The consequences of leaving isolated snoring untreated relate specifically to the concern: will untreated isolated snoring progress to OSA over time? According to a study that followed individuals with isolated snoring over 5 years with polysomnography, isolated snoring does not progress to OSA over 5 years in the absence of a significant change in body weight.[34] Thus, to date, there is no evidence that isolated snoring progresses to OSA in the intermediate term.

In summary, isolated snoring is a diagnosis of exclusion reserved for habitual snorers who are otherwise asymptomatic without metabolic syndrome and cardiovascular disease and who do not meet polysomnographic or OCST criteria for OSA. The potential for adverse long-term cardiovascular outcomes in isolated snoring remains uncertain at this time. Treatment of isolated snoring is currently limited to attempting to improve the sleep quality of the bed partner. Available treatments include lifestyle modifications, oral appliances, and soft tissue surgery. Most available treatment options lead to short-term success but fail in the long-term.

Upper Airway Resistance Syndrome

UARS is defined as the symptom of either hypersomnolence or fatigue together with the presence of IFL during sleep by in-laboratory polysomnography and an AHI of less than 5/hour (see the glossary earlier in this chapter). As a movement away from the paradigm that hypersomnolence among patients with sleep-disordered breathing requires the presence of sleep fragmentation by apneas and hypopneas, UARS was originally accompanied by a new paradigm that sleep fragmentation by RERAs can also lead to hypersomnolence in individuals with milder resistive events[5] (discussed previously under Background). In line with this new paradigm, ICSD3 absorbs UARS into OSA by including RERAs into the severity assessment of sleep fragmentation in OSA. ICSD3 criteria for OSA now classify any patient fulfilling the previously noted UARS definition with an RDI above 5/hour as having OSA. Clearly a portion of UARS has been absorbed into OSA by the clinical criteria of ICSD3. However, there are still patients meeting the definition of UARS elaborated in the chapter with an RDI of less than 5/hour who are not included within the ICSD3 definition of OSA and are not considered, clinically, to have sleep-disordered breathing. Nevertheless, to investigators of UARS and to clinicians attempting to treat the hypersomnolence of a patient without a clear diagnosis because of too few RERAs, the recognition that sleep-disordered breathing may, in fact, exist outside the limits of ICSD3 is important and worthy of consideration. In this section, we discuss the varied clinical presentation of UARS, its polysomnographic appearance, and its evolving paradigm. To facilitate this discussion, when we refer to OSA, we will use the ICSD2 definition of OSA—an AHI of at least 5/hour–to match the definition used in the research to be presented.

Anthropometric Features and Risk Factors

Compared with patients with OSA, UARS patients are younger, leaner, and more frequently female. Published studies of UARS patients as defined by the previous criteria have established a mean age of 40 years with the average body mass index between 23 and 30 kg/m^2 (normal weight or overweight; less often, obese) and approximately 50% female.[35-37] Although craniofacial abnormalities such as a narrow, elongated face characterized by a high arched palate, reduced upper and lower intermolar distances, and a narrow anterior nasal aperture (adenoid facies) have been reported in patients with UARS, these same findings are also commonly observed in patients with OSA[38] and so cannot be considered specific for UARS. The presence of these abnormalities suggests a disturbance of facial development caused by increased nasal resistance during early childhood with mouth breathing.[39]

Signs and Symptoms

The most commonly observed polysomnographic feature of UARS patients is nonapneic, habitual snoring or silent IFL with relatively few adjudicated apneic or hypopneic events (AHI <5/hour). In clinical practice, these patients will seek medical attention for their condition because they also suffer from nonrestorative sleep, fatigue, sleepiness, or insomnia. In fact, UARS patients are more commonly referred to a sleep disorders center for their symptoms than for their snoring. Before referring these patients for cognitive behavior therapy (CBT) for insomnia, a careful sleep-related history revealing snoring without witnessed apnea will prompt polysomnographic investigation with documentation of IFL during sleep. It is emphasized that a report of witnessed apnea does not preclude a diagnosis of UARS because about one third of UARS patients are reported to have witnessed apnea but an AHI below the threshold for OSA.[40] Similarly, the absence of audible snoring does not preclude a diagnosis of UARS because inaudible IFL is observed in about 10% of patients diagnosed with UARS.[40,41] Typically, these patients have been diagnosed with insomnia and, in the absence of a sleep-related history of habitual snoring, are referred for CBT without performing polysomnography. When CBT fails to improve their condition and a polysomnogram is performed to exclude an intrinsic sleep disorder, IFL in the absence of audible snoring can be demonstrated.

