doxepin, imipramine; cimetidine, mirtazapine, and oxybutynin.

Medications also can produce sleepiness by other mechanisms. In persons taking levodopa or dopamine agonists, an increased prevalence of excessive daytime sleepiness and sleep attacks has been noted.[143] Anticonvulsant agents such as gabapentin, lamotrigine, tiagabine, and levetiracetam frequently produce sleepiness in older adults. Morphine and other opiate analgesics can contribute to daytime somnolence and decreased alertness, as well as disrupting overnight sleep efficiency and architecture.

Medications that Activate the Central Nervous System

A large number of medications disturb sleep through excitation or activation of the CNS. Sleep quality may be affected if these agents are taken before the patient's bedtime or have a sustained half-life that extends into the typical sleep period. Common OTC products for cold and flu contain pseudoephedrine, ephedrine, or other sympathomimetics. OTC analgesics used for headache therapy may contain caffeine. Agents used to manage chronic lung disease such as inhaled and oral beta agonists, corticosteroids, and theophylline can contribute to sleep disruption. Activating antidepressants such as desipramine, bupropion, venlafaxine, reboxetine, and most selective serotonin receptor inhibitors (SSRIs) can sometimes adversely affect sleep initiation and maintenance. Insomnia has been reported as a frequent side effect with SSRI use, with a prevalence of 16.4% with sertraline, 15% with fluoxetine, and 14% with paroxetine.[144] With use of SSRIs, although patients may perceive an improvement in subjective sleep quality, objective sleep often worsens.[29] Activating medications such as methylphenidate, selegiline, and modafinil often are seen on geriatric medication lists. Careful evaluation of doses and times of administration for such medications may be considered to avoid interference with the desired sleep period.

Medications that Affect Sleep by Worsening other Conditions

Medications can sometimes interfere with sleep by worsening an underlying medical or psychiatric condition, which then adversely affects sleep. Medications that worsen heart failure such as nonsteroidal antiinflammatory drugs, calcium channel blockers, or sodium-complexed antibiotics have the potential to cause central sleep apnea, nocturia, or other sleep problems seen in this condition. Medications including nitrates and calcium channel blockers can decrease lower esophageal sphincter tone with resultant nocturnal gastroesophageal reflux. Amitriptyline and other anticholinergic medications, although potentially helpful with sleep because of their sedative effects, also can contribute to confusion as well as urinary retention, with subsequent arousals from delirium or nocturia. Late-afternoon or evening diuretic treatment may cause nocturia and sleep fragmentation. Many antipsychotic medications, which may be used for various symptoms in the elderly, have the potential to produce parkinsonian features, with the sleep difficulties commonly associated with these conditions. Quetiapine may be one of the least common offenders in this category of medications. Hypoglycemic agents, if they produce nocturnal hypoglycemia, can increase nocturnal arousals.

Medications that Can Exacerbate Primary Sleep Disorders

A number of medications have been reported to exacerbate primary sleep disorders. Nocturnal movement disorders

such as RLS and PLMS can worsen in the setting of treatment regimens featuring a number of antidepressant medications. In a study of 274 consecutive patients on antidepressants, as compared with 69 control subjects, those taking SSRIs or venlafaxine were five times more likely to have an elevated PLM index (greater than 20 movements per hour), whereas those taking bupropion had a risk of PLMS similar to that for control subjects.[145] Tricyclic antidepressants and lithium also are associated with a greater prevalence of nocturnal movement disorders. Caffeine, antihistamines, alcohol, and benzodiazepine withdrawal all can worsen RLS. Antipsychotic therapies are associated with greater PLMS prevalence.

As indicated by findings in a series of small studies and case reports, use of opiate analgesics, especially sustained-release or long-half-life formulations, is associated with increased central apneas, sustained hypoxemia, and prolonged duration of the abnormal breathing events.[146] These changes occur in the context of the well-established acute respiratory depressant effects. Hypnotics such as benzodiazepines also may worsen sleep-disordered breathing by lowering the arousal threshold.

Medications that Affect Sleep Architecture by Other Mechanisms

Certain medications may directly affect the sleep architecture. Beta blockers frequently are prescribed in older adults for the management of hypertension and heart disease. The more lipophilic agents such as propranolol and some of the newer-generation beta blockers have been shown to suppress melatonin, increase sleep fragmentation, and increase nightmares in some people.[147] Other agents such lithium, benzodiazepines (on withdrawal), benzodiazepine receptor agonists, and gamma-aminobutyric acid hydroxybutyrate are associated with a worsening of disorders of non-REM parasomnias. Tricyclic antidepressants, monoamine oxidase inhibitors, venlafaxine, and mirtazapine all have been documented to induce REM sleep behavior disorder, a parasomnia very specific to older adults. Oxybutynin is the most studied of the anticholinergic agents. Night terrors have been associated with use of this agent in case reports, in addition to mild sedation. Polysomnographic changes include a decrease in the amount of REM sleep of approximately 15%, increased REM sleep latency, and power reduction in theta, alpha-1, alpha-2, and beta-1 bands on the electroencephalogram.[148]

Reported effects of donepezil include an increase in REM sleep with a decrease in slow frequencies in REM sleep, decrease in stage 1, and increase in stage 2.[149] An increase in REM sleep density and a decrease in REM sleep latency and nightmares have been reported in healthy elderly volunteers.[150] Changes observed with galantamine in healthy volunteers include a decrease in REM sleep latency, an increase in REM sleep density, and a decrease in slow wave sleep.[151]

SUBSTANCE ABUSE IN OLDER ADULTS AND RELATIONSHIP TO SLEEP

Legal substances of abuse (alcohol, nicotine, and caffeine) as well as illicit ones (stimulants, marijuana, opiates) can disrupt sleep. A high rate of substance use has been documented among older adults with comorbid psychiatric conditions and health problems, which further contributes to and complicates sleep disturbances and warrants clinical assessment and treatment as a potential route of addressing sleep complaints. Among persons with a mental disorder, the lifetime prevalence of an addictive disorder not including nicotine or caffeine dependence is 29%, mostly accounted for by alcohol.[152]

Alcohol Dependence

The direction of sleep disruption and alcohol dependence is likely to be bidirectional, with 50% of alcoholic persons reporting sleep problems before the onset of alcohol dependence.[153] Quantity of drinking and depression predicted insomnia severity in a sample of more than 360 alcohol-dependent patients.[154] Sleep problems may increase the risk of an older adult's developing alcohol problems.[155] Alcoholics report high rates of insomnia, ranging from 36% to 72% in inpatient and outpatient studies. Community rates of alcohol dependence in the geriatric population are 2% to 3% for men and 1% for women.[156] In elderly clinical cohorts, rates are higher (4% to 23%), probably as a consequence of the increased comorbid medical disorders that accompany alcohol dependence.[157] Elderly alcoholics are quite likely to have other substance-related comorbid conditions, which may further impair their sleep, including nicotine dependence in 50% to 70% and dependence on prescribed sedatives, anxiolytics, and opioid analgesics (2% to 14%).[157]

Although acute ingestion may decrease the sleep latency, alcohol-induced sleep may be of poorer quality and shorter duration. Increased arousals occur as the blood alcohol level falls in the hours after alcohol intake, with resultant sleep maintenance insomnia.[158] Acute alcohol intake affects multiple neurotransmitter systems, including acetylcholine, glutamate, gamma-aminobutyric acid, norepinephrine, dopamine, and adenosine. Acute alcohol intake also disrupts the circadian cycle and body temperature, stimulates release of cortisol, and interferes with nocturnal release of growth hormone. Alcohol decreases pharyngeal muscles tone and lowers the arousal threshold, increasing the risk of apneas and more severe oxygen desaturations during apneas.

Chronic consumption results in long-term alterations of the neurotransmitter systems affected by alcohol. A majority of alcohol-dependent patients report disrupted sleep symptoms at the time of entering treatment to stop drinking.[159] Although sleep complaints vary, difficulty falling asleep is reported as the most significant factor associated with substance use.[155] Alcoholics older than 55 had higher sleep latency, lower sleep efficiency, and decreased delta sleep activity on the electroencephalogram when compared with younger alcoholics and with nonalcoholics of both age groups.[159]

An older person with alcohol dependence is likely to still have disrupted sleep even after quitting alcohol and maintaining abstinence, because alcohol dependence may result in permanent effects on the brain, as supported by animal studies that reveal alterations in the *PER* gene expression involved in circadian rhythm after alcohol consumption.[160] In acute withdrawal, PSG findings include increased sleep latency, decreased total sleep time, and increased REM percentage. Alcoholics who have been abstinent for 3 to 6 weeks have worse sleep than nonalcoholics by polysomnographic assessment,[161] with changes persisting at 2.5 years.[155,162] During abstinence, insomnia and sleep architecture changes are significant factors predicting alcoholism relapse.[159,163] In

abstinent male alcoholics, 75% of those older than 60 years of age had sleep-disorered breathing, compared with 25% for those in the 40- to 59-year-old age group and 3% for those younger than 40.[164] Higher rates of PLMS in abstinent alcoholics also have been observed.[165]

Caffeine

Consumption of caffeine in coffee, tea, and sodas, as well as medications, is common in the elderly and may contribute to sleep disruption. In a study of 1528 older adults, participants in the 60- to 69-year-old age group reported consuming 17.6 cups of caffeinated coffee per week, with a subsequent reduction over the next two decades of life to 12.8 cups of caffeinated coffee per week.[166] Caffeine has stimulatory effects on the cerebral cortex and medullary centers, with blood levels peaking 15 to 45 minutes after intake and a half-life of 3 to 7.5 hours. Because of the greater proportion of adipose tissue to lean body mass, a dose of caffeine determined as mg/kg of total body weight may result in higher plasma and tissue concentrations in elderly than in younger persons. Age and plasma caffeine concentrations significantly predict a poorer-quality sleep.[167] In adult populations, daytime sleepiness and insomnia were associated with high daily caffeine consumption.[168,169] Changes related to caffeine intake include a decreased total sleep time, increase in sleep onset latency, and increased number of awakenings. Intake shortly before sleep time has been shown to disrupt sleep in adults on objective and subjective measures.[170,171] Adults older than 67 years of age on caffeine-containing medications report significantly more trouble falling asleep, after institution of controls for multiple factors.[172] Hospital-dwelling elderly patients with higher serum caffeine concentrations reported sleep problems more often than did those with lower levels.[167]

Tobacco and Nicotine

Habitual tobacco use constitutes a chronic disease with multiple relapses, especially in older adults. Nearly 11% of the population 65 years of age and older are smokers.[173] Several studies have suggested that insomnia and sleep apnea are more common in smokers, but establishing a causal relationship has been difficult.[174] Current smoking was independently associated with an increased likelihood of snoring, short sleep, and poor sleep among U.S. adults.[175] In a cohort of almost 500 women studied over 25 years, chronically heavy-smoking subjects were more likely to report insomnia at a mean age of 65 years (adjusted odds ratio, 2.76)[176] Nicotine enhances acetylcholine neurotransmission in the basal forebrain and dopamine release, potentially influencing sleep-wake control mechanisms toward wakefulness.[177] A dose-dependent reduction in REM and slow wave sleep, along with an increase in wakefulness and total sleep time, has been observed with nicotine use.[178] Elderly smokers report more difficulties with sleep onset and staying asleep than nonsmokers. In all age groups, smokers drink more caffeine and are more likely to be depressed.[178] The overlap of nicotine dependence with psychiatric conditions is an important issue across all age groups. In clinic and community populations of depressed patients, 40% to 60% smoke, with even higher rates in those affected by PTSD and schizophrenia.[179] Quit rates also are much lower in people with psychiatric disorders. When offered the tools they needed, older smokers quit smoking at rates comparable to those for younger smokers.

SPECIAL CONDITIONS

Caregiving

Elderly caregivers represent 13% of all caregivers and are more likely to be caring for a spouse, often with dementia. Caregivers or a spouse of a person with dementia or disability are at increased risk for sleep problems. In a study of community-dwelling spousal caregivers of patients with Alzheimer disease, caregivers objectively slept less than older noncaregivers and subjectively reported more sleep problems and functional impairment as a result of poor sleep.[180]

Up to two thirds of older adult caregivers are afflicted with some form of sleep disturbance.[181] Predisposing factors for changes in the sleep of a caregiver include increasing age, female gender, and higher caregiver burden.[182] Caregiver burden encompasses the spectrum of physical, psychological or emotional, social, and financial problems experienced by the care provider. A study of the sleep quality of caregivers of persons with dementia demonstrated links between poor sleep and fluctuations in the status of the care recipient, the need for vigilance to safeguard the care recipient at night, and worry about current and future events, which caused rumination.[183] Caregivers identified barriers to health promotion activities, including lack of time, decreased energy, and additional costs for providing care for the care recipient.

The caregiver's situation is analogous to that of a rotating shift worker, who must be alert both at night and during the day, often on an inconsistent schedule.[181] The combination of depression and high-stress situations (e.g., caring for a spouse or a person with dementia, or living with the care recipient) increased the likelihood of sleep problems.[184] In addition, by virtue of their age, older caregivers are at risk for developing many of the chronic illnesses that can directly affect sleep, as described in previous chapters.

Sleep problems in a caregiver may be precipitated by changes in the nighttime routines of the person for whom they are caring, including agitation, sundowning, wandering, and sleep-disordered breathing. In the case of the vulnerable caregiver, it can be very difficult to fall back asleep after being awakened by a care recipient who needs assistance with toileting, administration of medication, redirection back into bed, orientation, or emotional reassurance, particularly when these nocturnal interactions are prolonged or emotionally charged. This situation puts the caregiver at risk for long-term partial sleep deprivation that may partially explain why one of the strongest factors in deciding to institutionalize a spouse or family member with dementia is poor overnight sleep of the affected person.[185]

Geriatric Syndromes

Falls and Mobility

Falls and gait problems are a common and serious problem facing older adults. Approximately one third of those aged 65 and older living in the community fall at least once a year. This proportion increases to 1 in 2 for persons aged 80 and older.[186] Falls typically are the result of multiple, interacting etiologic factors. It is well acknowledged that older persons with insomnia on hypnotic therapy are at higher risk for falls. Prevailing evidence suggests that this risk is due in part to the adverse effects of benzodiazepines and other hypnotics on balance, cognition, and reaction time,

with withdrawal of these agents reducing the risk for future falls.[187]

Increasing evidence suggests that it may be sleep itself, with its neurocognitive consequences, that predispose the older person to falls in selected populations such as in the nursing home.[168] Sleep quality has been linked to physical function. In a study of more than 2800 men, total sleep time less than 6 or more than 8 hours, sleep efficiency less than 80%, WASO of 90 minutes or longer, RDI of 30 or greater, and hypoxia were found to be associated with poorer physical function.[188] In a similar study, this time evaluating more than 800 women over a period of 5 years, shorter sleep duration, greater WASO, and lower sleep efficiency were risk factors for functional or physical decline.[189] A cross-sectional study of more than 2800 men and women (older than 55 years of age), after adjustment for lifestyle factors and diseases, indicated that longer sleep (9 hours or more) was associated with a decreased walking speed in women aged 65 or more years and shorter sleep (6 hours or less) with a higher likelihood of mobility limitation in women 65 years of age or older and in men 55 to 64 years of age.[190] A discrete sleep disorder or insomnia was independently associated with both decreased walking speed and mobility limitation in men 55 years of age or older but with only mobility limitation in women 65 years of age or older.

Consensus statements from expert panels advise a multifaceted approach to reduce future falls, including behavioral interventions for sleep, drug review, adjustment of psychotropic and hypnotic agents as possible, an exercise program, and evaluation and treatment of other comorbid medical problems as appropriate.

Delirium

Delirium is a serious acute neuropsychiatric syndrome with core features of inattention and cognitive impairment and associated features including changes in arousal, altered sleep-wake cycle, and fluctuating changes in mental status. Delirium is common in critically ill and palliative care patients and probably encompasses adverse effects of stress response pathways, induced by aberrations in the normally adaptive systemic and CNS responses to stressors. Sleep disturbances appear to have a bidirectional relationship with delirium and are part of many delirium assessment instruments, such as the Intensive Care Delirium Screening Checklist.[191] Such disturbances are defined as "sleeping less than 4 hours or waking frequently at night, sleeping during most of the day." In a series of 600 consecutive patients admitted to the intensive care unit for more than 24 hours, sleep-wake cycle disturbances occurred in almost 70% of patients with delirium, compared with 12% of patients without delirium, and were highly discriminating for the diagnosis of delirium.[192] Another study of 100 cases of delirium in a palliative care inpatient service reported sleep disturbances in 97% of patients.[193]

In a study of 13 patients (6 with delirium and 7 without delirium) employing actigraphy, delirious patients showed fewer nighttime minutes resting, fewer minutes resting over 24 hours, greater mean activity at night, and a smaller amplitude of change in activity from day to night. Rest and activity consolidation were significantly reduced in delirious patients, as was the amplitude of day-night differences in rest and activity.[194]

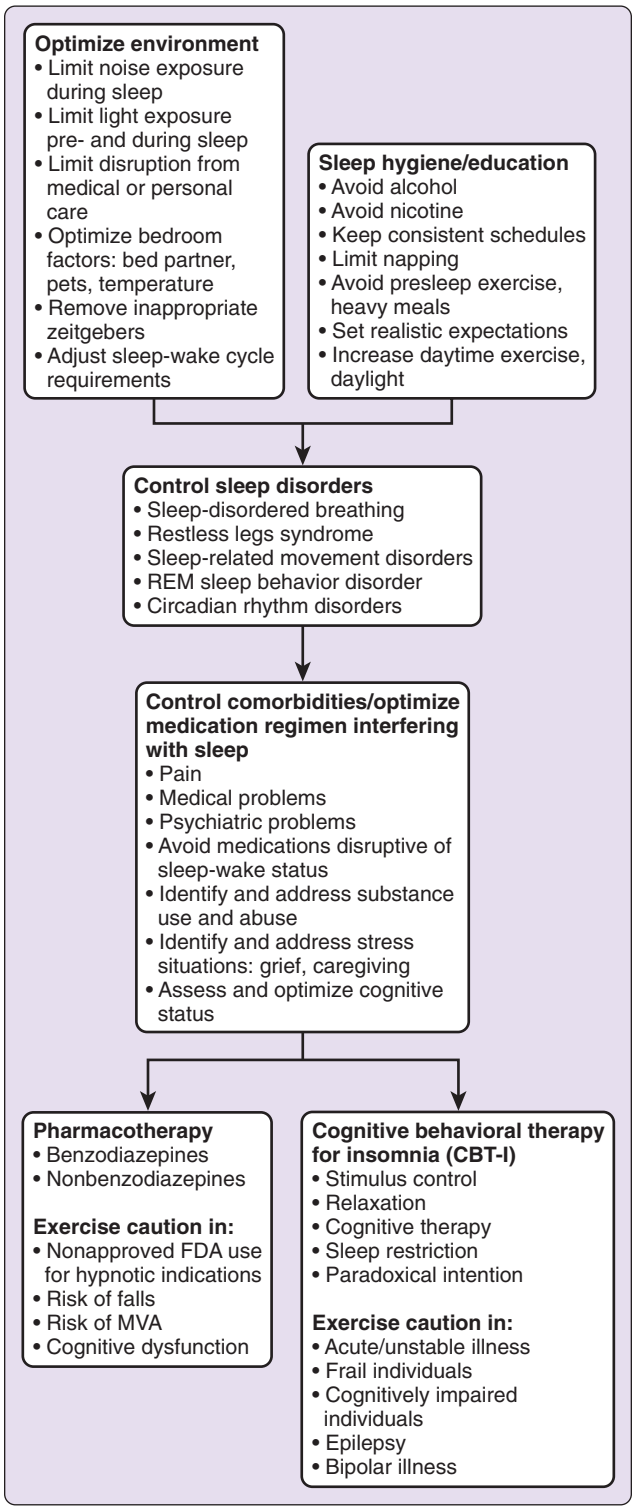

Figure 151-2 Interventions to be considered in comorbid insomnia. A multifactorial targeted intervention appears to be most appropriate in accordance with current concepts (see Figure 151-1) and as indicated by the available evidence. Considering all potential predisposing, precipitating, and perpetuating factors can increase the effectiveness of the therapeutic act while ensuring optimal control. Interventions should be balanced with regard to potential adverse consequences. MVA, Motor vehicle accident.

CLINICAL PEARLS

- Sleep complaints often are comorbid with chronic health issues, as well as the associated changes in the patient's lifestyle, sleep hygiene, and medication regimens that are secondary to the illness. Furthermore, these health problems rarely exist in isolation and instead frequently coexist with psychiatric diagnoses, neurologic diseases, and primary sleep pathology.
- In view of the multiple pathways of disrupted sleep, a multifaceted management approach is best in order to improve symptoms. This strategy includes optimizing control of the underlying illness and the environment, adjusting or eliminating potentially offending medications, using cognitive-behavioral approaches, and employing judicious hypnotic therapy based on current evidence.
- Older adults often are in special life situations (caregiving, hospitalization, end of life, abstinence after alcohol dependence) that make them particularly vulnerable to incident sleep disturbances. Heightened awareness and recognition of these situations are essential for optimal management.
- Many medications can alter patterns of sleep and wakefulness both during periods of administration and during periods of withdrawal. It is especially important to avoid using hypnotics or stimulants to treat sleep-related side effects of other medications unless all other options have been considered.

SUMMARY

As the field of medicine continues to advance, people are living longer, with more comorbid medical and psychiatric conditions. This higher burden of illness and the sheer number of medications used to treat these conditions play an important role in the quality and quantity of sleep in older adults. In approaching sleep complaints in geriatric patients, it is essential that practitioners recognize the multidimensional mechanisms by which illness affects sleep. Equally important, a balanced management approach (Figure 151-2) that includes optimizing the underlying illness, adjusting medications, using cognitive-behavioral approaches, and offering judicious hypnotic therapy seems justified as indicated by the current evidence.

Chapter
152

Obstructive Sleep Apnea in Older Adults

Barbara A. Phillips

Chapter Highlights

- The prevalence of obstructive sleep apnea (OSA) increases with age, but the peak prevalence of clinically diagnosed OSA is in middle age. Differences in the clinical presentation, severity, and manifestations of obstructive sleep-disordered breathing between older and younger persons probably account for much of the gap in diagnosis.
- More than half of older adults report sleeping difficulty.[1-5] Because sleep complaints are common in the older age group, clinicians may discount them. Sleep complaints in seniors, however, correlate with health complaints, depression, and mortality.[1-6] Undiagnosed OSA probably accounts for some of the sleep complaints voiced by older adults. Indeed, OSA leads both to sleep disturbance and to increased mortality and is likely to account for much of the association between sleep complaints and adverse outcomes in older people. Despite this, sleep-disordered breathing is woefully underdiagnosed and undertreated in the older adult population.
- Accumulating data indicate that continuous positive airway pressure use is associated with reduced cardiovascular morbidity, cognitive dysfunction, and all-cause mortality in seniors; clinicians caring for geriatric patients should consider sleep-disordered breathing in the older adult with sleep complaints. This chapter focuses on OSA in the older patient. For discussion of central sleep apnea, see Chapters 109 and 110.

EPIDEMIOLOGY AND DEFINITIONS

Although studies of clinical populations identify peak prevalence of clinically significant sleep-disordered breathing in middle age, population-based studies have shown that sleep-disordered breathing increases with age.[7,8] Longitudinal and cross-sectional studies also have shown that the prevalence of sleep apnea increases with increasing age[9-13] (Table 152-1).

Estimates of the prevalence of obstructive sleep apnea (OSA) in older people depend on how it is defined, so prevalence estimates for OSA in older people are moving targets. Indeed, there has been considerable variation in the definitions and measurements of respiratory events (such as apneas, hypopneas, and respiratory effort–related arousals used to identify sleep-disordered breathing, even since the last edition of this text. Furthermore, which respiratory events to "count" toward the threshold used to define "sleep apnea" has also varied. The apnea-hypopnea index (AHI) typically includes only apneas and hypopneas, but the respiratory disturbance index (RDI) may include other events, such as respiratory effort–related arousals, or may be defined on the basis of recording time rather than sleep time. Finally, the demarcation between "normal" and "abnormal" also has been somewhat fluid. In population-based studies, approximately one third of those older than 65 years of age have AHIs of 5 or more events per hour of sleep,[14,15] and some two thirds have RDIs of 10 or more events per hour.[15,16] Although measures of sleep-disordered breathing events alone do not establish a diagnosis of OSA, the classically associated symptoms of the disorder—sleepiness, hypertension, cognitive dysfunction—increase in prevalence with aging. Thus a majority of older persons who meet laboratory-defined numeric criteria for OSA also will have a clinical symptom that is commonly associated with the syndrome; for this reason, defining clear-cut criteria for sleep apnea in older persons is difficult. However, the Centers for Medicare and Medicaid Services, the primary provider of health care coverage for people older than 65 in the United States, defines OSA as an AHI 15 or greater, or an AHI of greater than 5 plus hypertension, stroke, sleepiness, ischemic heart disease, or mood disorder.[17] The Centers for Medicare and Medicaid Services now covers continuous positive arway pressure (CPAP) therapy as indicated by results of portable monitor testing and requires objective documentation of use for payment beyond the first 90 days.

Regardless of how sleep apnea is defined, its prevalence increases progressively from age 18 to approximately 70, when it may plateau.[18] On the basis of these findings, it is likely that the underdiagnosis of sleep apnea in older people is even more common than in younger people, and this may be especially true in minority populations[18]

Diagnosis of sleep-disordered breathing is evolving rapidly, with revised, more liberal diagnostic criteria[19] and the

Table 152-1 Differences between Younger (<60 years) and Older Patients with Obstructive Sleep Apnea (OSA)

Risk Factor	Older Patients	Younger Patients
Male gender	1:1	2:1
Obesity	Unimportant	Very important
Clinical features		
Witnessed apneas	Witnessed apneas rarely reported	Witnessed apneas strongly predictive
Snoring	Infrequently reported	Frequently reported
Prevalence		
AHI >5	30%-40%	9% for women, 24% for men
RDI >10	62%	10%
Consequences	Death, cardiovascular disease, stroke, nocturia, impaired cognition, atrial fibrillation	Death, ischemic cardiac disease, hypertension, cerebrovascular disease, depression, metabolic disturbances
Treatment	May require lower CPAP pressures No difference in tolerance or adherence	May require higher CPAP pressures No difference in tolerance or adherence

AHI, Apnea-hypopnea index; CPAP, positive airway pressure; RDI, respiratory disturbance index.

recognition that oximetry alone can be quite predictive of important outcomes. For example, in a study of 100 patients with a mean age of 62 years, Ohmura and associates reported that sleep-disordered breathing, as determined by predischarge pulse oximetry (based on oxygen desaturation index of 4% [i.e., ODI = 4]), was associated with significantly increased risks for necessity for readmission and death, independent of other risk factors.[20] In a study of patients with OSA and matched control subjects, oxygen saturation predicted cognitive function, but AHI did not.[21] In the Spanish Sleep Network study, oxygen desaturation predicted cancer risk, but again, AHI did not.[22] Similarly, time elapsed with oxygen saturation below 90% predicted 3-year mortality in older persons with cardiovascular disease. It also predicted self-reported insomnia.[23] These and other findings are likely to change, yet again, the diagnostic criteria for significant sleep apnea, at least for third-party payers, who are increasingly data-driven.

CLINICAL MANIFESTATIONS AND PRESENTATION

Most studies of the clinical presentation and manifestations of OSA have focused on the middle-aged. Reports derived from clinical populations tend to include people whose mean age is approximately 50. As more data accumulate about sleep-disordered breathing in older people, it is becoming increasingly clear that the phenotype of OSA can be quite different in younger and in older populations.

Perhaps most striking is the change in gender as a risk factor for sleep-disordered breathing with aging. Prospective data from the Wisconsin Sleep Cohort have demonstrated male sex is no longer an important risk factor for OSA after the age of approximately 50 years,[24] confirming work from other studies.[8] At least part of the reason for this phenomenon is that the prevalence of OSA rises strikingly for women as they go through menopause, which occurs at approximately age 50.[25–27] As a consequence, some investigators have reported a male-to-female ratio of 1:1 for older people.[24]

In addition to the loss of effect of male gender as a risk for OSA with aging, there is reduced importance of obesity as a risk factor. Beginning at approximately 60 years of age, obesity is no longer a statistically significant risk factor for sleep-disordered breathing.[24,26] These observation are of particular interest, in view of known decreases in obesity with increasing age.[28] Some data suggest that obesity is a more important risk factor for men than for women, but that aging, perhaps specifically achieving menopause, is a more important risk factor for women than for men.[24-27,29,30] However, in an 18-year follow-up study of 427 community-dwelling elderly persons, Ancoli-Israel and associates found that observed changes in RDI were associated only with changes in BMI and were independent of age[31]; they pointed out that this finding underscores the importance of managing weight for older adults, particularly those with hypertension.

In a study of nearly 100 community-dwelling adults aged 62 to 91 years, Endeshaw found that almost one third (equally divided between men and women) had an AHI of 15 or more events per hour of sleep, and that the "traditional" risk factors such as snoring, body mass index, and neck circumference were not significantly associated with OSA in this group.[32] Rather, those with an AHI of at least 15 were more likely to report not feeling well rested in the morning and to have higher Epworth Sleepiness Scale scores and a greater frequency of nocturia.[32] These findings confirm earlier work from the Sleep Heart Health Study, which reported that witnessed apneas are much less frequently reported in older patients than in younger ones.[33]

Studies of OSA in older people have tended to report "milder" disease, with lower AHIs, and better-preserved oxygen saturation than in younger adults.[9,14,26]

In short, the "classic" clinical presentation of OSA is uncommon in older adults, which may account in part for the reduced prevalence of clinical diagnosis of the disorder in this population.

PATHOPHYSIOLOGY

The pathophysiology of OSA may be different in older persons from that in younger people. Chapter 111 outlines the pathophysiology of OSA in adults. With aging, loss of tissue elasticity also may contribute to airway collapse. For older women, declining levels of sex hormones appear to be partly responsible for increased collapsibility of the posterior oropharynx.[34,35]

CLINICAL CONSEQUENCES

Overview

A majority of studies of the consequences of OSA have been undertaken in clinical samples of middle-aged people. Data specifically focusing on the consequences of OSA in older

persons are limited. OSA has long been associated with increases in the risk of death in younger populations, but early studies suggested that it was not associated with increased mortality in older groups.[36,37] A recent well-done study from the Spanish Sleep Network, however, clearly demonstrated a twofold increase in risk of death in a group of patients with severe OSA (AHI of 30 or greater) whose mean age was 71 years over that in the control group, after initiation of controls for age, body mass index, preexisting cardiovascular disease, smoking, diabetes, sleepiness, gender, dyslipidemia, and/or respiratory failure. Furthermore, CPAP use reduced risk of all-cause mortality, as well as cardiovascular death and death from stroke and heart failure, but did not reduce the risk of death from ischemic disease in this cohort. Indeed, even those seniors 75 years of age and older had reduced risk of cardiovascular death with CPAP use, and continuous adherence was associated with reduced risk of cardiovascular death as a continuous variable.[38] The inclusion of a large cohort with severe sleep apnea (AHI of 30 or higher) probably partly accounts for the ability of this study to demonstrate a mortality effect with sleep apnea and with CPAP. In a meta-analysis of prospective cohort studies of OSA and risk of cardiovascular disease, Wang and colleagues demonstrated a "dose-response" relationship between OSA severity and cardiovascular outcomes and calculated a 17% greater risk of cardiovascular disease for each 10-unit increase in AHI.[39] It is possible that older people tolerate milder degrees of sleep-disordered breathing better than do their younger counterparts, and that part of the past difficulty in demonstrating an association between OSA and adverse outcomes in older patients was because few patients with moderate to severe disease were included in earlier studies.

Other plausible explanations have been proposed for the inability to readily demonstrate the impact of sleep-disordered breathing on cardiovascular outcomes in older people. Lavie and Lavie, for example, speculated that the reduced effect of OSA on mortality in older people is because of ischemic preconditioning resulting from the nocturnal cycles of hypoxia-reoxygenation and pointed out that in patients with sleep-disordered breathing, there is an association of ischemic preconditioning with increased levels of vascular endothelial growth factor and increased production of oxygen reactive species, heat shock proteins, adenosine, and tumor necrosis factor alpha.[40]

Among the most striking manifestations of sleep-disordered breathing in aging populations are nocturia, cognitive dysfunction, and cardiac disease.

Nocturia

Nocturia is a particularly troublesome symptom of aging and appears to be related to the severity of sleep-disordered breathing. Because older adults with significant sleep-disordered breathing may not manifest classic symptoms of OSA, the presence of nocturia in the older patient should heighten clinical suspicion for OSA. Indeed, nocturnal urination more than three times nightly had positive and negative predictive values of 0.71 and 0.62, respectively, for severe OSA in one study.[41]

The postulated mechanism of nocturia in OSA is that the negative intrathoracic pressures resulting from occluded breaths cause distention of the right atrium and ventricle. This right-sided cardiac distention results in release of atrial natriuretic peptide, which inhibits the secretion of antidiuretic hormone and aldosterone and causes diuresis through its effect on glomerular filtration of sodium and water.[42] Several studies have demonstrated symptomatic improvement in patients with nocturia with use of CPAP.[43-45] The mechanism of CPAP-related improvement may involve promoting the normal nocturnal rise in antidiuretic hormone, resulting in increased resorption of sodium and water from the collecting tubules and production of lower volumes of more concentrated urine.[46] In a retrospective review of data on 196 patients whose mean age was 49 years, predictors of nocturia included increasing age and diabetes mellitus. Although a complaint of nocturia was equally likely to occur in patients with and without OSA, nocturic frequency was significantly related to age, diabetes, and severity of sleep-disordered breathing in those patients who had OSA. Furthermore, patients with OSA and nocturia who were treated with CPAP experienced significant reductions in the frequency of nocturnal voiding.[47] In a study of 21 women with a mean age of 65 years, the same group of investigators reported that OSA is present in a majority of women with nocturia, and that the presence of diluted nighttime urine in a patient with nocturia is a sensitive marker for OSA.[48]

Impaired Cognition

Impaired cognition, including sleepiness, impaired vigilance, worsened executive function, and dementia, increases in prevalence with aging. Neuropsychological assessment of patients with OSA demonstrates decline in cognition similar to that with aging. For example, patients with OSA experience sleepiness[49] and demonstrate impaired executive function,[50] working memory,[51] alertness,[52] and attention.[53] In general, the association between sleep-disordered breathing and impaired cognition has been best studied in middle-aged patients. Because of the association with aging itself on impaired cognition, the effects of OSA on cognitive function in older people have been difficult to tease out. In a small study with subjects older than 55 years of age who had OSA, Aloia and associates found that the degree of sleep-disordered breathing, especially oxygen desaturation, was associated with delayed verbal recall and impaired constructional abilities. After 3 months, subjects who were compliant with CPAP showed greater improvements in attention, psychomotor speed, executive functioning, and nonverbal delayed recall than in those who were not compliant.[54] Despite the logical notion that cognitive impairment associated with OSA in older people might be more severe than in younger people because of cumulative effects of age and sleep-disordered breathing, Mathieu and colleagues were unable to demonstrate any group-by-age interaction for any neuropsychological variable; in a study of matched older and younger patients both with and without OSA, they found that performance on most tasks deteriorated with advancing age in both control subjects and patients with OSA without evidence of a compounded effect.[55] Persons at high risk for OSA based on Berlin questionnaire scores (57% of whom were female) had lower cognitive function scores than those without, but the risk was most pronounced during middle age and was attenuated after age 70.[56]

The evidence indicates age- and gender-dependent relationships as well. In a large study of patients with OSA who were at least 40 years old, the risk of developing dementia

within 5 years of diagnosis was 1.70 times greater than in age- and sex-matched subjects who did not have OSA, after appropriate adjustment for some potential confounders. In this study, men aged 50 to 59 had a sixfold increased risk of developing dementia compared with matched control subjects, but women 70 years of age or older had a threefold increased risk of developing dementia. One large study reported that sleep-disordered breathing severity was not associated with indices of sleep-related symptoms or sleep-related quality of life in community-dwelling older women, suggesting that this group may be resistant to the adverse effects of OSA on cognition.[57]

In addition to age and gender differences in susceptibility to dementia in patients with OSA, genetic predispositions also are likely. Data from the Wisconsin Sleep Cohort suggest that apolipoprotein E epsilon 4 genotype (APOE4)-positive persons with sleep apnea of moderate severity have impairment of cognition and executive function comparable to that in persons without this genotype.[58] Preliminary work suggests an association between sleep-disordered breathing and Alzheimer disease biomarker in the cerebrospinal fluid of cognitively normal persons.[59] These early data point to genetic influences on the propensity to develop dementia in patients with SDB.

It is likely that many other factors affect susceptibility to cognitive dysfunction in patients with OSA. For example, Alchantis and coworkers have proposed that high intelligence may protect against cognitive decline caused by sleep-disordered breathing, perhaps as a consequence of increased cognitive reserve.[60]

The mechanism by which sleep-disordered breathing impairs neurocognitive function remains incompletely understood. Some investigators have suggested that sleep fragmentation is the primary culprit,[61] whereas others maintain that hypoxemia is the primary cause. It is likely that the functions are affected by hypoxemia differ from those affected by sleep deprivation. As suggested by Sateia, "Disturbances in general intellectual function and executive function show strongest correlations with measures of hypoxemia. Not unexpectedly, alterations in vigilance, alertness, and, to some extent, memory seem to correlate more with measures of sleep disruption."[62] However, in a small study of matched patients with OSA, AHI did not predict or correlate with cognition, but mean oxygen saturation correlated with executive functioning and access to long-term memory.[21]

Kim and associates demonstrated that moderate to severe OSA is an independent risk factor for white matter change in more than 500 people (mean age 59 ± 7.48 years) and presented an excellent discussion of potential mechanisms, including hypoxemia and hypercapnia during apneic events, which activate arousal- and chemoreflex-mediated increases in the cerebral circulation and activation of oxidative and imflammatory processes.[63]

Information about the effects of CPAP treatment on cognition in older people is limited, and data about CPAP's effects on cognition in older persons even more so. In a small group of patients whose mean age was 56 years, CPAP resulted in normalization in attentive, visuospatial learning and in motor performances after 15 days, but no further improvement was observed after 4 months of treatment. CPAP did not improve performance on tests evaluating executive functions and constructional abilities.[64] A meta-analysis of randomized, placebo-controlled crossover studies of CPAP treatment involving 98 patients with sleep apnea demonstrated mostly trends for better performance on CPAP than on placebo.[65] In a group of middle-aged adults with significant OSA, Zimmerman and associates demonstrated that memory normalized for the group that used CPAP at least 6 hours a night[66] but did not improve in those who were not adherent to CPAP treatment. In a review of CPAP adherence and benefits among older people, Weaver and Chasens noted that in general, older adults demonstrate increased alertness; improved neurobehavioral outcomes in cognition, memory, and executive function; and decreased sleep disruption.[67] These investigators also noted that older persons may require lower CPAP pressures than younger ones and tolerate CPAP well, with similar rates of adherence. Thus, despite differences in the clinical presentation and impact of sleep apnea in the elderly population, CPAP treatment is likely to be well tolerated and beneficial in symptomatic patients.[68,69]

With regard specifically to Alzheimer disease, the prevalence of OSA is higher among patients with this disorder than among nondemented seniors, and sleep-disordered breathing is believed to contribute to cognitive dysfunction in those with Alzheimer disease. A randomized double-blind, placebo-controlled crossover trial of CPAP in patients with OSA and Alzheimer disease demonstrated a significant improvement in cognition after 3 weeks of CPAP.[70] In addition to improving cognition, CPAP treatment may reduce sleepiness in patients with Alzheimer disease and OSA.[71]

In view of the facts that improvement in cognition is likely to depend on CPAP adherence, that gender, age, genetic, and intelligence are probable influences on susceptibility to impaired cognition, and that most studies addressing this issue have not included geriatric patients with OSA or objectively measured adherence, firm conclusions about the reversibility of cognitive deficits in older patients woth OSA are impossible at present.

Cardiovascular Disease

In addition to nocturia and cognitive impairment, sleep-disordered breathing also is strongly linked to *cardiovascular disease,* including hypertension, congestive heart failure, stroke, cardiac arrhythmias, ischemic events, and pulmonary artery hypertension.[72] Few studies of the relationship between OSA and cardiovascular disease are prospective and control for confounding variables such as obesity. Even fewer studies have been conducted in older adults. Hypertension, atrial fibrillation, and stroke, however, are particularly relevant comorbid conditions associated with OSA in older patients, because of their higher prevalence and clinical importance in that population.

Hypertension

That sleep-disordered breathing causes *hypertension* has been demonstrated by multiple studies, including prospective and CPAP sham–controlled work.[73-79] Recent data also have established that severe sleep apnea (AHI of 30 events or more per hour) is an independent risk factor for incident hypertension in older people (mean age, 68.2 years).[80] In general, CPAP has modest effects on blood pressure in patients with OSA but is most effective in those who have significant hypertension and are most adherent with its use.[73,81,82]

Atrial Fibrillation

Atrial fibrillation is strongly associated both with aging and with OSA.[72,83] The Sleep Heart Health Study investigators found that persons with severe sleep-disordered breathing had double or quadruple the risk of complex cardiac arrhythmias compared with those with no sleep-disordered breathing, after institution of controls for multiple relevant confounders.[83] In this study, atrial fibrillation was the arrhythmia most strongly associated with sleep-disordered breathing. Gami and coworkers reported that both obesity and nocturnal oxygen desaturation were independent predictors of incident atrial fibrillation, but only in subjects younger than 65 years of age.[84] However, Ganga's group noted that the presence of overlap syndrome (OSA combined with chronic obstructive pulmonary disease) is associated with a marked increase in new-onset atrial fibrillation in elderly patients over that associated with the presence of either OSA or chronic obstructive pulmonary disease alone.[85]

In a small, retrospective study of patients with atrial fibrillation, some of whom had either treated or untreated sleep apnea and some of whom did not have sleep apnea, the patients with untreated OSA had a higher recurrence of atrial fibrillation after cardioversion than that for the patients without sleep apnea.[86] Furthermore, treatment with CPAP in the sleep apnea group was associated with lower recurrence of atrial fibrillation at 1-year follow-up evaluation. This study is particularly relevant for the management of older patients because the mean age of the study population was approximately 66 years. A study of patients undergoing pulmonary vein isolation reported that the 32 patients who had OSA and used CPAP were less likely to have atrial tachyarrhythmias, use of antiarrhythmic drugs, and need for repeat ablations were compared to the 30 patients who did not use CPAP during a follow-up period of 12 months; the difference in atrial fibrillation–free survival rate was 71.9% versus 36.7% ($P = .01$).[87]

As in younger adults, sleep-disordered breathing is associated with subtle measures of myocardial injury. In a large study of patients whose mean age was 62.5 years, OSA severity correlated with measures of high-sensitivity troponin T and N-terminal pro–B-type natriuretic peptide, and high-sensitivity troponin was related to risk of death or heart failure in all categories.[88] Elderly patients with OSA exhibit cardiac structural changes and diminished left ventricular function compared with that in control subjects who do not have OSA.[89] In a nonrandomized, retrospective review of data on 130 patients aged 65 to 86 years, Nishihata and associates demonstrated that those with untreated sleep apnea had increased likelihood of cardiovascular death and hospitalization due to cardiovascular disease, including heart failure, over a follow-up period of approximtely 3 months. Furthermore, adequate CPAP treatment improved the cardiovascular outcomes in this cohort.[90]

Stroke

The prevalence of stroke increases with age, but untreated sleep apnea appears to impose an additive risk. In a 6-year follow-up study of more than 1000 patients whose mean age at enrollment was approximately 60, Yaggi and coworkers found that OSA was a risk factor for stroke, controlling for other important variables.[91] Treatment did not affect the risk of either stroke or death in this study.

A review of the findings in 10 reports that included 1203 patients who had experienced stroke or transient ischemic attacks noted a dose-response relationship between severity of sleep-disordered breathing and the risk of recurrent events and all-cause mortality; 3 of the studies included information about patients who received CPAP, but the data were too limited for a compelling argument that CPAP improves outcome in patients with stroke/transient ischemic attack.[92] In a study of patients with acute cerebral ischemia who underwent polysomnography, Kepplinger and colleagues showed that sleep apnea is associated with clinically silent microvascular brain tissue changes such as leukoaraiosis (white matter hyperintensities) and lacunar infarcts.[93]

In summary, OSA is strongly associated with cardiovascular disease in middle-aged populations, and the accumulating evidence suggests that sleep-disordered breathing increases the risk of cardiovascular disease and stroke in the elderly population. The best-proven association and evidence for benefit is with hypertension, for which the data are derived largely from middle-aged populations.

Other Effects

Sleep-disordered breathing is a systemic problem with systemic consequences. In addition to the adverse outcomes already noted, OSA in elderly persons is associated with multiple potential consequences.

In middle-aged men, OSA is associated with increased health care costs that decrease after treatment. CPAP treatment is cost-effective for treatment for severe sleep apnea in middle-aged people.[94] Within the sleep apnea population, expenditures for health care in older patients are approximately twice as high as they are in middle-aged patients. After adjustments for age, body mass index, and AHI, cardiovascular disease and use of psychoactive drugs were important determinants of health care costs for older patients with sleep apnea in one study.[95] An enormous study of elderly veterans documented that 4.4% (in all likelihood, representing only the "tip of the iceberg") were diagnosed with OSA, and these patients had many more comorbid conditions and much higher health care utilization than those who did not carry the diagnosis.[96]

Sleep apnea also was associated with an increased risk of pneumonia (the "old man's friend") in a large study.[97]

Nocturnal hypoxemia also is associated with increased risk of falls in older men[98] but paradoxically is associated with preserved bone mineral density in elderly men and women, even after adjustment for sex, BMI, metabolic values, and hypertension.[99]

Gender is likely to influence the effects of sleep-disordered breathing in older people, just as it does for younger persons. For example, a significant relationship between sleep-disordered breathing and hypertension, history of diabetes, and low high-density lipoprotein cholesterol has been reported in women older than 65 years of age, but these effects were not demonstrable in older men.[100]

TREATMENT OF OBSTRUCTIVE SLEEP APNEA IN OLDER ADULTS

Continuous Positive Airway Pressure

As with younger adults, CPAP is the treatment of choice in older patients. Because most studies of effects of CPAP have

been done in clinical (e.g, middle-aged) populations, evidence for the benefits of CPAP in older persons is not yet robust.

Complex sleep apnea appears to be more prevalent in older than in younger people. *Complex sleep apnea* is characterized as OSA in which central apneas and periodic breathing develop when CPAP is applied.[101,102] This phenomenon appears to be more prevalent in older men with congestive heart failure, and its clinical significance is unclear. In many cases of these "treatment-emergent central apneas," the central apneas will simply resolve over time. In a convenience sample of a variety of sleep-disordered breathing syndromes resistant to CPAP, the mean age of 72 years was much higher than typically observed in clinical populations of sleep apnea patients. In that cohort, adaptive servoventilation appeared to be effective and well tolerated in approximately half.[103] Because complex or treatment-emergent central apnea appears to be more prevalent in older adultss, formal, in-lab titrations may be more important for this group. (For a more detailed discussion of complex sleep apnea, see Chapter 110.) Adherence to CPAP therapy in older patients may be impaired by factors such as cognitive impairment, medical and mood disturbances, nocturia, lack of a supportive partner, and impaired manual dexterity. Older age in itself, however, does not affect adherence to CPAP treatment,[67,104,105] and behavioral interventions can improve CPAP adherence in the elderly.[106] The major predictors of CPAP nonadherence in older patients with sleep apnea are nocturia, current cigarette smoking, lack of symptom resolution, and advanced age at time of diagnosis.[107] Older men with nocturia may find CPAP particularly confining and may be particularly likely to have difficulty with its use, although CPAP may actually help with the nocturia.[104,107]

Patients with OSA who have dementia, including Alzheimer disease, have been demonstrated to tolerate CPAP, although depressive symptoms appear to predict worsened adherence in demented seniors with sleep apnea.[108]

Oral Appliances

Oral appliances are effective in treating snoring and mild to moderate OSA.[109-112] Although not as effective as CPAP, these agents improve sleep-disordered breathing, sleepiness, nocturnal oxygen saturation, and blood pressure. There are two basic types of oral appliances:

1. Mandibular repositioners, which pull the mandible (and with it, the tongue) forward
2. Tongue-retaining devices, which adhere to the tongue by suction and pull it forward. Because these are not approved by the U.S. Food and Drug Administration for treatment of sleep apnea, they are used much less commonly in clinical practice.

See Chapter 147 for a detailed discussion of the use of oral appliances.

Common side effects of oral appliances include dry mouth, increased salivation, tooth soreness, and jaw muscle or jaw joint discomfort. Pain occasionally can be severe enough that patients discontinue the use of the appliance.[112] Bite changes (e.g., the inability to close on the back teeth) combined with heavy contact of the front teeth on removal of the appliance in the morning also are reported, but these changes generally resolve on removal of the device.

Oral appliances can be made to fit over false teeth, although this is not optimal. The use of oral appliances in people who are edentulous may be attempted with a tongue-retaining device, but these devices are not U.S. Food and Drug Administration-approved, and the efficacy of this approach is unknown. A small prospective study of factors associated with efficacy of oral appliances has suggested that age older than 55 years may be associated with reduced efficacy.[113]

Surgery

As with younger adults, upper airway surgery is not particularly effective treatment for OSA for older patients and may be associated with especially high morbidity in the elderly.[114] However, as in younger patients with significant sleep-disordered breathing in the context of obesity, bariatric surgery, specifically laparoscopic-adjustable gastric banding, has been shown to be well tolerated and reasonably effective in resolving or reducing sleep apnea in people older than 70.[115]

Pharmacologic Treatment

Several medications have been applied to the treatment of sleep-disordered breathing. In general, no drug is effective enough to recommend for use in first-line treatment. Antidepressants, nasal steroids, hormone replacement therapy (HRT), and modafinil all have been studied in younger patients.

More than two decades ago, protriptyline was demonstrated to show modest efficacy in treating apnea, probably because it reduces REM sleep, when apnea is worst.[116] There is some early experimental work with the selective serotonin reuptake inhibitors (SSRIs) in the treatment of sleep apnea, but results have not been promising in humans.[117] SSRIs can suppress REM sleep, but not as much as that seen with the tricyclic antidepressants.

Nasal steroids have been demonstrated to have modest efficacy in the treatment of sleep-disordered breathing.[118]

In the Sleep Heart Health Study, women who were on HRT were less likely to have sleep apnea, but overall lifestyle and health care are significant confounders in drawing conclusions about the efficacy of HRT for OSA.[119] Although estrogen is an option to consider, it would need to be discussed carefully with the patient because of subsequently recognized complications of HRT.

Body Position

The supine position predisposes the sleeper to airway collapse and to reduced lung volume and has long been known to exacerbate OSA; indeed, some affected persons experience obstructive events exclusively when sleeping on their backs.[120-122] Upper airway size decreases with increasing age in both men and women, and upper airway collapsibility with supine positioning increases with age.[122]

In my own clinical experience, position-related obstructive apnea is relatively common among older individuals. Position therapy has not been well studied for any group of patients but shows promise as treatment for the older patient with mild disease.[123]

DRIVING AND THE OLDER PATIENT WITH OBSTRUCTIVE SLEEP APNEA

Untreated OSA is a well-established risk factor for involvement of drivers in motor vehicle crashes (see Chapter 114) and might be expected to affect older drivers as well. In a review of conditions increasing crash risk in older drivers,

Marshall found that several conditions were believed to be associated with increased risk of crash in older persons, including alcohol abuse and dependence, cardiovascular disease, cerebrovascular disease, depression, dementia, diabetes mellitus, epilepsy, use of certain medications, musculoskeletal disorders, schizophrenia, vision disorders, and, finally, OSA. He noted that these "conditions can serve as potential warnings for reduced fitness to drive, but many persons with these medical conditions would still be considered safe to continue driving."[124]

CLINICAL PEARLS

- The clinical presentation of OSA in older adults differs from that in their middle-aged counterparts, so the disorder may be overlooked by clinicians when it manifests in this age group.
- Female gender and obesity are less important risk factors in older people than in younger people.
- Symptoms of sleep apnea change with aging: Whereas the classic symptoms of OSA are witnessed apneas and sleepiness, older patients are more likely to present with sleep complaints, nocturia, and cognitive dysfunction.
- Moderate to severe OSA is associated with increased risk of cardiovascular morbidity and mortality as well as cognitive dysfunction, and CPAP treatment is associated with reduced risk.

SUMMARY

OSA is prevalent and potentially deadly in older people and may be overlooked by clinicians because the clinical presentation is different from that in younger people. Seniors with OSA tend to be "thinner" and are more likely to be female and less likely to report classic symptoms of witnessed apnea, snoring, and fatigue. Because CPAP use is associated with reduced morbidity and mortality in older (as well as younger) people, clinicians need to consider the possibility of OSA in older patients with sleep complaints.

Chapter 153

Insomnia in Older Adults

Tamar Shochat; Sonia Ancoli-Israel

Chapter Highlights

- Insomnia is a complaint of dissatisfaction with sleep characterized by difficulty initiating and/or maintaining sleep and/or nonrestorative sleep, resulting in significant daytime symptoms and functional impairments. Chronic insomnia affects approximately 10% of the adult population.
- Although late-life insomnia usually is attributed to medical and psychiatric comorbidity rather than to age-related changes per se, underlying age-related physiologic changes in sleep-wake regulation—that is, circadian rhythms and sleep homeostasis—have been identified. Other factors associated with insomnia in the elderly population include use of certain medications or other substances, psychosocial issues, and primary sleep disorders.
- Key elements in appropriate evaluation and management include considering the type of insomnia complaint, assessing sleep patterns including daytime napping, daytime health and wellness consequences, and comorbidity. Behavioral treatment should be considered first, and when necessary, the newer hypnotic medications may be added.

OVERVIEW

According to the American Psychiatric Association, as defined in the most recent *Diagnostic and Statistical Manual of Mental Disorders* (DSM5), insomnia is a complaint that involves dissatisfaction with sleep quality and/or quantity, difficulty initiating sleep, difficulty maintaining sleep, waking up too early, and/or nonrestorative or poor sleep, with a negative impact on daytime functioning and occurring at least three nights a week for more than 3 months.[1] Insomnia is a chronic condition, often lasting for several years. In the elderly population, chronic insomnia is common and often coexists with a medical or psychiatric condition, polypharmacy, and/or another sleep disorder. Growing evidence suggests that insomnia also is a potential contributor to subsequent morbidity.[2,2a] Yet owing to the widespread notion that insomnia is an inevitable consequence of aging, the problem often is ignored and not properly treated. It is therefore imperative to increase awareness in both clinicians and older adults of the significance of insomnia as a health issue, and of the importance of timely and appropriate interventions for successful treatment, to improve sleep and maximize wellness in this population.

EPIDEMIOLOGY AND RISK FACTORS

The prevalence of insomnia in the general adult population in Norway based on DSM5 criteria is estimated at 7.9%, controlling for sociodemographic and comorbidity factors.[3] In a U.S. study, the prevalence of nighttime symptoms and nonrestorative sleep complaints combined was 5%, whereas the prevalence of any sleep symptom was 18%.[4]

Prevalence of insomnia increases with age and is higher among women.[3-6,7] Age and gender differences may be related to differences in modes of measurement. In a sample of more than 5000 middle-aged and older adults from the Sleep Heart Health Study, older age was significantly related to poor sleep in men on the basis of polysomnographic recordings, particularly reduction in slow wave sleep and increased sleep stages 1 and 2, whereas in women, older age was related to subjective sleep complaints, particularly difficulty falling asleep.[8] In men and women, older age was associated with shorter sleep, lower sleep efficiency, and more arousals based on polysomnography (PSG), yet with fewer daytime complaints of unrest and sleepiness.

Furthermore, medical and psychiatric comorbid conditions as well as sociodemographic and lifestyle factors overshadow the risks of age.[6,9] In a study of more than 13,500 participants aged 47 to 69 years, 22% complained of difficulty falling asleep, 39% complained of difficulty staying asleep, and 35% complained of nonrestorative sleep.[5] Depression and heart disease were associated with all three complaints. Other related factors were medical illnesses, lower socioeconomic status and education level, and unhealthy behaviors such as alcohol use and cigarette smoking. Findings from the National Health and Nutrition Examination Survey (NHANES) of nearly 11,000 adults aged 20 and older found distinct risk factors for nighttime insomnia symptoms versus the nonrestorative sleep complaint.[4] Whereas nighttime insomnia symptoms were associated with increased age, lower income and educational level, and presence of cardiovascular disease, nonrestorative sleep was associated with primary sleep disorders such as sleep apnea, respiratory disease, thyroid disease, and cancer, as well as increased inflammation.

Other studies have examined the prevalence of insomnia and related risk factors in the elderly population. In a sample of more than 9000 participants aged 65 and older from the National Institute of Aging's Established Populations of Epidemiological Studies of the Elderly, more than 50% reported at least one sleep complaint, and 35% to 40% reported difficulty in initiating and/or maintaining sleep on a chronic basis.[10] At a 3-year follow-up evaluation, an annual insomnia incidence of 5% was reported.[11] Rates were highest in those with chronic medical conditions such as heart disease, stroke, and diabetes. Remission occurred in nearly one half of those with insomnia at baseline and was related to improvements in perceived health. Similarly, in a representative sample of general medical practice patients aged 65 years and older, the annual incidence of late-life insomnia was 3.1%.[9] Significant and independent risk factors in this sample were depressed mood, poor physical health, and low physical activity.

As indicated by the National Sleep Foundation survey from 2003, depression, heart disease, bodily pain, and memory problems were the disorders most commonly associated with insomnia.[12] In a more recent sample of 2000 South Korean community-dwelling older adults (older than 65 years of age), 29% reported nighttime insomnia symptoms and 17% also reported daytime impairments.[13] For all insomnia symptoms, prevalence was higher among women as well as among people with no education, those living alone, and persons with a diagnosis of restless legs syndrome or depression and/or a lifetime history of physical illness. Older age was again associated with increased nighttime symptoms but with decreased complaints of nonrestorative sleep. These findings lend further support to the epidemiologic evidence demonstrating that geriatric sleep complaints and disorders are not the result of age per se but rather cosegregate with medical and psychiatric disorders and related health burdens.[14]

Insomnia in elderly persons often is unrecognized by physicians.[2] In a study of older adults in primary care practices in the midwestern United States, 69% of patients confirmed the presence of at least one sleep problem, 40% had two or more sleep problems, and 45% experienced symptoms of insomnia, yet these complaints were reported in the medical charts only 19% of the time.[15] The two questions that best identified persons with poor sleep and those at risk for medical and psychiatric problems were "Do you feel excessively sleepy during the day?" and "Do you have difficulty falling asleep, staying asleep, or being able to sleep?" These two questions could easily be integrate into the standard patient history at clinical intake assessment.

HEALTH AND WELLNESS CONSEQUENCES

Studies have assessed the health consequences of insomnia as well as the effects of insomnia on physical functioning and performance.[2a,15a] Symptoms of insomnia, daytime sleepiness, and sleep medication use all predicted 4-year incidence of depressive symptoms in nearly 4000 older adults who were free of depression symptoms at baseline.[16] In a study of several thousand older men, lighter, fragmented sleep, particularly shorter total sleep time, sleep efficiency below 80%, and more than 90 minutes of wake time after initial sleep onset, was associated with poorer physical performance, particularly in age-adjusted models.[17] In the Study of Osteoporotic Fractures, poor sleep (i.e., fewer than 5 hours of nightly sleep and sleep efficiency of 70% or lower), but not benzodiazepine use, was an independent risk factor for falls in elderly women.[18,19]

The impact of insomnia on cognitive function in the elderly population is less clear. In an 8-year longitudinal study of nearly 5000 older adults in France, cognitively intact at baseline, excessive daytime sleepiness but not insomnia predicted global cognitive decline.[20] Similar findings were reported in longitudinal studies in the United Kingdom[21] and the United States.[22] Furthermore, in a 2-year prospective study assessing relationships among snoring, sleep duration, and sleep difficulties with cognitive functioning in elderly women, short sleep duration (5 hours or less) and insomnia complaints were related to lower scores on cognitive tests at baseline but not at 2-year follow-up evaluation.[23] Finally, in a 3-year longitudinal study, chronic insomnia was found to be an independent risk factor for cognitive decline in older men, but not in older women,[24] suggesting that cognitive decline related to insomnia may be gender-dependent. Alternatively, daytime sleepiness may be the underlying factor for cognitive decline, rather than insomnia.

On the other hand, cross-sectional analysis in the Study of Osteoporotic Fractures of approximately 3000 women 70 years of age or older showed cognitive decline associated with poor sleep (based on actigraphically measured sleep efficiency of 70% or less, long sleep latency, and increased wake time after sleep onset).[25] The study investigators also reported that preclinical cognitive decline predicted increased sleep disturbance (i.e., reduced sleep efficiency, longer sleep latency, and increased wake time after sleep onset), suggesting reverse causality.[26]

Population-based studies on the consequences of insomnia in middle-aged and older adults have identified additional negative functional outcomes. In a metaanalysis, symptoms of insomnia (except difficulty falling asleep) and short sleep duration were associated with an increased risk for hypertension.[27] In a longitudinal analysis of more than 80,000 postmenopausal women of the Women's Health Initiative who did not have heart disease at baseline, insomnia was associated with increased risks for incident coronary heart disease and incident cardiovascular disease in fully adjusted models.[28]

Longitudinal studies based from the Korean Genome and Epidemiology Study demonstrated that persistent insomnia predicted increased risks for depression and suicidal ideation and reduced physical and mental measures of health-related quality of life.[29,30] Similarly, disorders of initiating sleep but not other insomnia symptoms predicted incident depression in a nationally representative sample of older adults in Japan.[31] In a cross-sectional study of postmenopausal women, being unemployed or on a disability support pension, sedentary lifestyle, and reduced physical and mental measures of quality of life were strongly associated with insomnia symptoms and accounted for 28% of the explained variance.[32]

Insomnia also increases the risk of mortality. In a study of older adults followed for five years, those with initial sleep latencies longer than 30 minutes or sleep efficiency lower than 80% had close to twice the risk for mortality.[33] In the prospective MrOs study in 2500 older men (65 years of age or older) who were not frail at baseline, poor subjective sleep quality, more nighttime wakefulness, and greater nocturnal hypoxemia

were associated with increased risks for incident frailty or mortality at follow-up evaluation.[34]

ETIOLOGY

Underlying factors involved in the development of late-life insomnia include age-related changes in homeostatic and circadian sleep-wake regulation, psychiatric and medical comorbidity, use of certain medications and other substances, and primary sleep disorders. Evidence for each of these factors is reviewed next.

Age-Related Changes in Sleep Regulation

Developmental changes in elderly sleep are characterized by advanced sleep phase, including both earlier bedtimes and wake times, reduced sleep consolidation, and altered sleep architecture indicating a transition to lighter sleep. To understand the basis for these changes, it is necessary to understand some of the basic mechanisms of human sleep regulation.

Sleep regulation is based on an interaction between the homeostatic pressure for sleep and the output of the circadian pacemaker. Homeostatic sleep pressure reflects the increasing need for sleep which accumulates during the waking hours and then dissipates during sleep, as marked by increased slow wave sleep at the beginning of nocturnal sleep which gradually decrease throughout the night. The endogenous circadian pacemaker, located in the suprachiasmatic nucleus of the hypothalamus, regulates the synchronous timing of several physiologic variables including core body temperature and sleep/wake states. Regulation of the timing of sleep and wake states is achieved by promoting a signal of increased wakefulness throughout the day, and a signal of increased sleep consolidation throughout the night.[35,36] In young adults, daytime wakefulness and nighttime sleep consolidation are high owing to both of these bioregulatory mechanisms. However, both homeostatic and circadian mechanisms change with age. Advanced age has been associated with a marked reduction in slow wave sleep and an increase in lighter sleep. This reduction in slow wave sleep indicates weaker homeostatic sleep pressure in elderly persons.[37]

Under entrained conditions, habitual wake times are advanced to an earlier hour in the elderly population, and the amplitude of the circadian rhythm of core body temperature is decreased, indicating a reduced circadian signal, which would otherwise promote sleep in the early morning hours.[38] The circadian signal for wakefulness also is reduced, as reflected in sleep episodes and reports of sleepiness in the early evening hours.[39] In summary, reductions in both the homeostatic drive for sleep and the strength of the circadian signal for sleep in the early morning hours and for wakefulness in the early evening hours have been implicated as underlying factors for reduced sleep consolidation, advanced sleep phase, and early-morning awakenings in the elderly.

Medical and Psychiatric Comorbid Conditions

Numerous chronic medical conditions and illnesses are known to be associated with sleep disruption. Arthritis, angina pectoris, congestive heart failure, coronary artery disease, chronic obstructive pulmonary disease, end-stage renal disease, diabetes, asthma, stroke, gastroesophageal reflux disease, dementia/Alzheimer disease, Parkinson disease, cancer, and menopause all have been implicated.

In a representative U.S. survey of 1500 adults 50 years or older, those with heart disease, lung disease, depression, obesity, and bodily pain were more likely to report difficulties with sleep.[12] In addition, multiple medical conditions were associated with more sleep complaints and with poor self-perceived sleep quality. In another survey examining sleep and health in 1500 adults 60 years of age or older in 11 primary care offices, complaints of poor sleep and excessive daytime sleepiness were associated with both poor physical and poor mental health–related quality of life status.[15] Similar findings were reported in a longitudinal investigation of over 90,000 women who participated in the Women's Health Initiative (WHI), whereby incident and persistent insomnia were associated with increased risks of physical, mental, and mixed impairments.[2a] Yet another cross-sectional survey in six clinical centers with more than 3000 older men as participants demonstrated increased risks for poor sleep in men with depression. In multivariable-adjusted models, men with depression were nearly four times more likely to report poor sleep quality and nearly twice as likely to spend at least 1 hour falling asleep.[40]

Medical and psychiatric comorbid diseases may be considered as both risk factors and consequences of insomnia, and it often is difficult to determine the direction of causality. Accordingly, *comorbid* insomnia has been suggested as the appropriate term for insomnia associated with other, concurrent diseases, replacing the earlier designation of *secondary* insomnia.[41] Such a distinction has important implications not only in reassessing causal relationships between insomnia and comorbidity but also for considering treatment strategies. Treatment and management should be directed not only at comorbid illnesses but should also focus on insomnia as a discrete entity.

Medications/Substances

Polypharmacy is a serious problem in older adults, and the use of multiple medications also contributes to insomnia. Prescription medications known to be related to insomnia include antidepressants, such as selective serotonin reuptake inhibitors and serotoninergic-noradrenergic reuptake inhibitors, and numerous agents commonly used in the treatment of various medical conditions, such as bronchodilators, beta blockers, corticosteroids, decongestants, central nervous system stimulants, gastrointestinal drugs, and cardiovascular drugs.[2] Adjustment of the timing or amount of dosing and eliminating or substituting other medications with recognized contraindications or drug-drug interactions in elderly persons may lead to improvements in their sleep.

Other substances known to be related to insomnia in older persons include alcohol, caffeine, and nicotine. In a sample of more than 6000 adults 50 years of age or older, occasional and frequent binge drinking was associated with an increased risk for insomnia after controlling for demographic and clinical factors; this increase in risk was partially mediated by cigarette smoking.[42] Of note, however, in a study of nearly 10,000 adults 65 years of age or older in France, moderate alcohol and caffeine consumption reduced the risk for insomnia symptoms in women, demonstrating a protective effect.[43] Furthermore, in a study assessing sleep hygiene patterns in four sleep subgroups of older adults (i.e., with or without insomnia and with or without sleep complaints), there were no differences between the subgroups for alcohol, nicotine, and

caffeine use, and those who abstained entirely, indicating that lifestyle changes in sleep hygiene practices may not be an effective therapy in this age group.[44]

Primary Sleep Disorders

Insomnia often is comorbid with primary sleep disorders common in the elderly population, such as sleep-disordered breathing (SDB), periodic limb movement disorder, and restless legs syndrome.

Sleep-Disordered Breathing

SDB (see also Chapter 152) is characterized by episodes of partial (hypopnea) to complete (apnea) airway collapse, causing pauses in breathing during sleep and occurring repeatedly during the night. These respiratory events reduce blood oxyhemoglobin saturation and terminate in partial arousals. Clinical manifestations of SDB include excessive daytime sleepiness and loud snoring. The prevalence of SDB increases considerably with age, to as much as 62% for a respiratory disturbance index of 10 or greater in adults 65 years of age or older (70% in men, 56% in women).[45]

In a more recent study of older adults (60 years of age or older) in Korea, prevalence was 36.5% for an apnea-hypopnea index of 15 or higher (52.6% in men, 26.3% in women).[46]

Despite its high prevalence, the consequences of SDB are considered more benign in older than in younger adults, suggesting that considerations regarding management should take into account the severity of the disorder, its impact on functioning, and implications of therapeutic intervention.[47]

By some estimates, approximately one half of the patients with SDB also may have insomnia.[48] Cooccurrence of these disorders is more common in women and is associated with lower sleep quality and a higher rate of psychiatric disorders than in patients with SDB alone. In the elderly population, cooccurrence of insomnia and SDB has been associated with worse daytime dysfunction than that observed for either sleep disorder alone, suggesting an additive effect on functional impairment.[49] Although the underlying relationship between these two common sleep disorders is not clear, it has been suggested that hypoxia may be a mediating factor between SDB and insomnia in older adults with cardiovascular disease.[50]

An important consideration is that SDB may be veiled in older patients with insomnia. In a sample of 80 adults with insomnia older than 59 years of age in whom initial clinical intake evaluation showed no traditional signs of SDB, subsequent rigorous screening identified that 29% had an apnea-hypopnea index of greater than 15, indicating significant SDB.[51] These findings confirm that clinical interview alone may not suffice for identifying veiled SDB in older adults and stress the importance of referring patients with insomnia who demonstrate reduced functional capabilities for further evaluation in the sleep clinic.[49]

Periodic Limb Movements in Sleep and Restless Legs Syndrome

Periodic limb movements in sleep (PLMS) is a disorder characterized by involuntary leg jerks during sleep appearing in repetitive clustered episodes, often leading to brief awakenings from sleep. PLMS traditionally has been associated with insomnia and/or excessive daytime sleepiness. Clinical diagnosis of PLMS is indicated when the PLM index (PLMI), the number of limb movements per hour of sleep, is greater than 5. Although survey data do not demonstrate an increased prevalence of PLMS with age,[52] prevalence rates based on home PSG in community-dwelling women were high, with 66% for a PLMI of 5 or greater and 27% for PLMI 5 or greater accompanied by arousals.[53] In men and women, PLMS, particularly when accompanied by arousals, was related to polysomnographic indicators of disturbed sleep that are associated with insomnia.[53,54]

Despite its high prevalence, long-term follow-up evaluation of a cohort of elderly persons showed no change in PLMS severity with increasing age[55]; yet a study on the pathologic significance of PLMS in this age group has shown that in older men, increased frequency of PLMS both with and without arousals was associated with incident cardovascular disease, particularly in those who were nonhypertensive.[56]

Restless legs syndrome is a neurologic disorder characterized by dysesthesia in the legs and an irresistible urge to move them in order to relieve the discomfort. Symptoms of this disorder increase during the evening and at night, usually when the patient is in a relaxed or restful state, resulting in sleep disturbance. Based on survey data, the prevalence of restless legs syndrome increases with age, from 2.7% in teens to 8.2% in adults 80 years of age or older.[52] PLMS is a common finding in 80% of cases of restless legs syndrome, yet PLMS and related sleep disturbance also may appear without restless legs symptoms.[57] Both disorders are prevalent in the elderly population and are strongly related to insomnia. Accordingly, proper identification and management are warranted.

Pharmacologic treatment studies for PLMS and restless legs syndrome have mostly studied middle-aged to older adults. Management strategies for both conditions are similar, and treatment should be limited to symptomatic persons with comorbid insomnia and/or daytime sleepiness. Medications approved for the treatment of PLMS and restless legs syndrome may increase daytime sleepiness in the older adult, so monitoring and follow-up are recommended.[58]

EVALUATION AND DIAGNOSIS OF INSOMNIA

Despite its widespread prevalence, insomnia is underrecognized and often inadequately treated in health care systems.[15,59] Guidelines for the evaluation of insomnia in the adult population, based on the Standards of Practice Committee of the American Academy of Sleep Medicine (AASM),[60] call for a thorough sleep history and determination of specific sleep complaints, sleep-wake schedules, history of psychological symptoms such as depression or anxiety, comorbid conditions such as medical or psychiatric illness, use of certain medications and other substances, and other primary sleep disorders.

The assessment of insomnia does not necessitate overnight polysomnographic monitoring; however, symptoms and signs of comorbid sleep disorders, especially sleep-disordered breathing, warrant a full PSG study.[49,60] In accordance with AASM standard guidelines, the use of actigraphy is indicated in patients with insomnia, including the elderly and institutionalized elderly subgroups, for the assessment of circadian rhythms and sleep-wake patterns and their disturbances, as well as for monitoring treatment for insomnia and circadian rhythm disturbances.[61] Actigraphy is considered a

Table 153-1 Nonpharmacologic Therapies for Late-Life Insomnia

Therapy	Description
Stimulus control	Patient is instructed to go to bed only when sleepy. If sleep is not obtained in 20 minutes, patient leaves bedroom and returns to bed only when sleepy. This process is repeated as needed until sleep is obtained. Wake time is normal, and naps are not allowed.
Cognitive-behavioral therapy for insomnia (CBT-I)	Maladaptive beliefs and attitudes regarding the distinction between normal and abnormal sleep are identified, addressed, and redefined, to induce positive changes in sleep-related cognition and associated behavioral and emotional outcomes.
Relaxation training	Various relaxation techniques including meditation, muscle relaxation, and biofeedback for the reduction of somatic and cognitive arousal.
Sleep restriction	Time in bed is restricted to self-estimated total sleep time. Sleep efficiency (ratio between time asleep and time in bed) is assessed weekly. Time in bed may gradually be increased on confirmation of increases in sleep efficiency. No naps are allowed.
Paradoxical intention	Patient is instructed to lie in bed and attempt to remain awake with eyes open for as long as possible. Bedroom should be dark and quiet, and patient must not engage in other activities other than the continuous endeavor to remain awake.
Sleep hygiene education	On the basis of the sleep history, ineffective habits and behaviors related to poor sleep are targeted and clear guidelines for better sleep are provided, such as creating a stable sleep-wake schedule and maintaining a sleep-inducing bedroom environment, minimizing napping, and avoiding sleep-inhibiting substances and behaviors at night, including caffeine, nicotine and alcohol, heavy meals and high fluid intake, worrisome thoughts, and clock viewing.
Bright light	Patients are exposed either to a bright light fixture or to natural outdoor light in the evening hours.*

*Indicated for advanced sleep phase and early-morning awakenings.

more reliable measurement tool than sleep logs (although sleep logs often are used to complement actigraphy) and is particularly useful in populations with poor tolerance of PSG, such as institutionalized elderly persons.

TREATMENT OF INSOMNIA

The effectiveness of pharmacologic and nonpharmacologic treatments has been demonstrated for late-life insomnia. The evidence for their efficacy is reviewed next, followed by a summary of specific considerations for their use in the elderly population.

Nonpharmacologic Treatments

Nonpharmacologic treatments that have been investigated for insomnia in older adults include psychological, cognitive-behavioral, and bright light treatments (Table 153-1). In an update of the AASM practice parameters for psychological and behavioral treatments of insomnia,[62] stimulus control, relaxation training, and cognitive-behavioral therapies were recommended treatments for chronic insomnia with a high level of evidence from clinical trials. Treatments reaching moderate levels of evidence for efficacy included sleep restriction therapy, multicomponent therapy (without cognitive therapy), biofeedback, and paradoxical intention. These treatments have been found to be effective in older adults and in chronic hypnotic medication users. Insufficient evidence was available to determine the efficacy of sleep hygiene, imagery training, and cognitive therapy.

Cognitive-behavioral therapy for insomnia (CBT-I) has proved to be successful for older adults with primary and comorbid insomnia, and for those with hypnotic medication dependency.[62a] For example, in a clinical ambulatory PSG trial with 6-week and 6-month follow-up periods, CBT-I was compared with zopiclone and placebo in elderly patients with chronic insomnia. For the CBT-I group, wake time was significantly reduced, and both sleep efficiency and slow wave sleep were significantly increased at both 6-week and 6-month follow-up assessments, compared with the zopiclone and placebo groups.[63] In a sample of older adults with sleep maintenance insomnia, a brief (4-week) group-based CBT-I intervention showed significant improvements in sleep measures at completion of treatment and at a 3-month follow-up evaluation, including reduced wake time after sleep onset, increased sleep efficiency, and reduced time in bed, as reported in sleep diaries.[64] At the conclusion of treatment and at the 3-month follow-up assessment, 46.5% and 42.2%, respectively, were no longer in the diagnostic range for insomnia based on the Insomnia Severity Index (ISI).

In another study on late-life insomnia, comparing CBT-I with a sedative hypnotic medication (temazepam) and with both modalities combined (CBT-I and temazepam) for the treatment of insomnia, positive short-term efficacy was reported for all three regimens compared with placebo, with a small increased benefit for the combined regimen.[65]

However, at a 2-year follow-up evaluation, sustained long-term gains were achieved only in the CBT-I groups, especially in the CBT-I–only group, indicating that CBT-I alone is superior to combined therapy. As indicated by this evidence, CBT-I provides a particularly promising alternative for this age group. In the 2005 National Institutes of Health State of the Science Conference on Insomnia, CBT-I was found to be as effective as prescription medications for the brief treatment of chronic insomnia, with indications that in contrast with medications, the beneficial effects of CBT-I may last well beyond termination of treatment.[41]

Evening bright light exposure has been indicated for the treatment of advanced circadian sleep phase syndrome and insomnia characterized by early-morning awakening, both of which are common among elderly persons. The practical usefulness of bright light treatment in late-life insomnia, however, generally has not been supported by research findings.[66] In view of the importance of implementing feasible therapeutic alternatives to medication in this population, further investigation, possibly targeting specific subtypes of insomnia that may benefit from bright light therapy, is warranted.

Pharmacologic Treatments for Insomnia

Commonly used hypnotic prescription medications for the treatment of insomnia include traditional benzodiazepine sedative-hypnotics (temazepam, estazolam, flurazepam, quazepam, triazolam), newer selective nonbenzodiazepine sedative "Z-drug" hypnotics (eszopiclone, zaleplon, zolpidem, and zolpidem MR), the melatonin receptor agonist ramelteon, and low-dose doxepin. Other sedating antidepressants (e.g., trazodone), antipsychotics (e.g., quetiapine), and antihistamines (diphenhydramine) also are used off label, despite limited efficacy data and often considerable safety risk. Self-treatments for insomnia include over-the-counter medications and herbal or dietary supplements. In the 2005 National Institutes of Health State of the Science Conference on Insomnia, the panel concluded that the risks associated with off-label drugs outweigh the benefits; therefore it did not recommend the use of antidepressants, antihistamines, or antipsychotics, or of over-the-counter or herbal supplements, for the treatment of insomnia.[41]

In a representative sample of more than 32,000 noninstitutionalized American adults (i.e., the NHANESs) aged 20 to older than 80 years, the prevalence of medications commonly used for insomnia in the preceding month was 3%, with a significant increase between 1999–2000 and 2009–2010.[67] The most commonly used medications were Z-drugs and trazodone, and the frequency of concurrent use of two or more sedatives was high (55% for at least two and 10% for at least four concurrent sedatives). The likelihood of consuming sedatives for insomnia after multivariable adjustments was highest in older adults, those seeing a mental health provider, and those reporting polypharmacy in sedative use.

Although the Z-drugs are considered safer and more effective than the older benzodiazepines,[41] in a meta-analysis of data submitted to the U.S. Food and Drug Administration[69] assessing the effects of Z-drugs on objective (PSG) and subjective sleep latency in the adult population, small but significant improvements were found, yet these improvements were comparable to placebo effects and were more pronounced in younger persons, in females, and at higher drug doses. In view of the typically higher rates of sleep maintenance insomnia and the increased risk for adverse effects, particularly with higher doses, in older adults, the true efficacy of these sedatives in the elderly population remains questionable.

Hypnotic medication use is highest and most chronic in older adults, yet it has been suggested that the benefit of such medications is lower in older than in younger adults.[68,69] General guidelines for the use of sedative-hypnotics in the elderly population include selection of the appropriate drug (short- versus long-acting), determining the type of insomnia complaint (sleep onset versus sleep maintenance insomnia), starting with a low dose and increasing as needed, recognizing the risk of specific drug-drug interactions, and monitoring for adverse effects, particularly residual effects of daytime sleepiness, impaired cognitive performance, and increased risk of falls.[68] It is important to keep in mind that the adverse effects of sedative-hypnotic use may outweigh the benefits, particularly in persons with baseline cognitive impairment.

Nevertheless, use of selected nonbenzodiazepine hypnotics has been investigated in the older population. In an open-label 6- to 12-month investigation in older adults with chronic insomnia, long-term use of 5 and 10 mg of nightly zaleplon was found to be safe and effective, demonstrating improvements in subjective sleep measures with no rebound insomnia on discontinuation.[70] The efficacy of eszopiclone was evaluated in nearly 400 older adults 65 to 85 years of age who were randomly assigned in a double-blind trial to receive eszopiclone (2 mg/night) or placebo.[71] The eszopiclone group demonstrated significant improvements on subjective measures of sleep, including a mean increase of more than 60 minutes in total sleep time and a mean decrease of 36 minutes in wake time after initial sleep onset. Improvements were maintained for 3 months, and no rebound effects occurred on discontinuation.

Ramelteon is a selective agonist for melatonin subtype 1 and 2 receptors. Assessment of the efficacy of ramelteon 8 mg/night versus placebo for more than 5 weeks in 800 older adults with chronic insomnia has demonstrated significantly decreased sleep latency, with no withdrawal or rebound insomnia after discontinuation based on patient reports.[72] These findings were supported by a polysomnographic repeated measures design, with two treatment days for each treatment phase (8 mg and placebo) and an intervening washout period.[73] PSG results demonstrated reduced latency to persistent sleep and increased total sleep time and sleep efficiency for both doses compared with placebo. No residual effects were found for next-day cognitive and psychomotor performance.

Nevertheless, it is worthy of emphasis that although some evidence has demonstrated the safety and efficacy of the newer sedatives in older adults with chronic insomnia, the overall clinical significance of outcomes has been questioned, and these medications are not risk-free.

CLINICAL PEARL

Insomnia is very common in older adults and generally is related to medical or psychiatric illness, use of certain medications, circadian rhythm and sleep homeostatic changes, or other primary sleep disorders, rather than to aging per se. Clinicians should routinely screen for sleep problems in this age group and initiate appropriate treatment.

SUMMARY

Symptoms of insomnia are very common in the elderly population, and the problem is largely underrecognized and undertreated. Increasing evidence of the significant adverse

consequences of insomnia warrants careful assessment and appropriate treatment strategies for this age group. Proper treatment of insomnia in this age group is effective and may improve overall physical and mental health, subjective sense of well-being, and quality of life in the older patient. Further research is required in selected older adult cohorts to elucidate the mechanisms underlying the development of insomnia and its related comorbid conditions and consequences, and to determine how these processes can be effectively treated or prevented.

Circadian Rhythms in Older Adults

Gregory J. Tranah; Katie L. Stone; Sonia Ancoli-Israel

Chapter Highlights

- Aging is associated with altered circadian rhythms, the intrinsic physiologic cycles of approximately 24 hours that are critically involved in control of sleep-wake cycles and numerous physiologic processes.
- Wrist actigraphy can be used to measure 24-hour recordings of activity, from which sleep and wake can be scored. Activity patterns correlate strongly with entrained endogenous circadian phase.
- Older women and men with weak and shifted circadian activity rhythms have higher mortality rates.
- Older women with weak and late-shifted circadian activity rhythms are at higher risk for development of mild cognitive impairment and dementia.
- Older men with decreased circadian activity rhythm robustness are at increased risk for cardiovascular events, primarily those related to coronary heart disease or stroke.
- Older women with depression have more desynchronized circadian activity rhythms.
- If the benefits of interventions (e.g., physical activity, bright light exposure) that regulate circadian activity rhythms are confirmed in other populations, studies will be needed to test whether such interventions will improve health outcomes in elderly persons.

CIRCADIAN RHYTHMS AND AGING

Circadian rhythms are intrinsic physiologic cycles of approximately 24 hours that are critically involved in control of sleep-wake cycles and numerous physiologic processes. Several biologic functions are under circadian control, including release of certain hormones, body temperature, blood pressure and heart rate, bone remodeling, and sleep and activity cycles (rest-activity rhythm). In mammals, the suprachiasmatic nucleus (SCN), located in the anterior hypothalamus, receives light signals from the retina through the retinohypothalamic tract and serves as the primary circadian pacemaker, setting the phase and period of biologic rhythms throughout the organism. The SCN also regulates pineal melatonin biosynthesis to produce rhythmic melatonin levels that regulate sleep-wake cycles. Although the SCN is crucial for the generation of biologic rhythms throughout the organism, a series of peripheral oscillators also are distributed among the cells and tissues, including the liver, endocrine tissues, heart, and skeletal muscles.[1-3] These peripheral oscillators are similar to the SCN in terms of basic molecular organization[4] in that the individual cells generate self-sustained molecular and physiologic oscillations.[5,6] The sleep-wake cycle is synchronized to the time of day by a number of cues, the strongest of which is the environmental rhythm of light and darkness.

Aging is associated with alterations in circadian activity rhythms, including decreased amplitude (height or strength of rhythm),[7] fragmentation or loss of rhythms (weakening of rhythmic pattern),[8-14] shortened natural free-running period (period of rhythm without environmental cues), a tendency toward internal desynchronization,[15-17] and decreased sensitivity to phase-resetting signals, including light and those induced by sleep medications.[16] The timing of peak rhythm activity also typically advances with age, resulting in an earlier onset of sleepiness in the evening and an earlier morning waking time.[9] The disruption of circadian rhythms during aging is paralleled by decreased photic input secondary both to age-related losses in circadian photoreception[18] and to typically reduced light exposure in older people.[19] It has been hypothesized that disruptions in these rhythms may occur in part as a result of age-related deterioration of the SCN.[20] Animal studies suggest that aging also is associated with a number of molecular changes in the circadian system, including changes in expression patterns of clock genes and changes in the neurochemistry of the SCN.[16,21-23]

Little is known concerning the causes of age-related changes in circadian patterns and the subsequent effects of these changes on health and well-being. Circadian and sleep-wake rhythm abnormalities have been observed among older adults with a wide variety of medical conditions. For example, activity phase abnormalities in older adults with dementia have been shown to predict a shorter survival.[24] Disturbances of the sleep-wake cycle, which are reflected in poor activity rhythms, are particularly pronounced in Alzheimer disease[25-27] and are hypothesized to be one of the primary causes of institutionalization[28,29] of persons with this disorder, along with shifts in daytime activity patterns.[30] Patients diagnosed with Alzheimer disease also exhibit reduced amplitudes and phase delay of circadian variation in core body temperature and activity.[31] In patients with metastatic colorectal cancer,

two-year survival was five times higher among those with stronger circadian activity rhythms than among those with rhythm abnormalities.[32] Activity phase abnormalities in elderly persons with dementia have been shown to predict shorter survival.[24] Furthermore, those with more daytime than nighttime activity had an apparent better quality of life.[32,33]

It is not clear whether activity rhythms direct influence morbidity and mortality or whether they represent biomarkers of advanced physiologic aging that provide additional information on risk beyond that of traditional covariates. Indeed, van Hilten and colleagues[34] examined the influence of age on nocturnal behavior in 100 healthy older adults and concluded that in the absence of illness, age itself has only marginal effects on the sleep-wake cycle.

This chapter reviews the latest evidence from large, population-based cohorts of elderly participants that alterations in circadian activity rhythms are associated with increased mortality rates,[35,36] dementia and mild cognitive impairment (MCI),[37] cardiovascular disease (CVD),[38] and depression.[14,39]

MEASUREMENT OF RHYTHMS

A variety of methodologies have been used for analyzing circadian activity rhythms,[14,35,36,40-45] but no single standard approach has been accepted. *Actigraphy* records limb movements and allows for 24-hour recordings of activity from which wake and sleep measures can be scored. Traditionally, the actigraph is placed on a wrist, although sometimes activity from the leg or waist is recorded. Once actigraphic data are collected, the signal is displayed on a computer and examined for patterns of activity-inactivity and analyzed for wake-sleep patterns. Wrist actigraphy has the advantages of being cost-efficient, allowing the monitoring of sleep behavior in natural environments, tracking both daytime and nighttime activity, and recording for long time periods. Although actigraphy is not a replacement for electroencephalogram (EEG) or polysomnography (PSG) recording of sleep behavior or circadian measures based on 24-hour melatonin or cortisol, it provides several clear-cut advantages for data collection: Actigraphy is a valid marker of entrained PSG sleep phase and correlates strongly with entrained endogenous circadian phase.[46] It also is useful in identifying sleep that has been disturbed by circadian rhythm changes. Actigraphy allows the study of rhythms occurring over many days; it is therefore well suited to the study of circadian rest-activity rhythms. Actigraphy also is a useful adjunct to the routine evaluation of circadian rhythm disorders. Another advantage is that actigraphy can be deployed in large clinical studies to examine the role of activity rhythms in health and disease, as well as for tracking interventions targeting rhythm disturbances.

Use of the wrist actigraph may be particularly valuable for studying people who have difficulty sleeping in a sleep laboratory, or with the wires used for traditional PSG, such as those with insomnia, children, and demented elderly persons. With actigraphy, patients are studied in their natural environment. Mormont and colleagues[33] used actigraphy to study circadian rhythms and sleep-wake cycles in patients with cancer, as a preliminary step toward the advancement of chronotherapy. Studies have also been done to examine sleep schedules of adolescents,[46] shift workers,[47,48] and in-flight crews.[49]

Three large, population-based studies of elderly persons have measured activity rhythms using wrist actigraphy: the Study of Osteoporotic Fractures (SOF), the Osteoporotic Fractures in Men (MrOS) study, and the Rotterdam Study (RS). The SOF and MrOS studies collected activity data with a sleep watch–styled actigraph (SleepWatch-O, Ambulatory Monitoring, Inc., Ardsley, New York) and looked at activity rhythm association with increased mortality,[35,36] dementia and MCI,[37] CVD,[38] and depression.[39] In these two studies, an extension to the traditional cosine model was used to map the circadian activity rhythm to the activity data.[45] The following activity rhythm parameters were calculated from the extended cosine curve: *amplitude,* an indicator of the strength of the rhythm, is the peak-to-nadir difference in activity (measured in arbitrary units of activity [counts/minute]); *mesor,* mean level of activity (measured in arbitrary units of activity [counts/minute]); *pseudo–F value,* a measure of model fit, with smaller values indicating a less robust rhythmic pattern in rest-activity and hence overall reduced circadian rhythmicity; *acrophase,* timing of peak activity measured as time of day; *beta* (β) *statistic,* a measure of steepness of the curve, in which larger values represent more square-shaped waves, which would suggest a more constant level of daytime activity; *alpha* (α) *statistic,* a measure of peak-to-trough width, in which small values would represent curves where the troughs are narrower than the peaks, suggesting greater a daytime to nighttime activity ratio; and *minimum,* the lowest-level modeled activity in which large values may be indicative of greater nighttime activity. The RS collected activity data with the Actiwatch model AW4 (Cambridge Technology, Cambridge, United Kingdom) and examined several correlates of activity rhythms including depression.[14] The following activity rhythm parameters were calculated in the RS: *M10 onset,* onset of 10 most active hours (proxy for acrophase); *L5 onset,* onset of 5 least active hours; *amplitude,* difference between average activity level in M10 and L5 periods; *relative amplitude,* amplitude divided by the sum of M10 plus L5; *average,* average of activity over the day (proxy for mesor); *interdaily stability,* degree of regularity in rhythm over days; and *interadaily variability,* fragmentation of the rhythm.

FACTORS STUDIED IN ASSOCIATION WITH CIRCADIAN RHYTHMS

Mortality

A disrupted or less robust circadian activity rhythm has been associated with medical illnesses such as dementia and cancer. Indeed, disturbances of the sleep-wake cycle, which are reflected in poor activity rhythms, are hypothesized to be a major factor contributing to institutionalization.[28,29] Whereas the association between circadian activity rhythms and illness is fairly strong, evidence for an association between disrupted activity rhythms and ensuing death is limited.[24,32,33] Tranah and associates[35] examined whether circadian activity rhythms are associated with mortality in 3027 community-dwelling women from the SOF cohort (mean age, 84 ± 4 years; range, 77 to 99 years). Activity data were collected for a minimum of three 24-hour periods, and vital status, with cause of death determined from death certificates, was prospectively ascertained. Over an average follow-up period of 4.1 years, a total of 444 deaths (15%) occurred. Those women with lower peak (amplitude) and mean (mesor) levels of activity and less

robust rhythms had the shortest overall survival, and all-cause mortality risk increased from the highest to the lowest quartile of amplitude. Relative to that for women in the highest quartiles, approximate doubling of the adjusted higher all-cause mortality risk was observed for those in the lowest quartiles of amplitude (hazard ratio [HR], 2.18; 95% confidence interval [CI], 1.63 to 2.92), mesor (HR, 1.71; 95% CI, 1.29 to 2.27), and rhythm robustness (HR, 1.97; 95% CI, 1.50 to 2.60) after multivariate adjustment for age, clinic site, race, body mass index (BMI), cognitive function, sleep performance, exercise, instrumental activities of daily living impairments, depression, medications, alcohol, smoking, self-reported health status, marital status, and comorbid illness. An increased risk of death from atherosclerotic disease also was observed for the lowest quartiles of amplitude (HR, 1.81; 95% CI, 1.13 to 2.90) and mesor (HR, 1.61; 95% CI, 1.02 to 2.54) activity levels as well as the lowest quartile of rhythm robustness (HR, 2.31; 95% CI, 1.45 to 3.68). The relationships with atherosclerotic mortality were largely driven by associations between circadian activity rhythms and either coronary heart disease or stroke-related mortality, which accounted for 34% and 32% of atherosclerotic disease–related deaths, respectively. Increased risk of "other-cause" mortality was observed in the lowest quartiles of amplitude (HR, 3.11; 95% CI, 1.93 to 5.00), mesor (HR, 2.09; 95% CI, 1.33 to 3.28), and rhythm robustness (HR, 2.17; 95% CI, 1.43 to 3.31), compared with the highest quartiles. Further analysis excluding the two most common causes of "other cause" mortality (pulmonary and cognitive causes) produced similar results, suggesting that these two causes of death do not explain this association.

In this study, acrophase was examined in terms of the deviation from the population mean. The investigators identified three categories based on having a peak time of more than 1.5 standard deviations (SDs) above and below the mean for the study population. Phase-advanced participants were defined as having an acrophase of earlier than 12:50 PM (–1.5 SD from the mean), and phase-delayed participants were defined as having an acrophase of later than 4:33 PM (+1.5 SD from the mean). The mean peak range was 12:50 PM to 4:33 PM. Acrophase deviation was not associated with all-cause or "other-cause" mortality. However, older women with a delayed acrophase were at significantly increased risk for cancer-related (HR, 2.09; 95% CI, 1.04 to 4.22) and stroke-related (HR, 2.64; 95% CI, 1.11 to 6.30) death when compared with those in the mean peak range.

Paudel and colleagues[36] examined whether circadian activity rhythms are associated with mortality in 2964 community-dwelling men from the MrOS cohort (mean age, 76 ± 6 years). Activity data were collected for a minimum of five 24-hour periods, and vital status, with cause of death confirmed with death certificates and additionally with medical records when available, was prospectively ascertained. Over an average follow-up perod of 3.5 years, 233 deaths (8%) occurred. After adjustment for multiple potential confounders (age, age^2 [modeling non-linear associations], race, alcohol use, smoking status, caffeine use, education, self-reported health status, IADL impairments, cognitive impairment, depression, and number of medical conditions), men in the lowest quintile of rhythm robustness had a 57% higher mortality rate (HR, 1.57; 95% CI, 1.03 to 2.39) compared with men in the highest quintile. This association among those in the lowest quintile of rhythm robustness was even stronger with increased risk of CVD-related mortality (HR, 2.32; 95% CI, 1.04 to 5.22). Additionally, men in the latest quintile of acrophase (later than 3:09 PM) had a 2.8-fold higher rate of CVD-related mortality (HR, 2.84; 95% CI, 1.29 to 6.24) when compared with those with mean acrophase timing (1:58 PM to 2:32 PM). In general, amplitude, mesor and rhythm robustness steadily declined with advancing age. However, there was no association between amplitude and mesor and risk of CVD-related, cancer-related or other causes of mortality.

Dementia and Mild Cognitive Impairment

Circadian rhythms play an important role in rhythms associated with cognitive processing including alertness, learning, and memory. During waking, rhythms in synaptic plasticity,[48,49] focused attention, and behavioral flexibility have been confirmed.[50,51] Little is known concerning the causes of age-related changes in circadian activity patterns in nondemented older adults and the subsequent effects of these changes on health and well-being. Tranah and associates[37] examined whether circadian activity rhythms were associated with incident MCI and dementia in 1282 women from the SOF cohort, using both actigraphy data and findings on a follow-up visit that included an expanded cognitive assessment and adjudication of presence of MCI-dementia by an expert panel. After a mean follow-up period of 4.9 years from the collection of actigraphy data, 195 (15%) women were found to have dementia and 302 (24%) had MCI. An approximately 50% adjusted higher likelihood of developing dementia or MCI relative to that in the cohort without any dementia or MCI was observed for subjects in the lowest quartiles (n = 320) of amplitude (odds ratio [OR], 1.54; 95% CI, 1.07 to 2.21) and rhythm robustness (OR, 1.55; 95% CI, 1.08 to 2.22) when compared with those in the highest quartiles (n = 322).

Acrophase was examined in terms of the deviation from the population mean. Three categories were defined on the basis of a peak time of more than 1 standard deviation (SD) above and below the population mean for the study population. Phase-advanced participants were defined as having an acrophase of earlier than 1:34 PM (–1 SD from the mean), and phase-delayed participants were defined as having an acrophase of later than 3:51 PM (+1 SD from the mean). Acrophase deviation was associated with increased odds of developing dementia or MCI. A delayed acrophase, after 3:51 PM (n = 173, 13%), was associated with a significant increase in odds of developing dementia or MCI (OR, 1.83; 95% CI, 1.29 to 2.61) when compared with the mean peak range of 1:34 PM to 3:51 PM (n = 927, 73%). An advanced acrophase, before 1:34 PM (n = 182, 14%), was associated with an elevated but nonsignificant odds of developing dementia or MCI (OR, 1.36; 95% CI, 0.96 to 1.92) when compared with the mean peak range. All analyses were multivariate-adjusted for age, clinic site, race, education, BMI, walking for exercise, functional status, depression, benzodiazepine and antidepressant use, sleep medication use, alcohol use, caffeine intake, smoking, self-reported health status, and previous medical conditions. Results for all models were unchanged after further adjustment for sleep efficiency.

Cardiovascular Disease

Previous studies are consistent in suggesting that disruptions in circadian activity rhythms are associated with

cardiovascular death, such as increased risk of death from CVD, atherosclerotic disease, or stroke,[35,37] as well as short-term consequences in metabolic measures.[52] Although disrupted circadian activity rhythms and CVD events both are more common in the elderly population, little is known regarding associations between circadian activity rhythm variables and risk of CVD-related events in older adults. Paudel and associates[38] examined whether circadian activity rhythms are associated with risk of cardiovascular events in 2968 men from the MrOS cohort. Over an average follow-up period of 4.0 years, 490 cardiovascular events (16.5%) occurred. Overall, increased risk of such events was observed among participants with reduced amplitude (HR, 1.31; 95% CI, 1.01 to 1.71 for quartile 2 versus quartile 4) and greater minimum (nadir) (HR, 1.33; 95% CI, 1.01 to 1.73). In addition, reduced amplitude (HR, 1.36; 95% CI, 1.00 to 1.86) and greater minimum activity counts (HR, 1.39; 95% CI, 1.02 to 1.91) were associated with increased risk for coronary heart disease–related events. Reduced rhythm robustness (HR, 2.88; 95% CI, 1.41 to 5.87) also was associated with an increased risk of peripheral vascular disease events when the lowest quartile was compared with the highest quartile. Men in the lowest quartile of β (indicating less constant levels of daytime activity) had a 78% increased risk of incident stroke compared with men in the highest quartile in multivariable-adjusted models (HR, 1.78; 95% CI, 1.01 to 3.14). Additional analyses excluding men who reported having had prevalent CVD or models adjusting for traditional cardiovascular risk factors such as diabetes, blood pressure, total cholesterol, and HDL did not affect the statistical significance of results.

Depression

A considerable body of evidence supports a role for circadian rhythm disturbances in the pathophysiology of depression.[53-55] Circadian rhythm disturbances have been observed in unipolar depression, bipolar depression, and seasonal affective disorder.[56,57] In unipolar depression, multiple rhythms are disrupted including those governing secretion of prolactin, cortisol, growth hormone, and melatonin, along with body temperature and the sleep-wake cycle.[58] At the neuroanatomic level, depressed patients have been shown to have different patterns of regional brain glucose metabolism throughout the day compared with normal patients, and the expression of enzymes that control catecholamine metabolism may be regulated by clock genes.[59,60] Although aging promotes disruption in circadian rhythms, the relationship between depression and circadian rhythm disruption in older adults remains largely unexplored. Maglione and associates[39] examined the relationship between depressive symptoms assessed with the Geriatric Depression Scale (GDS) and circadian activity rhythms in older adults among 3020 women (mean age, 83.6 ± 3.8 years) from the SOF cohort. Higher levels of depressive symptoms on the GDS were associated with greater desynchronization (decreased amplitude, rhythm robustness, and mesor) of circadian activity rhythms in linear regression models. In addition, greater levels of depressive symptoms were associated with a later average time, becoming active in the morning but not with acrophase. When categorizing participants by GDS score as "normal" (0 to 2) (referent group, $n = 1961$), "some depressive symptoms" (3 to 5) ($n = 704$), or "depressed" (6 or higher) ($n = 355$), Maglione's group[39] also assessed the odds of falling into the lowest quartile for activity rhythm variables. Risk of falling into the lowest quartile of amplitude was elevated both for participants defined as having "some depressive symptoms" (OR, 1.32; 95% CI, 1.04 to 1.67) and for those designated "depressed" (OR, 1.51; 95% CI, 1.11 to 2.05). In addition, the likelihood of falling into the lowest quartile of mesor was elevated both for the "some depressive symptoms" group (OR,1.55; 95% CI, 1.24 to 1.94) and for the "depressed" group (OR, 1.62; 95% CI, 1.20 to 2.18). Additional adjustment for total sleep time and sleep efficiency did not affect the statistical significance of results.

Luik and coworkers[14] examined activity rhythm stability and fragmentation in 1734 middle-aged and elderly participants (mean age, 62 ± 9.4 years) from the Rotterdam Study cohort. Activity data were collected for a minimum of four 24-hour periods and investigated age, sociodemographics, mental health, lifestyle (coffee use, alcohol use, and smoking), and sleep characteristics as determinants of activity rhythms. The results of this study indicate that older age is associated with a more stable 24-hour activity rhythm but also with a more fragmented distribution of periods of activity and inactivity. Both BMI and smoking were associated with less stable and more fragmented activity rhythms. In concordance with the results from the SOF cohort,[39] more depressive symptoms were related to less stable and more fragmented activity rhythms.

PATHOPHYSIOLOGIC MECHANISMS

In interpreting the foregoing results, two possibilities should be considered. First, activity rhythms may directly influence morbidity and mortality in older adults independent of other features of aging. In support of this association, emerging animal and human data show the existence of both central and peripheral (e.g., in the liver, pancreas, and other organs) circadian rhythms, with evidence that misalignment of internal rhythms may be a predisposing factor for impaired glucose tolerance and alterations in immunologic and inflammatory processes. Previous studies suggested that some but not all peripheral circadian oscillators exhibit age-related changes in rhythmicity[61] and that some of these tissues retained the capacity to oscillate but were not being appropriately driven in vivo (e.g., by physical activity or feeding).[62] The presence of arrhythmic peripheral tissues may be due to weakened behavioral and physiologic rhythms that provide less effective signals to the peripheral oscillators.[54] The change in phase relationships of behavioral and physiologicl rhythms, therefore, may not be due to age-related changes in the entrained phase of the SCN itself but rather may arise from age-related alterations in other rhythmic components of the circadian system.[39] Evidence of an age-related phase advance is clear from studies involving body temperature, sleep-wake cycle, melatonin, and cortisol,[37] in which a phase difference of approximately 1 hour typically is found between young and old individuals. Age-related phase advances also are found in the circadian rhythms of blood pressure, levels of iron and magnesium, and numbers of neutrophils and lymphocytes.[38] Acrophase deviations from the mean may represent an altered phase relationship between the circadian activity rhythm and the light-dark cycle.

For example, the circadian timing system most likely affects memory, cognitive function, and behavior through a variety of neuroanatomic and neurophysiologic mechanisms.[63] The

circadian contribution to cognition also may arise from the synchronized activities of an integrated network of clocks in the brain under the direction of the SCN pacemaker.[64] It is also possible that circadian activity rhythms are biomarkers of advanced physiologic aging that provide additional risk over and beyond that of traditional covariates, but which may have no direct causal association with dementia or MCI. Sleep and rhythm disturbances are common in many neurodegenerative diseases including Alzheimer disease,[65-67] dementia,[68] and Lewy body disease.[69] The major sleep complaints associated with neurodegenerative diseases include insomnia, hypersomnia, parasomnia, excessive nocturnal motor activity, sleep apnea, and sleep-wake rhythm disturbances.[70] Sleep is disturbed early in the neurodegenerative process, and sleep disturbances are observed in the presence of MCI.[71,72] Furthermore, it has been suggested that sleep disturbance increases with severity of the neurodegeneration.[73] Although neurodegenerative diseases are believed to be proteinopathies resulting from excessive protein misfolding and intracellular protein aggregation, the role of sleep and rhythm disturbances in the neurodegenerative process has been largely unexplored. The accumulation of amyloid-beta in the brain extracellular space is a critical factor in the pathogenesis of Alzheimer disease, and both the sleep-wake cycle and orexin have been shown to play a role in regulating amyloid-beta dynamics.[74] Orexins and their receptors are involved in a number of central[75] and peripheral[76] functions and play an important role in maintaining wakefulness by preventing unwanted transitions into sleep, as seen in narcolepsy.[77]

A second possible mechanism to consider in interpreting the evidence to date is that circadian activity rhythms are biomarkers of advanced physiologic aging that provide additional risk over and beyond that of traditional covariates, but which may have no direct causal association with mortality. In this instance, available data may provide evidence that circadian activity rhythms are markers for a greater risk for disease or death not measured by conventional markers. Although the biologic mechanisms underlying the associations between disrupted activity rhythms and increased risk of cardiovascular events are unknown, the results of the study by Paudel and associates[38] suggest that the associations are independent of age, race, instrumental activities of daily living impairments, smoking status, cognitive function, use of antidepressants, walking for exercise, and history of CVD, stroke, or peripheral vascular disease. Although it generally is perceived that circadian rhythm disruptions precede CVD-related events, it is plausible that comorbid CVD and/or other conditions such as diabetes worsen circadian rhythm disruptions through their debilitating impact on sleep-wake activity. It also is possible that circadian rhythms and conditions such as diabetes share common causative factors.

IMPLICATIONS

Circadian rhythms and sleep are influenced by circadian and homeostatic processes. The results of recent work in large population-based cohorts of elderly participants suggest that weak and shifted circadian activity rhythms are associated with increased risks of mortality, MCI-dementia, and CVD. Depression also appears to be associated with more desynchronized circadian activity rhythms. If these associations are confirmed in additional cohorts, future studies should examine whether interventions such as physical activity and bright light exposure that influence activity rhythms will reduce morbidity and mortality in the elderly population.