The earliest reports of UARS emphasized the importance of hypersomnolence as a diagnostic criterion distinguishing it from isolated snoring.[5,13] Before those reports, polysomnographic technology used a thermistor or thermocouple to generate a qualitative airflow signal that could not be used to recognize IFL. Thus the link between hypersomnolence and IFL could not be made, and patients with UARS often received a diagnosis of idiopathic hypersomnolence. The earliest reports of UARS substituted a pneumotachograph recording of airflow for the qualitative airflow signal together with an esophageal pressure catheter measurement of inspiratory effort to establish the presence of IFL during sleep in UARS patients.[5,13] With time and the growth of clinical experience evaluating UARS patients, the diagnostic criteria for UARS have been expanded to include complaints of hypersomnolence or fatigue.[6,7,40]

Hypersomnolence and fatigue are not synonymous. Hypersomnolence indicates increased sleep pressure expressed by short sleep latency, a state that is inconsistent with a complaint of insomnia. Fatigue, on the other hand, is generally associated with longer sleep latencies, reflecting a state of hyperarousal commonly observed in patients with insomnia. Indeed, about one third of UARS patients complain of sleep-onset insomnia, and nearly two thirds report sleep maintenance insomnia.[35] Characteristically, the complaints of fatigue and insomnia among UARS patients are associated with the complaint of nonrestorative sleep.

Interestingly, UARS patients complain of more subjective sleep disturbance than OSA patients who have much more disrupted sleep.[41a] UARS patients can also experience a variety of parasomnias. Among these are sleep-related bruxism,[40] chronic sleepwalking in children[42] and catathrenia.[43]

Currently, there is not enough evidence to conclude that UARS is an independent cardiovascular risk factor. An increased prevalence of arterial hypertension among nonapneic snorers has been reported,[44] and borderline arterial hypertension has been lowered with nasal CPAP in a small series of UARS patients.[45] Hypotension and orthostatic intolerance have also been documented in about 20% of patients with UARS.[46]

Psychiatric symptoms such as depression[36,37,47,48] and anxiety[47-49] have been demonstrated among UARS patients and have responded dramatically to treatment using nasal CPAP and rapid palatal expansion in case reports.[47,48] Conversely, failure to diagnose and treat UARS is associated with a worsening of these symptoms over time.[36]

Currently there are limited data available regarding cognitive function among patients with UARS. Using a psychomotor vigilance task, Stoohs and associates[50] have reported increased reaction times among UARS patients compared with OSA patients. Research from Broderick and associates[51] suggests that, although UARS patients perceive themselves to have impaired cognitive function compared with healthy controls, objective testing fails to demonstrate such a difference.

UARS patients also commonly present with a variety of symptoms characteristic of the functional somatic syndromes.[40] In addition to insomnia, sleepiness, and fatigue, and the affective symptoms of depression and anxiety already mentioned, UARS patients may experience headaches and functional gastrointestinal symptoms and alpha-delta sleep, all common symptoms and signs of the functional somatic syndromes.[40] These functional somatic syndrome symptoms and signs (specifically, sleep-onset insomnia, headache, irritable bowel syndrome, and alpha-delta sleep) decrease in prevalence among sleep-disordered breathing patients as the AHI increases.[40] Conversely, when patients with functional somatic syndromes undergo polysomnography, IFL during sleep is commonly observed (fibromyalgia, temporomandibular joint syndrome, Gulf War illness, and irritable bowel syndrome have been studied).[21,22,52,53] In this setting, nasal CPAP has been shown to relieve the symptoms of functional somatic syndrome patients by relieving their IFL during sleep.[53,54]

Polysomnographic Findings

Polysomnographic findings among UARS patients can be subdivided into those characterizing breathing with associated arousals and those characterizing sleep architecture (electroencephalographic frequencies, sleep staging). Concerning sleep architecture, researchers have observed findings consistent with unstable, nonrestorative sleep among UARS patients.

Polysomnographic Findings Characterizing Breathing. Breathing in UARS is, by definition, characterized by an AHI below 5/hour of sleep and periods of IFL during sleep with flows greater than 50% of waking levels (exemplified in Figures 112-2 to 112-4), terminated by arousals or changes in the background electroencephalographic rhythm associated with a return of airflow to a non-flow-limited state (i.e., RERAs).[36] Oxyhemoglobin saturation generally remains above 90% throughout sleep.[35,37] In several large studies, the mean AHI for UARS patients is consistently 2/hour, and the frequency of RERAs is between 5/hour and 20/hour.[35-37] Describing the prevalence of flow-limited breaths during sleep among UARS patients has received little attention. One large study that used a snore microphone to determine the prevalence of breaths associated with audible snoring among 424 UARS patients observed a 21 ± 23% (mean ± standard deviation) prevalence of such breaths during sleep.[37] It is likely therefore that if a study were performed that included both a snore microphone and a pressure transducer for airflow measurement to identify both snoring and inaudible IFL (as explained previously), the prevalence of such breaths would be considerably higher and not a sporadic occurrence.