For example, identifying new approaches for interventions that slow the age-related decline in cognitive function will potentially benefit the health and well-being of elderly persons before the onset of cognitive impairment. Sleep interventions and light therapy in patients or rodent models have been shown to demonstrate acute beneficial effects.[78,79] Exposure to ambient light also is known to influence cognition and affective state,[49,60,80-82] and bright light has phase-shifting properties that have been shown to improve cognitive performance.[83] In addition, several studies examining the efficacy of bright light for treatment of depressive symptoms in older adults without dementia have yielded promising results,[84,85] although at least one has found no benefit.[86] In older adults, depression also has proved difficult to treat, with a high rate of refractoriness to first-line pharmacotherapies.[86] Meanwhile, several studies suggest that bright light therapy, a chronobiologic modality designed to correct circadian rhythm disruption, may be an effective treatment for depression in older adults.[84,85] Overall, further elucidation of the relationship between circadian rhythm disruption and age-related diseases is critical and may lay the groundwork for the development of better treatment strategies.

CLINICAL PEARLS

- Circadian rhythms are intrinsic 24-hour physiologic cycles that are critically involved in control of sleep-wake cycles and a variety of other physiologic processes.
- With aging, circadian rhythms tend to become weaker, and the timing of peak activity also may change.
- Twenty-four-hour patterns of activity, which can be estimated using wrist actigraphy to measure limb movements, serve as a marker for intrinsic circadian rhythms.
- Older women and men with weaker and time-shifted circadian activity rhythms are at greater risk of death, MCI and dementia, and CVD.
- Interventions that regulate circadian rhythms may improve health care outcomes in older adults.

SUMMARY

In mammals, circadian rhythms are driven by the primary circadian pacemaker, the suprachiasmatic nucleus, located in the hypothalamus. These 24-hour rhythms are entrained by light and control a variety of physiologic processes including release of certain hormones, blood pressure and heart rate, bone remodeling, and sleep and activity cycles (among others). Rhythms of rest and activity, which can be approximated by measuring limb movement using actigraphy, are correlated with intrinsic circadian rhythms. In older adults, disturbances in circadian rest-activity rhythms are associated with increased prevalence of CVD, increased risk of death, and higher frequency of cognitive impairment and dementia. Rest-activity rhythms also are disturbed in depressed older adults. It is unclear whether health is directly affected by deterioration in circadian rhythms, or whether changes in the strength and

timing of rhythms constitute a biomarker for other changes that occur with aging. Future studies are warranted to test whether interventions to improve circadian rhythms, such as physical activity or light exposure regimens, may improve health in older adults.

Sleep in Women

Chapter
155

Sex Differences and Menstrual-Related Changes in Sleep and Circadian Rhythms

Fiona C. Baker; Louise M. O'Brien

Chapter Highlights

- The risk for developing insomnia is greater in women than in men, starting at the onset of menses and persisting across the lifespan. Women also report more sleep difficulties, a need for more sleep, and a longer sleep duration. In contrast, objective sleep recordings with polysomnography or actigraphy show that women have a shorter sleep onset latency, better sleep efficiency, more N3 sleep, and more slow wave activity than men. The reasons for the different findings with subjective and objective measures is unclear. Possibly, polysomnography measures are appropriate measures of subjective sleep quality in men but not in women.
- Although some sex differences in sleep behavior are apparent in infants and young children, differences become more prominent during adolescence. On the basis of actigraphy data, boys sleep less and have a less efficient sleep than girls. The timing of age-related changes in sleep also differs, with later shift to eveningness as well as later adolescent decline in slow wave activity in boys than in girls, possibly related to a later onset of puberty in boys.
- In women, sleep is affected by the menstrual cycle. In the postovulatory luteal phase, amount of N3 sleep remains constant but that of rapid eye movement sleep is less, and spindle frequency activity increases. Amplitude of the body temperature rhythm, but not the melatonin rhythm, is reduced in the luteal phase compared with that in the follicular phase.
- Menstrual cycle–associated disorders affect sleep in different ways. Women with polycystic ovary syndrome are at increased risk for sleep-disordered breathing. Women with severe dysmenorrhea experience more wakefulness in association with their menstrual pain. Women with severe premenstrual syndrome exhibit differences in sleep and circadian rhythms that are evident in symptomatic and asymptomatic phases of the menstrual cycle.

SEX DIFFERENCES IN SLEEP FROM INFANCY TO ADULTHOOD

Sexual dimorphism describes morphologic differences between the sexes, although it also refers to any biologic process that differs between men and women. Extensive evidence from diverse species—fruit flies to humans—demonstrates sexual dimorphism in structure, function, and regulation of the brain. Differences between male and female brains are believed to result from the actions of gonadal secretions during a critical

period of brain development, although gonadal secretion is not the only mechanism, because gene expression in neuronal cells also plays a role in sexual dimorphism of the brain before gonadal secretion occurs. Animal studies show evidence of sex differences in sleep and circadian regulation, some of which are hormone-dependent.[1] However, research into sex differences in sleep and circadian rhythm regulation lags behind other studies of sex differences in both humans and animal models. Also, emerging evidence suggests that sex differences may vary depending on stage of reproductive development. Presented next is an overview of the current evidence regarding sex differences in sleep and circadian rhythms, from infancy to adulthood. Major findings are summarized in Table 155-1.

Table 155-1 Sex Differences in Sleep throughout the Life Cycle

Subjective Reports	Objective Measures
Infants	
Poor sleepers are more likely to be boys	*Video*: Girls have a longer sleep period and more quiet sleep than boys *Polysomnography*: Boys exhibit more infraslow activity (<0.5 Hz) during sleep than girls Boys have increased arousability compared with girls
Children	
Girls sleep longer than boys	*Actigraphy*: Girls sleep longer than boys *Polysomnography*: Girls have a higher sleep efficiency than boys Girls experience more arousals than boys
Adolescents	
Girls take longer to get to sleep and sleep longer than boys Girls are more likely to be extreme sleepers than boys (i.e., sleep periods of <6 hours and >10 hours)	*Actigraphy*: Girls have more efficient sleep and fewer awakenings than boys *Polysomnography*: Girls begin the decline in NREM delta power earlier than boys Depressed boys experience a greater degree of sleep disturbance than do depressed girls
Adults	
Women report more sleep difficulties than men Women have a longer sleep duration than men	*Actigraphy*: Women have better sleep quality and sleep more than men *Polysomnography*: Women have a shorter sleep latency, better sleep efficiency, and more sleep than men Women exhibit higher delta power activity during NREM sleep

NREM, Non–rapid eye movement.

Infancy

In humans, circadian rhythms exhibit a cyclic tendency, with a periodicity of approximately 24 hours. Individuals undergo a gradual development in rhythmicity after birth, strengthening from interaction with a 24-hour light-dark cycle, social cues, and other environmental conditions. In healthy newborns, robust circadian rhythms usually are entrained by 2 to 3 months of age. The development of sleep states and circadian rhythms in neonates has been reported in multiple studies, although few have reported on comparisons between the sexes. In those that have compared male and female infants, findings are contradictory. Some studies using nighttime video recordings of infants find no differences in sleep-wake state organization,[2] but others find that female infants have higher proportions of quiet sleep and longer sleep periods than male infants.[3,4] Of interest, preterm infant boys may have significantly less active sleep, more wake time, and more diffuse states than infant girls.[5] On electroencephalogram (EEG) recordings obtained during the first few months of life, however, no sex differences in sleep states were found,[6] although healthy newborn boys had more infraslow activity (less than 0.5 Hz) during sleep than newborn girls,[7] and boys in the first month of life had increased arousability in quiet sleep compared with girls, with this difference no longer evident by the age of 2 to 3 months.[8]

Taken together, these studies support the hypothesis that infant girls have a more mature central nervous system (CNS) than infant boys. Infant girls also have more mature respiratory systems than infant boys during the first 6 months of life—possibly related to accelerated CNS maturation.[9] In healthy infants, the ratio of nighttime sleep to total sleep becomes progressively greater with age and demonstrates a more organized pattern of sleep, particularly in female infants. The time course of rapid eye movement (REM) sleep development corresponds with brain maturation.[10] Higher proportions of REM sleep, together with a maturational lag in REM sleep, have been reported in infants at risk for sudden infant death syndrome,[11] for which a clear male predominance has been demonstrated.

Childhood

In many studies, the term *childhood* is not clearly defined, and this designation generally is used to refer to the period from the end of infancy to the onset of adolescence, with inherent variability in timing. This lack of standardization clearly contributes to inconsistent findings. Even so, most studies of sleep in children have not investigated potential sex differences, and when researchers do report results by sex, findings often are conflicting.

Survey Data

Worldwide, several cross-sectional survey-based studies of hundreds of school-aged children have found that girls report sleeping longer than boys.[12,13] Other large, survey-based longitudinal studies, however, have failed to find any sex differences in sleep parameters.[14] Lack of consistency between findings may be due to factors such as cultural or racial differences and the limitations of using questionnaires to investigate sleep. Although questionnaire-based sleep measures show few sex differences, the evidence does point to a higher risk for sleep problems in girls[15] and underscores interactions among sex, sleep problems, and hypothalamic-pituitary-adrenocortical axis responses to stress. Compared to boys

without parent-reported sleep problems, boys with sleep problems had lower diurnal levels of cortisol and lower cortisol levels in response to stress, whereas girls with sleep problems had similar diurnal levels of cortisol but higher levels of cortisol in response to stress.[16]

Actigraphy and Polysomnographic Data

Data from actigraphy recordings have been more consistent in showing sex differences in sleep of school-aged children[17,18] although data remain conflicting for preschool-aged children, with sex differences varying by age even within this narrow age range.[19-21] Several studies have found that girls sleep more and spend more time in motionless sleep than boys.[22,23]

Although many reports of sleep in children include polysomnography (PSG) data, few studies compare the sexes, and findings vary by age. A large community-based study of 542 children, 3.2 to 8.6 years of age,[24] found that younger girls (ages 3 to 5 years) had a higher sleep efficiency, less wake, and more stage 3 (N3) sleep than boys of similar age, although effect sizes were small. Among older children (6 to 8.6 years), girls had a higher proportion of stage 1 (N1) sleep than boys. Another large study of white children between 1 and 18 years of age found that girls had more arousals but no other differences in sleep compared with boys.[25] Measures of the cyclic alternating pattern, which refers to EEG activity characterized by sequences of transient episodes that differ from background basal EEG, suggest that girls have more non–rapid eye movement (NREM) instability, even when standard EEG criteria show no sex differences.[26] However, another study using similar methodology did not find these sex differences.[27]

These results suggest that young girls have a longer sleep duration but only marginal differences in sleep architecture compared with young boys. Sleep characteristics begin to diverge more between boys and girls after the onset of adolescence.

Adolescence

Survey Data

Adolescence is marked by dramatic biologic and social changes that can affect health and behavior, including sleep.[28] Using questionnaire-based methodologies, several studies have found sex differences in sleep behavior. Although sleep-time preference shifts toward eveningness across adolescence in both boys and girls, girls reach the peak in eveningness at an earlier age than boys,[29,30] and boys tend to go to bed later than girls.[31] A meta-analysis of data for more than 90,000 adolescents (9 to 18 years old) from 20 countries found that on average, girls reported a longer time in bed than boys on both school and nonschool days.[32] This finding matches reports of a longer ideal sleep duration in adolescent girls than in boys.[30] A large study in the United States, however, found that adolescent girls reported a slightly shorter—by 10 minutes—sleep duration than boys; this difference reversed after the age of 19 years, when young women reported a longer sleep duration—of more than 30 minutes—than young men.[33] Adolescent girls in this study sample also were more likely than boys to have a short sleep duration (less than 6 hours), and this pattern also reversed in emerging and early adulthood.[33]

Results may vary between surveys depending on whether participants are asked about sleep duration, time in bed, or actual clock times of sleep and wake, especially during adolescence, when a marked change in these variables is seen. Finally, a recent twin study reported a sex-age interaction effect in the contribution of nonshared environmental factors (such as playing video games or participation in evening sports) to variance in sleep duration, being a major factor in both young and older boys as well as older girls, but of lesser importance for younger adolescent girls.[34]

In investigating changes in sleep across adolescence, it is important to consider not only age but also pubertal development. The onset of menses is associated with an increased risk for insomnia in girls,[35] a sex difference that persists across the lifespan. This increased risk for insomnia in girls after menarche corresponds with an increased risk for depression,[36] which is a risk factor for insomnia; however, adjusting for depression did not reduce the association between menses onset and insomnia in girls.[35] Clearly the relationship among insomnia, depression, and pubertal development is complex, with several social and biologic changes occurring around the onset of menses that also may increase risk for both depression and insomnia.

Actigraphy and Polysomnographic Data

In studies using actigraphy, adolescent boys have been found to sleep less, have less efficient sleep, less motionless sleep, and awaken earlier than girls, probably related to greater movement activity during the night in boys.[22,37,38] Of interest, measures of total sleep time by actigraphy and PSG are in close agreement for adolescent girls, but actigraphy may underestimate total sleep time in boys, possibly because of the differential pattern of nocturnal movement between girls and boys.

In adolescence, a well-described EEG change in sleep is a steep decline in delta slow wave activity (SWA), and data from cross-sectional studies indicate that delta activity declines by approximately 50% between the ages of 10 and 20 years.[28,39,40] Longitudinal data from cohorts of 9- and 12- year-olds accumulated over a 4-year period have shown that girls begin the steep adolescent decline in SWA approximately 1.2 ± 0.25 years earlier than boys, which has been hypothesized to reflect an earlier onset of adolescent synaptic pruning in girls.[41,42] It has long been speculated that sexual maturation and declining SWA may be causally related, because the decline is significantly correlated with increasing Tanner stage and is independent of age.[43]

Recent longitudinal data for adolescents spanning ages 9 to 18 years indicated that the timing of the delta decline is linked to timing of pubertal maturation, even with introduction of controls for sex differences.[42] Indeed, sex differences and the relation to the timing of puberty jointly explained two thirds of the between-subject variance in the timing of the delta decline. The study investigators suggested that these data show a temporal relationship between puberty and an electrophysiologic marker of adolescent brain development. Additional evidence includes sex-specific differences in SWA that vary according to EEG scalp topography in adolescence, which could reflect underlying sex differences in cortical structure and function. Adolescent girls exhibit higher SWA over bilateral cortical areas related to language function compared with age-matched boys, and adolescent boys demonstrate increased SWA over the right prefrontal cortex, which is associated with spatial abilities.[44] Feinberg[45] suggests

that the delta decline during adolescence is a component of widespread brain reorganization, of which other manifestations include the emergence of adult cognitive capacity. It is possible that abnormalities in these maturational brain processes may give rise to abnormal circuits that cause psychiatric illnesses.

Major depressive disorder (MDD) is associated with altered sleep architecture in adolescents, with effects dependent on sex.[46] Depressed adolescent boys experience the greatest degree of sleep disturbance (more Stage 1 sleep, less SWS), whereas sleep in depressed girls does not differ significantly from that in healthy girls. However, temporal coherence of sleep EEG rhythms (a measure of synchronization of EEG frequencies of the same periodicity) is significantly lower in adolescents with MDD, with the lowest coherence in affected girls, even in those younger than 13 years of age.[47] In addition, children and adolescents with MDD, as well as those at high risk for MDD, exhibit lower spindle frequency activity during sleep, with a more prominent deficit in girls.[48] A striking finding is that almost one half of adolescents with the most abnormal coherence values showed either symptoms of depression at the time or met diagnostic criteria within 2 years.[49] Low temporal coherence represents a more chaotic organization of sleep EEG rhythms, suggesting that early-onset depression is associated with a reduction in synchronization of sleep EEG rhythms that shows a differential maturational course in boys and girls.[47] Girls with MDD demonstrate dampened amplitude of circadian rest-activity cycles, even when they have not yet reached developmental maturity.[50] By contrast, dampened circadian amplitude is not evident in depressed boys until adolescence. Together, these findings point to a differential developmental influence on sleep in early depression that is sex-dependent.[46]

Adulthood

Survey Data

In comparison with men, women report needing more sleep, spending more time in bed, and a longer sleep duration.[51,52] Women prefer to go to bed earlier[53] and are more likely to be morning types.[54] Women also report more sleep difficulties[52] and are more frequent users of sedative-hypnotic drugs[55] than men across adulthood. Women are at increased risk for insomnia (female-to-male ratio of 1.41:1) that emerges after menarche[35] and is maximal in the elderly age group.[56] Affected women are more likely to report two or more insomnia symptoms, whereas men typically report one symptom.[57] The sex difference in insomnia persists even after underlying psychiatric disorders are taken into account.[56] In a large study of primarily retired adults followed for 19 years, increased mortality was associated with nighttime sleep duration of more than 9 hours in women, but with daytime napping of more than 30 minutes in men.[58]

Actigraphy and Polysomnographic Data

Actigraph assessment of sleep has shown that women exhibit better objective sleep quality with higher sleep efficiency index and lower frequency of transitions between sleep and wakefulness than men.[59,60] Women tend to sleep more than men and have shorter sleep onset latency. Yet compared with older women, older men have a greater tendency for fragmented sleep.[61] Regardless of sex, age is a factor in sleep fragmentation because adults have a strong decline in actual sleep time and sleep efficiency, as well as increased sleep latency as they age.

In parallel with actigraphy, PSG data demonstrate better objective sleep quality, with shorter sleep onset latency, better sleep efficiency, less N1 sleep, more N3 sleep, and less time awake in women than in men.[62-64,65] Men also exhibit more SWA during NREM sleep than women,[66-68] although men and women show similar rates of decline in power density across the night.[68] Finally, men show a more rapid decline in N3 with age,[63,64,69] although no change in the amount of SWA across midlife years is seen for either men or women.[67] The discordance between perceived and objective sleep measures may possibly reflect a greater need for sleep in women that is not being met,[1,60] or objective measures of sleep quality such as total sleep time or sleep fragmentation may be appropriate measures of good subjective sleep quality in men but not in women.[70] Of note, subjective and objective assessments of sleep tap different constructs and should not necessarily be expected to align.

Sex differences in circadian rhythmicity also are apparent, with women having a shorter intrinsic circadian period, correlating with an earlier timing of core body temperature nadir and melatonin peak relative to sleep.[71] Accordingly, women tend to sleep at a later biologic time than men, which may contribute to a higher level of sleep-maintenance insomnia in women.

Under challenge conditions, further sex differences in sleep emerge.[72] For example, compared with young men, young women have a greater delta response to the stress of sleep deprivation,[73] and sex differences in sleep normally seen in healthy adults become even more magnified in comparing depressed men with depressed women. Men with MDD show less SWA than women with MDD or men and women without MDD, whereas depressed women show lower temporal coherence than control subjects.[72] Women, but not men, with MDD demonstrate significantly greater amounts of SWA in multiple cortical areas relative to control subjects.[74] These disturbances in sleep microarchitecture that are more apparent in women with MDD may be relevant to understanding the increased risk of MDD observed in women.

Women exhibit a greater increase in sleep spindle activity after zolpidem and a larger increase in SWA after gaboxadol administration compared with men.[75] It is hypothesized that these sex-dependent effects of hypnotics on the sleep EEG may be related to sex differences in pharmacokinetics, $GABA_A$ receptor subtypes and activation, or interactions between neurosteroids and $GABA_A$ receptors.[75] Women also have a more sustained response to zolpidem, requiring a lower dose for equivalent efficacy than that in men; the U.S. Food and Drug Administration stipulates that the recommended dose for zolpidem in women should be one-half the maximum dosage approved for men.[76]

Whereas women are at greater risk for developing insomnia and restless legs syndrome than men,[52,77] they have a lower risk for obstructive sleep apnea (OSA), with a male-to-female ratio of between 2:1 and 4:1, although up to 2% of women overall may have OSA.[78] OSA is underdiagnosed in women, possibly because they may not present with the classic symptoms (snoring, gasping, or apneic events) and may have additional nonspecific symptoms that make a diagnosis of OSA more difficult.[79] Sex differences in OSA can be explained by several mechanisms, including differences in obesity and fat

distribution, upper airway anatomy and function, and hormone status.[79] The prevalence of sleep-disordered breathing (SDB) in women varies across their reproductive life cycle, with higher levels seen in pregnant and postmenopausal women, as discussed in subsequent chapters (see Chapters 156 to 159).

Observed morphologic variation between men and women in the suprachiasmatic nucleus (SCN) and other hypothalamic structures, along with laboratory and clinical data on sleep and circadian rhythms, provides a strong neurophysiologic and neuroanatomic basis for sex differences in sleep regulation.[1] Although the evidence is strongest for adulthood, emerging data suggest a differential maturational time course in boys and girls that may influence circadian rhythms and sleep-wake cycles. Indeed, the roots of such maturational influences may be evident very early in development. Further longitudinal studies are necessary to determine the time period at which these sex differences emerge and how they are shaped by neuroendocrine function, gene transcription factors, environment, and maturation of sex steroids with menstrual cycle hormonal fluctuations.

In considering potential sex differences in sleep, it is important to be aware of the potential impact on sleep of the menstrual cycle, as described next, as well as other stages of a woman's life cycle, as discussed in Chapters 156 to 159.

THE MENSTRUAL CYCLE AND EFFECTS OF OVARIAN HORMONES ON SLEEP AND CIRCADIAN RHYTHMS

Female reproductive hormones, specifically estrogen and progesterone, not only regulate reproductive tissue function during the menstrual cycle but also have secondary actions in the CNS to influence other physiologic processes, such as sleep and circadian rhythms.

Conventionally, in a normal menstrual cycle of 28 days, day 1 is identified as the first day of bleeding (menses). Ovulation occurs around day 14, dividing the cycle into two phases: a preovulatory follicular phase and a postovulatory luteal phase[80] (Figure 155-1). Under the control of the hypothalamic pituitary ovarian axis, ovarian follicles grow during the follicular phase, with an associated rise in plasma follicle-stimulating hormone (FSH) and estradiol. Circulating estradiol levels peak just before ovulation, triggering a surge in luteinizing hormone (LH) secretion from the anterior pituitary. Ovulation occurs 12 to 16 hours later, around day 14. In the luteal phase, progesterone dominates, being secreted from the ruptured dominant follicle (corpus luteum), together with estradiol. Approximately 14 days after ovulation, if implantation of a fertilized ovum does not occur, hormone levels drop precipitously, heralding the onset of menstruation. Ovulatory cycles typically are between 25 and 35 days long, although menstrual cycle length tends to shorten as women enter their forties. Most menstrual symptoms are experienced by women during the last few days of the cycle, as progesterone and estrogen levels decline, and during the first few days of menstruation.[81]

The reproductive endocrine and sleep systems have the potential to profoundly influence each other. Sleep has a stimulatory effect on LH pulsatility during puberty but an inhibitory effect on LH pulsatility in the early follicular phase, raising the possibility that disturbed sleep patterns could influence reproductive function in women.[82] Receptors for

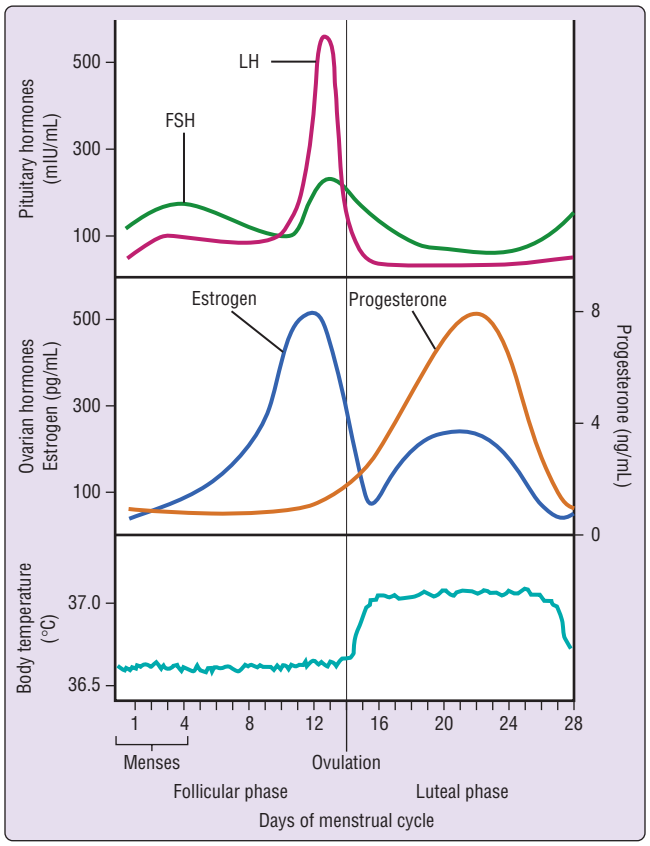

Figure 155-1 Mean daily plasma concentrations of estradiol, progesterone, follicle-stimulating hormone (FSH), and and luteinizing hormone (LH) and basal body temperature throughout a "typical" 28-day ovulatory menstrual cycle. (Modified from Pocock G, Richards CD. *Human physiology: the basis of medicine.* New York: Oxford University Press; 1999, p. 450.)

estrogen and progesterone are present in many sleep-wake–regulatory nuclei in the CNS, and estradiol induces increased arousal in rodents, possibly through its inhibitory effect on sleep-promoting neurons in the ventrolateral preoptic nucleus, an important sleep-active nucleus.[1] Estradiol also consolidates sleep-wake rhythms, possibly through its actions on the SCN.[83] The mechanistic framework is therefore in place for menstrual cycle–related changes in reproductive hormones to influence sleep and circadian rhythms.

Sleep across the Menstrual Cycle

Surveys research based on subjective reports have found that women across a wide age range (18 to 50 years) report more sleep disturbances during the premenstrual week and during the first few days of menstruation than at other times.[52] The Study of Women's Health Across the Nation, which included women in their late reproductive stage or just entering the menopausal transition, reported that trouble sleeping was more likely during the early follicular and late luteal phases of the menstrual cycle.[84] Young women (21 ± 3 years of age) without significant menstrual cycle–associated complaints also report poorer sleep quality around the time of menstruation.[85] As discussed later, women who experience severe menstrual cramps or premenstrual symptoms may experience more significant declines in sleep quality.

Studies that have investigated sleep objectively with PSG measures have found variable menstrual cycle phase effects on sleep that do not always corroborate findings from subjective sleep studies.[52,81,86] One reason for the inconclusive findings from studies of sleep in women across the menstrual cycle is the methodologic challenges for researchers, including variability in cycle length, presence and timing of ovulation, changes with age, and sampling times during the menstrual cycle.[81] Individual studies generally have been performed using small samples of women (fewer than 10) and at selected phases of the menstrual cycle.

Most studies have found that sleep onset latency and sleep efficiency remain stable at different phases of the menstrual cycle in young women. Percentages of N3 activity and SWA in NREM sleep, averaged across the night, do not change,[87,88] suggesting that sleep homeostasis is maintained across the menstrual cycle. The menstrual cycle has some influence on REM sleep. Women may have an earlier onset of REM sleep,[89] shorter REM episodes,[81,90] and less REM sleep in the luteal phase than in the follicular phase, with the amount of REM sleep negatively correlated with levels of progesterone and estradiol.[90] Women with ovulatory cycles have a shorter REM onset latency in the luteal phase compared with women with anovulatory cycles.[91] In the absence of ovulation, women do not secrete sufficient ovarian hormones or increase their core body temperature and thus do not experience a true luteal phase in the 2 weeks before menses. Variation in the timing and amount of REM sleep during the menstrual cycle may be related to altered circadian processes or the raised body temperature.[88,89]

Although not a finding in all studies, increased intermittent awakening or wake time has been documented during the late luteal phase compared with the follicular phase,[92,93] which corresponds with women's premenstrual reports of poorer subjective sleep quality. A recent actigraphy study of 163 women of late reproductive age reported a moderate decline in sleep efficiency (5%) and a decrease in total sleep time (by 25 minutes) in the premenstrual week.[94] With a larger sample that can be studied with actigraphy, subtle changes in sleep efficiency may be more apparent. Alternatively, these results raise the possibility that the menstrual cycle may have a more pronounced impact on sleep with advancing age. Hormone dynamics across the menstrual cycle also are relevant; a steeper rate of change in progesterone from the follicular to the luteal phase is associated with a greater amount of wakefulness after sleep onset in the luteal phase.[95]

The most dramatic change in sleep in association with the menstrual cycle is evident from spectral analysis of the sleep EEG. EEG activity in the 14.25- to 15.0-Hz band, which corresponds to the upper frequency range of sleep spindles, is significantly increased in the luteal phase over that in the follicular phase.[87,96] An increase in visually scored stage 2 (N2) sleep in the luteal phase also may be apparent.[87,88] The increased spindle frequency activity is reminiscent of the effects of the progesterone metabolite allopregnanolone on the EEG in rats[97] and may represent an interaction between endogenous progesterone metabolites and $GABA_A$ membrane receptors in the luteal phase.[87] Benzodiazepines and barbiturates also exert their sedative effects by binding to the $GABA_A$ receptor, but probably at a site that differs from that for progesterone metabolites.[98] Alternatively, the increased spindle frequency activity may be related to the increased body temperature in the luteal phase[81] and may help maintain sleep quality in the presence of substantial physiologic and hormonal changes in the luteal phase.[86]

Sleep is thus remarkably stable across the normal menstrual cycle, despite the large changes in the hormonal milieu. There are, however, some changes in sleep, most notably an increase in upper spindle frequency activity and a decrease in REM sleep in the luteal phase compared with the follicular phase.

Circadian Rhythms across the Menstrual Cycle

In women, circadian rhythms for hormone secretion, body temperature, and sleep-wake activity are superimposed on the menstrual cycle rhythm. As shown in Figure 155-2, men and women have the most similar temperatures when women are in their follicular phase. If ovulation occurs at the end of the follicular phase, the luteal phase is marked by an increase in body temperature of approximately 0.4° C, a consequence of the thermogenic action of progesterone secreted from the corpus luteum.[99] Most studies have found that the normal circadian nocturnal nadir in body temperature is blunted, reducing the amplitude of the temperature rhythm in the luteal phase compared with the follicular phase.[96] These findings have been confirmed in women monitored under controlled conditions of an ultrashort sleep-wake cycle procedure.[88] Under controlled conditions, no difference is seen in timing of the circadian temperature rhythm peaks and nadirs between the follicular and luteal phases.[88,100] The blunted amplitude of the temperature rhythm may be mediated by progesterone acting either directly on the SCN or downstream of the SCN; the amplitude of the body temperature rhythm is negatively related to progesterone concentration.[88]

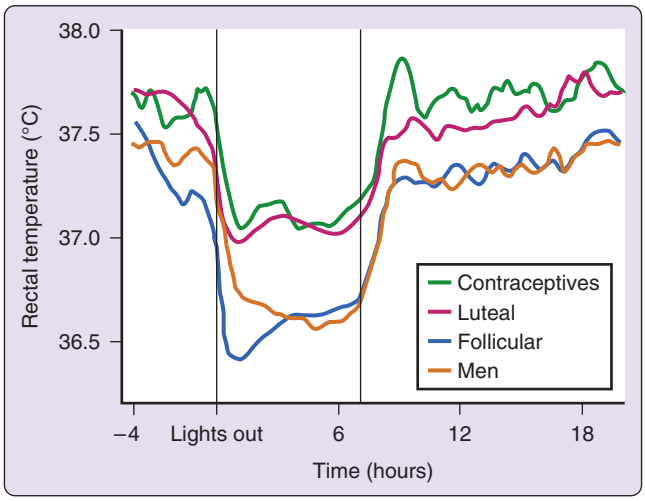

Figure 155-2 Mean diurnal rhythms in rectal temperature, plotted for 4 hours before "lights out" and 20 hours thereafter in 8 young men (*orange line*), 8 young women taking monophasic oral contraceptives (active pill) (*green line*), and 15 young women in the midfollicular and midluteal phases of their ovulatory menstrual cycles (*pink* and *blue lines,* respectively). *Vertical lines* indicate average time in bed. Subjects followed their usual daytime schedules and spent the night in a sleep laboratory. (With permission from Baker FC, Driver HS. Circadian rhythms, sleep, and the menstrual cycle. *Sleep Med* 2007;8:613–22.)

In studies with appropriate behavior controls, no difference was found in timing of onset or offset of melatonin secretion, duration, or acrophase of the melatonin rhythm between the follicular and luteal phases of the menstrual cycle in young women.[88,100,101] Two of the three studies also found no difference in amplitude of the melatonin rhythm across menstrual phases.[88,100] Taken together, findings show an interaction between the menstrual cycle and sleep/circadian factors. When the temperature rhythm is raised and blunted, REM sleep is decreased, and spindle frequency activity is increased in the absence of a change in sleep homeostasis or circadian phase in the luteal phase compared with the follicular phase.

Shift Work and Menstrual Rhythms

Women who work on schedules outside of a regular workday have disrupted circadian rhythms, which could lead to the development of medical problems, including altered reproductive function.[102,103] Female shift workers have more menstrual cycle irregularities, more painful menstruation (dysmenorrhea), and longer menstrual cycles compared with non–shift workers.[102,103] Shift-working women also are at increased risk for breast cancer, possibly because of exposure to artificial light and subsequent melatonin suppression.[103] Shift work nurses who report changes in menstrual function, compared with those who do not, report significantly more sleep disturbances, symptoms of shift work intolerance, and longer sleep onset latencies, suggesting an association between sleep disturbances and menstrual irregularities.[104]

Reproductive health problems associated with shift work could be due to increased stress as well as disrupted rhythms in hormone secretion, particularly LH and FSH, that directly influence ovarian hormone secretion.[104] Some evidence suggests that menstrual cycle irregularities and extended shift work may lead to fertility problems and increased risk for preterm birth.[105] However, meta-analyses of the literature investigating the association between various working conditions and fetal and maternal health concluded that shift work poses minimal risk to the female reproductive system,[106] and that the available evidence is insufficient for clinicians to advise restricting shift work in reproductive-age women.[107]

Sleep in Women with Menstrual Cycle Disorders

Menstrual cycle–related complaints, including mood disorders, pain associated with menstruation, and endocrine problems such as polycystic ovary syndrome (PCOS), are common among women of reproductive age. Women who suffer from a menstrual cycle–associated disorder may experience concomitant changes in their sleep. Women who have menstrual cycle–related problems are between two and three times more likely than other women to report insomnia and excessive sleepiness during the day.[108]

Polycystic Ovary Syndrome

PCOS affects 4% to 12% of women of reproductive age.[109] Women with PCOS typically present with irregular or absent cycles, androgen excess (evident as hirsutism), and bilateral polycystic ovaries. Insulin resistance also is an important component of PCOS,[110] and obesity is a factor in approximately 50% of cases.[111] Medical management of PCOS involves control of irregular menses, typically with oral contraceptives, management of infertility, and long-term management of insulin resistance.[109] The combination of obesity and excess androgen production places women with PCOS at increased risk for SDB, as well as for hypertension and cardiovascular disease. Indeed, women with PCOS have been found to be 30 times more likely to suffer from SDB than control subjects.[112] Obesity is an important risk factor for SDB, but even when compared with healthy age- and weight-matched control subjects, women with PCOS are more likely to have SDB during their reproductive years (Figure 155-3) and are more likely to report excessive daytime sleepiness (80%) than healthy women (27%), even after introduction of controls for body weight.[113]

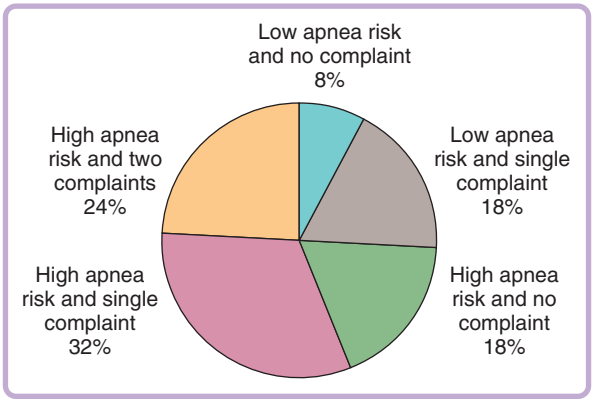

Figure 155-3 Frequency distribution of sleep apnea risk and sleep complaints in 40 women with polycystic ovary syndrome (PCOS). (With permission from Tasali E, Van Cauter E, Ehrmann DA. Relationships between sleep disordered breathing and glucose metabolism in polycystic ovary syndrome. *J Clin Endocrinol Metab* 2006;91:36–42.)

Increased central obesity, common in women with PCOS, may be more closely associated with increased risk for SDB than is elevated body mass index.[114] Increased severity of SDB is associated with glucose intolerance and insulin resistance in women with PCOS, suggesting that SDB may contribute to the metabolic abnormalities in these women.[113] Although larger trials are needed, preliminary evidence indicates that successful treatment with continuous positive airway pressure (CPAP) therapy in extremely obese women with PCOS leads to a modest improvement in insulin sensitivity and a reduction in diastolic blood pressure.[110]

Premenstrual Syndrome

Premenstrual syndrome (PMS) is characterized by emotional, behavioral, and physical symptoms that occur in the late luteal, premenstrual phase of the menstrual cycle, with resolution at the onset of menses or shortly thereafter. Many women of reproductive age experience some symptoms, but up to 18% of women have clinically relevant premenstrual symptoms that they perceive as distressing and impacting on daily function.[115] Premenstrual dysphoric disorder (PMDD) is a severe form of PMS that occurs in 3% to 8% of women.[115] PMDD is classified as a depressive disorder in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders—Fifth Edition*. A diagnosis of PMDD requires the occurrence of five specified symptoms, of which at least one must be a mood-related symptom, during the late-luteal phase, for at least two consecutive cycles. One of these symptoms is sleep disturbance (insomnia or hypersomnia).

Pharmacologic management of severe PMS/PMDD includes use of selective serotonin reuptake inhibitors (the drugs of choice recommended by the American College of Obstetricians and Gynecologists), anxiolytics, and agents that suppress ovulation.[116] Nonpharmacologic agents and approaches such as calcium supplements, L-tryptophan, and cognitive-behavioral therapy also have been shown to be effective.[116]

Women with severe PMS typically report sleep-related complaints such as insomnia, sleep perturbation by body movements and awakenings, disturbing dreams, and poor sleep quality associated with their PMS symptoms in the late-luteal phase.[117] They also report sleepiness, fatigue, less alertness, and an inability to concentrate during the premenstrual phase.[117] Laboratory studies, however, have found little evidence of PSG-defined disturbed sleep in the late-luteal phase. A recent study found that women with severe PMS/PMDD experienced a poorer subjective sleep quality in the absence of PSG measures of poor sleep quality, including measures of sleep efficiency, arousals, sleep onset latency, and the sleep EEG in the late-luteal phase relative to the follicular phase,[90] confirming findings from most earlier studies.[86,117] The perception of a poorer sleep quality correlated with anxiety levels, suggesting that the mood state of women with severe PMS affects their sleep assessments in the late-luteal phase.[90] Of interest, some evidence points to differences in sleep between control subjects and women with PMS/PMDD across the menstrual cycle (i.e., trait-like), although findings have varied between studies.[86,117] Two recent studies found that N3 sleep was increased in both the follicular and luteal phases in women with severe PMS or PMDD compared with control subjects.[90,118] This finding leads to the hypothesis that N3 sleep may be functionally linked with decreased melatonin secretion, which also was evident in the women with PMDD.[90,118,119]

Additional evidence shows altered circadian rhythms in women with PMDD. High mean nocturnal temperatures and disturbances in melatonin rhythms and in the timing of the rhythms of cortisol and thyroid-stimulating hormone have been reported in women with PMDD compared with asymptomatic control subjects.[86,96,120] Under controlled conditions, a small group of women with PMDD were found to have lower nocturnal melatonin levels in both menstrual phases and decreased melatonin amplitude in the symptomatic luteal phase compared with control subjects.[119] In view of these disturbances in circadian rhythmicity in women with PMDD, investigators have explored the possibility of treating PMDD by manipulating the timing of sleep, with sleep deprivation protocols or with light therapy. Appropriately timed light therapy has shown some promise as a treatment strategy for PMDD, possibly by altering nocturnal melatonin secretion.[121] A meta-analysis of clinical trials of bright light therapy, however, concluded that larger trials are needed to define the role of such therapy in the management of PMDD.[122]

For women with PMDD, sleep deprivation during the symptomatic luteal menstrual cycle phase may be therapeutic. Eight of 10 women responded to sleep deprivation in one study and maintained improved mood after a night of recovery sleep.[123] In a follow-up study, partial sleep deprivation had similar positive effects on mood in 60% to 67% of patients, but these effects were significant only after recovery sleep.[124] Changes in REM latency and REM density in the first REM sleep period from baseline to recovery nights were significantly correlated with improvement in mood in responders to sleep deprivation.[125] The effect of sleep deprivation on mood in women with PMDD differs from that found in patients with MDD, who have improved mood the day after total sleep deprivation but tend to relapse after recovery sleep.[126]

Dysmenorrhea

Dysmenorrhea, defined as painful menstrual cramps of uterine origin, is the most common gynecologic condition among women of reproductive age, and is very severe in approximately 10% to 25% of women.[127] *Primary* dysmenorrhea is menstrual pain without organic disease, and *secondary* dysmenorrhea is associated with conditions such as endometriosis and pelvic inflammatory disease. Dysmenorrhea is effectively treated with analgesics and nonsteroidal anti-inflammatory drugs in most women. Alternative therapies such as heat and dietary supplements of thiamine or magnesium also have shown some effectiveness.[128] Menstrual cramps experienced by these women every month significantly affect quality of life and are associated with a restriction of activity.[127] PSG studies in women with primary dysmenorrhea found that the menstrual cramps were associated with disturbed sleep, specifically poorer subjective sleep quality, lower sleep efficiency, more awake time and stage 1 (N1) light sleep, and less REM sleep than in pain-free phases of the menstrual cycle, and in comparison with asymptomatic women.[129,130] Disturbed sleep, in turn, may exacerbate pain, because sleep deprivation is associated with a decreased pain threshold.[131] Treatment of nocturnal pain with a nonsteroidal antiinflammatory drug alleviates nocturnal pain and restores both subjective and objective sleep quality in women with primary dysmenorrhea.[130]

Sleep Disorders and the Menstrual Cycle

In the most recent (2014) edition of the *International Classification of Sleep Disorders* (*ICSD3*), the only gynecologic disorder listed is menstrual cycle–related Kleine-Levin syndrome (or menstrual cycle–related hypersomnia). This exceedingly rare condition is characterized by hypersomnolence during the week before or during menses. The patient has no complaints of persistent, excessive sleepiness at other times in the menstrual cycle.[117]

Women with premenstrual hypersomnia have been successfully treated with either estrogen or combined oral contraceptives.[117] Little research has been conducted to investigate the variation in severity of sleep disorders such as insomnia and OSA according to menstrual cycle phase. The severity of OSA may be greatest in the follicular phase; upper airway resistance is lowest in the luteal phase in healthy women.[132]

Oral Contraceptives, Body Temperature, and Sleep

Oral contraceptives are combined formulations of a low-dose progestin and a synthetic estrogen and are taken by healthy women for long periods of time. Oral contraceptives suppress endogenous reproductive hormones and therefore prevent ovulation so that women taking these preparations do not have ovulatory cycles.

Women taking oral contraceptives, containing estrogen and a progestin, have raised 24-hour body temperature profiles, with the timing of temperature minima similar to that in ovulating women in the luteal phase[96] (Figure 155-2). This

body temperature elevation probably is caused by the thermogenic action of progestins contained in the contraceptive pill. During the 7-day placebo period of the oral contraceptive pack, 24-hour body temperatures remain elevated,[133] suggesting that continuous use of synthetic reproductive steroids may have long-term influences on thermoregulation. By contrast, body temperature rapidly decreases as progesterone levels decline before menstruation in women with ovulatory cycles.

Oral contraceptives also may influence melatonin levels, although findings are inconsistent.[96] In one study using a modified constant routine procedure, researchers found no significant differences in melatonin levels between naturally cycling women and women taking oral contraceptives, although a trend was observed in this small sample for increased melatonin levels in the latter part of the night in women taking oral contraceptives.[100]

Sleep architecture is altered by oral contraceptives. Women taking oral contraceptives have less N3 sleep than women with natural menstrual cycles.[81] N2 sleep is significantly increased in women taking oral contraceptive pills over that during the week of placebo pills, and compared with that in naturally cycling women in both menstrual cycle phases.[133] Also, use of a synthetic progestin (medroxyprogesterone) is associated with a specific increase in upper spindle frequency activity in women.[134] Other sleep effects reported in hormonal contraceptive users include a shorter REM onset latency and more REM sleep than in women with natural ovulatory menstrual cycles.[81,135] Exogenous steroid hormones therefore appear to influence sleep differently from the variations in endogenous hormones across the menstrual cycle. Consideration of oral contraceptive use also may be of importance in comparing healthy women and women with clinical disorders such as depression. The sleep effects of oral contraceptives may compromise sleep differences between healthy and depressed women.[135]

CLINICAL PEARLS

- As reviewed in this chapter, strong evidence supports neurophysiologic and neuroanatomic sex differences in sleep, particularly with maturation.
- Sex differences in sleep and rhythms may influence risk level for neurologic, immunologic, and psychiatric disease.
- The relationship between sleep and psychological health and behavior appears to be strongly influenced by sex-specific differences across the lifespan.
- Within groups of women, the menstrual cycle also affects sleep. REM sleep is reduced and spindle frequency activity is increased in the absence of a change in N3 amount in the luteal compared with the follicular phase. Women, especially those who experience severe premenstrual mood changes or menstrual pain, are likely to experience a decrease in sleep quality before and during menstruation compared with other phases of their menstrual cycle. Assessment of sleep complaints in women should include an investigation of any association between symptoms and menstrual cycle phase or menstrual cycle–related disorders.
- In view of the high incidence of SDB and its association with glucose intolerance in women with PCOS, screening for sleep apnea and appropriate treatment with continuous positive airway pressure may be beneficial in these women.

SUMMARY

A significant and still growing body of literature demonstrates that sex differences in sleep emerge at a very early age. Girls report longer sleeping periods and begin the adolescent decline in SWA (delta sleep) earlier than boys. Women report a poorer sleep quality and are at increased risk for insomnia compared with men across the adult lifespan. However, women have a better sleep efficiency and higher SWA during NREM sleep than men. Premenopausal women are at lower risk for development of SDB, mediated in part by a protective effect of sex steroids on the upper airway. Sex also is an important factor in considering sleep disturbances associated with disorders such as MDD; depressed men have lower SWA, whereas depressed women have lower synchronization between sleep EEG frequency bands compared with healthy control subjects. These observations highlight the importance of sex differences in sleep and circadian rhythm research studies and have broader implications for women's health issues relating to these topics. Within specific groups of women, sleep may be affected by variation in reproductive hormones, such as occurs over the menstrual cycle. The menstrual cycle is associated with changes in circadian rhythms and sleep architecture, most notably a blunted amplitude of the body temperature rhythm, increased spindle frequency activity during sleep, and reduced REM sleep in the luteal phase compared with the follicular phase. Women with PCOS are at increased risk for developing SDB, which may contribute to insulin resistance and other metabolic abnormalities. Women with severe PMS or dysmenorrhea (painful menstrual cramps) may experience transient sleep disturbances or insomnia coupled with their other mood and/or physical symptoms before and during menstruation. Assessment of sleep complaints in women should include an investigation of any association between symptoms and menstrual cycle phase or menstrual cycle–related disorders.

Sleep and Sleep Disorders Associated with Pregnancy

Bilgay Izci Balserak; Kathryn Aldrich Lee

Chapter 156

Chapter Highlights

- Sleep disturbances often begin with the onset of pregnancy and become quite common in the third trimester. Pregnancy-related physiologic and anatomic changes can influence sleep quality and duration.
- In the first trimester, hormonal fluctuations and associated physiologic changes may disturb sleep. By the end of the second trimester, discomfort associated with the enlarging uterus and anxiety regarding labor and delivery, as well as impending motherhood, are the main reasons for sleep disturbance, resulting in considerable daytime sleepiness and fatigue.
- Sleep disorders such as sleep-disordered breathing or restless legs syndrome may occur or worsen during pregnancy. Sleep-disordered breathing can result from added abdominal weight gain, nasal congestion, and changes in the respiratory system. Pregnancy-related restless legs syndrome is a secondary form of the disorder attributed to iron deficiency and hormonal changes.
- Complaints of nocturnal esophageal reflux and sleep-related leg cramps also are common and increase in frequency as the pregnancy advances.
- Emerging evidence suggests an association between sleep disturbance and pregnancy complications such as gestational diabetes, preeclampsia or pregnancy-induced hypertension, depression, and prolonged labor or cesarean birth.
- Sleep disturbances may represent novel and modifiable risk factors for adverse pregnancy outcomes. Early identification and management of prenatal sleep disorders may minimize adverse maternal and fetal outcomes.

OVERVIEW

Sleep disturbance during pregnancy is surprisingly common and multifaceted, beginning with conception and early hormonal changes. With increasing gestation and growth of the uterus and fetus, sleep is significantly disturbed by the third trimester of pregnancy.[1-4] In this chapter, *sleep disturbances* refer to internal and external factors that change the duration or structure of a normal sleep pattern and cause poor sleep quality or daytime sleepiness. Specific disturbances include disorders of initiating and maintaining sleep, disorders of sleep-wake schedule, and dysfunctions associated with sleep, sleep stages, or partial arousals in the absence of physical or mental disorders, prescribed medications, or substance abuse.[5] Pregnancy-related anatomic, physiologic, hormonal, and psychological factors, such as anxiety associated with labor or forthcoming life changes, can emerge in different stages of pregnancy and affect the degree and severity of sleep disturbances. Some of these pregnancy changes also can cause sleep disorders or exacerbate existing sleep disorders, which can threaten maternal and fetal health. Accordingly, clinicians need to be able to identify pathologic sleep disturbances in pregnancy. Early recognition and management of sleep problems during pregnancy can minimize or even prevent adverse maternal and fetal outcomes. Sleep-disordered breathing in pregnancy is covered in detail in the following chapter.

PREGNANCY-INDUCED HORMONAL CHANGES AND SLEEP EFFECTS

Pregnancy causes dramatic changes in melatonin and cortisol as well as gonadal steroids (estrogen and progesterone) and pituitary hormones (gonadatropins, prolactin, growth hormone). These hormonal changes not only directly influence the sleep-wake cycles and sleep structure but also cause physiologic changes that increase risk of sleep disorders (Figure 156-1). Sleep and circadian rhythms also have a role in regulating the secretion of these hormones.

Progesterone

The level of progesterone released from the placenta is 10 to 500 times higher at term than in the nonpregnant state.[6] Serum progesterone exhibits a diurnal change, with higher concentrations in the evening.[7] Progesterone, intracellular progesterone receptors, and progesterone metabolites acting on brain gamma-aminobutyric acid (GABA) receptors produce a soporific effect, with a significant increase in non–rapid eye movement (NREM) sleep.[8-10] This effect may partly explain daytime sleepiness and fatigue in the first trimester, when progesterone is steadily rising. Animal and human studies have demonstrated that exogenous progesterone administration shortens latency to sleep onset, lengthens latency to REM sleep onset, and reduces total

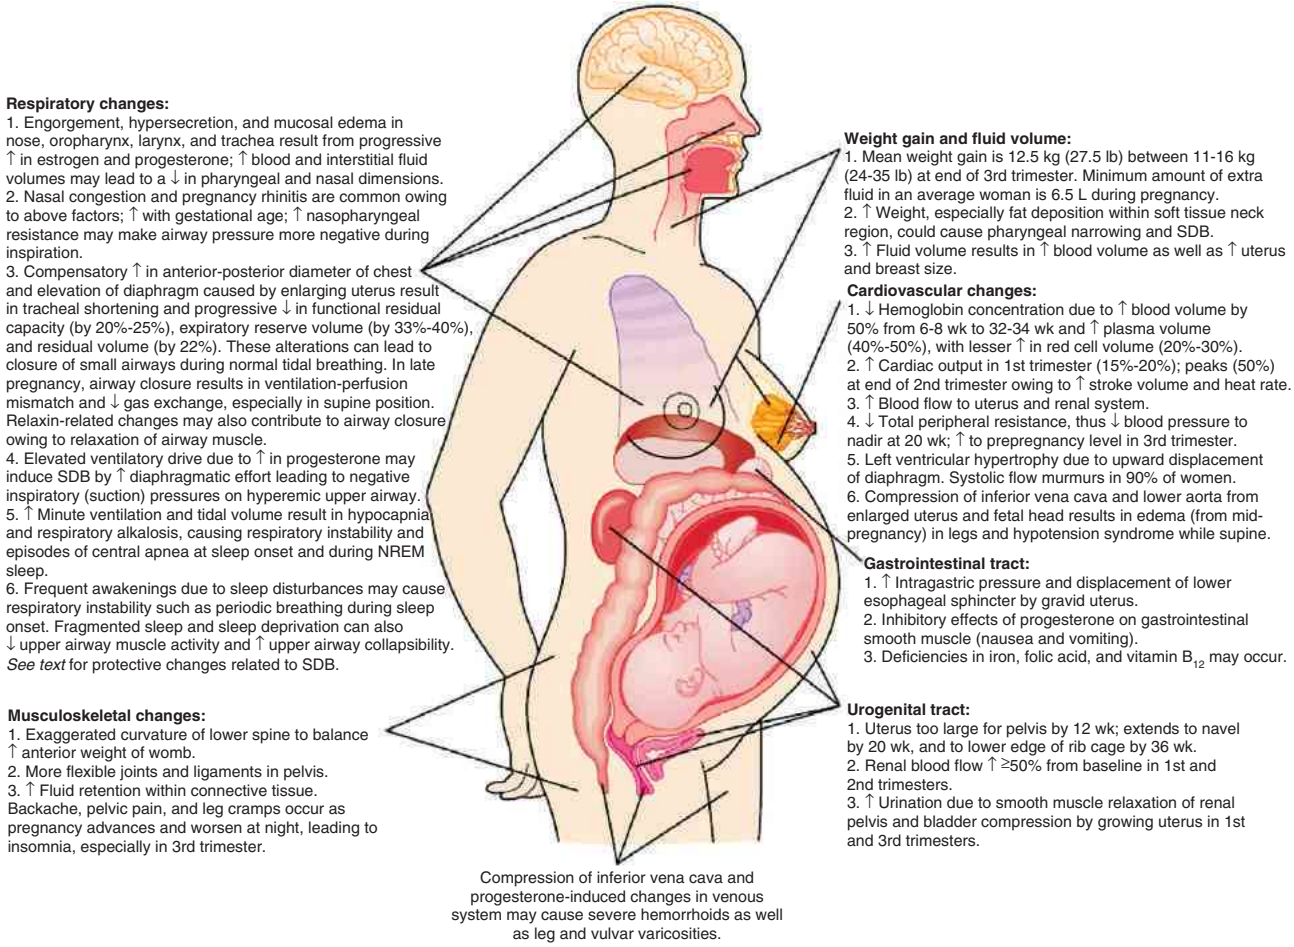

Figure 156-1 Pregnancy-related changes that can affect sleep. NREM, Non–rapid eye movement; SDB, sleep-disordered breathing.

amount of REM sleep.[9-11] Progesterone's soporific effect, its thermogenic effect that elevates core body temperature, and its inhibitory effect on smooth muscle (including gastrointestinal tract, ureters, and bladder) also indirectly influence sleep.[1,12-14] Furthermore, the increased respiratory rate caused by progesterone may protect the airway from occlusion, but complaints of feeling short of breath are common.[14]

Estrogen

Estrogen secreted by the placenta increases significantly during pregnancy, reaching peak levels before birth and declining thereafter.[6] Estrogen has excitatory effects on the nervous system and selectively decreases REM sleep activation of sleep-active neurons in the ventrolateral preoptic area.[15] Maternal plasma estriol has a 24-hour rhythm at 35 weeks of gestation, which occurs in the opposite direction of the cortisol rhythm.[7] The higher estrogen concentration during pregnancy, however, causes vasodilation, and with the extra fluid that accumulates during pregnancy, women typically experience nasal congestion and ankle edema.[6,14] Estrogen also stimulates prolactin production and suppresses dopamine release into the blood circulation, which may contribute to RLS.[16,17]

Cortisol

Cortisol starts to increase from the 25th week of pregnancy, with a two-fold increase seen in late pregnancy, followed by rapid return to normal concentrations after birth of the infant.[6,7] This elevation is mostly due to placental secretion of corticotropin-releasing hormone and adrenocorticotropic hormone (ACTH), and to increased synthesis of cortisol-binding globulin by the liver.[18] Progesterone and cortisol also share binding sites on cortisol-binding globulin.[7] Consequently, an increase in the level of progesterone during pregnancy leads to higher levels of free cortisol. The normal diurnal rhythm in cortisol includes a nadir level around midnight and marked elevation during early morning hours.[7,19] In pregnant women, the morning peak is not obvious, probably owing to the blunting effect of placental ACTH on maternal cortisol concentrations.[6,7] Sleep loss has been found to result in elevated cortisol levels the next evening.[20] Experimental studies in humans showed that cortisol infusions reduce rapid eye movement (REM) sleep but increase slow wave sleep.[18] Pregnant women with poor sleep in the third trimester have lower cortisol-melatonin ratios compared with good sleepers in the same trimester, as a result of a lower early-morning peak in their cortisol levels and a relatively higher concentration of melatonin.[7,19]

Melatonin

Melatonin is secreted by the pineal gland. Secretion is activated by darkness and suppressed by light. Melatonin is involved in the regulation of sleep patterns and circadian rhythms of reproductive hormones.[21] The circadian rhythm of melatonin secretion, peaking in the middle of the night and gradually decreasing by morning, continues during pregnancy.[21] The diurnal rhythm observed during the first and second trimesters is similar to that in a nonpregnant state, but levels increase in the third trimester.[19] In twin pregnancies, nocturnal melatonin levels are significantly higher after 28 weeks of gestation than in normal singleton pregnancies.[21]

Melatonin synergizes with oxytocin to promote the birth process.[21] The concentration of melatonin does not change in either labor induction or operative cesarean delivery.[22] Altered rhythm or low levels of melatonin secretion may potentially result in some pregnancy complications.[21] Research indicates that melatonin, of both pineal and placental origin, plays a role in fetal maturation and placental-uterine homeostasis[21] and is involved in correcting the pathophysiology of complications such as preeclampsia and fetal brain damage.[22] Plasma melatonin concentrations, particularly morning levels, are reported to be lower in depressed pregnant women but higher in depressed women in the postpartum period than in healthy control subjects.[23]

Prolactin

Prolactin concentrations are 10 times higher at term than those in the nonpregnant state.[6] Prolactin is involved in immunoregulation, lactogenesis, and mammary tissue growth. However, prolactin secretion rhythms do not differ between pregnant good sleepers and poor sleepers.[19] Studies with a small number of pregnant women show episodic prolactin secretion and elevated levels during nocturnal sleep.[7] During a normal vaginal delivery, prolactin levels peak for 4 to 6 hours and then descend back to a normal circadian pattern.[24] By contrast, prolactin concentrations are significantly lower in women who elect to undergo cesarean delivery.[24] Prolactin secretion may enhance slow wave sleep, as suggested by evidence that slow wave sleep is increased in patients with prolactinomas.[25]

Oxytocin

Oxytocin promotes uterine contractions and lactation.[11] In late pregnancy, it reaches the highest level at night, together with peaks in uterine activity rhythm.[26] In animals, oxytocin has been found to promote sleep at basal levels under stress-free conditions, but it may induce wakefulness in high concentrations.[11] Oxytocin and melatonin act synergistically to assist in the process of labor and birth. This interaction between oxytocin and melatonin during darkness, with increased oxytocin concentrations during the night, could explain the higher incidence of nocturnal births.[21,26]

Growth Hormone

The secretion of pituitary growth hormone (GH), crucial for tissue growth and protein anabolism, is regulated primarily by growth hormone–releasing hormone and neurons in the arcuate nucleus of the hypothalamus.[27] Levels of placental GH in maternal circulation increase throughout pregnancy starting as early as week 8, with a peak around week 35 of gestation.[28] Pituitary GH is released in a pulsatile manner, but the release of placental GH is continuous.[28] Ghrelin also is a GH stimulator produced by placental tissue.[6] These hormones are closely associated with slow wave sleep and play a significant role in sleep regulation,[25,27] suggesting that GH and maintenance of slow wave sleep are important for fetal development and maternal health.

Relaxin

The corpus luteum is the primary source of circulating relaxin during pregnancy. Serum relaxin peaks at the end of the first trimester.[29] Thereafter, levels fall to an intermediate value until birth. It is associated with connective tissue remodeling and relaxing pelvic ligaments to prepare for birth.[6,30] Relaxin can contribute to discomfort and sleep disturbances through relaxation of the airway, development of carpal tunnel syndrome from fluid retention in the connective tissue, and onset of low back pain associated with relaxation of supporting ligaments.[6,30] Precise mechanisms for these changes, however, remain to be clarified.

Leptin

Serum leptin levels increase during prgnancy, peaking during the second trimester and remaining two to four times those typical for the nonpregnant state. A significant amount of leptin is released by the placenta and the increasing number of fat cells associated with pregnancy weight gain.[6] Leptin has a key role in regulating body fat, energy expenditure, and fetal growth.[6,12] Extremes in either short or long sleep duration in early pregnancy are associated with altered leptin levels.[31]

The relationship between hormonal changes and altered sleep during pregnancy is thus bidirectional. Although these hormones have significant effects on sleep and circadian rhythm during pregnancy, altered sleep during pregnancy also can influence hormone levels. Further research is required, particularly to characterize sleep-induced hormonal fluctuations and implications for adverse obstetric outcomes.

PHYSIOLOGIC CHANGES IN PREGNANCY AND POTENTIAL FOR SLEEP PROBLEMS

In addition to hormonal changes, pregnancy leads to a multitude of anatomic and physiologic changes including changes in respiratory and cardiovascular systems, which are detailed in Figure 156-1.[6] These changes are essential to maintain a healthy pregnancy, but some changes contribute to expected and common sleep problems, whereas other changes have potential for adverse effects on either the fetus or the mother.

Sleep in Normal Pregnancy

With the physical and hormonal adaptations seen in pregnancy, changes in sleep[32-36] are common, with a majority of women (66% to 97%) affected. They report nocturnal awakenings that become more frequent in the third trimester.[2,37,38] Unlike other sleep parameters, both objective and subjective sleep measures show that sleep efficiency (SE) progressively decreases, not because of problems falling asleep but because of increased and longer episodes of nocturnal awakenings after sleep onset.[33,35,38,39] However, night-to-night and individual variability does exist.[34,40] For example, in several recent studies, women reported having no sleep disturbances or noted “improved” or “worsening” sleep, as well as short (6

hours or less), intermediate (7 to 8 hours), and long (10 hours or longer) sleep duration even in early pregnancy.[3,38,41]

Only a small number of studies have comprehensively evaluated sleep across pregnancy with validated tools to record sleep on multiple nights and at different weeks of gestation. Although numerous studies have attempted to describe sleep characteristics during pregnancy, findings are not completely in agreement. The discrepancy could be related to different research designs, settings (laboratory or home), assessment methods (PSG or actigraphy), small sample sizes, collecting data at different gestational periods, or comparing pregnant women at various gestational ages with nonpregnant control subjects in different menstrual cycle phases. Most studies also failed to record sleep during daytime naps, which complicates any sleep assessment. Furthermore, recent studies comparing objective (polysomnography or actigraphy) and subjective (questionnaire and sleep diaries) measures find discrepancies in sleep time estimates.[37,42,43] These discrepancies may lead to spurious associations between sleep duration and adverse pregnancy outcomes, particularly if a study relies on self-reported sleep parameters during pregnancy.

Sleep in First Trimester

Women experience daytime sleepiness and fatigue and report more frequent naps as early as the tenth week of pregnancy.[33,36,38,2,44-47] Increases in total sleep time (TST), longer sleep onset latency, and more wake time after sleep onset (WASO) also are reported. Increased TST may be ascribed to daytime naps.[33,34,39,48,44,45] Overall sleep quality and slow wave sleep decrease relative to pre-pregnancy assessments or the nonpregnant state.[2,3,33,35,36,38] Sleep disturbances occur mainly as a result of dramatic alterations in hormone levels in the first trimester.[6,9] These hormones are responsible for fatigue and daytime sleepiness, morning sickness, waking with nausea, increased urinary frequency, physical discomforts (tender breasts or back pain), and mood changes.[2,44-47] Psychosocial stressors, especially in the case of first-time or unplanned pregnancies, including absence of psychosocial support in first-time pregnancies, also have been reported.[49]

Sleep in the Second Trimester

In most cases, subjective and objective sleep parameters improve compared to the first trimester.[2,5,20,33,38] Most women report less fatigue and more energy[2,3,44-47] likely due to the stabilization of hormone levels. In a multicenter prospective cohort study of 369 first-time mothers monitored with actigraphy for 7 days, sleep averaged more than 7 hours per night in the second trimester.[50] It also has been noted that women in their second trimester have better SE and less WASO compared with those in the other trimesters[38,39,48] (Table 156-1). By the end of the second trimester, however, the number of awakenings increases.[5] Accordingly, women may experience disturbed sleep as a result of the onset of snoring, heartburn, irregular uterine contractions (Braxton-Hicks), fetal movements, leg cramps, or RLS.[2,3,44,51,52] Vivid dreams and pain in the back, neck, and joints were additional reasons for sleep disruption during the second trimester, according to a National Sleep Foundation survey.[52]

Objective measures of slow wave sleep and REM sleep during the second trimester are inconsistent.[33,34,53] A longitudinal PSG study in the home setting, however, showed that slow wave sleep (%) slightly decreased but REM sleep (%) did not change relative to these measures in the first trimester.[33]

Table 156-1 Sleep Pattern, Nocturnal Features, and Daytime Symptoms in Each Trimester and during Labor/Delivery

Characteristic	First Trimester	Second Trimester	Third Trimester	Labor/Delivery
Pattern	↑ TST ↑ Number of naps ↑ WASO ↓ SE ↓ SWS	↓ TST ↑ SE ↓ SWS ↓ WASO	↑ TST ↑ Number of naps ↑ WASO ↑ Stage 1 sleep ↓ SE ↓ SWS ↓ REM	↓ TST ↓ SE ↓ NREM ↓ REM
Nocturnal features	Urinary frequency Physical discomforts—tender breasts/back pain	Onset of snoring, restless legs, irregular uterine contractions Dreams Back, neck, and joint pain	Urinary frequency Physical discomfort Irregular uterine contractions Muscle/leg cramps Shortness of breath Heartburn Dreams/nightmares Snoring Restless legs	Anxiety Forceful uterin contractions
Daytime symptoms	Fatigue Drowsiness Waking with nausea Mood changes	Nasal congestion	Fatigue Drowsiness Impaired vigilance Nasal congestion	Fatigue Anxiety Pain

NREM, Non–rapid eye movement; REM, rapid eye movement; SE, sleep efficiency; SWS, slow wave sleep; TST, total sleep time; WASO, wake [time] after sleep onset.

Sleep in the Third Trimester

The overwhelming majority (75% to 98%) of women report sleep disturbances resulting in multiple nocturnal awakenings as they approach the 40th week of pregnancy.[1,2,47] Sleep patterns in the third trimester feature longer sleep latency, poor SE, more WASO, and increased stage 1 and 2 sleep, with some reduction in slow wave sleep.[2,3,20,32-38,47,52] Nocturnal sleep time is lower than the first two trimesters but TST may approach prepregnancy values.[2,33,35-37] This is likely because shortened night-time sleep may be compensated by more frequent and longer daytime naps. In fact more than 75% of the women reported at least one nap each week in the third trimester.[33,47,52] Despite inconsistent findings, most PSG studies show less slow wave sleep and REM sleep when compared with previous trimesters or data for nonpregnant control subjects.[33-35,38,39,54] Secondary analysis of a prospective study of 127 women showed that delta power in NREM sleep significantly decreased from the first to the third trimester after controlling for apnea-hypopnea index, age, TST, and other covariates.[55] In exchange for this decrease, women spent more time in light sleep stage 1 or 2.[33,35] An additional covariate is employment schedules, in that working women were less likely to nap and reported sleeping 1 hour less in the last month of pregnancy.[56]

Physical changes associated with a rapidly growing uterus, in addition to hormonal fluctuations, are the main causes of sleep disturbances in third trimester.[3,4,37,47] Most women complain of urinary frequency, general physical discomfort (e.g. backache), heartburn, leg cramps, spontaneous awakenings, and fatigue.[3,4,35,47,52] Fetal movements, difficulty maintaining sleep, shortness of breath, and other physical discomforts (breast tenderness, joint pain/carpal tunnel symptoms, and itching) often are reported.[1-4,44] Women also attribute their sleep loss to internal factors (vivid dreams/nightmares associated with anxiety about labor/delivery, the health of the fetus, and pregnancy complications) and external factors such as the needs of their other children or environmental noise.[1,4,44,49,52] Additionally, the risk of a primary sleep disorder increases during the third trimester, as discussed further on.[17,32]

By the third trimester, women also often complain about difficulties with attention, concentration, and memory. A meta-analysis of 14 studies comparing pregnant women with matched control subjects found that some memory measures, particularly for executive cognitive control, were significantly impaired, and these difficulties were attributed to sleep disturbance and fatigue.[57]

Sleep During Childbirth

Pain, anxiety, uterine contractions, and administration of medications all affect sleep and result in sleep loss and low sleep quality during labor and immediately after delivery.[34,58-60] The rhythm of nocturnal uterine activity, presumably a result of peaks in oxytocin secretion patterns, may contribute to nocturnal awakenings and most women experience spontaneous labor onset with forceful contractions at night.[21,26]

In a longitudinal study of 35 women, sleep quality deteriorated progressively over the last 5 days of pregnancy and was lowest the night before contractions started and admission to the hospital for delivery.[59] In one study, 20 women were asked about their experience of sleep during pregnancy and labor, and all reported they were unable to sleep once contractions started. As the latent phase of labor becomes prolonged, sleep is not possible even when sleep aids are used.[60] Significant associations between sleep duration in late pregnancy and adverse obstetric outcomes are reported, as discussed later on.[59,61,62]

Parity Differences in Sleep

Sleep during pregnancy may be influenced by parity or by the presence of other children living in the home. Studies using objective sleep measures found that TST, slow wave sleep, and REM sleep during pregnancy were not significantly affected by parity,[33,35,40] but nulliparas (no prior birthing experience), especially employed women, were at risk for poor sleep quality,[33,35,37,40] possibly due to challenges in adjusting to a new role. Additional studies indicate that parity influences SE, with nulliparas having significantly worse SE from third trimester to first month post partum.[46,63] Multiparas, who already have prior birthing experience, may be awakened during the night by children,[1,44] but when controlling for other children, multiparas have higher SE than nulliparas during pregnancy.[40,46]

During third trimester, younger women (<30 yrs), who are also more likely to be nulliparas, had more TST than older women (>30 yrs)[2,64] whose sleep may be affected by other children in the home[1,2,44] or by a primary sleep disorder. For example, increasing age is recognized as a risk factor for RLS, SDB, and insomnia.[3,17,47] Thus parity as well as age should be considered in sleep research with pregnant women.

In summary, most women experience sleep disturbance during pregnancy. Each trimester brings its own reasons for disrupting sleep, and the degree of sleep disturbance experienced throughout pregnancy is highly variable. If opportunities for napping are available, TST can be higher in each trimester compared with TST for nonpregnant women. Yet nocturnal TST and SE decrease progressively during pregnancy while sleep stage characteristics remain generally constant. Pregnant women have more light sleep and less deep sleep (i.e., slow wave sleep), owing to nocturnal awakenings. Nulliparity, age older than 30 years, and being employed each are associated with different aspects of poor sleep quality.

SLEEP DISORDERS DURING PREGNANCY

Primary sleep disorders can occur or worsen during pregnancy because of the pregnancy hormones and physiology as just discussed. In view of the potentially serious consequences for both maternal and fetal health, clinicians should consider the possibility of sleep disorders, particularly insomnia, SDB (see Chapter 157) and RLS, when symptoms associated with these disorders are observed.

Pregnancy-Associated Insomnia

Insomnia is defined as difficulty initiating or maintaining sleep, early-morning awakening or nonrestorative sleep associated with daytime consequences such as fatigue, irritability, and lack of concentration (see Chapter 83).[65,66] Pregnant women may experience some or all of these symptoms within the range of acute to chronic insomnia.[3,63,67,68] In some women, the acute insomnia[66] persists into a chronic state lasting a month or longer, even after pregnancy. A genetic disposition to chronic insomnia may have a pivotal role in this transition.[66,67]

Epidemiology

The prevalence of insomnia in the general and pregnant populations is difficult to estimate owing to various definitions of insomnia and the subjective nature of the symptoms. Symptoms can occur independent of primary insomnia or can be associated with a comorbid condition. Furthermore, the frequency, severity, and pattern of insomnia can vary during pregnancy. Many studies have used self-reported insomnia in assessing its prevalence and response to treatment.[12] As determined using the Women's Health Initiative Insomnia Rating Scale, Bergen Insomnia Scale and Insomnia Severity Index, a majority (52%) of women have some degree of insomnia at any point in pregnancy,[68] with 54% to 74% reporting insomnia during their third trimester.[3,63,67] In a national telephone survey of women in the United States, 84% reported one or more symptoms of insomnia at least a few nights each week during pregnancy.[52] Approximately 40% of women worry about their sleep during the first and second trimesters, and this rate increases to 57% by the third trimester.[44] The highest prevalence of insomnia and most wake episodes occur in the third trimester.[3,63,67,68]

Risk Factors

In adults with insomnia, the available evidence implicates physiologic hyperactivity and hyperarousal, commonly seen in pregnancy as a higher body temperature and metabolic rate, with increased secretion of ACTH and cortisol.[6,69] Increased pregnancy concentrations of estrogen and progesterone may result in insomnia due to changing GABA.[8-10] In pregnancy, however, this is a more complex phenomenon.

Insomnia in pregnancy is considered to be secondary to the many pregnancy-related discomforts described earlier. Although poor sleep quality and sleep loss among pregnant women can be the result of hormonal and physical factors, voluntary sleep restriction also is common owing to employment and household responsibilities.[3,56,64] Maladaptive sleep behaviors and coping strategies such as napping, spending more time in bed, or increasing caffeine intake[3,64,67] also can perpetuate insomnia. Weight gain and obesity contribute to sleep-onset or maintenance insomnia and SDB with multiple cortical arousals.[3,5,42] A recent study confirmed that arousals are associated with respiratory events and limb movements during late pregnancy.[35] Cortical arousals also can be associated with emotional distress, especially in a woman at risk for insomnia because of anxious thoughts about impending lifestyle changes with a new child, balancing employment and motherhood, and approaching labor and delivery, including concerns for the health of the infant.[35,49,60-63,66] Insomnia has not been adequately studied in pregnant women and cannot be treated effectively until the primary condition is better understood.

Other risk factors for insomnia in pregnancy include age older than 30 years,[2,3] nulliparity,[63] single motherhood,[20] preeclampsia or pregnancy-induced hypertension,[3,41] prepregnancy affective disorders,[48,63,70] perinatal depression,[58,63,70] smoking,[67] negative body image,[71] and environmental factors such as noise from other children, bed partners, or pets.[4,52] Exposure to light during the night also can reduce melatonin levels and exacerbate sleep disturbances.[72,73]

Management

The diagnosis of insomnia in a pregnant woman is challenging. Diagnosis requires adequate opportunity to sleep, with an inadequate ability to fall and stay asleep.[12,65] These criteria may be confused with multiple awakenings associated with pregnancy discomforts. Pregnant women also may have insomnia as a comorbid condition associated with SDB or depression. Current evidence suggests that untreated comorbid insomnia may reoccur even if the originating cause is treated.[66] In addition, insomnia in pregnancy can significantly affect physical and cognitive function and has potential implications for pregnancy outcomes.[74] Timely assessment and appropriate management (see Chapters 85 to 88) are essential to prevent potential adverse pregnancy outcomes and reoccurrence of chronic insomnia.

After considering the potential adverse effects of medication on the fetus during pregnancy, most women and clinicians opt for nonpharmacologic therapies to treat insomnia. Behavioral and cognitive therapies should be the initial treatment for women with pregnancy-related insomnia, after excluding primary sleep disorders. These nonpharmacologic therapies include cognitive-behavioral therapy for insomnia,[75] improving sleep hygiene, using relaxation techniques, and implementation of lifestyle modifications such as regular exercise and avoidance of smoking and alcohol. In an intervention study of 15 women attending mindful yoga classes, starting the classes in the second trimester improved SE and reduced nocturnal awakenings better than starting classes in the third trimester.[76] Further research is needed, however, to determine timing and optimal amount of exercise during pregnancy.

Of note, many pregnant women do not seek treatment for insomnia, because they either think it will naturally resolve after birth or wish to avoid medication owing to concerns about adverse effects on the fetus. In the United States, 11% of pregnant women used a sleep aid, including over-the counter medications, at least a few nights a week and 1% used alcohol at some point in pregnancy to help them sleep.[52] If nonpharmacologic therapies do not help ease the problem in cases of persistent and severe insomnia, medications should be prescribed at the lowest effective dose for the shortest possible duration after discussion of potential risks and benefits with the patient (Table 156-2). Currently, two hypnotic agents, diphenhydramine and doxylamine (histamine H_1 receptor antagonists with sedative) for insomnia during pregnancy are categorized as possible but unlikely to harm the fetus (former Category B drugs).[77,78]

In a recent randomized control study comparing trazodone (an antidepressant medication) or diphenhydramine with placebo, sleep profiles improved after 6 weeks of treatment in the third trimester, and depressive symptoms were reduced for 2 to 6 weeks after delivery.[77] Zolpidem and zaleplon, despite possible adverse fetal effects (former Category C drug), also may be an option owing to their short duration of action.[12] Most other sedative-hypnotics (Table 156-2) should be avoided or used with extreme caution in pregnancy. Drugs with human data showing fetal risks (formerly Category D) should only be used if the potential benefits outweigh the risk to the fetus. Drugs with clear evidence of abnormalities and high risk to the fetus are contraindicated (formerly Category X designation).

Table 156-2 Pregnancy Classification* of Medications Used for Sleep-Related Disorders

Disorder	Harm to Fetus Unlikely, but Possible (Formerly A Category B Medication)	Potential Benefit Outweighs Risk (Formerly A Category C Medication)	Evidence of Fetal Risk (Formerly A Category D Medication)	Contraindicated (Formerly A Category X Medication)
Insomnia	Doxylamine (7) Diphenhydramine (7)	Zaleplon (1) Eszopiclone (1) Ramelteon (1) Zolpidem (1) Gabapentin (2) Amitriptyline (5) Doxepin (5) Trazodone (5)	Alprazolam(1) Diazepam (1) Lorazepam (1) Midazolam(1) Secobarbital(1)	Estazolam (1) Flurazepam (1) Quazepam (1) Temazepam (1) Triazolam (1)
Restless legs syndrome (RLS)	Cabergoline (3) Pergolide (4) Oxycodone (4)	Zolpidem (1) Gabapentin (2) Oxcarbazepine (2) Pregabalin (2) Carbidopa/levodopa (3) Pramipexole (3) Ropinirole (3) Rotigotine (3) Methadone (4) Codeine-C/D* (4) Oxymorphone (4) Propoxyphene-C/D* (4) Hydrocodone-C/D* (4) Tramadol (4)	Clonazepam (1) Carbamazepine (2)	Temazepam (1) Triazolam (1)
Narcolepsy		Sodium oxybate (5) Fluoxetine (5) Venlafaxine (5) Selegiline (5) Clomipramine (5) Protriptyline (5) Dextroamphetamine (6) Mazindol (6) Methamphetamine (6) Methylphenidate (6) Modafinil/armodafinil (6) Protriptyline (5)		
Parasomnias			Clonazepam (1) Topiramate (2) Sertraline (5)	
Gastroesophageal reflux disease (GERD)	Sucralfate (8) Cimetidine (9) Ranitidine (9) Famotidine (9) Nizatidine (9) Metoclopramide (10) Lansoprazole (11) Rabeprazole (11) Pantoprazole (11) Esomeprazole (11)	Cisapride (10) Omeprazole (11)		

*Numbers in parentheses refer to medication classes: (1) sedative-hypnotics, (2) anticonvulsants, (3) dopaminergics agents, (4) opioids, (5) antidepressants and depressants, (6) stimulants, (7) antihistamines, (8) antacids, (9) histamine type 2 receptor antagonists, (10) promotility agents, and (11) proton pump inhibitors. Former U.S. Food and Drug Administration (FDA) pregnancy categories:

Category A: There is no fetal risk in first trimester in controlled human studies (no evidence in later trimesters). Possibility of fetal harm is remote.

Category B: Animal studies have not indicated a fetal risk but no controlled studies in pregnant women exist, or animal studies have shown an adverse fetal effect that is not confirmed in controlled studies in women in the first trimester (no evidence in later trimesters).

Category C: Animal studies have shown adverse fetal events, but no controlled studies in pregnant women exist, or studies in humans and animals are not available; thus, give if potential benefit outweighs the risk.

Category D: Risk to fetus is present, but benefits may outweigh risk if life-threatening or serious disease exists.

Category X: Studies in animals or humans show fetal abnormalities; drug contraindicated for pregnant women.

C/D: With prolonged use or in high doses, its Category C level of risk becomes a higher risk (Category D).

Studies provide some evidence that insomnia symptoms during pregnancy may be alleviated by mindful yoga, acupuncture, massage, or exercise.[74,76] The safety of acupuncture during pregnancy, however, needs further investigation. Alternative therapies (herbal or dietary supplements such as chamomile tea or lavender pillows) also are used as sleep aids,[12] but controlled studies are needed to assess the benefits and risks to fetal and maternal health.

Pregnancy-Related Restless Legs Syndrome (Willis-Ekbom Disease)

Restless legs syndrome (RLS) is a common neuromotor disorder characterized by an irresistible urge to move the legs to stop the uncomfortable sensations. Symptoms are distinctly worse at night while at rest, relieved by movement, and not solely accounted for by another medical or behavioral condition such as leg cramps or positional discomfort.[79,80] The diagnosis depends on five cardinal criteria[17,80] (see Chapter 95). Pregnancy-related RLS, or Willis-Ekbom disease, is classified as a secondary form of RLS because symptoms typically resolve at the time of delivery.[16,17,79] Pregnancy-related RLS is a risk factor for development of RLS that may occur several years after pregnancy.[79,81]

RLS may coexist with periodic leg movements in sleep (PLMS).[80] Such movements are characterized by rhythmic extension of the big toe and ankle dorsiflexion, with occasional flexion at the knee and hip during sleep. The resulting repeated brief arousals can contribute significantly to disturbed sleep during pregnancy.[80,82] Researchers using leg actigraphy monitoring found that the frequency of PLMS decreased by 50% to 100% after delivery in women with RLS.[83] RLS symptoms are associated with shorter TST, more difficulty initiating and maintaining sleep, and more daytime sleepiness compared with these measures in pregnant women without RLS.[16,17,79,84] In extreme cases, symptoms are so disturbing that evening relaxation and falling asleep are almost impossible, creating a high risk for depression.[79,85]

Epidemiology

Although the cause of RLS in pregnancy is uncertain, the association between RLS and pregnancy is not new. In 1940 Mussio-Fournier and Rawak made the first observation that RLS was exacerbated during pregnancy in German women.[17] Since 1940, numerous reports from around the world have estimated prevalence at 3% to 34% in pregnant populations,[16,17] and all agree that RLS is two to three times more common in pregnant women than among nonpregnant women,[16] even in ethnic groups in which RLS is a rare condition. Most prospective studies report that prevalence rates of RLS increase as pregnancy progresses, peaking in the third trimester and resolving a few days before delivery.[16,17,83,84] Variations in pregnancy-related RLS estimates can be attributed to use of differing diagnostic criteria (earlier studies were conducted before establishment of diagnostic criteria by the International Restless Legs Syndrome Study Group), self-report questionnaires based on retrospective symptoms, and different risk factors including maternal age, parity, ethnicity, regional variations, and genetics. In Western countries where studies used established diagnostic criteria for RLS, reported prevalence rates range from 11% to 34%.[16,17,79,83,84] In Asian countries, prevalence rates range from 3% to 20%.[16] In a recent epidemiologic study of 461 Taiwanese women interviewed using established criteria, the overall prevalence of RLS was 10.4%.[86]

One of the first prevalence studies using international criteria and a structured clinical interview was performed in Italy with 642 pregnant women.[79] The RLS prevalence rate was 26.6%, and the mean time of onset of RLS symptoms was around the sixth month of pregnancy. Although 16.7% had never experienced RLS symptoms before pregnancy, approximately 10% had preexisting symptoms, and 15% noted symptoms at least three times per week.[79] A recent prospective study in Switzerland, however, found a lower prevalence (12%) and earlier onset (before the fifth month).[83] These differences could be explained by ethnicity, because both studies used similar methodology and the same diagnostic criteria.[79,83]

Pathophysiology

The pathophysiology of pregnancy-induced RLS has yet to be established. Several factors are thought to be involved, including hormonal mechanisms, iron and folate metabolism, family history, depression, and multiparity.[16,17,84]

Iron and folate deficiencies, often seen during pregnancy, are associated with RLS.[16,79,84] Earlier studies reported that women in whom RLS developed by their third trimester had lower folate and ferritin levels at preconception and lower folate, plasma iron, hemoglobin values, and mean corpuscular volume throughout pregnancy, in comparison with healthy control subjects.[16,79,84] However, a later study of 19 pregnant women did not support associations between RLS and reduced iron, ferritin, or hemoglobin,[82] although levels were lower in the women with RLS. This conflict may be due to small sample sizes. Two recent epidemiologic studies also reported that ferritin, hemoglobin, and hematocrit values did not differ between women with and without RLS,[83,87] but iron intake was higher among women with RLS in one of these studies.[87]

Iron deficiency in the central nervous system, which results in the dysfunction of dopaminergic systems, may be responsible for RLS symptoms among women who have normal ferritin, an indicator of systemic iron storage. In this regard, cerebrospinal fluid (CSF) ferritin levels are informative because patients with RLS, even those with normal peripheral iron stores, have low CSF ferritin and high CSF transferrin.[17] Studies on central nervous system iron metabolism in pregnancy-related RLS are needed. However, the hypothesis of iron deficiency in pregnancy-related RLS cannot be supported for two reasons. First, all pregnant women in the second half of pregnancy have similar hemoglobin and ferritin reductions, attributed to fetal growth and hemodilution, regardless of iron and vitamin supplementation.[79,84] Second, RLS symptoms resolve just before labor onset, even though the largest loss of blood and iron is at delivery and it takes at least 3 months for repletion of storage iron.[6]

Hormones such as prolactin and estrogens may contribute to development of RLS. Prolactin may be involved in development of RLS during pregnancy as a consequence of its antidopaminergic activity.[17,82] However, no strong evidence for a causative role of prolactin in RLS is lacking,[82] because levels rise throughout pregnancy and continue to be elevated in breast-feeding women, yet RLS resolves with labor and delivery.[79,83] In addition, RLS is not associated with diurnal rhythms of prolactin in the general population.[16,82] Elevated

estradiol levels during pregnancy, and sudden decline with delivery of the placenta, were linked with RLS symptoms,[82] yet larger studies failed to confirm this association.[16,83,88] Progesterone levels do not differ between women with and without RLS.[16,82] Thyroid-stimulating hormone also has been implicated in the pathophysiology of RLS,[16] but levels did not differ between pregnant women with and without RLS in one recent study.[87] With these conflicting findings, more research on the relationships between hormonal factors and pregnancy-related RLS is needed.

Family history of RLS and multiparity (especially closely spaced pregnancies) may be independent risk factors for RLS.[16,79,81,83] RLS was reported by 75% of multiparas who experienced RLS in a previous pregnancy[83] but was not experienced between pregnancies.[2] The risk of RLS increases with the number of children in a "dose-dependent" way.[12,81] Other factors associated with RLS include older age, heavier maternal weight, smoking, peptic ulcer disease, varicosities, and concomitant SDB or depression.[16,79,83,86,87] Some medications such as SSRIs, antihistamines, and antiemetics also may trigger or exacerbate RLS symptoms.[12,16,17] Sleep deprivation, anxiety and stress, insomnia, and fatigue also are documented contributors to RLS in pregnancy.[16,17,79,81] In a prospective study of 1428 women, pre-pregnancy RLS was an increased risk factor for both antenatal and postnatal depression, whereas no added risk was seen in pregnant women with new-onset RLS during pregnancy.[85]

Management

RLS that develops during pregnancy is likely to be short-term and highly symptomatic until delivery. Pregnant women should consider nonpharmacologic comfort strategies (Figure 156-2), rather than medication that may affect the fetus. If sleep is severely disrupted by RLS, iron therapy may be warranted,[89] or the lowest dose of pharmacologic therapy (see Figure 156-2) can be considered (also see treatment options in Chapter 95).[81,90]

Sleep-Related Leg Cramps

Leg cramps are painful muscle contractions in the foot or leg. When the cramping occurs during sleep, a sudden awakening is typical, and the pain intensity can prevent return to

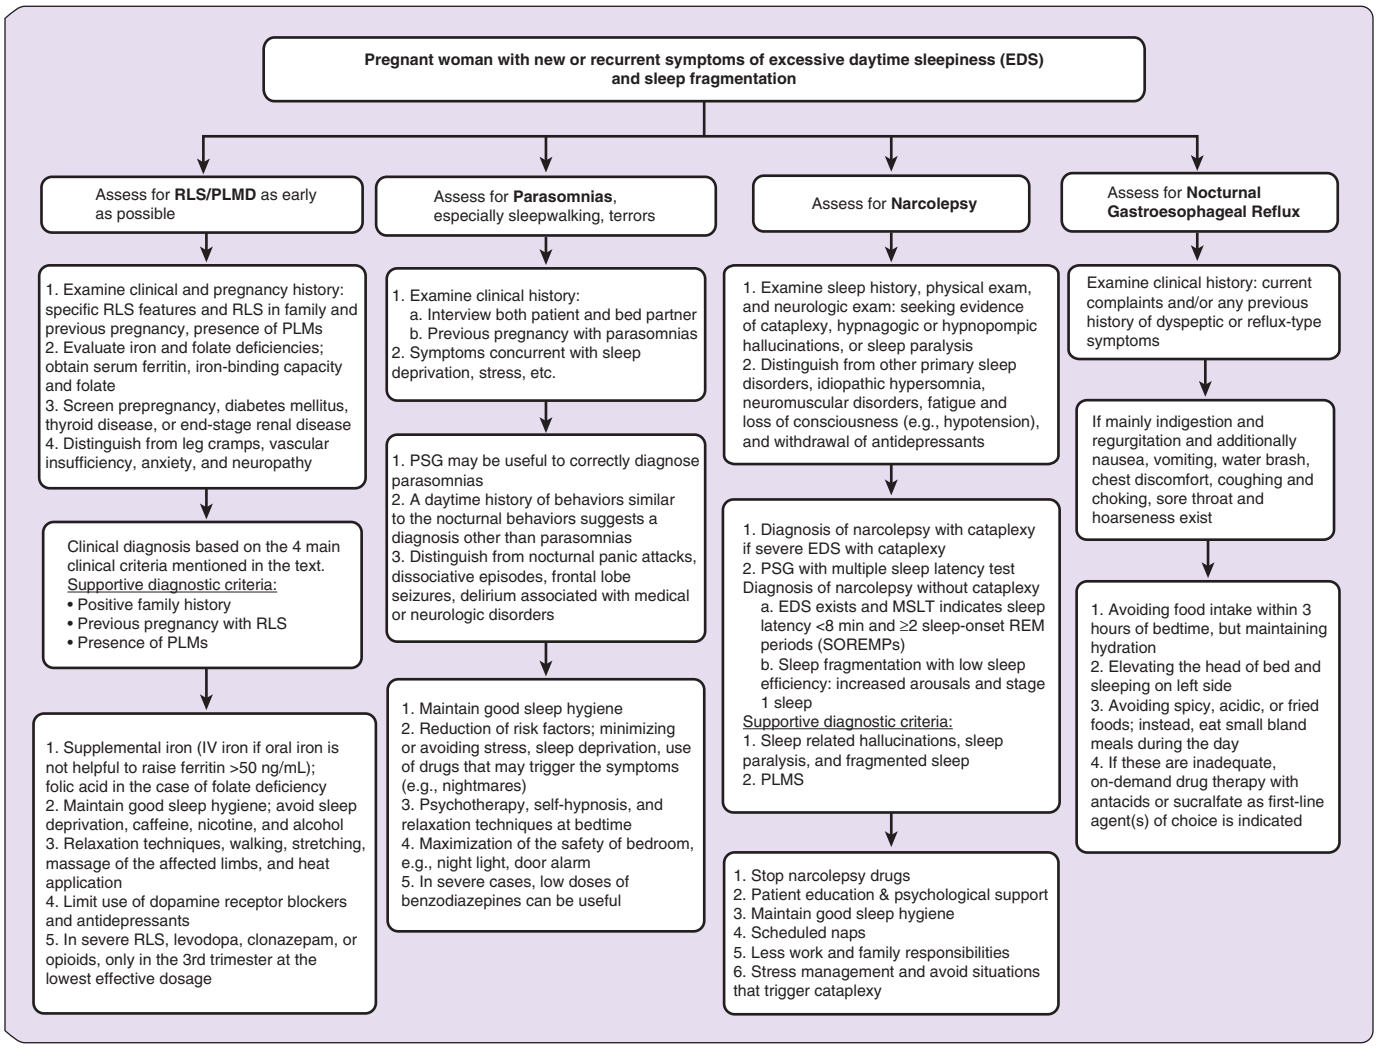

Figure 156-2 Management and treatment of sleep-related disorders. IV, Intravenous; MSLT, Multiple Sleep Latency Test; PLMs, periodic leg movements; PLMD, periodic leg movement disorder; PSG, polysomnography; REM, rapid eye movement; RLS, restless legs syndrome; SOREMP, sleep-onset rapid eye movement sleep period.

sleep for hours. Leg cramps during the night are one of the most common reasons for pregnancy-related sleep interruption.[91]

Epidemiology

The prevalence of nocturnal leg cramps increases from 10% before pregnancy to 21% in the first trimester, 57% in the second trimester, and up to 75% in the third trimester.[1,44,84]

Pathophysiology

It is unclear why these intense muscle spasms occur more often in pregnancy. One mechanism to consider is the altered metabolism of calcium, magnesium, and phosphate while fetal bones are developing, but muscle spasms increase in prevalence toward the end of pregnancy, when there is less demand for fetal bone formation. Other potential mechanisms include slowed venous return secondary to increased intraabdominal pressure and inhibitory effects of progesterone on the venous smooth muscle.[92]

Management

Abundant anecdotal evidence is available, but few studies have been performed to investigate the utility of treatment modalities to relieve or prevent nocturnal cramp attacks. These modalities include hyperextension to counter the contraction during the cramp, leg massage, and reducing intake of phosphorus-containing substances such as milk and meat.[44,92]

A systematic review of placebo-controlled trials involving 352 women showed no benefit from calcium supplements but suggested some relief with magnesium supplementation.[92-94] More recent research indicates that vitamin B is beneficial for eliminating leg cramps during pregnancy. In a 2-week clinical trial, 84 pregnant women were randomly assigned to one of four groups, receiving supplementation with either calcium, magnesium, or a combination of vitamins B_1 (thiamine) and B_6 (pyridoxine), with the fourth group consisting of control (no supplementation) subjects. Compared with that for the no supplementation group, B vitamin supplementation was most beneficial in eliminating the cramps over a 1-month time frame (72%) or in reducing their frequency and intensity (19%); only 2 (9%) of the 21 women in the vitamin B group reported no change in leg cramps.[94] By contrast, all 21 women in the magnesium supplementation group improved, but only 29% experienced absolute elimination of cramps. Although an adequate control group was in place and the sample size for each group was adequate, the researchers were not specific about any baseline pregnancy characteristics (parity, weeks of gestation, or age) and had no sleep parameters to report.[94] Vitamin B supplementation is found in most perinatal vitamins and should be discussed with the health care provider if leg cramps are disrupting sleep during the night.

Nocturnal Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is a chronic disorder in which gastric contents enter the esophagus, particularly after large meals, with ingestion of certain types of foods, or on reclining. This becomes problematic when the reflux leads to fragmentation of sleep while lying down at night. It is rare for younger healthy women to be diagnosed with GERD as a chronic condition before pregnancy. If a woman is already diagnosed with GERD and becomes pregnant, the condition can worsen because of the additional abdominal weight, the anatomic and hormonal changes that occur during pregnancy (see Figure 156-1),[95] and the different food items that may elicit symptoms. If reflux begins in pregnancy, the incidence typically peaks in the third trimester and resolves after childbirth, when anatomy returns to normal.

Indigestion or heartburn, acid taste, and regurgitation are common symptoms of GERD. However, other symptoms include nausea, vomiting, chest discomfort, coughing, choking, sore throat, and hoarseness that can be present on awakening in the morning. Nighttime symptoms include not only fragmented sleep but discomfort from injury to esophageal tissue caused by the acidic pH.[96,97] GERD impairs quality of life and also has the potential to interfere with healthy weight gain during pregnancy. Fortunately, GERD typically is confined to pregnancy, and long-term complications are rare.

Epidemiology

The incidence of GERD at any point in pregnancy ranges from 30% to 80%.[96] Overall, aproximately 25% of women experience reflux in each trimester.[97-99] In a recent prospective longitudinal study of 408 pregnant women, the prevalence of GERD symptoms doubled from 26% in the first trimester to 51% in the third trimester.[99] What remains unknown are the specific rates of reflux associated with nighttime awakenings while lying down, with all meals across the day, and with particular cultures and types of food choices.

Pathophysiology

The pathophysiology of GER in pregnancy is multifactorial (see Figure 156-1). One key factor is elevated progesterone hormone,[96,97,99] with its inhibitory effect on smooth muscle. In addition, as pregnancy progresses, repositioning of the stomach and intestinal tract occurs. Along with this repositioning, the mass effect of the growing fetus and abdominal weight gain increase intraabdominal pressure and reduce esophageal sphincter pressure, making GERD more common.[95]

Management

For the diagnosis of esophageal reflux during pregnancy, or the diagnosis of GERD as a longer-term disorder, a careful history should be obtained, focusing on current symptoms and pattern of weight gain in pregnancy.[96] Mild symptoms can be managed with temporary modifications to diet and lifestyle. Food intake should not occur within 3 hours of bedtime, but continued water intake into the evening hours is important to maintain hydration. Women with GERD symptoms are encouraged to eat smaller meals more frequently, and to sleep upright with more pillows to support the upper body. Sleeping on the left side with the head elevated can help counter the pressure from the repositioned esophageal sphincter, stomach, and intestines. The head of the bed also can be elevated with wedges, or the patient may feel more comfortable sleeping in a recliner chair, especially during the third trimester.[79,97]

When these lifestyle and dietary modifications are inadequate, sodium bicarbonate should not be used, because of high potential for electrolyte imbalance. Severe symptoms of GERD often are responsive to antacids, which have a low risk of harm to the fetus (see Table 156-2) and have no documented adverse effects in animal studies.[95] Antacid

regimens are useful to prevent or minimize GERD symptoms, reduce discomfort, improve sleep, and help maximize quality of life.[96]

In a European prospective study of 553 cases of first-trimester exposure to histamine H_2 receptor antagonists (e.g., cimetidine) to treat GERD, a higher relative risk of preterm birth (8.9%) compared with control cases (5.6%) (odds ratio [OR], 1.67; 95% CI, 1.18 to 2.35) was noted, and two cases of neural tube defect in the offspring of women taking famotidine were reported.[100] H_2 receptor antagonists have low risk to the fetus (formerly Category B; see Table 156-2), and although effective, may be best to use after any danger of preterm birth (before 36 weeks) has passed. With so few studies available, more data are needed from both animal studies and human research.

Parasomnias During Pregnancy

Parasomnias are undesirable physical events occurring during entry into sleep or during arousals from sleep, and the affected person usually is unaware that the event took place.[65] Parasomnias specific to NREM (e.g., confusional arousals, sleepwalking, sleep terrors) and to REM (e.g., sleep paralysis, nightmare disorder, REM sleep behavior disorder) have been well documented.[65] See Chapters 101 to 106 for more details on parasomnias in general.

Epidemiology

No strong evidence supports any increase in the incidence of parasomnias during pregnancy. In a longitudinal survey study of 325 women, sleep paralysis significantly increased in the second half of pregnancy (from 5.8% to 13.2%), but other findings included decreases in sleepwalking, sleeptalking, hypnagogic hallucinations, and sleep bruxism during pregnancy from values for the 3-month prepregnancy period, especially in nulliparas.[101] Data on dreams, nightmares, and their content during pregnancy are inconsistent, probably owing to different data collection methods and time frames. Although nightmares decreased significantly in the same sample overall in the survey study,[101] earlier reports have indicated increased frequency of dreams with gestational age.[44,93] At least one frightening dream about the infant or pregnancy has been reported by 25% of women during pregnancy.[93] Kennedy and associates[60] found that 80% of new mothers reported particularly vivid, peculiar, detailed and disturbing dreams during pregnancy. However, Nielsen and coworkers[102] noted that dream recall was equally prevalent among pregnant, postpartum, and nonpregnant women (88% to 91%). Pregnant women's dreams involved anxiety about the infant and birth outcomes, and the dreams often were accompanied by dream-associated behavior and confusional arousals. Nulliparas and multiparas also differed in dream recall, with more anxious dream content about the infant in nulliparas.[102] In a study of women with a previous pregnancy loss, 80% reported dreams associated with anxiety about the infant and pregnancy complications.[103]

A recent cross-sectional prospective study found that women in their third trimester and nonpregnant women have similar dream recall, but the pregnant women had more disturbing dreams.[104] The incidence of nightmares that exceeded criteria for moderately severe pathology (more than 1 nightmare/week) was three times higher in the same night among pregnant women (21%) than among nonpregnant women (7%).[104] Further research using polysomnography is required to clarify associations between sleep and pregnancy-related dream experiences.

Pathophysiology

Hormonal changes, fragmented sleep, and intense emotional stress may predispose pregnant women to frightening dreams, night terrors, or sleepwalking, especially in those with a genetic predisposition or previous history of parasomnia.[49,60,102,104] Cortisol levels may have a pivotal role in causation, with peaks occurring during the second half of the night, when REM sleep dominates and dream imagery and emotions are most intense.[104] Furthermore, pregnancy parasomnias may be associated with an undiagnosed sleep disorder (e.g., SDB) that fragments sleep. Finally, dreams and nightmares may be important indicators of the woman's psychological state. Pregnant women experiencing an active parasomnia with complex, vigorous, or violent behavior are at risk for sleep-related injury and injury to the fetus.

Management

Data on treating parasomnias during pregnancy are scarce, and more research is required. Informing women about the likelihood of parasomnias, such as disturbing dreams, may reduce anxiety. In the general population, clonazepam is prescribed for some parasomnias, but due to its high risk for fetal harm (formerly Category D), it is often discontinued during pregnancy.[105] In most cases, no special treatment is necessary, but effective measures include maintaining good sleep hygiene, reducing or avoiding stress and sleep deprivation, and making the bedroom safe (see Figure 156-2 and Chapters 101 to 106 for more detail).

Narcolepsy

Narcolepsy is a neurologic sleep disorder characterized by excessive daytime sleepiness, cataplexy (loss of voluntary muscle tone following emotion), hypnagogic hallucinations, and sleep paralysis.[65,106,107] Diagnostic criteria for narcolepsy are detailed in Chapter 90 and Figure 156-2. Diagnosis of the condition during pregnancy, however, may require special attention owing to pregnancy-related daytime sleepiness or vivid dreams. The weight gain that often accompanies pregnancy also could be falsely attributed to onset of narcolepsy.[107]

Epidemiology

The prevalence of narcolepsy in the general population is low (20 to 160 cases/100,000 population) in western Europe and the United States,[107-109] and the disorder usually emerges during young adulthood, thereby affecting women in the reproductive phase of life. The prevalence among pregnant women probably is similar to that in the nonpregnant population. The effects of pregnancy on narcolepsy, and how narcolepsy may affect the pregnancy, are not well understood. Symptoms of narcolepsy may be either exacerbated or attenuated during pregnancy.

Pathophysiology

Hypocretin (orexin) has a critical role in the pathophysiology of narcolepsy,[109,110] along with the loss of hypothalamic hypocretin-producing cells[65] in genetically susceptible persons who carry human leukocyte antigen (HLA)-DQB1*0602 and

HLA-DR2.[109] The significance of these gene abnormalities, especially in pregnancy, is not clear, but the relationship between narcolepsy and HLA type suggests an autoimmune disease that destroys hypocretin-producing cells.[109] Environmental factors also may play a causal role. Studies in northern Europe and China indicate that H1N1 virus infection may trigger narcolepsy.[109] Regarding pregnancy, however, symptoms of narcolepsy initially appeared in 16.6% of affected women up to 1 year after the birth of their first child,[107] so pregnancy is not a likely contributing factor in the pathogenesis of narcolepsy.

Consequences of Narcolepsy in Pregnancy

In retrospective European cohort studies, women with narcolepsy symptoms experienced before or during pregnancy tended to have a higher incidence of impaired glucose metabolism and anemia compared with asymptomatic women. However, these studies lacked control groups without narcolepsy.[106,107] Reported rates of cesarean births were higher in women with narcolepsy-cataplexy than in women with narcolepsy and no cataplexy.[106] Cataplexy itself can be dangerous and stressful during pregnancy owing to its uncontrollable nature. Mothers may worry about their children's inheriting narcolepsy. In addition, women with narcolepsy are inclined to develop obesity, which may increase the risk of SDB and pregnancy complications.[107] In a recent animal study, an association between pregnancy and increased risk of maternal death was evident in the narcolepsy-cataplexy mice with complete hypocretin deficiency.[110]

Management

The confirmation of narcolepsy diagnosis is based on PSG and a multiple sleep latency test (see Chapter 90 and Figure 156-2). Treatment is challenging in pregnant women. Detailed practice parameters for treatment of narcolepsy during pregnancy are not currently available. A standard narcolepsy treatment regimen includes scheduled daytime naps and may require multiple pharmacologic agents, including a stimulant to control excessive daytime sleepiness and an anticataplectic (sodium oxybate) or a selective serotonin reuptake inhibitor (SSRI) for cataplexy. However, most of these medications should be used with caution (formerly Category C drugs), as human data are lacking to determine pregnancy risks (Table 156-2).[111] Spontaneous miscarriages have been documented in women using sodium oxybate[111] and prematurity, low birth weight, and withdrawal symptoms have been reported in infants of women taking amphetamines.[12,111] A recent survey of 75 clinicians who treated narcolepsy during pregnancy, however, found no evidence of teratogenicity with modafinil, sodium oxybate, methylphenidate, amphetamines, or SSRIs.[111]

In a retrospective study of 249 pregnant women with narcolepsy, symptoms did not change in 40%, worsened in 40%, and improved in 18% who withdrew from medication during the first trimester.[106,111] These types of studies are limited by recall bias using retrospective data and small numbers of pregnancies that occur in women taking antinarcolepsy medication.[100,105] On the basis of current evidence, medication for narcolepsy should be discontinued for conception and during pregnancy and prescribed only if potential benefit outweighs potential risk. If a woman requires medication during pregnancy or decides to continue medication while attempting to conceive, however, she can be reassured that evidence for harm is largely lacking. With narcolepsy associated with cataplexy, an elective cesarean should be considered owing to the potential dangers for mother and newborn if a cataplexy episode occurs during labor.[111]

Patient education and psychological support are important for the woman and her family.[109] Good sleep hygiene and a supportive network are imperative to ensure adequate nocturnal sleep, adherence to scheduled daytime naps, and fewer role responsibilities. Behavioral interventions including scheduled naps, stress management, and avoiding situations that trigger cataplexy could decrease risk of physical injury as well as unpredictable sleepiness.

In summary, narcolepsy is a rare but disabling sleep disorder. Little is known about how pregnancy affects narcoleptic symptoms or how narcolepsy and pharmacologic treatments affect pregnancy. An autoimmune disorder in genetically predisposed women, possibly precipitated by infection, can alter hypothalamic hypocretin production. Based on animal studies, narcoleptic medications may be harmful to the fetus (formerly Category C medication), but human data are lacking for maternal-fetal risk.

SLEEP DURING PREGNANCY WITH PREEXISTING MEDICAL CONDITIONS

Sleep in pregnant women with medical conditions such as preeclampsia, affective disorders, asthma, and migraine headaches has not been widely studied. These conditions may have a further impact on sleep during pregnancy. Studies using objective sleep measures report that women with gestational hypertension have impaired sleep quality and markedly altered sleep architecture, with significantly more slow wave sleep and less REM sleep.[112-114] These women also napped more frequently than healthy pregnant women.[114] In a large cohort study (n = 1332) during early pregnancy, women with a psychiatric diagnosis reported shorter sleep duration, increased frequency of exhaustion, and higher perceived stress levels compared with women without such diagnoses.[115] A systematic review of earlier studies also noted that sleep disturbance, fatigue, and stress were more frequent during pregnancy among women with anxiety disorders than among other pregnant women.[58] In another cross-sectional study of 1335 pregnant women, women with a history of asthma experienced more sleep disturbances, including snoring, than did nonasthmatic women.[116]

MATERNAL AND FETAL CONSEQUENCES OF SLEEP DISTURBANCE

Sleep disorders, especially untreated apnea or extremes of sleep duration (both short and long), are potential contributors to adverse health conditions such as cardiovascular disease and type 2 diabetes. An analogous association in pregnancy also is recognized, with women at increased risk for development of adverse outcomes such as gestational diabetes or preeclampsia.[5] Adverse outcomes associated with SDB are covered in Chapter 157. Although study results in pregnant women should be interpreted cautiously owing to small sample sizes or other limitations such as recall bias, evidence supports the concept that sleep disturbances may be novel modifiable risk factors for preventing and managing pregnancy complications.

Obesity or Excessive Weight Gain

Experimental and observational studies reveal that both short and long sleep duration (generally defined as less than 6 hours and more than 9 hours, respectively), sleep restriction, and sleep disturbance can predispose affected persons to weight gain and obesity-related cardiometabolic disorders.[5,31] Although the evidence for a relationship between sleep duration and weight gain in pregnancy is limited, a few mechanisms have been proposed to explain the risk of excessive weight gain. Sleep deprivation associated with pregnancy discomforts may result in fatigue that leads to comfort eating, physical inactivity, and eventual obesity. Short sleep duration also allows additional time for food consumption. In a population-based cohort study of 710 pregnant women recruited before the 17th week of pregnancy and followed until delivery, sleeping less than 8 hours/day during the second or third trimester was a risk factor for inadequate gestational weight gain.[117] Sleep disturbance may also lead to altered leptin levels and contribute to obesity. In a study of 830 women during early pregnancy, Qiu and colleagues[31] noted that short sleep (5 hours or less) and, to a lesser extent, long sleep (9 hours or longer) was associated with elevated leptin levels if women also were overweight or obese.

Sleep loss, sleepiness, and fatigue, common conditions in pregnancy, are independently associated with insulin resistance,[118] resulting in increased risk of obesity.[5] Thus, avoiding obesity before and during pregnancy may minimize the risk of developing sleep disorders and adverse pregnancy outcomes.

Sleep-Disordered Breathing

Decreased REM sleep may prevent apneic events during pregnancy, but sleep onset and arousals from sleep can destabilize respiration (see Chapter 157). Studies and case reports in pregnancy revealed that sleep-disordered breathing (SDB) is associated with gestational hypertension and preeclampsia, gestational diabetes, pulmonary hypertension, and other cardiovascular diseases, as detailed in Chapter 157.

Pregnancy-Induced Hypertension and Preeclampsia

Pregnancy-induced hypertension, or gestational hypertension, is defined as repeated blood pressure recordings higher than 140/90 mm Hg, first diagnosed during pregnancy in a previously normotensive woman. If proteinuria also is present, the condition is called preeclampsia, but overt proteinuria is not an indication of severity and may not even be evident in some cases.[6] Gestational hypertension is a major contributor to maternal and fetal morbidity and mortality worldwide.[6,38,119]

The mechanisms linking sleep disturbance with gestational hypertension and preeclampsia are complex and involve several pathways detailed in Chapter 157. In nonpregnant populations, acute sleep deprivation is associated with intravascular inflammation and endothelial cell dysfunction, which also is a common pathway for gestational hypertension and preeclampsia.[119] Longitudinal studies of pregnant women indicate that poor sleep quality, fragmented sleep, and short sleep duration are associated with higher circulating inflammatory cytokines (interleukins IL-6 and IL-8, and tumor necrosis factor) and C-reactive protein.[36,120,121] Nevertheless, in view of the relatively small sample sizes and other study limitations, these results should be interpreted with caution.

In a recent study of 161 pregnant women, sleep diaries and actigraphy were used to evaluate sleep parameters, blood pressure, and BMI. Two measures of sleep continuity (latency to sleep onset and wake after sleep onset) were associated with higher blood pressures, even after controlling for covariates.[38] In a prospective cohort study of 1272 women, Williams and colleagues[41] found associations between self-reported nocturnal sleep duration and blood pressure. Both short (less than 6 hours) and long (more than 9 hours) sleep durations in early pregnancy were associated with elevated mean blood pressure in the third trimester. After controlling for confounding factors, they also observed the highest risk of preeclampsia in women who slept less than 5 hours per night.[41] Studies using objective measures confirm that women with preeclampsia have a significant increase in slow wave sleep (probably owing to cerebral edema and release of cytokines), less REM sleep, and more daytime naps compared with healthy pregnant women in the same trimester.[112-114]

Hyperglycemia and Gestational Diabetes Mellitus

Hyperglycemia (1-hour oral glucose tolerance test result of 140 mg/dL or higher) can be detected at any time during pregnancy. Severity ranges from glucose concentrations slightly above normal to gestational diabetes mellitus (GDM).[5] Accumulating evidence demonstrates an association between sleep duration and risk of hyperglycemia,[121a] but a causal relationship has not been established. Even mild hyperglycemia is associated with adverse maternal and fetal outcomes (i.e., preeclampsia and fetal growth retardation) and future development of type 2 diabetes, obesity, and cardiovascular disease in mother and child.[5] In a prospective study of 189 nulliparas with a singleton gestation, women who reported short sleep (less than 7 hours sleep/night) were 2.6 (95% CI, 1.3 to 5.7) times more likely to have a 1-hour oral glucose test value of 130 or higher and 10 times more likely to have GDM (95% CI, 1.3 to 85.5).[122] In a large prospective cohort study of 1290 women before 20 weeks of gestation, both short and long sleep durations were associated with hyperglycemia. Women sleeping ≤4 hours/night had a 5-fold increase (95% CI, 1.31 to 23.69) in risk of GDM compared with women sleeping 9 hours/night after adjusting for age and race. However, this association was no longer significant after adjustment for prepregnancy BMI.[123]

In a third study of 169 women who completed several sleep questionnaires, a significant inverse relationship was noted between sleep duration and 1-hour glucose values; for every 1 hour less sleep time, there was a 4% increase in glucose levels. Controls for risk factors for GDM, however, were lacking.[124] In a prospective study of 260 pregnant women, self-report sleep parameters were not significantly different between pregnancies with and without adverse outcomes including GDM.[20] Studies with small sample sizes ($n = 52$ to 104) are less likely to find statistically significant associations between sleep duration and hyperglycemia.[125,126] However, self-reported nap duration was associated with high glucose challenge test values in adjusted models. Bourjeily and associates[118] also have demonstrated that severe daytime sleepiness increases the risk of GDM in nonsnoring pregnant women, independent of confounding factors. These studies suggest that sleep, regardless of time of day, has modulatory influences

on glucose regulation. Further studies are required to elucidate whether napping may be therapeutic for preventing or treating GDM.

Adverse Obstetric Outcomes

Short sleep duration in pregnancy can be considered a physiologic stressor, leading to longer labor and cesarean delivery.[58] In a prospective observational study of 131 nulliparas in their last month of pregnancy, those who slept less than 6 hours/night had a significantly longer labor duration and higher rate (4.5-fold) of cesarean birth (with controls for infant birth weight) than nulliparas sleeping 7 hours or more by actigraphy measures.[61] A population-based study in 10,662 pregnant women confirmed these findings, indicating that short sleep in the last trimester is an independent risk factor for emergency cesarean delivery (adjusted OR 1.57; 95% CI, 1.14 to 2.16).[127] These correlations between sleep and length of labor or type of delivery also were confirmed by a cross-sectional study of 457 pregnant women after exclusion of hypertension, gestational diabetes, or emergency cesarean, noting that poor sleep quality and sleeping less than 7 hours were associated with longer labor and a higher rate of cesarean delivery.[128] The association between perception of sleep quality and duration of labor and type of delivery also was confirmed in subsequent studies. Using the Pittsburgh Sleep Quality Index (PSQI), poor sleepers (with a PSQI score above 5) were 20% more likely to have longer labor duration and to undergo cesarean delivery.[129] Despite these findings suggesting adverse effects of nocturnal sleep on labor and delivery, daytime sleep was not considered. In another study comprising 120 women, longer daytime sleep duration shortened the labor duration among women with vaginal delivery, after institution of controls for maternal age, but did not influence the need for cesarean delivery or prolong labor in women who subsequently underwent cesarean section.[62] Additional prospective studies are necessary to investigate whether daytime naps can offset the increased risk of adverse obstetric outcomes associated with poor sleep quality and short nocturnal sleep duration.

One mechanism for these adverse outcomes may be an increased perception of pain during labor. Beebe and associates[59] reported a significant relationship between pain perception and sleep duration recorded by wrist actigraphy the night before hospitalization in women with spontaneous labor onset. This finding suggests that women with less total sleep time and more wake time on the last night before labor starts may perceive labor as more painful. Furthermore, higher fatigue levels during pregnancy may increase risk of cesarean birth. Sleep loss before hospitalization may affect motivation to comply with planned strategies for labor progression.

Fetal Complications

Maternal sleep is important for fetal growth and well-being because the secretion of growth hormone and uteroplacental blood flow are at their peak during sleep.[6,7,113] Thus persistent poor sleep may alter the uterine environment and adversely affect fetal development.[130] A recent animal study found that fragmented sleep during late gestation induced epigenetic modifications in adiponectin in offspring visceral white adipose tissue adipocytes, along with a metabolic syndrome–like phenotype. The study investigators concluded that changes elicited by disrupted sleep can impose adverse long-lasting metabolic outcomes on the next generation.[130]

Sleep disturbance associated with preeclampsia and GDM may increase risk for fetal complications. The sleep disturbance associated with shift work carried a very low risk of preterm birth in a meta-analysis of epidemiologic studies on the effects of shift work.[131] Unfortunately, the available data on preeclampsia or GDM were very limited. Thus further research is warranted to better understand potential adverse obstetric outcomes related to different types of shiftwork schedules.

Sleeping less than 5 hours/day was a risk factor for preterm birth (RR, 1.7; 95% CI, 1.1 to 2.8) after adjustment for confounding factors in a prospective cohort of more than 10,000 nulliparas.[132] In a smaller study of 166 pregnant women who completed the PSQI each trimester, poor sleep quality was associated with higher risk for preterm birth. Researchers found that each 1-point increase in PSQI score increased the odds of preterm birth by 25% in early pregnancy and by 18% in later pregnancy.[45] Similarly, Reutrakul and coworkers[124] reported that short sleep and poor sleep quality were correlated with preterm birth in a study of 169 women. A cross-sectional study also noted that sleeping longer than 8 hours was associated with higher Apgar scores (> 9) compared with sleeping less than 8 hours, but no significant difference in birth weight was noted.[128] In a case-control study of 734 pregnant women, women sleeping less than 8 hours/day were at high risk for first-trimester miscarriage (OR, 3.80; 95% CI, 1.01 to 14.3) or second-trimester miscarriage (OR, 2.04; 95% CI, 1.24 to 3.37).[133] Some studies linking sleep parameters with preterm birth or stillbirth were limited by cross-sectional data and failure to adjust for confounding variables such as preeclampsia.[58] Accordingly, findings should be interpreted with caution. In a secondary analysis of pregnant women monitored with home polysomnography, 82.4% spent some time sleeping on the back, in the supine position.[134] The supine position for any length of time is a particularly strong risk factor for stillbirth or low birth weight, because the heavy uterus compresses the mother's vena cava, thereby decreasing placental perfusion to the fetus.[134]

Maternal Psychosocial Consequences

Accumulated sleep loss, regardless of the cause during pregnancy, affects level of energy, mood, interpersonal functioning, concentration, and memory. As mentioned earlier, insufficient sleep may even trigger depression.[1,34,58,85] In a population-based survey of more than 2800 women, depressive symptoms were strongly associated with insomnia during late pregnancy, especially when sleep duration was less than 5 or more than 10 hours, when sleep efficiency was below 75%, or when sleep onset latency was prolonged.[70]

These studies cannot prove causation owing to limitations in design. Nevertheless, these reported associations can be a helpful clinical guide. With accumulated data presented in a systematic review of the published evidence on associations between sleep and pregnancy outcomes, the investigators concluded that sleep loss may be a risk factor for the development of prenatal depression or for onset of preterm labor.[60] A study comparing depressed and nondepressed pregnant women suggested that giving birth to smaller infants was associated with short sleep duration or symptoms of insomnia (difficulty

initiating or maintaining sleep, or unrefreshing sleep) among the depressed women in the sample.[121]

Persistent sleep loss also is likely to interfere with the pregnant woman's ability to work efficiently, as a result of feeling very tired, especially by the third trimester.[60] Consequently, rates of absenteeism from the workplace may increase, and risk for accidents is higher at work and on the highway.

As indicated by the available evidence, maternal-fetal health, labor duration and type of delivery, mood status, pain sensitivity, work performance, and quality of life all may be affected by sleep disturbance. Good sleep is essential to optimal maternal physical functioning and mental health. Early intervention to promote sleep may improve health outcomes for both mother and infant.

CLINICAL PEARLS

- Good sleep quality is necessary for optimal maternal health and fetal development, and for the family's smooth transition from pregnancy to early parenting. Sleep disturbance is common during pregnancy, and emerging evidence indicates a link between sleep disturbance and adverse pregnancy outcomes. Nevertheless, a clinical sleep assessment has not been part of routine prenatal care. Associations between sleep disturbance and adverse pregnancy outcomes, the diagnosis and management of sleep disorders during pregnancy, and cost-benefit analysis and long-term benefits of treating sleep disorders during pregnancy have not been well studied, suggesting that well-designed, large prospective observational studies as well as intervention trials are required to clarify these issues.
- Recognition, management, and treatment of sleep disorders are of confirmed benefit for improving short- and long-term maternal and fetal health outcomes. Preferably, the obstetric clinician and the sleep specialist should communicate and share their clinical assessments and test results in an effort to prepare a successful management plan for pregnant women at risk for adverse outcomes or events. Clinical management of sleep disturbances during pregnancy should aim to inform women about the importance of sleep, the value of sleep hygiene and nonpharmacologic options as first-line therapeutic interventions, and the likely temporary nature of the disturbance during pregnancy. Women with a preexisting sleep disorder should be advised to take added precautions during pregnancy to maintain their own health and well-being as well as those of the fetus.

SUMMARY

Physical and hormonal changes during pregnancy can cause sleep disturbances and predispose women to development of a temporary sleep disorder (such as RLS, GERD, or SDB) or may worsen a preexisting disorder. Such disorders are associated with adverse maternal and fetal outcomes. Proper diagnosis and treatment of sleep disorders are necessary to decrease adverse pregnancy outcomes, to improve maternal health during and after pregnancy, and to promote both short- and long-term optimal health consequences for the child. Thus treatment of sleep disorders during pregnancy has implications for long-term benefits for public health.[74,135] Large longitudinal studies are needed to examine prevalence and to prospectively identify the gestational time frame for onset of a sleep disorder, to examine the dose-response relationship between severity of a sleep disorder and subsequent pregnancy complications, and to test interventions for these sleep disorders. Of most importance, validated screening tools to identify sleep characteristics and disturbances specific to pregnancy are needed.

Sleep-Disordered Breathing in Pregnancy

Francesca Facco; Judette Louis; Melissa Pauline Knavert; Bilgay Izci Balserak

Chapter Highlights

- Pregnant women may be particularly predisposed to obstructive sleep apnea and other major sleep-related breathing disorders as a consequence of the physiologic changes associated with the gravid state.
- Sleep-disordered breathing (SDB) symptoms are common during pregnancy and worsen as the pregnancy progresses.
- Outcomes that have been linked to SDB in the nonpregnant population, such as hypertension and insulin-resistant diabetes, have correlates in pregnancy (e.g., gestational hypertension, preeclampsia, gestational diabetes).
- This chapter reviews the physiology that may influence SDB prevalence and severity in pregnancy, the epidemiology of SDB in pregnancy, the possible link between SDB and adverse pregnancy outcomes, and special considerations in screening for and treating SDB in pregnancy.

PREGNANCY PHYSIOLOGY AND SLEEP-DISORDERED BREATHING

As reviewed in some detail in Chapter 156, pregancy is accompanied by certain alterations in physiology secondary to hormonal, mechanical, and circulatory changes characteristic of the gravid state. A Clinician who examines a pregnant woman for potential sleep-disordered breathing (SDB) needs to be familiar with these pregnancy adaptations; while some changes predispose to SDB, others may protect from it.

Respiratory System Changes that Predispose Pregnant Women to Sleep-Disordered Breathing

Multiple mechanisms lead to anatomic narrowing and increased resistance within the respiratory system during pregnancy. Increased levels of estrogen and progesterone induce capillary engorgement, hypersecretion, and mucosal edema of the upper airway.[1-3] These changes begin early in the first trimester and increase progressively throughout pregnancy. They may lead to a reduction in dimensions of the nasopharynx, oropharynx, and larynx, with consequent increased airflow resistance and an increase in the Mallampati score as pregnancy progresses.[4-6] Furthermore, pregnancy rhinitis is nasal congestion of pregnancy without other signs of respiratory tract infection and with no known allergic cause. This rhinitis results in difficulty breathing and resolves within 2 weeks after delivery. It occurs in up to 42% of women by the third trimester of pregnancy.[1,3]

Increased nasal congestion also may cause increased nasopharyngeal resistance and produce more intrapharyngeal pressure during inspiration. Elevated intrapharyngeal pressure during inspiration contributes to pharyngeal airway narrowing during sleep.[7] The narrowed airway results in snoring and obstructed breathing during sleep. Thus pregnant women are more likely to snore than nonpregnant women, and the prevalence of habitual snoring (on 3 or more nights/week) increases from the first to the third trimester.[5,8,9] Increased fat deposition within the soft tissue regions of the neck with weight gain of pregnancy also could cause pharyngeal narrowing and predispose affected women to snoring and SDB.[4,5,10,11] Pregnant women with a larger neck circumference and higher baseline body mass index (BMI) report more symptoms of SDB than other women.[4,5,10,12]

In addition, maternal blood volume peaks at 40% to 50% greater over baseline by third trimester. The combination of increased blood volume, interstitial fluid, and recumbent position during sleep displaces fluid, which could adversely affect upper airway patency.[2] Evidence regarding nocturnal displacement of fluid is conflicting. Whereas some studies indicated that nocturnal fluid shifting from the legs into the neck increases susceptibility to or severity of pharyngeal obstruction,[13,14] others reported that such rostral fluid shifts do not increase the frequency of obstructed breathing events.[15]

A compensatory increase in the anterior-posterior diameter of the chest and elevated diaphragm caused by the enlarging uterus result in tracheal shortening and progressive functional residual capacity reductions by 20% to 25%, expiratory reserve volume by 15% to 20%, and residual volume by 22%.[2,16] These alterations can lead to the closure of small airways during normal tidal breathing.[4,5,17] In late pregnancy, airway closure results in ventilation-perfusion mismatch and reduced gas exchange,[18,19] especially in the supine position, owing to gravity, increased intraabdominal pressure, and loss of muscle tone during sleep.[2,4,17,20]

Oxygen consumption and minute ventilation progressively increase during pregnancy by 20% and 30% to 50%, respectively.[2] The increased ventilatory drive may induce obstructive respiratory events by increasing diaphragmatic effort that creates negative inspiratory (suction) pressure on the hyperemic upper airway.[7] Furthermore, higher ventilatory drive, along with resultant respiratory alkalosis, may cause instability in respiratory control pathways, potentially increasing the

likelihood of central apnea episodes at sleep onset and during sleep.[2,20,21] However, findings from one recent study suggest that pregnancy does not increase risk for central apnea.[22]

Finally, frequent awakenings due to pregnancy-related discomfort may cause respiratory instability and periodic breathing at sleep onset.[21] The resulting sleep deprivation also can increase arousal threshold, impair upper airway muscle activity, and increase upper airway collapsibility.

Respiratory and Circulatory System Changes that May Protect against Sleep-Disordered Breathing

Several mechanisms that influence respiratory and cardiovascular changes in pregnancy may also lessen risk of apnea or hypopnea episodes. High circulating progesterone during pregnancy may protect the upper airway from obstruction by increasing upper airway dilator muscle (genioglossal) activity and its responsiveness to chemical stimuli (carbon dioxide) during sleep.[23] Pregnancy-related increases in heart rate, stroke volume, and cardiac output with reductions in peripheral vascular may diminish the impact of apneic episodes.[23] Furthermore, as pregnancy advances, women tend to spend less time in the supine position during sleep.[10,24] This may decrease the rate of adverse respiratory events during sleep, as the supine position is frequently associated with increased event rates.[9] However, a recent study reported that 82% of women spend some time sleeping in the supine position in the second and third trimesters of pregnancy.[25]

EPIDEMIOLOGY OF SLEEP-DISORDERED BREATHING IN PREGNANCY

A majority of studies evaluating the prevalence of SDB have been carried out in middle-aged nonpregnant women populations. General population studies have estimated that obstructive sleep apnea (OSA), occurs in 2% to 25% of middle-aged adults in the community, but certain populations are at greater risk,[26,27] particularly the obese and morbidly obese.[28-30] Among reproductive-age women, epidemiologic studies suggest a 2% to 13% prevalence of SDB, with higher rates in certain populations of women.[30,31] For example, among 420 premenopausal women with sleep complaints who were referred for polysomnography (PSG) sleep studies, SDB was present in 70% of those younger than 30 years and in 83% of those older than 30 years of age. Their apnea-hypopnea index (AHI) indicated that younger women had less severe SDB (AHI of 15.5 ± 22) than women older than 30 years of age (AHI of 22.4 ± 34.6).[32] Findings also suggested that SDB is common in pregnancy and worsens as pregnancy progresses.[9,33-35]

Frequent snoring during pregnancy has been well characterized, and studies have consistently demonstrated that SDB symptoms, including snoring, increase as pregnancy progresses.[8,36,37] The prevalence of pre-pregnancy snoring has been reported to be 7% to 11%.[8,36,37] By the third trimester, frequent snoring ranges from 16% to 25%.[8,36-38] Using the apnea symptom score from the Multivariable Apnea Prediction Index, one study found that SDB symptoms increased significantly from the first trimester to the month of delivery, and the increase in symptoms was not limited to snoring but included gasping, choking, difficulty breathing, and apneic events.[9] In this study, 11.4% of the participants reported an apnea symptom score increase of 2 units or more, consistent with a clinically significant increase in symptoms; these women also experienced a significant increase in subjective sleepiness compared with other women.[9]

Epidemiologic data on the prevalence of objectively assessed SDB are more limited. Olivarez and colleagues[39] performed sleep studies in 100 hospitalized pregnant women, admitted for a variety of obstetric and nonobstetric complications. The mean gestational age at the time of the sleep study was 32 weeks, and these investigators reported a 20% incidence of SDB (AHI of 5 or greater).[39] Louis and associates[40] used ambulatory sleep monitoring to assess SDB in 175 obese women at an average of 21 weeks' gestation. The prevalence of SDB was 15.4%, and most cases were mild (AHI of 5.0 to 14.9).[40]

Two studies have reported serial assessments of SDB across pregnancy.[12,41] Pien and colleagues[12] studied 105 women (28% normal weight, 24% overweight, and 50% obese). SDB was present in 10.5% of their subjects during the first trimester (median, 12 weeks). By the third trimester (median, 33.6 weeks), 26.7% had SDB.[12] Facco and associates[41] studied 128 high-risk pregnant women with one or more of the following risk factors: obesity, chronic hypertension, presentational diabetes, previous preeclampsia, and twin pregnancies.[41] Early SDB assessments were performed at 6 to 20 weeks of gestation (mean, 17 weeks) and late-pregnancy SDB assessments were performed at 28 to 37 weeks of gestation (mean, 33 weeks). In early pregnancy the frequency of mild, moderate, and severe SDB was 12%, 6%, and 3%, respectively, and these rates increased to 35%, 7%, and 5% in late pregnancy (Figure 157-1). Of the 128 women, 34 (27%) experienced a worsening of SDB during pregnancy; of the women so affected, 26 had new-onset SDB, and the other 8 had SDB in early pregnancy that became more severe. The incidence of new-onset SDB was 20%, and most of these new-onset cases were mild.[41]

Of note, all of the studies objectively assessing SDB in early or late pregnancy reported that most cases are mild

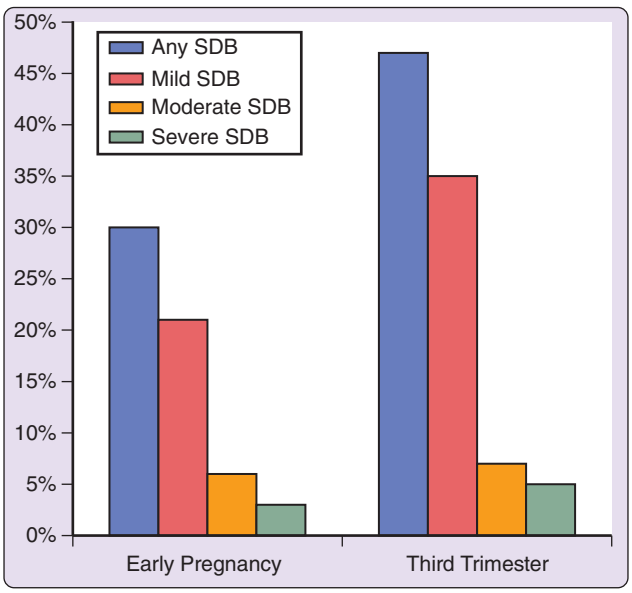

Figure 157-1 Trends in sleep-disordered breathing (SDB) across pregnancy in a high-risk cohort: early pregnancy (6 to 20 weeks), third trimester (32 to 37 weeks). (From Facco FL, Ouyang DW, Zee PC, Grobman WA. Sleep disordered breathing in a high-risk cohort: prevalence and severity across pregnancy. *Am J Perinatol* 2014;31:899–904.)

forms of SDB. Generalizability from these studies is limited, however, because they all studied high-risk populations. Pien et al attempted to correct for this limitation by using BMI distribution for all women screened for their study to estimate SDB among the general obstetrical population from which their subjects were recruited.[12] These investigators then estimated SDB prevalence in their sample at 8.4% (95% CI, 5.6% to 11.9%) in early pregnancy and 19.7% (95% CI, 15.6% to 24.4%) in the third trimester.

Risk factors for SDB in pregnancy have not been well characterized. Pre-pregnancy BMI, age, and chronic hypertension are known risk factors for SDB outside of pregnancy and are also associated with SDB in early pregnancy.[12,41] Excessive gestational weight gain is theorized to be a risk factor for developing new-onset SDB in pregnancy, but epidemiologic data supporting this theory are lacking. Facco and colleagues[41] reported that twin gestation is associated with increased risk of developing new-onset SDB in pregnancy. Although women with twin pregnancies in their cohort, as expected, had greater weight gain, weight gain did not significantly differ between women who developed new-onset SDB and women who did not. Similarly, Pien and colleagues[12] also reported that gestational weight gain was not associated with third-trimester SDB. Maternal weight gain and weight distribution may play a role in incident SDB in pregnancy, but assessing this variable by merely measuring total weight gain may be inadequate. Other measures such as changes in neck circumference, body fat composition, and trajectory of weight gain in relation to baseline BMI warrant further study as risk factors for incident SDB in pregnancy.

SLEEP-DISORDERED BREATHING AND ADVERSE MATERNAL OUTCOMES

Potential Mechanisms for Adverse Maternal Outcomes

Any underlying mechanistic pathway linking sleep disturbances and adverse outcomes for the mother is likely to be multifactorial.[42] Dysregulation of pregnancy adaptations to the cardiovascular, metabolic, and immune systems can make women vulnerable to complications.[43,44] Even small changes in sleep parameters and subtle obstructive respiratory events could exacerbate these adaptations and increase risk for adverse outcomes. SDB causes oxidative stress, autonomic dysfunction, inflammation, and altered hormonal regulation of energy expenditure.[45] These same pathways are associated with adverse pregnancy outcomes.[46,47] Figure 157-2 is a conceptual model depicting potential pathways linking SDB and pregnancy complications.

Oxidative stress, a consequence of intermittent hypoxia-reoxygenation cycles in SDB, plays a pivotal role in development of hypertensive disorders of pregnancy, inducing proinflammatory cytokines that trigger further oxidative stress, sympathetic activation, and endothelial dysfunction.[48] Increased oxidative stress also is linked to development of gestational diabetes.[49] In an animal model of SDB, gestational exposure to hypoxia was associated with increased pancreatic beta cell proliferation, cell death, impaired fetal growth, and hyperlipidemia.[50,51]

SDB leads to sympathetic nervous system and hypothalamic-pituitary axis activation.[52-54] Disproportionate sympathetic

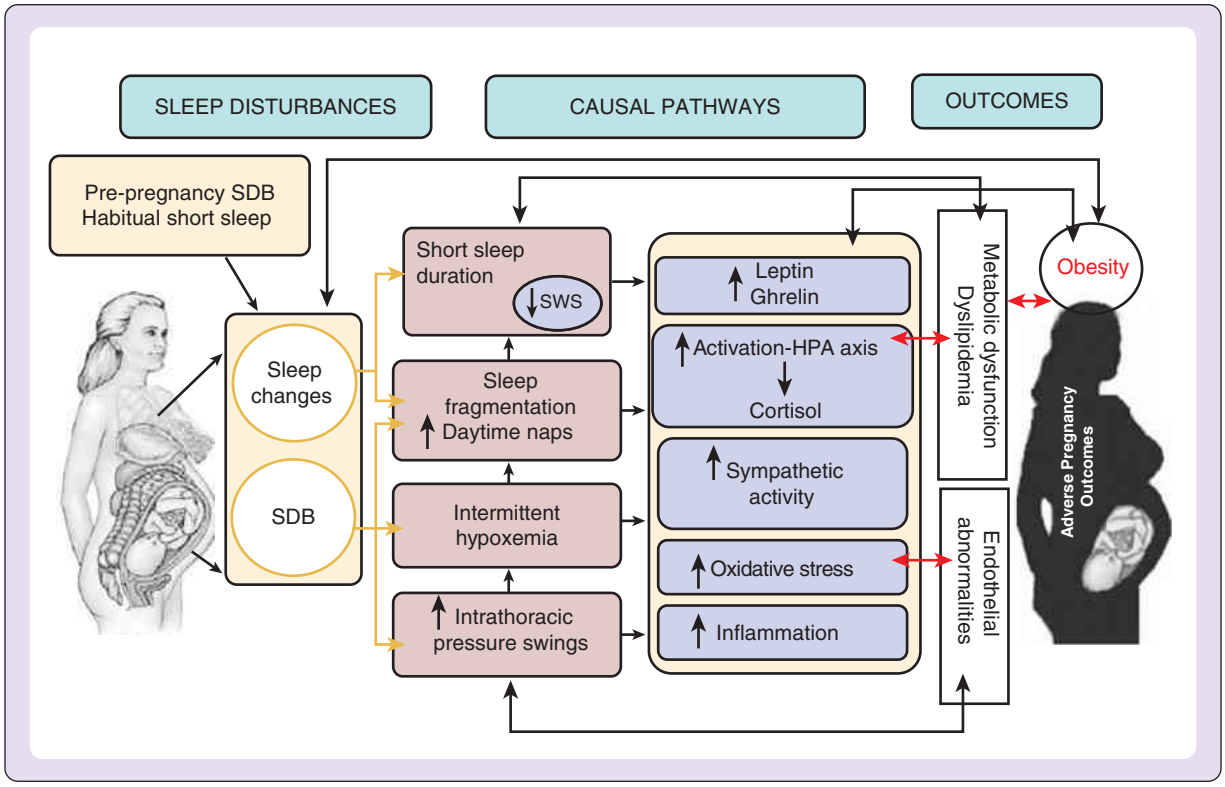

Figure 157-2 Schematic illustration of potential causal pathways linking sleep disturbances during pregnancy with adverse pregnancy outcomes. HPA, Hypothalamic-pituitary-adrenal; SDB, sleep-disordered breathing; SWS, slow wave sleep.

activation persists into the daytime, leading to increased peripheral vascular reactivity and catecholamine production, blunted baroreflex sensitivity, hindered pancreatic insulin secretion, and altered hepatic glucose release.[55] All of these downstream SDB effects have been linked to processes seen in preeclampsia: endothelial dysfunction, elevated systemic arterial blood pressure, and decreased cardiac output.[56-58] SDB also has been strongly linked to systemic inflammation, as evidenced by markers including elevated interleukin-6 (IL-6), tumor necrosis factor alpha (TNF-α), and C-reactive protein levels and leukocyte counts.[59-61] Increased inflammation in early pregnancy is associated with adverse outcomes, particularly preeclampsia and preterm birth.[46,62,63]

Slow wave delta sleep (N3 sleep) is disrupted as a consequence of SDB, and this effect may be the mechanism for adverse pregnancy outcomes. Experimental studies in healthy subjects have demonstrated that disruption of N3 sleep can adversely alter insulin and glucose metabolism, sympathovagal balance, and cortisol levels.[64-66] Sleep loss and intermittent hypoxia also have been reported to induce changes in leptin and ghrelin hormones that regulate appetite, satiety, and energy metabolism.[67-69] Recent data suggest that dysregulation of leptin and ghrelin may contribute to the pathophysiology of gestational diabetes and preeclampsia.[70,71]

Impact of Sleep-Disordered Breathing on Pregnancy

Considerable heterogeneity in the definition of SDB is apparent among the studies examining pregnancy outcomes. In some of the largest cohorts, SDB was defined on the basis of symptoms such as self-reported habitual snoring. The method of ascertainment of those symptoms varied, with some using interviews and others using questionnaires. Among studies using objective testing, both in-laboratory and portable PSG, there is variation types of devices used, AHI criteria for establishing a SDB diagnosis, and timing of assessment (prospective-longitudinal versus cross-sectional). These differences lead to difficulty in summarizing the research data and in determining significance for clinical practice.

Sleep-Disordered Breathing and Hypertensive Disorders of Pregnancy

Hypertensive disease complicates 5% to 10% of all pregnancies[72] and can be classified into subtypes according to clinical features: gestational hypertension, preeclampsia-eclampsia, and preeclampsia superimposed on chronic hypertension.[73] The risk factors include obesity and increased maternal age, which overlap with risk factors for SDB. This overlap makes it difficult to investigate potential links between the diseases. Substantial evidence, however, suggests a link between SDB and pregnancy-related hypertension, with most studies demonstrating a two-fold increase in odds of gestational hypertension and preeclampsia.[36,40,74,75]

In two of the largest epidemiologic studies to date, OSA diagnosis was associated with preeclampsia (adjusted odds ratio [OR], 1.60 and 1.89, respectively).[74,76] Although the two studies have been criticized for limitations in the quality of assessment for SDB and pregnancy outcomes, smaller studies using symptoms based on PSG-diagnosed OSA show similar findings of a two-fold increase in the likelihood of preeclampsia in pregnancies complicated by SDB.[77,78] Other studies, however, have failed to confirm this increased risk.[12,79]

Sleep-Disordered Breathing and Diabetes in Pregnancy

Gestational diabetes, a condition characterized by carbohydrate intolerance with onset or recognition during pregnancy, is a common complication, affecting 5% to 8% of pregnant women.[72,80] The incidence of gestational diabetes has increased in recent years, paralleling the increase in maternal obesity.[81] Recognized complications of diabetes include gestational hypertension, preterm birth, malformations, fetal growth restriction or macrosomia, and stillbirth.[79] Studies of gestational diabetes have included SDB as an outcome and as a predictor. The relationship between SDB and diabetes in the general population is well established. Although a causal link has not been demonstrated, SDB has been noted to precede the onset of diabetes, and initiating treatment of SDB with continuous positive airway pressure (CPAP) improves glucose control in nonpregnant populations.[82,83]

Independent of other risk factors, all patients with SDB are at increased risk for development of type 2 diabetes (see Chapter 118). Emerging data indicate that this relationship also may also occur in pregnant women specifically as it relates to gestational diabetes. A systematic review of five observational studies noted that pregnant women with SDB were at increased risk for development of gestational diabetes (adjusted OR, 1.86; 95% CI, 1.30 to 2.42).[78] The presence of SDB was ascertained with questionnaires in four studies and with PSG in one study. A prospective study using longitudinal, objective assessment of SDB demonstrated a dose-response relationship between SDB and gestational diabetes. The prevalence rates of gestational diabetes with no SDB, mild SDB, and moderate to severe SDB were 25%, 43%, and 63%, respectively.[79] Conclusions drawn from these data must consider that not all studies were able to demonstrate a relationship between SDB and gestational diabetes that was independent of BMI.

Sleep-Disordered Breathing and Severe Maternal Morbidity

Severe maternal morbidity refers to conditions or events that if uninterrupted are proximal causes of maternal death. After significant gains in reducing maternal mortality, recent years have been plagued by plateaus and slight increases in maternal death rates in even developed countries.[84] Although most studies regarding SDB and pregnancy have been underpowered to detect severe morbidity, data from a large database of delivery-related hospital discharges are compelling: Among 55,781,965 women, OSA was associated with increased risk of hospital death (adjusted OR, 5.28), pulmonary embolism (adjusted OR, 4.47), and cardiomyopathy (adjusted OR, 9.01).[74] These relationships persisted and were exacerbated by obesity.

Implications of Sleep-Disordered Breathing for Cesarean Delivery

In a large cohort study, pregnant women who snored were more likely to undergo elective cesarean (OR, 2.25; 95% CI, 1.22 to 4.18) or emergency cesarean delivery (OR, 1.68; 95% CI, 1.22 to 2.30).[85] This relationship also has been reported by other smaller, observational studies that have used both symptom-based and PSG-diagnosed SDB.[38,40,75] Although the reason for this association is not immediately clear, it is postulated to be secondary to the high prevalence of obesity,

hypertension, and diabetes among women with SDB. These conditions increase the rate of pregnancy complications and promote induction of labor, which in turn can result in a higher rate of cesarean births.

Sleep-Disordered Breathing and Adverse Fetal Outcomes

To date, the potential effects of SDB on the fetus have received limited attention. Effects may be exerted directly or indirectly by exacerbation of the underlying comorbid conditions that often track with SDB. Initial reports of fetal complications came from case reports of fetal growth restriction and fetal heart rate decelerations.[77] In many of those cases, however, confounding comorbid conditions such as hypertensive disease and diabetes coexisted and associations could not be assumed. More recent studies have attempted to examine that relationship more closely.

Stillbirth

Stillbirth is a fetal death at or beyond 20 weeks of gestation.[72] No large-scale studies have been conducted to examine the role of SDB in stillbirth. Risk factors for stillbirth overlap with SDB risk factors and include advancing age, African American ancestry, smoking, maternal conditions such obesity, diabetes or hypertension, fetal growth restriction, and previous adverse pregnancy outcomes.[86] These correlations provide biologic plausibility for an association between stillbirth and maternal SDB, but such an association has not yet been demonstrated.

Miscarriage

Miscarriage or spontaneous abortion involves the loss of a pregnancy, usually within the first 3 months of conception. The estimated frequency of spontaneous abortion is between 12% and 24% of all clinically identified pregnancies. The risk factors for miscarriage include extremes of age, smoking history, obesity, previous miscarriage, hypertension, and diabetes. All of these are also overlapping risk factors for SDB. Data linking SDB and miscarriage are limited, and any discussions are mostly theoretical in nature. In a retrospective review of sequential clinic charts of 147 premenopausal women who had been referred to a sleep disorders clinic for an evaluation of sleep complaints, an association between SDB and number of miscarriages was demonstrated. In that review, overweight or obese women with SDB, especially those with moderate to severe SDB, were more likely to have had a miscarriage than women without SDB.[87]

Preterm Delivery

Preterm births are births that occur before 37 weeks of gestation. Although preterm birth occurs in 11.6% of births, it is responsible for a significant amount of neonatal morbidity and mortality. Preterm birth may be classified as spontaneous or medically indicated if it was precipitated by obstetric intervention for maternal or fetal benefit.[72] Data on preterm birth and SDB have been inconsistent. Large cross-sectional studies of SDB in pregnancy have reported higher risk of preterm delivery.[74,88] However, these studies were unable to differentiate spontaneous from medically indicated preterm birth. One smaller retrospective study noted an increase in medically indicated preterm delivery associated with preeclampsia among women with SDB[75] and a higher rate of preterm birth among pregnant women with SDB (29.8%) compared with control subjects of normal weight (12.3%).

Fetal Heart Rate Abnormalities

The fetal nonstress test was introduced in 1975 to describe fetal heart rate acceleration in response to fetal movement as a sign of fetal health.[72] It currently is the most common form of fetal assessment in obstetrics. A few studies have attempted to examine fetal well-being in response to nocturnal desaturations and results are conflicting. In a small study, 3 of the 4 women with snoring had fetal heart decelerations that accompanied maternal desaturation, but types of decelerations were not characterized.[89] In larger prospective studies with sample sizes of 20 women with PSG evidence of SDB, findings have not been replicated.[90,91] In these studies, despite episodes of oxygen desaturation, no fetal heart rate decelerations were noted during apneic events. In summary, it is unclear whether fetal hypoxia during maternal apnea occurs and, moreover, whether it is a primary contributor to adverse pregnancy outcomes associated with SDB.

Fetal Growth Abnormalities

Intrauterine growth restriction (IUGR) is defined as retardation of fetal development resulting in small size in relation to gestational age, with most studies using less than the tenth percentile as a cutoff growth criterion.[72] Findings from retrospective and observational studies of SDB and IUGR are mixed, with some failing to show any association. However, studies point to an increased likelihood of fetal growth restriction among pregnant women with moderate to severe SDB (OR, 1.44; 95% CI, 1.22 to 1.71).[92]

Low birth weight is an important cause of neonatal morbidity and is defined as birth weight less than 2500 g. Two potential mechanisms for low birth weight are well documented: preterm delivery and growth restriction. Regardless of the etiology, low birth weight is associated with higher rates of short- and long-term morbidity[72] and with maternal SDB among pooled studies (unadjusted OR, 1.39; 95% CI, 1.14 to 1.65).[78] Most studies have not found a difference between mothers with and without SDB when birth weight is assessed as a continuous value.[78] Two large studies found significant differences in birth weight, with maternal SDB–exposed neonates weighing 100 g less than unexposed neonates. However, this difference is of questionable clinical significance.[75,93]

Most of the focus on growth abnormalities and SDB has been on growth restriction. However, it is also important to consider that there may also be an association with large for gestational age (LGA) neonates due to the increased prevalence of obesity and diabetes among women with SDB. LGA neonates have higher rates of birth trauma, respiratory complications, and short- and long-term morbidity.[72] One study found more LGA infants born to women with SDB than to obese and normal-weight control subjects (17% vs. 8% and 2.6%, respectively).[75]

SCREENING FOR SLEEP-DISORDERED BREATHING IN PREGNANCY

Despite the growing prevalence of SDB and risk factors for SDB in pregnancy, obstetric providers generally remain unaware of this important sleep disorder. In a survey of

practitioners and patients regarding prenatal sleep assessment, less than 3% of clinicians reported routinely asking patients about snoring. Yet 32% of women reported that they snored, and only 5% reported being asked about snoring during a prenatal visit.[94]

Investigators have struggled to identify the most appropriate screening tools for SDB in pregnancy. As with all screening tools, questionnaires need to be easily implemented, inexpensive, and useful in the clinical setting for identifying patients requiring referral for more definitive diagnostic testing. Canonical symptoms of SDB include excessive daytime sleepiness, snoring, and witnessed pauses during sleep. Excessive daytime sleepiness most typically has been assessed with the Epworth Sleepiness Scale (ESS). However, because daytime sleepiness is so prevalent in pregnancy, the ESS does not seem to inform risk assessment of pregnant patients for OSA.[95,96]

Pre-pregnancy BMI and maternal age are inconsistent predictors of SDB. Older women and those entering pregnancy with higher baseline BMI, however, are at high risk for pregnancy-onset SDB.[36] In a study using PSG to assess for SDB in the first and third trimesters, maternal weight before pregnancy and maternal age were major predictors of SDB risk.[97]

Snoring may be one of the most useful single symptoms to identify at initial clinical assessment. In nonpregnant patients, habitual snoring has good correlation with PSG.[98,99] For example, for women who say they "often" snore, the PSG odds ratio is 3.8 higher than for nonsnoring peers. Similarly, for women who say they usually (always or almost always) snore, the PSG odds ratio is 16.3 higher than that for nonsnoring peers.[98] Thus, in the first trimester, habitual pre-pregnancy snoring may be a useful indicator of *preexisting* OSA. The Berlin questionnaire is widely used for SDB screening in nonobstetric populations, and a high-risk Berlin score has a sensitivity ranging from 68% to 86% and a specificity ranging from 46% to 95% for OSA.[100] In pregnancy, however, the Berlin score has poor predictive capacity (sensitivity of 35% to 39%, specificity of 64% to 68%).[39,96] By contrast, a pregnancy-specific tool that includes frequent snoring ("yes or no"), chronic hypertension ("yes or no"), and maternal age and baseline BMI as continuous variables performed well in predicting SDB in early pregnancy.[96]

In summary, habitual snoring, chronic hypertension, baseline BMI greater than 25 to 30 kg/m^2, and older maternal age are easily ascertained assessment elements that can effectively indicate the risk for either preexisting SDB or pregnancy-onset SDB.

DIAGNOSING SLEEP-DISORDERED BREATHING IN PREGNANCY

The available evidence is insufficient to guide diagnostic evaluation of SDB specific to pregnant patients. Accordingly, pregnant women in whom SDB is suspected should be evaluated in line with standard guidelines that recommend evaluation by a sleep specialist for a sleep-directed history and physical examination and sleep testing.[101] Sleep testing can be reasonably accomplished by laboratory PSG,[97] or home testing can be performed using type 3 portable monitors.[40] Validation of home monitors for pregnant women is limited, but the convenience makes it a viable option for women who are unable to spend a night away from home for a PSG study. The usual caveats regarding decreased negative predictive value associated with home monitoring apply to pregnant patients, and the need for laboratory PSG for sleep testing in patients with comorbid cardiac, pulmonary, psychiatric, or neurologic disease also applies to pregnant women.[102]

TREATMENT OF SLEEP-DISORDERED BREATHING IN PREGNANCY

Women with a preexisting SDB diagnosis and an established treatment regimen should continue that treatment during pregnancy. CPAP is considered to be safe and effective during pregnancy.[103,104] AHI increases appear to be relatively modest for most women,[9] and a pressure setting increase of 1 to 3 cm H_2O during the second trimester usually is needed.[103,104] CPAP settings are now more easily monitored because devices function in an autoset mode that adjusts pressures within a designated range and reports compliance and residual AHI data. Pregnancy-induced nasal congestion and increased BMI may necessitate adjustments in mask fit and humidification.

Use of a mandibular advancement device (MAD) with previously documented efficacy could be continued during early pregnancy. One study, however, demonstrated autoset CPAP superiority over MAD plus nasal strip in treating SDB in pregnant women.[105] At the very least, effectiveness of MAD should be monitored and a sleep study should be done early in the third trimester, when women are likely to have a higher AHI and require increased CPAP support.[103,104] Positional therapy can be recommended as an adjuvant, in the absence of extenuating circumstances, because most women have a positional component to their SDB, and nonsupine sleep generally is preferred during pregnancy.[106] Postpartum AHI values can be expected to return to pre-pregnancy levels.[107]

In women with known preexisting SDB not already undergoing treatment, immediate initiation of a CPAP therapy regimen is indicated. Autoset CPAP with data download is appropriate for these women and allows for rapid treatment, tracking, and adjustment as pregnancy progresses. MAD treatment is not recommended, because it generally takes several weeks to months to fit, adjust, and test the device. In the absence of a preexisting SDB diagnosis, data are lacking to support a strategy of universal screening for SDB in pregnancy. It is important to recognize, however, that as the general population is becoming more obese, clinicians are likely to encounter more women with symptomatic SDB in pregnancy. Obstetric care providers should refer any patient with suspected SDB to a sleep specialist for diagnosis and possible treatment.

To date, studies examining the effect of CPAP treatment on pregnancy end points have been insufficiently powered or limited in the scope of the end points.[103,104,108-110] The largest of these trials followed women already diagnosed with preeclampsia who were treated with CPAP and used improvements in fetal movement and cardiac output as primary clinical end points.[108,109]

In caring for obstetric patients with SDB, it is important to consider increased risk of perioperative complications associated with SDB.[111,112] An analgesic strategy that minimizes the need for systemic opioids should be considered. If used, opioids should be prescribed as single doses rather than by standing order. Monitoring maternal oxygen saturation should

be considered if systemic opioids are administered, and women should wear their CPAP device while in the hospital recovering from labor and delivery, as well as after discharge to home. Predelivery consultation with an anesthesiologist to plan intrapartum and postpartum pain management also should be considered.

CLINICAL PEARLS

- SDB prevalence and severity increase from the first to the third trimester of pregnancy.
- Risk factors for SDB in pregnancy have not been well characterized. Habitual snoring, chronic hypertension, maternal baseline BMI greater than 25 to 30 kg/m^2, and older maternal age are easily obtained information that may effectively indicate risk of either preexisting SDB or pregnancy-onset SDB.
- Data suggest that SDB during pregnancy may increase the incidence of adverse pregnancy outcomes such as gestational hypertension, preeclampsia, and gestational diabetes. Many studies, however, did not control for obesity, a strong risk factor for both SDB and adverse outcomes, nor did they clearly define a temporal relationship between SDB and the subsequent development of adverse outcomes.
- In pregnant women with a preexisting SDB diagnosis and an established treatment protocol, treatment should be continued during the pregnancy and the AHI evaluated for an increase in the early third trimester.
- In pregnant women without preexisting SDB, data are currently lacking to recommend a strategy of universal screening for SDB in pregnancy.

SUMMARY

SDB in pregnancy is an ongoing area of research. It is clear that SDB prevalence and severity increase as pregnancy progresses, especially among high-risk obese women. Data also suggest that SDB during pregnancy may increase the incidence of adverse pregnancy outcomes such as gestational hypertension, preeclampsia, and gestational diabetes. Many of the reported studies, however, did not control for obesity, a strong risk factor for both SDB and adverse pregnancy outcomes, nor did they clearly define a temporal relationship between SDB and subsequent development of adverse outcomes. The optimal way to screen for SDB during pregnancy has yet to be determined, but data suggest that instruments used in nonpregnant populations (e.g., Berlin questionnaire, ESS) perform poorly in pregnancy. Pregnant women in whom SDB is suspected should be evaluated and treated using standard guidelines; however, the available evidence currently is too limited to suggest that treatment of SDB during pregnancy can alter pregnancy outcomes.

Postpartum Period and Early Motherhood

Robyn Stremler; Katherine M. Sharkey; Amy R. Wolfson

Chapter 158

Chapter Highlights

- Sleep patterns are greatly disturbed during the postpartum period, particularly in the first few months, resulting in considerable daytime sleepiness and fatigue in the new mother. Infant care demands contribute to the poor sleep and altered circadian rhythms experienced by postpartum women.
- Multiple influences on maternal sleep are recognized, including the presence of other children in the home, return to work outside the home, infant feeding method, and infant sleep location. Women who report significant sleep loss and infant sleep problems are more likely to experience postpartum depression. Few evaluations of interventions to improve maternal sleep in the postpartum period have been performed.
- Reviewed in this chapter are the sleep changes that occur during the postpartum period and the impact of sleep patterns on maternal health during the early months of motherhood. Conclusions are presented within the context of sleep and circadian rhythm disturbances for childbearing women, and the implications for maternal role functioning and maternal–infant interaction are discussed.

OVERVIEW

It is likely that as long as there have been mothers, the experience of sleep disturbance and fatigue in the postpartum period has existed. However, sleep is difficult to study during postpartum recovery and the first few months after birth for several reasons: As might be expected, new mothers find it difficult to attend sleep laboratories for study; home polysomnography (PSG) may be intrusive; and sleep data collection, even by actigraphy or questionnaire, may represent a significant burden in the face of the demands of infant care.

Sleep disturbance during the postpartum period and its effects on maternal role functioning and maternal-infant interactions are not well understood. Confounding factors such as maternal age, type of delivery, type of infant feeding, infant temperament, return-to-work issues, previous birth experience, number of other children in the home, and availability of nighttime support from the partner or others may have an impact on quality and quantity of sleep in new mothers, especially until the infant begins to sleep through the night. Interventions to improve maternal sleep and fatigue in the postpartum period are limited, perhaps because of the universal nature of the experience and the belief that disturbed sleep is an unavoidable part of motherhood. Furthermore, consensus is lacking on what intervention modalities are most effective or regarding which women are most likely to benefit from treatment, although one intervention study showed greater improvements in sleep in women at higher risk for sleep disruption, including those with worse baseline sleep and greater social disadvantage[1] (see later under Interventions to Improve Maternal Sleep in the Postpartum Period).

PHYSIOLOGIC CHANGES DURING THE POSTPARTUM PERIOD

First-time mothers experience more disrupted sleep patterns than experienced mothers[2] (Box 158-1). All new mothers are at risk for development of anemia from iron demands of pregnancy, blood loss during delivery, common infections (endometritis, urinary tract, mastitis), and thyroid dysfunction. Any woman experiencing high levels of fatigue in the first few months after childbirth should be assessed for these conditions and treated.[3]

CIRCADIAN RHYTHMS AND THE POSTPARTUM PERIOD

Although growth hormone, prolactin, melatonin, cortisol, and thyroid-stimulating hormone each have a distinct circadian pattern of secretion, little is known about changes that may occur in the postpartum period and effects on sleep and daytime sleepiness. Delivery of the placenta reduces estriol and progesterone levels,[4] with accompanying increases in oxytocin and prolactin.

Melatonin levels and patterns of secretion may be altered in postpartum women by increased nighttime light exposure during provision of infant care, and by decreased daylight exposure secondary to limited activity outside the home. Changes in circadian rhythms, including melatonin secretion patterns, may influence subsequent sleep quality. Yet few studies have examined the influence of circadian rhythm disruption on sleep disturbance or fatigue in the postpartum period. In fact, the most commonly dispensed advice

Box 158-1 TYPICAL HORMONE, SLEEP, AND BEHAVIOR CHANGES DURING THE POSTPARTUM PERIOD

Hormones

Abrupt drop in progesterone levels from those in pregancy
Abrupt drop in estrogen levels from those in pregnancy
Prolactin levels fluctuate with lactation
Melatonin amplitude decreased

Sleep Patterns and Architecture

Sleep disrupted owing to infant care and feeding
Sleep more disrupted for first-time mothers than for experienced mothers
Tendency to sleep later into the morning hours
Increased slow wave sleep (delta sleep [i.e., N3 sleep stage])

Sleepiness and Sleep Challenges

Increased daytime sleepiness
Difficulty with sleeping; new mothers may nap if not employed outside the home
Issues of bed-sharing emerge

Mental Health Concerns

Risk of postpartum depression

regarding maternal sleep, the admonishment to "sleep when the baby sleeps," may not promote circadian rhythm entrainment. Sleep at night is most restorative when it occurs during usual sleep hours; entraining the mother's sleep to the infant's is less ideal than finding ways to more quickly facilitate the newborn's sleeping through the middle of the night.

Preliminary evidence in 22 infants studied between 2 and 10 weeks post partum indicates that greater daytime light exposure is associated with higher circadian amplitude, suggesting that manipulating ambient light may promote development of more consolidated sleeping patterns in infants.[5] Women at 4 and 10 weeks post partum exhibited elevated daytime melatonin excretion as well as blunted circadian rhythm amplitude relative to those nonpregnant nulliparous women,[6] and a recent study of circadian phase across the perinatal period showed differences in the time of dim-light melatonin onset of up to 2.5 hours in 12 women from the third trimester to 6 weeks post partum.[7] In addition, most women in this small sample showed a shortening of phase angle between melatonin onset and self-selected bedtime, indicating that they may go to bed "earlier" in their biologic night during the postpartum period. These differences suggest that altered circadian rhythms or failure of circadian entrainment may contribute to postpartum sleep disruption.[6,7]

SLEEP DURING POSTPARTUM RECOVERY

For the most part, maternal sleep efficiency is poor on the first night after delivery but begins to improve over the following days.[8] Being in labor during the night may be related to depressed mood during the first week after delivery[9] (see later under Postpartum Depression and Disturbed Sleep). Postpartum recovery generally is defined as that occurring during the first 6 months after delivery, although most women would say that the postpartum period continues from birth until the infant is sleeping through the night with predictable day and night sleeping patterns.[10] Average maternity leave for employed women varies by region; it is 12 months in Canada and around 10 weeks in the United States.[11] These differences in return to employment undoubtedly affect the mother and her family's sleep experience in the first year, but such comparisons have not been studied.

In a qualitative study of women during both pregnancy and the postpartum period,[12] naps were used as a way of coping with sleep loss at night. However, paid work demands and partner availability for child care determined if naps could occur. In a study of Israeli mothers still on maternity leave at 4 to 5 months post partum, findings included more infant wake time at night, shorter infant daytime naps, more maternal night awakenings, and greater parenting stress when compared with the mothers who returned to work.[13] The investigators suggested that women on leave from paid employment may not find opportunities to nap, and that perhaps women who return to work experience less stress because they have more control over their own schedule, with breaks from continuous caregiving. An alternate explanation is that returning to work was more feasible for a woman if her infant was sleeping more at night and if her family was experiencing less stress.

In the early postpartum period, a rapid decline in all placental hormones is seen, and 35% to 80% of women experience postpartum distress or "blues" approximately 3 to 5 days after childbirth. For most women, theses blues are confined to the first 2 weeks, but a major episode of postpartum depression can manifest at any time between 4 weeks and 12 months after childbirth.[14,15] Approximately 10% to 15% of women experience a major depressive episode in the postpartum period, a prevalence that is similar to that for women at other stages of life (see later under Postpartum Depression and Disturbed Sleep).

Both self-report and actigraphy studies have demonstrated that mothers have disturbed sleep after the birth of their baby and that they experience more nighttime awakenings from disruptions during the first 4 weeks in comparison with the end of pregnancy and later postpartum months.[16-19] Although total sleep time may change little over this period, a mother's sleep is far more disrupted and less efficient during these early postpartum weeks than at other points in her life. Women seem to compensate for their sleep disruptions by spending more time napping and sleeping later in the morning during the first month.[16-20] Compared with those during early postpartum recovery, average wake and rise times occur earlier at 3 to 4 months and at 12 to 15 months,[19] presumably because some women have returned to paid employment by those time points.

Although women often are advised to "sleep when the baby sleeps," investigations of napping in the postpartum period are few. A study of 51 mothers of 3-month-old infants examined factors related to mothers' decisions to take naps.[21] Nap taking was predicted by maternal perceptions of sleep disturbance, rather than by actual amount of sleep or infant wake time at night. Mothers who were engaged in more hours of employment or who had more children at home reported less napping. Almost one half of the women took no naps at all, and among those who did nap, the average length was 30 minutes. Similarly, actigraphic evidence determined that after postpartum week 2, fewer than 50% napped at least once per week, and among women who did nap, it was an average of only twice

a week.[22] A small study designed to assess the relationships between maternal sleep disturbance and fatigue and mother-infant interactions found that maternal napping was associated with improved interactions related to fostering cognitive growth.[23] Further research is needed to determine optimal timing and duration of napping and its effects on daytime alertness and cognitive function in the postpartum period, as well as to investigate any deleterious effects of napping, such as circadian disruption or insomnia.

Researchers have examined changes in fatigue from pregnancy into the postpartum period and through the year after birth, using self-report and physiologic measures such as progesterone levels, thyroid functioning, and iron or other nutrient deficiencies.[3,24-26] On the basis of these studies, primiparas and multiparas do not differ significantly in their perception of fatigue. The 3 to 6 weeks after delivery is especially fatiguing for first-time mothers, however, and fatigue remains high during the first 3 months post partum compared with pre-pregnancy reports.[24,26] Postpartum fatigue is associated with reduced sleep time, low hemoglobin, and low ferritin levels.[24] When these measures are taken together, researchers have concluded that the level of progesterone is unrelated to fatigue and that social factors, such as employment and family responsibilities, influence perception of fatigue during the postpartum period.[24,26] Work is emerging to suggest that the chronic partial sleep loss and postpartum fatigue experienced by women in the early months of caring for a new infant are associated with impaired cognitive performance.[27] The time course over which women return to their baseline levels of sleep quality and daytime functioning after delivery is poorly understood.

A small number of studies have described sleep architecture in the postpartum period. It appears that mothers have less stage 1 (N1) and stage 2 (N2) sleep and a significant increase in N3 slow wave (delta) sleep at 1 month post partum.[2,16,24,28-30] These sleep pattern alterations may be caused in part by prolactin-mediated increases in N3 (see later under Breastfeeding versus Formula Feeding).

INTERVENTIONS TO IMPROVE MATERNAL SLEEP

Interventions to prevent infant sleep problems have focused on infant sleep outcomes without measuring parental sleep outcomes.[31-33] These interventions typically provided parents with information related to infant sleep and strategies to limit development of unwanted sleep associations, to increase the infant's self-soothing ability, and to facilitate day-night entrainment. Although none of these studies evaluated the effects of the intervention on parental sleep outcomes, Wolfson and colleagues[33] examined effects on parents' stress and found that parents who received training on infant sleep reported significantly fewer life "hassles" than parents in the control group when the infant was 6 to 9 weeks of age. Similarly, several randomized clinical trials (RCTs) conducted with older infants[34-37] focused on providing parents with information on infant sleep and strategies to decrease night feeding and waking, but with no advice related to improving parents' sleep. Three of the studies[34,35,37] included maternal sleep outcomes and found reductions in problematic infant sleep behaviors and a concomitant improvement in self-reported sleep outcomes using the Pittsburgh Sleep Quality Index (PSQI).

Inasmuch as infant and parent sleep are presumed to affect one another, it is surprising that few studies have examined strategies to improve parents' sleep. Two samples of expectant parents were enrolled in an RCT of a modified sleep hygiene intervention to reduce parental nighttime sleep disruption.[1] Subjects in the experimental groups were seen in the last month of pregnancy and instructed to have the infant in a bassinet close to the maternal bedside, to use a white noise machine, and to use a nightlight to ensure low lighting. The two samples of first-time expectant parents consisted of those in stable relationships (n = 118) from fee-based childbirth classes and women (n = 122) recruited from free prenatal classes and clinics serving low-income women. In the socioeconomically advantaged sample, no group differences were seen in any sleep outcomes measured by actigraphy. In the low-income sample (in which the subjects reported worse sleep at baseline than socially advantaged participants), the intervention group attained significantly more nocturnal sleep (7.1 hours vs. 6.5 hours), better sleep efficiency (80% vs. 75%), and less wake time after sleep onset (19% vs. 23%) than control subjects at 3 months post partum.

A pilot RCT tested a behavioral-educational intervention designed to increase nighttime sleep and sleep continuity for 30 mother-infant dyads in the early postpartum period.[38] First-time mothers in the intervention group received a 45-minute meeting with a nurse in the immediate postpartum period in hospital, a written booklet, and weekly phone contact to reinforce information and problem-solve. On the basis of actigraphy data, women in the intervention group achieved almost an hour more sleep than the control group. In the large-scale RCT (n = 246) that followed this pilot study, no group differences were found on any outcome at 6 or 12 weeks post partum.[39] Although women in the larger trial were ethnically diverse, high socioeconomic status and support may explain lack of effect of the intervention.

The few published intervention studies to improve parent sleep provide little support for such strategies. Socially disadvantaged families may benefit most from advice regarding infant and maternal sleep, and future interventions should be tested in this population. An exploration of parents' beliefs around infant and parent sleep, and their experience of barriers, facilitators, and motivations related to implementing sleep strategies, would provide insight for development and testing interventions at points farther along in the first postpartum year.

Cognitive-behavioral therapy for insomnia (CBT-I) may be a feasible and effective treatment for women with postpartum sleep difficulties. In an open pilot study of CBT-I, Swanson and colleagues[40] treated 12 new mothers with comorbid postpartum depression and insomnia. They adapted core CBT-I strategies to accommodate infant care and also included components on facilitating infant sleep and requesting assistance with infant care. Participants demonstrated significant improvements in diary-reported sleep efficiency, sleep latency, and total sleep time, as well as a reduction in depressive symptoms. Future studies could examine this intervention in larger, randomized samples and test its efficacy as a preventive strategy.

Hall and colleagues[41] tested an intervention to help parents resolve their infant's sleep problems. In this pre- and post-test study of 39 couples, a statistically significant improvement in subjective sleep quality (2.2 point decrease in PSQI scores

from baseline) was achieved for both mothers and fathers at 6 weeks after the intervention. Without a control group, it is difficult to ascertain whether the improvement was due to the intervention or to better infant sleep with development over the 6-week period of the study.

Breastfeeding versus Formula Feeding

During the first 2 weeks after birth, rapid eye movement (REM) sleep is stable for women who breastfeed, but it gradually decreases for women who are not lactating.[42] Some parents choose to supplement infant feeding with formula in the hope that the infant would be better satiated, settle faster, and sleep longer at night, so that they could achieve more nighttime sleep.[43] Studies examining the relationships between infant feeding method and parental sleep with objective measures of sleep have found either no difference in total nighttime sleep[20,44] or preservation of sleep[43] for parents whose infants are breastfed. Although the available evidence related to characteristics of parent and infant sleep is conflicting, promotion of breastfeeding is recommended to optimize many other important infant and maternal health outcomes. Because supplementation of breastfeeding with formula often is perceived as a strategy to increase infant sleep at night, parents should be made aware that research findings do not support a recommendation of formula feeding as a means to improve sleep. For women planning to breastfeed, it may be helpful to know that no study asking parents to report on the quality of their sleep has reported any difference between parents with breastfed and those with formula-fed infants.

For lactating women, basal levels of prolactin are high, and a burst of prolactin secretion occurs at the onset of each breastfeeding event, regardless of when sleep occurs, although these bursts seem to be of a higher magnitude in the evening than in the morning.[45] Both basal levels and bursts of prolactin diminish to pre-pregnancy levels by approximately 3 months post partum. Blyton and colleagues[46] studied 31 women in their home environment with portable PSG. Lactating women had less light sleep (N1 and N2), fewer arousals, and more deep sleep (N3), especially in the second half of the night, compared with nonlactating postpartum women. No difference was observed in the amount of REM sleep or total sleep time between the two groups.[46] Within 24 hours of weaning, prolactin levels return to low basal levels and to the circadian sleep–associated patterns found in healthy adults.[47]

Bed-Sharing and Room-Sharing

Bed-sharing is defined as an infant sleeping in the same bed with the caregiver; previously, this practice was commonly referred to as cosleeping. Room-sharing refers to sleep situations in which the infant sleeps in the same room as, and in close proximity to, a parent or caregiver, but does not occupy the same bed. Room-sharing is the infant sleep arrangement recommended by the American Academy of Pediatrics and the Canadian Paediatric Society. Although few studies have examined the relationship between bed-sharing or room sharing and mothers' sleep-wake patterns, bed-sharing has become increasingly common during the postpartum period.[48-50] The proportion of usually bed-sharing infants in the United States rose from 5.5% in the period 1993-1994 to 12.8% in 1999-2000[50] and to 13.5% in 2010.[51] Bed-sharing has been associated with longer duration of breastfeeding.[52,53] Some studies suggest that bed-sharing reduces the risk of sudden infant death syndrome (SIDS), because a bed-sharing infant has more arousals from the mother's body heat, sounds, oxygen and carbon dioxide exchange, smells, movement, and touch.[49] It has been postulated that infants are at risk for SIDS because of an immature neurologic system and difficulty arousing from sleep to breathe.[49] However, greater risk of SIDS or asphyxiation for bed-sharing infants may be directly related to overheating, the presence of pillows and soft surfaces, and exposure to adults who are smokers, extremely fatigued, intoxicated, or obese.[54,55] In contrast with risks imposed by bed-sharing, room-sharing may decrease risk of SIDS by providing infant proximity to parental cues for arousal.[54,55]

Bed-sharing mothers report disrupted sleep that also is objectively verifiable. Mosko and colleagues[48] assigned 20 usually bed-sharing and 15 usually separate-sleeping mother-infant dyads to bed-share for one night and then to sleep separately the following night. In this PSG study, bed-sharing had no effect on REM sleep but increased the number of arousals and modestly reduced N3 deep sleep while increasing light sleep (N1 and N2) in the group of breastfeeding women. Women who routinely had their infant sleep in a separate room rated their sleep quality as lower on the night when they were assigned to bed-share, indicating that occasional bed-sharing may be more disruptive to self-reported sleep quality than routine bed-sharing.

In another study, first-time mothers (n = 246) provided information regarding infant sleep location at 6 and 12 weeks post partum along with actigraphy evaluation of sleep and subjective maternal sleep disturbance ratings.[56] Room-sharing was the most typical sleeping arrangement (for 46% of infants at 6 weeks and 39% at 12 weeks). At 6 weeks, 17% of families were usually bed-sharing; rates decreased to 12% at 12 weeks. At 6 weeks, usually bed-sharing mothers had shorter stretches of sleep than mothers with infants sleeping alone (130 vs. 156 minutes; P = .03) and more awakenings than mothers who were usually room-sharing or whose baby slept alone (11 vs. 9 vs. 8; P = .001). At 12 weeks, usually room-sharing mothers had shorter stretches of uninterrupted sleep than solitary sleepers (164 vs. 192 minutes; P = .04). No significant difference in maternal subjective sleep disturbance was found between infant sleep location groups. Because the trend for infant bed-sharing is on the rise,[51] the impact of bed-sharing or room-sharing on sleep for new mothers and fathers, as well as the infant's sleep, requires further investigation.

Sociocultural Factors

International and cross-cultural studies have demonstrated that mother-infant sleep behaviors differ in the postpartum period. The international literature highlights significant cultural variation in the sleep environment, infant care practices, and, of course, the meanings attributed to them. Ethnographic data suggest that sleep is construed as a form of social behavior in many societies.[57] Whereas a solitary-sleeping infant is a common goal for families in Western postindustrial settings, close maternal-infant contact at night is the cultural norm in many other cultural groups.[58] For example, bed-sharing is a common practice in Malaysia, Brazil, Thailand, and Japan, and among Maori and Pacific Islanders.[59-63] Outside of bed-sharing at night, infant sleep may occur in other locations, such as outdoors, as practiced in Finland and other Northern European nations,[64] or while the infant is carried in a sling, as in African hunter-gatherer cultures while the mother works during the day.[65,66]

Common elements in the social structuring of the postpartum period within a culture, such as mandated rest or sleep and assistance in tasks from relatives or midwives,[67] are likely to have effects on maternal sleep and well-being. In keeping with evidence of variation in risk factors and rates of postpartum depression across cultures, new mothers' experiences vary greatly; accordingly, it is imperative that their sleep patterns continue to be studied across cultures. These types of studies will add to a more nuanced understanding of sleep changes for mothers as well as to development of new interventions and strategies to maximize the family's well-being.

POSTPARTUM DEPRESSION AND DISTURBED SLEEP

Postpartum depression is the most common complication of childbirth. Up to 50% to 60% of all new mothers experience postpartum blues during the first 2 postpartum weeks. The blues manifest as excessive and unpredictable crying episodes, labile mood, and sadness during a time that is expected to be joyful. At some point 3 to 6 months after delivery, between 10% and 15% of new mothers experience diagnosable postpartum major depression.[68,69] Symptoms are similar to those of depression experienced at other times of life (see Chapter 137) but also include difficulty sleeping when the baby is sleeping at night and worrying about hurting the baby.[68] Various mechanisms for development of postpartum depression have been proposed, including the dramatic drop in progesterone and estrogen levels during the first few postpartum days,[69] poor supportive relationships, overly high expectations regarding the baby and motherhood, unexpected difficulties with labor and delivery or postpartum infant care, and a sudden shift in attention from the mother to the baby. These contextual variables, however, have not been directly related to postpartum depression.[68,69]

One additional contextual variable that seems obvious but has previously been overlooked is sleep deprivation and disrupted sleep-wake cycles. Sleep deprivation is likely to contribute to postpartum mood changes.[29,30,42,70] Being in labor during the night and a previous history of sleep disruption at the end of pregnancy may result in a higher incidence of postpartum blues.[9,19] Specifically, one study reported that new mothers had increased dysphoric mood during the first postpartum week, but this significant effect was eliminated when "time awake" was controlled in the analysis.[18] The frequency of night awakenings, rather than a change in hormone levels, was related to negative mood at 1 month post partum, and REM sleep onset latency was significantly shorter (less than 60 minutes) for postpartum women who reported higher levels of depressed mood.[70]

Moreover, mothers in whom depressive symptoms developed at 2 to 4 weeks post partum had significantly different sleep schedules at the end of their pregnancies compared with nondepressed mothers, with less total sleep from the end of pregnancy to early in the postpartum period than that for nondepressed women.[19] On average, mothers with subsequent postpartum depressive symptoms reported later rise times, longer naps, and more total sleep at the end of their pregnancies. Increased time awake during the night and poor sleep quality were strongly associated with increased negative daytime mood, or "blues," particularly in the first 4 weeks after childbirth.[18,19,43] Lee and colleagues[70] compared sleep patterns for women with positive postpartum affect at 1 month post partum with those for women with negative postpartum affect. The positive mood group had stable sleep times from the last trimester to 1 month post partum, whereas the negative mood group slept 80 minutes less at 1 month post partum.[70]

Associations between depressed mood and sleep schedule changes across the perinatal period may be mediated by circadian disruption. Sharkey and colleagues showed that later circadian phase in the third trimester of pregnancy was associated with more depressive symptoms at 2 and 6 weeks post partum in a small sample of women with a history of major depression who were not depressed during their third trimester.[7] Studies are needed to further examine the effect of altered sleep patterns from pregnancy to weeks or months post partum on development of postpartum depression.

The effects of infant sleep patterns on maternal sleep and development of postpartum depression also are essential to consider. Women with no major depressive symptoms at 1 week post partum were evaluated at 4 and 8 weeks to examine relationships among infant sleep patterns, maternal sleep, and depressive symptoms.[71] Mothers exhibiting major depressive symptoms at 4 and 8 weeks post partum were more likely to report getting less than 6 hours of sleep in a 24-hour period during the past week and being awakened by their baby three or more times between 10 PM and 6 AM. These findings suggest that infant sleep patterns and maternal sleep deprivation and fragmentation are significant contributors to the pathogenesis of postpartum depression. Report of infant sleep problems at 6 to 12 months of age also is associated with maternal major depressive symptomatology, even after adjustment for known risk factors such as history of depressive illness.[72]

Because infant sleep problems in these studies were based on maternal report rather than on objective evaluations of infant sleep, the possibility exists that depressed mothers may perceive their infant's sleep more negatively than nondepressed mothers, or may be more likely to report sleep problems whether they exist or not. Some evidence, however, suggests that treatment of infant sleep problems results in decreased incidence of maternal depression. Two randomized controlled trials of brief behavioral interventions to reduce infant sleep problems significantly decreased maternal reports of infant sleep problems and maternal symptoms of depression.[34,35] Similarly, Wolfson and colleagues[33] showed that parent training focused on developing healthy infant sleep patterns improves both parental competence and marital satisfaction and also decreases parental stress.

Postpartum depression can have an impact on maternal-infant bonding, as well as on marital satisfaction and infant development.[33] In a few women, the disorder culminates in postpartum psychosis, of which insomnia is one of the most frequent symptoms.[68,69,73,74] New mothers with a history of bipolar disorder may be at particular risk for development of postpartum psychosis consequent to sleep deprivation and require close monitoring for inability to sleep or decreased need for sleep.

Women with major postpartum depression had more REM sleep than women without a pregnancy-related depressive episode,[75] suggesting a greater sleep-related risk for depression. By contrast, among women with a history of mood disorder, less REM sleep was noted early in pregnancy and persisted up to 8 months postpartum in one study,[29] and REM sleep was not different during pregnancy or the postpartum period from that in matched control subjects.[76]

Women with depression during the perinatal period, and clinicians who treat them, must balance the risk of medication side effects in the breastfed infant with the risk of untreated depression for the mother's health and the infant's well-being. For these women, it is recommended that any drug therapy start with a low dose, to be increased slowly in small increments.[68] Cognitive-behavioral therapy, total or partial sleep deprivation, and light therapy may be useful behavioral interventions (see Chapters 85 and 137). Women with postpartum depression who were allowed to sleep only from 9 PM to 1 AM responded more favorably to this schedule of sleep deprivation therapy than women allowed to sleep from 3 to 7 AM.[75,77] Light treatment for postpartum depression may be more effective if administered over weeks rather than days.[78]

OTHER POSTPARTUM HEALTH ISSUES ASSOCIATED WITH DISTURBED SLEEP

Sleep disorders that may arise during pregnancy, such as sleep-disordered breathing, esophageal reflux, or restless legs syndrome, typically resolve after labor and birth of the infant.[79,80] Pharmacologic treatment for insomnia during lactation is of concern because of potential effects on the newborn's growth and development, as well as safety concerns regarding the mother's ability to awaken to respond to the baby at night. One observational study in 124 women, however, showed minimal sedation among infants breastfed by new mothers taking benzodiazepines, suggesting that breastfeeding need not be contraindicated when benzodiazepines are being used post partum.[81] (See Chapter 56 for a summary of common sleep-related medications and their ratings for potential harm to the newborn.)

Severe sleep deprivation in the postpartum period contributes to substantial postpartum weight retention. Women reporting short sleep duration (5 hours or less in a 24-hour period) at 6 months post partum are more than twice as likely to retain at least 5 kg of the weight gained during pregnancy.[82,83] Strategies to decrease postpartum obesity should include interventions to increase maternal sleep duration.

CLINICAL PEARLS

- If a specific sleep disorder such as restless legs syndrome, sleep apnea, or insomnia developed during pregnancy, evaluations during the postpartum period should determine if the difficulties have resolved.
- Complaints of excessive sleepiness, fatigue, or sleep loss should be pursued and evaluated by health care providers because of increased morbidity and mortality in the mother, potential harm to the newborn, and relationship to anemia, infection, thyroid dysfunction, and postpartum depression or psychosis.
- Evaluation for sleep disturbance and depression should be included in routine postpartum assessments; advice related to optimizing sleep in the postpartum period should be provided, taking into account cultural sleep practices.
- Severe sleep restriction in the postpartum period may contribute to retention of much of the pregnancy weight gain, development of depressive symptoms, and poor maternal-infant interactions, with potential risk to the health and safety of the newborn.

SUMMARY

The postpartum period is a time in a woman's life when sleep patterns are greatly disturbed. The unpredictable sleep patterns of the newborn and intense infant care requirements contribute to the poor sleep and alteration of circadian rhythms common among new mothers. These women attempt to counteract sleep loss at night through changes in their sleep schedules, including more frequent naps and sleeping later in the morning. Nevertheless, many women experience considerable daytime sleepiness and fatigue through the first few months. Additionally, the prevalence of postpartum depression is approximately 13%, and women who report significant sleep loss and infant sleep problems are more likely to experience depression. Complaints of excessive sleepiness, fatigue, or sleep loss should be evaluated by health care providers because of increased maternal morbidity and mortality, potential harm to the newborn, and high risk of postpartum depression. Evaluation for sleep disturbance and depression should be a part of routine postpartum assessments, and advice related to optimizing sleep should be provided. Only a few studies have investigated the feasibility and efficacy of improving maternal sleep in the postpartum period, and although some results are promising, more work is needed in this area.

Chapter 159

Sleep and Menopause

Fiona C. Baker; Hadine Joffe; Kathryn Aldrich Lee

Chapter Highlights

- The prevalence of sleep disturbances, especially difficulty maintaining sleep, escalates as women undergo the transition through menopause. Hot flashes are an important contributor to the increase in sleep disturbances.
- Depression, which also increases in prevalence as women approach menopause, contributes to poor sleep and also may develop secondarily to disrupted sleep, especially sleep disruption associated with hot flashes.
- When hot flashes are a primary source of sleep problems in peri- and postmenopausal women, hormone therapy can be an effective treatment. Nonhormonal therapies for vasomotor symptoms, such as selective serotonin reuptake inhibitors, also have been shown to improve sleep quality. More trials are needed to determine efficacy of nonpharmacologic approaches, especially cognitive-behavioral therapy, for alleviating sleep disruption associated with hot flashes in perimenopausal women.
- The prevalence of sleep-disordered breathing increases with the transition to menopause, attributed to weight gain and/or changes in adipose tissue disposition, as well as declines in reproductive hormones that can have an adverse impact on the upper airway. The preferred treatment is continuous positive airway pressure along with weight loss and exercise programs.
- In women, aging and the transition through menopause are accompanied by an increased prevalence of clinical conditions such as breast cancer, arthritis, fibromyalgia, and hypothyroidism. These clinical conditions or their treatments can adversely affect sleep. Sleep disturbances associated with these conditions may be further exacerbated by menopausal symptoms such as hot flashes.

PHASES OF THE MENOPAUSAL TRANSITION

Menopause is the anchor point of a woman's transition during midlife to nonreproductive status and is confirmed to be present after 12 months of amenorrhea. The median age at onset of the menopause transition is 47 years, and the median age for the final menstrual period (FMP) is 51.4 years,[1] but can range between 40 and 58 years of age. For many years, menopause was simply considered to be a consequence of depleted ovarian follicles (the primary source of estrogen and progesterone). Today, however, it is well recognized to be a transitional process consisting of a series of complex and interactive changes in the central nervous and endocrine systems, beginning several years before complete cessation of menstruation and continuing for several years thereafter.[2]

A menopause staging system was developed in 2001 and updated in 2011 by the Stages of Reproductive Aging Workshop (STRAW) to provide a consistent way to describe reproductive aging through menopause[3,4] (Figure 159-1). The *menopause transition* is divided into early and late stages. The early transition is marked by increased variability in menstrual cycle length (variation by 7 days or more in the length of consecutive cycles), and the late menopause transition is marked by the occurrence of amenorrhea for 60 days or longer, usually accompanied by intermittent increases in follicle-stimulating hormone (FSH) level to greater than 25 IU/L.[3] During the menopause transition, breast tenderness, vasomotor symptoms (hot flashes and night sweats), and sleep difficulties within ovulatory cycles are maximal in the late-luteal phase,[5,6] and hot flashes become more prominent, with increasing frequency of anovulatory cycles, during the late menopause transition.

Postmenopause is divided into an early stage, lasting 5 to 8 years until levels of estradiol and FSH stabilize, and a late stage, when reproductive hormone changes are limited.[3] During the first 2 years of postmenopause, FSH levels continue to increase, estradiol levels continue to decrease, and vasomotor symptoms are most likely to occur. The term *perimenopause* describes the menopause transition and the first year of postmenopause.

Menopause is a universal phenomenon, but the timing and duration of these transitional stages and associated signs and symptoms vary considerably from woman to woman and cannot be easily predicted. Midlife (middle age) is considered to be between 40 and 60 years of age, but there is no "generic" midlife woman.[7] In addition to the complexity of menopausal stages and hormonal fluctuations, midlife women may have young children at home, have grown children leaving home, and be caring for elderly parents or spouses. Other common challenges and new-onset problems in this age group include

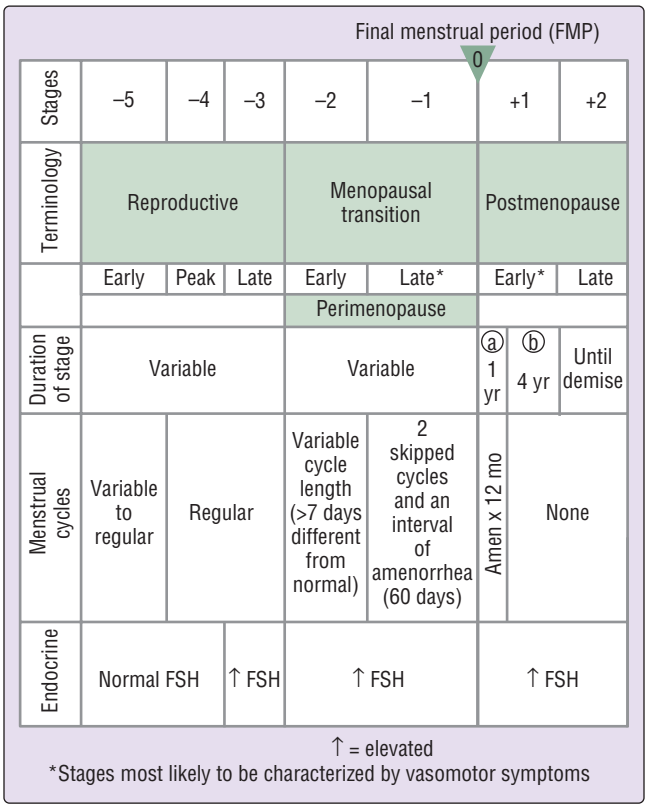

Figure 159-1 Stages of normal reproductive aging in women. The final menstrual period (FMP) is the time in a woman's life when she has missed 12 consecutive menstrual periods (amenorrhea) (*a*) and is considered early postmenopausal for the next 4 years (*b*) before becoming late postmenopausal for the duration of her life. Before permanent cessation of menstrual cycles, women vary in the duration of their cycles during the stage known as perimenopause. Follicle-stimulating hormone (FSH) is elevated throughout early and late perimenopause because of a lack of adequate levels of ovarian hormones to inhibit secretion of FSH from the hypothalamus. Note that the reproductive stages most likely to include hot flashes and night sweats are late perimenopause and early postmenopause, with wide and unpredictable variations in duration of these stages of normal reproductive aging. (Modified from Soules MR, Sherman S, Parrott E, et al. Executive summary: Stages of Reproductive Aging Workshop [STRAW]. *Fertil Steril* 2001;76:874-8.)

increasing career demands, changes in lifestyle, weight gain, and chronic health conditions. All of these scenarios can adversely affect a woman's sleep during menopause.

Surgical Menopause

Menopause can be induced by hysterectomy or bilateral oophorectomy (removal of both ovaries). After cesarean births, hysterectomy is the second most common surgery for women in the United States.[8] The average age at hysterectomy is 40 to 45 years; approximately 37% of American women have had a hysterectomy by the age of 60 years. Historically, at least one half of these women also underwent concurrent bilateral oophorectomy, although that percentage has declined in recent years.[9] In women who are premenopausal or perimenopausal, a bilateral oophorectomy induces an abrupt cessation of any ovarian hormone secretion, leading to a decline in estradiol and increased likelihood of menopausal symptoms. Although risk status for vasomotor symptoms may differ between women who undergo hysterectomy with ovarian conservation and those who have had a bilateral oophorectomy,[10] most studies have combined these two groups of women into a "surgical menopause" group and compared them with women who experience natural menopause.

NORMAL SLEEP PATTERNS DURING MENOPAUSE

Surveys and Self-Reported Sleep Measures

Population survey studies show that sleep problems are more common in midlife women transitioning to menopause and during postmenopause compared with premenopause (as confirmed in several reviews[11-13]). Intermittent awakenings are the most common sleep complaint and also are reported to be one of the most bothersome symptoms.[14,15] Being perimenopausal was associated with greater likelihood of trouble sleeping relative to being premenopausal, even after adjustments for age and ethnicity in the multicenter Study of Women's Health Across the Nation (SWAN).[6,16] These results were confirmed in the SWAN longitudinal analysis of women undergoing the menopausal transition (see Figure 159-2).[15] Similarly, the Australian Longitudinal Study on Women's Health found that difficulty sleeping was associated with menopause status, but not age, after adjusting for several confounders including mental health score and night sweats.[17] Another prospective study of midlife women in the United Kingdom reported increased trouble sleeping as the women progressed through menopause, although the relationship was most evident for women with severe as opposed to moderate sleep difficulties, especially after adjustment for factors such as vasomotor and psychological symptoms.[18] Longitudinal data from the Seattle Midlife Women's Health study also showed an increase in sleep problems, especially intermittent awakenings, across the menopause transition and early postmenopause.[19]

Sleep difficulties across the menopause transition and early postmenopause have been linked to several factors, including changing reproductive hormone levels (decrease in estradiol and increase in FSH),[15] hot flashes, depression, perceived poor health, and stress[19] (Table 159-1). Personality traits such as neuroticism have also been linked with midlife sleep difficulties.[20]

Sleep and Surgical Menopause

Surgical menopause (hysterectomy with or without bilateral oophorectomy) has been linked with poor sleep as well as other menopausal symptoms.[15,18,21] In a cross-sectional analysis of the SWAN cohort, a sample of women who had a bilateral oophorectomy and who were not using hormone therapy showed the highest prevalence of sleep difficulty, independent of age or years since surgery.[16] This effect was related to vasomotor symptoms. Women who undergo bilateral oophorectomy are at increased risk for more severe hot flashes than women in natural menopause,[10] and these severe hot flashes could have a greater impact on sleep. Disturbed sleep and fatigue are common postoperative symptoms after hysterectomy[22]; however, women who had a hysterectomy (with or without oophorectomy) were still more likely than other midlife women to complain of trouble sleeping even years after surgery,[23] suggesting greater vulnerability to sleep difficulties in these women. Increased sleep disturbances after surgical menopause is not necessarily only due to abrupt changes in reproductive hormone levels but could also be related to a worse health profile before menopause or worse health after hysterectomy compared to women with

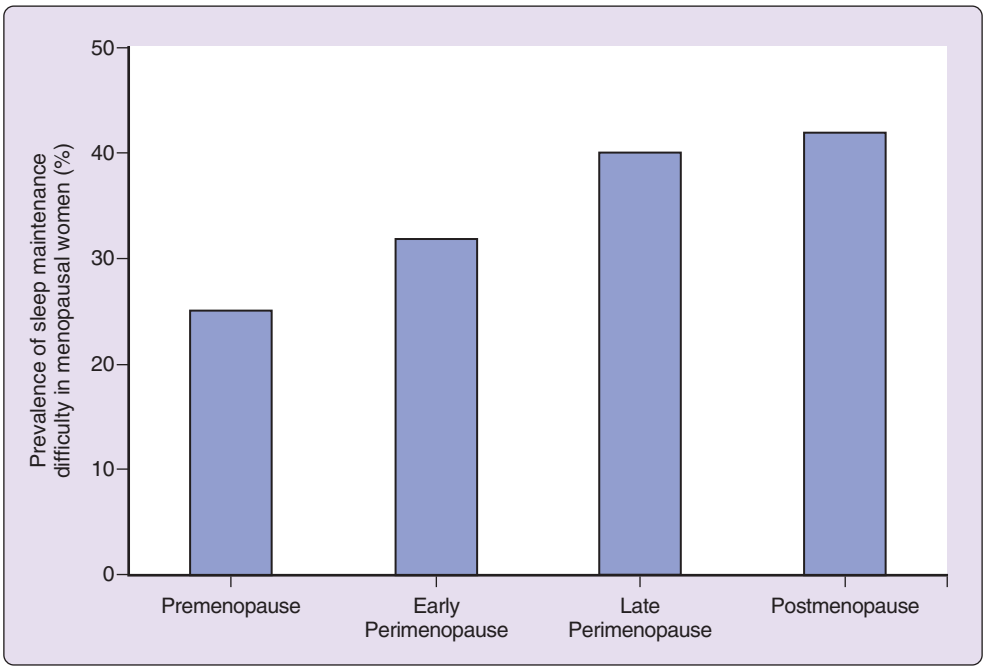

Figure 159-2 Percentage of women participating in the Study of Women's Health Across the Nation (SWAN) ($n = 3045$) reporting difficulty maintaining sleep at least three times per week in the past 2 weeks as they progress through menopause transition. Women in transition from pre- to early menopause were more likely to have difficulty maintaining sleep than women who stayed premenopausal. Women in transition from early to late menopause also were more likely to have difficulty maintaining sleep. (Data from Kravitz HM, Zhao X, Bromberger JT, et al. Sleep disturbance during the menopausal transition in a multi-ethnic community sample of women. *Sleep* 2008;31:979-90.)

Table 159-1 Common Sources of Sleep Disturbance in Peri- and Postmenopause

Menopause-Specific	General	Sleep Disorders	Mental Health Issues	Comorbid Illnesses

Evaluation and management of sleep disturbance during the menopause transition. *Semin Reprod Med* 2010;28:404-21; and from Hall M, Buysse DJ, Nofzinger EA, et al. Financial strain is a significant correlate of sleep continuity disturbances in late-life. *Biol Psychol* 2008;77:217-22.

natural menopause.[18] Significant depression or anxiety may occur after hysterectomy and contribute to sleep problems in some women,[22] although psychological symptoms are not more common overall after hysterectomy with or without oophorectomy.[24] As discussed later, use of hormone therapy (HT) effectively improves sleep in surgically menopausal women.

Race and Ethnic Factors

Limited evidence suggests that race and ethnicity influence the extent of sleep disturbances across the menopause transition. SWAN researchers have shown that prevalence rates for difficulty sleeping were lowest in midlife Japanese women (28.2%) and highest in midlife white women (40.3%).[25] In their longitudinal analysis, few interaction effects between race/ethnicity and menopausal status were found.[15] However, a recent meta-analysis of 24 studies investigating the relationship between menopausal status and subjective sleep disturbance reported that perimenopausal, postmenopausal, and surgical-menopausal white and Asian women, but not Hispanic women, are more likely to experience sleep disturbance than premenopausal women, suggesting that culture and ethnicity may influence the extent of sleep disturbance associated with menopause transition.[26]

Insomnia Disorder

In addition to an increase in symptoms of insomnia and dissatisfaction with sleep typical for the menopause transition, an increase in the prevalence of insomnia disorder also has been documented. Chronic difficulty initiating sleep, nonrestorative sleep, global sleep dissatisfaction, and a diagnosis of insomnia (as defined in the *Diagnostic and Statistical Manual of Mental Disorders,* 4th Edition) all are more frequent among perimenopausal women than among

premenopausal and postmenopausal women.[27] A major factor in the increased prevalence of insomnia disorder in midlife women appears to be hot flashes; experiencing hot flashes (mild, moderate, or severe) was strongly associated with a diagnosis of insomnia, along with chronic pain, poor health, and white race.[27] In this situation, nocturnal hot flashes and night sweats may be precipitating factors for the development of insomnia in vulnerable women. For women who have preexisting insomnia, the approach to menopause may exacerbate their symptoms, with hot flashes precipitating further sleep disruption and possibly worsening their insomnia.

Objective Sleep Measures

Although strong evidence from epidemiologic studies shows an increase in trouble sleeping during the menopause transition and early postmenopause, findings from objective polysomnography (PSG) studies have been mixed. Cross-sectional studies comparing sleep architecture in pre-, peri-, and postmenopausal women have shown few differences in sleep,[28] or show better sleep after menopause. The Wisconsin Sleep Cohort Study of 589 midlife women showed that postmenopausal women had more slow wave sleep and a lower proportion of time spent awake despite reporting less sleep satisfaction compared with premenopausal women.[29] Perimenopausal women in this study also had a better objective sleep quality with more slow wave sleep and less stage 1 sleep than premenopausal women. Kalleinen and colleagues showed that age had a much greater effect on PSG-recorded sleep than menopause status, and although women in late-reproductive stage (45 to 51 years of age) and postmenopausal women had similar PSG measures, their objective sleep quality was much poorer than that in a group of young women.[30]

It should be kept in mind that subjective and objective sleep variables measure different constructs, such that they may deviate in their estimates of sleep quality. It also is possible that the menopause transition may be associated with disturbances in the sleep electroencephalogram (EEG) or processes related to sleep that are not evident from PSG scoring, but that could adversely affect subjective sleep quality. Recently, Campbell and colleagues applied quantitative analysis to the sleep EEG in women participating in the SWAN study.[31] As reported by other investigators, no differences were found in PSG measures by menopause status, despite a subjective worsening of sleep with the transition to menopause. However, quantitative analysis of EEG activity revealed elevated beta EEG activity during sleep in late perimenopausal and postmenopausal women compared with early perimenopausal and premenopausal women; an effect partly explained by the presence of frequent self-reported hot flashes. Elevated beta activity during sleep suggests a greater level of hyperarousal in these women, which could contribute to their perception of a poorer sleep quality.

A theoretical basis for the menopausal hormone changes with potential impact on sleep comes from studies in animals showing that reproductive hormones, specifically progesterone and estradiol, affect sleep-wake regulation, although the precise mechanisms remain unclear.[32] In women participating in SWAN, an increase in FSH over time was associated with reports of difficulty staying asleep, and a declining level of estradiol over time was associated with trouble falling asleep and staying asleep.[15] Other studies also have reported associations between low or faster rates of change in estradiol levels and poor subjective sleep.[33,34] Changes in PSG sleep parameters also have been linked with hormonal changes. SWAN data showed that a more rapid rate of change in FSH over a 5- to 7-year period was associated with higher percentage of slow wave sleep and a longer total sleep time.[35] At the same time, a greater rate of change in FSH was associated with a poorer subjective sleep quality.[35] Change in estradiol was unrelated to any PSG measures, although a lower estradiol/testosterone ratio (sampled 3 to 6 months before the sleep study) was associated with less wakefulness after sleep onset.[35] Although these analyses have been limited by infrequent, annual assessments of hormonal profiles during a reproductive stage with frequent fluctuations in hormone levels, further longitudinal data can refine the current understanding of how objective and subjective sleep quality is impacted by the hormonal changes that characterize menopause transition.

Circadian Rhythm Influence during Menopause

One prominent theory of reproductive aging is that menopause results from the aging of multiple pacemakers in the brain and ovaries that control and coordinate a variety of circadian and other rhythms.[2] The suprachiasmatic nuclei of the hypothalamus are a primary source of these endogenous rhythms and their synchrony. The sleep-wake cycle is the most visible human circadian rhythm, and it is profoundly influenced by the suprachiasmatic nuclei and by other circadian rhythms, particularly rhythms of body temperature and melatonin secretion.

Numerous studies have shown estrogen's impact on circadian rhythms in female mammals.[32] These data suggest that circadian control of sleep might be perturbed by menopause, and preliminary data from studies in women suggest a change in the circadian system. For example, under constant routine conditions, postmenopausal women have an advanced melatonin acrophase time and tend to have an earlier time of melatonin onset compared with late-reproductive stage women, which could be a consequence of menopausal hormone changes, although an effect of chronologic aging cannot be completely excluded.[36] An advanced circadian phase could contribute to more fragmented sleep or early-morning awakening in postmenopausal women. Of interest, after 6 months of HT, postmenopausal women showed a delay in melatonin acrophase, with no change in absolute melatonin levels.[37]

SLEEP DISTURBANCE ASSOCIATED WITH VASOMOTOR SYMPTOMS

It has long been suspected that at least some component of the self-reported sleep disturbance associated with menopause is secondary to vasomotor symptoms (hot flashes and night sweats). A hot flash (often called a hot flush or "night sweat" when it occurs during the night) is a sudden, transient, and recurrent sensation of moderate to intense heat that usually begins in the upper body. It is primarily a thermoregulatory phenomenon,[38] with all the characteristics of a heat dissipation response: (1) peripheral vasodilation, which causes increased heat loss, and (2) increased sweating, which causes evaporative cooling.

Tremendous individual variability in the frequency of hot flashes between women and within women over the course

of menopause transition and postmenopausal years is characteristic, probably as a result of individual differences in hypothalamic thermoregulatory activity and higher levels of cortical activity in the insula.[39] Recent evidence suggests that inputs to the gonadotropin pulse regulator from KNDy neurons (kisspeptin, neurokinin B, and dynorphin) in the hypothalamus also may contribute to vasomotor symptoms during menopause transition.[40] A hot flash typically lasts no more than a few minutes, but such episodes can reoccur frequently throughout the day and night in some women. The perceived intensity of the flash also can vary widely, from mild to severely disruptive. Some women experience 20 or more hot flashes each day, whereas others report only 1 or 2 per week. Data from large population studies suggest that some women continue to have hot flashes for many years, even decades, after menopause, highlighting the potential importance of hot flashes as a source of sleep disturbance well after midlife.[41]

Although hot flashes most commonly are associated with menopause, they also occur after bilateral oophorectomy, with use of aromatase inhibitors and selective estrogen receptor modulators such as tamoxifen for treatment of estrogen-sensitive breast cancer, and during gonadotropin-releasing hormone agonist (GnRHa) therapy. These therapies are used in women to treat breast cancer, uterine fibroids, and endometriosis. These same therapies also are used in men to treat prostate cancer. Surgical menopause, smoking, obesity, depression, anxiety, and heightened somatic attunement increase the likelihood of hot flashes.[42] The prevalence of hot flashes also varies by racial/ethnic groups, with SWAN data showing that African American women are most likely, and Chinese American and Japanese Americans least likely, to report experiencing hot flashes.[42] It is not clear whether differences in the experience of hot flashes are the result of differences in lifestyle stressors, diet, cultural factors, or unidentified biologic factors,[43] although genetic variability plays a role.[44] Self-reported hot flashes and night sweats are consistently associated with reduced self-reported sleep quality and chronic insomnia.[6,15,16,27] However, results from several cross-sectional studies examining the association between hot flashes (either self-reported or objectively recorded with skin conductance measures) and objectively measured sleep quality have been mixed.[11] In a recent controlled model of new-onset hot flashes, nocturnal hot flashes were definitively linked with more frequent PSG awakenings, more wake time after sleep onset (WASO), and more stage 1 sleep in young premenopausal women treated with a GnRHa.[45] The results were the same when hot flashes were measured by both self-report in the morning and by physiologic changes in skin conductance during the night. These experimental data validate the subjective complaint of poor sleep quality associated with menopausal hot flashes. The magnitude of sleep fragmentation appears to be proportional to the number of nocturnal hot flashes, whereas daytime hot flashes show no association with objective or subjective sleep quality.[45] This finding suggests that interindividual variability in the link between hot flashes and sleep disruption may be explained in part by variability in the proportion of hot flashes experienced at night, as well as the absolute number of nocturnal hot flashes. Of interest, the sleep fragmentation occurring in women with nocturnal hot flashes induced after GnRHa treatment appears to exceed the number of hot flashes measured objectively or reported,[45] suggesting that factors other than individual hot flash events contribute to sleep disruption in these women. Another recent study quantified the impact of hot flashes on objective sleep in perimenopausal women by totaling the intervals of wakefulness associated with any hot flashes during the night. A majority of hot flashes (69%) were associated with awakenings across the night, and hot flash–associated wake time was responsible for more than 25% of objective WASO. Hot flash–associated wake time correlated with self-reported estimates of wakefulness.[46] These findings confirm that hot flashes are a significant—but not the only—contributor to subjective and objective sleep disturbance in perimenopausal women.

Recent studies have shown the importance of examining the impact of hot flashes on aspects of sleep other than traditional PSG measures and on non-EEG correlates of sleep. Campbell and colleagues[31] reported that beta EEG activity during sleep was related to menopausal status, a relationship that was partly explained by self-reported hot flash frequency. Other investigators have shown that hot flashes are associated with changes in autonomic nervous system activity,[47,48] with a reduction in parasympathetic (vagal) activity and increased heart rate at the onset of a nocturnal hot flash even in the absence of an EEG arousal.[49] When a hot flash is associated with an arousal or awakening, autonomic regulation is further affected, because even brief arousals are associated with a shift to sympathetic dominance.[50] Multiple hot flashes throughout the night could therefore affect nocturnal autonomic nervous system balance and, consequently, the restorative aspects of sleep.

Although nocturnal hot flashes constitute an important component of sleep disturbance during midlife, not all women who have menopause-related sleep problems complain of hot flashes.[11] As discussed later, sleep in midlife women may potentially be affected by the presence of a sleep-disordered breathing (SDB) problem, mood disturbance, or medical condition. It is therefore critical to evaluate other causes of sleep disruption in midlife women, many of which may co-occur with hot flashes.

PSYCHOLOGICAL SYMPTOMS AND SLEEP DISTURBANCE IN MENOPAUSE

Depression

Several longitudinal studies have found that depressive symptoms increase during menopause transition.[51] In addition to an increase in the proportion of women experiencing mild depressive symptoms during the transition, a smaller number of women experience a major depressive episode during this period of hormonal fluctuation.[52] The first onset of depression can occur in menopause[53-55]; however, the vast majority of women who experience depression during menopause transition have a previous history of depression, and their illness episode represents a recurrent depression episode.[52]

Depressive symptoms in menopausal women are strongly linked to vasomotor symptoms.[56,57,11] In some women, this association is explained at least in part by the fragmented sleep that occurs with a hot flash[45] and independently contributes to depressive symptoms.[57] Although fragmented sleep could contribute to depression, depression also has a significant negative impact on sleep in general (see Chapter 137), and this is equally the case for depression during menopause.

Peri- and postmenopausal women with depression report worse sleep quality[58] and have more objectively measured sleep disturbance than women without depression.[59] Compared with nondepressed women with hot flashes, women with concurrent hot flashes and depression spend less time in bed and have longer sleep onset latency, shorter total sleep time, and lower sleep efficiency, rather than more frequent awakenings.[59] Peri- and postmenopausal women with major depression also have increased levels of nocturnal melatonin, as well as a phase delay in their melatonin secretion.[60]

Anxiety and Life Stressors

Whereas the association between depression and sleep disturbance in perimenopausal women has been well studied, anxiety has received less attention, and it remains unclear whether the frequency of anxiety symptoms or anxiety disorder is increased in women undergoing the menopausal transition.[61] However, higher levels of anxiety[62,63] and perceived stress[16] have been linked with complaints of poor sleep quality in midlife women, and anxiety also is associated with PSG-measured longer sleep latency and lower sleep efficiency.[64] Financial strain, a chronic stressor associated with lower socioeconomic status, was found to be an independent correlate (along with race) of sleep complaints and lower sleep efficiency in SWAN study participants; financial strain, as well as other stressors, could interfere with sleep by way of stress pathways including negative affect and autonomic-endocrine dysregulation.[65] Multiple stressors for midlife women are recognized, including jobs, family responsibilities, relationships, and caring for sick or elderly relatives,[66] and these stressors may impact sleep. Midlife women may consider sleep a low priority that competes with many other demands of motherhood, career, marriage, and caring for aging parents.[67] Conversely, disrupted or poor sleep quality may affect a woman's ability to cope with life stressors. It has been suggested that being symptomatic during menopause transition is itself a unique stressor and may compound preexisting stressors.[66]

TREATMENT OF SLEEP DIFFICULTIES IN MENOPAUSE

Estrogen and progesterone levels fluctuate dramatically during menopause transition, ultimately declining to very low levels in the postmenopausal period. Consequently, estrogen therapy (ET), typically in combination with a progestin (together called hormone therapy [HT]), was commonly prescribed for midlife and older women on a long-term basis in an effort to counter hormone deficiency and to protect against osteoporosis, heart disease, and Alzheimer dementia. In 2003, however, the Women's Health Initiative clinical trial results abruptly reversed this practice by showing that use of a common HT regimen over an average of 7 years significantly increased risk of breast cancer, stroke, heart disease, and vascular dementia.[68]

Women are now being advised to avoid long-term exposure to HT, and to use HT for only a short time to provide relief from hot flashes and improve quality of life during menopause transition. As a result, although historical data are available on the benefit of ET or HT for specific sleep conditions, hormonal treatments are rarely used as firstline therapy for sleep conditions unrelated to hot flashes. Included in this section is information about the effects of HT, when available, on all sleep problems associated with menopause, because these conditions may be concurrent and complicate hot flash–related sleep disturbance.

Hormone Therapy and Sleep

Multiple studies in midlife women without sleep complaints show that ET, with or without a progestin, and progestin therapy (PT) alone, improve perceived and, to a lesser extent, PSG indices of sleep quality.[11,13] When PSG measures were obtained in several small studies of midlife women without sleep complaints, some showed inconsistent and small benefits of ET or PT for sleep fragmentation measured with PSG, and others showed no benefit or a negative effect. A limited number of investigations have examined the effectiveness of HT for insomnia in midlife women, and findings have been mixed. Some show improvement[69,70] and others show no effect[71] on perceived sleep quality and PSG measures for women with an insomnia diagnosis.

Inconsistent findings among studies may be attributed to differences in treatment duration, timing of treatment in relation to menopause transition, or even differences in HT formulations. Preliminary studies suggest benefit of natural progesterone over the synthetic progestin medroxyprogesterone on perceived sleep quality and selected PSG parameters.[11] One reason for these potential differences is that unlike medroxyprogesterone acetate, micronized progesterone is metabolized to potent neurosteroids such as allopregnanolone and pregnanolone. These neurosteroids interact with the same brain gamma-aminobutyric acid (GABA) type A receptors as for sedative-hypnotic medications, and they are soporific.[72] When taken in the morning, natural progesterone can result in drowsiness,[73] particularly at higher doses. Accordingly, women on HT may be advised to take progesterone at night.