The preceding description of breathing during sleep in UARS does not define the syndrome based on thresholds for IFL or RERAs. Empirically, periods of IFL during sleep in UARS may last a few breaths or be continuous for many polysomnographic epochs. The presence of IFL has not been defined by a consensus frequency of *resistive* events, but it is a characteristic of breathing during sleep that can be described in a polysomnographic report based on the sleep stages in which it occurs and an impression of the prevalence of flow-limited breaths in those sleep stages (e.g., continuous, intermittent, or uncommon; Figure 112-4 is one 30-second epoch of continuous IFL in a UARS patient). Similarly, in the UARS literature, RERAs have not been defined by a consensus length of the preceding period of IFL (as has been done in ICSD3). Rather, the duration of IFL preceding a RERA has been undefined,[5] 10 seconds[36] or one flow-limited breath,[23] depending on the study. Because the diagnosis of UARS is not dependent on thresholds for resistive events or RERAs, UARS cannot be classified as mild, moderate, or severe based on these events. Indeed, there are no published data relating the severity of hypersomnolence among UARS patients to RERA frequency or prevalence of IFL.

Polysomnographic Findings Characterizing Sleep Architecture. Polysomnography of UARS patients demonstrates findings consistent with unstable, nonrestorative sleep (the altered sleep quality referred to earlier under Background). Among these findings is alpha frequency intruding into sleep, increased sleep stage shifts, and cyclic alternating pattern (CAP).

Patients with UARS experience increased alpha frequency, a frequency observed during quiet wakefulness, within their sleep electroencephalogram.[40,55] This increased alpha frequency may be seen in stage N3 sleep, where it has been termed *alpha–delta sleep*[40,56] (Figure 112-5) or in N1 and N2 sleep[48] (Figure 112-6; also observed in Figure 112-4). It is emphasized that this alpha frequency occurs during continuous sleep and is not the consequence of an electroencephalographic arousal. Among patients with fibromyalgia and chronic fatigue syndrome, the intrusion of waking alpha frequency into the sleep electroencephalogram is hypothesized to reflect a state of *aroused*, nonrestorative sleep.[57,58] Although resolution of alpha frequency intrusion in sleep has never been described among fibromyalgia or chronic fatigue syndrome patients, such resolution has been observed among adolescent UARS patients when sleep quality improves following rapid palatal expansion[48] (Figures 112-5 and 112-6).

UARS patients also demonstrate sleep stage instability. This instability may be recognized as frequent shifting from deeper to lighter sleep stages or to wakefulness, with decreasing depth of sleep designated as the stage sequence: REM, N3, N2, N1, and wake. The frequency of sleep stage shifting in UARS patients is decreased by treatment with nasal CPAP[54] (Figure 112-7) and rapid palatal expansion,[48] which overcome upper airway resistance. The mechanism by which nasal CPAP eliminates sleep stage shifts is not simply elimination of sleep fragmentation associated with RERAs. Although shifts between stages N2, N1, and wake require an intervening arousal, stage shifts between REM, N3, and N2 do not require an arousal. Indeed the N3-to-N2 sleep stage shifts in Figure 112-7 that decrease in frequency with nasal CPAP all occur during continuous sleep (the difference between N3 and N2 being determined by the prevalence of delta waves) and do not represent the elimination of RERAs by nasal CPAP. The occurrence of frequent shifts from deeper to lighter sleep is hypothesized to be an adaptive response to a danger or *stressor*, lightening the individual's sleep and allowing for a quicker response to an emergency.[59] Increased shifts from deeper to