The mechanisms through which ET or HT may improve sleep are poorly understood. Animal models suggest that estrogen may increase homeostatic drive for sleep[74] and reduce prostaglandin synthesis in the ventrolateral preoptic nucleus of the hypothalamus,[75] whereas the hypnotic effect of progestins is mediated through an effect on GABA-active metabolites.[76] Because the greatest benefits of ET for sleep have been observed in women with co-occurring hot flashes, ET presumably may improve sleep as an indirect consequence of its salutary effects on nocturnal hot flashes.[77]

In summary, ET and PT independently and together have positive effects on sleep quality in midlife and older women, independent of hot flashes. Data are more extensive and stronger for self-reported sleep problems than for PSG sleep measures; several small studies on the latter report mixed results. Data supporting the efficacy of HT for primary sleep disorders in midlife women are limited and do not support use of these interventions for underlying sleep disorders. Progesterone also may contribute potential adverse sedating effects as well. As a result, HT is not typically recommended for sleep problems unless hot flashes are thought to be the primary source of the sleep disruption.

Hormone Therapy for Sleep Disturbance Associated with Hot Flashes

Sleep disruption associated with hot flashes may be treated in several ways. ET has historically been the standard treatment.

Numerous epidemiologic studies and small clinical trials have shown that ET/HT reduces hot flashes and concurrently improves self-reported sleep quality.[11,13] The effect varies, ranging from a significant but clinically small benefit to alleviation of hot flashes as highly predictive of improved sleep. PSG studies generally have replicated these findings. In women who experienced frequent hot flashes, ET decreased the number and duration of nighttime awakenings, increased REM sleep, and shortened sleep onset latency.[13] However, in several small studies of women with only mild or infrequent hot flashes, neither ET nor HT had a measurable effect on PSG measures of sleep stages.

Recent data also show efficacy of a novel treatment that combines estrogen therapy and a selective estrogen receptor modulator for perceived sleep quality in women with hot flashes, particularly at lower doses of the selective estrogen receptor modulator.[78] Overall, HT can be expected to have a therapeutic effect on perceived sleep quality among women with hot flash–related sleep disruption.

Hormone Withdrawal

When HT is discontinued, it commonly is stopped abruptly. The sleep effects of withdrawal from HT are unknown, although abrupt estrogen withdrawal is shown to result in significant hot flashes,[79,80] which points to probable sleep consequences with abrupt HT discontinuation. Among women who stop HT, sleep disturbance is an importance predictor of HT reinitiation.[81]

Selective Serotonin Reuptake Inhibitors, Serotonin-Norepinephrine Reuptake Inhibitors, and Gabapentin

In the past decade, nonhormonal therapies using selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), or GABAergic agents have become established treatments for vasomotor symptoms, both in patients with breast cancer and in healthy midlife women.[82] The vast majority of women enrolled in these hot flash clinical trials had comorbid insomnia symptoms, permitting investigation of the effects of these interventions on insomnia symptoms that commonly co-occur with hot flashes. In recent trials, the serotoninergic antidepressants escitalopram,[83] venlafaxine,[84] and paroxetine[85] all have been shown to be more effective than placebo in reducing insomnia symptoms and improving sleep quality. Although the magnitude of the effect on sleep symptoms is modest in some studies, it was unexpected that sleep concerns would diminish, inasmuch as these agents can induce or exacerbate sleep problems in other populations receiving such treatments for mental illness.[86] Similar to serotoninergic agents, the synthetic GABA-type neurotransmitter gabapentin is another nonhormonal agent used to treat hot flashes, and preliminary evidence also shows a benefit for sleep complaints.[87]

Hypnotics

Selective GABAergic agents such as zolpidem and eszopiclone have been shown to improve sleep onset[88,89] and sleep maintenance[89,90] in women with vasomotor symptom–associated insomnia.[88-90] Randomized controlled trials show efficacy of zolpidem 10 mg[90] and eszopiclone 3 mg[88] for ameliorating poor sleep quality and for managing sleep-onset and sleep-maintenance insomnia, resulting in improved quality of life. For those with hot flashes, eszopiclone also reduced the number of hot flashes reported at night, but not during the day,[89] suggesting that it helps women sleep through their hot flashes, although a direct benefit for alleviation of hot flashes may be obtained when drug levels are high. Zolpidem also has been shown to augment the therapeutic effect of SSRIs/SNRIs on sleep disruption in women with hot flashes, resulting in improved quality of life.[91]

Although these selective GABAergic therapies are effective, dosages may need to be adjusted in midlife women. Recent data show that women are more likely than men to have detectable zolpidem levels on the morning after ingestion, resulting in next-day slowed reaction time.[92]

Cognitive Behavior and Alternative Therapies

Although complementary and behavioral therapies may reduce hot flash frequency or severity in some women,[93,94] data from randomized clinical trials do not support the efficacy of treatments such as soy, black cohosh, or omega-3 regimens, or of yoga or exercise.[95-98] Exercise did have a modest salutory effect on insomnia symptoms in women assigned to an exercise regimen to treat hot flashes.[98] Studies assessing the efficacy of cognitive-behavioral therapy (CBT) for insomnia, specifically in women with hot flashes, are ongoing, and a initial trial of a menopause symptom–focused CBT trial in patients with breast cancer showed some benefit for sleep quality among women with hot flashes.[99]

PRIMARY SLEEP DISORDERS

As women proceed through the menopausal process and beyond, they are at increased risk for development of a primary sleep disorder such as SDB, attributed to aging as well as menopause-related factors. In a sample of midlife women with sleep complaints, 53% had sleep apnea, periodic limb movement disorder, or both. The major predictors of poor sleep efficiency were apnea-hypopnea index (AHI), periodic limb movement index, arousals associated with these disorders, and total number of arousals, whereas the presence of hot flashes was not a significant predictor of objective sleep efficiency in the model.[62] These data highlight the importance of recognizing and treating primary sleep disorders in midlife women.

Sleep-Disordered Breathing

The well-documented gender gap in prevalence of SDB[100] begins to narrow with menopause, and menopause has long been described as a risk factor for SDB.[101] Partial upper airway obstruction, characterized by hypoventilation and carbon dioxide retention, appears to be more common than sleep apnea in postmenopausal women.[102] In studies with large samples of women that have controlled for important confounders influencing SDB severity, strong support has emerged for the hypothesis that menopause increases the risk of SDB.[103-105] Bixler and colleagues[103] found a ratio of 1 woman for every 3.3 men with apnea in their sample of 1741 men and women between 20 and 100 years of age; this ratio fell to 1 postmenopausal women for every 1.44 men once women were matched with men by age and body mass index (BMI). In an analysis of the women in the sample, the prevalence rates for mild SDB (defined as AHI between 0 and 15, together with a self-report of moderate or severe snoring) and

more severe SDB (AHI of at least 15) were higher in postmenopausal women not using HT than in premenopausal women, even after adjusting for age and BMI. In another large study, the prevalence of sleep apnea was higher in women older than 55 years of age, presumed to be postmenopausal (47%), than in women younger than 45 years, presumed to be premenopausal (21%), even after controlling for BMI and neck circumference and confounding effect of age.[104] Postmenopausal women also had a higher mean AHI than premenopausal women.

Young and colleagues[105] examined cross-sectional and longitudinal PSG data collected on 589 midlife women participating in the longitudinal Wisconsin Sleep Cohort Study. The detailed attention paid to menopause staging in this study allowed the investigators to determine SDB prevalence and odds ratios for premenopause as well as perimenopause and postmenopause. Postmenopausal women were 2.6 times more likely than premenopausal women to have SDB (defined as AHI of at least 5) and 3.5 times more likely to have more severe SDB (AHI of at least 15). The likelihood of having SDB was not significantly higher for perimenopausal women than for midlife premenopausal women. However, the findings did suggest that the risk for SDB increases throughout the menopause transition. With stratification of data on the years since the subjects' last menstrual period, a significant linear trend emerged toward increased risk for AHI of at least 5, with increasing postmenopause duration up to 5 years (see Figure 159-3). Strengths of this study were the combined cross-sectional and longitudinal data analysis and the careful use of multivariate models to adjust for several known risk factors for SDB, particularly age, BMI, smoking, and alcohol use. Despite the inclusion of these potent risk factors in the analyses, menopause status remained a strong independent risk factor for SDB.

Several factors may contribute to an increased risk of SDB after menopause. An important factor is weight gain or a change in the distribution of adipose tissue, which progressively accumulates in the upper part of the body after menopause. Excess weight is a problem for midlife and older women, with more than 35% in the United States considered obese.[106] The prevalence of SDB is highly correlated with excess weight.[107] After menopause, there is also a preferential increase in intraabdominal or visceral deposition of fat relative to other areas of the body,[108] which may be due in part to menopause-related hormonal changes, as supported by the finding that HT decreases the shift to visceral adiposity and can lower serum lipid levels.[109,110] The relationship between visceral fat and SDB is especially strong and believed by some to be the principal culprit leading to SDB.[111] Thus the increased adiposity and visceral fat associated with menopause places women at increased risk for SDB. It would be worthwhile for future studies to consider these factors, in addition to BMI, when investigating predictors of SDB in midlife women. Another factor that could contribute to the increased incidence of SDB after menopause is the decline in levels of endogenous estrogen or progesterone.[101] Studies show that progesterone increases ventilatory drive and increases activity of upper airway dilatory muscles.[112] Popovic and White[113] found that genioglossus muscle activity was highest in the luteal phase of the menstrual cycle (when progesterone levels are high) in young women and lowest in a group of postmenopausal women, although upper airway resistance did not differ between the two groups of women. Muscle activity increased in the postmenopausal women after they received combination HT. Progesterone's stimulatory effect on respiration is believed to be mediated through estrogen-dependent receptors,[114] so the menopausal decline in both of these hormones presumably may affect respiratory function.

On the basis of the evidence for a protective role of progesterone on ventilation, together with epidemiologic evidence of the association between menopause and increased

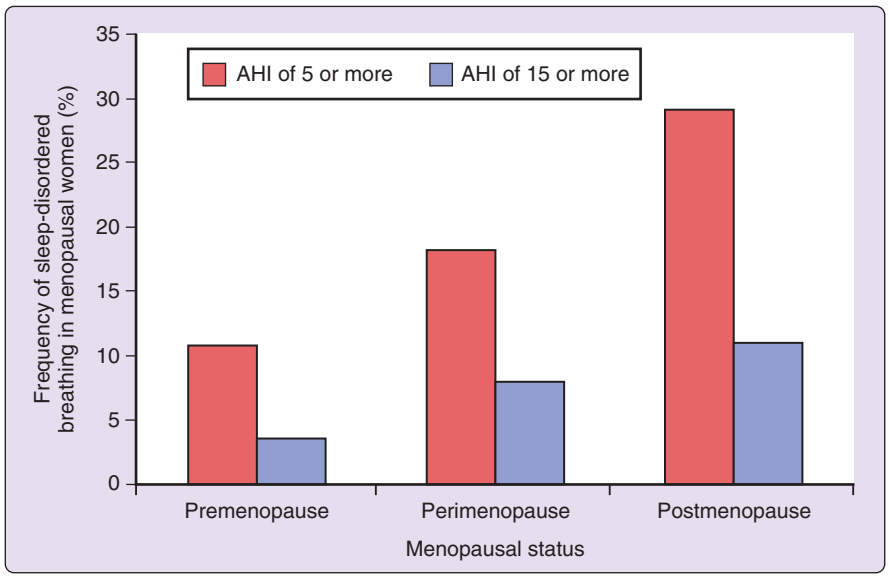

Figure 159-3 Prevalence of sleep-disordered breathing (SDB), indicated by apnea-hypopnea index (AHI) cut-off levels of 5 and 15 events/hour, in premenopausal ($n = 498$), perimenopausal ($n = 125$), and postmenopausal ($n = 375$) women who participated in the Wisconsin Sleep Cohort Study. Prevalence increased across menopausal groups. (Data from Young T, Finn L, Austin D, Peterson A. Menopausal status and sleep-disordered breathing in the Wisconsin Sleep Cohort Study. *Am J Respir Crit Care Med* 2003;167:1181-5.)

risk of SDB, it might be expected that HT would be effective at preventing or treating SDB. Indeed, in epidemiologic population studies, HT has been associated with a lower prevalence of sleep apnea in postmenopausal women.[103,105] This relationship was confirmed in the Sleep Heart Health Study[115] even after introduction of controls for well-documented differences (e.g., education level, body weight, health awareness) between women who used HT and those who did not. However, clinical trials that have evaluated the effects of estrogen, progesterone, or both on SDB in postmenopausal women have yielded conflicting results.[116] Although exogenous progesterone administration in postmenopausal women with SDB was associated with improved nocturnal ventilation in a number of studies, no change was seen in the number of apneas or hypopneas.[117-119] The wide variability in responses to HT among women suggests that if these hormones affect SDB, they do so through a specific mechanism that is not common to all cases of SDB. In view of the health risks associated with using HT, continuous positive airway pressure remains the treatment of choice for SDB in perimenopausal and postmenopausal women. Also, weight loss and exercise (specifically to reduce adiposity) should be strongly considered in the SDB treatment plan for any midlife or postmenopausal woman.

Restless Legs Syndrome and Periodic Limb Movement Disorder

The prevalence of restless legs syndrome (RLS) and periodic limb movement disorder (PLMD) increases with age, and women are 37% more likely than men to report RLS symptoms.[120] Women also are more likely than men to report the early-onset form of RLS (symptoms experienced before the age of 45 years). Whereas RLS and PLMD have been strongly linked with female reproductive life events such as pregnancy (see Chapters 95 and 156), an association between RLS or PLMD and the hormonal changes of menopause is less clear.

On the basis of survey data, most female patients with RLS (69%) retrospectively reported a worsening of their symptoms after menopause.[121] However, the prevalence of RLS among women increases with age,[122] which may confound the relationship between RLS and menopause per se. In a population study of Swedish women, a strong association was found between vasomotor symptoms and RLS; however, no relationship was noted between use of HT and RLS.[122] The incidence of PLMD is high in postmenopausal women,[123] and this disorder contributes to poor objective sleep quality in midlife women.[62] Evidence from current studies, however, does not support a strong link between PLMD and menopausal hormone changes. In a group of asymptomatic postmenopausal women, the incidence of periodic limb movements was unrelated to estradiol or FSH levels.[123] Furthermore, short-term ET did not alter the incidence or intensity of limb movements.[123] The increase in prevalence of RLS and PLMD after menopause may be related more to aging than to the menopause transition.

OTHER CLINICAL CONDITIONS WITH POTENTIAL EFFECTS ON SLEEP

As women age, coincident with the onset of menopause, health conditions are likely to develop, which can have an adverse impact on sleep. Cancer, neurologic disorders, cardiovascular or pulmonary disease, diabetes, hypothyroidism, gastroesophageal reflux disease, and musculoskeletal disease all are associated with sleep disruption.[13] Poor sleep could increase the risk of developing some of these conditions and/or exacerbate their severity.

Cancer

With age, women are more likely to develop cancer of the breast, lung, colon, ovary, gallbladder, or thyroid gland, and sleep disturbance is a common correlate. As discussed in Chapter 130, the etiology of cancer-related sleep disruption often is complex, with multiple factors likely to precipitate sleep problems. These include pain and discomfort, physical effects of the cancer itself, depression and anxiety, and side effects of chemotherapy or radiation treatment such as nausea, vomiting, diarrhea, or urinary frequency. In addition to the sleep-disrupting factors commonly experienced by most patients with cancer, women undergoing treatment for breast cancer are likely to experience hot flashes.[124] Hot flashes are a side effect of chemotherapy-induced ovarian disruption, and they also occur with the use of adjuvant hormone therapy.

Women with estrogen receptor–positive tumors are treated with the antiestrogen tamoxifen, aromatase inhibitors (e.g., anastrozole, letrozole, exemestane), and a GnRHa (e.g., leuprolide), or they undergo bilateral oophorectomy to prevent endogenous estrogens from stimulating the growth of residual tumors or micrometastases. More than 50% of tamoxifen users experience hot flashes, which usually are more frequent and more severe than hot flashes associated with natural menopause.[125]

Hot flashes could be a precipitating factor in the development of insomnia in breast cancer survivors.[126] As discussed in detail earlier, a strong association has been documented between hot flashes and sleep disruption in women going through menopause transition, and the same is true for women with breast cancer. Hot flashes in breast cancer survivors are associated with a less efficient, more disrupted sleep.[127] HT is not indicated for treatment of hot flashes in women with a history of breast cancer,[128] making alternative therapies a necessity. SSRIs and SNRIs, clonidine, and gabapentin have been shown to reduce the number and severity of hot flashes in women with a history of breast cancer.[129] Coadministration of a hypnotic, such as zolpidem, with an SSRI/SNRI improves sleep and quality of life more than use of an SSRI/SNRI alone in women with breast cancer who also have hot flash–associated sleep disturbance.[91] CBT also is beneficial, leading to improvements in subjective sleep as well as mood and quality of life that are maintained beyond 1 year in women with insomnia secondary to breast cancer.[130] Other interventions such as acupuncture, exercise, or melatonin also have shown some benefit for alleviating hot flashes and improving sleep quality, although larger clinical trials are needed.

Thyroid Dysfunction

The prevalence of thyroid disease, particularly hypothyroidism, increases with age and is far higher in women than in men. For midlife women living in iodine-replete areas, the prevalence of impaired thyroid function (i.e., thyroid-stimulating hormone [TSH] values outside the euthyroid range) is 9.6%.[131] In these cases, a majority (6.2%) of affected

women have elevated TSH, indicating clinical or subclinical hypothyroidism. Because hypothyroidism typically is characterized by tiredness and fatigue, and not sleepiness, such complaints in perimenopausal and postmenopausal women should be clinically evaluated in light of a TSH level.

Women with hypothyroidism may be more likely than euthyroid women to have SDB (see Chapters 20 and 132), suggesting that hypothyroidism also may be a risk factor for SDB.[132] Midlife and older women with hypothyroidism also should be screened for clinical signs and symptoms indicative of SDB.

Hypertension

The prevalence of hypertension rises sharply with onset of menopause. The etiopathogenic mechanism of this phenomenon is complex and still under investigation, but two factors strongly associated with hypertension are obesity and SDB, conditions common in perimenopausal and postmenopausal women.[133,134] The National Health and Nutrition Examination Survey III (NHANES III) documented a strong association between hypertension and BMI in women.[133] For women in midlife, the prevalence of hypertension was approximately 10% when BMI was less than 25 but rose to 39% when BMI was 30 or higher. For women older than 60 years of age, hypertension occurred in 52% with a BMI less than 25, but the prevalence was greater than 72% if BMI was 30 or higher. Midlife women are at increased risk for development of hypertension and SDB by virtue of the higher prevalence of obesity in this age group, rather than hormonal or menopausal factors per se. Sleep duration and efficiency were unrelated to hypertension with introduction of controls for several confounders in midlife women who participated in the SWAN study.[135]

Fibromyalgia

Fibromyalgia is a clinical disorder characterized by widespread pain and the presence of specific tender points. Sleep disturbance is a core symptom. The prevalence of fibromyalgia is higher among women (3.4%) than among men (0.5%), and the disorder is most common in women older than 50 years of age.[136] A sex difference in clinical presentation also has been noted, with symptoms of sleep disturbance and fatigue being three times more common in women.[136] A link between reproductive hormone changes and fibromyalgia has been hypothesized,[137] and some evidence suggests that at least for some women, fibromyalgia symptoms start after the onset of menopause,[138] when estradiol levels decline. However, estrogen therapy had no effect on pain thresholds or tolerance in postmenopausal women with fibromyalgia, but the potential benefit for relief of symptoms such as sleep disturbance and depression was not investigated.[139]

Neurodegenerative Disorders

Sleep disruption can be an early symptom of neurodegenerative conditions such as Parkinson or Alzheimer disease (see Chapters 92 and 96). These disorders occur more often in postmenopausal women than in age-matched men. Genetic factors and changes in biologic hormone mileu related to menopause may play an important role.[140] However, more research is needed to investigate possible associations among sleep disruption, estradiol decline, and development of neurodegenerative disorders in women.

CLINICAL PEARLS

- Sleep difficulties are more common in midlife women transitioning to menopause compared with premenopause, with intermittent awakenings being the most common and bothersome complaint. Nocturnal hot flashes are an important component of sleep disturbance in midlife women, and both hormonal and non-hormonal therapies that alleviate hot flashes are associated with improvements in sleep quality.
- Sleep-disordered breathing is more common in women after menopause, which may in part be attributed to a change in the distribution of adipose tissue, with an increase in intraabdominal fat. Reports of fatigue or sleep complaints in postmenopausal women, possibly combined with hypertension and excessive weight, should prompt consideration of snoring and SDB in a clinical evaluation regardless of whether excessive daytime sleepiness is reported.

SUMMARY

Menopause is a normal event in a woman's life. It is the physiologic centerpiece of a major developmental stage in the normal aging process, marking the transition from a reproductive to a nonreproductive stage of life. Most women now live long enough to become menopausal and can expect to live at least another 30 years beyond their FMP. The number of postmenopausal women in developed countries is increasing as a consequence of longer life expectancy. In the United States, approximately 1.5 million women reach menopause each year, and it is predicted that by the year 2020, 45.9 million women will be older than 55 years of age.[141] The transition to menopause and postmenopause is associated with an increased prevalence of sleep problems, which may be attributed partly to menopausal hormone changes and associated vasomotor (hot flashes and night sweats) and mood symptoms but also to concomitant primary sleep disorders, chronic health conditions, and midlife stressors.

Insomnia and fatigue are among the most frequent health complaints of perimenopausal women, including those who are not seeking treatment for menopausal symptoms. SDB is more prevalent in midlife women, which may be related to hormonal changes as well as increased adiposity and centripetal weight gain. An association between menopausal symptoms and sleep disruption, as well as the impact of SDB and other clinical conditions on sleep in menopause, has been well documented and is the subject of ongoing research. Hormonal and nonhormonal treatments for menopause-related sleep disruption of variable efficacy have been described.

Chapter
160 Polysomnography and Beyond

Max Hirshkowitz

Chapter Highlights

- Polysomnography began as a research method and provided fundamental descriptions of the sleep process. Sleep staging resulted. PSG evolved into a medical diagnostic procedure applied largely for diagnosing and treating sleep-related breathing disorders but also for identifying parasomnias and nocturnal seizures.
- Advances in biosensor and digital technologies improved polysomnography by eliminating paper, reducing data storage requirements, and allowing for additional signal analysis. A subset of polysomnographic cardiopulmonary recording channels were adapted for sleep apnea diagnosis and are now often used in home sleep testing.
- Actigraphy emerged as a research method for studying insomnia and circadian rhythm disorders. It too evolved into a medical technology.
- With advances in miniaturized sensor technology, wearable and other devices have become popular as consumer products for self-monitoring fitness and sleep. Whether these devices will advance the current understanding of sleep in large populations and/or improve sleep health remains to be seen.

Polysomnography (PSG) began as a research tool informing early investigators about brain activity during sleep. It provided an objective, quantifiable method and enabled scientific discovery. From PSG studies it became clear that sleep was not uniform throughout a sleep episode. Distinctly different processes emerged and took prominence in a fairly orderly manner. However, each polysomnogram produced massive amounts of data. Consequently, researchers needed a data reduction scheme to summarize and make generalizations about sleep; thus sleep staging was invented. Armed with sleep stage metrics, scientists could describe progressive changes across a night and across the lifespan, as well as differences between men and women. Concurrent activity of organs, tissues, muscles, and gland became focus areas. Sleep alterations occurring in response to interventions (e.g., sleep deprivation, drugs, stressors) were subjected to laboratory scrutiny.

When Eugene Aserinsky discovered rapid eye movement (REM) sleep,[1] another natural avenue for comparison opened. Because dreaming occurred during REM sleep, the REM

process captured the imagination of many researchers. Sleep science migrated to a place under the umbrella "psychophysiology." A research society formed with the moniker "The Association for the Psychophysiological Study of Sleep" (APSS). Animal studies revealed neuronal innervations arising from the pons, ascending to the lateral geniculate nuclei, and then continuing to the occipital regions (pons-geniculate-occipital [PGO] waves) during REM sleep. REM sleep was conceptualized as a different state of human consciousness (or, for more reductionist thinkers, as a unique state of central nervous system organization). REM's discovery reinforced conceptualization of sleep as being composed of unique states, rather than as an interplay of different processes. Immediately, any measurable phenomenon occurring during sleep became fair game for comparing activity during REM sleep versus all sleep states other than REM. Consequently, a major component of the sleep state became known as non-REM (NREM) sleep, even though REM sleep represented only 20% to 25% of sleep time.

With sleep divided into REM and four different NREM categories (stages 1, 2, 3, and 4) investigators applied PSG to characterize underlying and overt sleep processes.[2] The most obvious characteristic of the temporal relationship between NREM and REM sleep was a consistent alternation, with an approximate 90-minute cycle length. Intrigued also by REM sleep's seemingly independent homeostatic response to deprivation, neurologists, psychiatrists, and psychologists seized the opportunity to test hypotheses concerning the role of REM and NREM sleep in physical and mental functions.

Methodologic issues spawned innovation. Long-duration recording necessitated improved recording equipment. Sensor technology advanced to permit study of concurrent physiologic activities. Analytic techniques borrowed from other disciplines were applied to summarize finer-grain activity over time.

Although still the standard technique for scientifically studying sleep physiology, in the 1970s, PSG evolved into a medical procedure used to diagnose specific sleep disorders. Within a decade, the importance and prevalence of sleep-related breathing disorder became very apparent to sleep clinician-scientists. Before long, diagnosing obstructive sleep apnea developed as the predominant application for PSG (in Silicon Valley parlance, PSG's "killer app"). Even today, the vast majority of PSGs performed on any given night will be for diagnosing or treating sleep apnea.

As PSG's momentum increased clinically, recording techniques evolved dramatically. The digital age arrived and analogue amplifiers and paper chart drives rapidly became extinct. Computerization rendered PSG data storage problems (a huge issue when PSGs were recorded on paper) moot. Warehouses were replaced by filing cabinets and eventually by high-density disk drives or cloud storage. Quality, compatibility, and other technological issues emerged during this transition; over time, however, things steadily improved.[3] Ultimately, standards were adopted by clinical societies, and they continue to evolve.[4]

Of interest, PSG created "big data" long before tools were available to handle it all. Right out of the gate, sleep staging brought PSG summary down to less than 1000, 30-second pages. These stages could be summarized and indices calculated. Computerization made calculation easier, but very little changed with respect to the way sleep was analyzed. To a large extent, the computer became a recorder-reviewing station with basic parameter calculation capability. For decades, and even now, the signal processing and computational power of digital PSG are vastly underutilized. Computers can count specific waveforms (e.g., sleep spindles) and analyze wave patterns (using Fourier transforms, period-amplitude analysis, or complex demodulation). They can detect movements and respiratory events, calculate their periodicity, and determine their association with central nervous system changes. Initially, or at least up to the turn of this century, available computing resources were arguably stretched to accomplish such analysis in real time. Researchers faced memory, storage, and processor speed limitations. However, today's wireless (cloud) technology and inexpensive massive storage devices provide access to nearly unlimited computing resources.

The success of PSG for diagnosing sleep-disordered breathing may have ultimately rung its own death knell. Diagnostic procedures' goals involve disease verification and/or severity determination. Mainstream procedures are subject to close economic scrutiny by payers at all levels. Expensive procedures attract the attention of gatekeepers. Consequently, cardiopulmonary home sleep testing has arisen as a more economical alternative for confirming sleep apnea when clinical suspicion and pretest probability are high. PSG's indication for diagnosing insomnia had already been jettisoned by third party payers, except in cases in which all therapeutics remained notably unsuccessful. Nonetheless, PSG continues to be used as the objective technique for measuring sleep in scientific studies and clinical drug trials.

On a different technologic front, actigraphy arose as an alternate method for assessing activity-inactivity patterns over prolonged time periods. Harking back to Kleitman's basic rest-activity cycle (BRAC)[5] and creating a human analog to caged animals' wheel running, actigraphy provides information about sleep-wake patterns and circadian rhythm. Finer-grain analysis in connection with use of a light sensor potentially informs about insomnia, nocturnal awakenings, and circadian disorders. Integrating additional sensors (e.g., pulse, temperature, and skin conductance) stand to improve concordance between actigraphic and PSG-derived measures.

As often happens, after science's application to medical technology, consumer products begin emerging. The recent renaissance of interest in personal fitness using actigraphy opened the doors to sleep trackers. Wrist-worn consumer actigraphs quickly achieved market penetration. Uplink technologies to transfer data for cloud storage, analysis, and retrieval make devices affordable and promising. On any given night, more consumer product actigraphic data probably are uplinked than all of the research actigraphy ever recorded. Current understanding and knowledge garnered from actigraphy research are therefore ripe for application on a wider scale. A basic axiom in actigraphy research is that each device needs validation, and it is well recognized that reliability varies widely from device to device (see Chapter 171). Although this maxim regarding validation is undeniable, it represents a principle characterizing every new technology during its infancy. First-wave devices often perform erratically or marginally.[6-8] However, whether the main topic of discussion is wristwatches, automobiles, or airplanes, successive refinement ultimately improves performance and homogenizes the available products until a revolutionary new approach starts the process anew.

A research group in Munich has launched a human sleep project to collect actigraphic uplinked and downloaded data to elucidate sleep-wake patterns in the overall population.[9] In a completely separate initiative, the Consumer Electronics Association launched a project to standardize sleep terminology and performance criteria for wearable devices. These developments are already advancing the current understanding of different chronotypes, health consequences of sleep fasting and binging, and the medical costs of social jetlag.

The juggernaut of advancing sensor technology continues unabated.[10] Temperature, heart rate, blood pressure, blood sugar level, electrodermal skin conductance, heart sounds, breathing sounds, heart rate variability, cardiopulmonary coupling, pulse wave analysis—all are fair game for inclusion. Bedside monitors using static-charged strips, standing wave patterns in the room, and thermal sensors can detect breathing, snoring, movement, and heart rhythm noninvasively and unobtrusively. Another trend is use of sensors built into the sleep surface (i.e., mattress). Embedded transducers not only can detect high and low pressure points on the sleep surface but also can direct an air coil mattress to alter inflation to optimize comfort. These same sensors can detect movement, breathing, and heartbeat. Integrating these technologies and finding a desired or practical use for them consiititue the current challenge.

Are these consumer devices here to stay or do they represent a fad? Recall that more than 100 million Hula Hoops were sold between 1958 and 1960—whereas they are a rarity today. If self-monitoring for fitness persists, the data thus acquired undoubtedly will contribute much to the body of knowledge on sleep health worldwide. In the same manner in which satellite weather monitoring informed meteorologists about ocean currents, polar melt, and storm tracking, big-data analytic techniques applied to consumer uplinked actigraphs can be expected to answer many questions about sleep. These answers in turn will raise even more questions. For example, what population sleep effects correlate with seasonal variations, weather, daylight saving time changes, and latitude locations? What percentage of the population sample experiences disrupted sleep, exhibits different circadian chronotypes, and shows extreme long or short sleep periods?

Beyond these questions, the road ahead holds additional possibilities for us to further understand both sleep health and sleep disorders. Centralized electronic medical record systems are increasingly used and improving by leaps and bounds. With proper deidentification, such records meshed with uploaded sleep information potentially may uncover hitherto-unknown associations between sleep and health. Major issues must be resolved for this to happen, including techniques to ensure privacy, improved recording, validated analysis, and useful data summarization. The first hurdle—privacy—has social, political, and legal aspects. Important questions must be answered. For example, are wearable device data discoverable as evidence in legal proceedings? Technologic hurdles are easier to surmount.

Technologic challenges usually are met, given enough time and continued interest. Improvements proceed in a stepwise manner, much in the way mobile phones evolved from cumbersome, heavy, bulky, unreliable contraptions to the pocket-size devices of today (on which their users may thoroughly depend). Hopefully, self-monitoring fitness enthusiasts will begin to recognize sleep's value by its reflection on performance and daily mental outlook. Researchers, clinicians, and patients alike may be perched on the doorstep of sleep health with evolution from research laboratory to medical clinic and from medical clinic to personal device worn on the body or situated at the bedside. Interfacing self-monitoring devices and patient health care records remains wide open for innovation. Sleep represents a physiologic process critical to health; optimizing this process will undoubtedly improve health.

CLINICAL PEARLS

- PSG represents both a tool of discovery and the most sophisticated technique available for diagnosing sleep disorders.
- The cardiopulmonary channels can be used to verify sleep-disordered breathing in clear-cut cases.
- Actigraphy provides rest-activity patterns useful for interpreting sleep-wake and circadian rhythm patterns.
- The recent popularity of consumer self-monitoring fitness devices holds promise for future translational understanding of sleep health.

SUMMARY

PSG began as a research tool for objectively characterizing the sleep process. PSG studies create massive amounts of data, and sleep staging was a logical approach. Sleep studies provided a physiologic tool for investigating sleep correlates and functions. PSG's usefulness for differentially diagnosing sleep disorders soon became apparent, especially for evaluating sleep-related breathing disorders. Recently, the subset of cardiopulmonary recording channels is supplanting full PSG for apnea diagnostics. In a parallel development, actigraphy became popular for assessing insomnia and circadian rhythm disorders. New sensor technology and advanced analytical techniques increase the information extractable for biologic signals. The latest development involves entry of actigraphy into the consumer product space for fitness self-monitoring. Actigraphy devices can potentially provide information about sleep. If and when they meet performance standards, current understanding about sleep in large populations and overall sleep health can be expected to advance dramatically.

Chapter 161

Sleep Stage Scoring

Sharon Keenan; Max Hirshkowitz

Chapter Highlights

- The electroencephalogram (EEG) remains the most objective measure for determining level of consciousness and allowing determination of sleep stages. Fundamental to discoveries in sleep research and sleep medicine is our ability to appreciate subtle changes in brain activity.
- Human visual pattern recognition of the EEG in the context of changes in the electrooculogram and electromyogram remains the primary skill used to analyze these data to perform sleep stage scoring. The results of this analysis are used to inform interpretation of the data and recommendation for clinical care. Close collaboration between technical and medical members of the clinical team will facilitate these ends.
- In research, sleep stage scoring and the recognition of other patterns emerging from data remain active areas of intense study. More sophisticated analysis of EEG data using advances in technology holds great promise for expanding the current understanding of the central nervous system. Sleep provides a unique window for studying physiology, pathophysiology, and consciousness.
- This chapter reviews the basics of sleep stage scoring.

HISTORY

From a behavioral perspective, immobility and reduced environmental responsiveness characterize human sleep. This state stands in contrast to purposeful (presumably) activities and provides the basis for dichotomizing observable living existence as either sleep or wakefulness. Furthermore, sleep and wakefulness cycle in a lawful, orderly fashion. Some rhythms are seasonal, some are daily (circadian), and some occur more than once a day (ultradian). In addition to the underlying rhythms, the sleep cycle responds to reduced sleep time. This response testifies to sleep-wake cycle autoregulation, with a dynamic tension providing overall system homeostasis. Once techniques were developed to augment mere observation, electroencephalography revealed a complex array of brain activities clustered in a manner strongly suggestive of multiple sleep processes.

All scientific inquiry begins with observation and description. From there it proceeds to classification based ultimately upon measurement. Accordingly, when Loomis and colleagues[1] electroencephalographically reported their first studies, in 1937, they faced the daunting task of devising a system to describe sleep patterns in normal healthy human subjects. Thus sleep staging was born. In the original studies, amplified activity derived from electrodes that were placed on the scalp's surface at several loci produced ink tracings on paper wrapped around a slowly rotating cylinder. An enormous 8-foot "drum polygraph" enabled all-night sleep recording. One electrode was located near the eye and undoubtedly detected eye movement. However, rapid eye movement (REM) sleep remained unrecognized until 16 years later, when Aserinsky published, in part, his University of Chicago doctoral study results.[2] Aserinsky actually christened these movements "jerky eye movements" (JEMs) and in the first paper referred to the phenomenon as *periodic ocular motility*.

Perhaps it was the quirkiness of the original commercially available polygraph systems (e.g., Ofner, Beckman, Grass), with their tendency to polarize electrodes, problematic rechargeable car battery–like systems, and aperiodic (and difficult to predict) recording interference artifacts, or perhaps it was Loomis's silence on the matter of eye movements during sleep. In either case, Aserinsky's pilot work reportedly met with considerable skepticism. Ultimately, however, REM sleep's discovery, and particularly its correlation with dreaming by Dement,[3] altered the course of sleep research for decades. The near-exclusive focus on REM sleep, to the point that all other sleep states were considered simply non-REM (NREM), overshadowed substantial findings (and probably impeded progress) in other sleep research arenas (such as neuroendocrinology, physiology, and medicine). The spotlight on REM sleep made electrooculographic recording critical in performing sleep studies.

Meanwhile, in Lyon, France, Michel Jouvet noted postural differences during sleep in cats.[4] These differences correlated with sleep state and reduced skeletal electromyographic activity. REM sleep (and, by association, dreaming) coincided with marked hypotonia in descending alpha and gamma motor neurons. This hypotonia induced functional paralysis that was quickly ascribed the purpose of keeping the sleeper from enacting dreamed activities. This sleep state–related electromyographic alteration added the final compulsory recording component to the procedure now known as polysomnography (PSG).

Clinical PSG, in addition to brain wave, eye movement, and muscle tone recording, also assesses respiratory, cardiac, and limb movement activity (discussed in detail in other

chapters and elsewhere in the literature[5]). PSG in its simplest form, however—consisting of an electroencephalogram (EEG), electrooculogram (EOG), and electromyogram (EMG)—provides the basic information requisite for classifying sleep state and examining sleep processes.

ELECTRODE PLACEMENT AND APPLICATION

To record the EEG, EOG, and EMG, electrodes are placed on the scalp and skin surfaces. The site must be cleansed and properly prepared to ensure good contact and to maintain electrical impedance at or below 5000 Ω. Scalp electrodes can be affixed with collodion or electrode paste. Facial electrodes can be applied with double-sided adhesive electrode collars and paper tape. Although prescribed sites for electrode application have changed over the years, the system used to identify location remains the American Electroencephalographic society's international 10-20 system. In this system, the intersection of lines drawn from the left to right preauricular point, with the midpoint along the scalp between the nasion and inion, serves to landmark the vertex, designated Cz. Other loci can be found by measuring 10% and 20% along longitudinal and lateral surfaces. Specific locations are designated with a letter indicating the brain area below the electrode (e.g., C for central lobe, O for occipital lobe, F for frontal lobe) and a number ascribing specific points (odd numbers for the left side, even numbers for the right, and z for midline). EEG electrode placements should be precise; consequently, appropriate measurement techniques must be are essential to ensure accuracy. Additionally, EEG amplifiers require calibration at the beginning and end of PSG recording to document proper functioning. This calibration-recalibration provides verification that amplitude changes of the recorded signal accurately reflect oscillating voltages from brain activity.

The classic and amazingly long-lived standardized technique (i.e., the manual produced by the ad hoc committee chaired by Rechtschaffen and Kales) requires a single monopolar central-lobe scalp EEG electrode referenced to a contralateral mastoid electrode (either C3-M2 or C4-M1). This single-channel brain wave recording, when paired with right and left eye EOGs and submentalis EMG, sufficiently reveals brain, eye, and muscle activity for classifying sleep stages.[6] With evolution of PSG from a psychophysiologic research method to a clinical procedure, addition of an occipital lead supplemented centrally derived EEG for improved visualization of waveforms needed to differentiate sleep from wakefulness and to detect central nervous system (CNS) arousals.[7,8]

EOG recording capitalizes on the eyes' cornea-retina potential difference. Strong positive corneal potential fields affect electrodes placed near the right and left outer canthi of the eyes. The recording traces the response to this positive charge moving toward or away from the recording site. Each electrode is referenced to a neutral site, typically over the mastoid behind the ear. Thus lateral eye movements produce out-of-phase tracings for right and left EOG tracings as the cornea moves toward one electrode and away from the other (provided that two channels are dedicated to tracing eye movements). This arrangement makes eye movements easily differentiable from in-phase frontal lobe EEG activity that also is present on recording from these sites. To discern vertical eye movements, the right-side EOG electrode can be placed 1 cm above the outer canthus and the left-side electrode is positioned 1 cm below (or vice versa). An alternative recording montage devised to enhance vertical eye movement detection entails lowering both recording sites to 1 cm below the outer canthi and referencing each to the middle of the forehead (Fpz).

Skeletal muscle activity level is estimated from a pair of electrodes arranged to record submentalis EMG activity. An electrode placed approximately midline but 1 cm above the mandible's inferior edge is referenced to another placed 2 cm below and 2 cm to the right (or left). As a precaution, a backup electrode also is attached at a site at least 0.5 cm away from either of the previously described locations and on the same side (to decrease ECG artifact). Of note, this physical separation is critical to maintain the integrity of the electrode. If electrodes come in contact with one another, they merge to become one recording site. The resulting submentalis EMG recording serves qualitatively to provide an overall estimate for muscle activity level.

The American Academy of Sleep Medicine (AASM) published a standardized manual for conducting clinical polysomnography in their accredited sleep disorders centers.[7,9] This AASM standards manual makes recommendations for recording, scoring, and summarizing sleep stages, CNS arousals, breathing, various kinds of movement, and electrocardiographic activity. By bringing instructional guidelines for a range of techniques into a single volume, the AASM manual has strongly influenced practice, particularly in North America. Researchers, however, should not feel constrained by these clinical guidelines. New discoveries and future techniques need to continue unshackled by even a de facto standard clinical practice cookbook.

AASM specifies recording frontal, central, and occipital monopolar EEG from F4, C4, and O2. The contralateral mastoid (M1) serves as the ostensively neutral reference. Electrodes placed at F3, C3, and O1 sites (and referenced to M2) provide redundancy and serve as backup, if needed. The AASM manual sanctions the use of midline bipolar recordings for frontal and occipital EEG; however, the AASM "frequently asked questions" (FAQ) section states that frontal bipolar derivations are not appropriate for measuring frontal EEG activity. The FAQ also states that EEG amplitudes can be measured from the C4-M1 derivation. The AASM manual recommends using mastoid-referenced EOG with separate channels for E2 and E1, but it also approves a forehead-referenced alternative montage. Submentalis EMG is recorded as a bipolar derivation—that is, one of the surface EMG electrodes is referred to one of the other surface EMG electrodes on the chin.

DIGITAL RECORDING REQUIREMENTS

The first time a polysomnographic signal was digitized, whether it originated from analog or digital amplifying circuits, an entirely new set of factors required consideration. The two most important issues involved specifying amplitude and temporal resolution. Selection of voltage per digital unit (bit) and sampling rate probably had more to do with computer hardware limitations than with conceptual considerations. Amazingly, no standard was established for digital PSG until publication of the AASM standards manual.

The AASM standards manual specifies minimum 12-bit representation for amplitude, providing 4096 units to

represent a 2.5-volt regulated current (IREG) range, or its equivalent (Video 161-1). In this manner, even the smallest signals, exceeding the level of electrical noise, can be detected. Temporal resolution during recording depends on sampling rate and ultimately must allow accurate waveform reconstruction, provide enough data to potentially overcome frequency aliasing, and be appropriate for high- and low-pass digital filter settings. One size does not fit all: The minimum temporal resolution needed during data acquisition to meet these requirements varies for different bioelectrical signals (Table 161-1).

Additional digital specifications involve data selection, display pagination, and calibration. Recorded channels must be selectable, and the channel calibration must be available for display and documentation. The viewable data should provide user-selectable time frame compression and expansion (ranging from 5 seconds to an entire night shown on a page). Display screens definition should be at least 1600 × 1200 pixels. Digital polysomnographs should provide the capability to view data as they appear on the initial recording and also as they appear after sleep staging and sleep-related events have been marked and classified manually. Accompanying video at a minimum of one frame per second should be synchronized with the polysomnographic display.

ELECTROENCEPHALOGRAM BANDWIDTHS, WAVEFORMS, AND OTHER ACTIVITY

Bandwidths

One approach to differentiating EEG involves separating activity into dominant frequency bandwidths. *Delta activity* includes brain waves with a frequency less than 4 Hz. Sleep-related delta waves occurring at the low end of the frequency spectrum are called *slow waves.* Slow waves have high amplitude (greater than 75 microvolts) and low frequency (less than 2 Hz). *Theta activity* includes 5- to 7-Hz waves prominent in central and temporal leads. *Alpha activity* is characterized by an occipitally prominent 8- to 13-Hz rhythm, and *beta waves* include the low-amplitude waves at even higher frequencies (up to approximately 25 Hz for clinical purposes).

Waveforms

In addition to ongoing background EEG activity oscillating predominantly within one or another of the specific bandwidths, distinct transient waveform events occur. These include vertex sharp waves, K-complexes, sleep spindles, and sawtooth theta waves. *Vertex sharp waves* are sharply contoured, negative ("negative" meaning upward deflection of the signal, as per EEG polarity convention) wave forms that stand out from the background EEG activity. As the name implies, they appear prominently in EEG derived from electrodes placed near the midline or vertex region (Cz).

The *K-complex* begins much like a vertex sharp wave (i.e., it begins with a sharp negative waveform but is immediately followed by a large, usually much slower positive component). Overall, the K-complex usually is clearest in central and frontal regions and has a duration criterion of 0.5 second or more. A *sleep spindle* is a readily apparent 0.5-second (or longer) burst of 12- to 14-Hz activity generated by the thalamus and sent along thalamocortical pathways to the cortex. The name derives from its spindle-like shape. A *sawtooth wave* is a variant of theta activity, with each wave also containing a notch, making it sawtooth-shaped.

Table 161-1 Recording Recommendations for Digital Polysomnography

	Sampling Rate (Hz)*		Filter Setting (Hz)	
Recording Channel	Desirable	Minimal	Low *f*	High *f*
Central EEG (C4-M1)	500	200	0.3	35
Occipital EEG (O4-M1 or Cz-Oz)	500	200	0.3	35
Frontal EEG (F4-M1 or Fz-Cz)	500	200	0.3	35
Left EOG (E1-M2 or E1-Fpz)	500	200	0.3	35
Right EOG (E2-M2 or E2-Fpz)	500	200	0.3	35
Muscle tone (submental EMG)	500	200	10	100
ECG (lead II, modified)	500	200	0.3	70
Airflow sensors at nares and mouth	100	25	0.1	15
Oximetry (ear lobe or finger)	25	10	0.1	15
Nasal pressure	100	25	0.1	15
Esophageal pressure	100	25	0.1	15
Body position	1	1		
Respiratory effort				
Snoring sounds	500	200	10	100
Rib cage and abdominal movement	100	25	0.1	15
Intercostal EMG	500	200	10	100

E1, Left eye; E2, right eye; ECG, electrocardiogram; EEG, electroencephalogram; EMG, electromyogram; EOG, electrooculogram; *f*, frequency; Fpz, frontal pole; M, mastoid.

*Higher sampling rates increase file storage requirements but provide increased temporal resolution. The tradeoff between fidelity and practicality is a matter of debate.

Other nonpathologic sleep-related waveforms exist (e.g., benign epileptiform transients of sleep [BETS], sensory motor rhythm [SMR], wicket rhythm [mu rhythm], and positive occipital sharp transients of sleep [POSTS]. These normal variants do not occur consistently during polysomnography.

Activity Patterns

Sleep EEG also contains dynamic activity patterns not captured by sleep staging schema or identification of individual waveforms. The *cyclic alternating pattern* (CAP) includes waveform bursts (usually high-amplitude slow, sharp, or polymorphic waves) separated by quiescent periods.[10] The pattern's burst component sometimes includes transient alpha-bandwidth components meeting CNS arousal scoring criteria and thus can index sleep disturbance. However, a CAP occurring without frank arousals is thought to signify more subtle sleep instability.

SLEEP STAGING RULES AND CENTRAL NERVOUS SYSTEM AROUSALS

More than 40 years ago, the standardized technique described in *A Manual of Standardized Terminology, Techniques and Scoring System for Sleep Stages of Human Subjects*[6] provided a unifying methodology for human sleep research. This standardized manual combined elements from various systems that had evolved over time, and it provided adequate detail to achieve general use. To a large extent, however, its enormous success stems from the consensus it attained from the multinational, multidiscipline stakeholders that made up its development committee. That is, when the committee members returned to their respective laboratories, they used the techniques and taught them to scientists and clinicians in training.

Staging, as a summarizing technique, necessarily must define a period over which the summary applies. The standardized manual endorsed 20- and 30-second time domains (epochs). This flexibility deferred to extant technology—that is, generally available polygraph machine paper chart drive speeds. Over time, the 30-second epoch won out because it provided enough detail to see waveforms (EEG standards dictate minimal paper speed of 10 mm/second to ensure ability to discern individual EEG waveforms); at 10 mm/second, one epoch fits on a standard 30-cm wide paper fanfold polygraph page; and one 1000-page box of polygraph paper would hold a complete recording (or two if one also is recorded on the back) (Box 161-1).

Sleep Staging Rules

Wakefulness (stage W) in a relaxed subject with eyes closed is differentiated from sleep by the presence of alpha EEG activity in 50% or more of the epoch (Figure 161-1). Poorly defined alpha EEG activity complicates differentiation of sleep onset from wakefulness. The observation of the reactivity (disappearance) of the alpha rhythm to eyes open versus eyes closed provides a helpful contrast to facilitate detection of the background alpha rhythm in wakefulness.

Stage 1 typically is defined by exclusion; that is, it appears as a low-voltage, mixed-frequency background EEG signal devoid of sleep spindles and K-complexes, minimal slow wave activity, cessation of blinking, absence of saccadic eye movements, and alpha activity for less than 50% of the epoch duration (Figure 161-2). Stage 1 sleep may, but does not necessarily, include vertex sharp waves, background activity slowing, and slow eye movements.

Stage 2 characteristics include sleep spindles and K-complexes (Figure 161-3) occurring on a low-voltage, mixed-frequency background EEG and minimal (less than 20% of the epoch) slow wave (0.5 to 2 Hz, 75 μV) activity.

Box 161-1 CLINICAL TIPS FOR SLEEP STAGE SCORING

If the goal is to score an entire sleep study, a helpful approach is to familiarize oneself with the entire recording before beginning the epoch-by-epoch task of assigning a sleep stage to each 30-second epoch. A useful first step is a general review of the study recording to discern overall patterns—for example, the alpha background, the shape of the K-complexes, presentation of sleep spindles, and the appearance or lack of slow waves. Each person has an individual "signature of sleep," and familiarity with the data beforehand from each study makes scoring easier. The scorer "shakes hands," as it were, with the recording and asks general questions. For example, did the subject sleep or not? Does the person have robust, easy-to-discern eye movements? What do the K-complexes look like? Is the breathing regular or not? Do the patient's legs move or not? Are there any ECG rhythm abnormalities? This brief review creates a context for the scoring process. Also, it is common for the scorer to have to go back to a point earlier in the data, or to look ahead, before making a decision about a specific epoch, especially when determining the exact epoch on which REM sleep began or to make the decision about the precise moment of sleep onset. All individuals engaged in sleep stage scoring for a laboratory should engage in systematic interrater reliability checks to ensure that everyone is scoring the data in similar fashion.

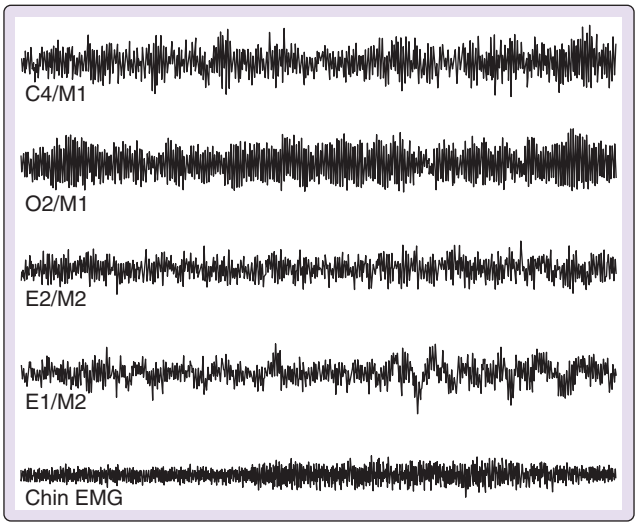

Figure 161-1 Stage wake (W), eyes closed. This example demonstrates a classic wake pattern, with alpha rhythm in the EEG and EOG. Alpha activity is most prominent in the occipital channel. The chin EMG displays normal muscle tone associated with relaxed wakefulness. C4/M1, Right central lobe EEG referenced to left mastoid; E2/M1, right eye (outer canthus) referenced to left mastoid; E1/M2, left eye (outer canthus) referenced to right mastoid; EEG, electroencephalogram; EMG, electromyogram; EOG, electrooculogram; O2/M1, right occipital lobe EEG referenced to left mastoid. (From Butkov N. *Atlas of clinical polysomnography.* 2nd ed. Medford [Ore.]: Synapse Media; 2010.)

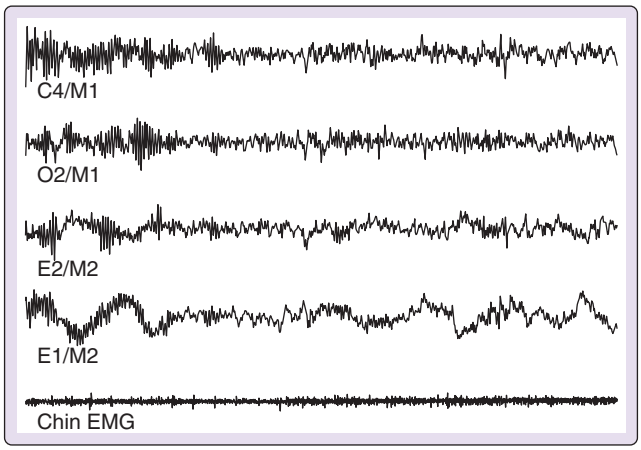

Figure 161-2 Stage 1 sleep (N1). The onset of N1 is identified by the disappearance of alpha rhythm, replaced by relatively low voltage mixed-frequency EEG with a prominence of theta activity in the range of 5 to 7 Hz. The chin EMG remains tonic, although it can attenuate slightly with sleep onset. C4/M1, Right central lobe EEG referenced to left mastoid; E2/M1, right eye (outer canthus) referenced to left mastoid; E1/M2, left eye (outer canthus) referenced to right mastoid; EEG, electroencephalogram; EMG, electromyogram; O2/M1, right occipital lobe EEG referenced to left mastoid. (From Butkov N. *Atlas of clinical polysomnography.* 2nd ed. Medford [Ore.]: Synapse Media; 2010.)

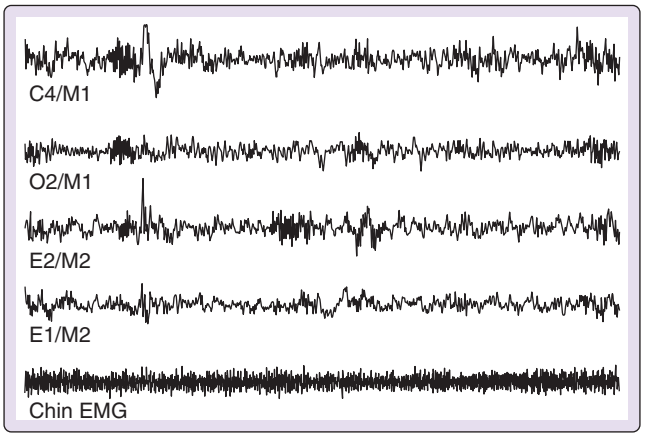

Figure 161-3 Stage 2 sleep (N2). Stage N2 is identified by the presence of K-complexes and/or sleep spindles against a background of mixed-frequency EEG. The chin EMG displays normal muscle tone, as expected during NREM sleep. C4/M1, Right central lobe EEG referenced to left mastoid; E2/M1, right eye (outer canthus) referenced to left mastoid; E1/M2, left eye (outer canthus) referenced to right mastoid; EEG, electroencephalogram; EMG, electromyogram; O2/M1, right occipital lobe EEG referenced to left mastoid. (From Butkov N. *Atlas of clinical polysomnography.* 2nd ed. Medford [Ore.]: Synapse Media; 2010.)

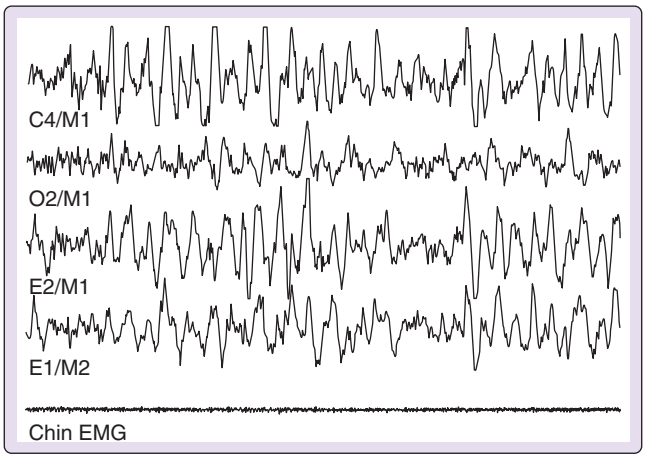

Figure 161-4 Slow wave sleep (N3). In this example, high-amplitude slow waves occupy greater than 50% of the epoch. By the Rechtschaffen and Kales (R&K) criteria, this epoch is scored as stage 4. By the revised American Association of Sleep Medicine (AASM) criteria, this epoch is scored as N3. (From Butkov N. *Atlas of clinical polysomnography.* 2nd ed. Medford [Ore.]: Synapse Media; 2010.)

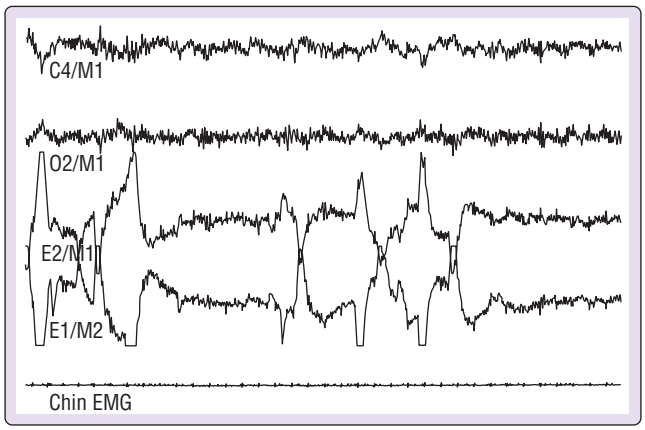

Figure 161-5 Rapid eye movement (REM) sleep. During REM sleep, chin muscle tone drops to the lowest level of the recording. REM sleep is identified by the presence of rapid eye movements in combination with relatively low-voltage, mixed-frequency EEG and low-chin EMG. C4/M1, Right central lobe EEG referenced to left mastoid; E2/M1, right eye (outer canthus) referenced to left mastoid; E1/M2, left eye (outer canthus) referenced to right mastoid; EEG, electroencephalogram; EMG, electromyogram; O2/M1, right occipital lobe EEG referenced to left mastoid. (From Butkov N. *Atlas of clinical polysomnography.* 2nd ed. Medford [(Ore.]: Synapse Media; 2010.)

Slow wave sleep (stages 3 and 4 sleep) contains delta EEG activity (recorded from a monopolar central derivation) with a 75-μV or greater amplitude enduring for 20% or more of an epoch (Figure 161-4). *Stage 3* is scored when the duration of slow waves constitutes 20% to 50% of the epoch, and *stage 4* is scored when duration reaches 50% or more.

REM sleep is scored when saccadic eye movements occur during epochs with low-voltage, mixed-frequency EEG activity in association with a very low level of submentalis EMG activity (Figure 161-5). Epochs with low-voltage, mixed-frequency EEG activity and continuing low-level submentalis EMG (without eye movements) falling between epochs of REM sleep (with eye movements) also are scored as REM sleep. Epochs falling before or after (and contiguous with) clear REM sleep that have comparable EEG and EMG features but lack rapid eye movements are scored as REM sleep until an arousal, EMG level increase, or resumption of K-complexes or sleep spindles occurs. These *smoothing rules* gloss over minor transitions on the supposition that REM sleep represents a persistent CNS organizational state distinct from wakefulness and NREM sleep.

In 2007 (last update 2015), the AASM standards manual provided revised criteria for scoring sleep stages. Changes are summarized in Table 161-2. Essentially, changes include standardizing epoch length at 30 seconds; combining stages 3 and 4 sleep and applying amplitude criteria for slow waves to

Table 161-2 Comparison of Traditional and AASM (2007) Sleep Stage Scoring Systems

Parameter	R&K Classification Criteria	AASM Classification Criteria
Epoch length	20 or 30 seconds, user's choice	30 seconds, mandated
Stage nomenclature	Wakefulness, stage 1 sleep, stage 2 sleep, stage 3 sleep, stage 4 sleep, REM sleep, movement time	Stages W, N1, N2, N3, and R
Wakefulness	EEG alpha activity for ≥50% of an epoch	Same
Slow wave sleep	EEG slow wave activity for ≥50% of the epoch for stage 4 sleep or ≥20% of the epoch for stage 3 sleep	Same, except that stages 3 and 4 are combined into N3
Stage 2 sleep	Sleep spindles or K-complexes; EEG slow wave activity for <20% of the epoch	Same
Stage 1 sleep	Low-voltage, mixed-frequency activity; possibly vertex sharp waves; possibly slow eye movements; no sleep spindles or K-complexes; EEG alpha activity for <50% of the epoch	Same
REM sleep	Low-voltage, mixed-frequency EEG activity; very low submental EMG activity; possibly saw tooth EEG theta activity; at least one unequivocal rapid eye movement	Same
Movement time	Polysomnographic activity obscured to the point of not being readable for more than 50% of the epoch; the preceding epoch is scored as stage 1, 2, 3, 4, or REM sleep	This epoch classification is eliminated
Smoothing rules	When an epoch is classified as a particular stage but is surrounded by epochs lacking unique features (e.g., a sleep spindle, slow-rolling eye movements, or CNS arousal) and would otherwise have been scored as stage 1 sleep, the *classified epoch* scoring is generalized to the surrounding epochs (but only for 3 minutes). These *smoothing rules* apply to stage 2 and REM sleep	Same, except that there is no 3-minute limit to the generalization

AASM, American Academy of Sleep Medicine; CNS, central nervous system; EEG, electroencephalogram; EMG, electromyogram; R&K, Rechtschaffen and Kales; REM, rapid eye movement.

frontal EEG activity; revising terminology (R for REM sleep, N1 for NREM stage 1, N2 for NREM stage 2, N3 for NREM stages 3 and 4, and W for wakefulness); and simplifying smoothing rules. Some changes are controversial.[11-16]

Central Nervous System Arousal Scoring

Sleep staging fails to represent brief CNS arousals because it summarizes EEG, EOG, and EMG activity over a 30-second time domain. Increasing clinical application of polysomnographic technique heightened the need to appreciate sleep fragmentation; consequently, a scoring system for arousals was developed[8] under the auspices of the American Sleep Disorders Association (later to become the AASM). Abrupt 3-second (or longer) EEG frequency increases to theta, alpha, or beta activity (but not to sleep spindles) are considered biomarkers for CNS activation. The arousals most often entail emergent occipital EEG alpha activity. To qualify as an arousal, 10 seconds of sleep must precede the event. In REM sleep, activity must also increase in submentalis EMG leads for at least 1 second (Figure 161-6). The 3-second duration represents the minimum duration that could be reliably scored by visual inspection (among the task force members). Events of shorter duration likely also have clinical significance. The AASM standards manual endorsed this scoring technique and simplified the original 11 rules to a single statement with 2 explanatory notes.

SUMMARIZING NORMAL SLEEP

The sleep stage pattern across the night can be represented diagrammatically (Figure 161-7). In healthy young adults, stage R (REM sleep) accounts for approximately 20% to 25% of total sleep time, stage N2 accounts for 50%, N3 accounts for 12.5% to 20%, and N1 accounts for the remainder. In normal sleepers, wakefulness characteristically accounts for 5% to 10% of the time in bed. Stage R typically does not appear until approximately 90 minutes after sleep onset, after which it reoccurs every 90 to 120 minutes in distinct episodes. These episodes increase in duration as sleep progresses; accordingly, the first half of the sleep session contains less REM sleep than the second half. By contrast, slow wave activity (stage N3) predominates in the first third of the night. Age-matched sleep architecture bears great similarity in men and in women; however, women may have slightly better preserved stage N3 with advancing age. Sleep can be quantitatively summarized, and Table 161-3 provides definitions for commonly used parameters.

AMBIGUOUS SLEEP STAGES AND SLEEP QUALITY

Sleep stage scoring was developed to summarize EEG, EOG, and EMG correlates of *normal sleep*. Under normal

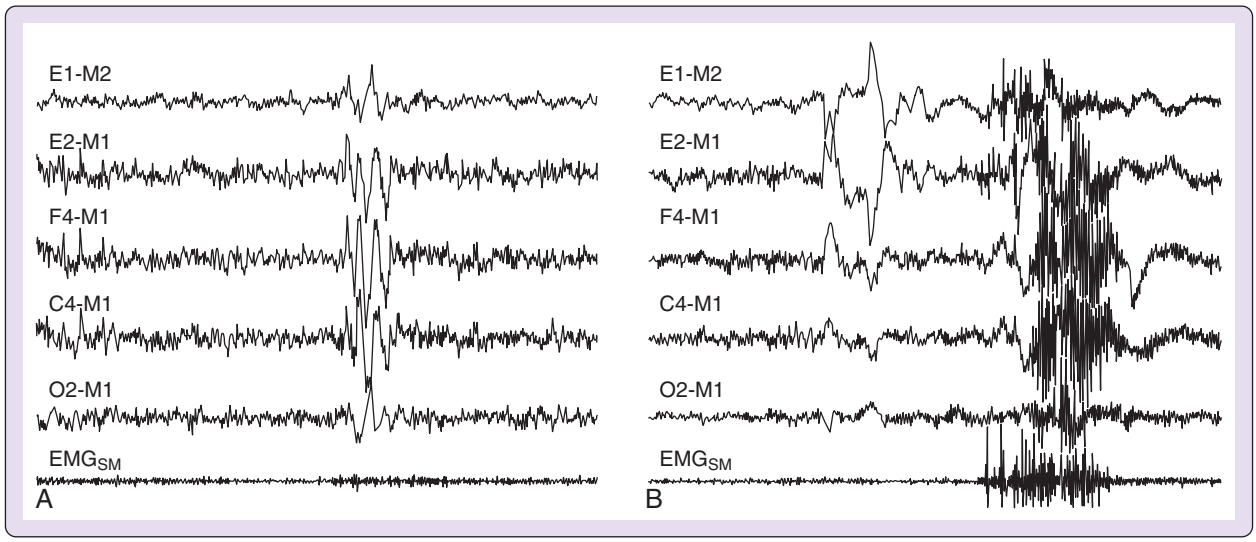

Figure 161-6 Arousals from NREM **(A)** and REM **(B)** sleep. **A,** A paroxysmal burst of high-amplitude slow wave activity appears near the center of the epoch. The distribution of the electrical field changes associated with this event can be seen reflected in the other EEG channels but with (expected) decreased amplitude. Little or no change occurs in the EMG channel in association with this event. It is common to see K-complex activity evoked by auditory stimuli. **B,** An increase in EMG activity is noted on the EMG and almost simultaneously in the E2-M1 channel. This is followed by a brief generalized presentation of EMG artifact throughout the EEG and EOG channels. Before the event, there is evidence of REM sleep: low-voltage, mixed-frequency EEG, rapid eye movements, and very low EMG. After the event, the EMG channel shows an increased tone, and the EEG background activity is low-voltage and fast. A continuation of EMG artifact is seen on the EEG channels after the short burst. These data, especially the burst of alpha activity seen in the O2-M1 channel, are consistent with a possible transition to wake from REM sleep. C4-M1, Right central lobe EEG referenced to left mastoid; E1-M2, left eye (outer canthus) referenced to right mastoid; E2-M1, right eye (outer canthus) referenced to left mastoid; EEG, electroencephalogram; EMG, electromyogram; EMGSM, submentalis EMG; EOG, electrooculogram; F4-M1, right frontal lobe EEG referenced to left mastoid; NREM, non–rapid eye movement; O2-M1, right Occipital Lobe EEG referenced to left mastoid; REM, rapid eye movement. (Courtesy Max Hirshkowitz, PhD, DABSM.)

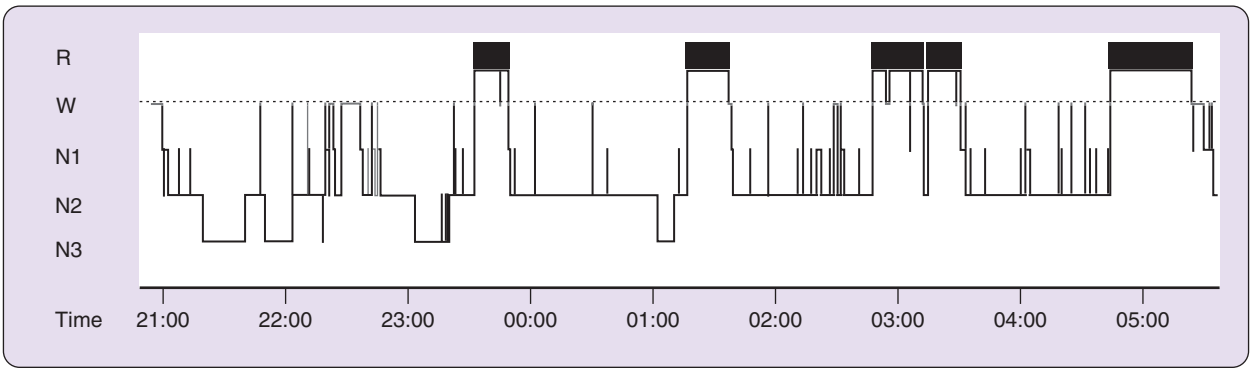

Figure 161-7 Normal sleep histogram illustrating sleep macroarchitecture (stages) for a young adult. N1, N2, and N3, NREM sleep stage 1, 2, and 3, respectively; R, REM sleep; W, wakefulness.

circumstances, particular events cluster for the vast majority of the time. By contrast, this tight coupling tends to loosen when patients rebound from sleep deprivation; sustain brain injury; are afflicted with sleep, medical, neurologic, psychiatric, or sleep disorders; or ingest psychoactive substances. The resulting intrusion, translocation, or migration of specific EEG, EOG, or EMG activity characteristic of one stage into another produces ambiguous epochs that are difficult to classify according to the usual scoring rules. This departure from normal processes can provide qualitative evidence of an underlying sleep dysfunction.

Perhaps the most common ambiguities accompany pharmacotherapy. Gamma-aminobutyric acid type A and benzodiazepine receptor agonists generally increase spindle activity in the EEG. These pharmacologically induced spindles typically are of higher frequency (16 to 18 Hz) and often of longer duration, occur more frequently (with a higher density), and can appear not only in N2 but also in other stages of sleep and in wakefulness.

Another commonly noted drug effect is serotonin agonist augmentation of eye movement activity. In some persons, rapid eye movements occur at sleep onset and in sleep stages

Table 161-3 Parameters Derived from Sleep Staging and Central Nervous System Arousal Scoring

Parameter	Notation	Explanation
AASM Recommended Parameters		
Lights out clock time	L-out	The clock time (in hh:mm) that the subject was instructed to allow himself or herself to fall asleep
Lights on clock time	L-on	The clock time (in hh:mm) that the subject was awakened
Total sleep time	TST	Minutes scored as stage N1, N2, N3, or R
Total recording time	TRT	Elapsed time from L-out to L-on (in minutes)
Sleep latency	SLAT	Elapsed time from L-out to first epoch of stage N1, N2, N3, or R (in minutes)
REM sleep latency	RLAT	Elapsed time in minutes from SLAT to first epoch of stage R
Wake after sleep onset	WASO	Minutes scored as stage W from first sleep epoch to L-on
Sleep efficiency	SEI	TST as a percentage of TRT
Time in each stage	MW, M1, M2, M3, MR	Minutes scored as W, N1, N2, N3, and R (individually)
Sleep stage percentages	P1, P2, P3, PR	Time scored as N1, N2, N3, and REM as a percentage of TST (individually)
Number of CNS arousals	NArsls	The number of CNS arousals
CNS arousal	CNS AI	The number of CNS arousals scored per hour of TST
Other Useful Parameters		
Latency to persistent sleep	LTPS	Elapsed time (in minutes) from L-out to first of 10 consecutive minutes of sleep
Latency to unequivocal sleep	LUS	Elapsed time (in minutes) from L-out to first epoch of N2, N3, or R or to three consecutive (or more) epochs of N1 If N1 is followed by an epoch of N2, N3, or R, LUS is calculated from L-out to the first epoch of N1
Sleep-period time	SPT	Minutes from first to last epoch scored as N1, N2, N3, or R
Number of REM sleep episodes	NREME	Number of stage R occurrences
Number of awakenings	NWake	Number of stage W occurrences
Wake index	WI	Number of awakenings per hour of TST
Sleep fragmentation index	SFI	Number of awakenings and CNS arousals per hour of TST
Number of stage shifts	NShifts	Number of stage transitions during TRT
Stage shift index	SSI	Number of stage transitions per hour of TRT
Latency to arising	LTA	Duration of final stage W if it was ongoing when L-on occurred

CNS, Central nervous system; REM, rapid eye movement.

N2 and N3, making the scoring of REM sleep a challenge. The phenomenon is so common that many sleep specialists refer to it as "Prozac eyes" (with reference to fluoxetine, the prototypical selective serotonin reuptake inhibitor).

Another serotonin agonist–provoked sleep alteration involves elevated muscle activity during REM sleep. In some cases, these medications produce a loss of atonia, permitting attempted dream enactments—that is, iatrogenic REM sleep behavior disorder (RBD). Individual PSG epochs during these events do not meet usual stage classification criteria. Similar REM sleep ambiguities occur in Parkinson disease–related and posttraumatic stress disorder–related RBD.

Patients suffering from neurodegenerative diseases or brain insult can manifest an overall erosion of EEG sleep events. This effect includes reduced sleep spindles, K-complexes, and slow wave activity. We also sometimes observe this effect in patients with sleep apnea, heart failure, and metabolic disorders. The resulting nearly featureless sleep EEG can be difficult to score according to normal staging rules. By contrast, another very different scoring problem can occur in persons with severely fragmented sleep produced by obstructive apnea, in whom a continual cycle of falling asleep, airway collapse, struggle to breathe, awakening, and falling asleep is observed. Thus the patient remains in a *t*ransition state that does not fit well into any sleep stage category. It was once proposed that this pattern be scored as *t-sleep*.

In some persons, copious EEG alpha activity permeates ongoing background activity. In sleep states marked by low-amplitude, mixed-frequency activity, alpha bursts meeting criteria for CNS arousal can be scored as such (alpha intrusion). However, when slow waves characterize the dominant ongoing background EEG activity and the alpha coincides with delta, arousals are not scored. This *alpha-delta* sleep sometimes accompanies pain syndromes, but it appears to lack

specificity. A related phenomenon, also ascribed to pain, consists of K-complex bursts followed by EEG alpha activity. Many sleep specialists consider this "K-alpha" activity to be a variety of the CAP.

CLINICAL PEARLS

- Sleep staging and CNS arousal scoring provide important clinical information about brain processes during sleep. Ultimately, persons who awaken sleepy or unrefreshed or who have difficulty initiating or maintaining sleep can be assayed for sleep integrity, quantity, and quality using polysomnography.
- Human sleep is a brain process. Pathophysiologic conditions such as increased airway resistance and leg movements produce CNS arousals that fragment and destroy the fabric of sleep. Disorders often alter sleep patterns and overall architecture.
- Appropriate treatments may promote return to normal. Quantitative analysis through staging and arousal scoring objectively documents sleep disruption and provides a severity index for sleep disorders.

SUMMARY

Polysomnography involves recording a wide assortment of bioparameters while a person sleeps. The only objective method for knowing if a person is sleeping is to examine brain wave activity (the electroencephalogram). Sleep stage scoring summarizes patterns in the electroencephalogram, electrooculogram, and skeletal muscle electromyogram. Well established, specific, scoring criteria exist for sleep stages N1, N2, N3, and R (previously called stage 1, 2, 3, 4, and REM, respectively). Scoring criteria depend upon EEG bandwidth activity (delta, theta, alpha, and beta), EEG events (vertex sharp waves, sleep spindles, and K-complexes), eye movement activity (slow and rapid eye movements), and the level of muscle tone. Stage N3 is characterized by high-voltage, slow wave activity. Stage N2 contains sleep spindles and K-complexes. Stage N1 has low-voltage, mixed-frequency background, possibly slow eye movements, and vertex sharp waves. If rapid eye movements accompany a low-voltage, mixed-frequency EEG and skeletal muscle tone is low, REM sleep is scored. CNS arousals also can occur from sleep, either spontaneously or resulting from pathophysiologic processes or environmental factors. Quantitative analysis of sleep stages and CNS arousals provides evidence for, contributes to the definition of, and indexes the severity of some sleep disorders. Similarly, these indices can provide objective outcome measures for assessing therapeutic interventions. This chapter summarizes recording, digital processing, and scoring techniques used for evaluating brain activity during human sleep and its disturbance by CNS arousals.

Central Nervous System Arousals and Cyclic Alternating Patterns

Liborio Parrino; Mario Giovanni Terzano

Chapter Highlights

- Conventional sleep measures based on static 30-second epochs have certain limitations compared with the more dynamic interpretation of sleep based on cyclic alternating pattern (CAP) scoring criteria. To apply the rules of CAP interpretation, the concept of electroencephalogram (EEG)-confirmed arousal has been expanded to include EEG features characterized by high-voltage slow waves that have activation properties correlated with autonomic functions and muscle activity.
- CAP parameters have been clearly defined and have found clinical application in all major sleep disorders. Automated analysis to improve and expedite CAP quantification also is now available.
- As the EEG marker of sleep instability, CAP offers a practical additional tool to investigate the physiology of sleep, the pathophysiology of sleep disorders, and the mechanisms of action of medications and other therapeutic modalities.

In 1968, the standardized Rechtschaffen and Kales (R&K) criteria[1] for sleep staging became the internationally accepted system for sleep scoring. This system remained the standard for almost 40 years. An enormous body of data based on the R&K criteria has been accumulated in the scientific literature. In 2007, the American Academy of Sleep Medicine (AASM) published a new manual for scoring sleep and associated events.[2] The updated AASM manual revised the R&K sleep staging criteria and also addressed the scoring of arousals, respiratory events, sleep-related movement disorders, and cardiac abnormalities. It also considered differences for pediatric and geriatric age groups. With the AASM criteria, the visual scoring of sleep derives from at least three EEG channels, specifically, frontal, central, and occipital leads, rather than from a single central lead as with the R&K system. The classic electrooculogram (EOG) and electromyogram (EMG) derivations are retained. This provides more extensive scalp area coverage, so that significant sleep-wake rhythms and waveforms (e.g., K-complexes, delta waves) are better represented. The distinction among wakefulness ("W"), non–rapid eye movement (NREM) sleep ("N"), and REM sleep ("R") is maintained, but to simplify daily clinical practice, a reduced number of NREM stages is used : N1 (previous stage 1), N2 (previous stage 2), and N3 (previous stages 3 and 4).

The AASM system standardized the 30-second epoch as the basic time domain for summarizing activity. The dominant role of tonic background EEG activity confers a stepwise outline to the sleep histogram (*sleep macrostructure*) characterized by periods of static configuration (sleep stages) interrupted by rapid shifts (stage changes). Scoring based on 30-second sleep epochs neglects short-duration events, which therefore are not represented in the classic sleep staging reports, although such events also carry important information. Various features—K-complexes, sleep spindles, delta bursts, and others—lasting for intervals shorter than the scoring epoch (phasic events) have been described and commonly are collectively referred to as *sleep microstructure*. Analysis of the cyclic alternating pattern (CAP)[3] represents a sophisticated method for recognizing and reporting specific sleep microstructural activity.

THE CYCLIC ALTERNATING PATTERN

Spontaneous cortical activity—that is, ongoing activity in the absence of sensory stimulation—can show very complex collective features, with, in some cases, the membrane potential making spontaneous transitions between two different levels called up and down states. This alternation of down states of network quiescence and up states of generalized spiking and neuronal depolarization has been observed to occur spontaneously in a variety of systems and conditions, both in vitro and in vivo, during slow wave sleep, anesthesia, and quiet waking. The precise mechanism by which these up state transitions occur is still unclear, but network mechanisms seem to be involved.[4]

CAP is a well-defined physiologic cerebral activity occurring under conditions of reduced vigilance (sleep, coma), translating to a state of arousal instability and involving muscle, behavioral, and autonomic functions.[3] During NREM sleep, CAP is organized in sequences. A CAP sequence is composed of a succession of CAP cycles. The CAP cycle is composed of a phase A and the following phase B (Figure 162-1). All CAP sequences (each made up of a series of CAP cycles) begin with a phase A and end with a phase B. Each phase of CAP is 2 to 60 seconds in duration. This cutoff value relies on the consideration that approximately 90% of A phase events occurring during sleep are separated by an interval of less than 60 seconds.[5] The absence of CAP for more than 60 seconds is scored as non-CAP (Figure 162-2) and coincides with a condition of sustained physiologic stability.[6]

Figure 162-1 Cyclic alternating pattern (CAP) sequence. The *black outline* limits a CAP cycle composed of a phase A (cluster of K-complexes) and a phase B (interval between two successive A phases). Note that CAP is a widespread phenomenon that involves several EEG channels, with a dominance of high-amplitude waves in the anterior regions. EEG, Electroencephalogram.

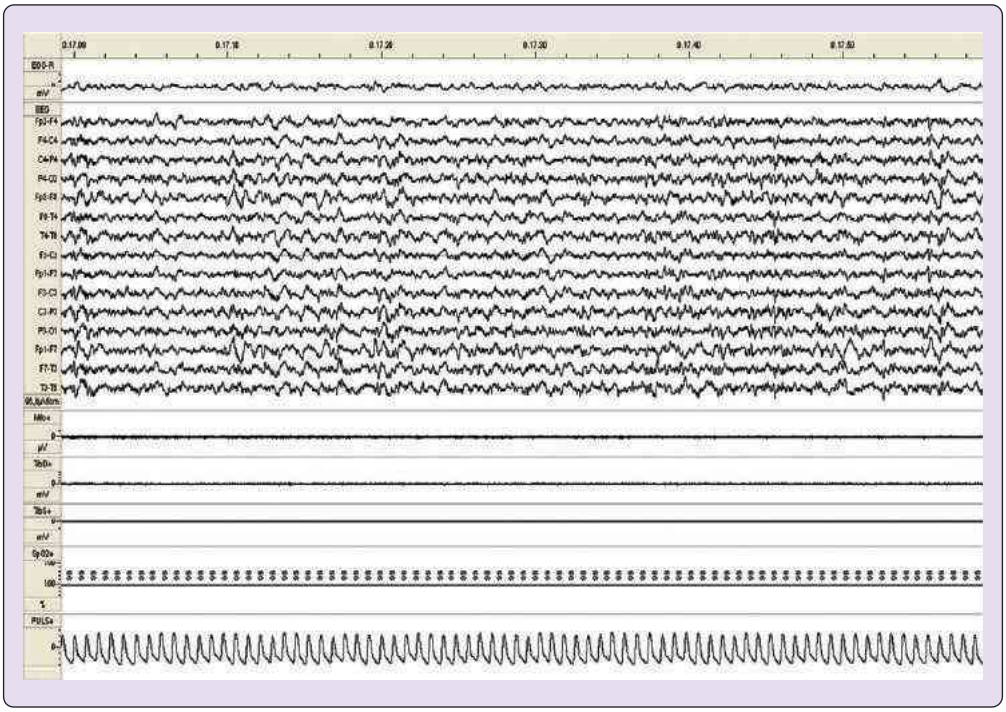

Figure 162-2 Non–cyclic alternating pattern (CAP) in stage N3 expressed by a sustained succession of slow waves, which correspond to the less-than-1-Hz oscillation of non–rapid eye movement (NREM) sleep. Arousals or other EEG phasic events are missing. Note the extreme stability of signal on the pulse and oximetry traces and the absence of muscle jerks. EEG, Electroencephalogram.

CAP and non-CAP can be manipulated by sensorial inputs. With separate application of the same arousing stimulus during the two EEG components of CAP, phase B immediately assumes the morphology of the other component, whereas the inverse transformation never occurs when the stimulus is delivered during phase A. This stereotypical reactivity persists throughout the successive phases of CAP, with no habituation. By contrast, when the same stimulus is presented during non-CAP, the EEG responses generally are brief, hypersynchronized (as slow waves), and proceed toward progressive habituation.[5] However, a robust or sustained stimulus delivered during non-CAP induces the immediate appearance of repeated CAP cycles that display the same morphology and reactive behavior of spontaneous CAP

sequences. The evoked CAP sequence heralds a lightening of sleep depth or continues as a damping oscillation before the complete recovery of non-CAP.[7]

CAP sequences have no upper limits for duration and number of CAP cycles, but at least two consecutive CAP cycles are required to define a CAP sequence. In the physiologic sleep histogram, CAP sequences occur during NREM stages, accompany most NREM stage shifts, and commonly precede the transition from NREM to REM sleep.[8] Under normal circumstances, CAP cannot be scored in REM sleep, because phase A features in REM sleep are separated by mean intervals of 3 to 4 minutes.[9] However, pathologic conditions characterized by repetitive A phase events recurring at intervals shorter than 60 seconds, such as periodic REM-related sleep apnea events,[10] can produce CAP sequences in REM sleep.

The Phase A Subtypes of Cyclic Alternating Pattern

Phase A activity can be classified into three subtypes. Subtype classification is based on the reciprocal proportion of high-voltage slow waves (EEG synchrony) and low-amplitude fast rhythms (EEG desynchrony) throughout the entire phase A duration.[6] The three phase A subtypes (Figure 162-3) are:

- *Subtype A1*: EEG synchrony (high-amplitude slow waves) is the predominant activity. If present, EEG desynchrony (low-amplitude fast waves) occupies less than 20% of the entire phase A duration. Subtype A1 specimens include delta bursts, K-complex sequences, vertex sharp transients, and polyphasic bursts with less than 20% of EEG desynchrony.
- *Subtype A2*: The EEG activity is a mixture of slow and fast rhythms, with 20% to 50% of phase A occupied by EEG desynchrony. Subtype A2 specimens include polyphasic bursts with more than 20% but less than 50% of EEG desynchrony.
- *Subtype A3*: The EEG activity is predominantly rapid low-voltage rhythms with greater than 50% of phase A occupied by EEG desynchrony. Subtype A3 specimens include K-alpha activity, EEG arousals, and polyphasic bursts with greater than 50% EEG desynchrony. A movement artifact within a CAP sequence also is classified as subtype A3.

CAP sequences include different phase A subtypes. A majority of EEG arousals occurring in NREM sleep (87%) fall within the CAP sequences and basically coincide with a phase A2 or A3.[11] In particular, 95% of subtype A3 events and 62% of subtype A2 events meet the AASM criteria for arousals.[12]

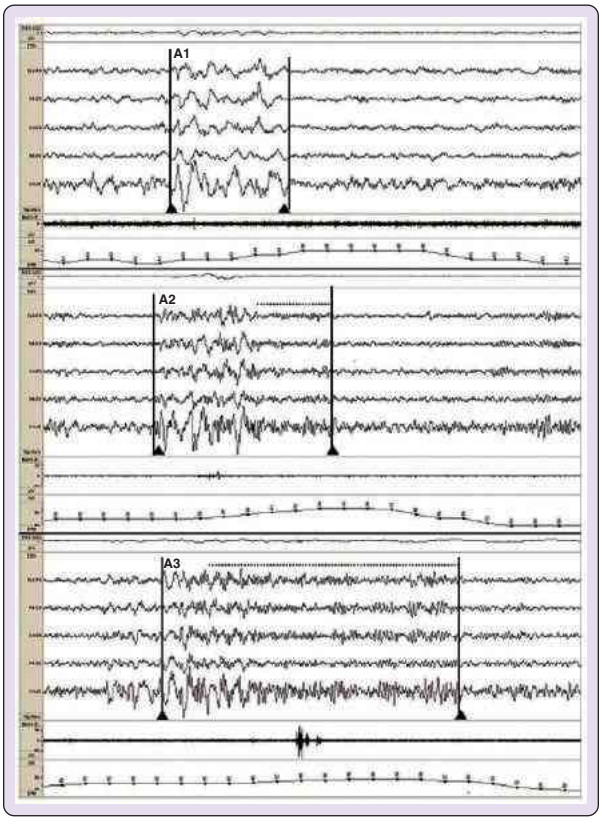

Figure 162-3 The three phase A subtypes, demarcated by *black vertical lines*. The A1 subtype is dominated by high-voltage, low-frequency waves, whereas subtypes A2 and A3 contain increasing amounts of low-voltage rapid EEG activity, identified by *dotted horizontal lines*. The A3 phase is accompanied by a mild EMG activation, whereas all three subtypes are associated with a transient heart rate acceleration. EEG, Electroencephalogram; EMG, electromyogram.

ELECTROENCEPHALOGRAPHIC AROUSALS

According to the online Psychology Dictionary, *arousal is "a state of physiological alertness and readiness for action," or "a pervasive state of cortical responsiveness believed to be associated with sensory stimulation and therefore, the activation of fibers from the reticular activating system," or "a state of excitement or energy expenditure linked to a strong emotion."*[13]

The concept of arousal has a long history that is closely connected with the development of sleep neurophysiology. Scoring criteria and measurement of arousal are controversial issues; consequently, several definitions have been proposed.[14] Behavioral and autonomic concomitants of arousal may or may not be present simultaneously. When they are present, they can be graduated in intensity, whereas presence or absence of the single components of the arousal constellation depends on the involvement of the specific cerebral compartments.

The AASM manual[2] confirms the definition of EEG arousal established in 1992 by the American Sleep Disorders Association[15] (Figure 162-4). According to the original framework, arousals are markers of sleep disruption representing a detrimental and harmful feature of sleep. For this reason, they were excluded from the conventional sleep staging procedures. Nevertheless a number of studies have established that spontaneous arousals constitute a natural concomitant of sleep and occur with increasing frequency along the life span, following the profile of maturation and aging.[16,17] Moreover, the spectral composition of arousals[18] and their ultradian distribution throughout the sleep cycle reveal that arousals are endowed within the texture of physiologic sleep[8,14,19] under the biologic control of REM-on and REM-off mechanisms.[20] In accordance with these indications, arousal scoring is now considered a fundamental process in sleep staging classification, as well as scoring of spindles and K-complexes. By contrast, in the R&K system,[1] a K-complex, with or without an arousal, was unmistakably a marker of sleep stage 2. According to the AASM manual,[2] instead, if a K-complex is associated with an arousal, the epoch is scored as N1. In other words, the R&K approach gives primacy to the role of EEG

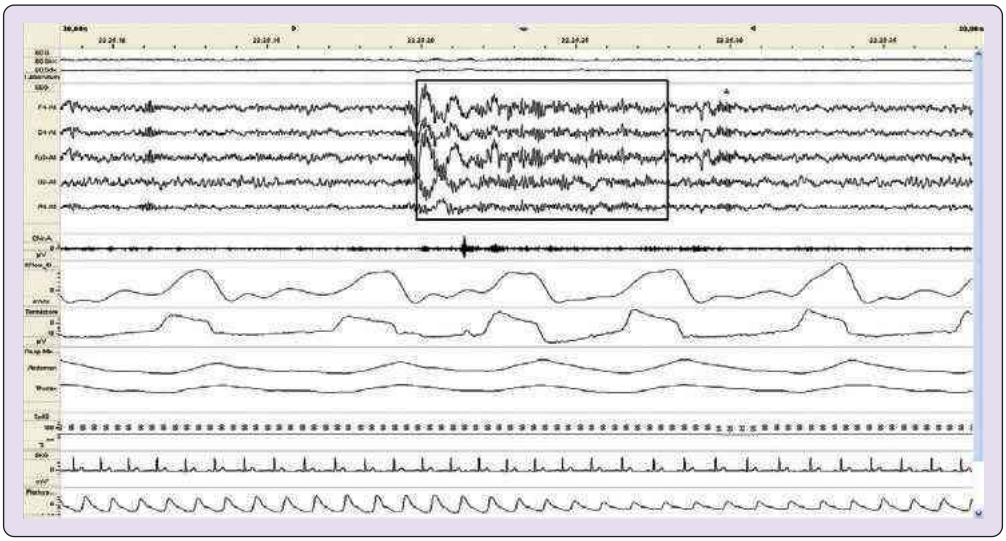

Figure 162-4 During sleep stages N1, N2, and N3 or rapid eye movement (REM) sleep, arousal is scored if there is an abrupt shift of frequency including alpha, theta, and/or frequencies greater than 16 Hz (but not spindles) that lasts at least 3 seconds, with at least 10 seconds of stable sleep preceding the change. Scoring of arousal during REM sleep also requires a concurrent increase in submental EMG activity lasting at least 1 second. Note that in non-REM (NREM) sleep, arousals often are heralded by one or more K-complexes. EMG, Electromyogram.

synchrony in the scoring process, whereas the AASM manual emphasizes the impact of EEG desynchrony.

A K-complex can be followed by other K-complexes, and in that case, stage 2 tends toward consolidation; or it can be followed by an arousal that reflects a regression toward a "shallower" neurophysiologic condition. Most arousals in NREM sleep (87%), however, are preceded by a K-complex or by a delta burst,[18] indicating that EEG synchrony and desynchrony may coexist in a natural dynamic succession as typified by CAP phases A2 and A3 (Figures 162-5 and 162-6).

Central Nervous System and Autonomic Arousals

> *Adaptive behaviour requires the selection of coherent sequences of action. What is needed for the production of organized sequential action is an internal representation of the temporal or task context, which can span periods during which the environment provides an indeterminate cue. An additional characteristic of human action is that it tends to assume a roughly hierarchic structure.*[21]

Somatosensory and auditory stimulation during sleep may result in cardiac, respiratory, and somatic modifications apparently without the EEG features of conventional central nervous system (CNS) arousal.[22] In particular, K-complexes and delta bursts are associated with activation of neurovegetative functions (heart rate, blood pressure) and can trigger muscle activity.[19] Despite their established arousal-related effect, however, K-complexes and delta bursts are neglected in scoring of arousals when they precede or occur independently of an EEG frequency speeding event.

This consideration does not imply that all arousal events are equal in terms of strength (i.e., immediate repercussions on motor and autonomic functions) and duration. It has been demonstrated that alpha EEG arousals lead to significantly different increases in systolic and diastolic blood pressure than do K-complexes, and studies carried out in patients with obstructive sleep apnea have ascertained that ASDA-defined arousals in NREM sleep are significantly longer after an apneic episode (12.6 seconds) than at the end of a hypopneic episode (9.9 seconds).[23] Moreover, quantifying arousal intensity in polysomnography (PSG) provides additional information on heart rate response.[24,25]

Taken together, these findings indicate that:

1. K-complexes and delta bursts are arousal equivalents; therefore any distinction between visible and nonvisible cortical arousals is misleading.
2. The arousal response is a continuous modulated phenomenon lying within a spectrum of EEG variability and having graduated effects on the ongoing polygraphic parameters.
3. The sleeping brain disposes of multiple arousal solutions that allow adaptive adjustments of the ongoing state to internal and external inputs.

Current knowledge about the arousal patterns has developed step by step, since the 1970s. The first step was taken by the Brussels school pioneers describing a "phase d'activation transitoire,"[9,26] the French version of AASM arousal. Subsequently, attention focused on the dual nature of arousals during NREM sleep, describing "desynchronization"- and "synchronization"-type components[14]—the latter named "antiarousal" by Hirshkowitz.[27] Finally, the whole arousal hierarchy was systematized by the Parma school in the CAP framework.[3,19] Accordingly, different expressions of arousal can be identified:

Behavioral arousal: Reported in the R&K manual[1] as movement arousal, it is characterized by any increase in electromyographic activity that is accompanied by a change in any other EEG channel.

Cortical arousal: Defined by the AASM committee as EEG arousal, it is identified by transient desynchronized EEG patterns interrupting sleep. It reflects a brief awakening of

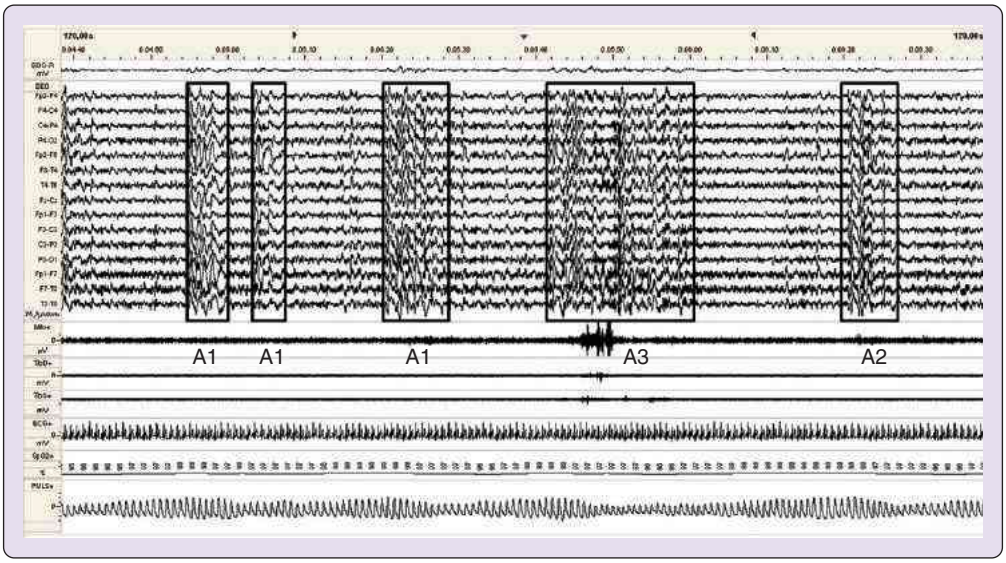

Figure 162-5 Different phase A subtypes may be scored within a common cyclic alternating pattern (CAP) sequence. The central phase A3 is combined with a strong activation of the chin EMG signal and a mild increase in muscle tone on both tibialis electrode traces. Note the waxing and waning of pulse wave amplitude (*bottom trace*), in phase with the periodicity and functional power of EEG oscillations. EEG, Electroencephalogram; EMG, electromyogram.

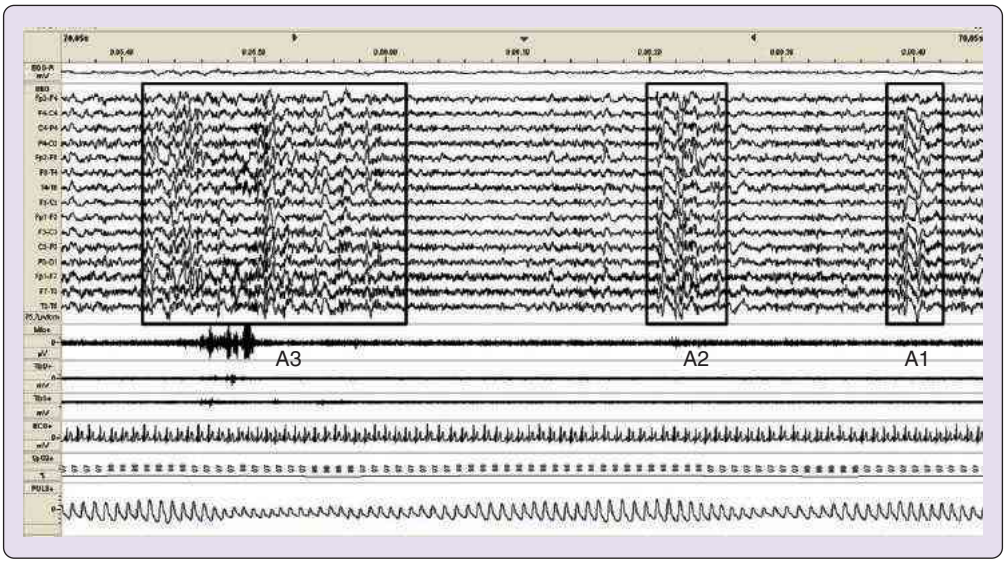

Figure 162-6 Specimen of cyclic alternating pattern (CAP) sequence with the three well-defined phase A subtypes (*black outlines*).

the cerebral cortex regardless of any concomitant participation of the autonomic system or behavioral components.

Subcortical activation: This arousal type is characterized by autonomic activation that is associated with a transient EEG pattern different from that for a conventional AASM arousal.[28-30]

Behavioral arousals and subcortical activations represent the two extremes of a gradual scale of cerebral activation. However, they are not separated by rigid boundaries. The temporal overlap between cortical, somatomotor, and autonomic events within the same arousal episode does not necessarily imply synchrony, and the order of activation of the single compartments can vary in different physiologic or pathologic circumstances.

In arousal phenomena during sleep, there is no mandatory chronologic and etiologic subordination. Such phenomena take place within interactive loops in which the cerebral cortex can be the starting or the ending point but in either case serves as a source of control. The origin of arousal is defined by the subsystem primarily activated or perturbed. The arousal can be generated directly by the brain with the physiologic

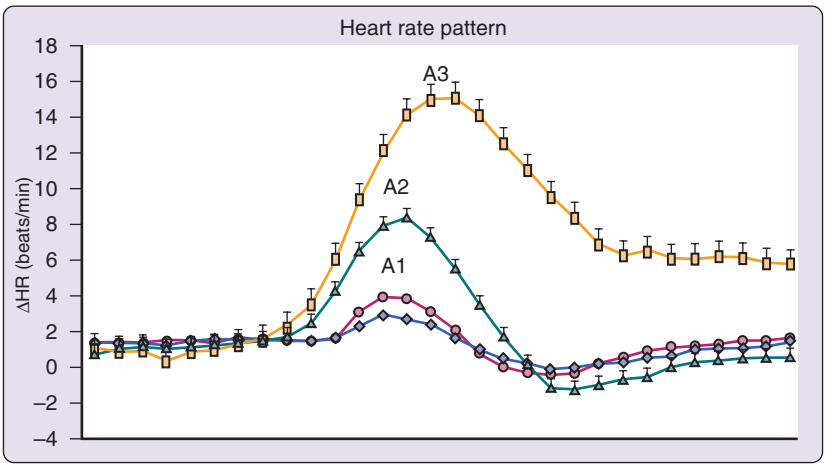

Figure 162-7 The hierarchical impact of the three phase A subtypes on heart rate (HR). The difference involves only the magnitude of reactivity, because they all induce heart rate increases. (Modified from Sforza E, Jouny C, Ibanez V. Cardiac activation during arousal in humans: further evidence for hierarchy in the arousal response. *Clin Neurophysiol* 2000;111:1611–9.)

evolution of sleep, such as with the transition from NREM to REM sleep, or in response to a sensorial perturbation, such as respiratory interruption, environmental noise, alteration of blood pressure or heart rate, or physical movements. In any case, it is the involvement of the brain that makes arousal a unitary phenomenon[31] in which activation is modulated through a hierarchy of phasic responses (Figure 162-7) ranging from slow wave high-amplitude EEG patterns (CAP subtypes A1) to fast low-voltage activity (CAP subtypes A3).

SLOW OSCILLATIONS AND THE HOMEOSTATIC NATURE OF CYCLIC ALTERNATING PATTERN

> *Any system in dynamic equilibrium tends to reach a steady state, a balance that resists outside forces of change. When such a system is disturbed, built-in regulatory devices respond to the departures to establish a new balance. All processes of integration and coordination of function are examples of homeostatic regulation.*[32]

Besides CAP, the other major EEG activity in the frequency range below 1 Hz is the so-called slow oscillation.[33] This 0.5- to 0.9-Hz EEG rhythm, which characterizes states of reduced tonic arousal, was outlined during anesthesia and NREM sleep in both animals (cats and rats) and human subjects. The slow oscillation is generated in cortical neurons and consists of phases of depolarization, characterized by intensive neural firing, followed by long-lasting hyperpolarization. Hence the two phases of the slow oscillation are characterized by opposite neural phenomena: cortical excitation, made up of synaptic potentials, and cortical inhibition, due mainly to disfacilitation in the network. The excitatory component of the slow oscillation is effective in discriminating the K-complexes and delta waves, which do not occur in isolation but are grouped into complex wave sequences. The coalescence of slow rhythms is especially visible during NREM sleep. In particular, during slow wave sleep, high-voltage slow waves rarely appear as isolated features; rather, in most cases they converge into discrete clusters, resulting in the phase A1 subtypes of CAP. The main frequency of slow oscillation occurrence during deep sleep is 0.8 Hz.[34] Accordingly, the mean interval between K-complexes and delta waves within A1 phase events hosting large portions of EEG synchronization actually ranges in frequency between 0.8 and 0.9 Hz. As NREM sleep progresses from N1 to N3, the differences in morphology and voltage between phase A (clusters of K-complexes and delta bursts) and the successive phase B (sleep stage background) become gradually less evident until the EEG is dominated by the uniform pattern of non-CAP (Figure 162-2), with the high-amplitude slow waves recurring in the frequency range of the less-than-1-Hz oscillation[35] (see Figure 162-2).

Neurophysiologic investigation reveals that slow cortical oscillation begins organizing in small territories, thereafter recruiting larger areas through coupling mechanisms, as sleep deepens. Halasz and colleagues[36] observed that sensory stimuli delivered during the descending slope of sleep cycles under high homeostatic slow wave pressure elicit a paradoxical sleep-like response (A1 phase of CAP), rather than the classic arousal response.

It is known that late components of sensory event-related potentials are sensitive to vigilance changes. The increased synchronization due to gating of the burst-firing thalamocortical working mode during slow wave sleep contributes to the enlargement of the late event-related synchronization components, taking the shape of polyphasic slow waves—the main components of K-complexes. The relationship of primary sensory-evoked potentials with K-complexes has been confirmed by Riedner and coworkers.[37] Recently, Laurino and associates[38] have shown that different modalities of sensory-evoked potentials act as traveling corticocortical excitations. When they reach the frontocentral region, depending on the proneness of the cortex at different NREM sleep levels, they elicit a biphasic slow wave response: the K-complex. In other words, during NREM sleep the impulses convey environmental information to the brain and at the same time fuel slow waves. Studies on artificial boosting of slow oscillations during NREM sleep indicate that sleep slow waves have a reactive nature. Marshall and coworkers[39] induced slow oscillation–like potential fields by transcranial application of polarizing

current through bilateral frontolateral electrodes during early nocturnal NREM sleep. The artificially induced slow oscillation subsequently increased slow wave sleep and entrained slow spindle activity over the frontal cortex. Massimini and associates[40] were able to trigger sleep slow waves, resembling spontaneous ones, by transcranial magnetic stimulation. Stimulation applied during stage 2 led to rapid transition to stage 4. Ngo and colleagues[41] enhanced slow oscillations in sleeping subjects by applying a random acoustic stimulation of 0.8 Hz. These convergent results suggest the existence of a basic slow wave–defending mechanism during NREM sleep. Its physiologic triggers are environmental or internal sensory stimuli resulting in K-complex or CAP A1 phase. It can also be artificially elicited by electrical stimulation of the brain or transcranial magnetic stimulation. This input-dependent, modality-independent stereotypical response could be considered as the elementary building block of NREM sleep.

DYNAMIC ORGANIZATION OF THE ELECTROENCEPHALOGRAM DURING CYCLIC ALTERNATING PATTERN

Interactions thus happen at all levels of organization between different objects within a level, and, internally to each level, they are not additive. Moreover, communication is both intra- and inter-level and, therefore, a change in one level may spread its effects at the same time to higher and lower ones.[42]

The dynamic properties of the EEG assessed by means of the nonlinear cross prediction test[43] indicate that sleep is a self-organized evolving process of different high- and low-dimensional states of the EEG. The CAP sequences express short periods of low-dimensional nonlinearity that interrupt a baseline EEG not distinguishable from high-dimensional noise (non-CAP). The decrease in dimensionality of the EEG structure, especially evident during the A1 CAP subtype, indicates a decreased complexity reached by means of an increased brain synchronization.[44] The different EEG frequency components of CAP are not uniformly distributed over the scalp. Two main frequency bands can be detected, characterizing, respectively, CAP subtype A1 events (0.25 to 2.5 Hz), showing a clear prevalence over the anterior frontal regions, and CAP subtype A3 events (7 to 12 Hz), located over the parietal-occipital areas. The two frequency bands coexist in the CAP A2 subtype.[45] Because the generators of the low-frequency CAP component are localized mostly over the frontal midline cortex, CAP subtype A1 events can be considered as frontal lobe arousals.[31] By contrast, those of the high-frequency band involve both midline and hemispheric areas within the parietal and occipital areas. The nonrandom association between the two different frequency components of CAP suggests the involvement of a complex pattern of EEG synchronization and resynchronization, including both longitudinal intrahemispheric pathways and transversal interhemispheric connections.[46-51]

MEASURES OF CYCLIC ALTERNATING PATTERN

But neither does time exist without change; for when the state of our own minds does not change at all, or we have not noticed its changing, we do not realize that time has elapsed, any more than those who are fabled to sleep among the heroes in Sardinia do when they are awakened; for they connect the earlier 'now' with the later and make them one, cutting out the interval because of their failure to notice it.
***Aristotle,* Physics**[52]

EEG features are highly sensitive markers of brain development. Accordingly, sleep reflects the physiologic changes accompanying different ages across the lifespan. CAP parameters also undergo dynamic changes across the maturational phases of life. The age-related values for CAP have been measured and defined to establish the physiologic ranges of normal sleep. In recent years, several studies in children revealed specific changes of CAP parameters in different sleep disorders, neuropsychological disabilities, and mental retardation.[53,54] An overview of CAP studies in childrens' sleep was published by Bruni and colleagues.[55]

A Phases

The percent of A1 subtype events for successive age groups can be plotted to show a bell-shaped curve, with reported values of 69.7% in infants, 63.2% in preschool-aged children, 84.4% in school-aged children, 85.5% in peripubertal children, and 71.3% in teenagers. This percentage tends to decrease and then slightly increase between the ages of 30 and 60 years (61.4% in young adultsand 62.0% in those of middle age) and, finally, declines after the age of 60 (46.6%). By contrast, subtypes A2 and A3 undergo a linear increase from infancy to old age, similar to the arousal pattern seen across the life span.[56]

Cyclic Alternating Pattern Rate

CAP rate is the most extensively used parameter for clinical purposes. Calculated as the percentage ratio of total CAP time during NREM sleep to that during NREM sleep time, CAP rate is the measure of sleep instability[57]; it typically increases when sleep is disturbed by internal or external factors,[58] and its variations correlate with the subjective appreciation of sleep quality, with higher values of CAP rate associated with poorer sleep quality.

In normal sleepers, CAP rate shows a low night-to-night intraindividual variability. CAP rate also shows a complex evolution during development. It is very low in the first months, then increases gradually, with a peak in adolescence, and then gradually decreases in adulthood, followed by an increase in old age.[56] As soon as NREM sleep emerges, CAP begins to develop, and the oscillating pattern of the different phasic EEG activities becomes evident. The gradual appearance of an oscillating pattern of slow EEG activities, representing the first prototype of CAP, appears at 46 to 55 weeks of conceptional age. CAP rate in infants 3 to 4 months of age increases from 6.83% ± 3.58% to 12.9% ± 2.21%, depending on the level of maturation of sleep patterns. Starting at the age of 3 years, there is a gradual increase in CAP rate that peaks at the peripubertal age and then decreases to its lowest values, in young adults (25.9% in preschool children aged 3 to 6 years old and 33.4% in school-aged children 6 to 10 years old; 62.1% in peripubertal children aged 8 to 12 years; 43.4% in teenagers; 31.9% in young adults; 37.5% in middle-aged adults, and 55.3% in elderly persons).[55,56] The age-related changes of CAP rate reflect the biologic growth processes that accompany the preparation for and onset of adolescence,

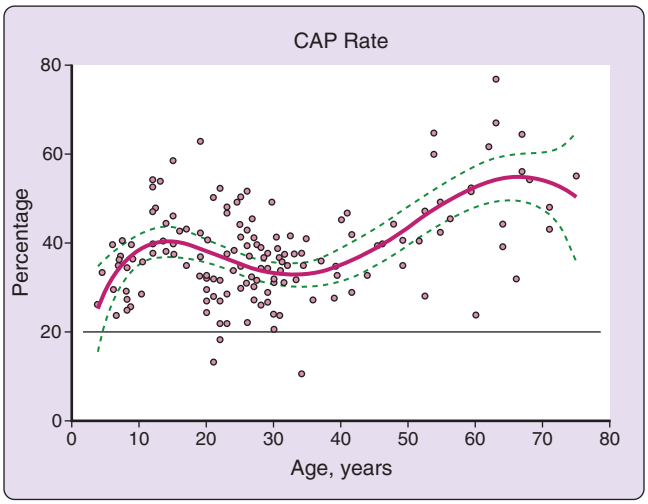

Figure 162-8 The age-related distribution of cyclic alternating pattern (CAP) rate in healthy subjects. The two peaks correspond to adolescence and senescence; the trough coincides with young adulthood. Note that almost all normal CAP rate values are higher than 20%. Narcoleptic patients and long-term benzodiazepine users and abusers usually show percentages below this threshold.

the maturational consolidation of development, and the process of senescence that increases the instability of sleep[57,58] (Figure 162-8).

CYCLIC ALTERNATING PATTERN AND SLEEP DISORDERS

Neuronal avalanches, i.e., cascade of activity with power law distribution of size and durations, are only one of the observed proprieties suggestive of criticality. Criticality is very advantageous for the brain, in terms of optimization of dynamical range, information transmission, and capacity (large repertoire of diverse activity patterns). All these intriguing results on spontaneous dynamics support the long-lasting hypothesis that brain can move in a landscape with multiple dynamical attractors, and that up states may be the result of the system falling in one of these attractors. From this point of view, the spontaneous fluctuations between up and down state may be the signature of the system posed at a non-equilibrium phase transition, where system fluctuates in the landscape, and flexibly switches from one state to another.[4]

Cyclic Alternating Pattern and Sleep-Disordered Breathing

A great body of evidence has confirmed that sleep fragmentation and punctuation of sleep with frequent, brief arousals reduce its restorative properties. Restoration is reduced even when arousals do not alter sleep macroarchitecture (as summarized using standard 30-second epoch sleep stage scoring). Correlation between the number of arousals and daytime sleepiness in patients with obstructive sleep apnea syndrome (OSAS) has been reported, but phasic delta activities during sleep (with diurnal consequences) also can exert activating effects. In subjects with upper airway resistance syndrome (UARS), airway opening may occur with a concurrent increase in delta power and not necessarily associated with a scorable EEG arousal.[59] Termination of respiratory events marked by an EEG pattern of delta waves also has been observed in patients with OSAS.[22] Involvement of either slow or fast EEG responses depends on the regulation of upper airway patency. Respiratory patterns that need correction activate the CNS. This activation varies, depending on the sensory recruitment and the adequacy of the response. A respiratory challenge is resolved by a cortical arousal only when the thalamocortical structures that control slow waves fail to modulate breathing or when ascending reticular volleys are required to restore respiration. The slow waves determine a "softer" autonomic reaction, which in certain pathologic conditions may be strong enough to overcome a disturbing factor, such as with an obstructive event. Otherwise, the slow rhythms are immediately replaced by faster EEG activities, which guarantee a more powerful activation of autonomic functions. Probably the effects on daytime function are linked not to a single phase A subtype but to the reciprocal amount and distribution of the single subtypes. In severe OSAS, CAP analysis shows increased values of CAP rate accompanied by enhanced percentages of subtypes A3 (Figure 162-9) and reduced percentages of subtypes A1.[10] When patients with OSAS are treated effectively with nasal continuous positive airway pressure (CPAP), the ventilatory-induced reduction in CAP rate, which correlates significantly with daytime sleepiness, is associated with a robust curtailment of subtypes A3 and a progressive recovery of the A1 percentage.[60,61] Different features occur in primary insomnia, in which high values of CAP rate are associated with an enhanced arousal index and increased percentages of all phase A subtypes. Compared with placebo, however, active medication significantly reduces CAP rate and percentages of subtypes A1 and A2 but exerts only marginal effects on subtypes A3 and on EEG arousals.[62]

Insomnia

In normotensive subjects with chronic insomnia, higher nighttime blood pressure and blunted blood pressure dipping are associated with brain cortical activation during sleep in the absence of arousal rate changes.[63] This correlation implies that scoring of single arousal events can be enriched by integrative sleep parameters, including the more general concept of oscillating activation. Previous studies ascertained that acoustic stimuli enhance the physiologic CAP rate and contribute to poor sleep and daytime dysfunction even without an increase in sleep fragmentation. CAP thus operates as a "double-edged sword": Whereas limited quantities of CAP mediate physiologic effects, larger quantities reflect difficulties in consolidation and preservation of sleep normally under cortical control and may therefore be associated with adverse effects. Whatever the nature of the disturbance, the outcome is the amplification of an otherwise physiologic process.[64] An investigation carried out in a large cohort of white patients with primary insomnia demonstrated that CAP parameters consistently demonstrate the reduced quality of sleep in persons with insomnia and can corroborate the efficacy of hypnotic medication. CAP rate is the PSG parameter that best reflects subjective sleep quality and is also the most sensitive sleep measure of effective drug treatment.[62] Similar findings have been reported for subjects in non-white populations. In Japanese patients with psychophysiologic insomnia, a randomized crossover comparative study with placebo showed that hypnotic treatment (with zolpidem) increased sleep stability by

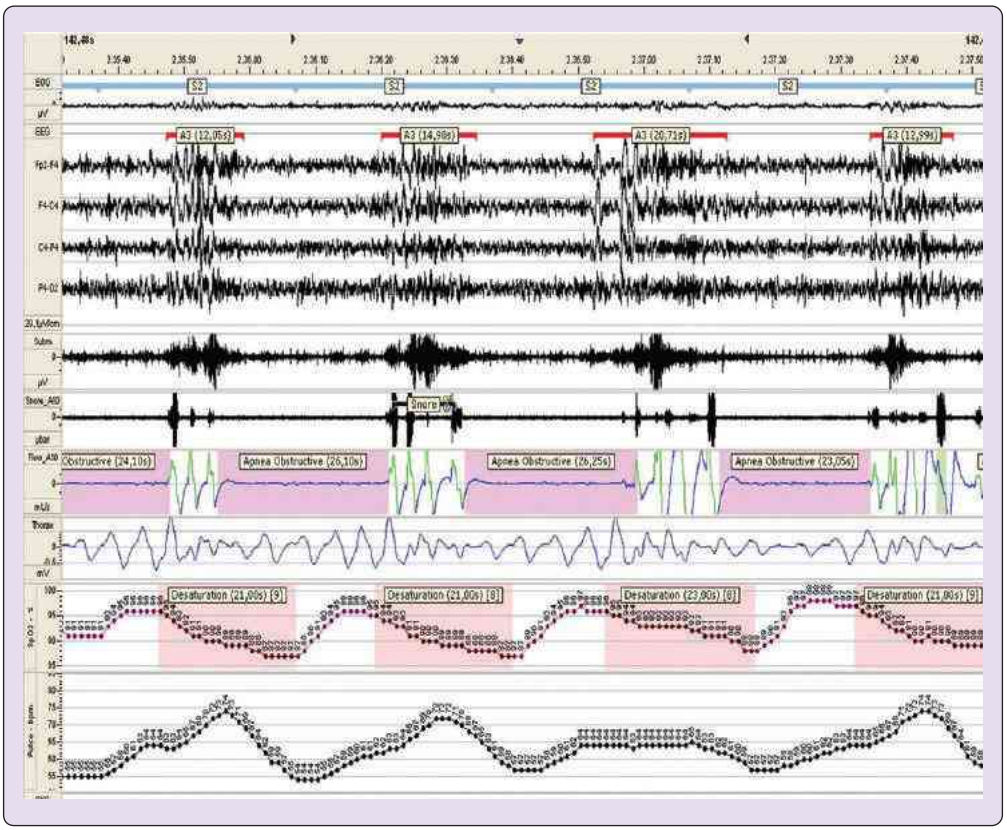

Figure 162-9 A cyclic alternating pattern (CAP) sequence of phase A3 subtype events that allow recovery of respiratory activity at the end of recurring episodes of obstructive apnea. Note the exaggeration of muscle and vegetative oscillations of what normally happens in nonpathologic conditions.

significantly reducing the overnight CAP rate as well as improving subjective sleep quality.[65]

CAP parameters also are useful tools for monitoring the effects of intermittent hypnotic treatment[66] and for investigating cases of paradoxical insomnia.[67] Compared with normal control subjects, insomniacs with so called sleep state misperception (i.e., "misperceptors") show significantly higher CAP rate in stage 1 and in stage 2 but not in slow wave sleep. The percentage of subtype A2 events, which include both sleep promoting and wake-promoting EEG features, is significantly higher ($P < .001$) in misperceptors (31%) than in control subjects (24%). Misperceptors report lower numbers but longer intervals of subjective awakenings (mean, 4) compared with objective findings (mean, 11). The mismatch could be explained in part by the large amounts of CAP between successive awakenings that were merged together in a single experience. In other words, if sleep between two successive awakenings is superficial (expressed by sleep stages 1 and 2), unstable (as reflected by increased amounts of CAP), and fragmented (increased arousal index), time separating the two events is perceived as continuous wake. These findings suggest a greater sensitivity of misperceptors to sleep problems.

Overall, assessment of sleep quality relies on a variety of PSG measures including sleep duration (quantified by total sleep time and sleep efficiency), sleep intensity (reflected by N3), sleep continuity (altered by nocturnal awakenings and arousals), and sleep stability (impaired by excessive amounts of CAP). These measures are susceptible to deterioration in various ways and in accordance with the clinical manifestations of insomnia. In the hierarchy of sleep measures, CAP variables are arguably the most sensitive to any source of internal or external perturbation during sleep.

Cyclic Alternating Pattern and Body Movements

CAP can promote or release motor activities ranging from physiologic body movements to periodic limb movements (PLMs), sleep bruxism, night terrors, and sleepwalking. Overall, the CAP A phase can be conceptualized as an "amplifier" that may facilitate the occurrence of pathophysiological events, whereas the B phase exerts a "filter" action. The magnitude and temporal variations of cerebral activity and autonomic responses before and during the motor event support the hypothesis of a continuum in arousal reactivity present not only on visual analysis but also at the spectral level. With respect to manual scoring, this continuum is translated by progression of the arousal response from delta and K-complex bursts to an EEG arousal and full awakening.[12,14] The same continuum can be detected by spectral analysis, starting with enhancement of delta activity and increase in heart and respiratory rates,[68,69] which may be followed by a transition to fast EEG activities. The hierarchy of the arousal response is related to severity provided by emergency. From a mechanistic standpoint, postapnea arousals in sleep breathing disorders are the most evident example of automatic and purposeful periodic movement during sleep.

PLMs reflect a pattern of motor phenomena and EEG changes, both recurring at intervals of 20 to 40 seconds. The periodicity of PLM parallels the recurrence of CAP cycles

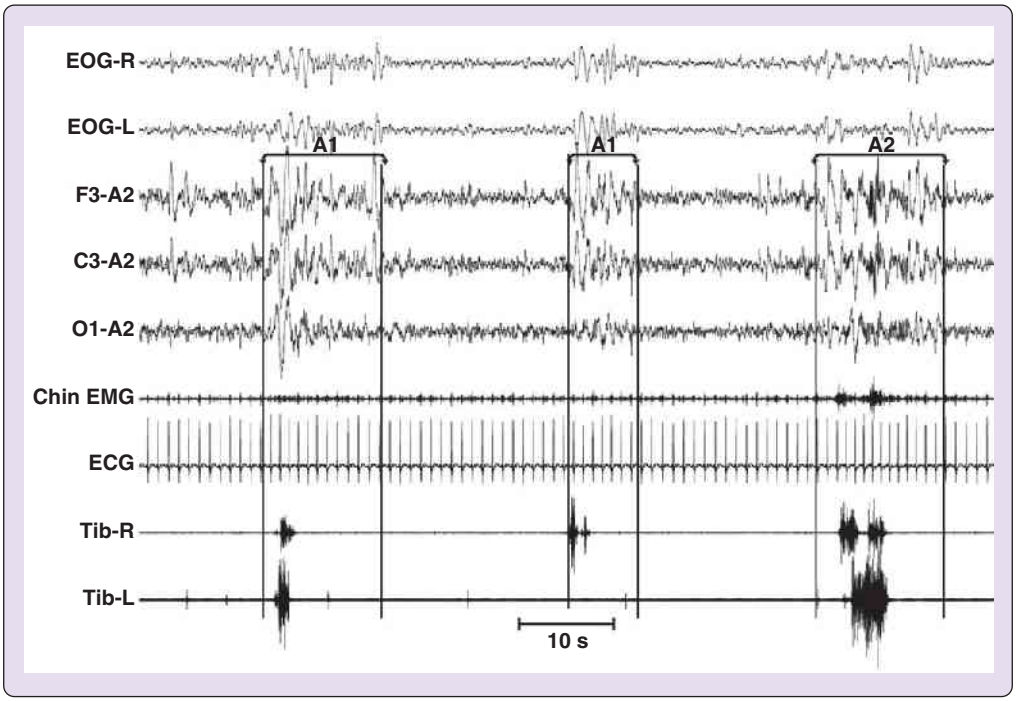

Figure 162-10 Cyclic alternating pattern (CAP) sequence coupled with periodic limb movements. Note that myoclonic jerks during non–rapid eye movement (NREM) sleep also can be associated with a phase A1 subtype event generally not scored as a conventional arousal. ECG, Electrocardiogram; EMG, electromyogram; EOG, electrooculogram; Tib, tibialis muscle.

(Figure 162-10). It is not surprising, therefore, that the two PSG manifestations (PLM and CAP) are mutually connected. This association does not imply that PLM is induced by CAP; rather, the latter represents a permissive framework that synchronizes rhythmicity. In patients with PLMs, 92% of all jerks detected in NREM sleep occurred in CAP, with the great majority of limb movements (96%) associated with a phase A, especially subtypes A2 and A3 (95%). Ninety-four per cent of the nocturnal jerks coupled with a phase A appeared in concert with onset of the phase or when it had already begun. In particular, 67% of the myoclonic events occur in the first 2.5 seconds of the A phase. PLM onset is heralded by a significant activation of delta activity power (the initial portion of the phase A2 or A3 subtype) starting approximately 3 to 4 seconds before occurrence of movement.[70-72]

Parasomnias and Disorders of Arousal

Some disorders of arousal show a typical EEG pattern defined as hypersynchronous delta activity, that corresponds to the high-voltage delta bursts of CAP A1 subtypes in slow wave sleep.[73-75] CAP recording and analysis provide a useful technique for evaluating parasomnias involving arousal. Subjects with sleepwalking or sleep terrors show an increase in CAP rate, a higher percentage of A subtype events in slow wave sleep, and a decrease in phase B and CAP cycle duration.[76-79] The shorter duration of CAP cycle and phase B determines an abnormally fast oscillatory pattern of the amplitude of EEG slow wave components (defined as hypersynchronous delta activity, slow wave sleep arousals, or CAP subtype A1), leading to recurrent arousals from slow wave sleep, with consequent sleep fragmentation, which contributes to trigger slow wave sleep parasomnias.[78] In chronic sleepwalkers, instability of NREM sleep, detectable by CAP analysis, is present even during nights without sleepwalking episodes. In children, this instability has been related to the presence of associated sleep disorders, such as upper airway resistance syndrome or PLMs.[80,81]

Cyclic Alternating Pattern and Epilepsy

Interictal Discharges

In primary generalized epilepsy, interictal discharges commonly are activated during unstable sleep, with the number of EEG paroxysms per minute of sleep significantly higher during CAP than during non-CAP. Phase A has a significant activation influence, whereas phase B exerts a powerful and prolonged inhibitory action.[82,83] In comparison with normal control subjects, the occurrence of interictal epileptiform discharges in patients with primary generalized epilepsy has no remarkable consequences on sleep macrostructure, but such events have significant effects on arousal stability, in that epileptic patients show higher CAP rate values.[84]

As occurs with primary generalized epilepsy, the presence of focal lesional interictal epileptiform discharges impairs the stability of sleep. By contrast, despite the high burst frequency during NREM sleep, interictal epileptiform discharges in benign epilepsy with rolandic spikes are not modulated by the arousal-related mechanisms of CAP.[85,86]

Ictal Events

Seizures require a process of changes in brain dynamics that start before clinical manifestation. Analysis of preictal synchronizations indicates that epileptic seizures do not occur in a behavioral vacuum, but that the functioning of the brain

before the seizure occurs is critical. Seizure foci are surrounded by pools of neurons functioning in local and large-scale interactions and are "pulled" into the seizure discharge once the seizure has started. The preictal period may reflect a state of increased susceptibility for pathologic synchronization, which acts as a route to the seizure.[87] In patients affected by focal epilepsy, the great majority of nocturnal partial motor seizures occur during NREM sleep, and almost always during a phase A.[88] These findings indicate that an NREM sleep condition of highly fluctuating vigilance constitutes a favorable substrate for the occurrence of focal epileptic seizures.

Nocturnal Frontal Lobe Epilepsy

Clinically, nocturnal frontal lobe epilepsy (NFLE) consists of a spectrum of paroxysmal motor manifestations ranging from major seizures to paroxysmal arousals and minor motor events. A common feature is the onset of all episodes during NREM sleep. Paroxysmal arousals and minor motor events may recur every night, sometimes several times per night, arising mainly from CAP in stage 2 sleep.[89] In NFLE, stereotypical features involve not only motor behaviors but also polysomnographic patterns.[90] Patients with NFLE show a significant increase in wake after sleep onset, slow wave sleep duration, and REM latency and a significant increase in CAP time, CAP rate, CAP cycles, and mean duration of CAP sequences. These findings are associated with a significant enhancement of all subtypes of the A phase of CAP (mainly subtype A1). Ninety percent of total NREM seizures occur during a CAP sequence, and CAP-related seizures occur in association with a phase A. Antiepileptic treatment effects a partial reduction in both major attacks and minor motor events. REM latency, wake after sleep onset, and sleep efficiency recover to normal values, but NREM sleep instability remains at a pathologically high level and is associated with persistence of daytime sleepiness.[91] The residual high level of NREM sleep instability probably is related to the persistence of epileptic discharges that act as internal triggers of subcontinuous arousal fluctuations during NREM sleep. Despite the reduction in nocturnal seizures, the persistence of epileptic events, high levels of NREM sleep instability, and impaired daytime vigilance under drug treatment suggest the need for new therapeutic options in this particular form of epilepsy.

AUTOMATED ANALYSIS OF CYCLIC ALTERNATING PATTERN

Consolidated evidence has demonstrated that CAP parameters provide more detailed information and are significantly more sensitive than conventional sleep measures. The visual scoring of CAP is time-consuming, however, and this requirement can limit its use in routine clinical practice. In other words, only the availability of an adequate system for automated detection of CAP can make it an easily exploitable tool. The problem of automated CAP recognition has been addressed in several studies, with interesting results.[92-94] Most proposed classification methods, however, require the preliminary measurement of sleep macrostructure, making it necessary for the human scorer to visually classify the sleep profile. Moreover, these methods rely on the extraction of spectral parameters from the EEG signal to compute descriptors on time windows and on the application of machine learning algorithms for classifying each window as belonging to a phase A of CAP or not. A preliminary study investigated a set of descriptors computed on 1-second-long windows with different techniques, and the information content of each descriptor was evaluated by means of receiver operating characteristic (ROC) curves.[95] The descriptors were used in a subsequent study training four different workers for the classification of CAP A phase subtypes, in which the linear discriminant was found to be the most accurate, with an average accuracy of 83%.[96] However, owing to the intrinsic characteristics of A phase activity, which consists of transient, nonstationary phenomena, the signal characteristics are likely to vary over time, and it is not convenient to define a fixed window length. A dataset of 16 PSG recordings from healthy subjects was used for this study, and the EEG traces first were subjected to an automated isolation of NREM sleep segments by means of an artificial neural network and then underwent a segmentation process based on the spectral error measure. The information content of the descriptors was evaluated by means of receiver operating characteristic curves and compared with that of descriptors obtained without the use of segmentation. Finally, the descriptors were used to train a discriminant function for the automated classification of CAP phase A subtypes. With respect to previous scoring methods, significant improvement was obtained in terms of both information content carried by the descriptors and accuracy of the classification. Average CAP rate obtained by automatd scoring was 44.83% ± 12.41%, versus 43.83% ± 10.13% measured with visual analysis.[96] Although the sensitivity was still not very high (69.55% ± 6.6%), the specificity (90.49% ± 2.8%) and the accuracy (87.19% ± 2.48%) showed a significant increase with respect to the previous study, indicating that EEG segmentation proves to be a useful step in the computation of descriptors for CAP scoring.

CYCLIC ALTERNATING PATTERN: THE MASTER CLOCK OF SLEEP

> *In biology, living systems dynamics are not a matter of stable or unstable equilibrium, but of far from equilibrium processes, i.e. which undergo a flow of energy or matter, yet they are "structurally stable" systems. This hard to understand simultaneous structural stability and non-conservative behavior is a blend of stability and instability due to the coexistence of opposite properties such as "order/disorder … integration/differentiation."*[42]

Objection could be raised on the usefulness of CAP in routine clinical practice.[97] Besides the multiple clinical applications of CAP,[98] attention should be focused on the underlying rationale for the CAP scoring methodology. The main assumption in CAP scoring is the fact that during certain periods of the night, the arousal level of sleep is unstable. Accordingly, CAP is decreased in narcolepsy[99,100] and multiple system atrophy,[101] with drug administration[102-104] and CPAP treatment for obstructive sleep apnea,[60,61] and during night-time recovery sleep after prolonged sleep deprivation.[105]

The concept of instability is a basic issue of all complex systems and supports the dynamics of biologic variability. Within certain ranges, instability warrants flexible and adaptive features for the complex system. To guarantee survival during prolonged unconsciousness (i.e., sleep), a strong interaction among all of the biologic subsytems is mandatory. CAP

analysis is not limited to the finding of a single event (e.g., an isolated arousal) but instead identifies a pattern (presence or absence of a CAP sequence) that translates to a physiologic state involving cerebral activities, autonomic functions, and behavioral features.

In normal sleep, CAP accompanies the stage transitions maintaining in phase both the EEG and autonomic functions through regular fluctuations. Accordingly, even without the EEG leads, the detection of an unstable cardiorespiratory pattern is likely to be associated with an oscillatory condition of cerebral activities.[106] In other words, what happens upstairs (brain) is reflected at the lower levels (autonomic and muscle parameters), and vice versa. Temporal patterns are generated within the sleeping brain, and CAP is a "master clock" that determines the framework within which temporal patterns can be generated and implemented.

With attribution of activation relevance to all A phases of CAP (including also K-complexes and delta bursts), a major advance has been to overcome the stark contrast between visible and nonvisible arousals[107] that for years froze the possibility of understanding the brain's flexible capacity to produce different EEG features in different neurophysiologic situations. The approach to arousals during sleep would be better conceived not as static single events but rather as a general dynamic process in which activating phenomena of differing intensity and morphology can be organized into sequences. Conventional EEG arousals represent the tip of an iceberg composed of other, more subtle but equally powerful activating events. This extensive interpretation of arousals and their nonrandom distribution into periodic sequences converges on CAP, a structured organization of sleep beyond the static stage setting. Perhaps the time has come to update the scoring rules of sleep and to quantify what is seen in the PSG and use CAP to evaluate brain function.[108]

> *Each of them contains all within itself, and at the same time sees all in every other, so that everywhere there is all, and all is all . . . . Each of them is great, the small is great; the sun, there, is all the stars and every star, again, is all the stars and sun. While some one manner of being is dominant in each, all are mirrored in every other.*
>
> ***Plotinus*, The Six Enneads *(ca. 250 CE)***

CLINICAL PEARLS

- The concept of instability is a basic issue of all complex systems and supports the dynamics of biologic variability. Within certain ranges, instability warrants flexible and adaptive features in the complex system.
- CAP is the EEG marker of NREM sleep instability. Conversely, non-CAP translates to a condition of stable sleep.
- CAP is the "master clock" that accompanies the stage transitions maintaining in phase both the EEG and autonomic functions through regular fluctuations.
- Conventional EEG arousals represent the tip of an iceberg composed of other, more subtle but equally powerful activating events often organized in the CAP sequences.
- K-complexes and delta bursts are arousal equivalents; therefore any distinction between visible and nonvisible cortical arousals is misleading.
- The arousal response is a continuous modulated phenomenon lying within a spectrum of EEG variability.
- The phase A subtypes of CAP allow adaptive adjustments of the ongoing state to internal and external inputs.
- CAP parameters undergo dynamic changes across the maturational phases of life and show specific alterations in the different sleep pathologic conditions.
- CAP plays a gate control role for a number of isolated and periodic events that characterize sleep disorders.
- EEG segmentation seems to be a useful tool for automated scoring of CAP.

SUMMARY

Sleep is a dynamic process with a self-regulating character. The nightly recurring sleep process is organized into consecutive cycles in which the sequence of NREM stages and the alternation between NREM and REM sleep show a quite stable tendency and a largely predictable pattern. These constraints produce the macrostructural development of sleep. However, transient EEG changes can interact with the expected development of sleep and ensure adaptation to both internal and external conditions. Arousals and CAP represent rapid adaptive adjustments of vigilance during sleep. Failure of these compensatory processes contributes to sleep disorders and nonrestorative sleep. Delineation of CAP parameters and of the role of CAP in the dynamic organization of sleep has led to multiple clinical applications of CAP, and various methods are available for the automated quantification of CAP measures.

Neurologic Monitoring Techniques

Beth A. Malow

Chapter Highlights

- The focus of this chapter is on the methodology and indications for V-EEG-PSG in the diagnosis of nocturnal events. Techniques and approaches that are described include routine electroencephalography, short-term continuous video-electroencephalogram (EEG) monitoring, long-term continuous video-EEG monitoring, and ambulatory monitoring.
- The EEG may show either a rhythmic evolving discharge characteristic of an epileptic seizure or interictal epileptiform discharges that occur apart from epileptic seizures. Lack of an EEG change, however, does not exclude some types of epilepsy, particularly those of frontal lobe origin.
- Included in this chapter are several case examples illustrating why a particular monitoring technique is selected for a specific clinical situation.

Nocturnal spells often present diagnostic problems in sleep medicine because the history alone may not provide sufficient information to differentiate among the various diagnostic possibilities. Standard polysomnography (PSG) is helpful in defining the state and stage of sleep from which such nocturnal spells emerge, but its diagnostic capability is limited because behavioral analysis often is not included, and only a certain number of channels are devoted to electroencephalography. These shortcomings are especially pertinent to the evaluation of suspected nocturnal epileptic seizures, defined by behavioral and motor manifestations in addition to electroencephalogram (EEG) criteria.[1] Both behavioral and EEG analyses are critical for characterizing epileptic seizures and for distinguishing them from parasomnias.

The behavioral and EEG manifestations of nocturnal spells caused by parasomnias, neurologic disorders, and psychiatric disorders can be characterized more precisely by combining standard PSG with video recordings and extensive (comprising 12 or more channels) EEG montages.[2] The focus of this chapter is on the methodology and indications for video-electroencephalography—PSG (V-EEG-PSG) in the diagnosis of nocturnal events. Specific techniques and approaches that are described include routine electroencephalography, short-term continuous video-EEG monitoring (STM), long-term continuous video-EEG monitoring (LTM), and ambulatory monitoring.

METHODOLOGY

Technical Aspects of Electroencephalography

The EEG measures the difference in electrical potential between pairs of electrodes placed on the scalp. These signals, reflecting synchronous postsynaptic potentials in large groups of neurons, are amplified and filtered to produce a recording.[3] The *international 10–20 system* of EEG electrode placement is customarily used, in which "10-20" refers to 10% and 20% of the distances between standard cranial landmarks[4,5] (Figure 163-1). In this system, each electrode site is identified with a letter representing the underlying region of the brain and with a number indicating a specific position above that region, with odd numbers indicating the left hemisphere and even numbers indicating the right hemisphere (e.g., T3 represents a left midtemporal electrode).

Each recording channel is derived from the signals from a pair of electrodes, and several pairs of electrodes, or derivations, are combined to form a *montage.* Montages may be either referential or bipolar. In *referential* montages, one of the electrodes in each pair is connected to a common electrode (e.g., channel 1: Fp1-A1; channel 2: F7-A1; channel 3: T3-A1; channel 4: T5-A1; channel 5: O1-A1). In *bipolar* montages, there is no common electrode. Bipolar montages usually are arranged in a chain with the same electrode in adjacent derivations (e.g., channel 1: Fp1-F7; channel 2: F7-T3; channel 3: T3-T5; channel 4: T5-01).

The EEG montages used in a combined electroencephalography-PSG study depend on the clinical indication and the number of channels available for recording (Table 163-1). The channels suggested in this chapter for inclusion in such studies are in addition to those recommended by the American Academy of Sleep Medicine for the scoring of sleep stages.[6] Physicians and technicians using EEG monitoring techniques require a solid knowledge of the principles of EEG recording and interpretation. Additional information regarding EEG methodology is available in a standard electroencephalography textbook.[3]

Computerized digital electroencephalography-PSG systems facilitate the review of large amounts of the acquired data by displaying scoring and event information in a format that allows the user to, for example, click on the stage or event of interest and bring up the corresponding EEG PSG segment.

The recording may be viewed at a variety of display settings. Filters, sensitivities, and montages may be adjusted to characterize events of interest and to help distinguish abnormalities from artifacts or normal variants. For example, certain montages can more easily identify and distinguish artifacts from interictal epileptiform discharges (IEDs), defined as epileptic-type activity occurring between seizures. Digital electroencephalography enhances the detection and review of IEDs by allowing for remontaging (displaying data in a different montage that may better reveal such activity), changing the display settings that influence temporal resolution, and isolating specific channels for review (Figure 163-2). For example, by altering the display settings, synchronous delta or theta activity characteristic of disorders of arousal from NREM sleep may be more easily distinguished from spike-wave activity or from an evolving ictal (seizure) pattern characteristic of an epileptic seizure disorder.

Several digital electroencephalography-PSG systems share a common platform with epilepsy monitoring systems, allowing data obtained during a PSG study to be analyzed by IED detection programs. Conversely, a study performed in the epilepsy-monitoring unit can be enhanced through addition of electrooculogram (EOG) and chin electromyogram (EMG) electrodes to score sleep and to determine the stage of sleep that precedes a particular event. This determination can be diagnostic in the case of distinguishing dissociative events, which rarely occur during sleep,[7] from epileptic seizures, which can occur during sleep or wakefulness.

Daytime Electroencephalography

Daytime electroencephalography is used to look for IEDs, to support the diagnosis of a seizure disorder in many clinical settings.[3] In addition to the electrode placements listed earlier, central (Fz, Cz, Pz) and ear (A1, A2) electrodes are included. Nasopharyngeal electrodes, although used in the past, are not recommended, because they are uncomfortable, are prone to artifact, and rarely provide additional information. The activating techniques of hyperventilation and intermittent photic stimulation are routinely performed and can bring out focal asymmetries or epileptiform activity.

Although seizures are not uniformly recorded during a routine EEG, focal IEDs or generalized spike-and-wave discharges may be observed and can assist in the classification of an epileptic syndrome as partial or generalized. The location of IEDs, determined with the use of an extended EEG montage, can clarify the nature of the epilepsy syndrome and its prognosis.[8] For example, benign epilepsy of childhood with centrotemporal spikes carries an excellent prognosis (Figure 163-3). By contrast, some temporal lobe IEDs may be refractory to medical treatment, and affected patients can become candidates for epilepsy surgery.

Daytime studies performed while the patient is asleep for at least a portion of the recording increase the yield of finding abnormalities, because in many patients, IEDs are more common in drowsiness and NREM sleep. Stage N2 sleep is usually, but not always, recorded on the routine EEG, whereas stage N3 sleep and REM sleep are rarely recorded. When the routine EEG does not show IEDs and the clinical picture is highly suggestive of seizures, a sleep-deprived EEG improves the yield of finding epileptiform activity, at least in part because sleep is more likely to be recorded. Digital EEG recordings permit the viewing of a segment of the EEG in a variety of montages and speeds, which can help distinguish an IED from an artifact.

Video-Electroencephalography-Polysomnography

When the patient's history is not sufficient for a reasonably confident diagnosis in the case of nocturnal spells associated

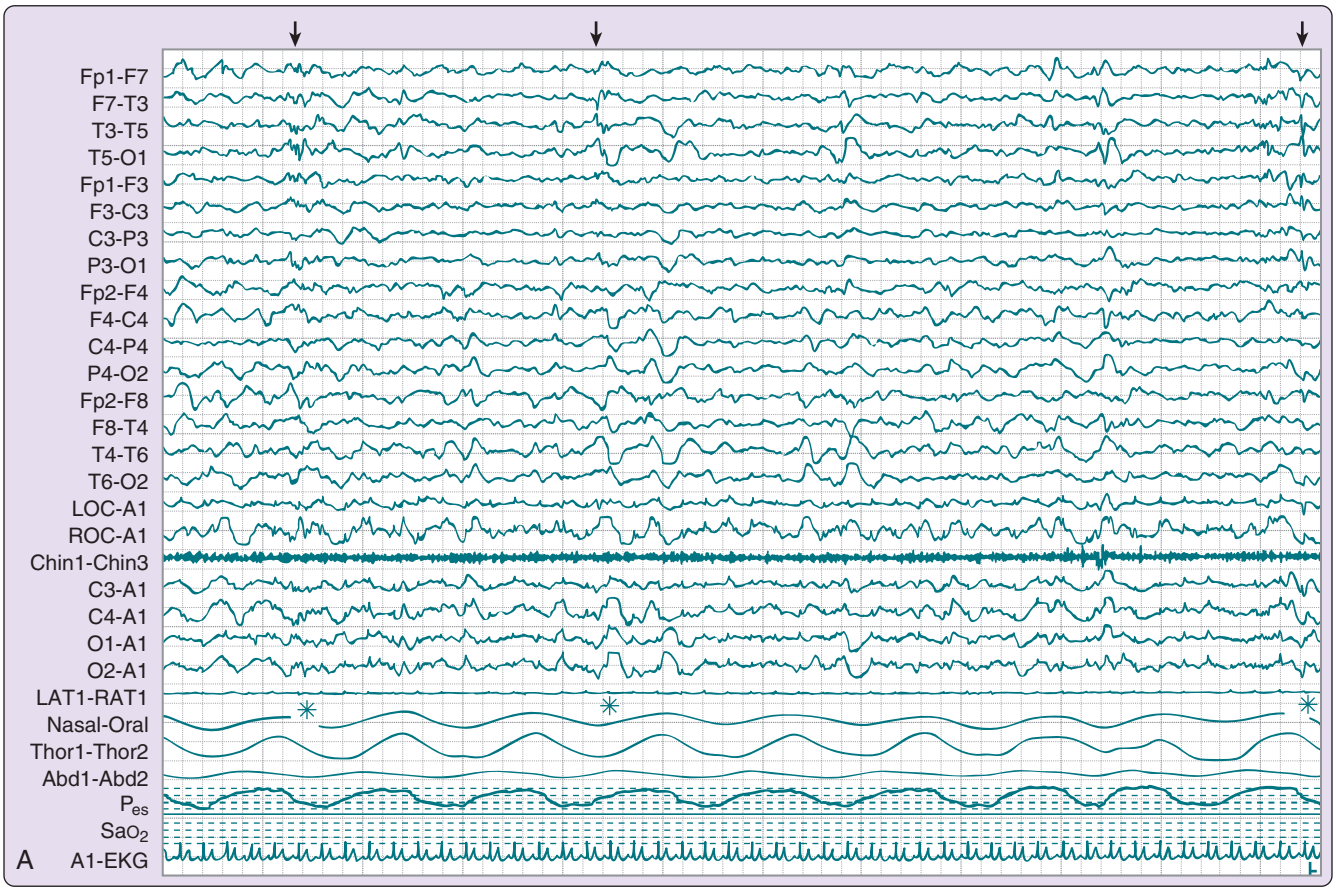

Figure 163-2 Use of different montages to enhance the review of interictal epileptiform discharges (IEDs). **A,** Left temporally dominant IEDs (*arrows*) on an extended electroencephalogram (EEG) montage that are not apparent in the central-to-ear channels (*asterisks*). **B,** Digital EEG allows the interpreter to select the relevant left temporal and parasagittal channels for review. The *arrows* highlight IEDs with phase reversals (*asterisks*) at T3 and F3, indicating maximal negativity at these electrodes, which defines the approximate location of the epileptic region. Both are 30-second epochs. Calibration symbol (*bottom right*): 100 μV.

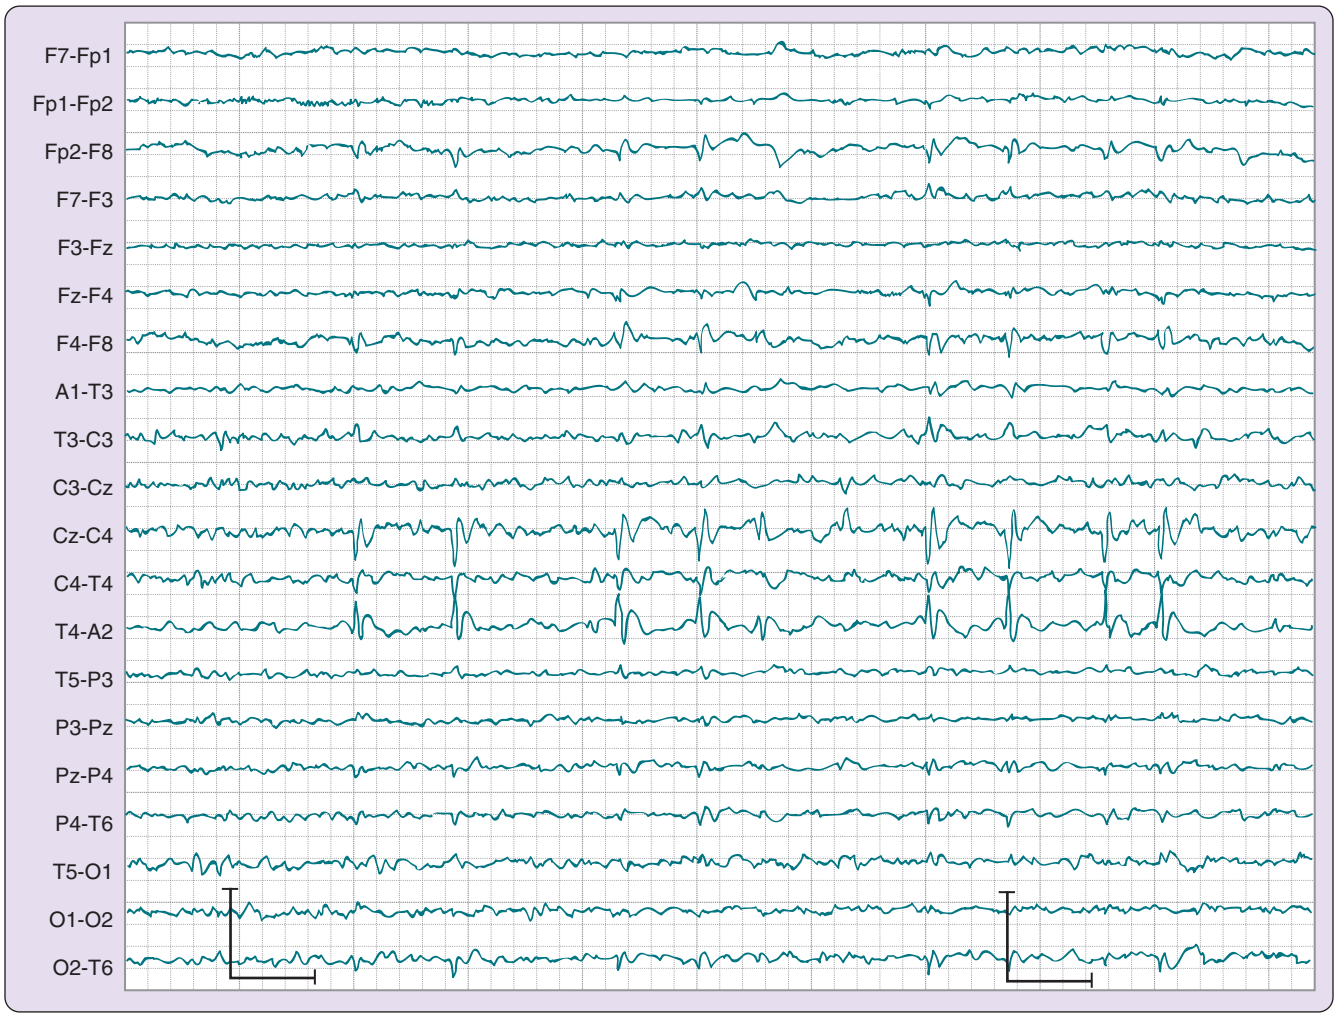

Figure 163-3 Runs of interictal epileptiform discharges with a centrotemporal dominance in benign epilepsy of childhood with centrotemporal spikes. The bipolar montage readily demonstrates peak negativity at the C4 and T4 electrodes. Such localization is not possible with electroencephalogram (EEG) montages commonly used with standard polysomnography (PSG). Calibration symbol: 500 μV, 1 second. (From Malow BA. Sleep and epilepsy. *Neurol Clin* 1996;14:774.)

with complex movements and behavior, recording of the sleep-related event in question may allow definitive confirmation. V-EEG-PSG, which combines video recording with an extended EEG montage and with other standard PSG physiologic monitoring, is useful in characterizing unusual behavior and movements during sleep. Diagnostic considerations for patients with complex actions at night can include epileptic seizures, disorders of arousal from NREM sleep, REM sleep behavior disorder (RBD), rhythmic movement disorder, or psychiatric disorders such as panic disorder or dissociative disorder. Episodes associated with these disorders have specific clinical features as discussed in Chapters 103 to 108. Events recorded with V-EEG-PSG are reviewed to characterize the motor and behavioral manifestations of the event and the EEG PSG features, including the stage of sleep preceding the event, the time of the event relative to sleep onset, and EEG patterns occurring during the event or between events. The time-locked video can be reviewed second by second along with the EEG PSG recording. Infrared cameras are useful for recording nighttime events. Movable cameras can be mounted in the patient's room and display close-ups or full-body views. Double cameras are useful for focusing on the face while simultaneously monitoring the body. During recorded events, the technologist should interact with the patient to test for level of consciousness and ability to perform commands.

The stage of sleep from which the spells emerge and the time of the spell relative to sleep onset provide useful diagnostic information. For example, the actions accompanying the disorders of arousal from NREM sleep arise from stage N3 or sometimes stage N2 sleep, usually in the first third of the sleep period (see Chapter 102), whereas those associated with RBD emerge from REM sleep, most commonly in the last third of the sleep period (see Chapter 103). Epileptic seizures are more common during NREM sleep than during REM sleep (see Chapter 97).[9] Rhythmic movements associated with rhythmic movement disorder usually occur during sleep-wake transitions, and dissociative episodes emerge from wakefulness. Nocturnal panic attacks occur from NREM sleep, usually at the transition from stage N2 to stage N3.[10]

If complex partial seizures are a diagnostic consideration, the EEG montage should emphasize the use of electrodes placed over the temporal lobes (e.g., F7, T1, T3, T5). If benign childhood epilepsy with centrotemporal spikes is a consideration, the montage should include the parasagittal region (e.g., C3, C4). The specific montage that is used depends on the number of channels available for electroencephalography. Sample montages for 8, 10, 12, 14, 16, 19, and 24 channels are shown in Table 163-1.

The following montage of 16 electrodes in anterior-to-posterior chains provides excellent coverage for suspected seizures:

- Left temporal: Fp1-F7, F7-T3, T3-T5, and T5-O1
- Left parasagittal: Fp1-F3, F3-C3, C3-P3, and P3-O1
- Right parasagittal: Fp2-F4, F4-C4, C4-P4, and P4-O2
- Right temporal: Fp2-F8, F8-T4, T4-T6, and T6-O2

This montage allows the evaluation of interictal and ictal activity during sleep. Two additional anterior temporal electrodes, T1 and T2, may be added because they are particularly useful for detecting anterior temporal IEDs. In one study comparing abbreviated EEG montages with a standard 18-channel bipolar montage, seizures were more readily distinguished from arousal patterns using 7- and 18-EEG channel montages as compared with 4-channel EEG records.[11]

Short-Term and Long-Term Monitoring

When the history suggests frequent daytime spells or spells occurring during daytime naps, STM, a video-EEG recording, typically obtained in an electroencephalography or sleep laboratory for 6 to 8 hours during the day, may be helpful. The value of such studies for assessing patients with strictly nocturnal spells, however, is limited. Occasionally, STM is useful if sleep attacks—spells of diminished responsiveness due to sleepiness—are included in the differential diagnosis of daytime spells.

Unfortunately, one or two nights of monitoring in the sleep laboratory is not always sufficient to capture and characterize spells. LTM, an extension of STM that allows continuous recordings for up to several weeks, is used mainly for patients with known or suspected seizures.[12] For patients who are taking antiepileptic medications, these drugs may be tapered and discontinued during LTM; intermittent sleep deprivation also is commonly used to facilitate spells. Because frequent seizures or status epilepticus can occur in epileptic patients discontinuing medication, LTM is generally performed in a hospital setting, usually a specialized epilepsy-monitoring laboratory.

The lack of ictal activity during a clinical event does not exclude a seizure, particularly if awareness is preserved during the clinical event (e.g., a simple partial seizure) or if the event originates in the frontal lobe. Ictal activity may be apparent only with intracranial electrodes, such as depth electrodes that penetrate the brain parenchyma, subdural strips, and subdural grids.[13] These invasive electrodes, which rarely are used in diagnosing nocturnal spells because of the risks of infection and hemorrhage, generally are reserved for patients who require localization of epileptic foci before surgical resection and in whom scalp recordings are inconclusive. If an ictal pattern is not recorded but clinical seizures are strongly suspected on the basis of the history and stereotypical behavioral spells recorded on videotape, an empiric trial of an antiepileptic medication may be appropriate.

Ambulatory Monitoring

Ambulatory monitoring combines the extended recording time of V-EEG-PSG with the convenience of recording in a patient's home. Several commercial products allow patients to go home with 12 or more channels of EEG electrodes and a recording device. The recording device sometimes includes video monitoring. Ambulatory recording systems may use analog or digital recorders. Patients and their bed partners are instructed to keep an activity log to document events.

The indications for ambulatory monitoring in the differential diagnosis of nocturnal events are not established. This monitoring technique appears promising for evaluating interictal epileptiform activity during sleep. Depending on the sophistication of the video recordings, ambulatory monitoring can identify some cases of epileptic seizures, NREM arousal disorders, RBD, rhythmic movement disorder, panic disorder, and dissociative disorder.

ARTIFACTS AND PITFALLS

Artifacts, which are common during sleep-related spells recorded with any of these modalities, must be distinguished from interictal and ictal epileptiform activity and from EEG activity associated with parasomnias. Although artifacts can obscure the EEG, making diagnosis more difficult, they are sometimes helpful; for example, head or body rocking artifact may be diagnostic of rhythmic movement disorder, and rhythmic myogenic artifact may support bruxism (Figure 163-4). Other examples of frequently encountered artifacts include those caused by head tremor, eye movements, and tongue movements (glossokinetic artifact). Associated rhythmic activities can resemble ictal EEG patterns.

Pitfalls in interpreting recorded events are common; the inexperienced interpreter can mistakenly identify an artifact as EEG activity characteristic of seizures or parasomnias. When the clinician is in doubt about an EEG PSG pattern, a trained electroencephalographer should be consulted. Apart from artifacts, many other normal physiologic variants may be mistaken for epileptic activity; these include positive occipital sharp transients of sleep (see Figure 163-4); frequent and sharply contoured vertex waves, particularly in young patients (Figure 163-5); sawtooth waves; benign epileptiform transients of sleep; wicket spikes; and rhythmic temporal theta of drowsiness.[14]

RELATIVE INDICATIONS, ADVANTAGES, DISADVANTAGES, AND LIMITATIONS

Although V-EEG-PSG and other neurologic monitoring techniques can be useful in diagnosing nocturnal events, the incremental cost of these techniques over standard PSG necessitates that specific indications be met. Unfortunately, no standards exist for determining when to choose a specific monitoring technique, and the reliability and validity of the monitoring techniques described here have not been formally studied. Consensus guidelines for interpretation have not been developed. In addition, the role of ambulatory electroencephalography in monitoring parasomnias is not well defined. The indications, advantages, disadvantages, and limitations outlined here are based on my own clinical experience and that described by others.

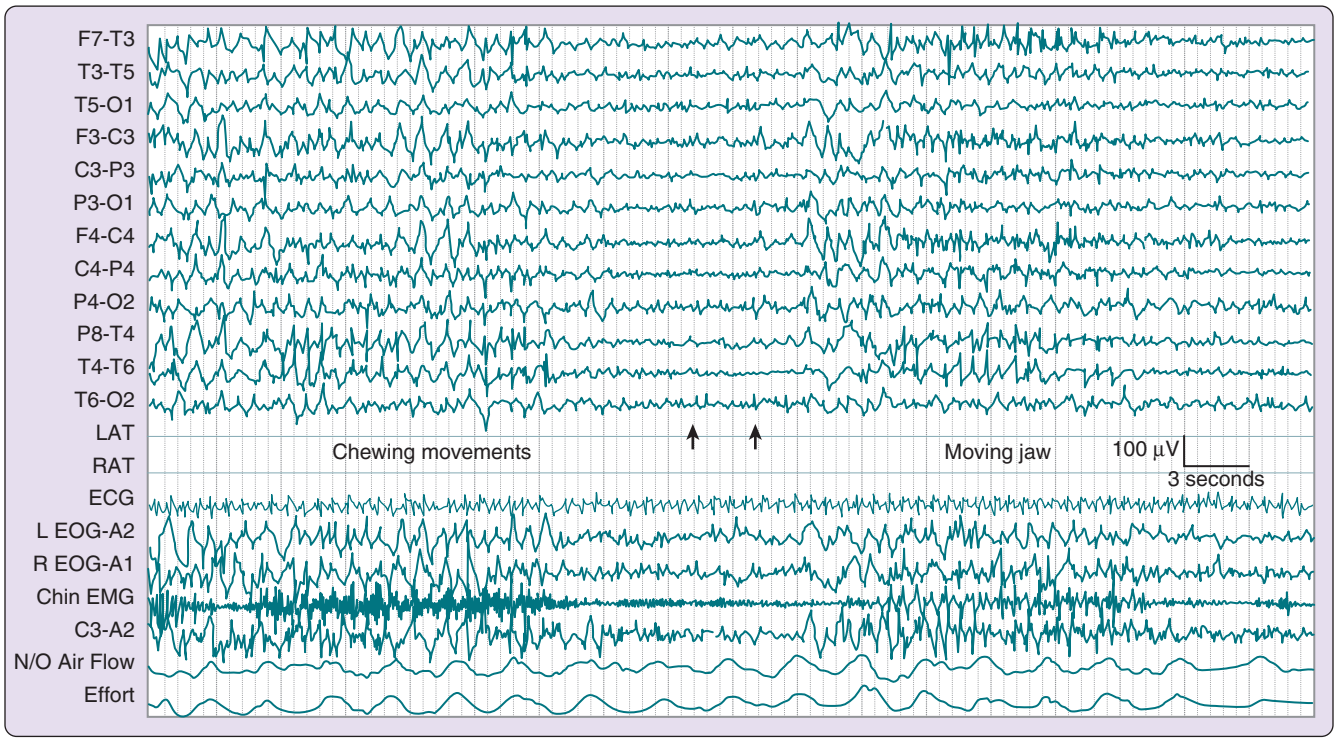

Figure 163-4 Artifacts resembling interictal epileptiform activity. Chewing movements produced by bruxism cause rhythmic activity with superimposed myogenic artifact in the electroencephalogram (EEG) channels, bearing a superficial resemblance to generalized spike-wave discharges. The *arrows* identify posterior occipital sharp transients of sleep, normal features of non–rapid eye movement (NREM) stage 1 sleep that appear sharply contoured and may be mistaken for pathologic occipital sharp waves at the standard polysomnograph paper speed of 10 mm/second. ECG, Electrocardiogram; EMG, electromyogram; EOG, electrooculogram; LAT, left anterior tibialis; N/O, nasal-oral; RAT, right anterior tibialis.

Video-Electroencephalography–Polysomnography

Indications for V-EEG-PSG include suspected sleep-related epileptic seizures, suspected NREM arousal disorders, RBD, and suspected dissociative disorder.

Suspected Sleep-Related Epileptic Seizures

Although some epileptic seizures can be diagnosed based on history (e.g., generalized tonic-clonic activity witnessed by a reliable observer), most events occurring frequently and suspected to be complex partial seizures are best confirmed with V-EEG-PSG monitoring. Monitoring is especially indicated for events that include the features of thrashing, kicking, hyperventilating, head rocking, screaming, or subtle arousals from sleep; such events may represent complex partial seizures.[15]

The advantage of V-EEG-PSG over conventional PSG or EEG without video in suspected epileptic seizures is the ability to analyze stereotypical activities characteristic of epileptic seizures, in association with ictal EEG activity. Figure 163-6 shows a recording with an extended EEG montage of an epileptic seizure, illustrating a clear evolution of activity. Apart from recording epileptic seizures, PSG with an expanded EEG montage allows sampling of IEDs throughout the night. The IEDs associated with partial epilepsy usually are more prevalent in sleep, especially delta NREM sleep, than in wakefulness.[16,17] Occasionally, IEDs missed on a routine daytime EEG are detected on an overnight recording.

CASE EXAMPLE 163-1

A 34-year-old woman with a remote history of daytime complex partial seizures presented with nightly nocturnal spells. Her husband reported that within 45 minutes of falling asleep she aroused, sat up, appeared frightened, breathed rapidly, looked around the room with a blank, wide-eyed stare, and then returned to sleep. These episodes were stereotypical and lasted less than 1 minute. She responded to his questions almost immediately and did not recall the episodes.

The differential diagnosis includes disorder of dissociative episodes as well as epileptic seizures. Nocturnal panic disorder is unlikely, because she does not recall the episodes. RBD is possible, but this disorder would be unusual in a young woman, usually does not cause stereotypical behavior, and rarely occurs soon after sleep onset.

Because the history was insufficient for diagnosis and because the spells were occurring nightly, V-EEG-PSG was performed, during which the patient exhibited several stereotypical spells arising from all stages of NREM sleep. These spells were associated with ictal discharges beginning over the right temporal lobe and consisting of rhythmic theta activity that increased in frequency and decreased in amplitude.

She was treated for complex partial seizures with carbamazepine, and the spells resolved. If this patient had been on antiepileptic medication chronically and had spells that were less frequent (e.g., once a week), an alternative approach would have been LTM with tapering of medications to promote occurrence of seizures.

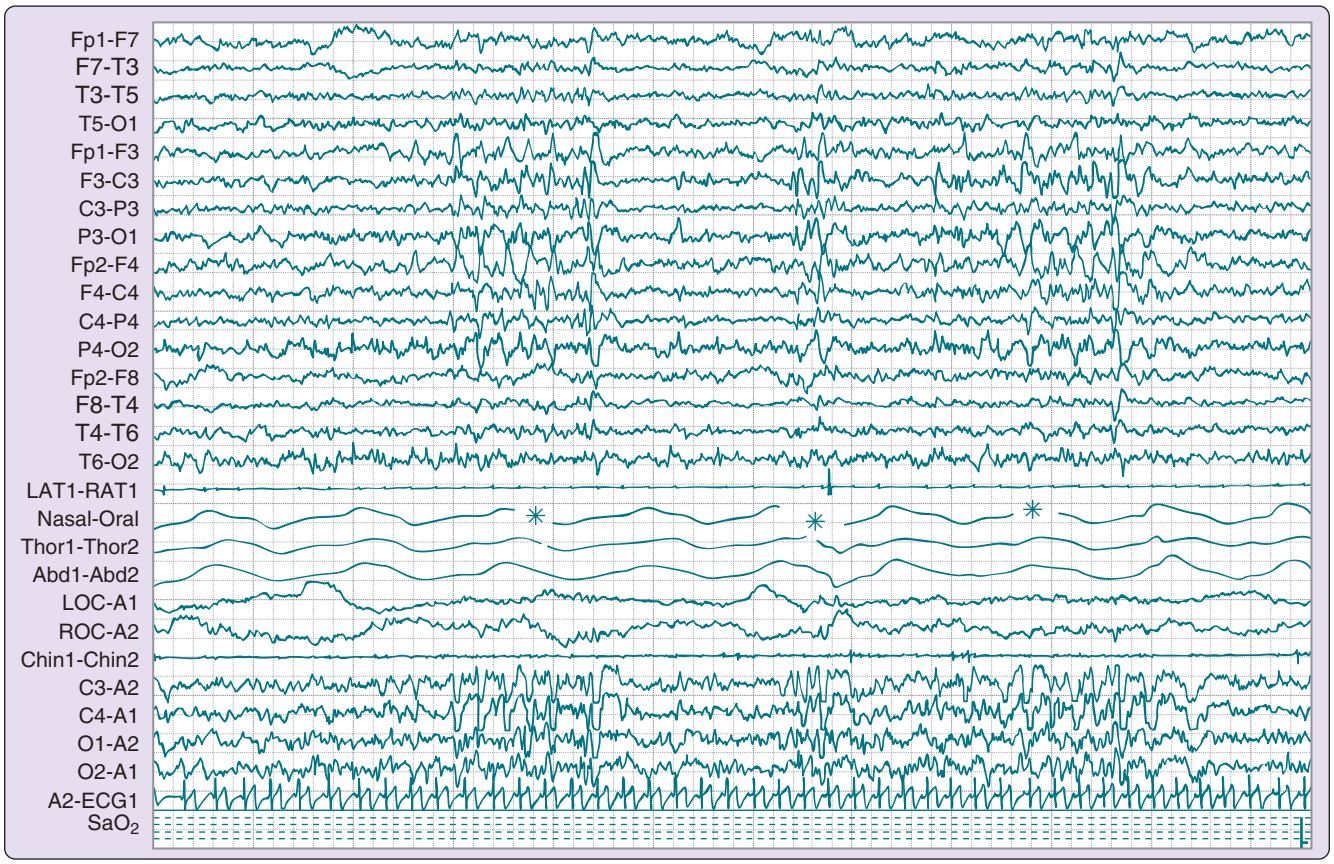

Figure 163-5 Sharply contoured vertex waves in a 6-year-old child. Although these physiologic waves resemble abnormal epileptiform activity, their morphology and distribution distinguish them from pathologic discharges. Compare with Figure 163-2. Thirty-second epoch. Calibration symbol (*bottom right*): 100 μV. ECG, Electrocardiogram; LAT, left anterior tibialis; LOC, left (electro)oculogram: RAT, right anterior tibialis; ROC, right (electro)oculogram; SaO_2, oxygen saturation.

Suspected disorders of arousal from NREM sleep (e.g., confusional arousals, sleepwalking, and sleep terrors) often can be diagnosed on the basis of history; V-EEG-PSG is indicated if behavioral features are atypical or stereotyped, multiple nightly episodes occur, onset is in adulthood, or spells do not respond to a trial of medications. An advantage of V-EEG-PSG in the diagnosis of NREM arousal disorders is the combination of video to characterize the event of interest, sleep scoring channels to determine the stage of sleep involved, and an extended EEG montage to exclude ictal EEG activity characteristic of epileptic seizures.

The V-EEG-PSG can capture a confusional arousal, night terror, or sleepwalking episode arising out of delta NREM (stage N3 sleep) accompanied by synchronous delta activity (Figure 163-7). Alternatively, the V-EEG-PSG recorded during an NREM arousal event might show asynchronous delta or theta activity, synchronous theta activity, a drowsy pattern, or nonreactive alpha activity.

Suspected REM Sleep Behavior Disorder

Although RBD may be suspected on the basis of the history, definitive diagnosis requires capturing a behavioral event on a video recording or demonstrating abnormal muscle tone or excessive limb movements during REM sleep (see Chapter 103). The advantage of V-EEG-PSG is that video is combined with sleep staging to identify REM, and an extended EEG montage is used to exclude ictal EEG activity.

CASE EXAMPLE 163-2

A 4-year-old girl had near-nightly episodes of screaming loudly with onset approximately 1 hour after falling asleep. During these episodes, her parents found her agitated and inconsolable. On rare occasions, she got out of bed and wandered out of her room. She was amnestic for these spells. An older sibling had had similar spells.

Because the history is compelling for sleep terrors, evaluation with V-EEG-PSG is not necessary. If any atypical features were present (e.g., automatisms or stereotypical behavior, multiple nightly episodes, or onset in adulthood) or if symptoms did not respond to treatment, a V-EEG-PSG would be warranted.

Suspected Dissociative Disorder

Dissociative episodes and other psychogenic spells occur during wakefulness, although the patient might appear to be asleep and might believe that he or she is asleep.[7] Because the manifestations of dissociative episodes can be quite bizarre and include thrashing, screaming, or bicycling movements, it often is impossible to distinguish these spells from epileptic

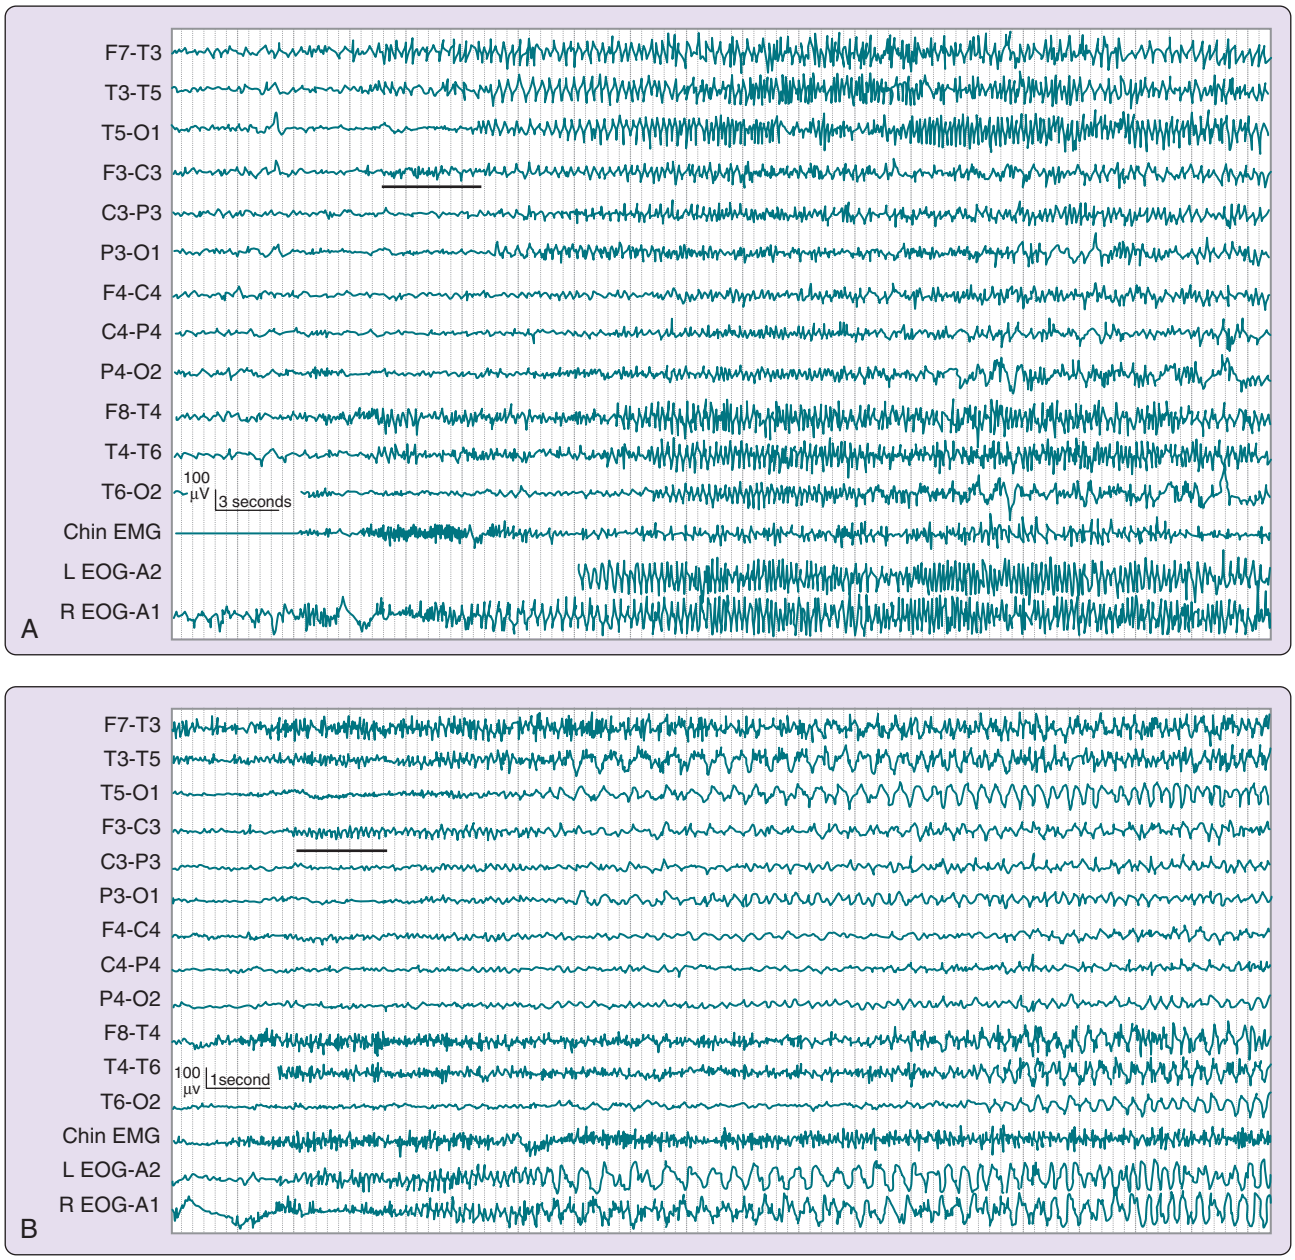

Figure 163-6 Partial seizure beginning during non–rapid eye movement (NREM) sleep. **A,** Polysomnogram recorded at 10 mm/second paper speed. Clinically, the seizure began with an abrupt arousal, followed by turning of head and eyes to the left and movements of the arms beneath the bedclothes. On the electroencephalogram (EEG), an initial reduction in voltage is followed by a progressive increase in the amplitude of the ictal discharge over the left hemisphere, with spread to the right hemisphere derivations. The *underlined activity* from the F3-C3 derivation appears to be muscle artifact; however, in **B,** at 30 mm/second paper speed, it is clear that the same *underlined segment* is the initial focal surface representation of the ictal discharge. Additional polysomnographic measures, recorded on channels 16 to 21, are not shown. EMG, Electromyogram; EOG, electrooculogram. (Modified from Aldrich MS, Jahnke B. Diagnostic value of video-EEG polysomnography. *Neurology* 1991;41:1060–6.)

seizures or parasomnias from the history alone. When nocturnal psychogenic episodes are suspected, V-EEG-PSG is advantageous in documenting the behavior of the patient, the presence of waking background EEG activity preceding onset of the spells, and the absence of ictal EEG activity.

The major disadvantage of V-EEG-PSG in the evaluation of suspected epileptic seizures, parasomnias, and dissociative disorders is the cost of the study. Additional technologist time is needed to place an extended EEG montage and to continuously observe patients throughout the study. In addition, physicians must review each spell to assess behavior and EEG patterns.

The V-EEG-PSG also has diagnostic limitations. The EEG recorded during a spell might not demonstrate an abnormality. Because epileptic seizures can lack surface EEG correlates, the absence of surface ictal EEG activity does not ensure that an epileptic seizure has not occurred. In addition, it can be difficult to differentiate an ictal EEG seizure pattern

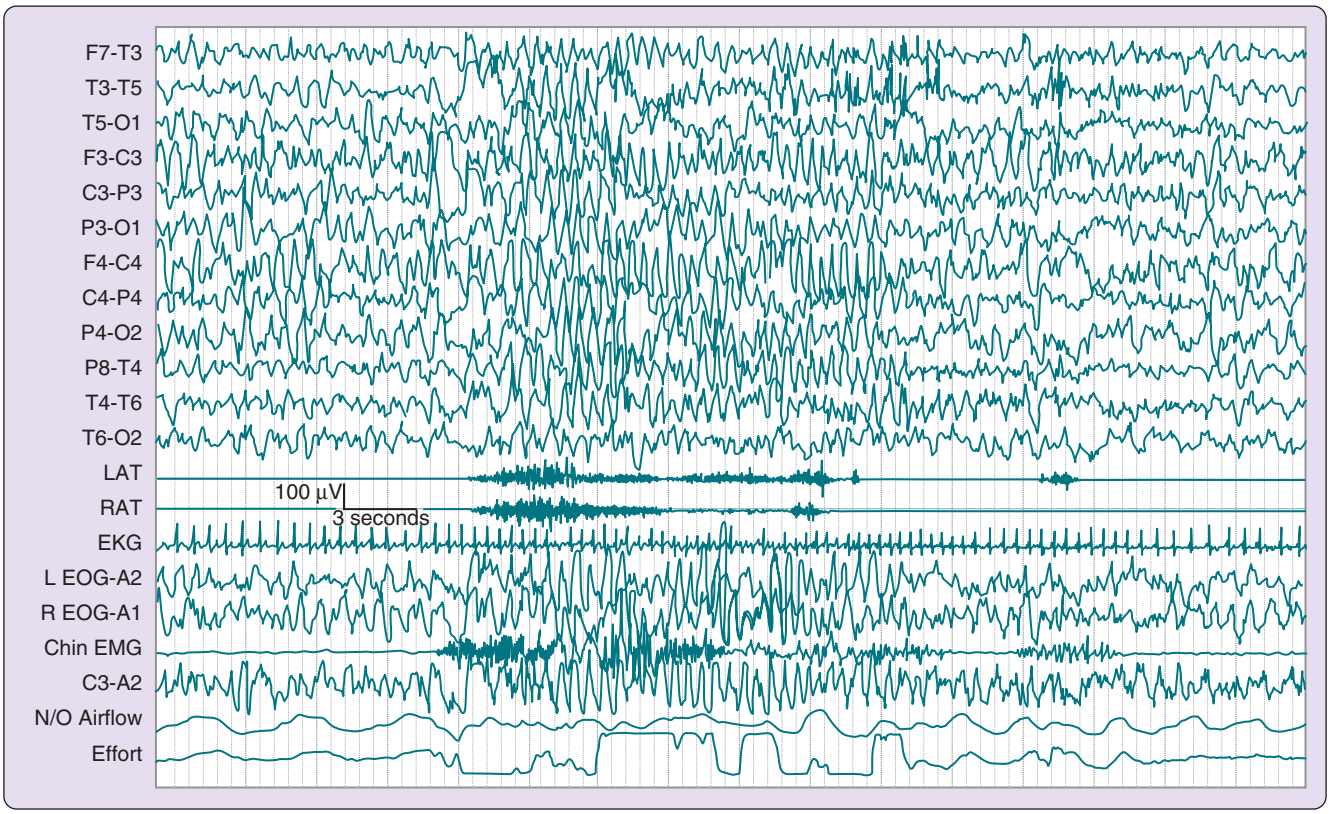

Figure 163-7 Arousal from delta non–rapid eye movement (NREM) sleep in a child with an NREM arousal disorder. Note synchronous delta activity during arousal from delta NREM sleep, associated with left anterior tibialis (LAT) and right anterior tibialis (RAT) EEG activity and a tonic increase in chin electromyogram (EMG). In contrast with the EEG of an epileptic seizure, the delta activity does not evolve in amplitude or frequency. EOG, Electrooculogram.

(which consists of rhythmic activity that evolves in frequency and amplitude) from the synchronous delta or theta activity or diffuse alpha activity occurring during an NREM arousal disorder. The best-developed portion of the ictal EEG pattern may be rhythmic delta or theta without a clear evolution, seizures can have bilateral onsets, seizures can arise from delta NREM sleep, and muscle or movement artifact can obscure the EEG. Two consecutive nights of V-EEG-PSG often are scheduled so that if no events are captured on the first night, the second night is available for study.

Daytime Electroencephalography

The advantage of daytime electroencephalography over V-EEG-PSG, standard PSG, or any of the other monitoring techniques is its brief recording time and low cost. The disadvantage is that spells, particularly sleep-related spells, are rarely captured. When the history is strongly suggestive of epileptic seizures, a routine EEG can demonstrate epileptic activity as supportive evidence of epilepsy. However, IEDs are not the equivalent of epileptic seizures and may be present in patients without epilepsy, such as those occurring in relatives of patients with benign childhood epilepsy with centrotemporal spikes. Conversely, patients with epilepsy might not have IEDs during EEG recordings. In addition, patients with epilepsy can have coexisting parasomnias. Therefore, in the absence of a compelling history, the occurrence of abnormal interictal epileptiform activity should not be used by itself to definitively diagnose nocturnal spells as epileptic seizures.

Short-Term and Long-Term Monitoring

The advantages of STM and LTM over routine electroencephalography are the acquisition of additional information over the longer recording time and simultaneous video monitoring. In patients with exclusively sleep-related spells, V-EEG-PSG is preferred over STM because the recording is performed during sleep. In patients with a mixture of daytime and sleep-related spells, STM is sometimes appropriate.

LTM is an alternative in patients in whom antiepileptic medication taper or discontinuation is planned. Medication taper or discontinuation is especially useful in facilitating seizure activity in epileptic patients with infrequent spells (e.g., once a week or less). The disadvantages of LTM are the cost of inpatient hospitalization and the need for a specialized epilepsy-monitoring laboratory. The limitations of LTM are similar to those of PSG in that spells may lack EEG correlates or might not occur even over many days of monitoring.

Ambulatory Monitoring

The advantage of ambulatory monitoring is the convenience of recording in the patient's home and the lack of need for continuous monitoring by a technologist. Cost varies, but it usually is lower than that of a recording in a sleep laboratory. A major disadvantage of ambulatory monitoring relates to the fidelity of the recording in the absence of a technologist. If electrodes become detached, ground wires break, or conductive media become dry during the study, adjustments cannot be made. In addition, systems may use a reduced number of

channels, thereby limiting the information provided, although some systems have the capability for expanded montages.

Furthermore, in contrast with the other monitoring techniques, the patient is not under constant observation and a technologist is not present. Consequently, interactions with the patient, critical for evaluating level of consciousness, are not possible. Also, interpreting rhythmic activities that resemble ictal discharges may be difficult in the absence of behavioral and consciousness assessment. The addition of synchronized video recordings to ambulatory monitoring has potential for facilitating correlation between EEG activity and clinical events.

CLINICAL PEARL

The clinician should consider performing video-electroencephalography in suspected cases of nocturnal seizures and parasomnias such as REM sleep behavior disorder or NREM arousal disorders. The video may be as helpful as the EEG in documenting stereotypical behavior in epileptic seizures.

SUMMARY

Patients with nocturnal spells present a unique diagnostic challenge to the sleep specialist and the sleep laboratory. Although standard PSG provides valuable information about the stage of sleep from which spells arise and the timing of the spell relative to sleep onset, the characterization of these spells is enhanced by video recording and an extended EEG (12 or more channels, and sometimes 21 or more). Addition of video and an extended EEG to the standard PSG is essential for precise definition of nocturnal spells, including epileptic seizures, REM sleep behavior disorder, and arousal disorders. The video component provides information on the behavioral and motor manifestations of the nocturnal spell. Depending on the clinical situation, a daytime EEG, an ambulatory EEG, daytime short-term monitoring, one or two nights of polysomnography, or long-term (over several days and nights) monitoring may be indicated.

Monitoring Techniques for Evaluating Suspected Sleep-Related Breathing Disorders

Max Hirshkowitz; Meir Kryger

Chapter Highlights

- Polysomnography evolved from a research tool into a medical diagnostic procedure largely applied for diagnosing and treating sleep-related breathing disorders.
- Principal components of an evaluation for sleep-related breathing disorders are airflow measurement, respiratory effort assessment, and oxyhemoglobin desaturation recording. Appreciating the relationship between sleep-disordered breathing events and sleep disruption also provides crucial information for patient care.
- Techniques are available to measure lung volume changes, blood pressure changes, and carbon dioxide; however, they are not routinely used for sleep-related breathing disorder evaluation in adults.

OVERVIEW

Soon after their discovery, sleep-related breathing disorders (SRBDs) became clinical polysomnography's dominant focus.[1] Polysomnography began as a laboratory research technique to study sleep, but with a few additional channels, it quickly found a new role as the "gold standard" modality for diagnosing obstructive sleep apnea. Penetration for assessing sleep-disordered breathing has been so complete that undoubtedly the vast majority of sleep studies performed tonight, or on any given night, will serve this function. Nonetheless, home sleep testing increasingly makes inroads as the technique to diagnose sleep-related breathing disorders.[2] With few exceptions, polysomnography and home testing devices use similar techniques. This chapter presents an overview of recording techniques and their application for evaluating breathing during sleep.

Abnormal breathing during sleep takes several different forms and arises from various underlying etiologies. It goes by many names, including sleep apnea, sleep apnea-hypopnea syndrome, sleep-disordered breathing (SBD), sleep-related breathing disorder (SRBD), periodic breathing, Cheyne-Stokes respiration (CSR), and hypoventilation (Box 164-1). However, obstructive forms of sleep apnea-hypopnea syndrome remain by far the most common SRBD. Detailed descriptions regarding SRBD-associated etiology, morbidity, and treatments appear elsewhere in this book.

The specific pathophysiologic events underlying SRBD include apnea episodes, hypopnea episodes, respiratory effort–related arousals, oxyhemoglobin desaturations, and snore arousals. As their names imply, *apnea* is cessation of breathing and *hypopnea* is shallow breathing. The face validity, that not breathing is undesirable for the health of the organism, seems obvious. However, the association between apnea and morbidity can be, but is not necessarily always, a matter of cause and effect. Other pathophysiologic processes, especially those related to metabolic and cardiac diseases, can produce downstream effects on breathing.

Polysomnographic and home sleep testing criteria for designating a breathing event as an apneic spell have been consistently defined for decades. Cessation of breathing for 10 seconds or longer constitutes an apnea. Ten seconds was chosen because it approximates missing two breaths. The definition for hypopnea, by contrast, remains controversial. *Hypopnea* essentially means "shallow breath." The difficulty in defining hypopnea stems from several sources. The first involves measurement technique, the second from the fact that hypopneas are not intrinsically pathophysiologic, and finally from decades of usage without any standard.

Polysomnographic and home sleep testing airflow monitoring techniques mostly rely on surrogate and uncalibrated measurements (as detailed further on). Furthermore, airflow signal magnitude from thermistors, thermocouples, capnographs, and nasal pressure transducers correlates poorly with tidal volume. Consequently, operational definitions for hypopnea based on a percentage decrease of flow signal use arbitrary cutoff points (regarding which considerable disagreement continues).

Brief hypopneic intervals routinely occur during wakefulness without causing harm. For example, hypopnea accompanies speaking, and except in extraordinary circumstances, talking does not produce adverse health consequences. During sleep, however, a hypopnea may provoke significant oxyhemoglobin desaturation or a central nervous system (CNS) arousal. Thus the consequence of the hypopnea (not the hypopnea itself) conceivably may be deemed pathophysiologic. Accordingly, prerequisites for designating sleep hypopnea as abnormal involve (1) accurately measuring physiologic consequences, (2) determining at what point these consequences reach significance, and (3) demonstrating their role in morbidity.

Box 164-1 SLEEP-RELATED BREATHING EVENTS, DISORDER CLASSIFICATIONS, AND PARAMETERS

- **Apnea** (A): The complete or near-complete cessation of breathing for 10 seconds or longer in an adult.
- **Oxyhemoglobin desaturation event** (ODE): A decrease in blood oxygen saturation. Usually, the magnitude must be 3% or greater to distinguish it from signal noise.
- **Hypopnea** (H): A reduction in (but not cessation of) ventilation. To be clinically significant, the hypopnea must be associated with an oxyhemoglobin desaturation event or a CNS arousal.
- **Desaturating hypopnea** (DH): A hypopnea with oxyhemoglobin desaturation of 4% or greater (also known as a "Medicare hypopnea").
- **Respiratory effort–related arousal** (RERA): A CNS arousal terminating obstructive breathing events that do not meet the criteria for apnea or hypopnea.
- **Obstructive apnea** or **hypopnea** episode (OA or OH): Breathing event caused by upper airway obstruction or reduced upper airway patency.
- **Central apnea** or **hypopnea** episode (CA or CH): Breathing event caused by absent or reduced respiratory effort (i.e., decreased output to inspiratory muscles from CNS respiratory control centers).
- **Mixed apnea** or **hypopnea** episode (MA or MH): Breathing event with both obstructive and central features. Many laboratories assign mixed events to the obstructive category.
- **Periodic breathing** (PB): A regularly repeating pattern in which normal or increased ventilation alternates with decreased or absent ventilation.
- **Central sleep apnea syndromes** (CSASs): These syndromes include primary central sleep apnea, Cheyne-Stokes breathing pattern, high-altitude periodic breathing, central sleep apnea due to medical conditions other than Cheyne-Stokes, and central sleep apnea due to drug or substance use/abuse.*
- **Obstructive sleep apnea syndromes** (OSASs): These syndromes include obstructive sleep apnea and obesity-hypoventilation syndrome (see Sleep-Related Hypoventilation Syndromes†). Primary snoring is a normal variant of an obstructive airway process.*

*Opiate and other sedatives are known to depress respiration by blunting respiratory drive.
†*ICSD-2* diagnostic classification.
CNS, Central nervous system.

Unfortunately, measurement and morbidity determination issues have remained unresolved for many decades. Many operational definitions for hypopnea* have appeared in published clinical and research literature. Emergence of differing criteria for percentage airflow decrease and oxyhemoglobin decrease and inclusion versus exclusion of CNS arousal as part of the definition seriously complicated matters. Definitional criteria set forth in a standardization attempt sponsored by the American Academy of Sleep Medicine, often referred to as the "Chicago Criteria," were adopted for research but not for clinical use.[3]

Subsequently on April 1, 2002, like it or not, the Centers for Medicare and Medicaid Services (CMS) defined a hypopnea as "an abnormal respiratory event lasting as least 10 s with at least a 30% reduction in thoracoabdominal movement or airflow as compared to baseline, and with at least 4% desaturation."[4] Eliminating CNS arousal from the hypopnea criteria and requiring 4% desaturation (rather than 3%) decreased the number of scorable hypopneic spells in many patients.[5,6]

On the face of it, respiratory-related and snore-related arousals certainly seem irrefutably abnormal (because they compromise sleep integrity); however, issues have arisen concerning detection reliability (and impossibility with use of many home sleep testing devices). Ignoring CNS arousal provoked by respiratory events seemed so ridiculously misguided to many clinicians that they began tabulating such events (even though they fell short of the 4% desaturation criteria). The designation *respiratory effort–related arousals* (RERAs) was commandeered from the Chicago Criteria even though it originally had quite different criteria.

In a major effort to standardize sleep medicine clinical practice, the AASM published *The AASM Manual for the Scoring of Sleep and Associated Events: Rules, Terminology and Technical Specifications* in 2007,[7] sometimes referred to as the *AASM Manual*. With regard to hypopnea, two definitional criteria were offered, neither of which agreed with the CMS criteria. Member centers were required to adopt and use the AASM criteria to maintain accreditation. One of the definitional criteria used a 3% oxyhemoglobin desaturation and the other included CNS arousal. These conflicting mandates and ambiguities placed American sleep specialists in an intellectual, clinical, and legal dilemma. Clinicians seeing even a single Medicare- or Medicaid-covered patient are required to use CMS criteria for all patients seen in their practice. Failure to comply with this regulation constitutes Medicare fraud. This CMS directive's intent is to prevent a two-tier medical system from developing. AASM issued clarifications of the rule in 2012, and ultimately, in 2013, AASM adopted CMS criteria[8] for scoring hypopnea.

Mitterling and colleagues examined scoring outcome using the different definitions.[9] Applying the 2012 scoring criteria produced higher apnea-plus-hypopnea indices compared with scoring based on the 2007 rules. These investigators used a sample of 100 healthy sleepers, ranging in age from 19 to 77 years.

Apnea and hypopnea episodes can be further categorized as obstructive, central, or mixed, depending on the presence or absence of respiratory effort during the entirety or some part of the breathing event. Beyond mere presence or absence, changes in the effort's magnitude can provide information concerning airway resistance. Increasing effort leading to a CNS arousal provides insight regarding pathophysiology. Therefore respiratory effort represents a crucial measure for evaluating patients with SRBD.

Sleep-disordered breathing severity can be based on a clinical dimension (e.g., sleepiness), event frequency (e.g., number of events per hour), or magnitude of the consequence (e.g., degree of oxyhemoglobin desaturation). Table 164-1 provides examples for dimensionally classifying severity of sleep-disordered breathing. General agreement is lacking on assignment of severity descriptors to indices of sleep-disordered breathing; however, two schemes are commonly used. In the first, "liberal" classification, an apnea-hypopnea index (AHI) between 5 and 15 is mild, between 15 and 30 is

*At last count, this author (MH) is aware of more than 15 different definitions for hypopnea.

Table 164-1 Clinical/Laboratory Features of Obstructive Sleep Apnea Syndrome by Severity

Dimension	Mild	Moderate	Severe
Sleepiness or unintended sleep episodes	During activities requiring little attention (e.g., watching television)	During activities requiring some attention (e.g., business meeting)	During activities requiring active attention (e.g., driving)
PSG SRBD events: number per night	5–15	15–30	>30
PSG/HST SRBD events and oxyhemoglobin (Sa_{O_2})	RDI or AHI 2–20 and/or Sa_{O_2} nadir >85%	RDI or AHI 20–40 and/or Sa_{O_2} Nadir 65%-85%	RDI or AHI >20 and/or Sa_{O_2} nadir <65%

AHI, Apnea-hypopnea index; HST, home sleep test; PSG, polysomnography; RDI, respiratory disturbance index; Sa_{O_2}, arterial oxygen saturation; SRBD, sleep-related breathing disorder.

moderate, and greater than 30 is severe. In the second, "conservative" classification, an AHI between 10 and 20 is mild, between 20 and 50 is moderate, and greater than 50 is severe.[10]

MEASURING AIRFLOW

General Considerations

Most clinical techniques use qualitative surrogate measures to estimate airflow changes. Fully quantitative airflow determination requires pneumotachography or having the patient sleep in a "body box"; however, such techniques are unsuitable for routine clinical sleep studies. Although semiquantitative measures are attainable using calibrated inductance plethysmography, most clinical evaluations rely on qualitative nasal-oral thermography and nasal pressure. This approach provides adequate data and minimizes patient discomfort, reduces costs, and simplifies data acquisition. The AASM Manual recommends using a thermal sensor to identify apnea and a nasal pressure sensor to detect hypopnea.[7] However, other methods also provide reliable assessment. Airflow also can be measured qualitatively by detecting chemical differences between ambient and expired air (e.g., capnography). However, respiratory activity requires careful classification. Sometimes the patient's airway can be completely occluded during inspiration but release small puffs upon expiration (detectable by thermistor or CO_2 analyzer). Such events are erroneously categorized as hypopneas or even normal (unobstructed breathing). Figure 164-1 illustrates the problem.

ERROR IN DETECTING APNEA

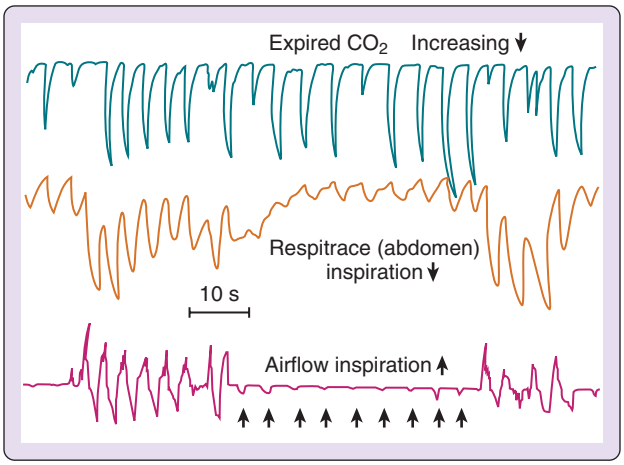

Figure 164-1 An example of the limitations of noninvasive airflow detection. Airflow is recorded simultaneously with a CO_2 analyzer and a pneumotachograph. During the obstructive apnea event, periods of expiratory airflow occur (recorded by the pneumotachograph and the CO_2 analyzer) in the absence of inspiratory flow (obvious in the pneumotachograph recording and unclear in the CO_2 recording). Without the information from the pneumotachograph, the recording from the CO_2 analyzer would be interpreted as evidence of uninterrupted inspiratory and expiratory airflow. *Top,* Airflow is detected with the CO_2 analyzer. *Middle,* Respiratory inductance plethysmograph (RIP) ("Respitrace"). *Bottom,* Airflow measured with a pneumotachograph. With each apnea-related expiratory deflection documented by the pneumotachograph (*arrows, bottom*), there is a sustained shift in the baseline of the RIP tracing. This correlation suggests an incremental decrease in functional residual capacity resulting from absence of inspirations with continued small expiratory puffs. If only the top two tracings were available, this pattern would have been mistakenly called hypoventilation or hypopnea, whereas it clearly reflects total occlusion on inspiration. (From West P, Kryger MH. Sleep and respiration: terminology and methodology. *Clin Chest Med* 1985;6:706.)

Measuring Temperature

Exhaled air usually is warmer than ambient temperature. Air in the lungs is warmed by core body heat, thereby creating a temperature difference between air entering and exiting the respiratory system. Consequently, measuring temperature fluctuation at the nares and in front of the mouth provides a simple surrogate measure of airflow. Measurement is possible using several different technologies.

Thermistors are thermally sensitive variable resistors that produce voltage alterations when connected in a low-current (but constant-current) circuit. Low current minimizes the tendency for the thermistor to heat itself. Thermistors maximize sensing area while minimizing sensor size and mass. Small temperature changes can produce large resistance changes that can in turn be transduced with a bridge amplifier. Care must be taken to ensure that the thermistor remains below body temperature (i.e., it must not rest on the skin); otherwise, expired air will not be warmed, and no resistance change will occur. In such a case, inspiratory activity and a respiratory pause will not be differentiable.

Thermocouples also sense temperature change but use a different approach. Different metals expand at different rates when heated. This difference can be transduced to voltage alterations displayable on polygraph systems. Like thermistors, thermocouples are placed in the airflow path in front of the nares and mouth, where expired air heats the sensor and increases its resistance. The transduced signal reflects oscillation between exhaled warm air and cooled inhaled air, thus providing a trace roughly corresponding to respiratory airflow.

Nasal Airway Pressure

During inspiration, airway pressure is negative relative to atmosphere. By contrast, expiration produces a relatively positive pressure in the airway. The resulting alteration in nasal airway pressure can provide a surrogate estimate of airflow and correlates favorably with pneumotachographically recorded signals.[11] The nasal pressure signal also offers greater sensitivity than that of nasal-oral thermography for detecting subtle flow limitations (Figure 164-2) when patients breathe through their noses.[12] Airflow limitation shows as pressure trace plateauing during inspiration. A direct current (DC) amplifier provides optimal interface; however, long time-constant alternating current (i.e., a very slowly coupled signal) can suffice. By contrast, rapid coupling can create artifact (Figure 164-3).

Expired Carbon Dioxide Sensors

CO_2 concentration in air leaving the lungs far exceeds that in ambient air. Thus measuring CO_2 in front of the nose and mouth can detect expiration. Infrared analyzers can determine the concentration. Because exhaled CO_2 reflects physiologic chemical change, it offers several advantages compared with physical changes detected by thermistor, thermocouple, and nasal pressure recordings.

In some patients, the end-of-breath CO_2 concentration provides evidence of elevated end-tidal Pco_2. The catheters sampling CO_2 typically entrain some room air, making the measured CO_2 lower than actual end-tidal Pco_2. Therefore an elevated CO_2 indicates that true Pco_2 is even higher, thereby providing a noninvasive technique (merely sampling the air stream) for detecting hypoventilation. The shape of the expired CO_2 curve can also offer useful information. When the patient's baseline expired CO_2 curve shows a clear-cut plateau, the loss of this plateau (or the curve's becoming smaller or dome-shaped) indicates a change in breathing pattern, usually a reduction in expiratory volume.

During central apnea, a low-volume catheter system set at its most rapid response time can show cardiogenic oscillations in the CO_2 signal. These oscillations result from small volume displacements caused by the beating heart.[13] These heartbeat-synchronized oscillations signify upper airway patency (Figure 164-4).

Capnography can be used in the sleep labratory to titrate noninvasive ventilation in patients with hypoventilation syndromes.[14] In infants and children with upper airway obstruction, severe hypoventilation may occur during sleep without observable apnea or hypopnea. Measuring expired CO_2 provides evidence for hypoventilation not detectable using thermistors or thermocouples.[13]

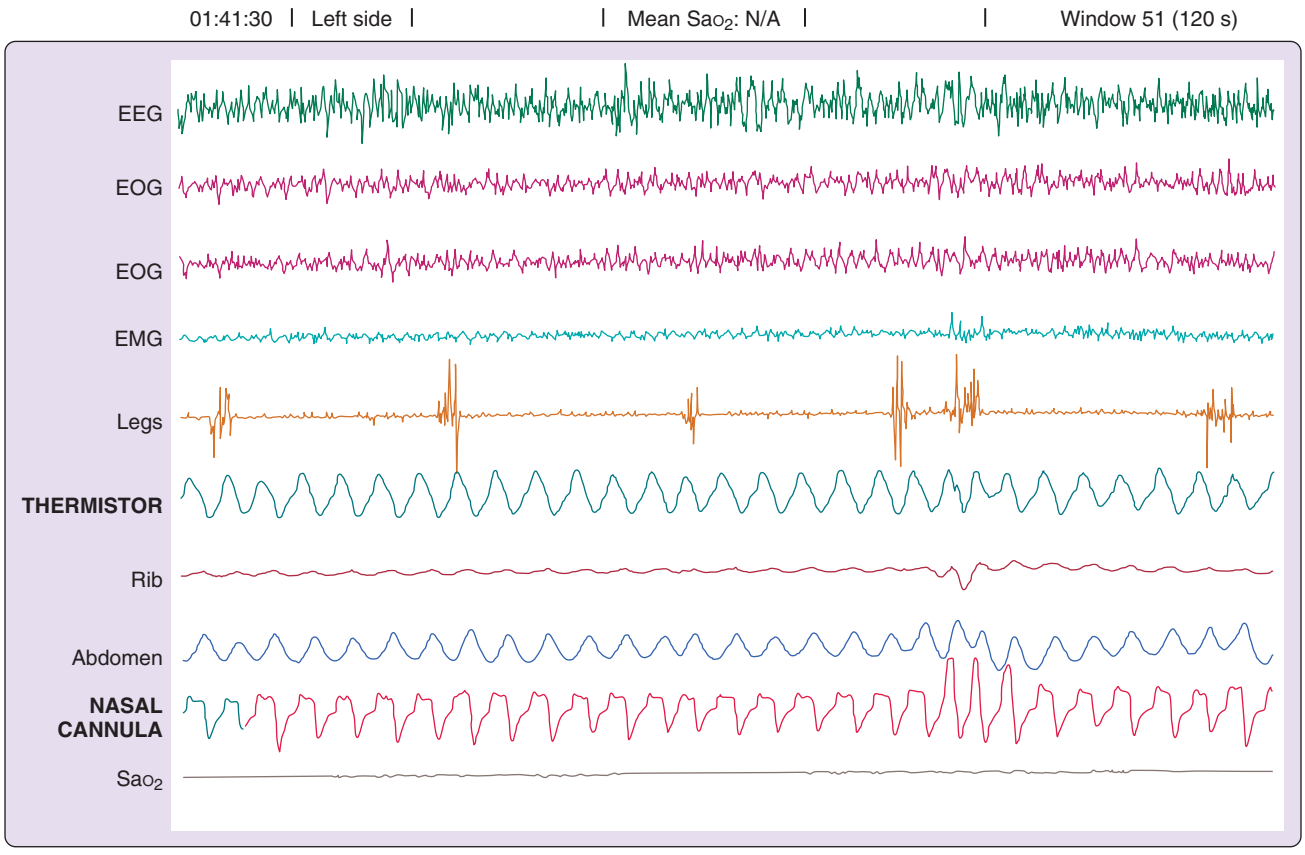

Figure 164-2 A 120-second section from a nocturnal polysomnogram in a subject undergoing simultaneous recording with a conventional thermistor and with a nasal cannula used for recording pressure. Nothing in the thermistor tracing suggests a respiratory event, and subtle movement barely registers in the rib and abdominal inductance plethysmographic tracings. In the nasal cannula tracing, however, the end of one flow limitation episode and the beginning of another are easily detected. Note the plateaus (*chopped-off tops*) of the pressure traces during flow limitation. EEG, Electroencephalogram; EMG, electromyogram; EOG, electrooculogram; Sao_2, oxygen saturation in arterial blood. (Courtesy Dr. David Rappaport, New York University, New York.)

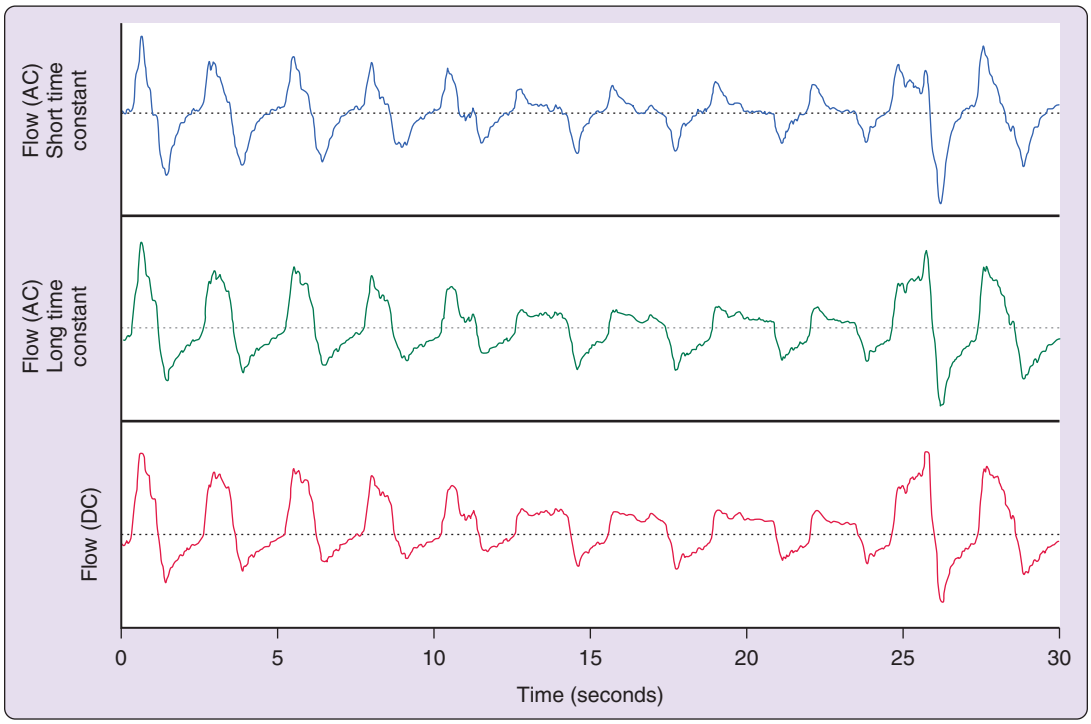

Figure 164-3 A flow limitation event recorded from the nasal cannula measuring pressure simultaneously amplified by three different amplifiers. The bottom signal is from a direct current (DC) amplifier with no filtering. The top two signals are from alternating current (AC) amplifiers with low-frequency filters, with time constants of 1.6 (*top*) and 5.3 (*middle*). The shorter time-constant filter (*top*) causes the flow signal to decay to baseline rapidly during a period of relatively constant flow (flow limitation plateau). The longer time-constant filter (*middle*) provides reasonably good reproduction of these constant flows.

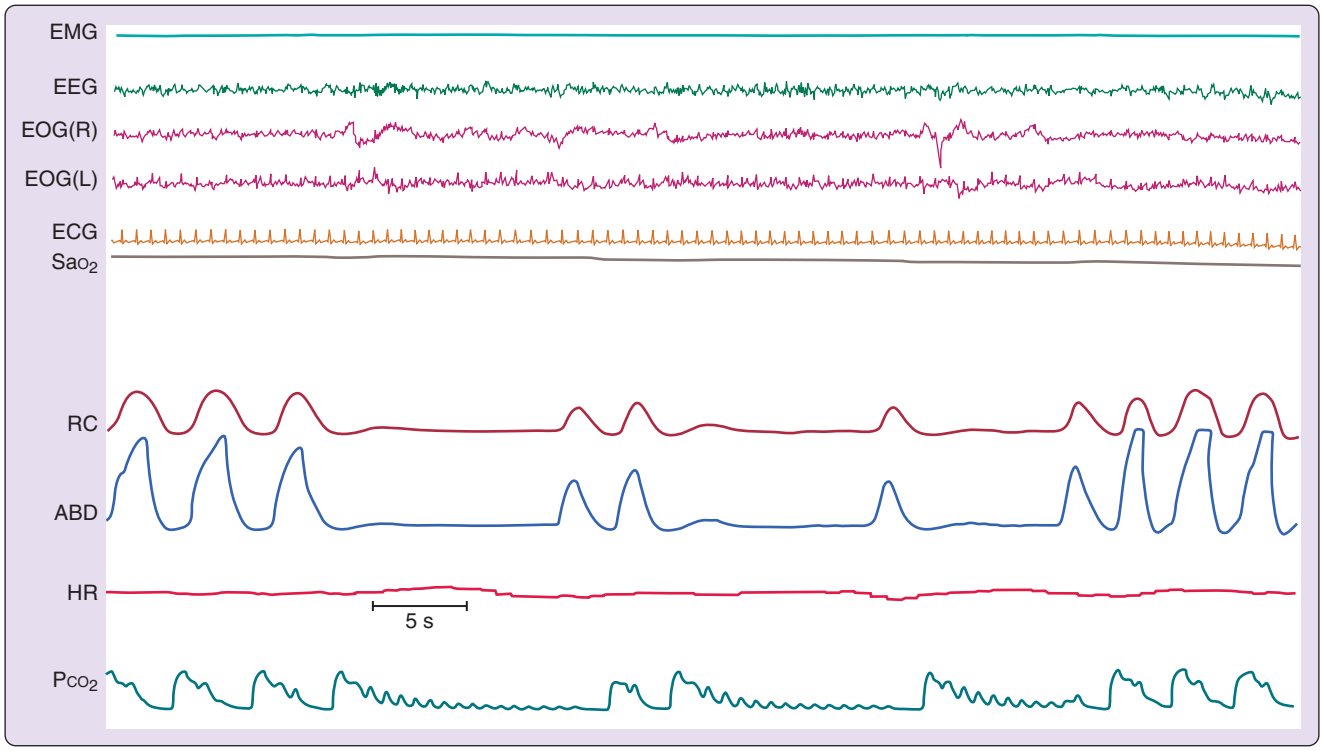

Figure 164-4 Cardiogenic oscillations in CO_2 are seen in the *bottom channel* of the recording in this example of central apnea. The presence of these oscillations, synchronous with the heartbeat, signifies that the upper airway is patent. ABD, Abdominal (movement); EEG, electroencephalogram; ECG, electrocardiogram; EMG, electromyogram; EOG, electrooculogram; HR, heart rate; RC, rib cage (movement); P_{CO_2}, partial pressure of carbon dioxide; Sa_{O_2}, oxygen saturation in arterial blood.

Pneumotachography

Pneumotachography accurately and quantitatively measures airflow volume. The patient usually wears a face mask, and the procedure can be uncomfortable. In awake subjects, pneumotachography is known to alter breathing; it increases tidal volume and reduces respiratory rate. Some positive airway pressure machines contain an integrated pneumotachograph usable to monitor airflow during laboratory titration. Pneumotachography is seldom used for routine SRBD diagnostics.

Several types of pneumotachographs are available. These devices differ with respect to measurement technique: They use either (1) differential pressure airflow transducers, (2) ultrasonic flow meters, or (3) hot-wire anemometers. Discussion is limited here to differential pressure flow transducers because they are the most widely used. In this technique, airflow directed through a cylinder exits through a small resistive field, usually composed of small parallel tubes or a grill promoting laminar flow. The pressure drop across this resistive field is measured using a differential manometer. When flow is laminar, the relationship between the pressure differences and flow is linear. Changes in gas density, viscosity, and temperature alter the pressure-flow relationship. To prevent condensation on the resistive element requires heating, so calibration should be conducted when the pneumotachograph is heated. After correction for errors introduced by alterations in these physical factors, the flow signal is integrated to determine volume.