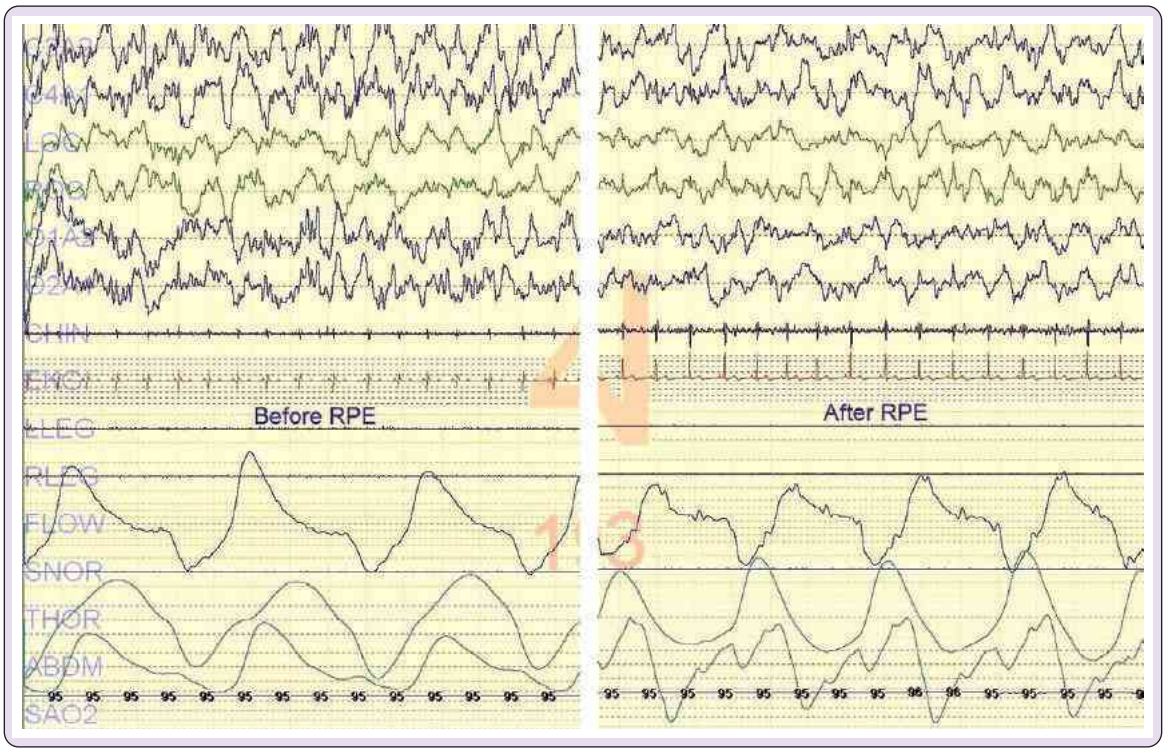

Figure 112-5 This figure demonstrates two 15-second periods of NREM stage 3 (N3) sleep recorded at the same time of night, before and after rapid palatal expansion (RPE; 13 months between studies) in a 16 year-old boy with severe chronic fatigue who was diagnosed with upper airway resistance syndrome. Recording includes four electroencephalographic channels (*purple*; C3A2, C4A1, O1A2, O2A1), left and right electrooculograms (*green*; LOC, ROC), electromyograms of the chin (CHIN) and left and right tibialis anterior muscle (LLEG, RLEG), and an electrocardiogram (EKG). Respiratory channels include pressure transducer airflow (FLOW), a snore microphone (SNOR), thoracic and abdominal wall movement (THOR, ABDO), and oxygen saturation (SaO_2). Before RPE, the patient demonstrates alpha-delta sleep characterized by low-frequency, high-amplitude delta waves with superimposed prominent 7- to 11-Hz alpha waves observed best in electroencephalographic leads C3A2 and C4A1. After RPE, the alpha frequency is greatly decreased in amplitude or gone. Associated with this change, The EKG demonstrates a decrease in heart rate between studies from 72/minute before RPE to 64/minute after RPE, suggesting decreased sympathetic nervous system tone between studies.

Figure 112-6 This figure demonstrates 30 seconds of stage N2 sleep recorded at the same time of night, before and after rapid palatal expansion (RPE), from an 18-year-old man with severe depression who was diagnosed with upper airway resistance syndrome. The two recordings each include three electroencephalographic channels (F_3M_2, C_3M_2, O_1M_2). As in Figure 112-5, the recording before RPE shows prominent alpha frequency (at approximately 7 Hz; seen well above the *orange line*). After RPE, the alpha frequency is greatly reduced in amplitude and the underlying theta frequency of 3 to 5 Hz is seen more clearly. (Reproduced with permission from Miller P, Iyer M, Gold AR. Treatment resistant adolescent depression with upper airway resistance syndrome treated with rapid palatal expansion: a case report. *J Med Case Rep* 2012;6[1]:415.)