MEASURING RESPIRATORY EFFORT

Measuring respiratory effort provides information needed to distinguish between respiratory events of obstructive versus nonobstructive (central) etiology. Categorizing an apnea or hypopnea as obstructive, mixed, or central in origin derives from differential respiratory effort and airflow patterns. As reviewed next, several techniques are available to detect and/or measure respiratory effort, including rib cage and abdominal motion, electromyography, pleural pressure changes, movement detected by static charge sensors in or on the bed surface, movement detected by standing wave patterns in the bedroom, and digital video recording.

Rib Cage and Abdominal Motion

Currently, the most common polysomnographic technique for measuring respiratory effort involves detection and quantification of rib cage and abdominal movements. During normal breathing, the major inspiratory muscles produce rib cage expansion and a downward movement of the diaphragm. These movements cause the pressure around and in the lung to become negative (relative to atmospheric pressure). The pressure gradient between ambient air and the lung draws air through the airways into the alveoli. Thus a change in lung volume is the sum of the volume changes of the structures surrounding the lungs, the rib cage, and the abdomen.[15] Other respiratory muscles (e.g., intercostal, sternocleidomastoid) also play a role in stabilizing the thoracic cage. Some clinicians erroneously interpret the abdominal and rib cage motion changes as implying separate activities of abdominal and thoracic respiratory muscles, but this is not the case. Virtually all of the changes in abdominal and rib cage volumes (including paradoxical motion) can be explained by changes in the status of the respiratory muscles directly inserting onto the thoracic cage. Paradoxical motion of the rib cage and abdomen can result from several changes, including loss of tone of the diaphragm, loss of tone of the other respiratory muscles, and upper airway obstruction (complete or partial). The mechanisms underlying this asynchronous motion of rib cage and abdomen are described in Box 164-2. Regardless of the pattern or its underlying mechanism, rib cage and abdominal movement reflect effort to breathe.

Box 164-2 MECHANISMS UNDERLYING PARADOXICAL MOTION OF THE RIB CAGE AND ABDOMEN

Loss of diaphragm tone. When the diaphragm ceases to contract and becomes flaccid, it merely reacts to pressure changes around it instead of generating pressure changes. In this situation, when the other respiratory muscles contract, the rib cage is enlarged, and pleural pressure becomes negative, sucking the diaphragm into the chest. This condition results in an increase in rib cage volume and a reduction in abdominal volume.

Loss of accessory respiratory muscle tone. When the accessory muscles lose tone, the rib cage, particularly the upper part of the rib cage, becomes unstable. When the diaphragm then contracts, the negative intrathoracic pressure causes the unstable part of the thorax to be sucked in during inspiration.

Partial upper airway obstruction. With partial upper airway obstruction, the diaphragm must generate very strong negative pressures for inspiration to occur. As the diaphragm contracts, it both pushes out the abdomen and creates great negative intrathoracic pressure. This highly negative intrathoracic pressure can overcome the mechanisms maintaining chest wall stability (accessory muscle tone and rigidity of the cage), so that the least stable portions of the rib cage will tend to move inward with inspiration. This potential for inward movement of the rib cage is a problem mainly in the very young, in whom the rib cage is quite pliable.

At a minimum, a single uncalibrated abdominal movement sensor can *detect* respiratory effort. Respiratory effort during airflow cessation usually signifies airway obstruction. Common approaches for *measuring* rib cage and abdominal movement use (1) strain gauges, (2) inductance plethysmography, and (3) piezoelectric transducers.

Strain gauges are sealed elastic tubes filled with conductive material through which an electric current is passed. When length is constant, current and resistance are constant. Stretching the strain gauge lengthens and narrows the cross-sectional area of the fixed-volume conductor. This deformation produces a proportional increase in electrical resistance. Current varies inversely in relation to the length of the gauge, thereby becoming an index of gauge length. A Whetstone bridge amplifier transduces this change to voltage for continuous display showing rib cage or abdominal expansion (depending on placement).

Inductance plethysmography electronically measures changes in the cross-sectional area of the rib cage and abdominal compartments by determining changes in inductance. Inductance is a property of electrical conductors characterized by the opposition to a change of current flow in the conductor.

Transducers are placed around the rib cage and abdomen—the physiologic equivalent of conductors. Each transducer consists of an insulated wire sewn into the shape of a horizontally oriented sinusoid and onto an elasticized band.

Piezoelectric transducers are used in yet another method of detecting movement. These sensors can be placed on the rib cage and abdomen and are sensitive to changes in length. When a piezoelectric crystal is squeezed, an electrical potential appears across its sides. The crystals can be arranged (usually as part of a belt) so that movement can be detected (see next).

Combined Sensors

Thermocouples, thermistors, and strain gauges are fairly old technologies. More recently, new materials such as polyvinylidene fluoride film have been introduced into the sleep laboratory. Such film has the interesting property of converting heat and mechanical energy into electrical energy that can be measured. Polyvinylidene fluoride films have both piezoelectric (responding to mechanical changes) and pyroelectric (responding to thermal changes) properties. The output from these films can be configured to measure airflow[16] (pressure and temperature), snoring[17] (pressure waveforms), and changes in length caused by abdomen and rib cage movement.[18-20]

Respiratory Muscle Electromyography

Recording intercostal muscle activity on the electromyogram (EMG) is one of the oldest polysomnographic techniques for detecting respiratory effort (Figure 164-5). These uncalibrated recordings are made using standard surface electrodes placed in pairs in the intercostal spaces on the right anterior chest. Obtaining an optimal signal requires practice, patience, and skill; recordings are prone to artifact, especially artifact from the electrocardiogram (ECG). Intercostal EMG activity, when recorded properly, can be extremely valuable for differentiating among central, obstructive, and mixed sleep-disordered breathing events. Furthermore, although signals are not calibrated, cascading increases in respiratory effort are readily apparent from recordings.

Pleural Pressure Changes

Some sleep centers use esophageal pressure to index inspiratory effort. In our experience, most patients undergoing all-night polysomnography find esophageal balloons unacceptable. However, the thin water-tip or catheter-tip piezoelectric transducers are better tolerated. Esophageal pressure measurements help verify central apnea or hypopnea episodes with a high degree of certainty. This technique also can detect very subtle respiratory events. However in subtle cases, a repeat

(From Butkov N. *Atlas of clinical polysomnography.* Ashland [Ore.]: Synapse Media; 1996, p. 224.)

polysomnogram may be preferable to using an esophageal catheter.[21]

In patients with *upper airway resistance syndrome*, the classic findings include progressively more negative pleural pressure until occurrence of a CNS arousal. The arousal is sometimes associated with an audible snort (Figure 164-6). After arousal, pleural pressure swings temporarily decrease until the next cycle begins, upon which pressure swings increase until another arousal occurs. Sometimes the CNS activation falls short of AASM duration criteria for arousal. However, the AASM's 3-second rule was established for determining reliability of spontaneous arousals using visual scoring.[22,23] On the electroencephalogram (EEG), signal changes of shorter duration are conceptually thought to represent CNS arousals, as are spectral analysis indices of alpha power loading, even when it is difficult to see on the raw data tracing.

Movement Detected by Static Charge and Pressure Sensors

The static charge–sensitive bed technology has been evaluated in sleep disorders.[24] The transducer is embedded within a thin mattress that responds to the slightest movement. Output from the bed is sensitive enough to detect heartbeat as a ballistocardiogram. Respiratory signal amplitude differs with body position changes; however, output is otherwise stable.

Figure 164-7 Synchronized digital video can be extremely helpful, as in this example in which a child with retrognathia slept with his neck arched and his mandible thrust forward (*arrow*). This sleep posture resulted in an unoccluded upper airway. The conventional polysomnography recording missed that a significant sleep breathing problem was present. (From Banno K, Kryger MH. Use of polysomnography with synchronized digital video recording to diagnose pediatric sleep breathing disorders. *CMAJ* 2005;173:28–30.)

A similar but newer technology uses piezoelectric sensors embedded in a strip placed perpendicular to the sleeper's body. Changes in pressure resulting from breathing movement and heartbeat can be analyzed.[25]

Movement Detected by Wave Technologies

Several systems approach movement detection using microwaves, radar, and/or changes in standing wave patterns in the bedroom. One approach directs a beam at the bed surface and analyzes the returning signal to evaluate the sleeper's upper body movement. In one such system, laser radiation can be used. Microwave and other radar-like technologies also can be applied. Additionally, a series of sensors could be used to monitor movement. Application of some of these emerging technologies to sleep medicine for evaluating SRBD is an important aspect of ongoing developments in the field.

Polysomnography-Synchronized Digital Video

Digital video is now a common feature of computerized polysomnography. Although recordings are widely used to evaluate parasomnias and seizures, they can be helpful in assessing SRBD. When the recording is properly synchronized with polysomnography, ambiguous and difficult-to-interpret tracings often become obvious. For example, it is easy to recognize a small dip in arterial oxygen saturation (Sao_2) as a significant sleep-disordered breathing event when it is followed by oxygen resaturation after an audible snort, a repetitive moving forward of the jaw, an arching of the neck, or a closing of a gaping mouth. Video is especially helpful in children, whose polysomnographic recordings may be difficult to interpret (Figure 164-7). An Sao_2 dip, without the other visual information, is quite likely to be missed, ignored, or dismissed as artifact. Video recordings are particularly useful in thin persons, who might not experience oxygen desaturation with their abnormal respiratory events. Furthermore, showing the sleep study video to patients can be very effective for promoting understanding of the problem and an appreciation of its severity.

MEASURING CHANGES IN LUNG VOLUME

Several methods can estimate tidal volume. These measures provide semiquantitative data concerning presumed airflow while also documenting respiratory effort. Calibration is

crucial in attempting to use these devices to gauge ventilation. Postcalibration movements, changes in body position, and shifting in placement of the recording device can introduce error. In sleep laboratories, strain gauges, inductance plethysmography, and impedance pneumography are sometimes used to measure volume changes. Other techniques include magnetometry, body plethysmography, canopy with neck seal, the barometric method, and pneumotachography; however, these are seldom used in a clinical setting.

Strain Gauges, Inductance Plethysmography, and Piezoelectric Transducers

In principle, length-sensitive devices can be used qualitatively to detect breathing abnormalities. If properly calibrated, these devices can be used quantitatively to measure dynamic volume changes.[26] Normally, the enlargement of the thorax and the outward movement of the abdominal wall occur together; that is, they are in phase. For a given change in lung volume, then, it is possible to quantify a change in rib cage volume and abdominal volume. For a given breath, the relative contributions of the rib cage and abdominal compartments also can be determined.

To quantify actual volume changes, the transducers must be calibrated against an independent volume-measuring system. In practice, two length-measuring devices are required for measuring changes in lung volume: one for the rib cage and one for the abdomen. The rib cage device is placed at the level of the axilla, and the abdominal device is placed just superior to the iliac crest. If it is assumed that the fractional contributions of the abdomen and the rib cage are constant, then changes in lung volume can be measured by calibrating transducers sensitive to rib cage and abdominal displacement. Once the transducers are calibrated, the sum of the rib cage and abdominal excursions will describe volume changes.

Unfortunately, the relative rib cage and abdominal contributions can change with posture and muscle tone occurring in sleep. Movement-related device migration from its original site and device deformability also must be considered. Such factors adversely affect calibration accuracy and stability. Nonetheless, calibrated inductance plethysmography appears to be sensitive enough to detect upper airway resistance syndrome events.[27]

Impedance Pneumography

Impedance defines the combined effects of two previously discussed properties of an electrical conductor: *resistance* and *inductance*. In physical terms, when impedance pneumography is used, the conductor is the thorax. Impedance is measured by applying a small current across the thorax using a pair of electrodes placed at the site of maximal thoracic excursion.

Transthoracic impedance changes reflect variations in the amount of conductive materials (liquids, including interstitial fluid, blood and lymph, and tissue) and nonconductive material (air) between the electrodes. The conductive and nonconductive materials affect the total impedance differently. Increased air in the lung increases impedance, and increased fluid in the thorax decreases impedance. A recording of the volume of air exchanged and the total of impedance changes can allow the differentiation between air-related and fluid-related changes in impedance. If total impedance is recorded in a single channel, changes related to air volume and fluid are measured.

Impedance alterations in obstructive apnea are complex. During apnea, lung volume decreases, whereas the negative intrathoracic pressure most likely temporarily pools blood in the pulmonary circulation. For these reasons, a precise measurement of respiratory volume and pattern may not be possible. Nonetheless, rate-adapting cardiac pacemakers using transthoracic impedance to drive ventilation have been used to screen for obstructive sleep apnea.[28]

MEASURING THE PHYSIOLOGIC CONSEQUENCES OF SLEEP-RELATED BREATHING DISORDERS

As previously mentioned, some SRBD events (e.g., hypopnea) are not intrinsically pathophysiologic; however, their consequences are. SRBD event consequences include oxyhemoglobin desaturations, carbon dioxide elevations, blood pressure changes, electrocardiographic abnormalities, and CNS arousals.

Oxygen and Carbon Dioxide Alterations

Routine clinical sleep evaluations require noninvasive, continuous, rapidly sampled measures to determine blood oxygen concentration. Thus directly measuring blood oxygen with an indwelling arterial catheter is ruled out on all counts. Pulse oximetry, however, serves the need well; consequently, it has become the standard technique for recording oxyhemoglobin desaturations during sleep. Pulse oximeters usually determine Sao_2 spectrophotoelectrically using a two-wavelength light transmitter and a receiver placed on either side of a pulsating arterial vascular bed (usually a finger, a toe, an ear, or the nose). Alternatively, in reflectance pulse oximetry, the light transmitter and the receiver are on the same surface. The light transmitted into the vascular bed is scattered, absorbed, and reflected. The amplitude of light detected in particular spectra by the receiver depends on the magnitude of the change in arterial pulse, the wavelengths transmitted through the arterial vascular bed, and the oxygen saturation of arterial hemoglobin (deoxygenated blood is bluer). These devices are sensitive only to pulsating tissues; consequently, venous blood, connective tissue, skin pigment, and bone theoretically do not hamper determination of Sao_2. Accurate measurement, however, requires a minimal pulse amplitude. Dyshemoglobinemias can cause problems.

Correct alignment of the light transmitter and receiver is critical to ensure measurement accuracy. If the sensor is applied to a digit, that digit must be immobilized. Significant bending of the digit can compromise detection of pulsatile flow and invalidate results. Although all pulse oximeters are based on similar technology, response characteristics differ both across manufacturers and even within a specific manufacturer's product line.[29] Sensor placement and device programming are crucial technical factors in obtaining optimal results. Reflectance oximeters also must contend with weaker pulse signals, because much less light is reflected back to the sensor. Differences in response characteristics and effect of sensor location cannot be overemphasized (Figure 164-8), because some oximeters appear to be completely insensitive to hypoxemia episodes clearly detected by other devices (Figure 164-9). Such devices can produce false-negative SRBD test outcomes.

A review of specific oximeters would be beyond the scope of this chapter; nonetheless, generalizations about (1) sensor location, (2) instrument filtering and sampling rates, and (3) potential pitfalls are worth noting here.

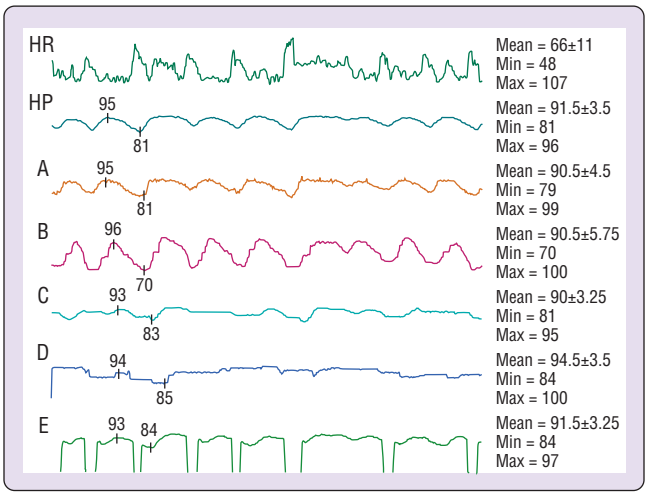

Figure 164-8 Heart rate (HR) and arterial oxygen saturation (Sa_{O_2}) during a 5-minute period in a patient with sleep apnea. The *top two traces* are for the HR monitor and a Hewlett Packard (HP) oximeter; A to E are traces for five different pulse oximeters. The scales for the six oximeters are identical. The *numbers* on the tracings represent the instantaneous Sa_{O_2} measured during the peak and trough of an apneic episode. The data listed to the *right* of the figure are the mean, standard deviation, and minimum and maximum values for HR and Sa_{O_2} for the six oximeters. Note that oximeters C and D do not track Sa_{O_2}, and that the recording for oximeter E has numerous artifacts.

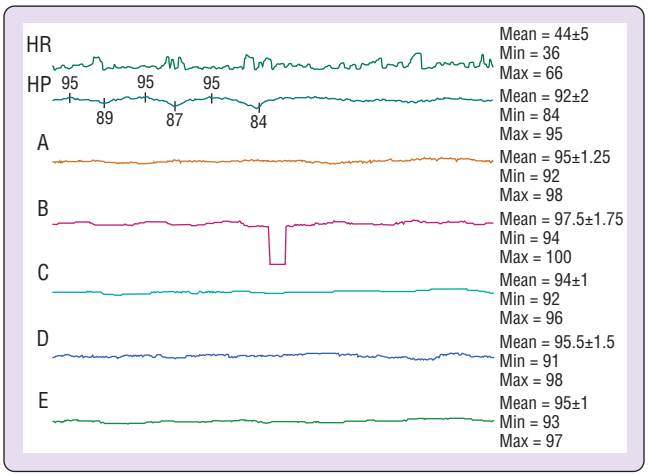

Figure 164-9 Heart rate (HR) and arterial oxygen saturation (Sa_{O_2}) during a 5-minute period in a patient with sleep apnea and bradycardia. Tracings are taken from six oximeters, as described in Figure 164-8. In this example, three apneic episodes are missed entirely by all of the pulse oximeters. This patient's problem would have gone completely undetected by pulse oximetry screening. HP, Hewlett Packard (oximeter).

Sensor Location

In our experience, the preferred sensor location in adults is the earlobe. Poor perfusion can be enhanced by applying a trace amount of vasodilator (e.g., nonylic acid vanillylamide plus nicotinic acid—Finalgon ointment [Boehringer Ingelheim, Ridgefield, Conn.]). Technicians must take care to avoid contact of the perfusion-enhancing agent with their own or the subject's eyes, because it is a powerful cutaneous vasodilator. When the ear site is not usable, reflectance pulse oximeter sensors placed on the forehead or another well-perfused surface will suffice. Recording from the ear also reduces circulator delay (compared with the finger). This advantage becomes especially important for associating a respiratory event with its subsequent oxyhemoglobin desaturation in patients with congestive heart failure.

Instrument Filtering and Sampling Rate

Most pulse oximeters filter the signal, and some filter algorithms use the heart rate. The degree of filtering is inversely related to heart rate; brief, mild hypoxemic episodes may therefore be missed during periods of very low heart rate, because they are filtered more strongly. During polysomnographic recording, filtering should be minimized (i.e., by setting the oximeter to the fastest response or the highest sampling rate, or both) to reduce missing transient oxyhemoglobin desaturation events.

Potential Problems

Because pulse oximeters use two wavelengths of light to estimate Sa_{O_2}, they cannot distinguish three or more hemoglobin species. In the presence of carboxyhemoglobin (as in heavy smokers, in whom carboxyhemoglobin levels can reach 10% to 20%), Sa_{O_2} is overestimated.[30] In the presence of a rising methemoglobin concentration, oximetry-determined Sa_{O_2} will plateau at approximately 85%, regardless of whether true saturation is much higher or lower.[31] Because light is transmitted through tissue, pigment in the skin can degrade oximeter performance, producing incorrect "probe-off" or "perfusion-low" error reports.[32] Some finger-clip devices can produce pressure-related injuries when worn for an entire night.

Partial pressure of arterial oxygen (Pa_{O_2}) estimated from the skin's surface depends on oxygen flux through the skin, local oxygen consumption, and the skin's diffusion barrier.[33] This measurement technique is most commonly used in neonates, whose skin is thin. Accurate measurement of transcutaneous P_{O_2} (P_{O_2}tc) requires maximal dilation of the local vasculature in the upper dermis. This is achieved by heating (to 43°C); however, heating shifts the oxyhemoglobin dissociation curve to the right, increases the resistance of the skin stratum corneum to oxygen permeation, increases the metabolic rate of the dermal tissue, and increases the rate of cutaneous blood flow. The shift in the oxyhemoglobin dissociation curve and the increase in metabolic rate effectively cancel each other out, leaving permeability and flow as the dependent factors in correlating P_{O_2}tc and Pa_{O_2}. An important advantage of heating is that the amount of blood present is maximal, and P_{O_2}tc is therefore unaffected by small changes in blood supply to the tissue.

The P_{O_2}tc may be misinterpreted when the state of blood flow is unknown. When flow and Pa_{O_2} are adequate, P_{O_2}tc reflects Pa_{O_2}. Under conditions of compromised flow and adequate Pa_{O_2}, P_{O_2}tc will change with flow. If Sa_{O_2} and flow are compromised, P_{O_2}tc tracks oxygen delivery. Transcutaneous measurement accuracy also depends on correct sensor application. To convert P_{O_2}tc measurements to Pa_{O_2} values precisely, a calibration curve for each subject is required, so this technique is too labor-intensive for use in routine clinical practice. In most laboratories, P_{O_2}tc serves to track, in relative terms, arterial oxygenation status. Device responsiveness is too slow for tracking rapid blood gas changes associated with brief SRBD events (less than 30 seconds), because oxygen diffuses slowly across the skin. The conditions governing transcutaneous Pc_{O_2} measurement are remarkably similar to those described for Pa_{O_2}. Although transcutaneous blood gas determinations are

of greatest value in neonates and young children, Pco_2tc is useful for assessing hypoventilation in adults.

Central Nervous System Arousals and Awakenings

Awakenings and CNS arousals provide critical information concerning sleep disturbance and fragmentations. Standardized scoring derives from electroencephalographic activity, preferably recorded from occipital sites. CNS arousals often take the form of bursts of alpha (7 to 13 Hz) activity, and the term *EEG speeding* is sometimes used to describe the event. When scored visually, a 3- to 15-second burst of alpha activity in non–rapid eye movement (NREM) sleep is considered an arousal. During rapid eye movement (REM) sleep, when alpha bursts can be an ongoing part of background activity, the alpha intrusion must be accompanied by increased muscle tone. In any sleep stage, a burst exceeding 15 seconds in duration is scored as an awakening.

The CNS arousal represents a clinically significant sleep parameter because it is associated with (in cross-sectional studies) and provokes (in intervention studies) tiredness, fatigue, and sleepiness. As a pathophysiologic consequence of obstructive sleep apnea, the arousal is thought to result from increased respiratory effort (and accompanying increase in autonomic nervous system sympathetic activation) triggered by increased airway resistance. Presumably, the CNS arousal terminates the SRBD event, because the arousal returns ventilation to voluntary control. As a result, the airway can be dilated and breathing resumes. However, some controversy exists about resumption of breathing after an obstructive event without CNS arousal and about the presence of arousals at the termination of central events.

Blood Pressure Changes

Clinical laboratories do not routinely record sleep-related blood pressure. Nonetheless, many pulse oximeters also can track pulse pressure (a magnitude index of pulsation occurring at the oximetry sensor site). In addition, pulse transit times (PTTs) have been used to indirectly estimate blood pressure.[34] PPT represents the time interval from heartbeat (ECG R wave) to its pulse recorded in the periphery. Negative pleural pressure provokes a blood pressure drop and in so doing lengthens PTT. The progressive increase in pleural pressure during obstructive apnea correlates with rising oscillations in PTT amplitude. During central apnea, this does not occur. Thus it has been suggested that PTT might provide an opportunistic estimate of inspiratory effort and thereby provide a means to differentiate obstructive from central apnea.[35]

Automatic self-inflating arm-cuff sphygmomanometers have long been available but are problematic for routine clinical use because they disturb sleep. By contrast, miniature finger cuff systems disturb sleep much less. Devices obtaining data in alternating fashion from adjacent fingers reduce finger injury risk, and some systems automatically perform hydrostatic correction when arm movement occurs. Finger flexion artifacts, however, remain a problem.

Cardiopulmonary Coupling

Cardiopulmonary coupling uses a single-channel ECG recording to extract signal features modulated by breathing.[36] Respiration induces small alterations in heart rate and amplitude variations in R-wave amplitude. Using computerized frequency domain analysis, a high-frequency component can be isolated that represents variations in breathing-induced vagal sinus pressure heart rate. A low-frequency component can be extracted that provides data about interbreath intervals. By examining a weighted composite of these data (increased variability and the envelope of amplitude change), time-domain periods (usually 2 to 10 minutes) with breathing pauses can be discerned by examining coherence and cross-power spectrums. In general, normal breathing loads high-frequency bands, and SRBD events mass in low-frequency troughs. For detailed information about cardiopulmonary coupling, see Chapter 166.

HOME SLEEP TESTING

In addition to standard attended polysomnography, guidelines for home sleep testing have been published.[37] Chapter 165 provides methodologic details. Because home sleep testing devices are less sensitive than laboratory polysomnography, the home test can rule in, but not rule out, SRBD.

To succeed diagnostically and economically, home sleep testing requires proper patient selection, appropriate portable recorder application, study interpretation by a qualified sleep specialist, readily available access to laboratory polysomnography when needed (as after a negative result on home sleep testing, or to investigate continuing problems despite treatment), and systematic follow-up assessments. Many health care coverage plans (including those administered by the Centers for Medicare and Medicaid Services) reimburse home sleep testing for diagnosing sleep apnea. Unattended studies are more prone to data loss as a consequence of uncorrected technical failures (e.g., electrode detachment) and patient tampering. Consequently, only patients with a high clinical suspicion for SRBD should be referred for HST.

CLINICAL PEARLS

- Detecting sleep-related breathing events and classifying each as obstructive, central, or mixed require measures of airflow, respiratory effort, and oxyhemoglobin saturation.
- Information about sleep-disturbing effects of SRBD events provides better sensitivity for the diagnosis of sleep-disordered breathing.
- Standardized guidelines developed by the AASM were developed to advance clinical practice and should not be construed as an impediment to advancing scientific inquiry.

SUMMARY

Evaluating patients with SRBDs is the most common application of laboratory and home sleep studies. Over the past four decades, some of the more frequently used procedures have evolved and become commonplace in clinical sleep laboratories. The American Academy of Sleep Medicine also published guidelines and a standards manual. Standard assessment for breathing disorders during sleep includes measures of airflow, respiratory effort, and oxyhemoglobin desaturation. Laboratory evaluation also includes sleep disturbance assessment. In this chapter we describe techniques to assess these and other, related physiologic activities. The underlying mechanism, advantages, and problems are also discussed.

Home Sleep Testing

Thomas Penzel

Chapter Highlights

- Home sleep testing for diagnosing sleep-disordered breathing outperforms attended cardiorespiratory polysomnography. Diagnostic sensitivity and specificity are high enough for effective clinical application.
- Home sleep testing protocols have been established in terms of required signals. Monitoring usually includes respiratory effort and airflow, oxygen saturation, and body position/activity. Visual scoring is a necessary component. Clinical symptom assessment and home sleep testing should be combined to achieve high sensitivity and reliability.
- New developments are targeting use of fewer signals for diagnosing sleep-disordered breathing. Different systems achieve this with variable success. An economic benefit can be realized if sleep-disordered breathing can be diagnosed or managed using single-channel devices versus four- to six-channel devices, and such approaches currently are under investigation.

OVERVIEW AND BACKGROUND

Home sleep testing refers to portable monitoring for diagnosing sleep-disordered breathing. The term was introduced in the past decade. In 2014, a National Library of Medicine (NLM) PubMed database search for "home sleep testing" in all fields found 19 publications. The reference method for the diagnosis of sleep-disordered breathing is cardiorespiratory polysomnography. The recording technology and the scoring criteria used in home sleep testing are derived from this modality. Many studies on individual systems and a considerable number of evidence-based reviews indicate that home sleep testing for sleep-disordered breathing can be as specific and as reliable as sleep laboratory–based polysomnography recordings[1-3] in properly referred patients. Finally, adequate data are available to validate home sleep testing's use clinically, although it does have certain limitations.[4] A workshop consensus report presented the view of the participating medical societies (American Thoracic Society, American Academy of Sleep Medicine, American College of Chest Physicians, European Respiratory Society) on the use of this diagnostic procedure and provides directions for further research.[5] A clinical practice guideline from the American College of Physicians now recommends portable sleep monitors for diagnostic testing in patients suspected of having obstructive sleep apnea without serious comorbidity, and as an alternative to polysomnography when polysomnography is not available.[6] In Europe, home sleep testing has been widely used for several decades to diagnose sleep-disordered breathing.[7]

With respect to the guidelines and recommendations on home sleep testing, which are partially evidence-based, it is essential to consider the basis of the underlying studies used for evidence evaluation. The clinical studies evaluated for the guidelines usually are those performed by sleep centers on their patients, which correspond with clinical populations available in sleep centers.[8,9] Clinical populations differ from the general population in that the patients have been referred for evaluation for suspected sleep disorders. This selection leads to a high pretest probability for sleep disorders and for sleep apnea in particular.[1,10] Factors associated with this increased pretest probability include various physical examination measures and complaints reported by the patient or the bed partner, as follows:

- Loud and irregular snoring
- Observed or reported nocturnal cessation of breathing
- Excessive daytime sleepiness
- Nonspecific mental problems such as fatigue, low performance, or cognitive impairment
- Movements during sleep
- Morning dizziness, general headache, dry mouth
- Impaired sexual function
- Obesity
- Arterial hypertension and cardiac arrhythmias

A grading of the pretest probability factors could be useful to determine which patients may be more likely to suffer from sleep apnea or even from more severe sleep breathing disorder. This potential application has not been investigated in clinical practice.[11] Instead, clinicians commonly use a combination of validated questionnaires in conjunction with home sleep testing to confirm the suspected diagnosis.[12]

As revealed in a literature search, published reports are of several different types. Some papers describe new devices and comparative studies of such innovations with polysomnography. Reviews of data on existing devices are scarce. However, a good systematic review of data on existing systems that also provides categories for evaluation has been presented.[4] These categories are sleep, cardiovascular, oxygen saturation, position, effort of respiration, and respiratory flow—the SCOPER acronym. Sensors and systems are evaluated using these categories. A majority of published studies, however, focus on the role of home sleep testing in sleep apnea diagnosis. Some reports in the literature concentrate on general management

of patients with sleep apnea, whereas other reports focus on home sleep testing. Presented next is a short technical overview of available systems, followed by a discussion of home sleep testing with respect to requirements and special considerations.

HOME SLEEP TESTING WITH FOUR- TO SIX-CHANNEL SYSTEMS FOR DIAGNOSING SLEEP-DISORDERED BREATHING

Systems for diagnosing sleep-disordered breathing generally fall into one of four classifications defined in an American Sleep Disorders Association (ASDA) standard of practice guideline.[13]

- level I: attended cardiorespiratory polysomnography with at least 7 signals
- level II: cardiorespiratory polysomnography at home with at least 7 signals, unattended
- level III: unattended portable sleep apnea testing with at least 4 signals including airflow, respiratory effort, oxygen saturation, ECG, or heart rate or pulse rate
- level IV: unattended one or two signal recording, such as actigraphy or oximetry

Most diagnostic systems for home sleep testing attain level III device status and record four to six physiologic signals but do not record the electroencephalogram (EEG). Evidence-based home sleep testing reviews commissioned by health technology assessment agencies[3] revealed limited reliability. Up to 17% false-negative and between 2% and 31% false-positive findings of sleep apnea have been reported. These high error rates compared with those for polysomnography are considered unacceptable, and Ross and colleagues[3] concluded that portable monitoring of sleep apnea is not recommended. A few years later, studies with revised recording systems showed substantial improvement.[9,14] If systems incorporate a thoughtful selection of physiologic measures, have good signal acquisition, and use good signal processing technique, the number of false-positive diagnoses declines considerably.[1] When studies sampling from the general population are compared with studies using clinical populations, the importance of a high pretest probability becomes clear. A high pretest probability reduces the number of false-positive diagnoses. Altogether, the specificity increases enough to permit a conclusion that home sleep testing for sleep apnea can be recommended under certain conditions[4,6]:

1. Systems should be used only by certified sleep physicians based in certified sleep centers. This recommendation attempts to improve quality control and quality assurance. An interview of the patient and assessment of complaints should be conducted before home sleep testing is performed. This screening increases the pretest probability as explained earlier.
2. Home sleep testing for obstructive sleep apnea is recommended when no other comorbid pulmonary, cardiovascular, mental, neurologic, and neuromuscular disorder, or heart failure or another sleep disorder, is present. Other sleep disorders to rule out include central sleep apnea, periodic limb movement disorder, insomnia, circadian sleep-wake disorders, and narcolepsy.
3. In the earlier published studies, home sleep testing systems could not distinguish between central and obstructive sleep apnea events.
4. Home sleep testing for diagnosing sleep apnea needs to record oronasal airflow (using a thermistor or nasal pressure sensor); respiratory effort (using inductive plethysmography); oxygen saturation (with a short averaging period over few [3 to 6] pulses; pulse or heart rate; and body position.
5. Evaluation of the recordings should incorporate visual scoring of respiratory events using the same rules specified for polysomnography.[15,16] Editing of recorded events is necessary to remove artifacts occurring during the recording period. Furthermore, the visual scoring should be performed by trained personnel.
6. The technical specifications and sampling rates for the digital recording should be the same as specified in the evidence-based recommendation for cardiorespiratory polysomnography.[16]

Today, many devices fulfill the requirements necessary to meet level III device criteria. The home sleep testing devices all include pulse oximetry technology to record oxygen saturation and pulse rate. Many systems record oronasal airflow, which reflects intranasal pressure. Few systems still use thermistors for flow recording. Most devices record respiratory effort using either piezo sensors or respiratory inductive plethysmography. Some devices use one belt for rib cage movements, whereas others use two belts (for recording abdominal movements as well). Most systems record body position to identify positional apnea. Very few systems record the raw electrocardiogram (ECG), but many report heart rate derived by other means. A number of systems offer specific options to record signals in sleep apnea patients under therapy. The options are the recording of CPAP mask pressure in addition or as an alternative to other airflow signals. The signal will be split into a CPAP pressure reading, corresponding to set pressure level and to a respiratory flow reading which may be observed superposed to the CPAP pressure set. This may vary depending on pressure mode selection (e.g., bilevel or flex modes). This option is an important feature for using home sleep testing for treatment follow-up studies. Some systems allow an option for recording additional electromyogram (EMG) tibialis activity to detect leg movements; thus far, however, no systematic studies on this option's utility have been conducted.

It remains an open question whether home sleep testing can reliably diagnose periodic limb movement disorder. Similarly, a few systems can add electroencephalography channels for recording the sleep EEG, but no systematic studies have evaluated this option for its potential added diagnostic value or validated its sleep-related parameters. Nonetheless, many systems have been validated for clinical use with their basic signal setup together with their scoring and analysis software. Ingeneral, most systems show good performance, with some minor differences. No overall preference for one or another system emerges from published studies.

HOME SLEEP TESTING WITH ONE- TO THREE-CHANNEL SYSTEMS FOR DIAGNOSING SLEEP-DISORDERED BREATHING

Systematic reviews of home sleep testing for diagnosing sleep-disordered breathing have revealed that systems with one to three channels (pulse oximetry, long-term ECG, actigraphy, and oronasal airflow) are not suitable for routine diagnostic use. Specifically, these devices yield too many false-negative

(up to 17%) and too many false-positive (up to 31%) results.[3] This finding remained valid in the review by Collop and associates[1] and in a more recent systematic review using the new SCOPER criteria.[4] Therefore the application of these devices is not recommended for definitive diagnostic testing for obstructive sleep apnea, or to exclude the presence of obstructive sleep apnea.

Some of these devices, however, provide results in patients with severe sleep apnea that clearly suggest sleep-disordered breathing. Therefore high-quality recordings achieved with validated systems of this category can be used to increase the pretest probability before performance of cardiorespiratory polysomnography or even before four- to six-channel home sleep testing for sleep apnea.

Many technical innovations are currently emerging in this category of devices. A major challenge has been development of one- to three-channel devices that perform well and can diagnose sleep-disordered breathing. If reliable, such devices could facilitate diagnosis in new patient groups and provide tools for clinicians trained in other specialties with only basic knowledge of sleep medicine. Before initiation of therapy for sleep breathing disorders, however, a physician with a solid background in sleep-disordered breathing who is very familiar with the different treatment options should review the case.[17]

Described next are new technologies applicable with both one- to three-channel systems and four- to six-channel diagnostic devices.

NEW METHODS FOR HOME SLEEP TESTING

Different approaches are being explored for development of new technologies for diagnosing sleep-disordered breathing. Some approaches focus on developing new sensors to assess respiration for detecting breathing disturbances occurring during the night. Other technologies concentrate on assessing the patient's cardiovascular risk or sleep pathophysiology.

Assessment of Respiration

Several new sensors use surrogate signals to derive respiratory effort noninvasively. Some of these devices try to derive respiratory measures from direct respiration-related signals. These systems and concepts are discussed next.

A first-line approach entails recording respiratory airflow at the nose and the mouth. Usually these recordings are accompanied by pulse oximetry to determine oxyhemoglobin saturation. These simple screening devices provide a straightforward analysis for respiratory cessations. They even may distinguish obstructive from central respiratory events by analysis of flow limitation. Problems with obstructed nostrils, partial breathing through the mouth, blocked air tubes, and various artifacts pose logistical challenges to differentiating among the different types of apnea. Nevertheless, good validation studies are available,[18,19] with some limitations.

One approach tries to analyze respiratory sounds from the chest, with the goal of less obtrusive measures for detection of increased respiratory effort.[20] In other systems, respiratory sounds are recorded at the throat, and signal processing separates cardiac and movement signal first from breathing sounds and snoring. Together with oximetry, such recording quantifies respiratory measures, and snoring is tracked to detect respiratory cessations.[21,22]

Another approach involves recording midsagittal jaw movements based on magnetic distance determination.[23] A magnetic sensor is placed on the chin and another on the forehead to allow continuous determination of relative jaw movements. From this setup, it is possible to derive respiration and snoring. Analysis of this information is then used to detect respiratory events to diagnose sleep apnea.[24] By further analysis, a sleep wakefulness profile may potentially be estimated.[25,26] Combined with pulse oximetry and perhaps a cardiovascular parameter, this magnetic sensor–jaw movement detection feature is both simple and promising for clinical usefulness.

Pulse Wave Analysis

Many systems try to exploit the pulse wave on the finger or other peripheral sites. Such systems attempt to derive parameters from the pulse wave to assess cardiovascular event risk. The pressure wave may be detected with the photoplethysmograph already placed to measure oxygen saturation. In principle, this can be used to detect all forms of respiratory events[27] and cardiovascular event risk as associated with sleep apnea.[28,29]

Peripheral arterial tonometry[30] can be used to assess cardiovascular risk by measuring endothelial function during sleep-disordered breathing episodes. Arousals terminating sleep apnea events are accompanied by attenuated pulse amplitude. This decrease is due to peripheral vasoconstriction caused by sympathetic tone activation. If pulse rate also is analyzed, probability analysis can be used to distinguish between slow wave sleep and rapid eye movement (REM) sleep.[31] Several validation studies were published on use of the Watch-PAT, based on peripheral arterial tonometry, in patients with sleep apnea, with very good results.[29,32,33] A meta-analysis for this methodology is available and substantiates the diagnostic value of this device, even though it does not incorporate proximal sensors for effort and flow to record respiration, as recommended.[34]

Assessment of Electrocardiographic and Heart Rate Variability Parameters

ECG-derived respiratory parameters are very attractive for simple detection of sleep apnea owing to low costs and wide availability. To detect sleep apnea from the ECG alone does not require additional electrodes or additional hardware. The respiratory information is derived entirely from analytical software. This kind of analysis also could be performed retrospectively using previously recorded data. Sleep apnea is accompanied by a cyclic variation of heart rate, as already described many years ago.[35] Periodic changes in heart rate are related to the changes in sympathetic tone with apnea events.[36] Modern analysis of heart rate variability can satisfactorily derive cyclic variations of heart rate.[37,38] In addition, the morphology of the ECG wave itself is modulated by respiration. The derived respiratory curve—*ECG-derived respiration*[39]—correlates with respiratory effort and thus can be used to detect sleep-disordered breathing.[40,27] By combining ECG-derived respiration and sleep apnea–related heart rate variability, sleep apnea detection is possible.[41]

Electrocardiographic and Oximetry Assessments

A number of devices that use the ECG analysis techniques mentioned previously also try to link this approach to previous

techniques. Early on, pulse oximetry was applied (with limited success) for portable diagnosis of sleep apnea. Pulse oximetry alone has large diagnostic limitations in patients with arrhythmias or with additional lung diseases such as chronic obstructive pulomonary disease. Combining ECG-based sleep apnea analysis and oximetry is therefore a very promising approach.[42] An early study using pulse rate in addition to oximetry[43] could show that this improves the detection of sleep apnea. One retrospective study showed the advantage over pulse oximetry alone when combined with ECG analysis.[44] In that study, the ECG from a parallel polysomnography recording was evaluated. Based on these results, a combined long-term ECG recording system with oximetry was tested prospectively and provided very convincing results in terms of sleep apnea detection.[42]

MANAGEMENT OF HOME SLEEP TESTING IN A SLEEP CENTER SETTING

Many new studies show high reliability of home sleep testing in detecting sleep apnea.[19] A number of open research questions needing clarification concerning the conditions and restrictions for using portable monitoring are now being addressed in recent studies.[1,5] The important parameters are no longer technical limitations but often study limitations such as the preselection of patients. The inherent screening process corresponds with the characteristic high pretest probability of sleep apnea. This aspect prohibits the use of portable monitoring as a screening tool to exclude sleep apneas, such as in professional drivers and people with supervision tasks (in which symptoms and complaints have not been assessed and may conflict with employability or other issues).

Diagnostic and therapeutic approaches to management of sleep-disordered breathing differ among countries worldwide.[45] The development of sleep medicine in some countries is very advanced. In others, economically affordable strategies constitute the primary consideration.[46,47] In certain settings, sleep medicine may be very basic, with only home sleep testing available for diagnosing sleep apnea.[45] One potential reason for this restriction to home sleep testing alone is the limited availability of sleep medicine centers owing to unmet needs for qualified experts and funding for polysomnography beds. This is the case in countries in which sleep medicine is a young discipline. A second reason is that even in countries with a long history of sleep medicine, and with enough sleep centers and polysomnography beds, an economic decision may be made to limit access to such studies to patients with comorbid illnesses, and those with regular sleep apnea are diagnosed with home sleep testing alone. With improvements in the knowledge base for sleep disorders and sleep-disordered breathing among general physicians, the individual clinician can decide whether a particular patient should be evaluated for suspected sleep apnea alone or exhibits some comorbidity or has other risk factors. Then the patient can be referred for either home sleep testing or cardiorespiratory polysomnography. This approach would allow economic and thoughtful management of patients with respect to diagnosis and subsequent treatment, as appropriate.[46] In Germany a debate was initiated on different levels of sleep medicine service that would include different levels of medical expertise and correspondingly different levels of equipment complexity. Family physicians may have some basic knowledge about sleep-disordered breathing and already sometimes apply simple tests. A limited number of clinical centers would have clinical expertise, training, research, and other technical know-how as required in specialized sleep centers.[47] Many community-based centers may have basic sleep medicine knowledge and home sleep testing with four- to six-channel systems.

The other issue is health economy and patient care. A threshold regarding sleep apnea severity and assessing risk still remains to be established. How many apneas, how many hypopneas, what duration of apnea events, how much sleep fragmentation, or what degree of hypoxia represents substantial cardiovascular risk with increased mortality? How much increase in mortality justifies treatment with continous positive airway pressure (CPAP) or another lifelong therapy? In view of limited therapeutic adherence, how strict should researcher-clinicians be with respect to treatment follow-up studies? As the field of sleep medicine approaches the point at which diagnosis can be done easily with home sleep testing, a need is emerging for new clinical and economic decisions key for developing new strategies in managing sleep apnea.

Patients may be diagnosed and even treated at home. One home sleep testing study showed that the 4-week outcome in sleepiness and CPAP adherence was similar to that for sleep laboratory–based diagnosis and treatment.[48] An important limitation of the study was the short follow-up period.[49] Sleep-disordered breathing is a chronic condition, and long-term adherence with CPAP therapy may decline more at home. Thus more research is needed.

CONCLUSIONS

Attended cardiorespiratory polysomnography is the reference standard for diagnosing disordered breathing during sleep. Evidence-based literature, however, indicates that diagnosis of obstructive sleep apnea can be performed using home sleep testing under certain conditions in adults. The recording must include oxygen saturation, airflow, respiratory effort, heart or pulse rate, and body position. The SCOPER parameters summarize these requirements in a comprehensive and quantitative scheme.[4] Visual evaluation is needed to avoid misclassification of sleep apnea severity.[15] It is not possible to distinguish between central and obstructive respiratory events with certainty. Home sleep testing is reliable if it is performed under the supervision of personnel trained in sleep medicine and if screening has been adequate to achieve a high pretest probability among the study subjects of suffering from sleep-disordered breathing. In addition, the patients should not have other significant sleep or comorbid disorders (e.g., heart failure, stroke, diabetes mellitus, obstructive or restrictive lung diseases, or severe cardiac arrhythmias).

Home sleep testing systems with fewer channels can indicate the likelihood of sleep-disordered breathing but are not sufficiently validated for diagnostic purposes. Currently, these systems can point to the probable need for home sleep testing. Technological advances can be expected to improve these systems. Accordingly, it may well be that in the near future, systems with fewer channels may provide a sufficiently reliable diagnosis for disordered breathing during sleep. To prove the advanced usefulness of new technologies, good clinical studies, with sufficient sample size and testing of the new modality against a reference standard, are needed.

Technologic advances need to be accompanied by economy-driven strategies to diagnose and treat patients with sleep apnea. Recent approaches to diagnosing and even treating patients at home seem to provide effectiveness, in terms of outcome, similar to that for sleep laboratory–based studies. Economically proven home-based studies may be more feasible than sleep laboratory–based studies in light of the high prevalence of the disorders and the still-unmet clinical needs to recognize and treat patients with sleep-disordered breathing.

CLINICAL PEARLS

- Home sleep testing has been used for the portable diagnosis of sleep-disordered breathing for many years worldwide.
- Home sleep testing has been thoroughly compared against cardiorespiratory polysomnography.
- Sensitivity and specificity of home sleep testing are sufficient for a diagnosis if adult patients have a high pretest probability for sleep-disordered breathing.
- Home sleep testing requires monitoring of airflow, respiratory movement, oxygen saturation, pulse rate, and body position.
- Use of systems with fewer signals shows promising diagnostic results, but such streamlined systems require further validation.

SUMMARY

Home sleep testing is a well-validated technique to diagnose sleep-disordered breathing outside of the sleep laboratory and other clinical settings. Different devices are available. These devices usually record respiratory flow, respiratory effort, oxygen saturation, pulse or heart rate, and body position and/or activity. Some of these signals may be recorded indirectly and derived. The diagnostic sensitivity and specificity have been validated against those of polysomnography and generally show good agreement in patients with a high pretest probability for sleep-disordered breathing. Visual evaluation is needed to prevent misclassification of sleep apnea severity. Overall, the available evidence indicates that home sleep testing should be used in combination with a clinical assessment for factors and symptoms associated with sleep-disordered breathing. In view of the high prevalence of sleep-disordered breathing, methods to diagnose sleep apnea in a sufficiently accurate and economic way are urgently needed. Today, home sleep testing to assess sleep apnea is indispensable. In addition, home sleep testing offers a method for conducting therapy follow-up studies that may improve therapy compliance. Home sleep testing is developing an ever-more important role in the management of patients suffering from sleep-disordered breathing.

ACKNOWLEDGMENTS/DISCLOSURES

Several companies have furnished equipment for research or otherwise supported the work on which this chapter is based. Itamar Medical (Caesarea, Israel) provided sensors/consumables for research with the Watch-PAT device. Neuwirth Medical (Obernburg am Main, Germany) provided equipment to the Sleep Center for Research Studies. Cidelec (Sainte-Gemmes-sur-Loire, France) provided a grant for a validation study of its Pneavox system for laryngeal pressure and sound recording. Nomics (Liege, Belgium) provided a grant for a validation study of the Brizzy system. Somnomedics (Randersacker, Germany) provided Somnowatch equipment to the Sleep Center for Research Studies. Weinmann GmbH (Hamburg, Germany) provided Somnocheck equipment to the Sleep Center for Research Studies. Nox Medical (Reykjavik, Island) provided equipment and sensors for testing. Studies were done at the Interdisciplinary Sleep Medicine Center at Charite-Universitätsmedizin Berlin.

Cardiopulmonary Coupling Sleep Spectrograms

Robert Joseph Thomas

Chapter 166

Chapter Highlights

- Cardiopulmonary coupling is a technique that uses heart rate variability as a measure of autonomic drive, in addition to respiration, to generate sleep spectrograms. The electrocardiogram contains a convenient set of signals for extracting both HRV and tidal volume fluctuations measured as R-wave amplitude fluctuations. Cardiopulmonary coupling analysis supports a bimodal (having only two distinct types) of non–rapid eye movement (NREM) sleep, rather than the conventional graded classification.
- High-frequency (0.1 to 0.4 Hz) coupling is a biomarker of integrated, stable NREM sleep, which is characterized by stable breathing, high vagal tone, generally a non–cyclic alternating pattern on the electroencephalogram, high relative delta power, and blood pressure dipping. This state may be considered to be "effective" NREM sleep. Effective sleep enables the normal functions of sleep, across multiple dimensions (e.g., neuronal network health, metabolic), such that spending periods in this state enables recovery and restoration processes.
- Low-frequency (0.1 to 0.01 Hz) coupling is a biomarker of integrated unstable NREM, with exactly opposite features: low-frequency tidal volume fluctuations, cyclic variation in heart rate, cyclic alternating pattern, electroencephalogram, low relative delta power, and stable (non-dipping) blood pressure. This state may be considered "ineffective" NREM sleep. Ineffective sleep fails to accomplish the normal functions of healthy sleep. Very-low-frequency (0.01 to 0.001) coupling is seen in the wake state and during healthy REM sleep; fragmented REM sleep has low-frequency coupling characteristics.
- A subset of low-frequency coupling, termed elevated low-frequency narrow-band coupling, identifies sustained periods of central apneas and periodic breathing.
- Sleep-fragmenting stimuli increase low-frequency coupling, and sleep-consolidating stimuli increase high-frequency coupling as a percentage of sleep, thereby allowing dynamic tracking of sleep physiology and pathology in health and disease.

In humans, the conventional scoring systems divide sleep into rapid eye movement (REM) and non-REM (NREM) types. NREM sleep is subdivided into grades of depth. These classifications are more than 50 years old and were developed at a time when the understanding of neurobiology was limited, modern brain imaging did not exist, and computational resources did not apply network concepts to biologic states. The primary features of REM sleep hold up well with modern neurobiologic circuit analysis. Stage N3 is known to have desirable biologic associations, such as blood pressure dipping.[1] By contrast, the current NREM sleep classification suffers from a major limitation in that deep and restorative "slow wave sleep" (once stage III and IV but now N3) makes up only a fraction of sleep time. Sleep restriction experiments clearly show that even minor reductions in total sleep time have adverse consequences, suggesting that other components of the sleep state must have restorative functions. It is equally plausible that the N3 stage does not capture all NREM sleep with restorative properties. A further limitation of the conventional staging system is that N3 decreases across the life span and may be "normally absent" after the age of 60 to 70 years even in persons who have excellent subjective and objective sleep quality (other than the absence of N3). The recognition and description of the network dynamics of slow (frequency of less than 1 Hz) oscillation as the basic underlying rhythm of NREM sleep[2] and the concept of coalescing multisite local sleep processes[3,4] remain largely unintegrated into clinical practice. Moreover, sleep is a multiphysiology state with specific changes in respiration, heart rate, and blood pressure, besides slow waves on the electroencephalogram (EEG).

The biologic role of NREM sleep associated with low delta power is unclear. Restricting such periods produces adverse consequences similar to those of total sleep deprivation, including sleepiness and metabolic dysregulation.[5-8] Electroencephalographic delta frequency activity (usually 0.5 to 4 Hz) is considered a biomarker of homeostatic sleep drive.[9] These slow waves are the scalp surface representation of a highly complex ensemble of oscillatory activity during NREM sleep, including the cortical "up" and "down" states that constitute the slow, less-than-1-Hz oscillation.[10-12] Delta power, as a proportion of total EEG power, is highest during the initial cycles of NREM sleep, decreases across the biologic night, and shows rebound effects after a period of sleep

deprivation.[13,14] The preponderance of slow wave (less than 1 Hz in frequency) oscillation is far greater in the first than in the final NREM period.[15] The "biologic worth" of stage N2, however, may not be fully accounted for by conventional scoring or by absolute delta power profiles. These disparities are especially apparent in persons older than 40 to 50 years of age, in whom stage N3 makes up less than 20% of the sleep period.[16]

Alternate characterizations for NREM sleep are available. The most extensively researched is cyclic alternating pattern (CAP). In essence, CAP proposes that NREM sleep has two fundamental modes of expression, one with phasic activity predominating and another relatively devoid of phasic activity.[17] Sleep-fragmenting stimuli increase CAP, whereas sleep-consolidating stimuli increase non-CAP. Heart rate variability analysis shows periods of NREM sleep with especially high vagal tone and strong sinus arrhythmia,[18-20] that is not restricted to stage N3 itself but is correlated with delta power. Sleep apnea researchers have long recognized periods of stable breathing that "come and go" during NREM sleep.[21,22] Figure 166-1 shows this "bimodality" of NREM sleep, in recordings from the same subject, within the same hour of sleep, in the same body position. Finding an appropriate term to describe these patterns of NREM sleep is challenging, but one proposal is for "effective" and "ineffective" NREM sleep, denoted by $NREM_E$ and $NREM_{IE}$, respectively.

Analysis of coupled sleep oscillations offers a complementary approach to sleep state estimations from a single signal. In theory, any two or more signals from physiologic subsystems during sleep may be coupled. Examples are blood pressure plus respiration, heart rate variability plus respiration, EEG plus heart rate variability, and so on. The cardiopulmonary coupling approach described here uses heart rate variability and electrocardiogram(ECG)-derived respiration, the latter being the R-wave amplitude fluctuations with tidal volume changes during respiration.

THE CARDIOPULMONARY COUPLING ELECTROCARDIOGRAPHIC SLEEP SPECTROGRAM

The cardiopulmonary coupling technique is based on a continuous ECG signal and uses the Fourier transform to analyze two features of the signal: (1) heart rate variability and (2) the

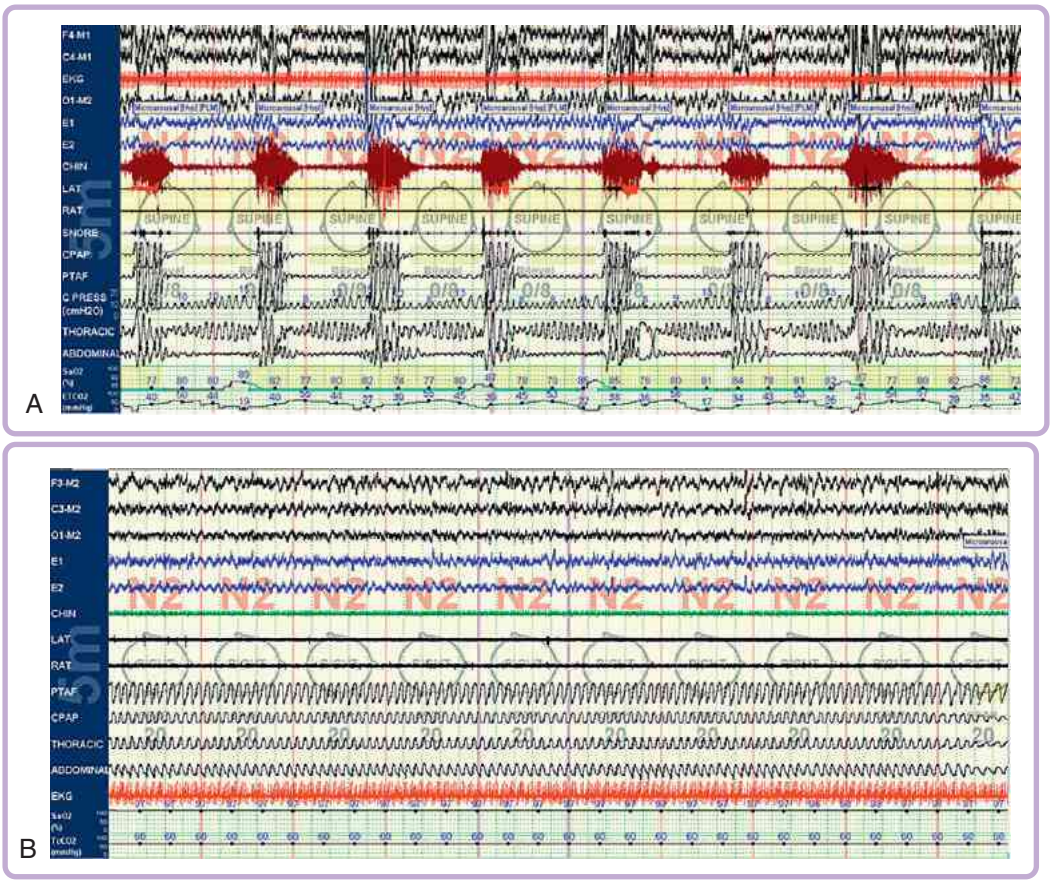

Figure 166-1 A, $NREM_{IE}$ in stage N2, 5-minute compression. Sleep apnea (in this case, poorly responsive to positive-pressure ventilation) readily brings out the features of $NREM_{IE}$. This snapshot shows temporally synchronized oscillations of EEG, EMG (chin), respiration (PTAF, C PRESS, THORACIC, ABDOMINAL), and oxygenation. **B, $NREM_E$ in stage N2, 5-minute compression.** This recording, from the same subject as in **A,** shows successful sleep apnea treatment, manifested by stable breathing, paucity of phasic EEG activation (non-CAP), and prominent sinus arrhythmia (not readily seen at this compression). Note prominent breathing amplitude modulation of ECG R-wave amplitude, which is one of the input signals for the cardiopulmonary analysis technique. C PRESS, Positive airway pressure device pressure trace; CAP, cyclic alternating pattern; ECG, electrocardiogram; EEG, electroencephalogram; EMG, electromyogram; $NREM_{IE}$, non–rapid eye movement sleep, ineffective; PTAF, pneumotachograph airflow.

fluctuations in R-wave amplitude induced by respiration.[23] These signals tend to have two basic patterns: a *high-frequency component* due to physiologic sinus arrhythmia reflecting breath-to-breath fluctuations and a *low-frequency component* reflecting cyclic variation across multiple breaths. Quantifying cardiac and respiratory interactions involves calculating the cross-power (measures the common power of the two signals at different frequencies) and coherence between these two signals.

The steps involved in the calculation of cardiopulmonary coupling are as follows:

1. An automated beat detection algorithm is used to detect beats, classify them as either normal or ectopic, and determine amplitude variations in the QRS complex. From these amplitude variations a surrogate ECG-derived respiratory signal (EDR) is obtained.
2. A time series of normal-to-normal sinus (N-N) intervals and the time series of the EDR associated with these N-N intervals are then extracted from the R-R interval time series.
3. Outliers due to false or missed R-wave detections are removed using a sliding window average filter with a window of 41 data points and rejection of central points lying outside 20% of the window average.
4. The resulting N-N interval series and its associated EDR are then cubic spline resampled at 2 Hz.
5. The cross-spectral power and coherence of these two signals are calculated over a 1024-sample (8.5-minute) window using the fast Fourier transform applied to the three overlapping 512-sample subwindows within the 1024-sample coherence window.
6. The 1024-sample coherence window is then advanced by 256 samples (totaling 2.1 minutes) and the calculation repeated until the entire N-N interval/EDR series is analyzed. For each 1024-sample window the product of the coherence and cross-spectral power is used to calculate the ratio of coherent cross power in the low-frequency (0.01 to 0.1 Hz) band to that in the high-frequency (0.1 to 0.4 Hz) band.

A preponderance of power in the low-frequency band tends to be associated with periodic sleep phenomena, whereas predominance of power in the high-frequency band is associated with respiratory sinus arrhythmia and sleep with stable respiration and EEG. High power in the very-low-frequency (0 to 0.01 Hz) band is associated with periods of wakefulness or REM sleep. This technique thus generates a moving average of the dominant oscillatory frequencies of autonomic drive coupled with respiration during sleep (Figure 166-2).

The discovery of this technique was largely serendipitous. Software developed to detect apnea fortuitously detected stable and unstable NREM periods. It was noted that these periods were clearly demarcated and did not associate strongly with conventional NREM stages but showed better correlation with CAP/non-CAP.[23] Sleep spectrogram analysis reveals that NREM sleep has a distinct bimodal-type structure marked by alternating and abruptly varying periods of strong high- and low-frequency cardiopulmonary coupling intensity, respectively. Much of high-frequency coupling occurs during stage N2, especially with the EEG non-CAP morphologic pattern. This pattern is associated with periods of stable breathing, a paucity of phasic EEG transients, and physiologic blood pressure dipping and is reduced in sleep apnea and fibromyalgia.[24,25] High-frequency coupling tags periods of stable breathing and repeated drops in blood pressure during sleep. The phenomenon of blood pressure dipping occurs exclusively during such periods (Figure 166-3).

Cortical slow wave kinetics can impact autonomic and respiratory function. Slow oscillation–like activity has been recorded in downstream neural elements (as reviewed by Vyazovskiy and Harris[26]), including the hippocampus, cerebellum, thalamus, basal ganglia, and even the locus ceruleus.[27] Increased slow wave activity after sleep deprivation in cats was reported in subcortical structures such as the hippocampus, amygdala, hypothalamus, nucleus centralis lateralis of the thalamus, septum, and caudate nucleus and the substantia nigra.[28] Cortical slow wave activity is likely to strongly modulate neuronal functions in "lower" brain centers and networks. This modulation of activity may in turn provide feedback to the cortex to enhance generation of sustained periods of high-density slow oscillations. Brainstem centers that induce slow wave sleep (e.g., subparafacial zone[29]) or arousals (e.g., parabrachial complex[30]) are potential targets for top-down modulation. Moreover, an increased probability of a stable breathing period enabled by the slow oscillation could, in turn, reduce arousing respiratory afferent stimuli, thus enhancing the likelihood of undisturbed and sustained slow-oscillation dense periods. These multicomponent and multisynaptic loops can stabilize the sleep state during a period of effective sleep.

The relationship between EEG delta power and cardiopulmonary coupling was tested using the Sleep Heart Health Study dataset. This analysis showed that slow wave power fluctuations positively correlate with high-frequency cardiopulmonary coupling. Furthermore, it identified stage N2 periods with potentially similar physiologic characteristics as N3 (Figure 166-4).[31] The key findings were as follows:

- Delta power measured from the surface EEG correlated with ECG-derived cardiopulmonary coupling high-frequency power, further supporting a link between cortical EEG electrical activity and brainstem-related cardiorespiratory functions.
- Normalized delta power provided improved correlation over that based on absolute delta power.
- A consistent lag (median of approximately 4 minutes) was observed between the start of the high-frequency power increase in relation to delta power increase.
- Correlations were reduced but still highly significant in the second half of the night compared with the first half.
- Age effects appeared to be small, with correlations being reduced only in the 80 years and older age group.
- Arousals tended to reduce the strength of the correlations.

This correlation between delta power and high-frequency cardiopulmonary coupling is consistent with strong "top-down" modulation of autonomic and cardiorespiratory activity. Delta power is positively correlated with high-frequency heart rate variability power—fluctuations of delta power across the night are associated with temporally linked heart rate variability power changes.[20,32-34] High-frequency heart rate variability, related to respiratory sinus arrhythmia, is a marker of a vagal-tone dominant state. The apparently paradoxical 4-minute lag between the onset of high-frequency power and delta power increases was unexpected but has several potential explanations. First, the lag could be an "artifact" of the filtering properties of the skull. Second, directly recorded thalamic

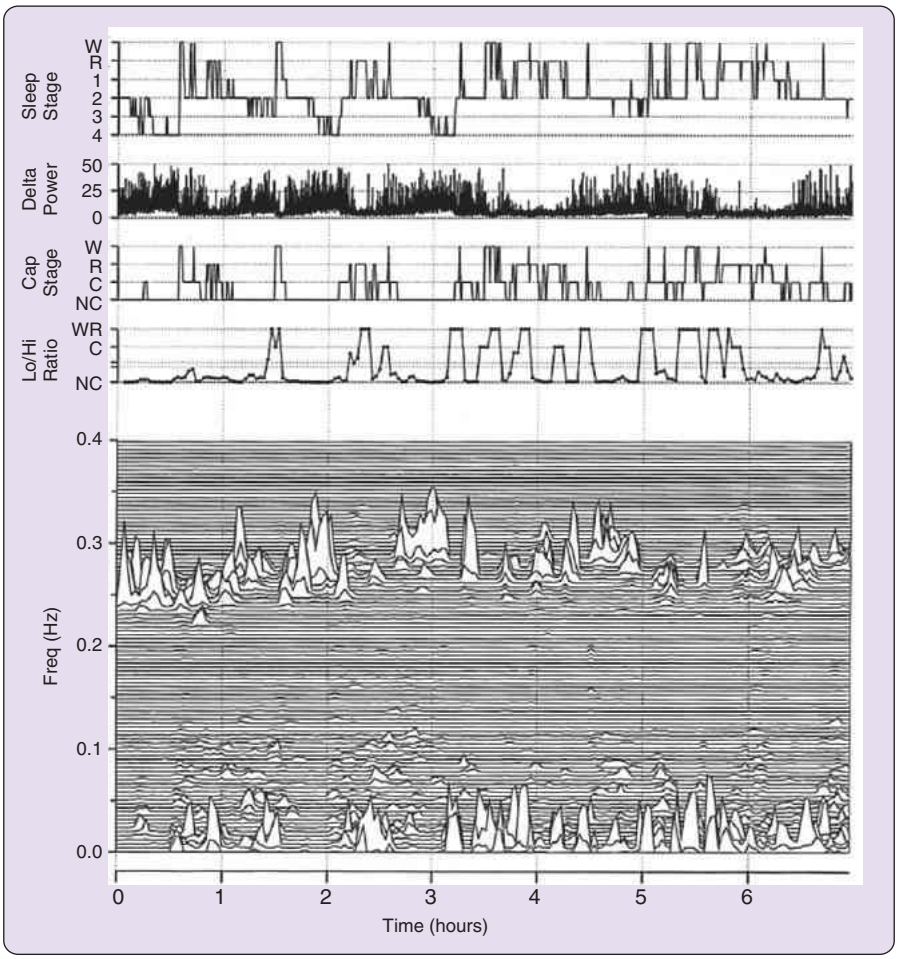

Figure 166-2 Cardiopulmonary coupling analysis in a 22-year-old healthy woman. The *four top panels* show (*top to bottom*) conventional sleep stage scored in 30-second epochs, second-by-second delta power from the C4-A1 electroencephalogram (EEG) montage (μV2/Hz), EEG-based manual cyclic alternating pattern (CAP) scoring, and the ratio of low-frequency (0.01 to 0.1 Hz) to high-frequency (0.1 to 0.4 Hz) coherent cross power (Lo/Hi ratio) used to detect sleep state. The *bottom panel* shows the cardiopulmonary coupling spectrogram across 7 hours of sleep in which the magnitude of the coherent cross power at each frequency is indicated by the height of the peak. The sleep spectrogram reveals spontaneous switching between high-frequency and low-frequency coupled states, represented by the two distinct bands of spectrographic peaks. Throughout the night, occurrence of cycles of increased delta power and high-frequency coupling that correlate with non-CAP sleep continues. Body position was supine throughout the study. C, CAP; NC, non-CAP; R, rapid eye movement sleep; W, wake.

spindles can appear before simultaneously cortical surface recordings, such that the lag could reflect a subcortical-thalamic sleep generation process that then entrains the cortex, followed in turn by increasing cortical influences on thalamic and downstream processes as sleep progresses.[35-37]

DETECTION OF STRONG RESPIRATORY CHEMOREFLEX ACTIVATION

Conventional scoring of central apneas and periodic breathing is impeded under certain conditions: The airway may be closed during "central" events, and flow limitation often is seen in otherwise typical periodic breathing. The two pathophysiologic mechanisms, obstructive (either upper airway collapsibility or a poor negative pressure response) and high loop gain, with or without a low arousal threshold, can coexist.[38-42] Alternative approaches to quantify excessive respiratory chemoreflex activation (high loop gain) include recognizing dominance in NREM sleep, measuring the CO_2 reserve with bilevel ventilation, pressure "dial-down," and use of proportional assist ventilation. These methods generally perturb stable NREM sleep and assess stability and instability characteristics.[40] Conventional scoring of central apneas and periodic breathing assesses unstable components of sleep respiration. An extension of respiratory instability analysis is possible by determining the spectral dispersion of single or coupled signals, the logic being that if the respiratory chemoreflex is driving the abnormality, metronomic self-similar oscillations will dominate. The cardiopulmonary coupling technique has been used to generate such spectral dispersion metrics and to quantify strong chemoreflex influences, without needing to consider an individual respiratory event's exact morphology (including flow limitation, described further on).

Cardiopulmonary Coupling Analysis and Estimation of Elevated Low-Frequency Coupling Subtypes

Analysis of the PhysioNet Sleep Apnea Database (http://www.physionet.org/physiobank/database/apnea-ecg/) using

the cardiopulmonary coupling technique showed that elevated power in the low-frequency coupling region coincided with periods of scored apnea/hypopnea. Optimal detection thresholds required that the minimum low-frequency power be greater than 0.05 normalized unit and that the low- to high-frequency ratio be greater than 30 to define periods of probable apnea-hypopnea, which has been termed *elevated low-frequency coupling* (e-LFC). Because the apneas and hypopneas in this database were scored in 60-second epochs and cardiopulmonary coupling measurements were made every 2.1 minutes, 60-second linear interpolation between consecutive 2.1-minute measurements was done. The 70 recordings in this database contained a total of 34,243 minutes, of which 13,062 (38%) were scored as containing episodes of apnea/hypopnea. Sensitivity and specificity rates for minute-by-minute apnea detection were calculated for a range of low-frequency coupling powers and low-frequency/high-frequency coupling ratios. Receiver-operator curves were then calculated, and the threshold giving the maximum combined sensitivity and specificity for apnea/hypopnea detection was selected as optimal. Thus e-LFC is defined here as a subset of low-frequency coupled cardiopulmonary oscillations, periods of which correlated significantly with periods of manually scored apneas and hypopneas in the PhysioNet Sleep Apnea Database.

Cardiopulmonary coupling analysis was modified to detect central apnea and periodic breathing. The PhysioNet Congestive Heart Failure Database (http://physionet.org/physiobank/database/chfdb/) was used, and a majority of samples were

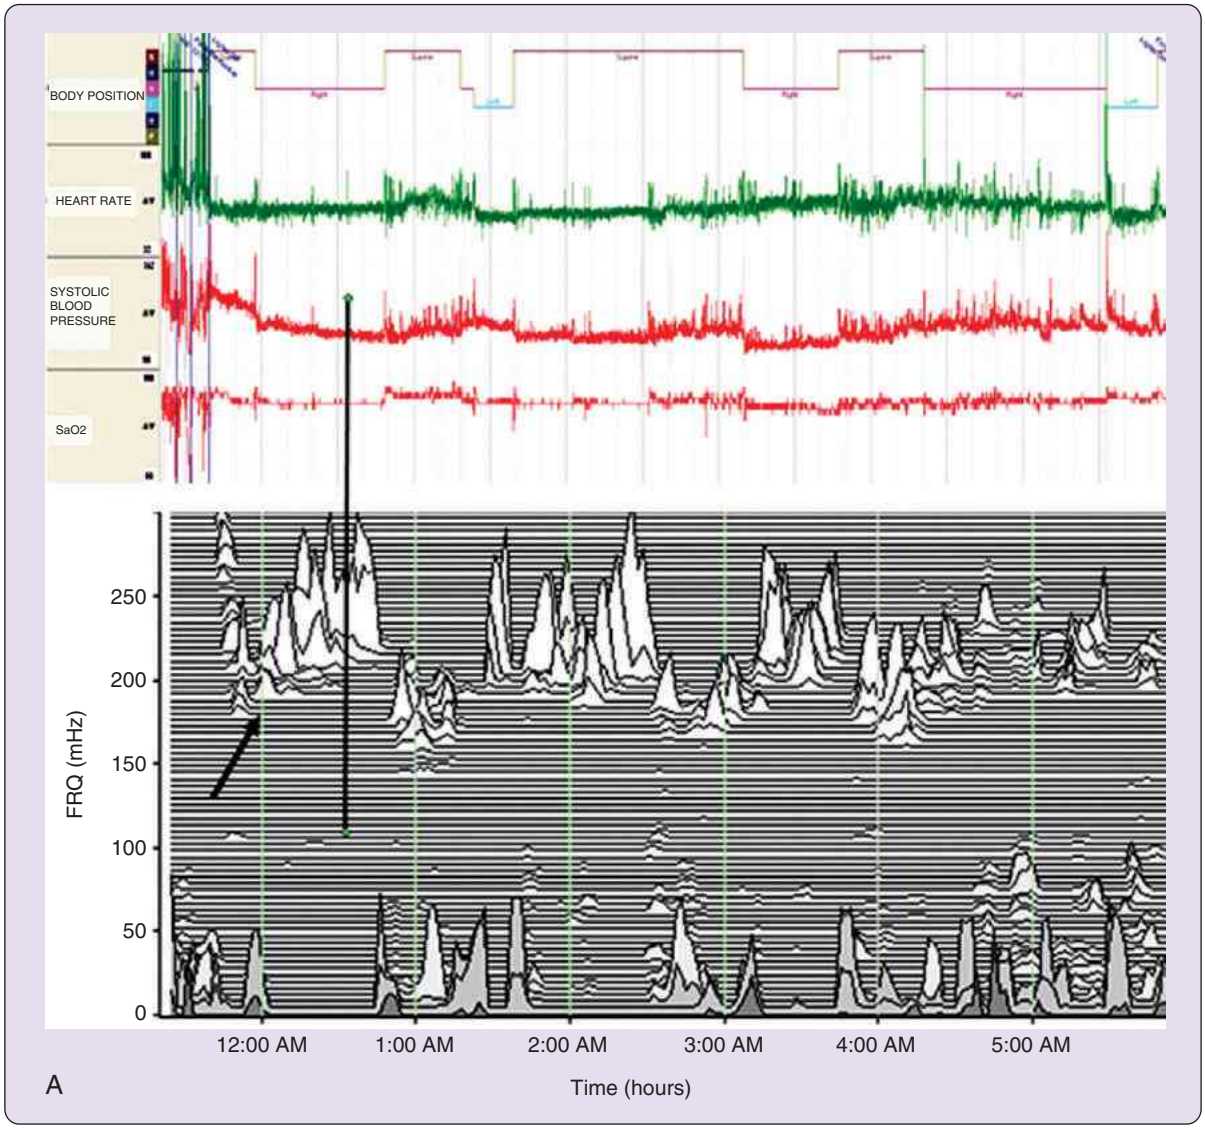

Figure 166-3 A, Blood pressure dipping and high-frequency coupling. Beat-to-beat systolic pressure, derived from pulse transit time, showing the simultaneous (*vertical line*) occurrence of blood pressure drop during sleep with a period of high-frequency coupling (*arrow*). This combined set of features occurs intermittently through the night. Standard ambulatory blood pressure, with measurements obtained on the half-hour or at 1-hour intervals, cannot capture this dynamic.

Continued

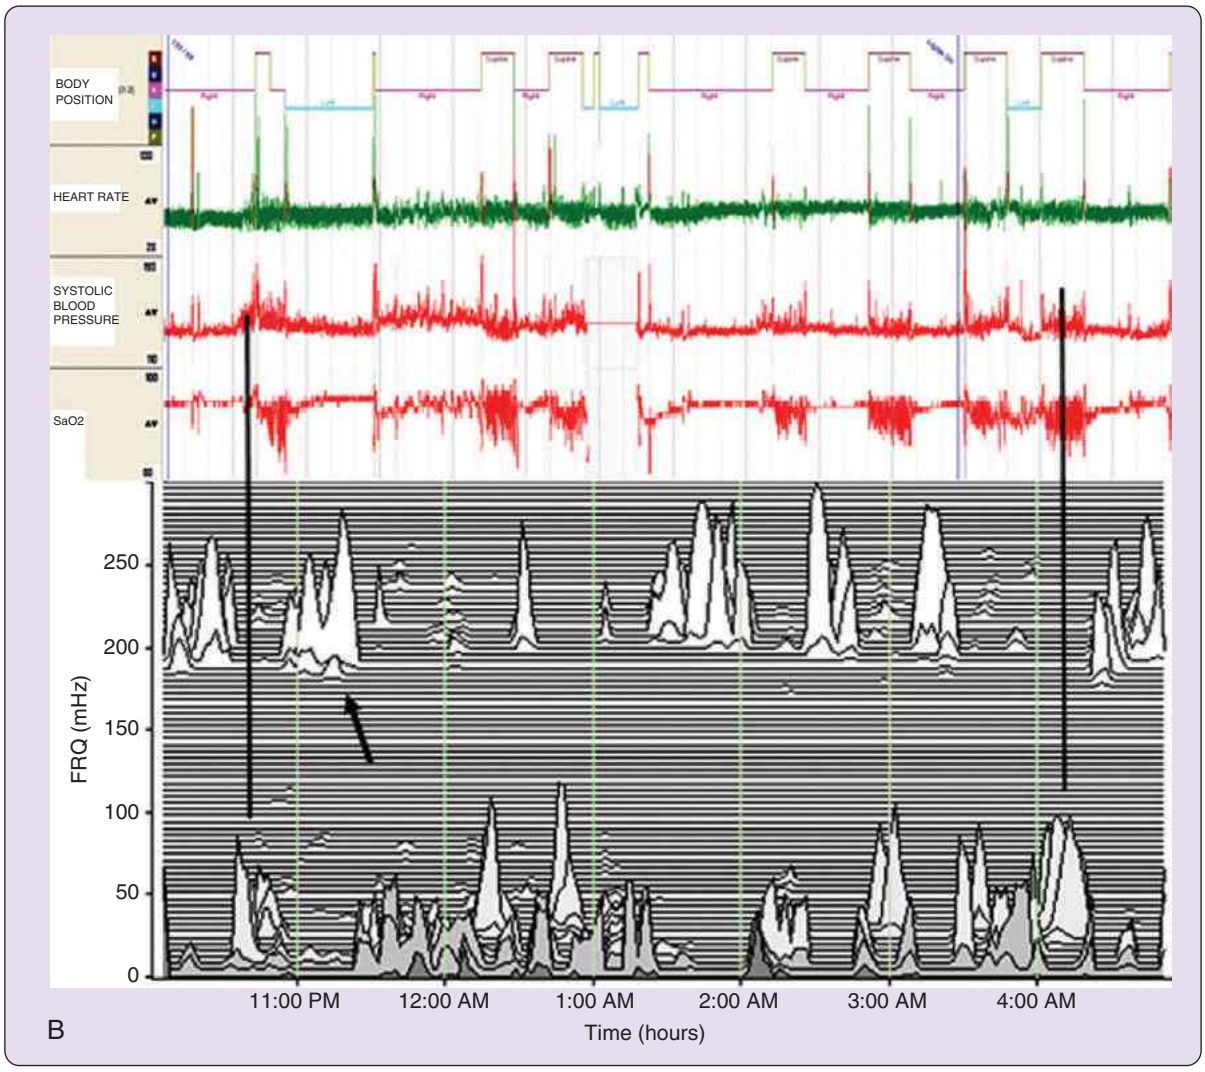

Figure 166-3, cont'd B, Blood pressure non-dipping or reverse dipping and low-frequency coupling, periods of stable breathing, and high-frequency coupling in a subject with sleep apnea. Note rise of blood pressure (*vertical lines* showing temporal concordance) during a period of low-frequency coupling; also note stable oxygenation, reflecting stable breathing, during periods of high-frequency coupling (*arrow*).

from subjects with Cheyne-Stokes respiration. To detect metronomic self-similar oscillations, which are characteristic of Cheyne-Stokes respiration, the researchers required that the coupling frequency of each pair of consecutive measurements remain within 0.0059 Hz of each other over five consecutive sampling windows, identifying narrow-band e-LFC.[43] The presence of e-LFC_{NB} increases the likelihood of emergent central sleep apnea[43] and is associated with increased hypertension and stroke risk.[25]; e-LFC_{NB} also has been found to have heritable characteristics.[44] Figure 166-5 shows the distinctive spectral dispersion characteristics of broadband and narrow-band coupling. Because the ECG spectrogram can be generated using ambulatory wearable devices, point-of-care tracking of sleep apnea and of the emergence or resolution of central sleep apnea and periodic breathing during therapy is possible (Figure 166-6).

SLEEP SPECTROGRAM APPLICATION TO DISEASE AND PATHOPHYSIOLOGY

ECG-derived sleep quality metrics show the following:

- The metrics are independent of absolute EEG amplitudes and thus are not constrained by the "loss" of slow wave sleep with age.[23]
- Specific spectrographic signatures of fragmented sleep are biomarkers of strong chemoreflex effects on sleep respiration.[43]
- Metrics are associated with EEG-defined stable and unstable sleep (CAP and non-CAP)[23] such that high-frequency coupling correlates with non-CAP/stable sleep. Blood pressure dipping occurs only during periods of EEG-defined non-CAP.[45]
- High-frequency coupling sleep is reduced in depression,[46] heart failure,[47] and fibromyalgia syndrome.[48]

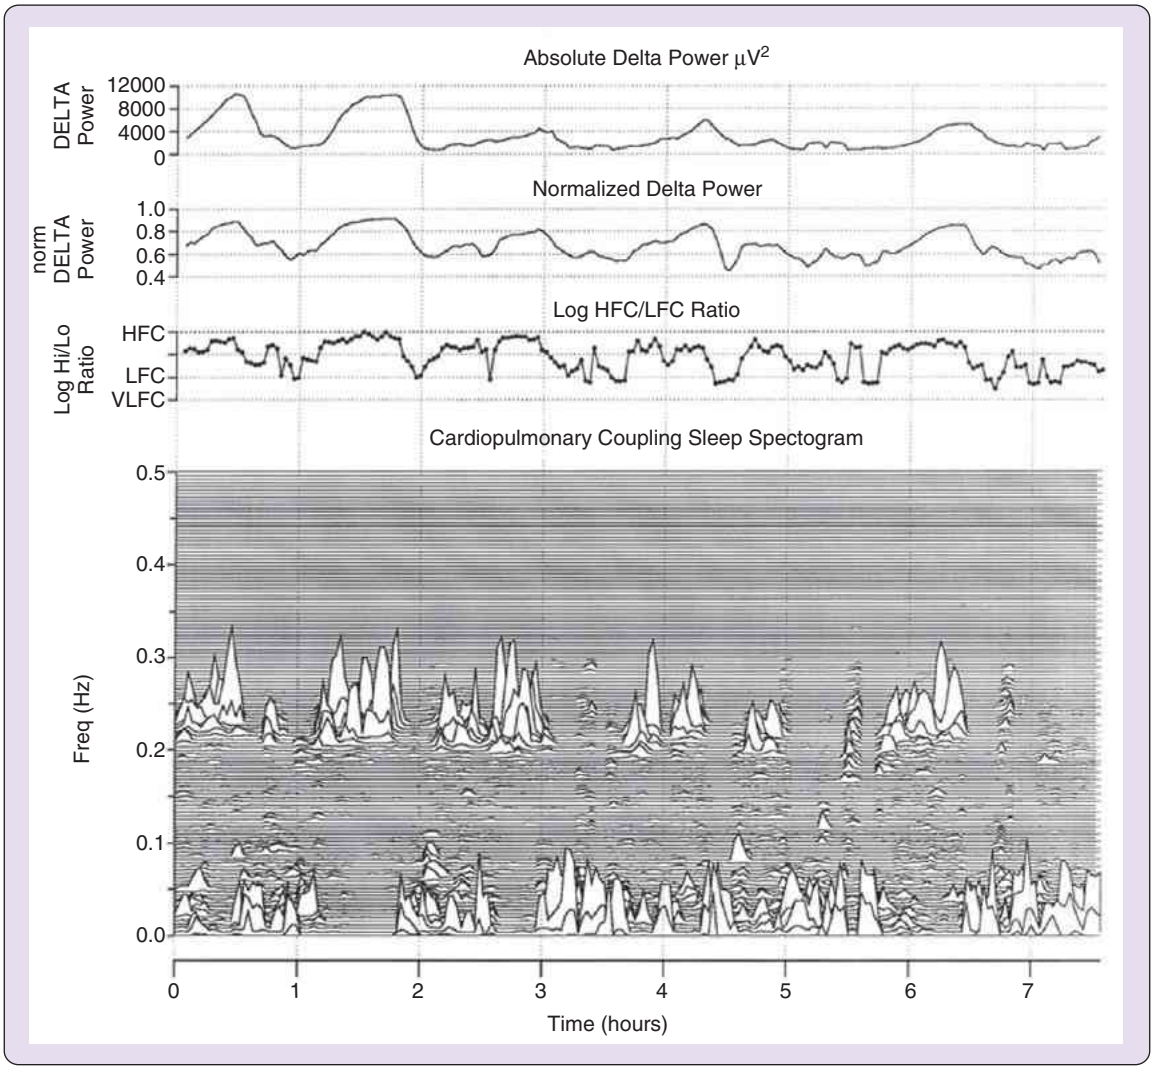

Figure 166-4 Correlations of EEG delta power (0 to 4 Hz) power and high-frequency coupling power. Delta power (0 to 4 Hz), cardiopulmonary coupling, and their cross-correlations for a representative subject in the Sleep Heart Health Study database. Absolute delta power of 0 to 4 Hz (μV^2). Note the higher absolute delta power in the first half of the night compared with the second half. Delta power (0 to 4 Hz) normalized to total EEG power. Note that the relative delta power in the first half and and that in the second half of the night are of relatively equal maximal magnitude. The logarithm of the ratio of high-frequency to low-frequency cardiopulmonary coupling (HFC/LFC). Note the correspondence between delta power fluctuations and the cardiopulmonary coupling ratios. The cardiopulmonary coupling sleep spectrogram. The cross-correlations between absolute and normalized delta power and high-frequency coupling in this subject were $r = 0.61$ and 0.75, respectively. EEG, Electroencephalogram; HFC, high-frequency coupling.

- High-frequency coupling is an independent determinant of the glucose disposition index.[49]
- Pre- and posttreatment effects in sleep apnea with use of an oral appliance[50] or upper airway surgery[51] are captured by changes in the ratio of high-frequency to low-frequency coupling.
- These metrics are improving the current understanding of subjective versus objective sleep characteristics in insomnia.[52,53]
- Certain metrics allow assessment of the impact of sleep fragmentation–related stress effects (e.g., leukocyte telomere lengths).[54]

AMBULATORY ASSESSMENT OF CARDIOPULMONARY COUPLING

The ease of acquisition of the ECG allows cardiopulmonary coupling to be assessed from any continuous ECG signal source, be it a formal polysomnogram or a continuous ECG monitor used for detection of cardiac arrhythmias. The software has been developed commercially through the SleepImage system (MyCardio LLC, Broomfield, Colo.). The first such device is called the M1 and records the ECG, body position, and trunk actigraphy (www.sleepimage.com). Five nights of recording is possible with one battery set, enabling

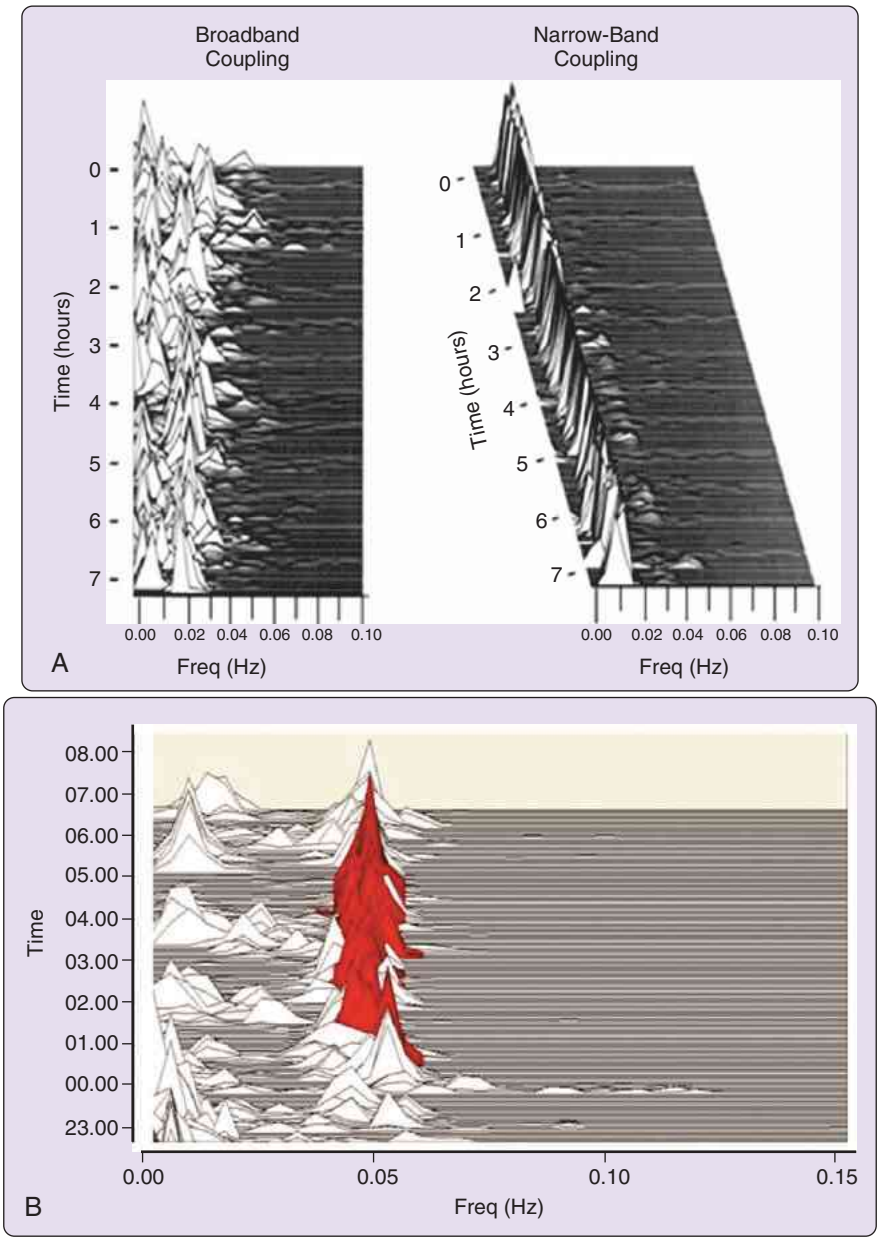

Figure 166-5 A, Broadband *(left)* and narrow-band *(right)* low-frequency coupling. Note the variable and tight dispersion of coupling frequencies across the night. The differences are visually recognizable and mathematically quantifiable, as percentage of analysis period with elevated narrow-band low-frequency coupling (e-LFC_{NB}). **B,** Ambulatory detection of e-LFC_{NB} on continuous positive airway pressure (CPAP) therapy.

assessment of night-to-night variability and minimizing the effects of such variability by averaging. The percent of the actigraphic sleep period in high-frequency, low-frequency, and very-low-frequency coupling and in narrow-band and broadband e-LFC is calculated through a cloud-based system. As the number of wearable devices proliferates, any continuous ECG may be used to generate the ECG spectrogram. Analysis can be readily accomplished using a smartphone application format. The night-to-night stability of the signals is high, with the intraclass coefficient of high-frequency coupling over 14 consecutive nights of recording in the range of 0.7 to 0.8 (unpublished data). In a given state or stage of sleep and body position, sleep physiology or pathology is relatively stable. The proportions of these "combinations," however, interact with time-of-night effects to provide mean values for a night.

CLINICAL PEARL

Cardiopulmonary sleep spectrograms suggest that NREM sleep is bimodal, with concordant and predictable sets of signal (and thus physiologic) characteristics from multiple sleep subsystems. Because sleep-fragmenting and sleep-consolidating stimuli move the proportion of high-frequency and low-frequency coupling in predictable directions, both absolute values and ratios can be tracked over time to measure sleep quality. The detection of strong respiratory chemoreflex activation using the narrow-band coupling biomarker allows tracking of the dynamics of sleep respiratory control in sleep apnea management.

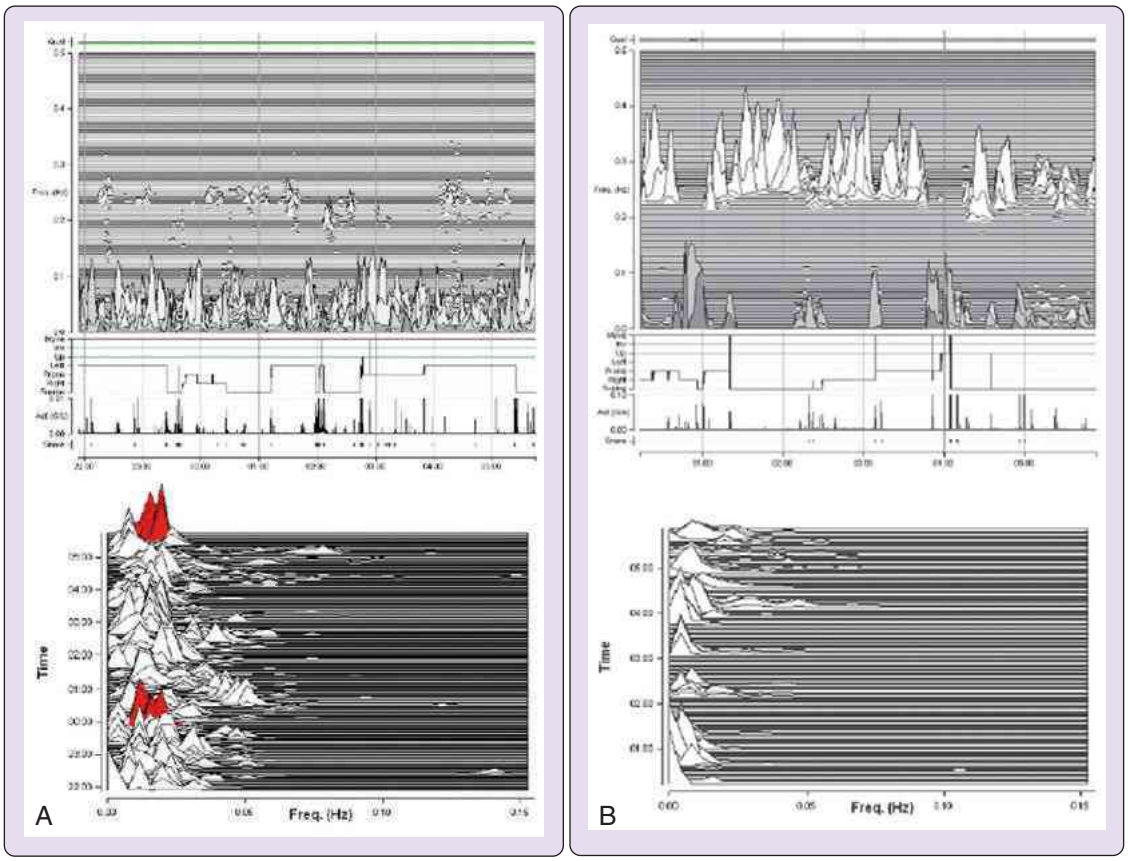

Figure 166-6 **Ambulatory tracking of cardiopulmonary coupling using the M1 device.** Both snapshots show body position and activity transients; actigraphy allows analysis to be restricted to the actigraphic sleep period. An actigraphic fragmentation index, sleep efficiency, and total sleep time also are calculated. **A, Failing CPAP.** Note low high-frequency coupling, predominance of low-frequency coupling, and two periods of elevated narrow-band low-frequency coupling (e-LFC_{NB}), suggesting treatment-persistent or emergent/complex sleep apnea. **B, Successful CPAP.** Note predominance of high-frequency coupling periods. CPAP, Continuous positive airway pressure.

SUMMARY

Mapping coupled oscillations during sleep provides new insights into sleep physiology and pathology. Both intrinsic brain oscillations and those driven by influences outside the brain (such as respiratory control) can sculpt these signals. The ECG is a readily available and repeatable study and is increasingly available through mobile technology, allowing tracking of long-term dynamic features of sleep. From a physiologic standpoint, the readout of the cardiopulmonary coupling ECG spectrogram strongly suggests that NREM sleep has spontaneously switching bimodal characteristics or modes. In one mode, desirable sleep features dominate, including high vagal tone/sinus arrhythmia, blood pressure dipping, high slow wave power, and stable breathing. In another mode, generally less desirable features dominate, such as cyclic variation in heart rate, absence of blood pressure dipping, tidal volume fluctuations (with sleep apnea of a degree exceeding clinical thresholds), and lower delta power. These features probably reflect the integrated output of network activities of multiple sleep subsystems.

Pulse Wave Analysis During Sleep

Ludger Grote; Ding Zou

Chapter Highlights

- The beat-to-beat digital pulse wave signal can be monitored by various recording techniques (e.g., photoplethysmography from pulse oximetry, peripheral arterial tone). Characteristics of the finger pulse wave form are modulated by skin sympathetic nerve activity and hemodynamic variables such as stroke volume, blood pressure, and central arterial stiffness.
- There has been increasing interest in using information embedded in the finger pulse wave signal alone or in combination with other physiologic signals to detect autonomic activation, sleep stage, and sleep-disordered breathing. Sleep diagnostic devices based on finger pulse wave signal analysis have been integrated in clinical routine procedures. They are recognized by the American Academy of Sleep Medicine for home sleep testing (e.g., peripheral arterial tone technology).
- Additional information on cardiovascular reactivity, beyond that obtained by classic diagnostic devices, can be assessed using finger pulse wave signal. Pulse rate variability, blood pressure, arterial stiffness measures, and signs of vascular aging can be detected from the pulse wave contour. One novel approach involves overall cardiovascular risk assessment using several parameters derived from the oximeter-based photoplethysmography signal. The clinical relevance of pulse wave derived cardiovascular parameters needs further validation in larger prospective outcome studies.

INTRODUCTION

We spend approximately one third of the 24-hour cycle during sleep, and sufficient and restorative sleep is essential for both physical and mental health. Consequently, the diagnosis of sleep-related dysfunction is of major clinical interest, and several recent developments are aimed to simplify and improve the methodology of sleep studies. Polysomnography (PSG) is the gold standard to quantify sleep time, to differentiate sleep stages, and to assess sleep fragmentation. In addition, respiratory and motor dysfunction can be assessed in the context of sleep. However, technical demands, required technical skills, and high costs may limit the widespread use of PSG in daily clinical practice. Consequently, efforts have been made to simplify and improve sleep diagnostic methods. On the other hand, additional dimensions of sleep, like autonomic activity and cardiovascular reactivity, derived from pulse wave analysis, may be of importance for health-related outcomes like quality of life or survival, when compared with the classical PSG outcome variables.[1]

Pulse wave signals can be obtained in different vascular compartments like the ear lobe, the limbs, or any other suitable vascular bed. However, photoplethysmography (PPG) in the finger is the state-of-the-art technology in sleep diagnostics, and we will mainly address finger as the measurement site for pulse wave analysis.

THE PHYSIOLOGY OF THE DIGITAL VASCULAR BED

Like in other extremities, the finger skin vascular beds are rich in arteriovenous anastomoses amounting to approximately 500/cm^2 in the fingernail beds. Arteriovenous anastomoses are coiled vessels with thick, muscular, and densely innervated walls connecting the arterioles and venules in the dermis. Blood from the digital artery bypasses the high-resistance arterioles and the capillaries of the papillary plexus, flows directly through the dermal arteriovenous anastomoses, and returns to the deep plexus of veins. This special feature enables large variations of digital skin blood flow, which ranges from 1 to 90 mL/minute/100 mL of tissue.[2] The skin vascular bed accounts for the majority of total digital blood flow.

The finger vascular bed is highly innervated. Despite local factors affecting finger blood flow, the microcirculation in the digital skin vascular bed is mainly controlled by the systemic vasoconstrictor tone. A high correlation between increased peripheral sympathetic nerve activity and reduction of finger pulse wave amplitude (PWA) has been shown during temperature changes.[3] Vasodilation is induced by elevated ambient temperature, sedation, and vasoactive drugs like nitroprusside. Vasoconstriction is induced by sympathetic excitation (e.g., stress, pain), cold, and vasoactive drugs such as noradrenalin and ephedrine.[4]

Autonomic and cardiovascular regulation relevant for pulse wave analysis during sleep is complex, sleep-stage dependent, and regionally differentiated. Non–rapid eye movement (NREM) sleep is associated with reduced sympathetic and increased parasympathetic activity when compared with wakefulness. Rapid eye movement (REM) sleep, in this aspect, is similar to wakefulness. Peripheral vascular smooth muscle sympathetic nerve activity measured by microneurography is reduced by approximately 50% during NREM sleep (stage 4) and doubled during REM sleep compared with wakefulness.[5,6] Regional differences in sympathetic output during sleep may also exist. For instance, sympathetic activity in vasoconstrictor fibers of limb skeletal muscle is increased in parallel with reduced output to the splanchnic, cardiac, lumbar, and renal vascular beds in a pharmacologic model of REM sleep.[7] Skin blood flow measured by laser Doppler showed a clear increase during sleep compared with wakefulness possibly due to thermolytic vasodilation.[8]

Quiet NREM sleep is characterized by general hemodynamic stability. However, arousal from sleep creates a significant change; the most pronounced changes can be noticed in the acceleration of heart rate combined with a peripheral vasoconstriction resulting in a marked elevation of systolic and diastolic blood pressure.[9] The autonomic response to an arousal from sleep, when started, appeared to follow a stable pattern over time. The amplitude of the cardiovascular reactivity is positively associated with the degree and the duration of the electroencephalographic (EEG) arousal. In some cases, a typical autonomic activation during sleep can be observed without an activation pattern in the cortical EEG, the so-called autonomic arousal. In this chapter, we are going to focus on different pulse wave analysis methods during sleep to assess autonomic arousal, sleep stages, sleep-disordered breathing, and cardiovascular function and risk.

METHODS FOR THE ASSESSMENT OF THE DIGITAL PULSE WAVE

Plethysmography is a well-established method for the quantitative assessment of volume changes over time and has been frequently used in humans for the quantification of respiratory and hemodynamic function. A number of different noninvasive plethysmographic techniques are available using water, air, strain gauge, impedance, or PPG to quantify volume changes of the peripheral pulse wave. For studies on finger microcirculation, additional methods like radioisotope clearance, capillaroscopy, and laser Doppler flowmetry have been used. In sleep medicine, the PPG and the peripheral arterial tone (PAT) are the most frequently used methods to assess the digital pulse wave. Recent developments in home sleep diagnostics have incorporated these technologies.

Water or Air-Based Plethysmography

The historic development of research related to the cardiovascular system was started with water or air-based plethysmography. The arm, finger, or leg is placed in a tightened compartment filled with water or air. Any pulsatile change in volume is transferred on paper or, more recently, to a digital signal in order to quantify blood flow and vascular resistance at rest and after certain type of provocations. For sleep-related assessments, this technology is less feasible due to obvious interference with sleep and artifacts during body movements.

Strain Gauge Plethysmography

The strain gauge technique for the in vivo assessment of blood flow has been used for decades. An elastic mercury in Silastic strain gauge is placed around the circumference at the area of interest (e.g., the forearm, the finger, or the leg). When using the venous occlusion technique, pulsatile volume increases of the compartment are recognized by changes in the circumference. The calibrated signal gives an exact measure of blood flow in milliliter per second. When blood pressure is monitored, even resistance of the vessels can be calculated. Characteristics of the pulse wave contour are similar when using strain gauge or digital PPG with a high correlation ($r = 0.9$).[10] The strain gauge technique has been widely used to quantify vascular reactivity after local arterial infusion or systemic application of vasoactive drugs. The concept of vascular and endothelial dysfunction in obstructive sleep apnea (OSA) patients was introduced by the findings of impaired responses to vasodilatory or augmented response to vasoconstrictor agents in normotensive and hypertensive OSA patients when compared with controls using venous occlusion plethysmography.[11,12]

Photoplethysmography

PPG measures the absorption/reflection of infrared light emission (wavelength around 940 nm) in the applied microvascular bed by a photosensor. The degree of light absorption/reflection correlates directly with the blood volume changes in the catchment, and a continuous pulse wave signal can be derived. This pulsatile component of the pulse wave is called the *AC signal component*. In addition, the baseline of the pulsatile wave may vary, and this component is described as the *DC component* and reflects to average blood volume and finger tissue.[13] This DC component may be affected by respiration, autonomic nerve activation and vasomotor activity, Traube-Hering-Mayer waves, hypovolemia, and thermoregulation.

The information embedded in the pulse wave can be divided in several aspects (Table 167-1; Figure 167-1). First, the systolic amplitude is correlated with the pulse volume increases in the finger compartment. The amplitude is modulated by both the cardiac stroke volume and the degree of skin sympathetic activity (high activity means reduced flow and low amplitude).[3] Using a daytime infusion protocol, PWA, derived from the finger plethysmography, was sensitive to the α–receptor agonist norepinephrine but not to the β_2–receptor agonist isoproterenol.[14] Second, the peak-to-peak interval of two consecutive pulse waves is considered as a surrogate measure of the electrocardiogram (ECG)-based RR interval and can be used for pulse rate calculation (see following sections). Third, the diastolic point of the pulse wave reflects the time taken for the pressure waves to pass from the heart to the sites of reflection at small arteries in the trunk/lower limbs and back to the upper limbs. This interval, also called *pulse propagation time* (PPT), has been proposed as a surrogate marker of pulse wave velocity and arterial stiffness.[15,16] A shortening of PPT indicates rigid and atherosclerotic vessels. The augmentation index (AI), calculated as the ratio between the systolic and the diastolic amplitude, is another way to mirror central arterial stiffness. Both PPT and the digital AI have been shown good agreement with the AI derived from radial artery or the pulse wave velocity calculated along the aorta and applied for assessment of atrial stiffness and

Table 167-1 Different Variables Derived from the Digital Pulse Wave Signal

Pulse Wave Parameter	Function Assessed	Modified by Dysfunction or Disease
Systolic pulse wave amplitude	Digital pulse volume, reduced by skin sympathetic activation (vasoconstriction), elevated by vasodilating drugs, correlated with stroke volume and blood pressure	Arousal from sleep, REM sleep, sleep-disordered breathing, hypertension, atherosclerosis, and metabolic disease
Pulse to pulse interval	Pulse rate and pulse rate variability	Bradycardia/tachycardia, arrhythmia (e.g., atrial fibrillation), ischemic heart disease, marker of central/autonomic arousal from sleep, baroreflex
Time between systolic and diastolic peak of the pulse wave (e.g., stiffness index, pulse propagation time)	Central and peripheral vascular wall compliance and stiffness	Atherosclerosis, vascular aging, hypertension, diabetes mellitus
Time between R wave of the ECG and systolic peak of the peripheral pulse wave (e.g., pulse transit time)	Marker of central arterial stiffness, correlation with blood pressure, sympathetic activation	Central or autonomic arousal, hypertension
Respiratory-related baseline shifts of the pulse wave DC component	Respiratory effort and negative intrathoracic pressure changes, repetitive Müller-/Valsalva maneuver	Obstructive vs. central sleep apnea, snoring
Proportion of pulse rate in the respiratory frequency band	Degree of respiratory sinus arrhythmia	Baroreflex sensitivity, autonomic neuropathy, cardiovascular aging, diabetes mellitus, disturbed breathing during sleep
Pulse amplitude ratio before and after Valsalva maneuver	Elevated left ventricular end-diastolic pressure	Heart failure with increased pre-load

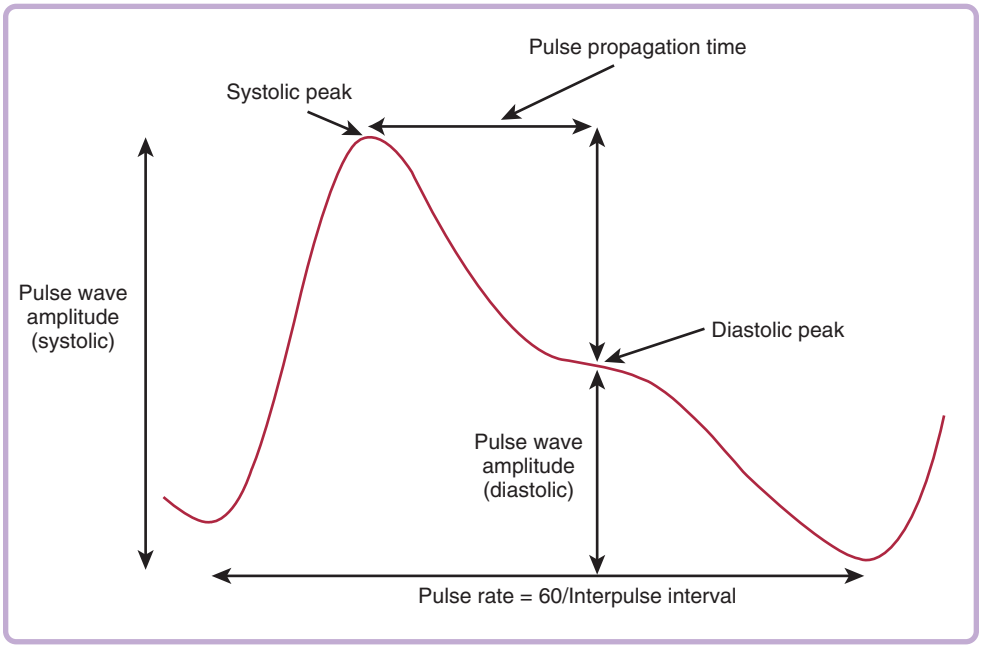

Figure 167-1 A typical PPG signal and its characteristic parameters.

cardiovascular risk.[15,17,18] During signal processing, first and second derivatives of the plethysmographic curve are used to more accurately calculate the pulse wave parameters explained above.[19]

The probe placement for assessment of the pulse wave form has been studied. It was suggested that the ear pulse wave may reflect better the passive effect of systemic hemodynamics, whereas the finger pulse wave may reflect local vasomotor fluctuations, including the neural mechanisms of skin sympathetic activation.[20] These studies were performed in spontaneously breathing wake subjects, and the site of pulse wave investigation may have quite different influences on the results

during sleep recordings. Indeed, one study looking on noninvasive markers of acoustically induced arousal from sleep showed that finger PPG was more sensitive for arousal response than ear PPG.[21] In addition, the finger site is most feasible for use during sleep recordings.

Peripheral Arterial Tone Technique

PAT is a novel technology for monitoring pulsatile arterial volume signals using a pressure-applied optical probe.[22] The technology is comparable to classic PPG with the difference of the specific probe features improving the signal quality. In detail, the PAT probe has a compliant elastic membrane surrounded by an outer rigid casing. Compared to conventional finger plethysmography, a pressurized region is used to cover the surface of the distal end of the finger. This region prevents the induction of venoarteriolar reflex vasoconstriction.[23] The balloon-like outer membrane creates a constant pressure leading to an unloading of arterial wall tension, thereby increasing the arterial wall motion and the size of the arterial volume change. The sensor region is also prevented from retrograded venous blood pooling commonly observed during finger movement. A transmission mode PPG is used to measure the optical density changes associated with pulsatile blood volume changes.

Pulse Transit Time

Pulse transit time (PTT) reflects the time interval for an arterial pulse wave to propagate from the aortic valve level to a given peripheral site. PTT is often measured as the time lapsed from the appearance of the R wave in the ECG to the start or the middle point of the systolic pulse wave appearing in the finger PPG recording. The PTT depends on the degree of stiffness of the arterial wall, and a shortened PTT is associated with vascular aging, atherosclerosis, and increase of blood pressure.

Finally, the usefulness of the three methods—PPG, PAT, and PTT—is limited in patients with cardiac arrhythmias, such as atrial fibrillation or frequent extra systolic activity. The high variability of cardiac stroke volume creates a beat-to-beat variation in the systolic PWA and the pulse contour, which sometimes invalidates the information embedded in the pulse wave signal. Indeed, existence of arrhythmia (but not type of arrhythmia) can be detected by PPG.

CLINICAL APPLICATIONS OF DIGITAL PULSE WAVE ANALYSIS

Periodic cardiovascular autonomic changes during sleep in patients with sleep-related disordered breathing have been documented since the 1970s. Heart rate and arterial blood pressure are the traditional physiologic parameters to study hemodynamic autonomic changes associated with sleep apnea events. More recently, the finger pulse wave signal in combination with other biosignals has been evaluated for the detection of autonomic arousal, sleep stages, sleep-disordered breathing, and the assessment of cardiovascular function[24] (Table 167-2). Improved and novel insights into the sleep state can be made with this rather simplified methodology. Despite the fact that even more outcome-based validation of such methods is needed, it is anticipated that they will be part of the state of the art in sleep diagnostics in the near future.

Identification of Autonomic Arousal/ Sleep Fragmentation

EEG arousal has been traditionally used for quantification of sleep fragmentation. However, it has been shown that transit sympathetic activations during sleep are not necessarily associated with visible EEG changes.[25] Hence, the term *autonomic arousal* is used to represent transit changes of autonomic activity associated with cardiac activation (e.g., heart rate and blood pressure increase). The finger vascular bed is densely innervated, and finger PWA drop has been shown to associate with increased EEG power density, suggesting that PWA attenuation is a useful surrogate marker for changes in cortical activity during sleep.[26] Other studies found digital vascular response (e.g., PWA) to variable degrees of arousal stimulus during NREM sleep to be more sensitive than other autonomic markers (e.g., heart rate, PTT, and pulse wave velocity).[21] Hence, digital vasoconstriction (PWA attenuation) may provide a useful tool to detect episodes of autonomic activation during sleep. By means of the PAT method, an autonomic arousal event was defined as ≥50% PAT attenuation or ≥30% PAT attenuation plus a 10% pulse rate increase, which correlated closely (r^2 = 0.67) with PSG scored EEG arousal.[27] Modified criteria for autonomic arousal detection in the ambulatory PAT device are based on either PAT attenuation plus increase of pulse rate or PAT attenuation ≥40% and short movement detected by actigraphic signal.[28] The correlation coefficient between PSG-derived arousal index and PAT autonomic arousal index (using actigraphy to detect sleep time) was 0.76. It should be noted that other conditions, such as periodic limb movements, can cause autonomic arousal without simultaneous cortical activation. It has been recently suggested that combined analysis of PWA amplitude and area under the pulse waveform may be helpful to reduce failure rate in respiratory arousal detection.[29]

The potential role of PAT for arousal detection was also studied in children. In general, EEG arousal in children is associated with sympathetic activation reflected by PAT attenuation.[30,31] However, PAT signal is a highly sensitive but less specific tool in this context. In fact, a substantial proportion of autonomic activations defined by PAT was found to occur in children without visually recognizable EEG changes. Whether these attenuations represent normal fluctuations of the autonomic sympathetic nervous system activity in children or reflect subtle sleep disruption that failed to be detected by traditional EEG scoring remains unclear. In children with upper airway obstructive disease undergoing noninvasive ventilation, a combination of 4% oxygen desaturation and microarousal detected by finger PWA was reported to be associated with movement and fragmentation index assessed by actigraphy.[32]

There is evidence for a gender-specific difference in the pulse wave response to arousal. Using conventional PPG, both spontaneous and acoustic arousals induced a strong pulse wave response in males but a less clear response pattern with a high inter-individual variability in females.[33] In addition, respiratory instability after arousal was also more pronounced in males. It is unclear whether those gender-specific findings in a small number of healthy subjects can be extrapolated to patients with cardiovascular disease or sleep disorders like sleep apnea or insomnia.

Table 167-2 Clinical Application of the Overnight Pulse Wave Analysis in Sleep Diagnostics

Method	Pulse Wave Parameter and Additional Signal	Results
Sleep Classification and Sleep Fragmentation		
PAT	Systolic PAT amplitude and PAT pulse rate	Autonomic arousal classification with high correlation to respiratory and nonrespiratory EEG-arousal in adults, overestimation in children
PPG	PPG systolic amplitude and pulse rate	Good correlation with EEG-arousal in adults
PPG and ECG	PTT and pulse rate	Good correlation with EEG-arousal in adults, overestimation in children
PAT and actigraphy	PAT amplitude and pulse variation (fractal signal analysis), actigraphy	Sleep/wake detection, REM/NREM classification, deep and light sleep classification
PPG	PPG signal (breathing related systolic amplitude variation)	Sleep wake analysis via PPG by breathing shape and breathing rhythmicity
Type and Amount of Sleep-Disordered Breathing		
PAT and oximetry	Pulse wave amplitude, pulse rate, and oxygen saturation	High correlation between AHI_{PAT} and AHI_{PSG} in multiple validation studies, AASM recommended method
PPG and nasal flow	PPG-derived respiratory effort	Improved differentiation between obstructive and central/mixed sleep apnea
PAT and oximetry	Pulse wave amplitude, pulse rate, and oxygen desaturation	Detection of Cheyne-Stokes respiration
PPG	Pulse wave amplitude, pulse rate, and oxygen desaturation	Detection of Cheyne-Stokes respiration
Cardiovascular Function and Risk		
PAT	Systolic PAT amplitude attenuations	Associations between overnight attenuations and office blood pressure
PTT and office blood pressure	A continuous measure of beat-to-beat blood pressure	Associations with intraarterial or oscillometric measure blood pressure at daytime and during sleep
PPG	Pulse wave derived augmentation index or pulse propagation time	Associated with vascular stiffness in atherosclerosis, vascular aging, and cardiovascular and metabolic disease; sensitive to vasoactive drugs
PPG and oximetry	PPG and oximetry-derived parameters reflecting cardiovascular, autonomic, and respiratory function during sleep	Associated with traditional cardiovascular risk prediction matrixes (e.g., ESH/ESC, Framingham, EU SCORE); identification of vascular stiffness in atherosclerosis, vascular aging, cardiovascular and metabolic disease; sensitive to cardiovascular medication

AASM, American Academy of Sleep Medicine; AHI, apnea hypopnea index; ECG, electrocardiogram; ESC, European Society of Cardiology; ESH, European Society of Hypertension; EU, European; NREM, non–rapid eye movement; PAT, peripheral arterial tone; PPG, photoplethysmography; PSG, polysomnography; PTT; pulse transit time; REM, rapid eye movement.

A transit dip in the PTT signal from baseline was reported to associate with EEG arousal.[34] Several studies have shown that PTT can improve microarousal detection in children and infants.[35,36] However, similar to PAT, this technique can sometimes be oversensitive for detection of arousal in children.[31]

Classification of Sleep Stages and Wakefulness

Wakefulness and the NREM/REM sleep stages differ in autonomic and hemodynamic regulation. This difference can be reflected by changes of the PWA and derived pulse rate signals.[37,38] For instance, a typical reduction of the PAT amplitude could be observed during REM compared with NREM sleep.[37] An automatic REM sleep detection algorithm based on a combination of the PAT signal and actigraphy was developed.[39,40] Subsequently, features from two time series of PAT amplitude and inter-pulse periods were used to further analyze NREM sleep and differentiate deep sleep from light sleep.[41] These sleep-staging algorithms were further validated and showed moderate agreement in a multicenter study.[42] In 38 normal subjects and 189 patients with suspected OSA, the overall agreement for detection of light/deep and REM sleep were 89 ± 6% and 89 ± 6% between PSG and PAT, respectively. OSA severity did not affect the sensitivity and specificity of the algorithm. However, in elderly patients with suspected OSA, deep sleep stage classification was underscored in PAT when compared with PSG.[43]

In a different approach, the PPG signal derived from single channel pulse oximetry has been used for sleep/wake detection.[44] The morphology and rhythm of breathing were derived from the PPG signal and analyzed. The similarity of consecutive breath and the "complexity of the breathing rhythm" were indicative for sleep and wake state, respectively.

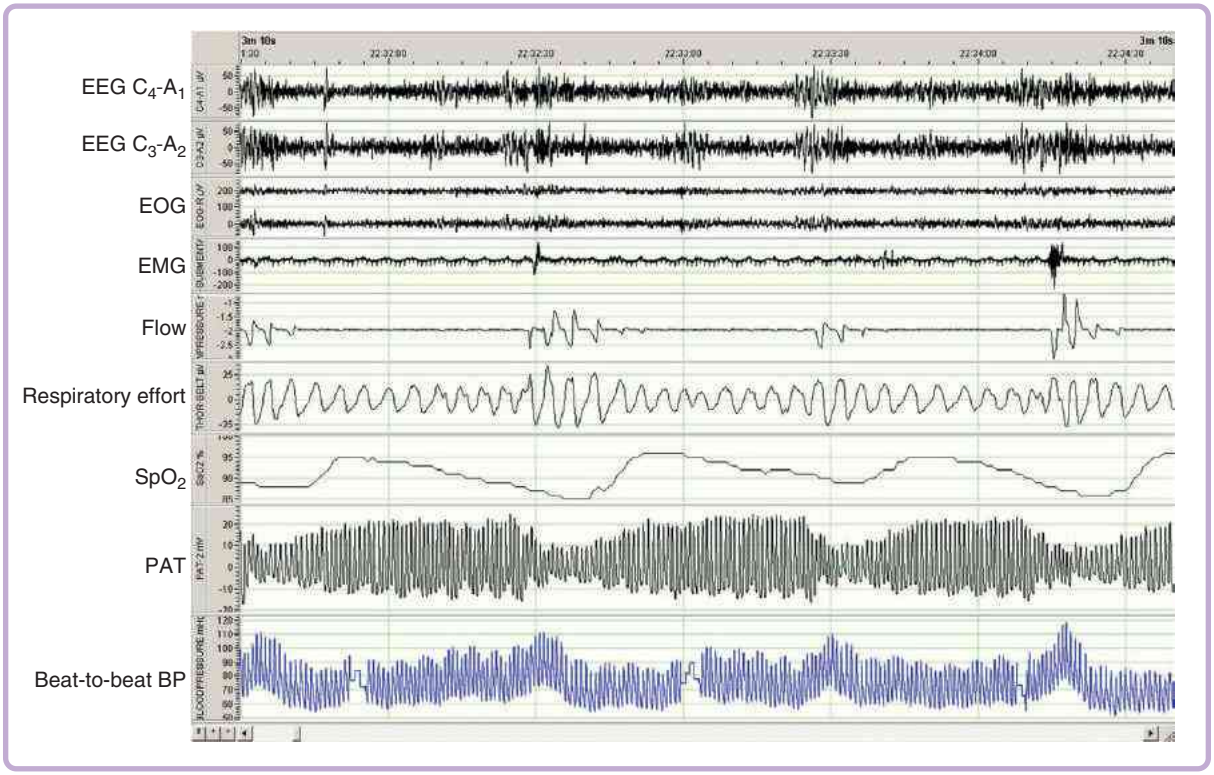

Figure 167-2 A 3-minute recording showing pulse wave amplitude changes from the peripheral arterial tone (PAT) signal associated with obstructive sleep apnea and arousal. The PAT signal fluctuates with increasing respiratory effort during apnea. The systolic PAT amplitude decreases significantly during central nervous arousal from sleep and subsequent resumption of breathing.

Sleep periods were identified when strong correlations between adjacent breaths, a constant rhythm, or periodic oxygen desaturation occurred. All noise and movement events were marked as wakefulness. In a study of 74 patients with sleep-disordered breathing, an agreement of 75% with PSG derived sleep classification was reached.[44] Two follow-up studies in a general population and in sleep apnea patients found a positive correlation/no correlation with PSG derived total sleep time, respectively.[45,46] The reliability of this interesting, but simplified, sleep/wake classification is therefore difficult to estimate, and further studies are meaningful.

Recognition of Obstructive Sleep Apnea

The use of plethysmography has demonstrated a typical attenuation pattern of PWA in the courses of repetitive obstructive apneas and hypopneas.[14,47] Similar changes could be observed by means of the PAT method[22,48] (Figure 167-2). Indeed, experimental data showed that the response is mainly mediated by the arousal response and, to a minor degree, by the response to significant upper airway obstruction.[49] Further, intra-arterial infusion of the alpha-receptor blocker phentolamine showed that this typical apnea-related response can be blocked, suggesting a strong association between PAT attenuation and alpha receptor sympathetic activity in the skin vasculature during apnea and subsequent arousal.[48]

The PAT technology uses the pattern recognition of pulse wave attenuations, oxygen desaturations, heart rate responses, and the above mentioned recognition of wake and sleep phases in a combined algorithm.[50] A recent meta-analysis of relevant validation studies performed in the general population and in several patient populations showed that this pulse wave based technology has a high agreement with PSG-derived indices of sleep apnea activity.[51] No specific effect of gender or age on the accuracy of the PAT technology for apnea detection has been found.

A similar approach was recently published with the use of single channel oximetry where saturation and the PPG signal were used together for sleep apnea recognition.[44] The PPG signal recognizes respiratory signals (effort and breathing frequency) and the sleep and wake rhythm (see previous description). A conventional oxygen desaturation pattern with the threshold of ≥3% is also used to detect breathing events. Although the algorithm is less well described in the publications, validation studies showed good agreement between PSG–apnea hypopnea index (AHI) and PPG–AHI, for example, the receiver operator characteristic (ROC) curve for an AHI threshold of 15 events/hour was 0.9.[46] At least, this technology can be seen as a significant improvement when compared with traditional single channel oximetry. In this context, an additional, so-called principal-component-analysis technique has been described, which allows the detection of respiratory efforts from the oximetry-derived PPG signal.[52]

The PAT and PPG signals have also been evaluated in the follow-up of patients with sleep-disordered breathing. The PAT technology was suggested to be specifically useful in the follow-up of treatment like positive airway pressure, oral device, and weight reduction.[53-55] The sleep structure, degree of remaining sleep fragmentation, and hypoxic load can be easily quantified in an outpatient setting. In particular, the capability of the PPG signal to detect arousal was validated

against PSG standard measures in patients using noninvasive ventilation. A good agreement between the methods was established at least for sleep fragmentation during NREM sleep.[56] The PPG technology was suggested to be used for simplified follow-up investigations in the growing number of patients with home ventilation.

During the past decade, the PPG signal has been made available in a number of PSG devices. One study postulated that the use of the PPG signal on top of all standard PSG channels was helpful to reduce interscorer variability.[57] The data have not, so far, been confirmed in a larger study, and the results may be highly dependent on the actual scoring rules used. However, it shows that the PPG signal as a marker of arousal and respiratory effort may be helpful in the quantification of sleep-disordered breathing in several settings.

Cheyne-Stokes Respiration and Central Sleep Apnea

Cheyne-Stokes respiration (CSR) is a condition that includes cyclic oscillation of breathing amplitude along with periodic fluctuation of sympathetic nerve activity. Interestingly, the PAT signal showed a sinusoid shape in accordance with the symmetric pattern of both respiratory effort and oxygen desaturation. The relative attenuation of the PAT amplitude was lower during wake CSR periods compared with CSR during sleep, and the maximum attenuation lagged the start of the crescendo breathing phase by 3 to 8 seconds. The sensitivity for CSR recognition varied between 73% (awake) and 91% (entire sleep period) with a specificity of 70% (REM sleep) and 97% (awake) when compared with PSG in a small study of 10 patients with CSR and heart failure.[58] These first positive results have not been replicated in a larger cohort, and it remains unclear whether the PAT technology in the absence of effort and flow signals can recognize CSR in a reliable way.

Another approach starts from the flow signal analysis and uses the PPG to indirectly assess respiratory efforts for improved apnea classification. The PPG-derived respiratory effort separates central/mixed apneas from obstructive ones. The correlation coefficients between flow/PPG signal derived and polygraphic scored central apnea index was 0.95 in a study of 66 sleep apnea patients.[59] This technology appeared to be useful for a better characterization of apnea type in limited channel devices.

PULSE WAVE ANALYSIS OF CARDIOVASCULAR FUNCTION DURING SLEEP

Blood Pressure

There are several methods using the PPG-based digital pulse volume curve for beat-to-beat analysis of systolic and diastolic blood pressure during sleep. The electropneumatic vascular unloading technique was introduced by Jan Peňáz to measure central blood pressure through a pressurized finger probe.[60] This method has been mainly used in research activities to assess continuous blood pressure change (Finapress or Portapres device). Another method uses the PTT to assess blood pressure continuously. Because central arterial stiffness is associated with blood pressure, shortening of the PTT is a marker of elevated blood pressure. This principle has been introduced recently in a sleep diagnostic device. The blood pressure values from the PTT curve need a calibration procedure against resting office blood pressure in order to enable continuous monitoring of the blood pressure surges associated with sleep apnea and/or arousal from sleep. Validation studies suggest a reasonable agreement for PPT-derived blood pressure when compared with values obtained by the conventional oscillometric method and finger arterial PPG (Finometer).[61-63] It is clear that the PTT method has advantages because it does not disturb sleep when compared with the oscillometric method or the Peňáz technique. However, accuracy of the diastolic pressure level and movement artifacts may limit the PTT methodology for continuous blood pressure assessment. Finally, the PWA alone using the PPG technology has also been used to calculate systolic blood pressure on a beat-to-beat basis during sleep.[64] The results showed also a reasonable agreement between PPG blood pressure and Portapres-derived pressure.

Pulse Rate Variability

Impaired heart rate variability is a marker of increased cardiovascular risk in patients with established ischemic heart disease and cardiac failure. The method is based on the recognition of RR interval by high resolution sampling of the ECG signal. The PPG signal can be used as a surrogate marker of heart rate variability. A large number of studies have been performed to analyze the accuracy between ECG-based heart rate variability and PPG-based pulse rate variability. Both methods are leading to quite similar results during resting conditions and undisturbed sleep.[65] However, frequency analysis during sleep apnea may differ between the two analysis methods.[66] In addition, respiratory sinus arrhythmia measured from pulse rate signal has been used for cardiovascular risk assessment.[67]

Vascular Stiffness

The peripheral pulse wave signal contains clinically important information about stiffness of the conduit arteries relevant for cardiovascular function and risk assessment.[16-18] The AI derived from finger pulse wave showed good intra-individual agreement during repeated measures. The PPG-AI demonstrated a dose–response relationship with mean arterial blood pressure and cardiovascular risk classification of the European Heart Score.[17,18] The mean PPG-AI increased in parallel with the classes of average to very high cardiovascular risk scores in 247 individuals and subjects with diabetes, hypercholesteremia, and hypertension had a significantly higher AI compared with healthy adults.[17] In hypertensive patients, it was shown that the measures indicating vascular stiffness in the PPG pulse wave were influenced by age, blood pressure, body mass index, and heart rate.[68] The vascular aging index was increased in the elderly and patients with uncontrolled hypertension. Finally, it has been shown that modification of vascular stiffness by vasoactive drugs can be mirrored by parallel changes in the finger pulse wave.[14-16,69,70]

ASSESSMENT OF OVERALL CARDIOVASCULAR RISK FROM A SLEEP RECORDING

Sleep-related respiratory and cardiovascular parameters are related to cardiovascular morbidity and mortality. For instance, failure to produce nocturnal dipping of blood pressure or heart rate has been independently associated with increased all-cause mortality.[71,72] The high frequency component of heart rate variability during sleep is blunted in patients with coronary artery disease, and the nocturnal arterial vascular tone

Table 167-3 Clinical Relevance of Physiologic Variables Derived from the Finger Photoplethysmography Signal for Cardiovascular Risk Assessment

Parameter	Function Assessed	Dysfunction Reflected by Parameter
Hypoxic variability	Recurrent hypoxia and reoxygenation	Hypoxic cardiovascular stress
Pulse wave attenuation	Frequency of pulse amplitude attenuations	Microvascular dysfunction, increased vascular sympathetic tone
Pulse rate acceleration	Sympatho-vagal balance at sinus node level, baroreflex	Coexisting cardiac/vascular/metabolic disease
Periodic pulse rate changes	Cardiorespiratory coupling, baroreflex sensitivity	Coexisting cardiac/vascular/metabolic disease
Pulse propagation time	Vascular wall compliance	Vascular aging, hypertension, atherosclerosis
Time of saturation <90%	Degree of nocturnal hypoxic load	Significant respiratory disease
Degree of symmetric nocturnal desaturation	Occurrence of central apneas and Cheyne-Stokes Respiration	Significant cardiac or CNS disease (e.g., heart failure, post stroke)
Cardiac response to nocturnal hypoxia	Heart rate response to intermittent hypoxia, chemoreflex	Cardiac or metabolic disease affecting autonomic response (e.g., diabetes)

CNS, central nervous system.

determined by finger PPG is elevated in patients with essential hypertension.[73,74] Sleep-related hypoxia, specifically intermittent hypoxia in sleep apnea, has been associated with increased cardiovascular mortality.[75] Therefore, there is a strong rationale for a systematic combined analysis of cardiac, vascular, and respiratory reactivity during the sleeping period as a measure of cardiovascular risk.

In a multicenter study, physiologic components of PPG signal were derived from the overnight finger oximetry recording using a Matching Pursuit algorithm for cardiovascular risk assessment (Table 167-3).[1,76] The parameters were selected based on their relevance in reflecting cardiovascular regulatory homeostasis and feasibility from the finger PPG signal. Variables reflecting cardiac rate variability were identified. A similar process was initiated for variables reflecting peripheral vascular reactivity and stiffness. In order to quantify autonomic events independent of respiratory and arousal events, PWA attenuations between 10% and 30% were included in the analysis. The PPT was used as a surrogate measure of pulse wave velocity and arterial stiffness. Finally, several measures of nocturnal oxygenation (constant, symmetric, and recurrent hypoxia) were also included in the analysis. A 2% oxygen desaturation was chosen for the hypoxia event threshold. The interaction between respiration and cardiovascular function using the respiratory frequency band of pulse rate and the heart rate response pattern to episodic hypoxia were calculated. The respiratory sinus arrhythmia is considered to reflect vagal-cardiac nerve activity, and a decrease in this pattern may reflect elevated cardiac sympathetic activity. Although these variables were modestly interrelated, the multivariate analysis suggested that all parameters contributed significantly to the cardiovascular risk assessment.[1] A composite cardiovascular risk score (range 0–1) was generated using a neuro-fuzzy system.[76]

In a cross-sectional validation study of this novel algorithm, all patients were classified according to the European Society of Cardiology/European Society of Hypertension (ESC/ESH) risk matrix.[1] The algorithm based on overnight PPG signal allowed the identification of high cardiovascular risk patients (high and very high added cardiovascular risk, according to the ESC/ESH matrix)[77] with sensitivity and specificity values of 74.5% and 76.4%, respectively, and area under the ROC curve was 0.80. Corresponding values for the AHI and the oxygen desaturation index were below 65%. The current data provide evidence that an algorithm based on a PPG signal offers a reasonable estimate of cardiovascular risk as expressed in standard matrix used in clinical medicine. However, it remains to be determined whether findings from this cross-sectional analysis can be extended to a prospective analysis. Such studies have been initiated.[78]

The PAT technology has also been evaluated regarding associations with cardiovascular risk markers. The magnitude of overnight PAT attenuations reflected daytime blood pressure in the general population independent of apneic measures from PSG.[79] This finding implies that vascular or autonomic phenomena recorded during the sleep period provide a marker for cardiovascular disease (e.g., hypertension). The AI calculated from PAT at rest was studied in 186 patients from a cardiology clinic.[80] Although PAT-AI significantly correlated with cardiac risk factors and coronary artery disease, the diagnostic capacity of this single pulse wave variable to differentiate patients with/without coronary artery disease was limited (area under the ROC curve 0.604), suggesting that multiple information processing of pulse wave signals for cardiovascular risk assessments may be needed.

SUMMARY

This chapter describes the hemodynamic and autonomic influence on the pulse wave signal during sleep. The information can be used for a better understanding of the associations among pulse wave change and autonomic arousal/sleep fragmentation, sleep stages, and sleep-related disordered breathing. A broad clinical application of digital pulse wave analysis in sleep medicine and sleep-related research is reviewed. The potential usefulness of using finger pulse wave signal for cardiovascular function assessment is discussed.

Given the simplicity, the cost-effectiveness, and clinical acceptance of the oximetry technology, the pulse wave signal obtained by modified oximeter technology opens new possibilities serving as an important additive or even alternative parameter in future sleep diagnostic device. Research is very active in the field and results are very promising.

CLINICAL PEARL

The finger pulse wave can be easily derived from PPG. Supportive information for sleep-stage classification, identification of autonomic arousal, and differentiation of obstructive versus central breathing event can be achieved, which improves the utility of ambulatory sleep diagnostic devices. Validation of the methodology has shown good agreement with conventional information gained from PSG. In addition, valuable information on cardiovascular dysfunction and risk can be obtained by advanced pulse wave analysis. Prospective outcome studies on cardiovascular risk prediction based on pulse wave analysis during sleep are necessary to establish the definite role of this novel methodology for sleep diagnostic procedures.

Recording and Scoring Sleep-Related Movements

Chapter 168

Raffaele Ferri; Stephany Fulda

Chapter Highlights

- The development of scoring rules is a dynamic process with constant exchange between clinicians and researchers.
- The exchange between sleep medicine and research is vibrant, but the necessary time lag in incorporating new evidence into clinical scoring rules has led in many instances to the parallel existence of clinical rules and research rules for the same phenomenon.
- This chapter reviews both clinical and research recording techniques and scoring rules for sleep-related movements, with a focus on the most common ones, such as periodic limb movements during sleep, rapid eye movement sleep without atonia, and sleep-related bruxism. In addition, rhythmic movement disorder, propriospinal myoclonus of sleep onset, benign myoclonus of infancy, excessive fragmentary myoclonus, neck myoclonus, and leg movements other than periodic limb movements during sleep are briefly discussed.

The establishment and standardization of recording techniques and scoring criteria both reflect and afford progress in clinical sleep medicine and research. The development of scoring rules is a dynamic process, with constant interchange between clinical practice and research. This is illustrated by the fact that one of the standard references for clinical scoring rules, the manual published by the American Academy of Sleep Medicine (AASM),[1] is now continuously reviewed and updated based on new clinical evidence or advances in technology.

The exchange between sleep medicine and research is vibrant, but the necessary time lag in incorporating new evidence into clinical scoring rules has led in many instances to the parallel existence of clinical rules and research rules for the same topic. Presented in this chapter is an overview of both clinical and research recording techniques and scoring rules for sleep-related movements. The focus is on the most common such movements, such as periodic limb movements during sleep (PLMS), rapid eye movement (REM) sleep without atonia (RSWA)—manifested clinically as REM sleep behavior disorder (RBD), and sleep-related bruxism (SB). In addition, rhythmic movement disorder, propriospinal myoclonus of sleep onset, benign myoclonus of infancy, excessive fragmentary myoclonus, neck myoclonus, and leg movements other than PLMS also are briefly discussed. The finding of abnormal movements in sleep is important from both a diagnostic and a prognostic standpoint.

BASIC RECORDING METHODS

Electromyography

Surface electromyography is the "gold standard" for recording most muscle movements during sleep. The electromyogram (EMG) is acquired by means of silver chloride electrodes attached to the inputs of a differential amplifier, to obtain a bipolar derivation. It usually is recommended that interelectrode impedance be less than 10 KΩ (but better below 5 KΩ)[1,2]; the skin preparation procedure, before electrode placement, is very important (e.g., cleansing the skin with an alcohol pad, with light skin abrasion, and sometimes shaving excess hair). For better adhesion of the electrodes, the use of collodion is recommended because it is nonconductive, holds through hair (not only on the scalp), withstands oils and perspiration, and provides high performance for long-term recordings. Collodion is highly flammable, however, and produces fumes, so appropriate air purifier, fume extractor, or ventilation systems should be used. Finally, for long-term recordings, a conductive paste is needed to ensure good electrical contact between the skin and the electrodes.

EMG signals are produced by the muscle situated under the skin and by adipose tissue below the electrodes, which essentially record activity of superficial muscle. Muscle size and amount of adipose tissue significantly influence the amplitude of the surface-recorded EMG signal. This is the reason why surface EMG signals are considered semiquantitative and calibration of EMG activity is recommended.[2] The amplitude of surface EMG potentials depends also on the distance between the recording electrodes and can range between less than 20 μV and up to several millivolts, depending on the various factors noted previously.

EMG signals are constituted of superimposed motor unit action potentials produced by several motor units, each with a typical repetition rate of firing of approximately 7 to 20 Hz. Surface EMG records the sum of this activity and produces a signal with a wide spectrum. Figure 168-1 shows two examples of the EMG power spectrum from chin and tibialis anterior muscles (recorded with a sampling rate of 500 Hz); it is possible to note the wide extent of the power spectrum and the effects of notch filtering at 50 Hz.

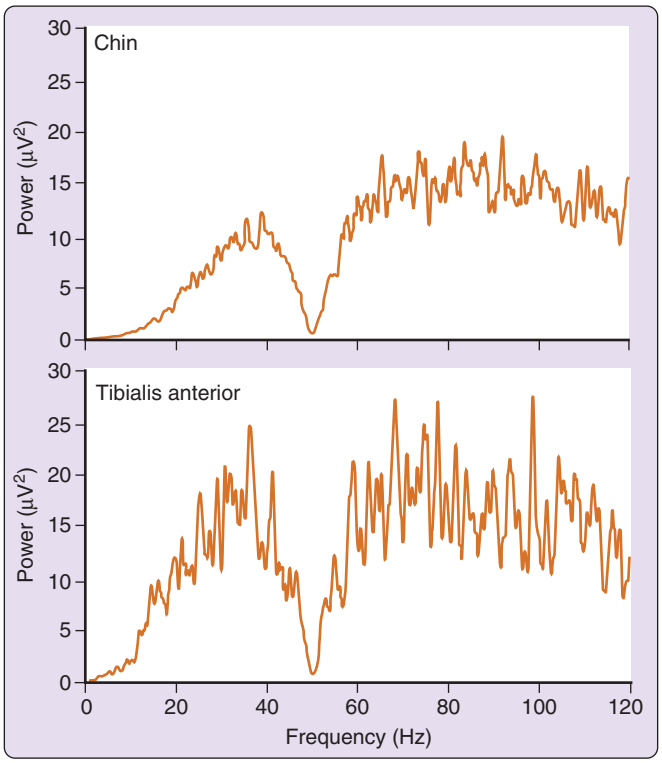

Figure 168-1 Average power spectrum of the electromyogram (EMG) signal sampled at 500 Hz and recorded from the chin and tibialis anterior muscles.

The spectral content of the EMG signal requires high sampling rates that should never be lower than 200 Hz; 400 to 500 Hz is usually recommended.[2,3] Band-pass filtering usually is applied, with typical settings at approximately 10 to 100 Hz and with a notch filter at 50 or 60 Hz, depending on the power line frequency.

Video Polysomnography

Video (and audio) recording, synchronized with the polysomnographic signals, is offered by most recording systems. This tool offers the possibility to examine simple or complex motor behaviors and vocalizations in conjunction with their accompanying electrophysiological correlates. Video polysomnography (PSG) is essential for the assessment of movements and behaviors that occur in several sleep disorders and allows their differentiation.[4-7] For example, this modality has a key role in differentiating parasomnias from nocturnal seizures and from behaviors arising during episodes of wakefulness, as sometimes occur in psychiatric conditions.

It should not be overlooked that video PSG provides objective documentation of all actions occurring in the laboratory, for both clinical and legal issues.

PSG equipment manufacturers can recommend fixed-focus video cameras, but devices that allow remote directional and zoom control (pan-tilt-zoom cameras) are preferable. Today's digital systems now allow "zooming" within the image also at the scoring or review stage.

To ensure darkness for the patient, an infrared light source is needed, with a corresponding appropriate camera.

A major limit of this method, however, is its high costs for both the recording and the reviewing/scoring processes. The evaluation of complex behaviors picked up by video PSG recordings is essentially a visual process that can be helped by the use of appropriate scales, developed for each sleep disorder.[7-15]

Time-lapse video recording, based on old time-lapse photography techniques,[16] has been proposed also to reduce the time (and costs) needed to review real-time video recordings, which are replayed in a much shorter time. The possibility to stop when a meaningful event occurs and to return to real-time replay allows finding the desired periods in a shorter time and analyzing them in detail.

In the future, automated video analysis can be expected to provide reliable help for the assessment of sleep-related behaviors, and some preliminary approaches have already been attempted.[17]

Actigraphy

Actigraphy is carried out using devices, usually worn on the wrist, containing motion sensors called accelerometers. These sensors integrate motion amplitude and speed, and their output is a signal with magnitude and duration depending on these motion features. This signal is appropriately amplified, filtered, and digitized to be stored in the device memory, most often in terms of movement counts per epoch. The length of the epoch is of crucial importance and can be fixed at 1 minute or can be chosen by the user (from a fixed list of epoch lengths).

In conjunction with the memory capacity of the actigraphic device, epoch length determines the maximum recording time. Because the most important clinical application of actigraphy is in the assessment of the circadian rhythm sleep-wake disorders,[3] it is necessary that these devices can reliably carry out recordings over a period of at least 7 days. Even if 5 nights have been indicated to be the minimum required to obtain reliable actigraph measures of sleep for children and adolescents,[18] it appears important to include all weekdays and the weekend for a complete report.

Data are stored in essentially three different ways by currently available actigraphs, some of which allow the user to select the preferred mode, whereas others do not. With the "Time Above Threshold" mode, the amount of time per epoch during which activity exceeds the set threshold is stored; the "Zero Crossing" mode assesses the number of times per epoch that the activity signal produced by the accelerometer crosses a threshold set around zero; finally, with the "Proportional (or Digital) Integration" mode, the area under the curve is stored for each epoch. Some devices allow the simultaneous use of multiple modes. Different studies have provided support for the various measurement modes. Conclusive statements regarding which is the most accurate among these modes are thus far lacking in the literature.

After the recording phase, data usually are downloaded on a computer for scoring. Each system has specific software tools but they typically are based on the algorithms proposed by Cole and associates[19] or Sadeh and coworkers.[20]

Actigraphy cannot be used for staging sleep; it can overestimate sleep, because when subjects are lying still while awake, they do not produce movements. Actigraphy shows good agreement with PSG in the measurement of total sleep time (TST) in healthy subjects, but in patients with sleep disorders (characterized by frequent arousals and reduced TST), it shows lower agreement. Actigraphy should always be

accompanied by a careful monitoring of sleep, along with a sleep diary kept by the patient, which allows a more reliable estimation of TST and wakefulness after sleep onset (WASO).

Actigraphic monitoring of foot or leg movements has been proposed,[21,22] and because it offers the possibility to record multiple nights in a home environment, it has been proposed as a tool to overcome the problems caused by the relatively large night-to-night within-subject variability reported to occur for periodic leg movements during sleep (PLMS).[23] Actigraphy alone, however, is unable to discriminate between PLMS and leg movements occurring during wakefulness; moreover, arousal or other related events (apnea) cannot be detected.

The technical aspects of actigraphic recordings are important and able to influence the results; earlier published criteria for reliable actigraphic recording should be carefully applied.[2] A recent review and meta-analysis[24] of the use of actigraphy for the measurement of PLMS has demonstrated significant heterogeneity among the few studies available, regarding the type of actigraph, position of the sensors on the legs, and methods for counting PLMS. In particular, an important limitation was noted in the possibility to reliably combine data from actigraphs placed on both limbs, in most devices.

Thus, at present, actigraphy cannot substitute for polysomnography within the process of diagnosing restless legs syndrome (RLS) but is useful in screening for RLS in large groups of subjects and may be more suitable for evaluation of the degree of night-to-night variability of PLMS.[23]

Other Methods

Several producers propose piezoelectric sensors for the recording of limb movements during sleep. These sensors, placed around the ankle or around the leg, transduce motion, vibration, and tension into an electrical signal. They are very sensitive, and there is no guarantee that the signal produced corresponds exclusively with events generated by the limb. No convincing validation studies are available for the use of these sensors, and they are not recommended by any guideline. The only advantage that they offer is that no skin preparation is required; however, this is counterbalanced by a cost higher than that for silver chloride electrodes.

A variety of other movements can be recorded during sleep; among them, of particular importance are those needed for the diagnosis of the different types of sleep apnea, such as thorax and abdomen movements. Strain gauges and piezoelectric sensors have been used, but the most recent and reliable belts are based on inductive sensors, which also allow estimation of volume changes in these anatomic structures.

PERIODIC LIMB MOVEMENTS

The first PSG EMG recordings of PLMS were carried out in Bologna by the group led by Lugaresi in 1965.[25,26] Some 20 years later, duration, amplitude, periodicity, and symmetry of PLMS were defined and manually measured in paper recordings by Coleman,[27] who created the bases of the scoring criteria established by the American Sleep Disorders Association (ASDA),[28] in 1993, which subsequently have been used for more than 20 years.

Currently, two sets of similar (but not identical) rules for scoring PLMS and periodic leg movements during wakefulness (PLMW) exist. These were partly informed by algorithms proposed for the automatic detection of leg movements in PSG[29] and include mathematically defined parameters such as thresholds, intervals, and amplitude.[29,30] First, in 2006 a task force of the International Restless Legs Syndrome Study Group endorsed by the World Association of Sleep Medicine (WASM/IRLSSG)[2] introduced a major revision of the scoring rules, which were then substantially (but not entirely) adopted by the AASM in 2007.[1,31,32] Table 168-1 lists the similarities and differences between the two sets of rules; in the following paragraphs, unless otherwise stated, recommendations, descriptions, and definitions refer to both sets.

Recording Methods

Surface EMG electrodes should be placed at 2 to 3 cm apart or a distance from each other that is one third of the length of the anterior tibialis muscle, whichever is shorter. Electrodes must be located longitudinally on the muscles, symmetrically around the middle. Impedance should be 10 KΩ or less for clinical studies, but a setting of 5 KΩ or less is recommended (AASM) or required for research studies (WASM/IRLSSG). EMG signals must be obtained from both the right and the left leg. Recording the two signals in one channel is strongly discouraged. For research studies, signals from each leg must be recorded separately (WASM/IRLSSG). Recording activity from other muscles besides the tibialis anterior is recommended only for research purposes or for special clinical conditions (e.g., arm restlessness). For the WASM/IRLSSG criteria,[2] sampling rate should be 200 Hz or greater (clinical settings) or 400 Hz or greater (research settings), whereas for the AASM criteria,[1,31,32] sampling rate should be 200 Hz or higher (minimal) or 500 Hz (desirable). Filter settings should be 10 to 100 Hz; for research purposes, settings of 10 to 200 Hz are recommended (WASM/IRLSSG); the AASM additionally recommends that use of the 60-Hz notch filter should be avoided.

Baseline resting EMG amplitude (i.e., in the relaxed muscle) should be ±2 to 3 μV (4 to 6 μV peak to peak; WASM/IRLSSG) or 10 μV or less (AASM). The WASM/IRLSSG rules recommend that before the recording, a calibration should be carried out to obtain from the relaxed anterior tibialis muscles a nonrectified signal of power no greater than ±5 μV (or 10 μV peak to peak; 5 μV for rectified signals) for clinical purposes and ±3 μV (or 6 μV peak to peak; 3 μV for rectified signals).

Scoring Rules

The scoring of periodic leg movements follows several general, sequential steps:

1. Leg movements are identified by the amplitude and duration of the EMG activation.
2. Bilateral leg movements are combined if a single PLMS index is to be calculated.
3. Leg movements occurring in the vicinity of sleep-disordered breathing events (e.g., respiratory-related leg movements [RRLMs]) are identified and excluded.
4. The remaining leg movements are classified as periodic or nonperiodic (isolated) on the basis of their occurrence within a series of such movements characterized by their number and the interval between movements.

The scoring process begins with the identification of candidate leg EMG events. Their onset is defined as an EMG increase of 8 μV or greater above the resting baseline, whereas

Table 168-1 Recording and Scoring of Periodic Leg Movements According to the Guidelines of the World Association of Sleep Medicine/International Restless Legs Syndrome Study Group (WASM/IRLSSG)[2] and the American Academy of Sleep Medicine (AASM)[1,32]

Feature/Component	WASM/IRLSSG	AASM
Recording of Leg Movements		
Electrodes	Surface electrodes	Surface electrodes
Electrode positioning	Tibialis anterior muscles Placed longitudinal, symmetrically around the middle, 2–3 cm apart or one third of length of anterior tibialis muscle, whichever is shorter	Tibialis anterior muscles Placed longitudinal, symmetrically around the middle, 2–3 cm apart or one third of length of anterior tibialis muscle, whichever is shorter
Combined recording of left and right legs	Bilateral recordings are required. Use of two channels, one for each leg, is strongly recommended for all studies and is required for research Clinical applications may, however, combine the electrodes from both legs into one recorded channel, although this practice is discouraged	Both legs should be monitored for the presence of leg movements. Use of separate channels for each leg is strongly preferred Combining electrodes from the two legs to give 1 recorded channel may suffice for some clinical settings, although this strategy may reduce the number of detected leg movements
Sampling rate	≥200 Hz in clinical studies ≥400 Hz in research studies	≥200 Hz 500 Hz desirable
Filter	10–100 Hz in clinical studies 10–200 Hz in research studies	10–100 Hz Use of 60-Hz (notch) filters should be avoided.
Impedance	≤10 KΩ in clinical studies ≤5 KΩ in research studies	<10 KΩ <5 KΩ preferred
Definition of Leg Movement		
Onset	EMG increase ≥8 μV above the resting baseline	EMG increase ≥8 μV above the resting baseline
Offset	EMG decrease to <2 μV above the resting level for ≥0.5 s	EMG decrease to ≤2 μV above the resting level for ≥0.5 s
Duration	Time between onset and offset, 0.5–10 s	Time between onset and offset, 0.5–10 s
Baseline	Resting EMG Relaxed muscle Absolute signal amplitude, 4–6 μV peak to peak *Calibration*: Relaxed anterior tibialis lasting: ≤10 μV in clinical setting ≤6 μV in research setting *Special criteria for events during wake time*: If EMG > 6–10 μV for ≥15 s, then new increased baseline is defined as average amplitude during this period	Stable resting EMG Relaxed muscle Absolute signal amplitude, ≤10 μV peak to peak
Scoring of Periodic Leg Movements (PLMs)		
Intermovement interval (IMI)	Onset-to-onset: 5–90 s	Onset-to-onset: 5–90 s
Number of leg movements	≥4 (Leg movements lasting <0.5 s or >10 s are disregarded)	≥4
IMI >90 s	PLM series ends	PLM series ends
IMI <5 s	PLM series goes on; leg movement with IMI <5 s is disregarded	*Not specified*
Sleep-wake	All leg movements form PLM series For PLMS, only those during sleep are counted	Only leg movements during sleep form PLM series
Bilateral leg movements	Offset-to-onset <0.5 s	Onset-to-onset <5 s
Respiratory-related leg movements (RRLMs)	Excluded from PLM series	Excluded from PLMS series
RRLM definition	Any leg movement occurring within: ±0.5 s around the ending of an apnea/hypopnea event	Any leg movement occurring within: 0.5 s before the start to 0.5 s after the end of an apnea or hypopnea, respiratory effort–related arousal, or sleep-disordered breathing event

EMG, Electromyogram; PLMS, periodic leg movements during sleep.

offset is marked at the point when the EMG amplitude decreases to less than 2 μV above the resting level and remains below that value for at least 0.5 second. An event can contain one or more periods with EMG amplitude below the offset level that each last less than 0.5 second. The duration of the event is the time between its onset and offset; it must be at least 0.5 second and no longer than 10 seconds; 15 seconds are allowed for research purposes (WASM/IRLSSG). All other events not meeting these criteria are discarded and not considered any further.

Next, if a single PLMS index is to be calculated, as opposed to a separate PLMS index for each leg, bilateral leg movements are combined. The WASM/IRLSSG criteria consider leg movements to be bilateral if the offset of the first event is less than 0.5 second before the onset of the subsequent event. By contrast, the AASM rules consider leg movements to be bilateral if the onset of the first event occurs less than 5 seconds before the onset of the next event. Because leg movements can be between 0.5 and 10 seconds in duration, the AASM rule also classifies some overlapping leg movements as bilateral.

Both sets of rules exclude leg movements that occur in the vicinity of sleep-disordered breathing events (RRLM), from the inclusion into PLMS series, and these leg movements have to be identified and excluded before calculating the PLMS index. For the WASM/IRLSSG,[2] a leg movement must be excluded from the PLMS analysis when it is associated with the resumption of respiration at the end of an apnea/hypopnea event, defined as any part of the leg movement in the interval of ±0.5 second around the end of the breathing event. By contrast, for the AASM,[1,31,32] a leg movement should not be counted when it occurs during a period starting 0.5 second before the beginning of a sleep-disordered breathing event to 0.5 second after the end of this event. Sleep-disordered breathing events include apneas and hypopneas and respiratory effort–related arousals.

After identifying leg movements, combining bilateral leg movements, and discarding RRLMs, among the remaining leg movements, those belonging to periodic leg movement sequences are identified. For this step, the crucial parameter is the interval between consecutive movements, measured from onset to onset—that is, between 5 and 90 seconds. If the interval between one leg movement and the next is greater than 90 seconds, any possible PLMS series ends with the previous leg movement. A crucial question is what happens when the interval between one leg movement and the next is less than 5 seconds. The WASM/IRLSSG rules specify that if the interval is less than 5 seconds, the second leg movement should be ignored, and the series goes on if the interval between the first leg movement and the next leg movement after the one that is being ignored is less than 90 seconds. The AASM rules, however, do not give any specification for this case.

Subsequently, a periodic sequence is defined as a series of four or more leg movement separated from each other by 5 to 90 seconds. A further crucial point at this step is the question of whether only leg movements during sleep or also those during wake are part of a periodic leg movement series and how intervening wakefulness affects a possible periodic leg movement series. Here, the WASM/IRLSSG rules recommend that all leg movements during sleep and wake can form part of a PLM series, and that for calculation of the PLMS index, only those during sleep are counted. Periodic leg movements during wakefulness are counted for the PLMW index. By contrast, in the AASM rules, this question is not addressed; the scoring of leg movements during wake is not foreseen, and it is unclear whether intervening wake categorically ends a PLMS series or whether in the case of short-lived (less than 90 seconds) wakefulness the series can go on, provided that the interval between the last leg movement during sleep before the wakefulness event and the first leg movement during sleep after the wakefulness event is less than 90 seconds.

Leg movements are considered to be associated with an arousal event when they are separated by less than 0.5 second—that is, between the end of one event and the onset of the other, regardless of which is first.

Once PLMS and PLMW are scored, several summary measures can be obtained. The following measures are recommended:[2]

- PLMS index: number of PLMS divided by the number of hours of sleep with leg movements recorded (PLMS/hour)
- PLMS with arousals index: number of PLMs associated with arousals divided by the number of hours of sleep with leg movements and arousal recorded (PLMA/hour)
- PLMW index: number of PLMW divided by the number of hours of wake with leg movements recorded (PLMW/hour)

Whenever possible, it also is recommended to report the PLMS index during non–rapid eye movement (NREM) sleep only; the PLMS index during REM sleep only; duration of PLMS and PLMW (separate for REM and NREM sleep), and intermovement interval of PLMS and PLMW (separate for REM and NREM sleep). Optional parameters are PLMS by sleep stages (including duration and intermovement intervals) and isolated leg movements.

Advanced Measurements of Periodic Leg Movements during Sleep and Periodic Leg Movements during Wakefulness

Sleep PSG recordings in patients affected by RLS or other sleep disorders usually also contain a significant amount of leg movements that cannot be classified as "periodic"[33-35]; moreover, it has been reported that leg activity during wakefulness in normal subjects is nonperiodic.[36] To analyze, in a more comprehensive way, this admixture of periodic and nonperiodic activities, new advanced measurements have been proposed as an important integration of the information provided by the previously reported scoring methods.[37]

In particular, an additional measure has been established, the *periodicity index,* indicating the degree of periodicity of the total leg movement activity.[33] This index quantifies the proportion, over the total, of intermovement intervals of $10<i\leq90$ seconds that are preceded and followed by another interval of the same length (this is equivalent to a series of 4 leg movements all separated by intervals of $10<i\leq90$ seconds). The numerical value of this index can range between 0 (absence of periodicity, with none of the intervals having a length between 10 and 90 seconds) and 1 (complete periodicity, with all intervals between 10 and 90 seconds long).[33] It is important to note that for the correct calculation of this index, leg movements occurring within 5 seconds from a previous movement should not be deleted from the analysis, taking into account intervals as short as 1 second (minimum movement duration

0.5 second + minimum interval duration 0.5 second). In a departure from the rules just presented, the range of the possibly periodic leg movement intervals also is considered to be 10 to 90 seconds by this measure.

The periodicity undergoes significant age-related changes, with a trajectory significantly different from that of the total leg movement count, indicating the need of age-adjusted normative reference values,[36,38] especially in elderly people, older than 75 years of age, and in children/adolescents, in whom a low periodicity can be expected even in the presence of clinically evident RLS.[39]

Another important feature characterizing PLMS is their time distribution during the night. In a majority of patients with RLS, PLMS count progressively decreases during the night.[38,40]

Unresolved Issues

Unresolved issues concern the discrepancies between the two set of rules. Among those, a major issue is the consideration of RRLMs. As detailed previously, the WASM/IRLSSG rules exclude RRLMs if they occur at the end of respiratory events, whereas the AASM rules exclude also LMs at the start of and during respiratory events. Neither of the sets of criteria to identify RRLMs were evidence-based. Recently, a study[41] on RRLMs as identified by the WASM/IRLSSG rules has argued that RRLM might represent part of a phenotypic spectrum that includes PLMS and has questioned the need to exclude these RRLMs from the analysis of PLMS. In addition, a further recent study,[42] and the first one to systematically analyze the distribution of LMs with respect to respiratory events, has reported that LMs in patients with sleep-related breathing disorders (SRBDs) were not increased at the beginning or middle of respiratory events but clustered around the end of events over a period significantly longer than specified by the AASM and WASM/IRLSSG rules. Of importance, both sets of rules underestimated the number of RRLMs and thus overestimated the number of PLMS in patients with SRBD. Together, these studies underline the need for continued evaluation and development of scoring rules for PLMS.

REM SLEEP WITHOUT ATONIA

RSWA is the polysomnographic hallmark of REM sleep behavior disorder (RBD), a parasomnia characterized by dream-enacting behavior in which the physiologic atonia during REM sleep is absent or greatly diminished (see Chapter 103). According to the current *International Classification of Sleep Disorders* (ICSD3),[3] among the criteria for the diagnosis of RBD is the demonstration of RSWA based on the definition provided by the most recent AASM guidelines.[1]

The AASM guidelines[1] distinguish between sustained, tonic muscle activity and excessive, transient, phasic muscle activity in REM sleep and provide scoring rules to identify REM epochs with atonia and/or excessive phasic activity based on chin and tibialis anterior EMG during REM sleep. Besides these guidelines, there is a multitude of different recording set-ups and scoring algorithms, both visual and automated, currently used in research protocols.

Recording Methods

It generally is accepted that scoring sustained, tonic muscle activity during REM sleep is based on the chin EMG.[1,43,44] Thus far, no consensus has emerged regarding practices or recommendations for assessing phasic muscle activity during REM sleep. Various approaches have been used, such as the recording of the chin muscles only,[45-50] or of chin muscles in different combinations with tibialis anterior,[51,52] brachioradialis,[53,54] biceps brachii,[55-57] extensor digitorum,[58,59] or carpi radialis.[60]

Comparing quantitative EMG analysis in 13 different muscles in patients with RBD, the Sleep Insbruck Barcelona (SINBAR) group showed that phasic EMG activity differed significantly depending on which muscles were evaluated.[61] Although the highest rate of phasic EMG activity was found in the mentalis muscle, reliance on only this muscle misses 45% of all phasic activity.[61] As indicated by analysis of different combination of muscles, the three-muscle combination that detected the highest number of mini-epochs with phasic activity was that composed of the mentalis muscle, the flexor digitorum superficialis in the upper limb, and the extensor digitorum brevis in the lower limb. Use of this combination identified 82% of all mini-epochs containing phasic EMG activity during REM sleep, in any recorded muscle. This montage was adopted as the SINBAR EMG montage. The SINBAR group subsequently reported that behavioral events and vocalizations during REM sleep in patients with RBD were almost exclusively (94.4%) linked to phasic EMG activity identified with this EMG montage.[62] Of importance, recording of the mentalis muscle alone did miss 35% of the behavioral events.[62] An important implication of this observation is that the quantification of RSWA and subsequently determined cutoff thresholds for the diagnosis of RBD probably will vary, depending on the specific montage and number of EMG signals used.[43,44] Several different protocols are currently in use for recording and scoring RSWA:

- *AASM recommendations*[1]: The AASM scoring system is based on the chin EMG for assessment of sustained, tonic EMG activity and on the chin and tibialis anterior EMG for assessment of excessive phasic activity.
- *SINBAR EMG montage*[61]: On the basis of the study in 13 different muscle groups just described, the SINBAR group has recommended the recording of the mentalis muscle, in association with the flexor digitorum superficialis in the upper limb and the extensor digitorum brevis in the lower limb, for research protocols. This group has recently proposed normative values for RSWA based on the SINBAR EMG montage.[43]
- *Montreal research group recommendations*[44,45]: The Montreal research group and many other researchers have assessed tonic and phasic EMG activity based on the chin EMG alone.[11,45,46,51,55-58,63-72] Cutoff values for the diagnosis of RBD have been recently evaluated.[44]

Scoring Rules

Visual Scoring of REM Sleep without Atonia

Since the first introduction of scoring rules for RSWA by Lapierre and Montplaisir in 1992,[45] there has been a wide variance in scoring approaches, many research and clinical groups defining their own, often with only slightly different rules (see Table 168-2 for a nonexhaustive list; a more complete list is available in the review by Fulda and colleagues[73]). The main differences concern the amplitude criterion to

Table 168-2 Scoring and Quantification of Tonic, Phasic, or Any Electromyogram (EMG) Activity during REM Sleep*

Definition No.	Study	Epoch Length (s)	Duration (% of Epoch)	Scoring: Amplitude of EMG Activation	Quantification: Name	Quantification: Measure	Reference(s) to Relevant Studies
Tonic Activity

identify EMG activations and the duration of phasic EMG bursts (see Table 168-2). In addition, besides scoring and quantifying tonic and phasic EMG activity during REM sleep, several groups of investigators defined and used summary measures that quantify "any"[43] EMG activity during REM sleep. Usually, tonic activity is scored as such only when it occupies more than half of an epoch. At the same time, phasic activity has a maximum duration that is between 5 and 10 seconds, depending on the definition used. Consequently, EMG activity that lasts longer than the maximum duration for phasic activity and shorter than half of the epoch seems to be neglected by most scoring approaches. The term *"any" EMG activity* was therefore introduced to take into consideration EMG activity of any length during REM sleep.

Lapierre and Montplaisir Scoring Rules[45] and Variations. The first formal scoring rules were introduced by Lapierre and Montplaisir in 1992.[45] They quantified:

- *Atonia* as the percentage of 20-second epochs that contained tonic EMG activation in the chin EMG for more than 50% of the epoch
- *Phasic EMG* as the percentage of 2-second mini-epochs that contained EMG bursts of between 0.1 to 5 seconds that had amplitude larger than 4 times the background

This influential definition continues to be used with some modifications (see Table 168-2). The penultimate modification (Table 168-2, definition 1a, modification 5) was reported in 2010, in the first study[44] that explored diagnostic thresholds for the diagnosis of RBD based on this scoring of RSWA (see further on). In this study, the following rules were applied:

- *Tonic EMG density* was defined as the percentage of 20-second epochs that contained tonic EMG activation with an amplitude at least twice the background or larger than 10 μV.
- *Phasic EMG density* was scored as the percentage of 2-second mini-epochs that contained EMG bursts with amplitude larger than four times the background and lasting 0.1 to 10 seconds.

Finally, in 2014[74] the scoring rules for tonic EMG were adopted to an epoch length of 30 seconds (Table 168-2, definition 1a, modification 6) and diagnostic thresholds for the diagnosis of RBD were evaluated.

AASM Scoring Rules.[1] The AASM scoring rules evaluate each 30-second epoch for the presence of sustained, tonic or excessive, phasic EMG activity:

- An epoch with *sustained, tonic activity* is characterized by at least 50% of the epoch with chin EMG activation with amplitude greater than the minimum amplitude during NREM sleep.
- An epoch with *excessive phasic activity* contains at least 5 mini-epochs, based on the division of the 30-second epoch into 10 sequential 3-second mini-epochs, which contain EMG bursts of 0.1 to 5 seconds each with an amplitude at least four times the amplitude of the background EMG activity.

The AASM rules[1] provide no recommendation on how many epochs scored as tonic and/or with excessive phasic activity would be considered abnormal or consistent with a diagnosis of RBD.

SINBAR Scoring Rules.[43] The scoring approach of the SINBAR group quantifies tonic, phasic, and "any" EMG activations during REM sleep, for which normative values have recently been proposed.[43]

- *Tonic EMG activity* is defined as the percentage of 30-second epochs with chin EMG activity with an amplitude at least twice the background or larger than 10 μV present for more than 50% of the epoch.
- *Phasic EMG activity* is scored as the percentage of 3-s mini-epochs containing EMG activity with duration 0.1 to 5 seconds and an amplitude that is at least twice the background EMG amplitude. The end of a phasic EMG burst is determined by a return of 0.25 second or longer to background EMG levels. To score phasic activity in the presence of tonic activity the amplitude has to be at least twice the amplitude of the tonic background as determined in the same 3-second mini-epoch and the phasic burst has to have a waxing and waning morphology.
- *"Any" EMG activation* is scored as the percentage of 2-second mini-epochs that contain EMG activity of any length with an amplitude that is larger than twice the background amplitude.

Automated Scoring of REM Sleep without Atonia

Currently, several automated scoring algorithms are available for scoring EMG activity during REM sleep[75-78] or sleep in general.[79] Of note, all of the available algorithms quantify different entities and measures of EMG activity that are not directly comparable with those derived from visual scoring. Among the algorithms evaluated in larger groups of patients with RBD and control subjects are the so-called STREAM algorithm,[80] discussed next, and the REM atonia index.[78,81]

The Supra-Threshold REM EMG Activity Metric (STREAM)[80] was proposed by Burns and coworkers. It quantifies the percentage of 3-second mini-epochs during REM sleep with increased muscle activity identified by the variance of the EMG signal, which has to be above the fifth percentile of variance values during NREM sleep. The correlation between STREAM scores and the average of percentages of epochs with tonic and phasic activity visually scored, according to Lapierre and Montplaisir, was 0.87.[45]

The *REM atonia index* (RAI) is by far the most widely used automated scoring algorithm for RSWA. Introduced by Ferri and coworkers in 2008,[78] it was improved in 2010[81] with the addition of a noise reduction technique. The RAI is based on the automated analysis of the rectified, bandpass (1 to 100 Hz) and notch (50/60 Hz) filtered submentalis muscle EMG signal. For each 1-second mini-epoch, the average amplitude is corrected for the local noise level by subtracting the minimum amplitude of the EMG signal in the ±30-second interval around it.[78] The resulting average amplitude for each 1-second mini-epoch is classified in 20 distinct categories as 1 μV or less, between 1 and 2 μV (i.e., greater than 1 μV up to 2 μV or less), between 2 and 3 μV, and so on, until the

category of between 18 and 19 μV and the final category of greater than 19 μV.

The RAI is calculated as the proportion of 1-second mini-epochs with average amplitudes of 1 μV or less, reflecting atonia, with respect to all other mini-epochs except those with average amplitudes between 1 and 2 μV, which are thought to reflect both atonia and EMG activation. The RAI can vary, ranging from 0 to 1—from complete loss of atonia and the absence of mini-epochs with average amplitudes of 1 μV or less (RAI = 0)—to complete atonia with the amplitudes of all mini-epochs 1 μV or less (RAI = 1). Aside from the RAI, the algorithm quantifies the number of movements during REM sleep, defined as the number of consecutive 1-second mini-epochs with average amplitudes greater than 2 μV, which are additionally classified by their duration in 20 distinct categories (from 1 second to more than 19 seconds).

Evaluation of the original algorithm[82] compared against visual scoring of loss of atonia and phasic density as proposed by Lapierre and Montplaisir[45] showed adequate agreement. The average correlations in four large groups of subjects—young control subjects, old control subjects, patients with iRBD, and patients with MSA—were between 0.745 and 0.963 for the REM sleep atonia index and percentage of visually scored atonia, and between 0.628 and 0.915 for the number of EMG activations and visually scored phasic density. This has recently been confirmed for the improved RAI with noise correction.[74] In approximately 80 patients with RBD and 80 healthy control subjects, the correlation between the RAI and the visually scored tonic density (definition 1a, modification 6 in Table 168-2) was 0.87.

The RAI has been used in several studies employing larger samples of healthy control subjects in different age groups[83] and of patients with RBD,[78,81,82,84-86] Parkinson disease,[87,88] or other neurologic disorders[81,82,86] and cutoff values for the diagnosis of RBD have been established.[81]

Classification of Movements during REM Sleep

The classification of movement events during REM sleep is a dynamically evolving field. Approaches include a simple listing of observed behaviors,[48] the categorization in a few broad categories,[55,56,62,89,90] classification of each event along several dimensions,[11] and the development of a standardized rating scale.[14] Examples of these approaches are given in Table 168-3.

The only standardized rating instrument currently in use is the REM Sleep Behavior Disorder Severity Scale (RBDSS).[14]

Table 168-3 Examples of Reported Descriptions/Classification of Movements during REM Sleep

REM Behavioral Manifestations:	Classification	Descriptive Categories	REM Sleep Behavior Disorder Severity Scale (RBDSS)
Gagnon et al., 2002[48] Grimaces; limb and body jerking Sitting; gesturing; reaching; kicking Grimaces; talking; limb and body jerking Talking; limb and body jerking Grimaces; limb and body jerking Grimaces; limb and body jerking Grimaces; talking; limb and body jerking; gesturing Limb and body jerking Grimaces; talking; gripping; reaching; turning; gesturing Grimaces; talking; punching; leaping	**Sforza et al., 1988**[89] Simple motor behaviors Complex motor behaviors **Kumru et al., 2004**[55] *Mild*: Excessive proximal or distal limb jerking with minimal separation from the body, head or body jerking, murmuring, whispering, groaning, smiling, repetitive mouth opening *Moderate*: Gesturing, raising the arms, turning the head abruptly >90 degrees, talking, laughing, crying, singing *Severe*: Waving the arms vigorously, kicking, punching, sitting up in bed, jumping out of bed, loud talking, shouting **Iranzo et al., 2011**[62] Movements: • Head • Right upper limb • Left upper limb • Right lower limb • Left lower limb Vocalization: • Present • Absent	**Frauscher et al., 2007**[11] 1. Type of motor event Elementary motor events • Myoclonic • Simple • Stereotypical Complex behaviors • Complex/scenic motor events • Violent motor events Orofacial events Vocalizations • With comprehensible speech • Without comprehensible speech • Without visibile motor events 2. Emotional state (for vocalizations and complex/scenic events) • Positive • Negative • Unchanged 3. Involved body parts • *Segmental*: one or more contiguous body parts • *Multifocal*: noncontiguous body parts • *Generalized*: multiple or all body parts 4. Laterality • Unilateral • Bilateral	**Sixel-Döring et al., 2011**[14] 1. Motor events 0—no visible movement but registration of RSWA 1—slight movements of the distal extremities 2—movements involving proximal extremities, complex and/or violent behaviors 3—any axial movements with the possibility of falling or observed falls 2. Vocalization 0—absent 1—present *RBDSS score*: the highest score in each of the two categories, separated by a full stop (from 0.0 to 3.1)

The scale was created by Sixel-Döring and colleagues[14] to provide an easy-to-use classification of motor events during REM sleep. As detailed in Table 168-3, based on video PSG, all motor events are classified on a scale from 0 (RSWA but no visible movements) to 3 (any axial movements with the possibility of falling or observed falls. The motor event score is the highest score observed for each patient and on each night. In addition, vocalization is classified as absent (0) or present (1). The overall RBDSS score for a single night and for an individual patient is the combination of the motor score with the vocalization score, usually separated by a full stop (period). The score ranges from 0.0—that is, RSWA but no visible movements and no vocalizations—to 3.1 observed axial movements with either an observed fall or the distinct possibility of a fall and vocalizations. This scale has since been used in an increasing number of studies.[9,85,91,92]

Diagnostic Thresholds for REM Sleep Behavior Disorder

Some motor activity during REM sleep commonly occurs in healthy sleepers, mostly in the form of short, transient muscles activity and twitches.[1] Because motor activity during REM sleep forms a continuum ranging from occasional transient muscle activity to complete loss of atonia, it is essential to establish cutoff values that distinguish RSWA from physiologic REM sleep movement activity and can serve as a diagnostic threshold for the diagnosis of RBD. Of importance, neither the ICSD3[3] nor the AASM manual[1] provides definite cutoff values for RBD diagnosis.

One important methodologic challenge in the establishment of such thresholds is the need to independently replicate and validate them in independent samples. Usually, thresholds are identified as a cutoff value in a discovery sample that is optimized with regard to sensitivity or specificity, or their combination. Accordingly, a diagnostic marker developed and evaluated using a single clinical dataset will tend to overestimate sensitivity and/or specificity. The importance of these replications has recently been nicely illustrated by the study by Frauscher and associates[93] that explored sleep-related movements in a large sample of well-screened, healthy adult sleepers of a large age range. The same group of investigators had previously reported[43] normative values for various measures of RSWA with cutoff values in their discovery sample optimized to a specificity of 1; that is, none of the non-RBD cases had a value above the cutoff values. In the subsequent study[93] in healthy subjects, the specificity was considerably lower with 8% to 25% of healthy sleepers showing RSWA values above the previously established cutoff values (see Table 168-4). The only RSWA cutoff that continued to show a specificity of 1 was a value of 9.6% for tonic chin EMG activity.

Table 168-4 lists studies that have proposed RSWA cutoff values for the diagnosis of RBD and have been independently replicated to some extent.[43,44,74,81,94,95] Other cutoff values for different RSWA measures have been proposed[49,94,96] but await independent confirmation. As is apparent from Table 168-4, there is a tradeoff between *sensitivity*—here, the ability to correctly identify patients with RBD—and *specificity*—the correct exclusion of non-RBD cases. In addition, the table also illustrates that sensitivity and specificity can vary considerably between samples, with elderly subjects who do not have RBD posing a specific challenge.

Unresolved Issues

The scoring of RSWA is complicated by the particularly large variety in applied scoring criteria. Currently unknown is what—if any—is the magnitude of the effect that these variations have on the respective RSWA measures and on their ability to distinguish between patients with RBD and healthy subjects. Variations seem to be minor for the assessment of tonic EMG activity during REM sleep, because a large consensus favors use of the chin EMG and an epoch-wise quantification. For phasic EMG, by contrast, a rather substantial variation in applied scoring rules is evident, and standardized international criteria would greatly benefit the field. In addition, it must be stressed again that currently neither the ICSD3[3] nor the AASM manual provides any quantitative cutoff values for the diagnosis of RBD.[1]

SLEEP-RELATED BRUXISM

Sleep-related bruxism refers to regular or frequent teeth grinding during sleep (see Chapter 144). According to the ICSD3,[3] the diagnostic criteria for SB are the presence of regular or frequent teeth grinding sounds occurring during sleep and either the presence of abnormal teeth wear consistent with this report or transient morning jaw muscle pain or fatigue or temporal headache or jaw locking on awakening.

Several approaches and protocols are available to record and score SB activity, including the following:

- The ambulatory recording of masticatory muscle EMG (mmEMG), in which the identification and scoring of nocturnal bruxism activity are based only on the mmEMG signal[97,97-100]
- The ambulatory recording of mmEMG and heart rate with identification and scoring of nocturnal bruxism activity based on criteria for mmEMG and heart rate[101-103]
- Ambulatory PSG with additional recording of mmEMG but without video-audio recording, in which scoring of SB activity is based on mmEMG[104] or mmEMG and heart rate[105] during the PSG-identified sleep period
- AASM recommendations[1]: standard PSG with video-audio recording including chin EMG and only optional recording of mmEMG, in which SB activity is identified by chin EMG or chin and mmEMG activity and teeth grinding episodes are identified by audio recording during the sleep period
- Research diagnostic criteria (RDC)[106,107]: standard PSG with video-audio recording and mmEMG, in which SB activity is identified and scored on the basis of mmEMG and video-audio recordings during the sleep period

The main difference between these approaches is in the availability and/or use of video-audio recording to distinguish between SB activity and other nonspecific orofacial movements.

Orofacial movements with visible increases in mmEMG are very common during a night of sleep both in healthy sleepers and subjects with SB. Many of these movements may be unspecific and unrelated to SB activity but are indistinguishable from the mmEMG activation patterns that are used to define SB activity. Some examples of nonspecific movements are given in Table 168-5. In general, and as detailed subsequently, SB activity is being identified by EMG activations above a specified threshold that are either series of phasic, short activations or sustained tonic activations or

both—that is, a mixed episode. The total set of all mmEMG activations during sleep, then, has the following components:

A: activations that do not fulfill EMG criteria for SB episodes

B: activations that fulfill EMG criteria for SB episodes but are nonspecific movements such as coughing or swallowing (see Table 168-5) as identified with audio-video recording

C: activations that fulfill EMG criteria and are indeed SB episodes

Table 168-5 Examples of Orofacial Movements and Sounds that May Be Confused with Sleep-Related Bruxism Activity

Movements	Sounds
Swallowing	Coughing
Coughing	Grunting
Yawning	Snoring
Lip and tongue movements	Sleeptalking
Eye blinking	Tooth tapping
Light head movements	Temporomandibular joint clicking
Head rubbing or scratching	Tongue clicking
Lip sucking	Throat clearing

Rhythmic masticatory muscle activity (RMMA) is a subset of SB episodes (as defined for component C) that contains only the phasic and mixed episodes (see later). Within the complete set of mmEMG activations (A + B + C, or B + C), "true" SB episodes account for only 15% to 30% in healthy subjects and for 55% to 70% in patients with SB.[106,108,109] Audio-recording can help identify SB episodes with audible teeth grinding sounds but less than 30% of SB episodes are accompanied by teeth grinding noise.[106,110,111] For this reason, mmEMG recording with audio-video recording is the gold standard for assessment of SB activity, and the nonavailability of audio-video signals is a major limitation for the ambulatory assessment of SB.

The magnitude of misclassification of mmEMG activations as SB activity when audio-video recording is not available can be estimated from two recent studies. In healthy sleepers, Yamaguchi and colleagues compared RMMA episodes identified by the gold standard (video-PSG with

Table 168-6 Recording and Scoring of Sleep-Related Bruxism (SB) Using Research Diagnostic Criteria (SB-RDC), American Academy of Sleep Medicine (AASM) Criteria, and Rhythmic Masticatory Muscle Activity (RMMA)*

Feature/Component	SB-RDC[106,107]	RMMA[110]	AASM Criteria[1]

mmEMG) with events recorded with a telemetric masseter muscle EMG device.[112] Both the telemetric mmEMG signal and the mmEMG signal of the PSG study were scored manually using the same criteria. Video-audio recording was then used to exclude nonspecific events from the scoring of RMMA episodes. The telemetric device correctly identified close to 99% of RMMA episodes identified by video PSG. However, 77% of all episodes identified by the telemetric device were other oromotor events and not SB-related. The positive predictive value (PPV) was therefore only 0.23—that is, the probability that an event identified with the telemetric device was indeed an RRMA episode was only 23%. When only the sleep period was considered, with information provided from video PSG, the PPV increased to 0.52.

These results correspond with those in another study in patients with SB,[113] in which video PSG was scored twice, without and with access to the audio-video recording. Thus the study was designed to compare PSG with video PSG, and the scorer had access to the complete PSG recording, including electroencephalogram (EEG) and electromyogram (EMG) recordings for other muscle groups, and used this information to distinguish RRMA from other orofacial activities. With use of video PSG, 33% of all masseter muscle EMG activations did not satisfy EMG criteria for RRMA. Of EMG activations that satisfied RRMA EMG criteria, approximately 69% represented other nonbruxism activity. These would have been false-positive identifications if only the masseter EMG activity had been available for scoring (PPV, 0.31). With use of the complete information provided by the PSG recording (with the exception of audio-video), the number of RMMA events was overestimated by only 23.8% relative to that for video PSG–RDC (PPV, 0.81)—a considerable improvement. Misclassification of nonspecific EMG activity, however, was still pronounced for tonic EMG activations: Only 41% of episodes identified without audio-video were indeed "true" RMMA events (PPV, 0.41).

Recording Methods

Surface EMG electrodes placed on masticatory muscles are the key component in assessment of SB activity. The different protocols vary in the selection and number of masticatory muscles, but most include the masseter muscles. Masseter muscles are easily identified by the muscle bulges between the cheekbone and the angle of the jaw during teeth clenching. The registration of other masticatory muscles, such as the temporalis muscle, often is optional but may increase reliability of SB activity identification.[114] Electrode positioning for the temporalis muscle usually is 1 to 2 cm above the zygomatic arch (cheek bone) and 1 to 2 cm behind the outer canthus orbital border (the cavity of the skull in which the eye is situated). The following recommendations have been made concerning the recording of SB activity:

- *ICSD3 recommendations*:[3] Although PSG is not strictly necessary for the diagnosis of SB, when SB activity is to be recorded and scored, the minimal requirement is one masseter muscle recording. Audio-video recording is strongly recommended to exclude nonspecific movements from the scoring of SB activity. For optimal diagnostic specificity and sensitivity, bilateral masseter and temporalis muscle EMG recordings, referenced to ear, mastoid, or zygomatic bone, are advised.
- *AASM criteria*:[1] AASM recommendations refer to in-laboratory PSG with the recommended parameters (EEG, EOG, ECG, EMG, respiration, oxygen saturation, body position), which include EMG of the chin muscles. Scoring rules for SB have been formulated for chin EMG only; the addition of masseter muscle recording is left to the discretion of the clinician. In addition, the audio signal is used to identify SB episodes with teeth grinding sounds.
- *RDC*[106]: Standard PSG with video-audio recording and bilateral masseter EMG is the minimum requirement for the scoring of SB activity according to RDC. The addition of temporalis muscle recording is recommended but not mandatory.[115]
- *Ambulatory recording*: There are no generally accepted recommendations for the ambulatory recording and scoring of SB activity. Currently used recording setups range from a single, unilateral EMG channel[100,112] to ambulatory PSG with additional mmEMG.[104,105]

Scoring Rules

Sleep Bruxism Episodes Scored According to Research Diagnostic Criteria

The scoring of SB activity according to RDC (SB-RDC)[106] involves the following general steps:

1. Identify all masseter muscle activations with mean amplitude above a predefined threshold.
2. Classify the identified EMG activations on the basis of their duration as myoclonic (less than 0.25 second), phasic bursts (0.25 to 2 seconds), or tonic bursts (more than 2 seconds).
3. Use video and audio recording to exclude non–(bruxism)-specific oromandibular activity.
4. Classify the remaining phasic bursts as belonging to a phasic episode if 3 or more phasic bursts are separated by less than 3 seconds; the remaining tonic bursts are considered tonic episodes.
5. Combine phasic and/or tonic episodes to one episode if they are separated by less than 3 seconds.
6. Classify episodes as phasic, tonic (episode with one or more tonic bursts), or mixed (episode with tonic and phasic episodes).
7. Characterize SB episodes regarding the presence or absence of audible teeth grinding sound, as recorded by audio.

These scoring criteria have been widely adopted in research studies. The only major variation concerns mmEMG threshold: In the original publication in 1996,[106] the mmEMG threshold had been set at 20% of background signal during maximal voluntary clenching (MVC) in the wake state. Since then, and based on later studies by the same group of investigators, a modification of this threshold to 10% MVC has been proposed and is generally used.[107,115]

Descriptive summary measures for SB activity include the number of phasic, mixed, tonic, and all SB episodes either as a total number per night or as the number per hour. In addition, the number of bursts per hour and the proportion of SB episodes with audible teeth grinding sound usually are reported.

Rhythmic Masticatory Muscle Activity

The scoring of rhythmic masticatory muscle activity (RMMA)[110] follows the outline described for the scoring of

SB episodes according to RDC, with the exception of two aspects:

- The threshold to identify mmEMG activations is 10% MVC.
- RMMA includes only phasic and mixed SB episodes as defined previously.

Because only approximately 10% to 20% of SB-RDC episodes are classified as tonic episodes,[106,116,117] a large overlap between RMMA and SB-RDC is to be expected. Perhaps because of this overlap, the distinction between RMMA and SB-RDC has become blurred over time, as evidenced by the fact that more and more recent research studies now include the tonic episodes in the scoring of RMMA.[113,118,119] In addition, in research studies, the tendency is to adopt a mmEMG threshold that is twice the background EMG,[113,120] as has been proposed by the AASM rules[1] (see further on).

RMMA usually is reported as the number of RMMA episodes per hour and the percentage of RMMA episodes with audible teeth grinding sound.

Sleep Bruxism Episodes Scored According to AASM Criteria

The AASM has specified scoring rules for bruxism based on chin EMG activity.[1] Bruxism is scored in accordance with the following criteria:

1. Chin EMG elevation is at least twice the amplitude of the background EMG, *and*
2. a. *Either* at least three brief, phasic chin EMG activity elevations (lasting 0.25 to 2 seconds) occur in a regular sequence,
   b. *Or* a sustained, tonic chin EMG activity elevation (lasting longer than 2 seconds) is present.
3. Chin EMG elevations that fit these criteria are counted as one episode when they are separated by less than 3 seconds.

Of note, audio-video recording is not used to exclude nonspecific orofacial movements from the scoring of bruxism episodes. Nevertheless, some use is made of the audio recording, because the manual states that "bruxism can be scored reliably by audio in combination with polysomnography by a minimum of 2 audible teeth grinding episodes/night of polysomnography (section VII.E).[1] Currently, the AASM manual provides no information about the reporting of bruxism activity.

Sleep Bruxism Episodes Described in the Current International Classification of Sleep Disorders

As mentioned previously, according to the ICSD3,[3] PSG documentation of SB activity is not a necessary diagnostic feature. Nevertheless, in the ICSD3 "Objective Findings" paragraph, some features of PSG patient monitoring are described, including minimum standards for recording that include the registration of at least one masseter muscle EMG (see earlier). According to the ICSD3,[3] three EMG patterns of SB episodes are described:

1. a. Phasic activity at 1-Hz frequency with EMG bursts of duration 0.25 to 2 seconds,
   b. Sustained, tonic activity with duration 2 seconds or longer, and
   c. Mixed patterns
2. SB episodes begin after 3 seconds or longer with no muscle activity.

Audio-video recording is recommended to identify teeth grinding sound and to distinguish SB from other orofacial or masticatory movements that normally occur during sleep, and from specific movement disorders.[3]

Sleep Bruxism Activity in Ambulatory Recordings

Currently, no generally accepted or validated criteria are available for the scoring of SB activity in ambulatory recordings without video-audio recording. Consequently, a wide variation in scoring criteria are in current use. Many, however, seem to be inspired either by the RDC formulated for video PSG[106] (see earlier) or by the criteria proposed by Ikeda and colleagues in 1996[101] for the identification of bruxism events based on ambulatory masseter muscle EMG and heart rate. These investigators[101] proposed to score as bruxism those events with the following features:

1. Masseter muscle EMG activity increases greater than 10% MVC for 3 seconds or longer
2. Separated by more than 5 seconds from other events—otherwise, events are combined
3. Accompanied by a change in heart rate greater than 5% over a 5-second period, compared with preevent baseline

A point worthy of emphasis is that these criteria were based almost exclusively on theoretical considerations and have never been empirically validated.

Scoring criteria used in research studies and in commercially available devices differ in the following ways:

- The amplitude thresholds for the identification of mmEMG activations (e.g., greater than 10% MVC[99,102,103,121-123]; greater than 30% MVC[124])
- The duration of identified mmEMG activations (e.g., longer than 0.25 second[99,102,103,121,122]; 0.25 to 2 seconds[125]; longer than 3 seconds[123,124])
- The interval between identified events (e.g., greater than 2 seconds[99]; greater than 3 seconds[121,122]; greater than 5 seconds[123,124])
- The classification[99,102,103,121] or nonclassification[122-124] of mmEMG activations in phasic, tonic, or mixed events

Partly responsible for this variation is the lack of validation studies for ambulatory SB assessment. Because both the gold standard and most ambulatory devices record the same signal, (i.e., mmEMG), measurement reliability per se is not the issue. The mmEMG signal from ambulatory devices has been shown to be in good agreement with the mmEMG signal from ambulatory or in-laboratory mmEMG. The main concern in validating ambulatory SB assessments is the lack of video-audio recording, with the probable misclassification of many mmEMG activations as SB episodes (see earlier). Two basic approaches to this dilemma can be postulated. In one approach, a direct comparison between the events identified by ambulatory assessments with the events identified by the gold standard, which includes video observation and a demonstration of adequate specificity in the identification. Several attempts have been made to develop automated classifiers that recognize different oromandibular movements from the EMG signal alone and could therefore distinguish between SB and nonspecific movements. So far, however, these have been tested with only simulated movements during wakefulness.[100,126-131] The second approach would be the validation of criteria that are specific to ambulatory assessments and take the lack of specificity into account. Such a validation study would establish

the sensitivity and specificity of new diagnostic criteria in distinguishing between healthy subjects and patients with SB, previously diagnosed according to the gold standard.

Research Diagnostic Criteria

Currently, only research diagnostic criteria are available for the identification of patients with moderate to severe SB.[106] In the pivotal study by Lavigne and coworkers,[106] using the RDC scoring criteria detailed earlier, various parameters of SB activity were assessed in 18 healthy sleepers and in 18 patients with moderate to severe SB. By considering sensitivity and specificity of different combinations and cutoff values, the following criteria were identified:

A + (B1 or B2 or C or D)

with:

A indicating 2 or more bruxism episodes with teeth grinding sounds/night
B1, >30 episodes/night
B2, >4 episodes/hour
C, >6 bursts/episode
D, >25 bursts/hour

The combination of criterion A with any one of the other criteria—B1, B2, C, or D—had a positive predictive value (PPV) (i.e., the probability that a subject identified with these criteria does indeed have SB) between 93% and 100% and a negative predictive value (NPV) (i.e., the probability that in a subject identified as not meeting the criteria for-SB, tooth grinding activity does not in fact occur) between 76% and 93%.[106] These criteria have been widely adopted[107]; over time, however, the most used and recommended combination of criteria is A + (B2 or D).[107,115]

The ability of these criteria to discriminate between patients with SB and healthy sleepers has recently been evaluated in a larger sample of 100 patients diagnosed with SB and 43 healthy sleepers.[116] The recording and scoring of SB activity were identical in both studies, with two critical differences: First, although general inclusion and exclusion criteria were identical, the original study included patients with SB who reported the nocturnal teeth grinding sounds at least 5 times per week during the last 6 months; by contrast, the other study included patients with SB reporting nocturnal teeth grinding sounds at least 3 times per week during the last 6 months—that is, with a wider spectrum of SB frequency. In addition, the diagnostic criteria employed in the study were any two of the following three: (A) two or more bruxism episodes with teeth grinding sounds per night, (B2) more than 4 episodes/hour, and (D) more than 25 bursts/hour, that is, different from the original study criterion (A) was no longer mandatory. With these modifications, only 54 of 100 patients with SB fulfilled the RDC criteria for SB, as did 9 of 43 healthy sleepers. Consequently, the sensitivity of the RDC was only 54% (PPV, 86%) and the specificity was 79% (NPV, 42%). These results emphasize the continued need for large and systematic studies in this field.

Unresolved Issues

The major unresolved issue in the recording of SB is currently the scoring without the availability of video-audio recording. As detailed earlier, nonexclusion of unspecific orofacial movements will considerably overestimate SB activity. In addition, diagnostic criteria include the observation of episodes with teeth grinding sounds, which also are not confirmable without at least audio recording.

Other issues concern the diagnostic criteria, which may lack sensitivity or specificity when applied with variations, and the inconsistent scoring of RMMA.

RHYTHMIC MOVEMENT DISORDER

Rhythmic movement disorder (RMD) is characterized by stereotypical rhythmic body movements occurring predominantly during sleep or drowsiness before sleep, which may involve the head, neck, trunk, or limbs in isolation or in combination. The criteria for scoring RMD are based on their PSG features[1]: frequency of 0.5 to 2.0 Hz; presence of at least four single movements, as required to form a rhythmic cluster; and a minimum amplitude for a single rhythmic movement that is twice the background EMG activity. In healthy infants or young children, the movements and behaviors frequently are self-limited and are called "benign rhythmic movements of sleep," to distinguish them from RMD[132]; however, no strict quantitative threshold has been established. The duration of rhythmic movement episodes may vary, ranging from some seconds to several minutes, and can be observed as well during wakefulness preceding sleep or after sleep onset. The most common pattern of RMD involves the head (head banging, or *jactatio capitis nocturna,* and head rolling), but also the body (body rocking) or occasionally the legs (leg rolling or leg banging) can be involved. The clinical diagnosis can be based on anamnesis, sometimes supported by homemade video recording; however, video PSG is useful in doubtful cases and allows definition of the type and site of movements. Additional EEG and EMG leads, in particular on the limbs, may help to distinguish RMD from other sleep-related repetitive movements (e.g., PLMS, ALMA) or motor seizures.

PROPRIOSPINAL MYOCLONUS

Propriospinal myoclonus (PSM) at sleep onset[133,134] is characterized by generalized and symmetric jerks, occurring at the wake-sleep transition, starting from the axial muscles of the abdomen, thorax, or neck and then spreading rostrally and caudally to the other myotomes by means of slow propriospinal polysynaptic pathways.[135] PSM is facilitated by relaxed wakefulness or drowsiness and inhibited by mental activation and sleep deepening. In PSM, there is no urge to move; however, the frequently repeated (but not periodic) jerks prevent the patient from falling asleep and reaching a deeper sleep stage, when the jerks disappear. No accepted quantitative PSG features have been documented for PSM, and its description is basically qualitative.

BENIGN SLEEP MYOCLONUS OF INFANCY

Benign sleep myoclonus of infancy (BSMI) is characterized by repetitive myoclonic jerks that occur during sleep in neonates and infants.[3] Its diagnostic features include the observation of repetitive myoclonic jerks involving limbs, trunk, or whole body. This movements occur only during sleep and stop abruptly and consistently when the infant is aroused. BSMI occurs in early infancy, typically from birth to 6 months of age.

Standardized scoring criteria for BSMI are lacking, but the muscle jerks last between 0.04 to 0.3 second and occur usually in clusters of 4 to 5 jerks per second.[3,136] These clusters may repeat in irregular series for 1 to 15 minutes, and in rare cases up to 60 minutes. The jerks often are bilateral and typically involve large muscle groups. BSMI is benign and relatively rare, but it has been included in the ICSD3 as a sleep-related movement disorder because it often is confused with epilepsy.[3]

MISCELLANEA

Excessive Fragmentary Myoclonus

Excessive fragmentary myoclonus (EFM)[137-139] is characterized by small EMG activations, not always corresponding with movements (twitches), of the fingers, toes, or corners of the mouth, resembling either physiologic hypnic myoclonus or fasciculations, occurring at the sleep-wake transition or during sleep. PSG recordings show recurrent and persistent, very brief (75 to 150 milliseconds) EMG bursts in various muscles, occurring asynchronously and asymmetrically, in a sustained manner, without clustering. The PSG criteria for scoring EFM are as follows: EMG burst duration usually is 150 milliseconds or less; EFM must be present in at least 20 minutes of NREM sleep; and at least 5 EMG potentials per minute must be recorded.[1] Regarding quantification, it has been proposed to quantify EFM rate as the number of EMG potentials of 150 milliseconds or less divided by the minutes of sleep.[139] Alternatively, a *myoclonus index* has been proposed by Lin and coworkers[140]; this index is defined as the number of 3-second mini-epochs containing at least one fragmentary myoclonus potential fulfilling the criteria, counted for each 30-second epoch, with totals ranging between 0 and 10. A mean fragmentary myoclonus index of 39.5 events per hour of sleep has been reported in patients with sleep disorders, and this index increased with age, was higher in men than in women, and was influenced by the presence of sleep breathing disorders.[141] The male predominance was recently confirmed in a large, well-screened sample of healthy sleepers.[93] Some fragmentary myoclonus was observed in all participants, however, and 9% even fulfilled criteria for EFM, suggesting that the criteria for quantification of EFM may benefit from an appropriate statistical revision.

Neck Myoclonus (during Sleep)

Neck myoclonus (head jerks) during REM sleep has been described in recent years[142] and is recognized by presence of a characteristic high-amplitude, short ("stripe-shaped") movement-induced artifact over the EEG lead signals that is verified in the video recording, which shows sudden myoclonic twitches of the head of variable intensity. It seems to be a frequent finding on routine PSG, being present in more than 50% of patients, but with a low frequency during the night (1 ± 2.7 events per hour of REM sleep) and an age-related decline. Neck myoclonus has been observed in 35% of healthy subjects, with variable frequency,[93] suggesting that it constitutes a physiologic phenomenon.

Other Leg Movements during Sleep

Alternating leg muscle activation (ALMA) indicates a rapidly alternating (frequency, 0.5 to 3 Hz) pattern of anterior tibialis activation (duration, 100 to 500 milliseconds) occurring during sleep, organized in sequences of at least 4 alternating activations,[1] lasting up to 20 to 30 seconds. ALMA can occur in all sleep stages but is seen particularly during arousals.[143,144] It is not yet clear whether ALMA is a separate nosologic entity or whether it belongs to the wide spectrum of nocturnal motor activities of RLS.

Hypnagogic foot tremor (HFT)[145,146] is a clinical condition similar to ALMA, with foot movements occurring at the transition between wake and sleep or during light sleep. PSG recordings show repeated short EMG potentials, typically at 1 to 2 Hz (range, 0.3 to 4Hz), in one or both feet, in sequences of at least 4.[32] The EMG events appear to be of longer duration than myoclonus (more than 250 milliseconds) and usually last less than 1 second; moreover, they are organized in trains lasting 10 or more seconds.[3]

The term *high-frequency leg movements* (HFLMs) has been proposed more recently for a phenomenon similar to both ALMA and HFT.[147] It was defined as a sequence of 4 or more short leg movements occurring, unilaterally but sometimes bilaterally, at a frequency of 0.3 to 4 Hz. Most HFLMs are observed during wakefulness, with only approximately one third occcurring during sleep. Thus far, no clear criteria have been established to score this phenomenon.

ALMA, HFT, and HFLMs are very similar phenomena of small or short EMG activations of the feet and legs: They all occur at sleep onset and are correlated with arousals, and they usually occur in trains. It is not clear yet if these phenomena are really separate entities or if they constitute slightly different definitions of the same condition; moreover, it is not yet established to what extent they are correlated with PLMS and/or RLS. In addition, it is unknown whether these are simple, physiologic phenomena or have any pathophysiologic significance. A case in favor of the first possibility is the observation that HFLMs have been found in 33% of well-screened, healthy sleepers.[93]

CLINICAL PEARLS

- Video polysomnography is the gold standard for recording and scoring sleep-related movements.
- For many sleep-related movements, more than one system of criteria or definitions exist. It is therefore essential to specify which scoring rules are applied.
- Scoring rules may and do change over time. In particular, those of the AASM are continuously reviewed and updated on the basis of new clinical evidence or advances in technology.
- The current *International Classification of Sleep Disorders* (ICSD-3) refers to the manual of the American Academy of Sleep Medicine (AASM) for the definition of sleep-related movements.

SUMMARY AND FUTURE DIRECTIONS

As reviewed in this chapter, a variety of clinical and research recording and scoring techniques have been applied to define, quantify, or diagnose sleep-related movements. By now, the use of computers and digital recordings is standard in sleep medicine and research. This approach offers numerous advantages, among them the precise measurement of sleep-related movement events. Many criteria to visually detect and measure motor events during sleep were introduced during the "paper era" of sleep medicine and continue to be the basis of the current rules. With the easy availability of very powerful

computers nowadays, it could be expected that such criteria would have become obsolete and substituted by more modern approaches that take full advantage of the digital possibilities. Nevertheless, many old rules still pervade the field and often are used with a simple transposition from the paper to the screen. The adoption of new approaches based on more quantitative and data-driven methods has been slow. The necessary programs and independent validations are prerequisite to effect change. In view of the strengths (e.g., objectivity and precision) of the new approaches, however, they can be expected to gradually enhance and ultimately replace many of the scoring techniques presented in this chapter.

Chapter 169

Evaluating Sleepiness

Max Hirshkowitz; Amir Sharafkhaneh

Chapter Highlights

- Evaluating sleepiness presents a difficult task for clinicians. Although sleepiness generally is regarded as an introspectively judged sensation, sleepiness assessment also must consider physiologic sleep drive and behavioral manifestations.
- Common methods used to assess introspective, physiologic, and manifest sleepiness include self-administered questionnaires, the Multiple Sleep Latency Test, the Maintenance of Wakefulness Test, the Epworth Sleepiness Scale and vigilance testing.
- Practical issues emerge in evaluating sleepiness in the regulatory, legal, and adjudication arenas. These include establishing the goal of testing, recognizing the specific purpose of a test, interpreting results, and considering safety and on-the-job performance.

OVERVIEW

Sleepiness is a sensation. Much like hunger and thirst, sleepiness occurs naturally as a physiologic drive informing the behavioral system about a presumed biologic need. Sleepiness naturally occurs at night, after prolonged wakefulness (sleep deprivation), or in response to rapid translocation across time zones. However, sleepiness also can arise from medical, neurologic, or psychiatric disorders. Many drugs also can provoke sleepiness, either by stimulating sleep-inducing mechanisms or by inhibiting wake-promoting brain centers.

Sleepiness (and wakefulness, for that matter) represents the composite output of different neurologic systems producing wakefulness and those generating sleep. Thus sleepiness reflects a dynamic balance between systems with opposing functions. When an increased physiologic drive to sleep begins to overwhelm the alerting system's ability to stave off that drive, sleepiness becomes excessive. The affected person, however, may or may not sense being sleepy.

Nonetheless, when excessive, drowsiness poses a potential hazard. The danger affects not only the drowsy person but possibly also family members, coworkers, and society at large. Excessive sleepiness during driving and work activities can constitute a serious, potentially life-threatening condition. When sleepiness surpasses the affected person's ability to maintain vigilance, response slowing, response lapsing, and transition into sleep can occur. This level of drowsiness constitutes dangerous sleepiness.

The focus of this chapter is on clinical assessment for sleepiness. Accordingly, three measurement issues merit special attention: problems associated with self-report; the need for normative-adjusted measures; and whether a particular measurement is appropriate given the circumstance.

In the clinical environment, the most common tool for assessing sleepiness involves self-report. Self-reported sleepiness can be ascertained easily and inexpensively. Multiple factors, however, compromise the reliability and validity of self-report measures. Some people stoically minimize their symptoms, whereas others tend to exaggerate. Both primary and/or secondary gain may color symptom self-disclosure (e.g., a person may deny sleepiness to avoid losing a motor vehicle license necessary for employment). Finally, sleepiness can influence self-perception of sleepiness.

Useful clinical measures usually require standardization to facilitate comparison with normative values. Unfortunately, many sleepiness measures can reliably detect changes in before-and-after experimental designs but not the differences from one subject to another. Consequently, although a measure can provide a superb metric for assessing change, it may fail miserably for determining whether a specific patient presenting for evaluation is sleepy.

The third measurement issue addresses metric validation. The commonly used term *excessive daytime sleepiness* underscores this point. Normative values for most sleepiness metrics rely mainly on data collected during the day. When clinical necessity requires nighttime assessment (e.g., in shift workers), the choices of validated instruments are limited. In other words, how sleepy must the subject be for sleepiness to be considered *abnormal* at 4:00 AM? or to be considered *excessive* at 4:00 AM? or to be considered *dangerous* at 4:00 AM? Although answers to these three questions may not differ at noon, they are likely to differ at 4:00 AM!

Carskadon and Dement[1] proposed a useful conceptualization for characterizing sleepiness. They considered sleepiness along three dimensions: introspective, physiologic, and manifest. *Introspective* sleepiness (when unbiased by a person's motives) derives from an individual self-reported assessment of his or her internal state. *Physiologic* sleepiness refers to the underlying biological drive to sleep; indexed by the speed with which a person falls asleep. *Manifest* sleepiness includes behavioral signs of sleepiness, inability to volitionally remain awake, and performance deficit on psychomotor or cognitive tasks. In theory, manifest sleepiness occurs when sleep drive overwhelms the system that maintains wakefulness.

The Carskadon-Dement model provides an organizational device for understanding differences between sleepiness measures. If sleepiness were a single measurable core phenomenon, rather than a composite output of multiple sleep and alertness mechanisms, one might expect equivalence between measures. However, different tests for sleepiness often produce varying results because they index quite different (although related) phenomena. The best concordance usually emerges at the sleepiness-wakefulness spectrum's extremes. That is, when all sleepiness dimensions are at nadir (no sleepiness) or when sleepiness reaches its zenith (maximum sleepiness), all measures usually agree. Thus, most of the time it is illogical to use physiologic, manifest, and introspective sleepiness measures interchangeably; it also misses the important differences between them.

INTROSPECTIVE SLEEPINESS

Introspective sleepiness is measured using self-administered questionnaires. In this section we describe the most commonly used clinical and research instruments. Some of these questionnaires request subjects to predict their own behavior (e.g., "How likely are you to doze off when . . . ?") or to judge their perceived symptoms over some time interval in the recent past (e.g., in the past month). By contrast, other instruments involve *momentary assessment* and query the person about how he or she feels right now. In general, questionnaires evaluating longer time domains (e.g., in the past month) are more useful clinically than those using momentary assessment. By contrast, momentary assessment instruments are more sensitive to variations in the level of sleepiness, making them more useful for investigating circadian oscillation or drug-induced alterations in sleepiness.

Ultimately, introspective sleepiness relies on self-report. In one respect, self-report constitutes the only means by which it is possible to know how another person feels. Self-disclosed information, however, is modified by individual ability to recognize internal states, memory, tendency to minimize or exaggerate feelings, capacity for honesty, and any underlying agenda.

Epworth Sleepiness Scale

The Epworth Sleepiness Scale (ESS) is the most widely used clinical instrument for evaluating sleepiness. This specialized, validated, eight-item, pencil-and-paper instrument was developed by Murray Johns at the Epworth Hospital in Melbourne, Australia.[2] The ESS questions subjects about their expectation of "dozing" in differing circumstances. Dozing probability is designated as none (0), slight (1), moderate (2), or high (3) for eight hypothetical situations, as shown in Table 169-1.

The popularity of the ESS stems in part from its simplicity, brevity, and validation. Johns established reliability and validity using 54 patients with sleep apnea (before and after continuous positive airway pressure therapy) and 104 medical students.[3,4] Student control subjects had a mean score of 7.6, compared with 14.3 at baseline for patients with sleep apnea. After treatment, the mean score for patients with sleep apnea declined to 7.4. In another study, normative values were gathered from 942 patients waiting at outpatient clinics (e.g., dermatology, audiology, and ophthalmology clinics) and 1120 healthy people attending health fairs or community health lectures. The mean ESS total scores for these two groups were 8.1 and 5.2, respectively.[5] On the basis of this study and subsequent work in our clinic, we have categorized ESS scores ranging from 0 to 8 as normal, 9 to 12 as mild, 13 to 16 as moderate, and greater than 16 (double that of high normal) as severe.

Table 169-1 Epworth Sleepiness Scale Items

Question	Hypothetical Situation to Be Rated
1	Sitting and reading
2	Watching television
3	Sitting inactive in a public place (e.g., a theater or a meeting)
4	As a passenger in a car for an hour without a break
5	Lying down to rest in the afternoon when circumstances permit
6	Sitting and talking to someone
7	Sitting quietly after a lunch without alcohol
8	In a car, while stopped for a few minutes in traffic

The ESS differs from other tests in that respondents are not asked about how they feel but rather to make a probability judgment about their own behavior. Thus the ESS asks subjects to rate their own sleep drive; this may explain why ESS results correlate (albeit weakly) with Multiple Sleep Latency Test (MSLT)-determined sleep latency (an objective index of sleep drive). The ESS's main disadvantage is its questionable utility when it is readministered within a brief time interval.

Stanford Sleepiness Scale and Karolinska Sleepiness Scale

For many years, the Stanford Sleepiness Scale (SSS) served as the standard measure of introspective sleepiness.[6] Persons taking the SSS test choose one of seven statements to describe their self-assessed current state (choices are shown in Table 169-2). The SSS is a momentary assessment scale and can detect sleepiness as it waxes and wanes over the course of a day. Advantages include its brevity, its ease of administration, and its ability to be administered repeatedly. Experimentally induced sleep deprivation increases SSS scores; however, normative data do not exist, making it difficult to use for clinical decision making or comparisons between persons.

The Karolinska Sleepiness Scale (KSS) is quite similar to the SSS and consists of a nine-point scale ranging from 1, "very alert," to 9, "very sleepy, great effort to stay awake or fighting sleep." Scores of 7 or above are considered pathologic. The KSS has become increasingly popular for evaluating sleepiness in drug trial participants, flight crews, oil-rig workers, train engineers, and professional drivers. Its brevity, validation against EEG and behavioral parameters,[7] and its now-proven sensitivity to sleepiness put KSS on equal footing with the SSS.

Sleepiness-Wakefulness Inability and Fatigue Test

The Sleepiness-Wakefulness Inability and Fatigue Test (SWIFT) is a 12-item self-administered questionnaire

Table 169-2 Stanford Sleepiness Scale Items

Code	Scale Description Statement
1	Feeling active and vital, alert, wide awake
2	Functioning at a high level, but not at peak, able to concentrate
3	Relaxed, awake, not at full alertness, responsive
4	A little foggy, not at peak, let down
5	Foggy, beginning to lose interest in remaining awake, slowed down
6	Sleepy, prefer to be lying down, fighting sleep, woozy
7	Almost in reverie, sleep onset soon, lost struggle to remain awake

validated against the Epworth scale in normal subjects, patients with sleep-disordered breathing, and persons with narcolepsy.[8] The test asks how much of a problem the person has staying awake or how much of a problem he or she has with fatigue, tiredness, or lack of energy (i.e., "not at all," "just a little," "pretty much," "very much"). Six items focus on sleepiness (generally during the day, while driving, while stopped at a traffic light, while at work or while doing other daily tasks, while reading, in social situations) and six on fatigue (generally during the day, while driving, while at work or doing tasks, while reading or studying, in social situations, and when doing tasks that are not urgent). A validation study found good internal consistency (0.87), retest reliability (0.82), and criterion group differentiation (control subjects versus patients with sleep disorder). The SWIFT shows great promise, but clinical use would benefit from normative values establishment and further validation.

Pictorial Sleepiness Scale

Maldonado and colleagues[9] developed a nonverbal sleepiness scale for testing young children and poorly educated adults. They had subjects rank-order seven cartoon faces depicting sleepiness. Rankings were transformed to approximate linearity, and two cartoons were eliminated. The resulting five-picture scale was re-ranked by a different group of subjects to verify order for a final scale. Finally, a validation test indicated significant correlation with KSS and SSS scoring using a mix of normal adults, patients with sleep apnea, shift workers, and school-aged children. Whether this pictorial sleepiness scale will gain popularity remains to be seen.

Profile of Mood States

Although principally designed to assess mood, the Profile of Mood States (POMS) has often been used in sleep research.[10] Originally, the POMS was to include a dimension for sleepiness; however, the "sleepiness" proved to be nonindependent and was therefore eliminated. The "sleepiness" items loaded negatively on the Vigor scale and positively on the Fatigue and Confusion scales. To a lesser extent, sleepiness also emerged on Depression and Anger scales. The Confusion scale elevates more in response to severe sleepiness and the Vigor scale appears sensitive to partial sleep deprivation.[11]

Thus, early on, psychometricians found sleepiness to be a composite measure—a measurement difficulty that persists, because some researchers heedlessly view sleepiness as a unitary factor.

PHYSIOLOGIC SLEEPINESS

Multiple Sleep Latency Test

The feeling people refer to as "sleepiness" can be conceptualized as arising from a physiologic drive. One could therefore use the rapidity with which a person falls asleep to represent the drive's intensity. This relationship between sleepiness and sleep onset provides the foundation for the MSLT.[12] The MSLT provides nap opportunities across the day and indexes physiologic sleep drive with mean sleep latencies. Sleep deprivation hastens sleep onset (decreases sleep latency) when opportunity to sleep occurs. In a series of elegant studies, increased sleep drive provoked by aging, total sleep deprivation, partial sleep deprivation, and disorders of excessive somnolence were well characterized by MSLT-determined sleep latency.[13-15] Data relating homeostatic influences and sleepiness derive directly from MSLT studies.[16] Circadian influence also manifests as shorter MSLT latencies on midafternoon test sessions.

Methodology

The MSLT provides a widely used technique to scientifically assess physiologic sleep drive. In its traditional form, the MSLT involves a series of nap opportunities (four to six) presented at 2-hour intervals beginning approximately 2 hours after initial (morning) awakening (for details, see the report by Carskadon and associates[17]). To establish the prior night's sleep quantity and quality, the patient undergoes attended laboratory polysomnography the night before testing. A careful history of sleep habits, schedule, and drug use in the past month is essential (a sleep diary should be obtained). A clinical MSLT should not be conducted during drug withdrawal (especially from stimulants or from medications that suppress REM sleep), while sedating medications are pharmacologically active, or after a night of profoundly disturbed sleep.

Persons undergoing an MSLT are instructed to allow themselves to fall asleep or to not to resist falling asleep. Subjects are tested under standardized conditions in their street clothes and are not permitted to remain in bed between nap test sessions. Similarly, subjects should not engage in vigorous activity before nap opportunities, because this can alter test results.[18]

Obtaining reliable results depends critically on using standardized test conditions and techniques.[19] Sleep rooms must be dark and quiet during testing. Electroencephalographic (EEG; central and occipital), electrooculographic (EOG; left and right eye), and electromyographic (EMG; submentalis) recordings are used to recognize sleep onset and distinguish between sleep stages. MSLT guidelines also call for monitoring respiratory flow and sounds in patients known to snore (Box 169-1).

Two protocols exist for conducting the MSLT—one designed for research and the other for clinical assessment (Figure 169-1). The research protocol minimizes accumulated sleep by awakening the person when unequivocal sleep onset occurs. To meet criteria for unequivocal sleep, one of the

following must occur: (1) three consecutive 30-second epochs of stage N1 sleep or (2) a single 30-second epoch of stage N2, N3, or R (rapid eye movement [REM]). By contrast, the clinical MSLT protocol continues for 15 minutes after sleep onset occurs. The clinical MSLT attempts not only to index sleep drive but also to detect abnormally increased REM sleep tendency. Increased REM sleep tendency characterizes narcolepsy, and the added sleep time provides diagnostic information. Table 169-3 illustrates MSLT reliability in distinguishing patients with narcolepsy from control subjects on the basis of whether REM sleep occurred. Documentation of short sleep latency and REM sleep on two or more MSLT nap recordings confirms the diagnosis, especially in patients with cataplexy, sleep paralysis, or hypnagogia (or hypnapompia).

Table 169-3 Multiple Sleep Latency Test: Example Results

Parameter	Patients with Narcolepsy	Control Subjects
N (male/female)	57 (33/24)	17 (6/11)
Age (SD) in years	43.3 (12.3)	33.4 (9.9)
Percent who slept	99.0	63.5
Sleep latency mean (SD)	3.0 (2.7)	13.4 (4.0)
Minimum	0.6	4.8
Maximum	14.1	20
REM score	3.5	0

REM, Rapid eye movement (sleep).

In both the research and clinical versions of the MSLT, the test session is terminated after 20 minutes if no sleep onset occurs. Sleep latency is defined as the elapsed time from the start of the test to the first 30-second epoch scored as sleep. Sleep latency in normal adult control subjects ranges from 10 to 20 minutes. Traditionally, clinicians classified mean sleep latency on the MSLT of 5 minutes or less as highly pathologic sleepiness.[20] The *International Classification of Sleep Disorders* considers values of 8 or less to indicate sleepiness for diagnostic purposes.[21]

Utility

The MSLT can objectively document treatment response[22] and residual physiologic sleep drive[23] in patients independent of whether they self-reported sleepiness after treatment. The sensitivity of the MSLT to physiologic sleepiness makes it especially useful for detecting persistent sleepiness in patients with occult comorbid sleep disorders, ineffective treatment, poor adherence to a therapeutic regimen, or concomitant soporific medication.

As a technique to demonstrate a person's underlying sleepiness, the MSLT has the advantage of being a direct, objective, quantitative approach. It is generally thought that under normal circumstances, nonsleepy persons cannot make themselves fall asleep. By contrast, a sleepy person (if not overwhelmingly sleepy) can remain awake. Thus false-positive tests (MSLT-indicated sleepiness when the person is not sleepy) are theoretically minimal. Polysomnography documents the previous night's sleep quality and quantity, and if significant sleep disruption or disturbance has occurred, the MSLT should be rescheduled. Drug screening helps rule out pharmacologically induced sleepiness. The availability of a specific numerical criterion for characterizing pathologic sleepiness made the MSLT the standard modality for assessing sleepiness for many years.

Clinical Standards of Practice

In 2005, the American Academy of Sleep Medicine (AASM) published revised clinical practice parameters for the MSLT's clinical use.[24] Clinical standards, guidelines, and options were derived from a comprehensive evidence-based medicine review and a systematic protocol for expert consensus.[25] The conclusions can be summarized as follows:

- The MSLT is indicated as part of the clinical evaluation for patients with suspected narcolepsy.

- The MSLT may be helpful for clinical assessment of patients with suspected idiopathic hypersomnia.
- The MSLT is not indicated for routine evaluation of obstructive sleep apnea.
- The MSLT is not indicated for routine reevaluation of patients with sleep apnea treated with positive airway pressure therapy.
- The MSLT is not indicated for routine clinical assessment of insomnia, circadian rhythm disorders, or dyssomnia associated with medical, psychiatric, or neurologic disorders (other than narcolepsy and idiopathic hypersomnia).

Other Measures of Physiologic Sleepiness

Pupillography

Pupil stability and size are affected by exposure to light and by the level of nervous system arousal. In a darkened room, the pupil dilates to improve vision by widening the aperture and allowing more light to enter the eye. However, if the person begins to fall asleep, parasympathetic activation constricts pupillary diameter. Sleepiness also provokes pupil size instability and alters the magnitude and speed of pupillary constriction in response to a flash of light. These alterations reflect the autonomic nervous system balance changes associated with sleep and wakefulness.

Several researchers used pupillography to measure sleep tendency and evaluate narcolepsy.[26] Advanced mathematical techniques provide within-subject differentiation of sleepiness versus alertness using the spectral F-test.[27] Although pupillography would seem to be an attractive approach to objectively measure sleep drive, several barriers continue to impede its clinical utility. First, the procedure is not easily mastered. Second, it remains difficult to compare one patient with another and to designate a clinical numeric threshold for sleepiness. Finally, normative data are not currently available. Research continues on the development of this technique.[28]

Electroencephalography

Quantitative digital EEG analyses seems an obvious approach for assessing central nervous system arousal level. In essence, the MSLT uses the EEG (in conjunction with the EOG and the EMG) to quantify sleep onset from which sleep drive is deduced. It would therefore seem reasonable to expect subtle EEG waveform patterns (microarchitecture) to characterize physiologic sleepiness. Just before sleep onset, alpha frequency decreases and its amplitude increases. Additionally, it has long been thought that EEG delta activity might index sleepiness, because it increases in response to experimental sleep deprivation.[29] Fatigue-related differences, especially in alpha and theta EEG bandwidths are reported.[30] Some researchers believe the EEG cipher lies not in examining resting EEG spectral content but rather in assessing EEG responsiveness to sensory input. If sleepiness alters neurologic reactivity, ongoing task-related EEG changes or event-related potential alterations might better index physiologic sleepiness. Some recent work following this approach focuses on drowsy driving. The "B-Alert X10" system examines EEG power spectral densities recorded at frontal, central, parietal, and occipital scalp sites.[31] The study investigators replicated previous findings and found within-subject EEG indices associated with fatigue.

Although these approaches hold promise for within-subject comparison, the normative data limit their clinical application. The high degree of between-subject variation makes it difficult to compare results between individual subjects. Finally, techniques are not standardized, and many use proprietary algorithms that are declared as trade secrets.

MANIFEST SLEEPINESS

Manifest sleepiness encompasses observable signs and measurable behavior indicating that the person is either sleepy or about to fall asleep, is in the process of falling asleep, or has fallen asleep. Observable signs can include yawning, ptosis (upper eyelid drooping), and head bobbing. Of interest, continuous observation may actually be more sensitive than current EEG measures. Several investigators found EEG measures to be less predictive of task-related performance lapses than video recordings showing eyelid drooping and closure.[32] Manifest drowsiness signs, however, are not specific to sleepiness; for example, ptosis may be neurogenic (as in oculomotor nerve palsy) or myotonic (as in myasthenia gravis), and head bobbing can signify cysts in the third ventricle. By contrast, EEG-EOG-EMG polysomnographic recordings can objectively determine if the person is falling, or has fallen, asleep during a controlled test session. This determination provides the basis for the Maintenance of Wakefulness Test (MWT).

Maintenance of Wakefulness Test

The procedures for conducting the MWT are similar to those used for the MSLT.[24-25] The most significant difference is that rather than instructing the subject to not resist sleep, the examiner instructs the subject to attempt to remain awake. In this manner, the MWT is used to assess a person's capability to, as the name implies, maintain wakefulness. The subject's task is to resist being overwhelmed by sleepiness. To a large extent, the MWT evaluates the magnitude of sleepiness in relationship to the underlying wakefulness system's functioning. If the wakefulness system fails, sleepiness becomes manifest. This laboratory situation parallels circumstances in which sleep onset occurs inadvertently while the person remains passively sedentary in a nonstimulating environment. The MWT gauges the potential threat of inappropriately and nonvolitionally lapsing into sleep—that is, dangerous sleepiness.

Potentially identifying dangerous sleepiness has attracted the attention of regulatory agencies. With growing interest in sleepiness and public safety, the demand for tests to assess sleepiness has increased. Indeed, the Federal Aviation Administration recognizes the MWT as a means to determine whether noncommercial pilots may be licensed after treatment for sleep apnea.[33] Trucking companies and safety officers for companies with high-risk processes are beginning to follow suit, especially as the liability for and financial costs of accidents increase. MSLT and the MWT findings, however, do not correlate well with self-reported sleepiness.[34-35] Patients who fall asleep when not resisting the sleep drive (as on the MSLT) may be able to remain awake during the MWT.

Methodology

In the MWT, the subject's only task is to remain awake. The subject sits in a dimly lit but not totally darkened room. Dressed in street clothing and situated reclining on the bed with a bolster pillow, the subject is not permitted to read, watch television, or engage in other activities. During testing,

EEG, EOG, and EMG are recorded. As with the MSLT, test sessions are scheduled at 2-hour intervals, beginning approximately 2 hours after awakening from the previous night's sleep. Test sessions are terminated when unequivocal sleep occurs (i.e., either three consecutive 30-second epochs of N1 or a single 30-second epoch of N2, N2, or REM sleep).

Sleep latency for each test session, regardless of unequivocal sleep determination, is determined by the first epoch of sleep. The average sleep latency across the four test sessions provides the primary index. The recording also may be evaluated for microsleep (3- to 10-second) occurrences. As expected, studies comparing the MWT and the MSLT find longer mean sleep latencies when subjects are instructed to remain awake than when they are told not to resist sleep. Unlike with the MSLT, a prior night sleep study is not required, because if a subject successfully maintains wakefulness, how he or she slept the night before is moot. However, an important factor involves stimulant use. Consequently, caffeine consumption is restricted on the MWT (and MSLT) test day. Urinalysis and/or blood chemistry also may be required.

For many years, the MWT lacked standardization. Researchers and clinicians used various protocols. The MWT test session duration ranged from 20 to 60 minutes, with the longer tests attempting to avoid ceiling effects. An additional issue for clinical MWT interpretation stemmed from an absence of normative data. Fortunately, however, this situation has changed.[36] Normative data gathered by a consortium of sleep disorders centers established a range for expected values. The raw data from this project were provided for additional analysis by the AASM Standards of Practice Committee. The results enabled MWT to ascend to the status of preferred clinical tool for objectively indexing alertness.

Studies demonstrate MWT clinical utility for evaluating treatment outcomes in patients with narcolepsy and sleep-related breathing disorders. Also, MWT measures can detect improvement in treated patients with persistent MSLT-indexed sleep drive; thus MWT can extend sensitivity range for multiple sleep latency testing.[37] Nonetheless, MWT changes induced varying amounts of sleep deprivation, age, time of testing, and drugs remain grist for researchers' mills.

Standards of Practice Parameters

The AASM developed MWT clinical practice parameters and based standards on an evidence-based literature review[25-26] and expert consensus (when data were inadequate). MWT testing is indicated for clinical assessment of persons whose inability to remain alert constitutes a personal or public safety hazard. Another indicated use includes determining pharmacotherapeutic response in patients with narcolepsy or idiopathic hypersomnia. Clinicians are cautioned that although falling asleep rapidly during an MWT logically would seem to be a powerful indicator for dangerous sleepiness, direct evidence linking MWT sleep latency to real-world accidents is largely lacking. Thus clinical evaluation must integrate MWT findings with signs and symptoms, history, and treatment adherence.

Specific recommendations include conducting four 40-minute trials. Based on statistical analysis of normative data, a mean sleep latency less than 8 minutes is abnormal. Scores between 8 and 40 (the maximum value) are of uncertain significance. The mean sleep latency for presumed-normal volunteer subjects was 30.4 minutes. The ability to remain awake for the entire 40 minutes on all four test sessions (which is the upper limit of the 95% confidence interval) provides the strongest evidence for normal alertness. Nonetheless, clinical judgment is critical because even completely normal values do not guarantee safety.

Vigilance Tests

Response slowing and lapsing during vigilance tests also offer evidence for the consequence of sleepiness, inattention, or both.[38] Therefore a variety of tests requiring simple psychomotor responding (i.e., signal detection reaction time tasks) can index a sleep drive manifestation. Such assessments are called "vigilance tests" because they evaluate the person's ability to remain heedfully vigilant. Typically (but not always), these tests attempt to mimic the tedious, palling situation of watching for blips on a radar screen or for ships on the horizon.[39] Loss of vigilance, when faced with a nonstimulating task, is particularly relevant for patients with disorders of sleep and arousal. The task's monotony theoretically unmasks underlying sleepiness.

Vigilance tests measure arousal level, attention, or both. As with the MWT, performance cannot exceed ability or maximum effort. Although a person could intentionally perform poorly (i.e., faking "bad"), he or she cannot fake "good." However, teasing apart arousal and attention can make test interpretation difficult. Attention deficits in nonsleepy persons can confound test results. Fortunately, sleepiness and inattention often coexist; consequently, long, experimenter-paced, monotonous tasks are sensitive to sleep loss, sleep disruption, and circadian variation. The landmark studies of the 1970s, collectively referred to as the Walter Reed experiments (named for the institute where they were conducted), documented the effects of sleep deprivation on performance.[40] These pioneering studies established that increasing duration of prior wakefulness and time-on-task provoked response slowing and lapsing (for an excellent review, see reference [41]).

A variety of vigilance tests are available; however, the psychomotor vigilance test (PVT) developed by Dinges and colleagues is currently the best-validated and most widely used.[42-43a] The PVT is a visual signal detection test, approximately 10 minutes long, administered either by computer or by a hand-held display-and-response unit. Response latencies to visual target stimuli are recorded. Response slowing and lapsing correlate with findings on the SSS and the MSLT; these results provide convergent validity. Additionally, PVT results have been reported for a variety of subject groups, including normal control subjects, sleep-deprived volunteers, and patients with major sleep disorders. The test provides exquisitely sensitive within-subject measures for before-and-after experimental designs. PVT normative data are limited, however, making clinical between-subject comparisons difficult. Programs using portable devices are now available.[44]

The other vigilance test popular for sleep research is the Oxford Sleep Resistance (OSLER) test.[44a,45] The testing paradigm mimics that for the MWT but uses a visual signal detection task rather than EEG-EOG-EMG monitoring. The test uses four 40-minute test sessions, during which visual target signals are presented. Subjects are instructed to respond

Table 169-4 Comparison of Tests for Evaluating Sleepiness

Sleepiness Type Assessed	Test	Are Normative Data Available?	Is It Possible to Fake Sleepiness?	Is It Possible to Fake Alertness?
Introspective sleepiness	ESS	Yes	Yes	Yes
	SSS	No	Yes	Yes
	SWIFT	No	Yes	Yes
	Pictorial sleepiness scale	No	Yes	Yes
	POMS	Yes	Yes	Yes
Physiologic sleepiness	MSLT*	Yes	No	Yes[†]
	Pupillography	No	No	Unknown
	EEG	No	No	Unknown
Manifest sleepiness	MWT*	Yes	Yes[‡]	No
	Vigilance and performance tests	No	Yes[§]	No
	Postural balance test	No	Yes	No

*Standard protocol described in an American Academy of Sleep Medicine Practice Parameter: Test involves 4 to 6 test sessions per day, at 2-hour intervals. Test sessions are sometimes scheduled at shorter intervals (e.g., for children); however, this practice is not recommended by the authors.
[†]Assuming that the subject is not overwhelmingly sleepy, attempting to remain awake can undermine the test result.
[‡]Assuming that the subject is physiologically sleepy, not attempting to remain awake will make it appear that overwhelming sleepiness is present.
[§]Intentionally not attending or responding to the task can make the subject appear sleepy.

to each signal with a simple button press. A test session is terminated either after 40 minutes or after significant response lapsing (which is considered a failure to maintain wakefulness). OSLER has been validated against MWT test results, but specific normative data supporting clinical threshold scores are not currently available.

Postural Balance Testing

Sleep-deprived people experience difficulty maintaining balance. Extended periods of wakefulness also impair balance.[46] Time-of-day variation also occurs.[47] Research suggest posturographic indices may provide a technique for assessing manifest sleepiness. Balance can also be adversely affected by psychoactive drugs. One approach records pressure shifts on a force platform on which the subject stands, feet together, with crossed arms at the chest. The subject's direction of gaze is on a fixed point straight ahead. The body's *center of pressure* is sampled for 30 seconds at a rate of 1000 samples/second. Some studies conduct a trial at 2-hour intervals, but protocols are not yet standardized. Whether this approach can be refined for use as a clinical tool remains to be seen; however, it shows promise.[48,49] Standardized evaluation protocols, optimized data processing, normative data, and validation against other measures of sleepiness and sleep drive are needed.

PRACTICAL ISSUES AND CONCLUSIONS

Before initiation of an evaluation for sleepiness, several practical issues warrant consideration. An important distinction to be made is whether the goal is to (1) establish the presence of sleepiness, (2) confirm the absence of sleepiness, or (3) identify changes in sleepiness. Is testing being conducted for clinical assessment, research, or legal purposes? Does the subject have a self-interest in the outcome? (i.e., Is there any primary or secondary gain?) With increasing frequency, sleep specialists provide expert opinions in legal matters involving accidents and disability claims. Expert panels often render opinions concerning fitness for duty or disability adjudication. In such cases, objective testing is crucial. Furthermore, a normal test result does not guarantee fitness for duty. Table 169-4 summarizes characteristics of the tests described in this chapter. Ideally, physiologic, manifest, and introspective sleepiness should be assessed. In general, if the subject claims to be sleepy and the goal is to demonstrate sleepiness, the MSLT is likely to be the best confirmatory test. If the subject claims not to be sleepy and the goal is to demonstrate an ability to remain awake (as when concerns arise about the person's ability to operate a motor vehicle), the MWT has certain advantages.[50,51]

For clinical purposes, self-reported measures combined with MSLT have long been the sine qua non for establishing sleepiness. Sometimes, however, in cases involving severe sleepiness, the MWT can demonstrate improved alertness after treatment, whereas the MSLT shows little or no change. Such persons continue to be pathologically sleepy, but they are not overwhelmed by sleep during the brief testing interval. The relationship between this pattern of change and performance or behavior requires further study.

The dangers posed by excessive sleepiness are becoming increasingly apparent. The National Commission on Sleep Disorders Research catalogued a substantial list of sleep-related industrial and transportation accidents. Long ago, Kleitman proposed sleepiness as resulting from accumulation of bloodborne or cerebrospinal fluid hypnotoxins; however, clinical tests for such substances have not been developed or validated. Nonetheless, the search continues. Therefore the clinician can use one or a combination of the evaluation techniques described in this chapter to measure the underlying physiologic drive for sleep; the subjective, internalized consequence of that drive; and/or sleepiness's behavioral manifestations.

CLINICAL PEARLS

- Measuring sleepiness in a clinical setting is not a simple matter. The MSLT and the MWT represent standardized tests evaluating patients for physiologic and manifest sleepiness.
- Clinical practice standards recommend use of the MSLT for evaluating narcolepsy and idiopathic hypersomnia.
- The MWT is indicated for testing the person's ability to remain awake when safety is at stake.
- Sleepiness testing must always be viewed within a larger context of the clinical history and examination findings.

SUMMARY

Excessive sleepiness, although central to sleep medicine practice, remains a poorly defined concept. In clinical practice, assessment usually involves self-report; however, objective measures are available. The conceptual framework used in this chapter is based on the three faces of sleepiness: introspective, physiologic, and manifest sleepiness. The indications and techniques used to evaluate sleepiness in standard clinical practice include the ESS (for introspective sleepiness), the MSLT (for physiologic sleepiness), and the MWT (for manifest sleepiness). Other assessment procedures, each with its relative merits and limitations, include postural balance testing and vigilance testing. Practical considerations in choosing and evaluating sleepiness tests include the goal of testing, the purpose of the test, and interpretation of results.

Chapter 170

Chronobiologic Monitoring Techniques

John H. Herman

Chapter Highlights

- The suprachiasmatic nucleus is the master biologic clock of the mammalian brain and drives an organism's circadian rhythm. Suprachiasmatic nucleus properties can be estimated by measuring input variables such as light or food and output variables such as variations in temperature or the nightly onset of melatonin secretion.
- Under experimental conditions of continuous darkness for many days, the daily onset of wheel running by experimental animals (i.e., rodents) unmasks the period length of the circadian rhythm. The animal will begin running several minutes earlier or later each 24-hour period with remarkable consistency. Plotting the time of wheel running with consecutive days stacked upon each other reveals the period length of the animal's circadian rhythm, or tau.
- Humans are capable of entraining only to dark-light schedules close to 24 hours. In a forced desynchrony protocol, humans are exposed to dark-light schedules to which they cannot adapt. In these protocols subjects are permitted to sleep in the dark portion of the cycle only. The result is desynchrony—that is, sleep and wake lose their normal relationship to body temperature, endocrine secretion, alertness, and behavioral performance.
- Sleep onset normally occurs approximately 2 hours after the beginning of melatonin secretion. Melatonin secretion is emblematic of biologic night. The timing of dim-light melatonin onset can reveal the presence of phase advance or phase delay disorders. Recently, inexpensive salivary melatonin collection kits have been developed that enable sleep specialists to readily measure dim-light melatonin onset in patients.

BASIC CONCEPTS AND TERMINOLOGY

The purpose of chronobiologic monitoring techniques in humans is to measure biologic and behavioral properties related to circadian rhythms. These methods help promote understanding of normal and abnormal clocks controlling human alertness and sleepiness. Chronobiology research is based on the assumption that a given organism contains within it a core mechanism or clock for generating rhythmic expression of physiologic parameters. The fluctuations in any biologic or behavioral parameters that display an approximately 24-hour periodicity are assumed to be the direct or indirect consequence of an underlying pacemaker that possesses its own inherent and autonomous periodicity.

The internal clock has properties that are indirectly studied in circadian rhythm research by examining output variables. These include amplitude, period length (tau), phase, rate of change, and relative duration of the active period. *Amplitude* is the quantity of change in a parameter that occurs from apogee to nadir by measuring variables such as core body temperature, cortisol, or cognitive problem solving. *Period length* is the temporal duration of one complete circadian cycle under free-running conditions. *Phase* is the relation of the internal clock to the environment, such as sunrise and morning awakening. *Rate of change* is the rapidity with which a circadian parameter switches from its active to dormant or dormant to active modes. Finally, it is possible to measure the *duration of the active period* relative to the duration of the dormant period. Chronobiologic techniques can measure each of these variables and define how they may be manipulated and how they are interrelated.[1]

The process by which the internal clock stays in synchrony with the environment is called *entrainment.* Stimuli, such as light, that bring about entrainment are called *zeitgebers.* The circadian mechanism is always subject to the influences of masking. *Masking,* which is further described later in the chapter, is the ability of an external variable, such as light, sound, or physical activity, to alter a behavioral or physiologic parameter without affecting the core pacemaker. Much of the foregoing terminology, especially the melatonin secretory profile, is illustrated in Figure 170-1.

The definitions of entrainment and masking overlap to some extent. Exposure to daily sunlight, for example, entrains humans to their local time zone and masks their internal clock from expressing its endogenous rhythm. Thus daily exposure to normal sunlight both entrains mammals to and masks the true periodicity of the endogenous pacemaker. In animals, masking influences may be removed by placing the animal in continuous light or dark conditions.

As simple and straightforward as it would seem to be to measure the human circadian period length, the field of circadian rhythms research has undergone several modifications

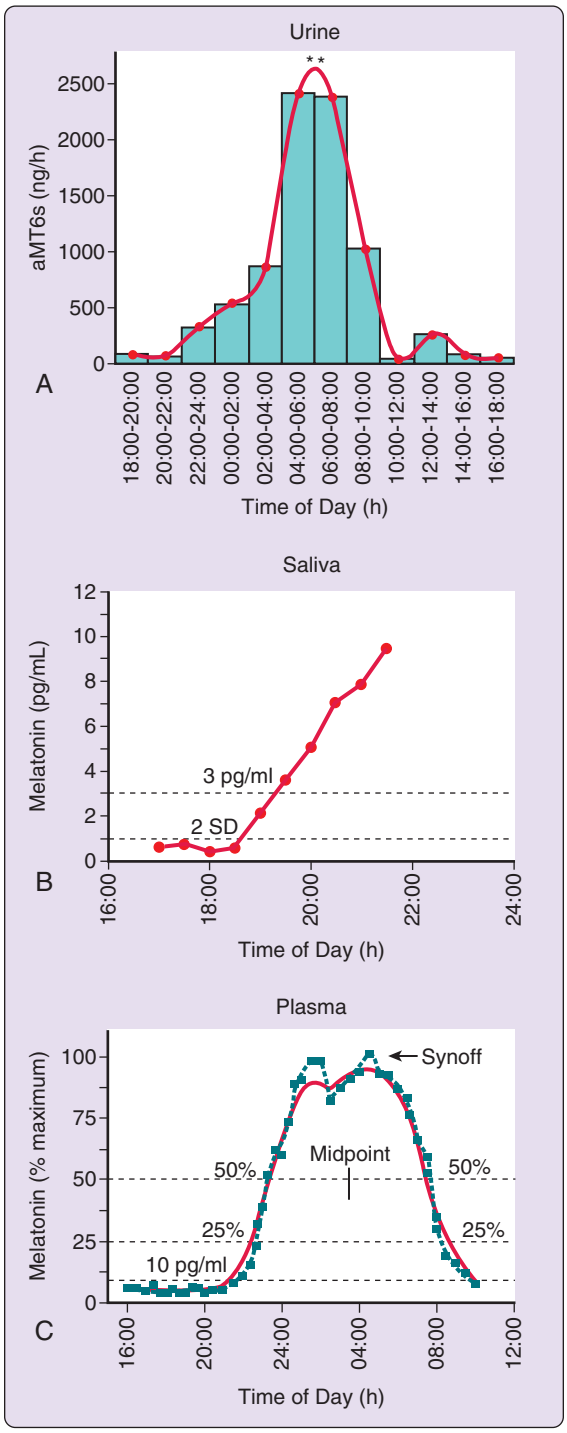

Figure 170-1 Three melatonin sample types and their associated phase estimates. **A,** 24-hour rhythm of the primary urinary melatonin metabolite 6-sulfatoxymelatonin (aMT6s) derived from urine samples collected in 2-hour bins under dim light. The fitted curve reveals a significant 24-hour rhythm with maximum levels observed between 04:00 and 08:00 (**$P < .01$). **B,** Salivary melatonin profile collected under dim-light conditions. The low-threshold dim-light melatonin onset (DLMO) was defined as either the first sample to exceed and remain above a threshold of 3 pg/mL or that was 2 SD above the mean of the first three baseline samples (2 SD). **C,** Overnight plasma melatonin profile, plotted as a percentage of maximum (*dashed line*) and smoothed with a Lowess curve fit to the raw data (*solid line*). Some frequently used phase markers are shown: DLMO at 10 pg/mL, DLMO or dim-light melatonin offset (DLMOff) at 25% or 50% of maximum levels, the midpoint, and the termination of melatonin synthesis (Synoff). (From Benloucif S, Burgess HJ, Klerman EB, et al. Measuring melatonin in humans. *J Clin Sleep Med* 2008;4:66–9.)

of estimated human cycle length. Estimates improve as methodologic errors are eliminated by new and more accurate paradigms. In humans, a number of corrections of the period length of the free-running circadian rhythm length, or period, have been introduced. Period length currently is estimated at slightly greater than 24 hours, 24.18 hours being the most recent value.[1]

In addition to a core pacemaker, each circadian system has input and output components. Input components are principally responsive to photic information but respond to a variety of stimuli. These stimuli are manipulated in circadian studies to examine the effect on output variables such as the sleep-wake cycle, temperature, or behaviors such as reaction time or problem-solving ability.

METHODOLOGIC CONSIDERATIONS IN THE INVESTIGATION OF CIRCADIAN RHYTHMS

During the preceding five decades, estimates of human circadian period length range from 13 to 65 hours.[2] Also, in humans, greater interindividual inconstancy in circadian variables had been observed than that seen in other mammals. In nonhuman animals, circadian rhythms are remarkably stable from day to day. In humans, there have been continued corrections (and narrowing) of the period length of the circadian rhythm of sleep-wake; most recent estimates indicate a period slightly longer than 24 hours, with a precision not that different from that in mammalian relatives.

Disagreements continue over what stimuli are capable of acting as zeitgebers to entrain or shift circadian rhythms. Initially, only bright light (7,000 to 12,000 lux) was considered to be capable of shifting the timing of circadian rhythms.[3] Subsequently, light of moderate intensity was described as being capable of shifting circadian rhythms,[4] and most recently, studies now maintain that ordinary room light is capable of inducing a circadian shift.[5,6] Some investigators claim that extraocular light is capable of influencing circadian rhythms. One study demonstrated that behind-the-knee (popliteal region) bright light exposure is capable of inducing shifts in circadian timing,[7] but multiple failures to replicate this finding have been documented.[8-11] As chronobiology research progressed, a series of modifications of experimental design successively eliminated some masking artifacts and external zeitgebers that previously introduced artifact.[1]

The field also has experienced some controversy regarding what constitutes a zeitgeber, or a stimulus capable of entraining a circadian rhythm. Some evidence suggests that nonphotic stimuli are capable of shifting the timing of such rhythms.[12] Exercise,[13,14] social activity,[15] feeding schedule,[16] ambient temperature,[17] napping in darkness,[18] administration of melatonin,[19] and knowledge of time of day or night[20] each have some capacity for circadian rhythm entrainment in human subjects. Some studies suggest a major role for such nonvisual zeitgebers,[12] whereas other studies imply a more modest role.[21] The extent to which exogenous melatonin administration is capable of shifting circadian rhythms was controversial until recently.[22]

Another area of research involves separating behavioral and biologic properties of circadian rhythms from other physiologic processes. Many behavioral and biologic phenomena are influenced by the sleep-wake cycle or the duration of previous wakefulness period. The homeostatic model describes an

increasing pressure to sleep with increased duration of wakefulness and a decreased pressure to sleep with increased duration of sleep.[23] Circadian rhythm studies must separate variance in a biologic or behavioral parameter into homeostatic and circadian components; that is, they must identify what portion of the parameter's variance is circadian and what portion is homeostatic.[24,25]

An additional area in which agreement is not universal is what biologic metric is best used to approximate the properties of the output of the underlying core pacemaker, such as period length. Core body temperature[24] and melatonin[26] secretory profiles have been used in most studies. Some research uses dim-light melatonin onset (DLMO) as the marker for the beginning of a new circadian cycle; other studies use dim-light melatonin offset (DLM offset),[26] but many use the core body temperature nadir. However, no stable point is identifiable as the minimum of temperature or the onset of melatonin secretion. Temperature fluctuates from moment to moment, and the minimum or maximum must be extracted mathematically. Melatonin rises gradually after sunset, and an arbitrary level must be selected to denote onset or offset. A modified RAND consensus panel consisting of melatonin investigators came to the conclusion that blood, saliva, or urinary melatonin concentration may each be optimal under different experimental circumstances.[27] Figure 170-1 shows (1) the urinary secretory profile of melatonin; (2) the salivary DLMO, and (3) the secretory profile of melatonin as determined from blood samples. It must be emphasized that extracting circadian rhythm data relies on mathematical criteria and data-analytic techniques selected in each experimental protocol. One study used nonorthogonal spectral analysis to identify core body temperature minimum in humans.[1]

The amount of information uncovered in the past few decades in the field of circadian rhythm research has been truly astounding. It includes the identification of basic anatomy, novel photoreceptors, and genetic mechanisms. However, researchers have not agreed on specific definitions in the areas of contention listed previously, nor has any chronobiologic monitoring technique been accepted as the "gold standard." Findings using different experimental paradigms contribute to the turbulence in this field.

This chapter describes various paradigms recently used in circadian rhythm research and reviews their strengths and weaknesses. For in-depth detailed descriptions of each model, the reader is directed to a few key references at the end of the chapter in which a fuller exposition is offered.

PARADIGMS

Fixed Light-Dark Schedules, Double-Plotted

The most common model for animal studies of circadian variables and activity schedule consists of placing the animal in a cage with a running wheel and subjecting it to a fixed schedule of light and dark. The running wheel's turns are counted continuously. Typically, the animal's running behavior on the wheel is plotted as a vertical or horizontal line per unit time, or as wheel turns per unit time. These counts are plotted successively for 24 hours, yielding a visual representation of when and how much the animal ran that day. Successive days are stacked, enabling the reader to visually appreciate changes in the timing of activity that occurred during the experiment. The entire plot is duplicated side by side, called *double plotting,* because seeing the image next to itself enables the reader to appreciate what happened in the experiment more readily. For example, if the animal's principal expression of wheel-running activity drifts from before to after midnight, double plotting allows the reader to more easily follow the continuity of changed wheel-running times. Drinking or feeding may be plotted in the same manner. Protocols are labeled as LL (constant light), LD (fixed light-dark schedule, most commonly 12 hours light and 12 hours dark), or DD (constant darkness). Constant dim light is sometimes used in such protocols, or light dim enough to prevent suppression of secretion of melatonin in the experimental animal (hamster or rat). In some studies, the LD period length may be longer than or shorter than 24 hours, and use of a period as short as 1 hour has been described.

The DD paradigm successfully demonstrates the remarkable consistency of a given species' free-running activity rhythm in constant darkness or dim light, elucidating the period length of its biologic clock.[1] Often, the timing of light and dark ise abruptly changed to measure the animal's reaction; adaptation can take several days. Such paradigms are at the core of much genetic research, in which normal (wild-type) animals (+/+) are compared with heterozygous (+/–, –/+) or homozygous (–/–) knockout animals. Studies reveal genetic phenotypes (behavioral expression), because knockout animals display altered periodicity, diminished rhythmicity, or absence of any circadian rhythm in running, feeding, or drinking behavior.

The strength of the fixed light-dark schedule with activity monitoring is its ability to accurately and economically measure an animal's rest-activity schedule. Alterations in rest-activity schedules after genetic knockout modifications constitute a standard genotype-phenotype model. One design weakness is an inability to examine complex interactions that would occur in more natural circumstances. If only light, dark, or light versus dark is studied, then all effects appear to be a function of the animal's illumination schedule. The paradigm is subject to overly simple interpretation, the implications of which are discussed later.

Entrained 24-Hour Protocol

In entrained 24-hour studies, subjects live in laboratory conditions with constant bedtime, wakeup time, meal time, and timed activities. Subjects are aware of time of day and are not isolated from normal zeitgebers such as light from windows. This protocol is used to study biologic or behavioral parameters (e.g., hormone secretory profiles or cognitive processes) under constant conditions. Often, subjects are fitted with indwelling catheters for recurring blood sampling.

Phase-Shifting Protocols

One of the most experimentally robust circadian rhythm research findings is the capacity of zeitgebers, such as bright light, to change the time of day at which the circadian system switches from its active or day mode to its dormant or night mode. This switching is referred to as a *phase shift.* It is similar to jet lag or shift work in the real world.

Many studies have examined the capacity of light, at various intensities and durations, to alter the timing of sleep, melatonin secretion, or the temperature nadir. These studies share a common methodologic feature: Environmental light

is controlled at baseline, but typically the timing is similar to that for natural environmental light. Often the baseline consists of dim light ranging in intensity from approximately 70 lux (equivalent to romantic restaurant lighting) to as low as 1.5 lux (similar to the light from a candle). In the experimental condition, light is then delivered to the subject in what normally would be the dark or night portion of the circadian rhythm.[28] Light is delivered for the same duration but at a different time during this experimental condition for one or several days. Some studies include a subsequent condition in which the subject is in constant dim light or in a constant routine (described later). One study examining the intensity of light required to accomplish a phase shift or melatonin suppression showed a "ceiling effect" at approximately 1000 to 3000 lux[29]

Circadian variables such as wheel running in rodents and hamsters, the timing of sleep, or the timing of melatonin secretion are monitored during each condition.[1-3] The magnitude of change in a circadian variable after the altered timing of light is measured. A phase response curve (see Figure 170-2) shows the magnitude of response to light exposure (typically 1 to 3 hours) at different times throughout the circadian cycle in changing the timing of a circadian output variable.[30] Most studies show circadian rhythm shifts in response to light occurring only if the light is delivered at specific times, typically at or near normal hours of darkness. This finding indicates that mammals are not responsive to bright light administered during normal hours of daylight.[31] Other studies claim that there is no dead zone and that bright light delivered at any hour, including normal daylight hours, has a phase-shifting effect.[32] It is possible that many subjects have partial desynchrony between sleep-wake and temperature or feeding rhythm.

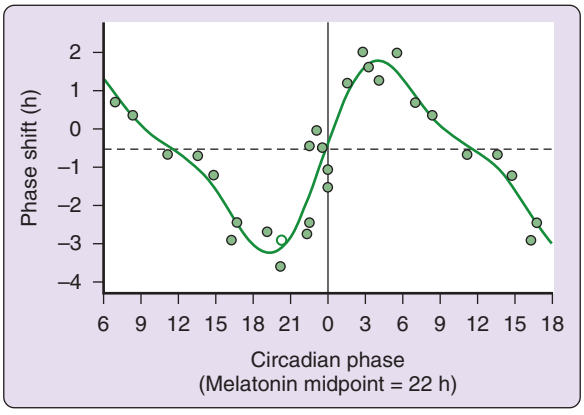

Figure 170-2 Accurately identifying the effect that light and melatonin have on advancing or delaying circadian timing is at the core of much circadian rhythm research. The magnitude of the phase advances (falling asleep and awakening earlier, represented by positive numbers) and delays (falling asleep and awakening later, represented by negative numbers) are plotted against the center of the period of light exposure relative to the core body temperature minimum at 0 hours. The *filled circles* represent data from plasma melatonin, and the *open circle* represents data from salivary melatonin in one subject from whom blood samples were not acquired. The *solid curve* is a harmonic function fitted through all of the data points. Light's phase-delaying effect increases as it approaches the temperature minimum; then it flip-flops in the 6-hour period surrounding the temperature minimum to a maximum phase-advancing effect 6 hours after the temperature minimum is reached. (From Khalsa SB, Jewett ME, Cajochen C, Czeisler CA. A phase response curve to single bright light pulses in human subjects. *J Physiol* 2003;549[Pt. 3]: 945–52.)

Time-Isolation Protocols

In time-isolation protocols, animals may be kept in total darkness or in light dim enough to presumably not entrain their circadian timing mechanism. Human subjects typically have been isolated in an environment free of time cues, such as an underground facility or an internal suite of rooms in an enclosed bunker. Great pains are taken not to provide any clues regarding time (including use of double-door entry chambers and randomized schedules for technicians interacting with subjects). In such studies, for many years, subjects were permitted to turn off their room lights and retire when they wished and awaken when they wished. Subjects were instructed not to nap.

One of the more unexpected findings in circadian rhythm research is that the subjective sense of sleepiness, or the wish to sleep, is at its minimum at the normal time of sleep initiation and that sleepiness is greatest at the normal time of awakening.[33-37] This finding of greatest alertness in the hours preceding sleep is called "the sleep-forbidden zone," and the occurrence of greatest sleepiness soon after awakening is called "sleep drunkenness." However, the tendency to be most alert in the hours preceding bedtime and to feel most sleepy at the hour of awakening is attributed to the respective maximum and minimum of the circadian systems effect on wakefulness. These phenomena demonstrate the capacity of circadian rhythms to influence subjective sleepiness and alertness.

Under conditions of time isolation, a variety of studies showed great variability in human sleep-wake cycle length. By contrast, the sleep-wake cycle in most other mammals is consistent and stable. Human studies showed sleep-wake cycles as long as 36 hours and great day-to-day variability in both sleep and wake duration.[38] Subjects who remained in time-isolation conditions for a sufficient interval developed desynchrony between their temperature rhythm and their sleep-wake cycle. Under normal conditions, the temperature minimum occurs somewhat after the middle of the sleep period. In subjects in temporal isolation protocols, the interval from one temperature minimum to the next has a cycle length of 24 to 25 hours, but the interval between sleep initiation on successive nights is longer. Consequently, the temperature minimum eventually strays elsewhere in the sleep-wake schedule.[39]

The time-isolation protocol is no longer used, because results from these studies are widely disparate from those for circadian rhythm studies in all other mammalian species. Of note, however, by disregarding this experimental approach, a basic attribute of human behavior is being ignored: Most persons appear to prefer a sleep-wake schedule longer than 24 hours, when allowed. This perhaps unique human preference for longer wake and sleep episodes has been overlooked in the circadian rhythm field's fervor to produce human data as similar as possible to those acquired in other mammals, invertebrates, and plants.

Forced Desynchrony Protocols

In forced desynchrony protocols, subjects are scheduled for rest-activity cycles anywhere from every 20 minutes to 28 hours. Forced desynchrony is obtained by subjecting the study participant to a sleep-wake schedule to which adaptation is impossible. The human circadian system is capable of adapting

to sleep-wake schedules within only a certain range surrounding 24 hours. If the forced sleep-wake schedule is outside of that zone, then the circadian rhythms of all other biologic and behavioral phenomena become desynchronized with the enforced sleep-wake schedule. In such studies, core body temperature, melatonin, or both are monitored continuously. Subjects live in dim light during the active part of their rest-activity cycle and in darkness during scheduled sleep episodes. Dim light is defined as a level from 1 to 70 lux in various studies. Under such conditions, the endogenous circadian pacemaker, as measured by DLMO or temperature rhythm, displays a stable period and is unable to follow the scheduled 28-hour (or 20-minute) sleep-wake cycle. The temperature rhythm then becomes desynchronized from the imposed sleep-wake schedule. The 20-minute sleep-wake cycle is referred to as the ultrashort sleep schedule.[40] The forced desynchrony protocol allows investigators to determine the extent to which various biologic rhythms are sleep-dependent or independent of sleep.

In forced desynchrony protocols, subjects are placed in a sound-attenuated and windowless room and have no access to any timepiece for the duration of the study. The contacts with staff members are limited, and they are trained not to transmit any information about the time of day. In such studies, technicians have only brief contact with the subjects to announce the moments for rising, meals, showering, testing, and going to bed. Subjects watch videos, listen to music, or engage in their own preference of leisure activities. In some studies, subjects are allowed caffeine-containing beverages in the scheduled morning.

In forced desynchrony protocols, subjects spend two thirds of their time in light or waking conditions and one third of their time in dark or sleep conditions—for example, 60 minutes of activity and 30 minutes of scheduled sleep in a 90-minute day, and 18.66 hours of activity and 9.33 hours of scheduled sleep in a 28-hour day paradigm. In all forced desynchrony protocols, from 20-minute to 28-hour cycles, the scheduled day cycle length is outside the range of entrainment of the human circadian clock (under dim-light conditions).[41] Under such conditions, the circadian clock becomes unmasked as it continues to oscillate at its near-24-hour intrinsic period despite sleep permitted only on the 28-hour schedule (Figure 170-3).

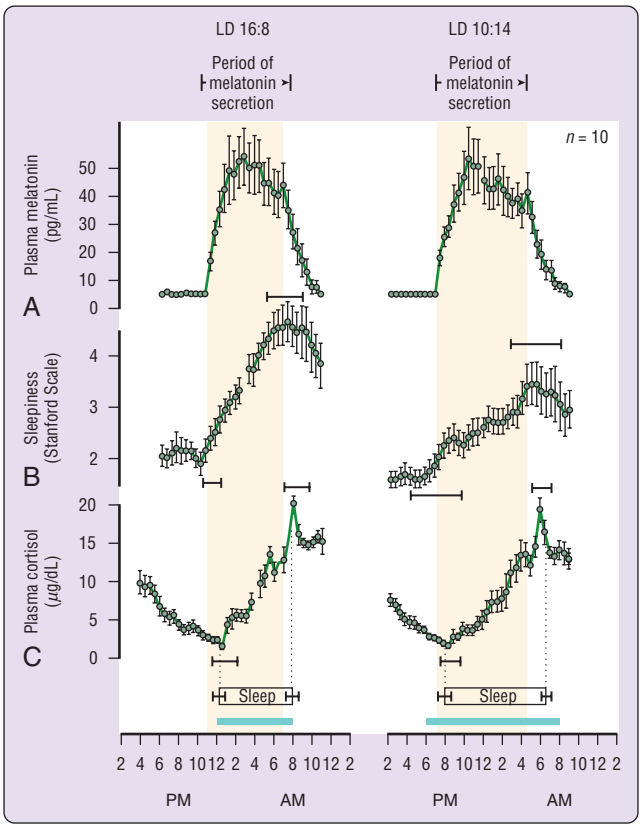

Figure 170-3 *Left plots,* Data for subjects in a 16-hour day and an 8-hour night (LD of 16 : 8), equivalent to midsummer at a latitude of 39 degrees (Washington, D.C.). *Right plots,* Data for subjects in a 10-hour day and 14-hour night, which occurs in midwinter at the same latitude. The circadian pacemaker imposes a pattern of neuroendocrine secretion influenced by the length of daylight. **A,** In summer and winter, the pattern of melatonin secretion is characterized by distinct diurnal and nocturnal periods with relatively discrete transitions between them. Melatonin is either at high levels (biologic night) or virtually absent (biologic day). **B,** The paradox described in the text: Subjects are sleepiest when they wake up and most wide awake when closest to bed time (as measured by the Stanford Sleepiness Scale). Of note, subjects are far sleepier during short nights than during long nights. This means that the introduction of artificial light has increased sleepiness of the human population as a whole. **C,** In humans, diurnal periods of absence of melatonin secretion, and falling levels of cortisol alternate with nocturnal periods of active melatonin secretion and high and rising levels of cortisol. The timing and duration of endocrine secretion are matched to the timing and duration of solar day and night. The pacemaker adjusts the duration of the biologic day and night to match seasonal variation in the duration of sunlight. After humans have been chronically exposed to long nights (*right*), the duration of melatonin secretion and rising levels of cortisol is longer than it is after they have been chronically exposed to short nights. (From Wehr TA. Effect of seasonal changes in daylength on human neuroendocrine function. *Horm Res* 1998;49:118–24.)

Constant Routine Protocols

The constant routine protocol requires the subjects to remain in a semirecumbent posture throughout the protocol's experimental phase, typically 24 to 48 hours, sometimes continuously awake. For this protocol, the subject remains in temporal isolation in dim light. Normal caloric and liquid intake is provided in hourly, equally divided portions. Food and beverages are at room temperature. In such studies, salivary melatonin samples may be acquired hourly, core body temperature may be monitored continuously, and psychometric testing may be administered at hourly intervals. Blood samples may be drawn at hourly intervals through an indwelling intravenous catheter. Constant routine protocols eliminate the effects of activity, light-dark cycles, sleep, and meals on temperature, enabling a more accurate estimate of the period length of the hypothetical "master clock" in the suprachiasmatic nucleus (SCN).[42] Other chapters in this book provide adequate evidence that the SCN is the body's master clock, synchronizing the clock cells throughout the body.

Long Nights Protocol

In the long nights protocol, subjects have an enforced dark period longer than the permitted light period. Such studies have been used in adults and adolescents. This protocol reveals an aspect of the human circadian rhythm that typically is ignored: the capacity of humans to adapt to an extended dark period with enforced immobility. Historically, humans in temperate zones of the northern and southern hemispheres obviously spent approximately half of the year with dark periods exceeding light periods. Society has used artificial light to impose permanent light conditions similar to the long

days of summer, to which humans are capable of entraining. The long nights protocol reverses the circumstances, testing the ability of the human circadian system to adapt to short days (10 hours) and long nights (14 hours) (Figure 170-3). Such studies have revealed increased total sleep time, increased duration of cortisol suppression, increased duration of melatonin secretion, increased duration of temperature suppression, and decreased daytime sleepiness under these conditions.[43] During long nights, subjects spend some of this time awake, typically after rapid eye movement (REM) sleep periods.[44] In this manner, the portion of the time spent with the body geared for sleep is increased and the time spent with the body geared to be awake is decreased (see Figure 170-3). This demonstrates an aspect of adaptability in the human circadian system that is not revealed in other circadian protocols.

Phase Shifting of Gene Expression Protocol

Many people work at times not in keeping with their biologic clocks. Many studies indicate that night shift or graveyard shift workers maintain their daytime peak and nocturnal drop in circadian activity, probably as a consequence of light exposure during and surrounding their hours of sleep and switching back to a normal day-awake schedule on days off. Night shift work is recognized as a health risk, increasing the likelihood of several serious, chronic morbidities.

The following study describes a protocol for flipping circadian rhythm activity to peak in the nocturnal work hours of night shift employees. One of the techniques used to measure phase shift was measurement of circadian genes in blood cells. This study examined clock gene expression in peripheral blood mononuclear cells in comparison with melatonin and cortisol secretion. In a laboratory study, five subjects awakened, worked, and slept 10 hours later than they normally would. Subjects were exposed to very bright white light of 6000 lux, equivalent to being outdoors in the shade on a sunny day, during their night shifts. They were restricted to dim light after night shifts and slept in total darkness for 8 hours, beginning two hours after the night shift. After 9 days on the night schedule, melatonin and cortisol secretory rhythms adapted to the shifted schedule. Gene expression of *HPER1* and *HPER2* in blood also shifted to the night work schedule. This study is significant for two reasons: First, it conclusively demonstrates that proper light exposure completely shifts circadian activity to a night shift schedule, and second, it shows that the underlying biology of these shifts can be measured with traditional hormonal sampling or with genes extracted from peripheral blood.[45]

Measuring Circadian Rhythms with Salivary Melatonin

A commonly used technique in human circadian research involves measuring melatonin in blood or saliva. Measuring melatonin levels in blood was first accomplished in 1978,[46] and suppression of melatonin secretion by the presence of bright light was soon demonstrated.[47] The evening rise in blood levels of melatonin, called *dim-light melatonin onset* (DLMO), and the decline in blood levels of melatonin, called *dim-light melatonin offset* (DLM offset), are markers used as the basis for standard techniques for measuring duration of the human circadian period in many experimental protocols as described earlier.

Melatonin Salivary Assays

More recently, melatonin salivary assays have replaced blood testing for measuring the timing of DLMO and DLM offset. This noninvasive procedure permits a clinician or investigator to indirectly measure circulating melatonin levels. Results plotted consecutively estimate time of melatonin onset and offset, from which a subject's circadian phase can be determined.[48] Salivary melatonin correlates directly with sleep propensity and inversely with core body temperature.[49]

Collecting Saliva

During the sampling period, subjects should avoid heavy exercise. Samples are taken under controlled light conditions to avoid light inhibition of melatonin: 250 to 300 lux for daytime and less than 50 lux for nighttime. Saliva is collected by placing a wool swab in the mouth and having the subject chew for 5 minutes. Saliva samples may be acquired once or multiple times over a 24-hour period.[50]

Salivary Melatonin and Cortisol Assay

Melatonin in saliva is measured by a direct radioimmunoassay. Various kits are manufactured in North America and Europe and are specially made for the quantitative determination of melatonin in saliva. The cross-reactivity of the assay for closely related chemical structures is less than 1%. The sensitivity of the assay is approximately 1 ng/L.[51]

Statistics in Salivary Melatonin Studies

To characterize the salivary melatonin profile for a given subject, the periodic function may be fitted to a set of data points using the baseline cosine function. The peak height (amplitude), acrophase, and duration of secretion are then calculated and may be subjected to further calculations or common statistical analysis.

Standardized procedures for measuring DLMO and DLM offset have been published, including guidelines for collecting and analyzing urinary, salivary, and plasma melatonin, to help clinicians and researchers to determine which technique of measuring melatonin is most appropriate for their particular needs. It is hoped that such standardization will facilitate comparison of data among laboratories.[51] One study showed that salivary estimation of DLMO is consistent with the time of sleep onset when samples are gathered from normal subjects and those who meet criteria for delayed sleep phase syndrome in the *International Classification of Sleep Disorders,* 2nd edition (ICSD2), occurring in each subject approximately 10.75 hours before wakeup time.[52]

Another study established a phase response curve for melatonin. This study found the greatest phase advance to be approximately 6 hours before the habitual hour of sleep onset and the greatest phase delay soon after habitual wakeup time. Also observed was a "dead zone," for melatonin to have a phase-shifting effect, lasting from shortly before sleep onset to midsleep, a period that encompasses the time when exogenous melatonin most typically is administered to patients with sleep onset difficulties.[53]

ACTIGRAPHY

Details concerning actigraphy methods appear in Chapter 171. Actigraphy is a noninvasive method for monitoring human rest-activity cycles. Actigraphs record activity using

accelerometers usually mounted in a wristwatch-like device. Actigraphy is used in circadian rhythm research and in sleep disorders centers. Clinically helpful for quantifying and diagnosing various sleep disorders, it is extremely valuable for providing objective data confirming a suspected circadian rhythm disorder. Typically, the patient wears the actigraph for 1 to 3 weeks and then returns to have the data uploaded. The plot of data for active versus quiescent periods can reveal circadian rhythm disorders, the degree of phase shift, and the consistency of the sleep-wake pattern. Specifically, the data also can be used for visual display of the normal timing and continuity of sleep in a normal adult (Figure 170-4). Advanced sleep phase disorder consistently shows an early bedtime and rising time (Figure 170-5). Delayed sleep phase disorder usually shows the patient's enforced wakeup time on weekdays and delayed wakeup and sleep onset on weekends (Figure 170-6). In delayed sleep phase disorder, the difference between the timing of sleep on work days and non–work days quantifies the magnitude of the disturbance. Free-running sleep disorder shows an incremental delay in the onset of sleep and wakeup time (Figure 170-7).

MEASURING CIRCADIAN RHYTHM PARAMETERS IN GENE EXPRESSION

A new method for measuring circadian rhythms has evolved recently. It is well known that most cells contain clock-like genes that express proteins in a manner similar to gene expression in the SCN. Studies reveal that different organs express gene products in a circadian manner, in vitro or in vivo, and each organ has its own rhythm of gene expression. It is believed that the SCN acts as the conductor or organizer of the expression of gene products throughout the body. What follows is a brief description of the methodology and some applications of the technique of studying circadian rhythms from blood, organs, or muscle fibroblasts.

The expression of clock genes in peripheral leukocytes is believed to reflect the circadian clock system. *Per1* and *Per2* demonstrate circadian oscillations in messenger RNA expression in mouse leukocytes, and these rhythms are virtually abolished in *Cry1-Cry2* double-knockout mice in which circadian rhythms are abolished.[54] In human leukocyte clock genes, only *PER1* exhibits a robust circadian rhythm, making this gene a candidate for further investigation.[54]

The suprachiasmatic nuclei are believed to synchronize biologic rhythms in peripheral tissues. In humans, blood is the most accessible tissue source. Various investigators have examined clock gene expression in human peripheral blood mononuclear cells. Clock genes in peripheral blood and in peripheral organs have been found to express circadian rhythms.[55] The liver, kidney, and spleen express the most clock genes—*Per1, Per2, Cry1, Cry2, Rev-erb-α, Clock,* and *Bmal1*—in a circadian rhythmic manner. Clock genes are examined simultaneously in peripheral tissues in rodents or humans every 4 hours for

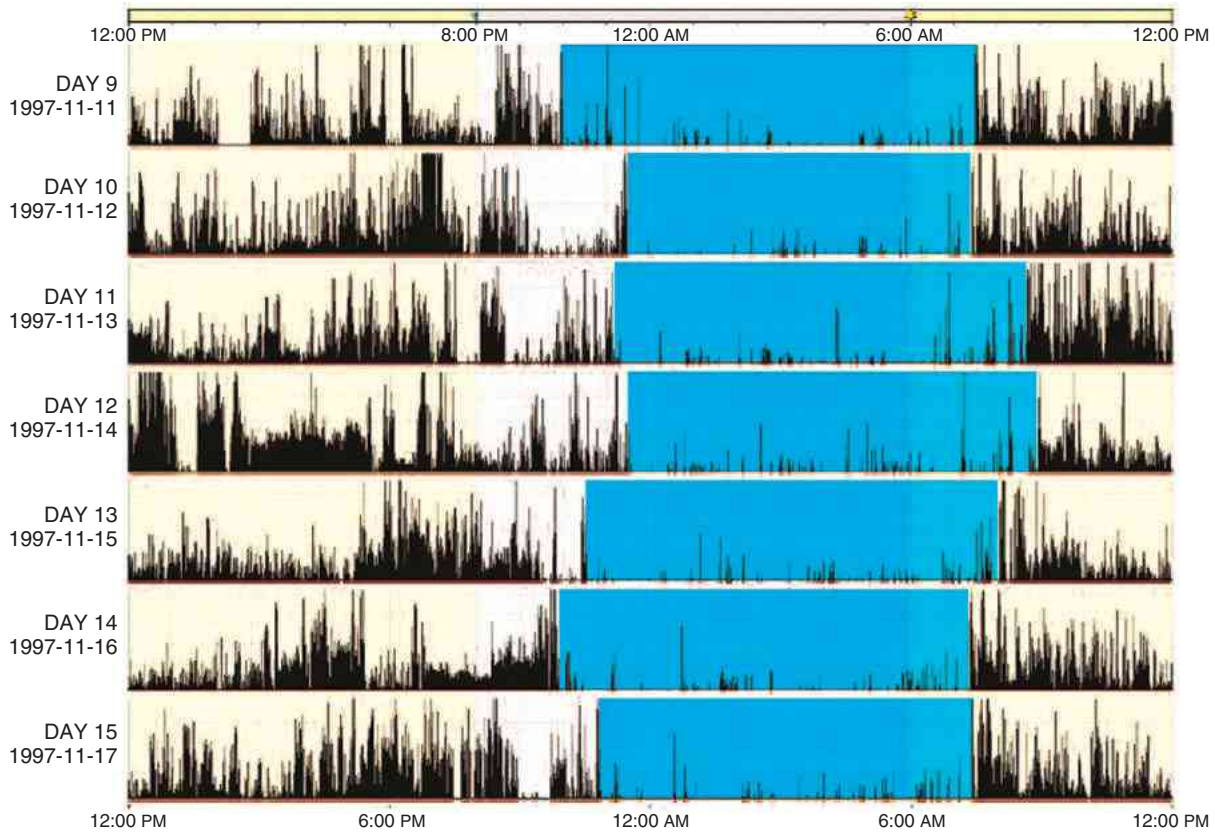

Figure 170-4 Traces from an actigraphy watch worn by a normal subject. The *blue shading* indicates the periods during which sleep most likely occurred. Data were generated by software developed by the actigraph manufacturer. Days 11 and 12 probably represent the weekend, because the subject sleeps later. (Permission granted by and copyright 2009 Koninklijke Philips Electronics NV.)

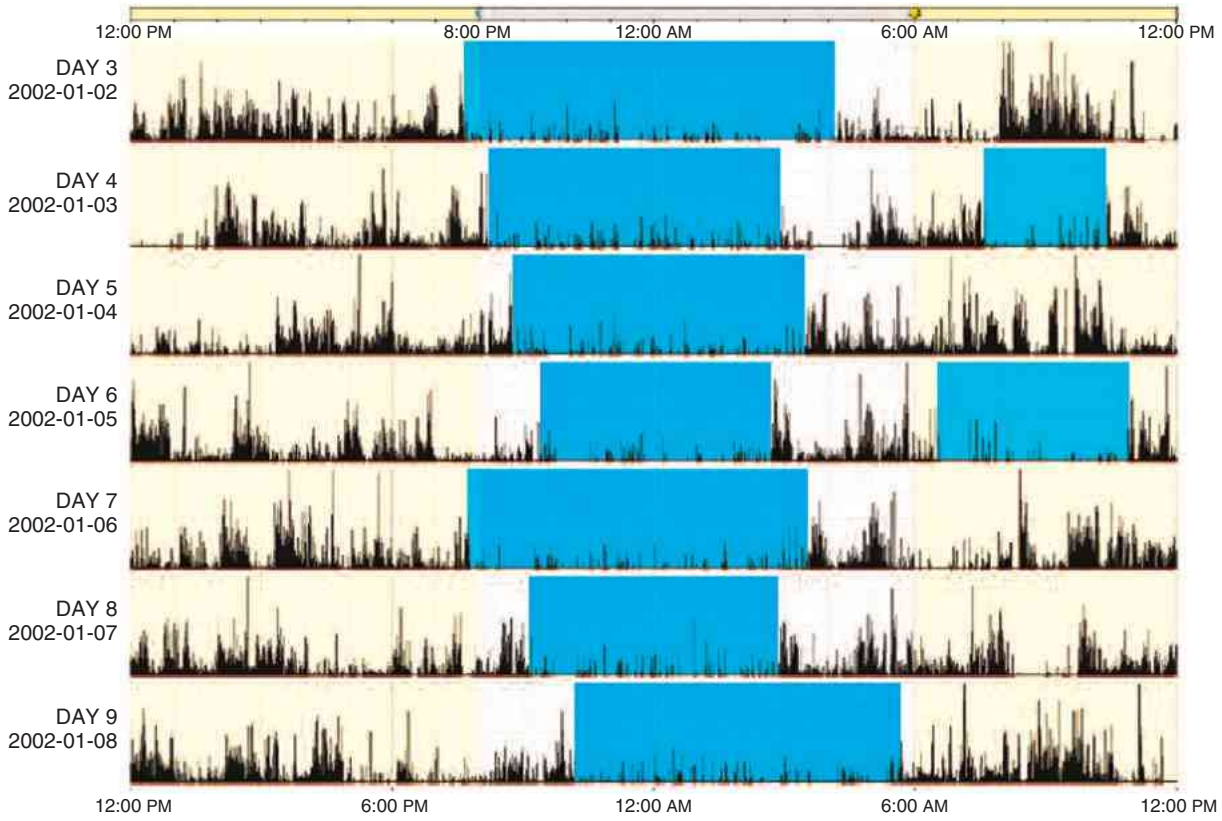

Figure 170-5 Actigraph traces showing typical features of advanced sleep phase disorder. The subject begins sleep by as early as 7:00 PM and as late as 10:00 PM. The subject awakens anywhere from 3:00 AM to 5:45 AM. The subject takes lengthy naps on two of the mornings, suggesting insufficient sleep. (Permission granted by and copyright 2009 Koninklijke Philips Electronics NV.)

24 hours in synchronized light-dark conditions using real-time polymerase chain reaction assays. One study using this methodology showed that different tissues expressed various genes to differing extents. For example, *Bmal1* and *Cry1* are more abundant in the thymus; *Per1, Cry1,* and *Cry2* are more abundant in the testis; and *Cry2* and *Per2* are expressed at a lower level in the kidney, spleen, and thymus. All genes tested are less abundant in peripheral blood. Of all peripheral tissues, the greatest circadian changes occur in the liver and kidney.[56] Of all circadian clock genes, *PER1, PER2,* and *PER3* are most rhythmically expressed in human blood samples.[56] One study claimed to be able to measure both circadian period and chronotype (owl versus lark) from genes from human blood.[57]

Perhaps the most interesting development in measuring circadian rhythms involves studying human and mouse fibroblasts. Most cells express circadian clock genes similar to those of the SCN. It is possible to engineer a lentiviral circadian reporter gene that permits characterization of circadian rhythms from forearm skin biopsy specimens, because the selected cell glows in proportion to gene expression as measured by a light meter. Several findings have emerged from these studies. First, the circadian period mean of gene expression from fibroblasts, 24.5 hours, is approximately the same as it is in behavioral (wheel running) and physiologic studies (melatonin secretion) in mice and humans.[58] However, the range of rhythms of human fibroblasts (from 23.5 hours to 26 hours) is greater than what is observed in human behavioral studies (23.9 to 24.5 hours).[1] In mice, the fibroblast period length correlates with the period length of wheel running.[58] A recent study in human volunteers examined the fibroblast period length of "larks" and "owls"—morning and evening chronotypes.[59] Morning types had significantly shorter fibroblast period lengths than evening types. Some of the morning types and evening types turned out to have normal period lengths, 24.5 hours ± 0.5 hour. In these subjects, a greater amplitude of the fibroblast gene signal was linked to more evening-type behavior. This novel finding suggests that the amplitude of circadian gene activity in addition to the cell's period length influences chronotype.[59]

As described previously, researchers can transfect cells with luciferase (glowing) to measure circadian period length of fibroblasts taken from mice and humans. Transfected cells glow in proportion to gene activity. With use of a photomultiplier tube, the gene's activity can be measured over time, revealing that it glows in a sine wave–like circadian pattern. Peak-to-peak or trough-to-trough luminance demonstrates the gene's period length. Trough-to-peak luminance demonstrates the gene's circadian amplitude. In one study of this phenomenon, the position of peak activity in the luminance cycle, early versus late, revealed the phase ("owl" versus "lark") of peak activity. Moreover, the transfected cells continued to

Figure 170-6 Actigraph traces for a subject with delayed sleep phase disorder. Sleep apparently begins at approximately 2:00 AM or later, and wakeup time is as late as noon. On days 3, 4, 5, and 8, there are periods of inactivity between noon and 2:00 PM suspicious for drowsiness. (Permission granted by and copyright 2009 Koninklijke Philips Electronics NV.)

glow in vivo for more than 20 cycles, showing little degradation. Fibroblasts were selected because they are easily obtained and their genetic period has been found to be similar to that of the mouse's SCN.[60] In both mice and humans, with different circadian behavior, fibroblast luminance characteristics correlated closely with the individual subject from which or whom the genes were taken. In mice, gene luminescence period length is similar to the period of wheel running in the same animals: If the mouse's clock genes are mutated to shorten, lengthen, or abolish the circadian period of wheel running, a similar effect is observed in the luminescence characteristics of the fibroblasts taken from these mice.[60]

Another study of dermal fibroblasts from normal humans and persons with bipolar disorder found that the amplitude of the clock gene's circadian rhythm was damped in the latter group.[61] An interesting application of the fibroblast technique was the extraction of fibroblasts from pregnant mouse dams in a forced-feeding protocol when food was available only during the dam's biologicl night. As expected, the dams developed a secondary feeding rhythm while maintaining their normal day-night circadian rhythm. The pups were sacrificed shortly before birth, and fibroblast analysis showed the pups' most active time, from a gene transcription perspective, was when the mother fed, and not during her biologic day, as measured by the mother's wheel-running activity and by her fibroblast gene activity.[62]

FUTURE DIRECTIONS

Monitoring techniques employed to elucidate various parameters of circadian rhythms continue to evolve. One novel protocol is based on the changing color of the sky observed at twilight. Previously, circadian rhythm studies have focused exclusively on brightness, or irradiance, as the light signal to entrain the circadian clock. Rodents are housed in cages exposed to light or dark but not to the normal color changes of the sky that occur in the field at twilight. As sky brightness changes at twilight, the illuminance stimulating retinal receptors decreases at dusk and increases at dawn (during sunset and sunrise). Another novel research technique monitors the changing color of the sky at twilight. The ratio of blue light to yellow light changes by a factor of 4 at twilight as blue wavelength light increases and yellow wavelength light decreases with increasing darkness at dusk.[63]

By measuring both sky irradiance and blue-yellow color ratios locally over a period of months (in Manchester, United Kingdom) at both dawn and dusk, it was found that the blue-yellow chromatic changes during twilight were more consistent on a day-to-day basis than the changes in irradiance at twilight. Irradiance varied more than the blue-yellow color ratio owing to the erratic presence of varying degrees of cloud cover.

This change in the ratio of blue to yellow light is detected by blue-yellow spectral opponent neurons in the SCN.

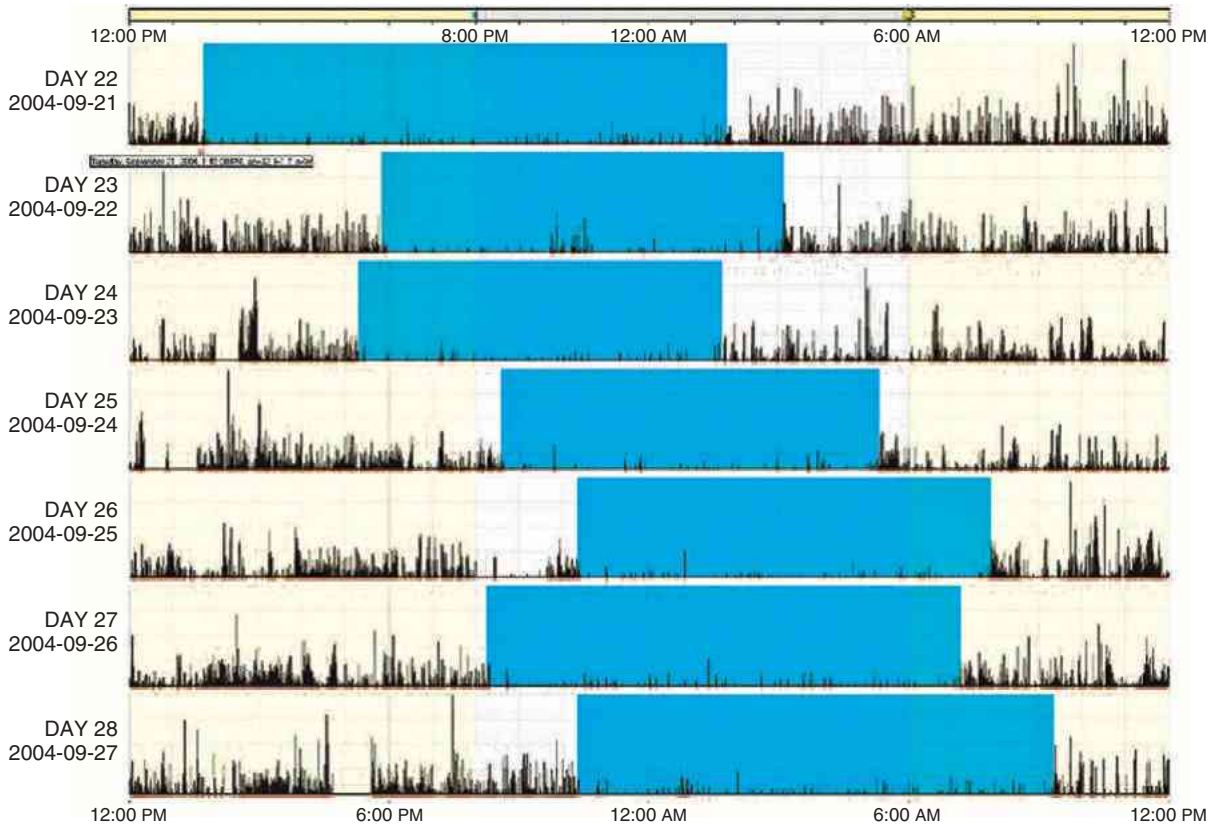

Figure 170-7 Actigraph traces showing the rest-activity pattern in a subject with free-running or nonentrained-type circadian rhythm disorder. This disorder most typically occurs in blinded persons whose biologic circadian rhythms are not entrained or masked by conventional time. The time of sleep onset does not follow an orderly progression, suggesting that social factors may contribute to the variance. (Permission granted by and copyright 2009 Koninklijke Philips Electronics NV.)

Electrophysiologic recordings of these neurons demonstrate changes in firing rates at twilight based on changes in blue-yellow light ratios independent of changes in illumination. These blue-yellow sensitive clock neurons are highly responsive to changes in spectral composition at twilight, which could be a basic mechanism for its detection and critical to detecting twilight and setting the body's clock.

Experimentally created simulated twilight transitions demonstrated that spectral changes that occur during twilight are sufficient to entrain circadian alignment to them. This novel technique for detecting twilight would be potentially of benefit to all mammalian species capable of blue-yellow light discrimination.[63]

Another novel experimental technique used to manipulate neural firing rate both in vivo and in vitro is optogenetics. With the technique, genes that express optically sensitive proteins are inserted into target cells make them respond to light. Then light is delivered by fiber optics to excite or inhibit the targeted cell. Widely used in neuroscience, this technique has recently been employed in the study of circadian rhythms.[64] Recent studies have combined optogenetically induced alterations of firing rate in the SCN with electrophysiologic recordings of SCN neurons in conjunction with observations of behavioral circadian rhythms. This is achieved with bioluminescence imaging and locomotor activity monitoring.[65]

Manipulating the firing rate optogenetically is capable of resetting the circadian rhythms in wild-type rodents, either phase advancing or phase delaying the sleep-wake cycle. This suggests that SCN firing rate is fundamental to circadian pacemaking as both an input to and an output of the molecular clockwork. The significance of the foregone study is in demonstrating that the firing rate of SCN neurons is not passively controlled by environmental illumination (dark versus light) but that the firing rate of neurons in the SCN is capable of resetting an organism's circadian rhythm. This study changed an animal's sleep-wake rhythms by artificially stimulating the neurons in the SCN by means of a laser light source and an optical fiber.

Until this study, neuroscientists had thought that the firing rate of SCN neurons was strictly an output of the biologic clock's activity. In accordance with this concept, experimentally altering the level of neuronal activity would not be expected to result in a phase shift of the circadian pacemaker. This study, however, demonstrated that stimulating (increasing) or suppressing (decreasing) the SCN's neurons in a fashion that emulates their day and night activity levels can force the clock to reset.

The project involved genetically engineering a strain of mice to manifest neurons in the SCN containing an optically sensitive protein that triggers neuronal activity when exposed to light and genetically engineered another strain of mice with

neurons expressing a similar protein that suppressed neuronal activity when exposed to light.

Current methods for assessing circadian pacemaker properties are indirect. In the future, current experimental techniques probably will be viewed as clever but rudimentary. Temperature is an indirect output of the core pacemaker, and melatonin also is indirectly related to it. Genetic advances in chronobiologic technique could allow measurement of gene transcription or translation products that are direct outputs of the circadian pacemaker. Studies using techniques such as functional magnetic resonance imaging could make it possible to directly monitor the functional activity of neuronal assemblies with purported pacemaker activity, such as the suprachiasmatic nuclei, which, after all, is the heart of the matter.

IMPLICATIONS

Methodologies in circadian rhythm research are rapidly evolving. Much has been learned about the circadian pacemaker in humans, its inputs and outputs, and factors that affect circadian rhythms. The protocols described in this chapter are continually being refined; additional controls are incorporated to eliminate unintended factors that could have masking effects.

Some of these protocols are complex and require sophisticated laboratories with extensive time-isolated floor space and equipment. Human data mostly derive from young male subjects, and little is yet known concerning sex differences. Each protocol has advantages and disadvantages.

Forced desynchrony studies can have a major psychological impact that may disrupt the emotional well-being of subjects. Subjects live continuously in a timeless environment; have no contact with the outside world; are awakened at various times throughout the night and day; are permitted to sleep only at times when natural sleep is unlikely; and have meals at times when the person would not be hungry. In countries where physical torture per se is not permitted, circumstances similar to forced desynchrony are used to interrogate prisoners of war. It is possible that the results from forced desynchrony protocols are affected by the unusual and unsustainable nature of the experimental conditions.

The long nights protocol reveals great flexibility in the human capacity to adapt to long periods of darkness, both biologically and behaviorally. It reveals biologic changes with such adaptation, such as longer cortisol suppression and decreased daytime sleepiness. These changes may prove o be advantageous in certain populations, such as children, people with narcolepsy, or patients with affective disorders. Little is yet known about this chronobiologic approach.

Chronobiology research in human subjects appears to be searching for experimental protocols that minimize differences between humans, other animals, and plants. Rodent studies have become the gold standard to which human circadian research aspires. Rodent and human studies maximize stability of period length and minimize variability. If gathering phenotypic information for genetic studies is the goal, it is understandable that maximal stability and minimal variance are sought. However, something about what makes us human is lost when sleep scientists abandon paradigms that show individual variance in preferred day length and design studies to exclude people who prefer to remain awake and asleep for extended periods.

CLINICAL PEARLS

- Circadian monitoring techniques have evolved rapidly and improved dramatically.
- Persons with suspected circadian rhythm disorders, such as phase advance, phase delay, and non–24-hour circadian rhythms, may be rapidly and accurately diagnosed using a wrist-worn actigraph or by measuring nightly onset of melatonin secretion using inexpensive saliva-gathering kits.
- The phase response curve to light and exogenous melatonin administration in advancing or delaying circadian rhythms is well established.
- In general, morning administration of bright light or melatonin advances a subject's circadian rhythm and evening administration of bright light or melatonin delays the subject's circadian rhythm.

SUMMARY

In adition to the fundamental methodologies in circadian rhythm research, among those reviewed in this chapter, exciting advances in recent years have occurred in techniques for measuring circadian rhythms. It is now possible to measure circadian rhythm period length from saliva gathered from a subject or patient, and to measure circadian rhythm period length, phase, and amplitude from genes extracted from a subject or patient's forearm. These are remarkable advances considering that the earliest studies of circadian rhythm properties required that the subject live in a cave for several weeks (and the results were flawed). Although methods can be described to measure the circadian rhythm properties of single-celled organisms, worms, flies, or mammalian organs, methodologies applicable to mammalian and, most specifically, human research probably are of greatest interest to sleep medicine professionals. As highlighted in this chapter, controversies and unresolved issues remain, and ongoing critical evaluation of the various chronobiologic protocols is indicated.

Recent studies using optogenetic techniques have demonstrated the ability to advance or delay circadian rhythms by manipulating suprachiasmatic nuclei firing rates indicating an unexpected ability of neural activity to influence circadian rhythms.

Chapter 171

Actigraphy

Katie L. Stone; Sonia Ancoli-Israel

Chapter Highlights

- Wrist actigraphy offers many advantages over polysomnography for estimating sleep. It is more convenient and cost-effective, as well as less invasive, and allows data collection in a more natural sleep environment. It also is possible to collect data for a longer duration of time, over a period of days to weeks, for a more representative characterization of sleep patterns.
- Actigraphy is reliable and valid for detecting sleep in normal populations; however, it has limitations for detecting specific sleep disturbances.
- Actigraphy is a useful adjunct to the routine evaluation of insomnia, circadian rhythm disorders, and excessive sleepiness. It is helpful for diagnosing periodic limb movements in sleep and/or restless legs syndrome.
- Actigraphy is useful in special populations, such as children or demented elderly, who may not tolerate polysomnography.
- Actigraphy is increasingly used in clinical settings and research. Several cohort studies have used actigraphy to determine the association between sleep patterns and health outcomes. Actigraphy also is very useful for examining treatment effects in randomized trials.

INTRODUCTION

The "gold standard" modality for evaluating sleep is polysomnography (PSG) incorporating, at a minimum, electroencephalogram (EEG), electrooculogram (EOG), and submentalis electromyogram (EMG) recordings. Depending on the patient's sleep complaints, monitoring of other physiologic variables may be added (e.g., respirations, heart rate, tibialis muscle movement, oximetry). PSG, therefore, allows for the collection of detailed and comprehensive information about sleep. The EEG, EOG, and EMG records can be scored for sleep stages (non–rapid eye movement [NREM] stages N1 to N3, and rapid eye movement [REM]), total sleep time, total wake time, sleep onset latency, and percent time in REM versus NREM sleep.

This information is crucial for certain types of evaluations; however, the recording process may disturb the subject's sleep, and PSG studies are very costly both to record and to score. In addition, PSG typically provides data about sleep episodes during the time of recording, typically lasting 6 to 10 hours. Because recordings generally are made during the major sleep period, little information is available about daytime (waking) or napping behavior. In certain instances, the only information required may be on whether the person is awake or asleep, and knowledge of the specific stage of sleep and other physiologic variables is not necessary.

By contrast, actigraphy is much less expensive than PSG and provides 24-hour recordings of activity from which wake and sleep can be scored. Actigraphs (or actimeters) record limb movement. Traditionally, the actigraph is placed on the wrist, although sometimes activity from the leg is recorded. The data collected are displayed on a computer and are examined for activity-inactivity and analyzed for wake-sleep. This chapter reviews the major clinical applications for actigraphy, provides tips for successful performance of the actigraphy study, and identifies limitations with its use.

BACKGROUND

Wrist activity technology is based on the fact that during sleep, little movement occurs, whereas during wake, periodic increases in movement are seen. Activity monitors have been available for many years.[1] With the advent of microprocessors and miniaturization, most contemporary actigraphs include a movement detector (such as an accelerometer) and sufficient memory to record for long time periods. The only time the actigraph needs to be removed by the patient is during bathing or swimming, although many actigraphs now are water-resistant. Thus nearly continuous 24-hour recordings over several days or weeks are possible. Newer models are the size of a wristwatch and collect digitized data. Physical movement generally is sampled several times per second and stored in 1-minute epochs, although sampling and epoch rates can be set by the clinician or investigator. The three primary ways in which signals can be digitized are *time above threshold* (TAT), *zero crossing mode* (ZCM), and *digital integration mode* (DIM) (Figure 171-1).[2] The TAT method counts the amount of time per epoch that the motion signal is above a given threshold.

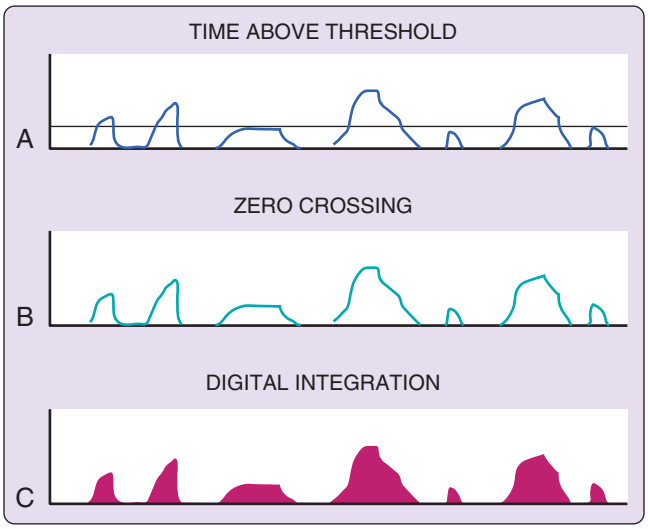

Figure 171-1 Three methods of deriving activity counts in actigraphy. The time above threshold method **(A)** derives the amount of time per epoch during which the activity is above some defined threshold (represented by the *thin horizontal line*). Zero crossing mode **(B)** counts the number of times the activity reaches zero (represented by the *solid baseline*). Digital integration mode **(C)** calculates the area under the curves represented by *dark pink shading*. (From Ancoli-Israel S, Cole R, Alessi CA, et al. The role of actigraphy in the study of sleep and circadian rhythms. *Sleep* 2003;26:342–92.)

However, neither the amplitude of the signal nor the acceleration of the movement is reflected in this strategy. The ZCM method counts the number of times per epoch that the signal crosses zero. In this strategy, once again neither the amplitude nor the acceleration is taken into account, and high-frequency artifact could potentially be counted as movement. DIM, on the other hand, samples the accelerometry output signal at a high rate and then, for each epoch, calculates the area under the curve. This result reflects the amplitude and acceleration of the signal but not the duration or frequency of the signal. In studies comparing the three methodologies, DIM was best for identifying movement amplitude, followed by TAT and then ZCM.[3] Some actigraphs use more than one method, thereby decreasing the deficits of each method alone.

Once the data are digitized, computer algorithms automatically score wake and sleep and provide the user with summary statistics. These computer algorithms generally supply information on total sleep time, percent of time spent asleep, total wake time, percent of time spent awake, number of awakenings, time between awakenings and sleep onset latency.[2,4] The use of actigraphy in sleep disorders medicine has gained popularity. Research has examined the reliability of activity versus EEG for distinguishing wake from sleep. Results vary depending on the populations studied and on the actigraph and scoring software used. Most studies indicate actigraphy estimates of total sleep time correlate well with PSG data in normal sleep; reliability coefficients range from 0.89 to 0.98.[2,5] Correlations are somewhat lower for severely disturbed sleep. For example, in patients attending a sleep disorders clinic, reliability ranged from 0.78 to 0.88.[6,7] In infants and in children, the reliability ranges from 0.90 to 0.95.[8,9] Actigraphy has been compared to sleep and wake EEG in demented nursing home residents.[10] Correlations with total sleep time were 0.91 for averaged activity (i.e., the average activity recorded per minute) and 0.81 for maximum activity (i.e., the maximum activity recorded per minute). Given the problems with obtaining EEG recordings in this setting, actigraphy offers a relatively accurate and feasible alternative in these patients.

A multicenter study of 68 community-dwelling older women (mean age, 82 years) participating in the Study of Osteoporotic Fractures examined the reliability of estimates of total sleep time. All three modes of actigraphy data collection—ZCM, TAT, and DIM—were compared with unattended in-home EEG recording. Results showed that estimates based on DIM mode were most highly correlated with EEG activity; reliability coefficient (r) was 0.76.[11] A similar study compared actigraphy with electroencephalography as part of the Osteoporotic Fractures in Men (MrOS) sleep study (n = 889). In older men, total sleep time based on actigraphy scored in DIM mode was more highly correlated with EEG-based total sleep time as compared with ZCM and TAT modes. Even based on scoring in DIM, however, the correlations were more modest (Pearson correlation coefficient of 0.61).[12] Furthermore, actigraphic total sleep time systematically overestimated total sleep time by an average of about 13 minutes per night in this cohort of older men. Correlations were lower in certain subgroups, such as subjects taking antidepressants and those with severe sleep apnea (apnea-hypopnea index of 30 or higher). In another study involving similar methods in a sample of 181 adolescents, TAT mode performed best in terms of agreement with EEG activity, but overall agreement was modest (r = 0.41). Further analysis, however, revealed better concordance in girls than in boys (r = 0.66 versus 0.31), and among those without sleep-disordered breathing (0.55).[13]

Reliability of estimated sleep time from actigraphy varies considerably, depending on the device used, the setting, and the specific population being studied. In addition, although total sleep time generally correlates well with EEG signal, the actigraph data do not necessarily correlate well on a minute-by-minute basis, particularly if sleep is very disturbed. Most studies are in agreement that with correct use, the actigraph is reliable for certain populations. Actigraphs with different algorithms are now commercially available; accordingly, reliability has become a major question. Ideally, each actigraph needs its own reliability studies, and results from one population may not be generalizable to other populations. In general, validation studies for normal subjects show greater than 90% agreement with EEG recording.[14] To date, however, few head-to-head comparisons between different actigraphs have been performed, so no conclusion can be drawn about which collecting and scoring method agrees better with PSG results.[2] In one study, two common research models of actigraphs were compared with each other and with overnight PSG. The sample included recordings from 115 adolescent boys and girls.[15] Each device had fairly high sensitivity (for detecting sleep) but relatively poor specificity (for detecting wake) compared with PSG. The investigators also noted that reliability of the actigraphs versus PSG recording varied considerably, depending on scoring mode, specific age group studied, and sensitivity setting. Furthermore, the two devices compared poorly with each other, suggesting the need for caution in comparing results across different studies and populations in which various devices have been used.

Wrist actigraphy records continuously for long time periods, so behavior occurring both during the night and during the day can be studied. For example, collecting nighttime and daytime information for long time periods is particularly useful in evaluating the sleep of patients complaining of insomnia. It economically allows recognition of a pattern of difficulty sleeping. Among patients with complaints of insomnia, sleep can vary in quality and quantity from night to night and is easily disturbed by novel environments. The actigraph therefore has potential for examining sleep over several nights in the patient's home environment. Compared with a sleep diary, actigraphy yields data that are continuous and objective, rather than discrete and subjective.

Another advantage of collecting data over long periods is the ability to examine the circadian rhythms of the sleep or activity cycle, particularly in studies of patients with sleep-wake schedule disorders (e.g., jet lag, shift work, advanced or delayed sleep phase). Most commercial software will now perform circadian rhythms analysis, including parameters such as the mesor (mean of the rhythm), the amplitude (peak of the rhythm), and the acrophase (time of the peak of the rhythm). These analyses need 5 to 7 days of data collection to be most accurate. Several adaptations and alternative methods of circadian rhythm analyses in humans have been proposed.[16]

The wrist actigraph may be particularly valuable for studying patients who would have difficulty sleeping in a laboratory or sleeping with the wires used by traditional PSG biosensors—for example, people with insomnia, children, and demented elderly persons. With actigraphy, patients sleep in their natural environment. In demented elderly subjects, it has been shown that the traditional recording process disturbs sleep. In addition, the EEG in such patients often does not allow distinguishing wake from sleep.[17] Actigraphy avoids both of these problems and enables the recording of sleep-wake activity in an easy, unobtrusive manner.

Some actigraphs may record other parameters in addition to activity, such as ambient light, skin temperature, and sound. These additional features enhance the capability of actigraphy to allow for both clinical and investigational studies of circadian rhythms in the home environment. Most actigraphs also have optional event buttons that the subject can push when turning out the lights or for noting other events. Additionally, some devices include software to estimate both sleep-wake parameters and energy expenditure.

An actigraph's concurrent recording of light is particularly useful for determining "lights out," as well as observing the beginning of morning light when the sun begins to rise. Light measurements also are helpful in studies of advanced and delayed sleep phase because they help determine light exposure amount and duration. For example, several studies using activity monitors that also record light exposure found that normal elderly persons are exposed to only 58 minutes of bright light per day,[18] patients with Alzheimer disease living at home are exposed to 30 minutes of bright light a day,[19] and nursing home residents are exposed to only 1.7 minutes.[20] These data aid the current understanding of the changes occurring in sleep in these populations and can assist in developing treatment plans.

In recent years, numerous consumer-oriented devices and smartphones have begun to provide interested users with estimates of their sleep characteristics, such as nighttime sleep duration, awakenings, and even time spent in various sleep stages (see also Chapter 160). Many of these products are lightweight wearable devices (usually worn on the wrist or placed in a clothing pocket, but sometimes provided as a necklace or clip) that include accelerometers and sometimes include other sensors to monitor heart rate, skin temperature, and other physiologic parameters. Typically, these devices interface by way of Bluetooth or similar software to a smartphone application that the user may use to view summary reports including both daytime activity and nighttime sleep patterns. Although these devices are appealing because they generally are lightweight and inexpensive and provide user-friendly reports of sleep characteristics, some limitations to their use in research or clinical applications have become evident. In particular, device manufacturers often use proprietary algorithms for sleep-wake parameter estimation, and it often is unclear how well the estimated sleep parameters compare with PSG data, or even to similar estimates from research-grade actigraphs. Another limitation has been the lack of access to raw (i.e., epoch-by-epoch) data, which many sleep researchers use to perform more complex analyses. For some of the devices, problems also have emerged with continuous long-term collection of data, based on the need to remove the device regularly for recharging. In keeping with the widespread use and popularity of such devices, however, interest in their potential use for research is growing. A few recent studies have independently explored the reliability of consumer-level devices with research-grade accelerometers/actigraphs for sleep estimation. In one study of healthy young adults, estimates for total sleep time were compared among seven consumer-level monitors and two research-grade devices. Correlations generally were above 0.80.[21] In another study, sleep estimates were compared for 23 subjects with simultaneous collection using a consumer-level wearable monitor and a multisensor device including a piezoelectric sensor that is placed under the bed sheets, as well as sensors for temperature and light, and a microphone.[22] Overall agreement was poor, with R^2 values of 0.25 for total sleep time, 0.11 for sleep efficiency, 0.30 for sleep onset latency, and 0.09 for number of awakenings. However, agreement was found to be excellent for some subjects and poor for others. Technology is rapidly evolving in this area, and many new developments are likely over the coming years.

APPLICATIONS OF WRIST ACTIGRAPHY

Because actigraphy is unobtrusive and can record multiple days and nights, it is a useful tool for evaluating insomnia, particularly because insomnia can vary from night to night. In addition, actigraphy eliminates laboratory effects as patients can be recorded sleeping in their own beds in their own homes. However, the convenience of actigraphy must be weighed against its reliability and validity versus polysomnography.[2]

The American Academy of Sleep Medicine (AASM) published recommendations on the use of actigraphy in clinical assessment of sleep disorders.[23] The AASM investigators concluded that actigraphy is reliable and valid for detecting sleep in normal healthy adult populations and in patients suspected of certain sleep disorders. These sleep disorders include advanced sleep phase syndrome, delayed sleep phase syndrome, and shift work disorder. Additionally, when polysomnography is not available, actigraphy may be

useful to estimate total sleep time in patients with obstructive sleep apnea. In patients with insomnia, the use of actigraphy is recommended for characterizing circadian rhythms and sleep-wake patterns. The practice recommendations also specify that actigraphy is useful in special populations such as children or elderly populations, who may have reduced tolerance to PSG.

Insomnia

Several studies have used actigraphy to evaluate sleep in the patient with insomnia, yet few of the studies validated the actigraphy findings against those with PSG. In a large sample of subjects with insomnia, a high concordance was demonstrated for actigraphic estimates of total sleep time and measures of sleep fragmentation with corresponding data derived from PSG.[24] However, estimates of sleep onset latency were much less reliable. The study report noted the lack of standardization of actigraphy devices and scoring methods across studies. Consequently, the findings of this particular study are not sufficient to support a blanket recommendation regarding the use of actigraphy to assess sleep among persons with insomnia. Another study reported that actigraphy tended to underestimate total sleep time, sleep efficiency, and sleep onset latency and to overestimate sleep onset latency. However, actigraphy was more accurate than the sleep diary when both were compared against PSG.[25]

Although actigraphy cannot determine the etiology of insomnia, it can help evaluate the severity of the condition. In patients with insomnia, the most difficult distinctions for the actigraph to recognize are the transitions between sleep and wake and the ultra short sleep-wake cycles. In patients with insomnia and coexisting circadian rhythm disturbances, actigraphy can detect sleep phase alterations.

Sleep Apnea

Actigraphy cannot determine the presence or absence of breathing abnormalities. However, patients with sleep apnea have more disrupted sleep and thus more body movements. Several studies tested wrist activity for recognizing patients with sleep apnea. One study showed that compared with control subjects, persons with sleep apnea had significantly higher movement and fragmentation indices.[26] Once sleep apnea therapy began, activity recordings indicated decreased indices, indicating successful treatment. Activity measures of sleep also have been shown to successfully differentiate patients with sleep apnea from those with insomnia and from control subjects.[8]

In general, the conclusion from studies is that actigraphy may be capable of distinguishing normal patients from those with moderate or severe sleep apnea, particularly because actigraphy is more sensitive than sleep logs in identifying brief awakenings. It is unlikely, however, that a distinction could be made between the different types of sleep disorders that cause brief arousals.[2] The real value of actigraphy in sleep apnea is in combination with cardiopulmonary recorders or other apnea detection equipment that do not measures of wake or sleep. The addition of an actigraph to such a recording would allow determination of whether all respiratory events actually occurred during sleep. In a recent update, the Standards of Practice Committee of the American Academy of Sleep Medicine concluded that actigraphy is indicated for the assessment of total sleep time among patients with sleep apnea when PSG is not available.[23]

Periodic Limb Movements in Sleep

Evaluation for periodic limb movements in sleep (PLMS) generally is accomplished by measuring the EMG signal at the tibialis muscle. Because the leg movement is the primary characteristic of this disorder, the ability of actigraphy to measure movement is thought to be an advantage. One study found high reliability between tibialis EMG and actigraphy for the number of leg movements per hour of sleep.[27] Another study that compared alternative placements of the actigraph for assessment of PLMS in comparison with PSG found that locating the device at the base of the big toe provided good validity.[28] The intensity and severity of PLMS can greatly vary from night to night, so actigraphy may offer an advantages in that multiple nights can easily be recorded. Actigraphy also has been useful in the assessment of treatment efficacy.[29] More research is needed to determine optimal procedures for detecting PLMS using actigraphy.

Treatment Effects

Actigraphy is particularly appropriate for the study of treatment effects because it can identify changes over time. Because actigraphy is noninvasive and less expensive than PSG, it holds promise for assessing treatment effects. Furthermore, single-session measures of sleep (which frequently is all that is feasible with PSG) may not accurately reflect habitual behavior.[30] Actigraphy also has been used to monitor drug and behavioral treatment effects, suggesting that it also can be used for screening some patients before ordering the more expensive PSG. Similarly, it can be used for follow-up assessments once treatment has begun or to evaluate changes in sleep over the course of the treatment period.

Circadian Rhythms

Actigraphy allows the study of sleep-wake patterns occurring over many days; it is therefore well suited to the study of circadian rhythms. Activity is a valid marker of entrained PSG sleep phase and correlates strongly with entrained endogenous circadian phase.[2] It also is useful in identifying sleep altered by circadian rhythm changes.

Actigraphy has been used to study circadian rhythms in patients with cancer [31] and demented elderly persons.[32] Studies also have examined sleep schedules of adolescents,[33] shift workers,[34] in-flight crews,[35] and travelers with jet lag.[36]

More recently, actigraphy recordings collected in two large cohort studies of older adults—the Study of Osteoporotic Fractures and the MrOS sleep study—were used to study the relationship of circadian rest-activity rhythms and aging-related outcomes such as mild cognitive impairment and dementia,[37] depression,[38] cardiovascular disease,[39] and death.[40,41]

A variety of methodologies are available for analyzing circadian parameters of activity.[42-44] However, no studies have compared one methodology with another across different populations. Finally, no one standard methodology has been accepted.

Special Populations

Pediatric Patients

Using actigraphy in the pediatric population is becoming increasingly popular, particularly for evaluation of children

with behavioral, psychiatric, or neurologic problems. Actigraphy has been used successfully to characterize sleep of infants,[45] developmental differences,[46] and sleep in children with autism,[47] and to demonstrate sleep differences between children with depression and those who were abused and normal children.[48] One study used wrist activity to study treatment effects on the sleep patterns of 50 infants whose parents complained of sleep disturbances in their children.[49] Objective activity recordings were compared with parental reports. The activity records showed that percent sleep increased and the number of awakenings during the night decreased with behavioral treatments. By examining data from each successive night, it was determined that most changes occurred during the first night of intervention. In addition, parental subjective reports significantly differed from objective actigraphy on quality of sleep, with parents reporting fewer awakenings during the night. The presence of objective measures allows for the evaluation of activity during sleep that would otherwise be missed by observation alone.

Actigraphy was used to assess sleep and wake in children with sleep-disordered breathing. One study compared actigraphic estimates of sleep and wake with PSG data on an epoch-by-epoch basis, using various activity thresholds. Overall, very high predictive values and sensitivity were found for detecting sleep (all parameters were higher than 90%), but predictive values and sensitivity for detecting wake were much lower.[50] In a study of preschoolers with and without autism, poor agreement in detection of nocturnal awakenings was found between actigraphy and video observations.[51] Although actigraphy offers many advantages for quantifying sleep and wake in children, results may be less reliable for detecting awakenings. Validation studies are needed for the specific devices and for use in the specific population of children.

Elderly Patients

At the other end of the age spectrum, actigraphy has been used to study sleep-wake patterns in the elderly population. Older adults are particularly susceptible to sleep complaints secondary to circadian rhythm changes, sleep-disordered breathing, PLMS, medical illness, and medication use.[52] Although evaluation of and for some of these complaints may be accomplished in the laboratory, elderly persons often are more set in their ways, need to stay home to take care of a spouse, or just find it more comfortable to sleep in their own beds. In many large studies in older adults, actigraphy represents the only viable option for obtaining objective measures of sleep. Although many studies tend to rely on self-report of sleep duration, this may be quite inaccurate in older populations, particularly among elderly persons with poor cognition and functional disabilities.[53]

Using actigraphy, a number of studies show that sleep in nursing home residents is extremely fragmented, with most patients never sleeping for a full hour and never awake for a full hour throughout the 24-hour day.[54] In these settings, actigraphy was then used to show that a trial of light treatment consolidated sleep but did not lessen degree or prevalence of agitation in this population.[43,55]

Measures of sleep using actigraphy have been incorporated into several large epidemiologic studies of older adults. For such application, standardization of techniques across multiple clinic sites is essential. In one such study of older women participating in the multicenter Study of Osteoporotic Fractures, excellent agreement was reported between results of an expert scorer and of a second scorer when both followed standardized scoring procedures.[56] Further details are provided in the subsequent section Epidemiologic Studies of Sleep.

Other Medical Conditions and Populations

Actigraphy is increasingly used in clinical research in populations in which it would be difficult to conduct PSG studies. Actigraphy has been used to study sleep and circadian rhythms in menopausal women,[57] in older patients with schizophrenia,[58] and in patients with cirrhosis,[59] with coronary artery disease,[60] or with cancer.[61-63]

EPIDEMIOLOGIC STUDIES OF SLEEP

Actigraphy is useful for studying sleep in large populations, particularly when recording in the laboratory is potentially cost-prohibitive, leading to attrition of enrolled subjects.

Ancoli-Israel and Kripke, along with their colleagues,[64,65] used actigraphy to determine wake and sleep patterns in large samples of elderly (n = 426) and middle-aged adults (n = 355). Measurements were used to determine prevalence of sleep apnea and PLMS (that were recorded with additional sensors). Many of these volunteers would have been less willing to participate had they been required to sleep in the laboratory.

Over the past decade, several other large observational studies have incorporated measures of sleep using actigraphy. In the multicenter Study of Osteoporotic Fractures, actigraphy was performed in nearly 3000 older women, whereas in another multicenter study, the Outcomes of Sleep Disorders in Older Men (MrOS sleep study), actigraphy data were collected in more than 3000 subjects. Using actigraphy in these populations helped identify the relationship between poor sleep and increased risk of falls,[66] poor cognitive function,[67] and poor physical performance and functional limitations.[68,69] The Rotterdam Study, which collected actigraphy recordings in nearly 1000 older men and women, has been used to demonstrate a relationship between actigraphic sleep duration and fragmentation and risk of obesity[70] and serum cholesterol levels.[71] Actigraphy also has been used to obtain objective measures of sleep characteristics in early middle-aged (38 to 50 years of age) men and women in the Coronary Artery Risk Development in Young Adults study.[30]

TRICKS OF THE TRADE

Actigraphs traditionally are placed on the wrist of the nondominant hand. However, two groups of investigators have shown that either wrist can be used. Both groups found that although activity levels were different for the two hands, rates of agreement with PSG were essentially equivalent for data collected from both hands.[9] In studies in infants, actigraphs also have been placed on the baby's legs.[72]

Most actigraphs come with bands similar to plastic watch bands. For persons who might be sensitive to such bands, or who find it uncomfortable to wear them for long time periods, bands made of terry cloth and self-stick fabric (Velcro) can

be customized. To discourage patients from removing the bands, the two Velcro straps were reversed, with one opening from right to left and the other from left to right. Some investigators use locked hospital bands to keep actigraphs in place in "difficult" populations. These techniques have worked to keep even the most diligent patient from removing the devices; they also are effective in young children.

Patients wearing actigraphs should be asked to keep a sleep log or diary. They should note information about daily time to bed, time out of bed, and any unusual activity or times when the device is removed (such as for showers or swimming). This information is extremely helpful for editing and analyzing data.

When data are collected in 1-minute epochs and accumulated over a period of more than a few weeks, it is prudent to download data every week to minimize data loss. In those units with batteries that need to be replaced, battery levels should be checked on initializing the device and again during downloading. Batteries with levels below 90% of the original battery voltage should be discarded, because they are likely to fail. The battery life is approximately 30 days. In our laboratory, a battery log is kept that records the battery number, date of initialization of the activity monitor, date of the data download, total number of days of battery use, and starting and ending battery levels.

When actigraphy is used in large samples, with multiple examiners administering the instructions and downloading the data, it is strongly recommended that standardized protocols be developed, and that centralized training and certification be incorporated into the overall data quality assurance plan.

With devices that also record light exposure, it is extremely important that the light sensor not be covered by the person's sleeve. The sleeve can be tucked under the actigraph or pinned up to ensure that it does not occlude the light sensor. Another important consideration is that because the angle of the wrist differs from the angle of the eye, the lux reading from a light sensor may differ from that for ambient illumination. Some devices have external light sensors, in addition to the internal sensor, that can be clipped to a collar and conceivably may give more exact readings. All activity and light monitors should be checked on a regular basis to determine if calibration is needed.

In patients with sensitive skin, the bands can be removed for a few minutes each day to avoid pressure sores. The time the device is removed, the time it is replaced, and whether or not the person was awake for the few minutes it was removed all should be noted on the log. This information is needed during the data editing process.

EDITING ACTIGRAPHY DATA

Different software packages are available for scoring the rest-activity data and inferring sleep-wake status. Data are edited on a computer screen with the use of the daily sleep log. Time intervals during which the device is removed should be manually changed to wake status only if the investigator is sure that the person was awake (e.g., in the shower); otherwise, these data points should be marked as missing data. Lack of movement scored as sleep, such as when the device is removed for especially vigorous activity, also can be manually changed to the wake category. For example, in a study involving adolescents, some subjects removed the actigraph during football or volleyball practice. No activity was recorded during that time period; however, it was clear that the subjects were awake.[73] If no information is provided in the log about the activity during the time the device was removed, that time period should be scored as missing data.

Figure 171-2 shows examples of two actigraph outputs.

LIMITATIONS

Actigraph data scorers need to be aware of the limitations of these devices.[2] When compared with PSG, actigraphy is fairly valid and reliable in healthy normal subjects. It is best at estimating total sleep time. As sleep becomes more disturbed, the actigraphy recording becomes less accurate. In general, actigraphy may overestimate sleep and underestimate wake, particularly during the day.

CLINICAL PEARLS

- Actigraphy has good reliability and validity for the detection of sleep in normal populations but is less reliable for identifying disturbed sleep.
- Actigraphy is a useful adjunct to the routine evaluation for insomnia, circadian rhythm disorders, and excessive sleepiness and may help in the diagnosis of periodic limb movements in sleep and/or restless legs syndrome.
- Actigraphy is useful for sleep study in special populations such as children or demented elderly persons.
- Actigraphy is becoming a valuable tool for investigating sleep and sleep disturbances in large-scale epidemiologic studies.

SUMMARY

Wrist activity has several important advantages over PSG: It allows the recording of sleep in natural environments and of behavior that occurs both during the night and during the day, as well as for long time periods, and is cost-efficient. Although not a replacement for EEG or PSG recordings, in certain instances actigraphy provides clear advantages for data collection.

Actigraphy is particularly useful for evaluating patients who cannot tolerate sleeping in the laboratory—for example, patients with complaints of insomnia, small children, or elderly persons. It may provide a more accurate estimate of typical sleep durations by permitting patients to adhere more closely to their scheduled sleep and wake times. Actigraphy also is becoming an important tool in follow-up studies and for examining treatment efficacy in clinical outcome.

Actigraphy has some value in the assessment of sleep disorders, although it may not necessarily distinguish among different sleep disorders. The newer scoring algorithms have great accuracy in determining those variables that are most important in insomnia—specifically, improved ability to detect wake versus sleep, sleep latency, awakenings during the night, and total sleep time. Actigraphy is particularly superior to sleep logs for detecting brief arousals during the night. It also can be used for the evaluation and clinical diagnosis of circadian rhythm disorders. The ability to detect movements holds promise in the identification of sleep disorders characterized

by frequent movements, such as PLMS, sleep apnea, or REM sleep behavior disorders. Actigraphy provides a particularly useful tool in situations requiring long-term monitoring.