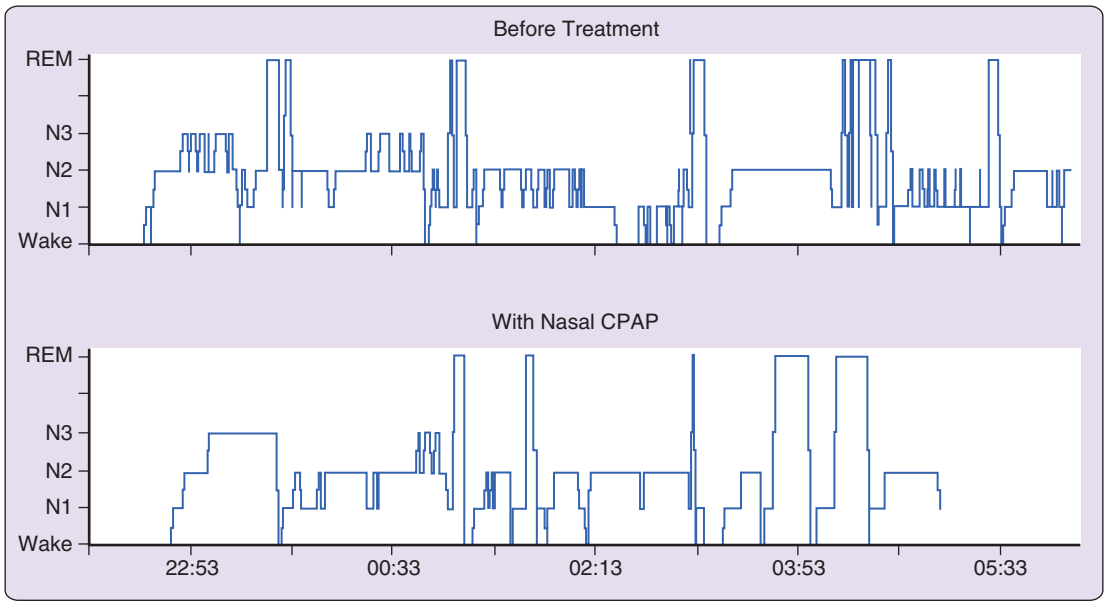

Figure 112-7 This figure demonstrates two hypnograms (plots of sleep stages against time of night with increasing depth of sleep staged as: wake, N1 [NREM stage 1], N2, N3, REM) from a 43-year-old veteran of the first Gulf War (1990–1991) who returned with complaints of moderate fatigue and severely impaired sleep quality (symptoms of Gulf War illness) and was found to have an apnea hypopnea index of 5/hour.[21] The upper hypnogram is derived from his polysomnogram before treatment, and the lower hypnogram was obtained from a polysomnogram performed (while sleeping with nasal CPAP at 9 cm H_2O) after the veteran slept with nasal CPAP nightly for 3 weeks and experienced improvement of his fatigue and sleep quality. The initial hypnogram demonstrates frequent shifts from deeper to lighter sleep stages throughout the night. The hypnogram obtained following symptomatic improvement demonstrates fewer sleep stage shifts. Frequent shifts from deeper to lighter sleep are thought to be an adaptive response to stress that enables the individual to respond more quickly to an emergency. (Reproduced with permission from Amin MM, Gold MS, Broderick JE, Gold AR. The effect of nasal continuous positive airway pressure on the symptoms of Gulf War illness. *Sleep Breath* 2011;15[3]:579–87.)

lighter sleep commonly occur in healthy people sleeping for the first night in a new location, such as a sleep laboratory.[60]

A second manifestation of sleep stage instability among UARS patients is the occurrence of CAP, which is defined by a periodic disruption of NREM sleep by electroencephalographic events that do not meet the threshold for an arousal by conventional sleep staging criteria.[61] Indeed, these electroencephalographic events constitute the changes in background rhythm associated with the return of airflow to a non-flow-limited state, referred to earlier concerning RERAs. Among UARS patients, increasing levels of these nonarousal electroencephalographic events correlate with increasing levels of sleepiness and fatigue.[61] Furthermore, the presence of CAP is a marker for increased sympathetic nervous system tone[62] commonly found under conditions of stress (see later). Therefore, CAP is one of the manifestations of unstable, nonrestorative sleep that leads to daytime sleepiness and fatigue among UARS patients.

Pathophysiology and Clinical Correlates

Hypotheses concerning the pathophysiology of UARS continue to evolve as the manifestations of the disorder and the body systems affected increase in number. The first case report of UARS patients published by Guilleminault and associates presented the disorder as one of sleep fragmentation by RERAs associated with hypersomnolence that improved with nasal CPAP treatment.[5,13] The new insight was that apneas and hypopneas associated with pronounced arousals from sleep, characteristics of OSA, were not necessary to produce hypersomnolence. Rather, the investigators hypothesized that mildly increased upper airway resistance, with its associated increase in inspiratory effort, could, episodically, produce brief periods of alpha frequency intrusion into sleep (alpha arousals), also producing hypersomnolence. Although this paradigm of UARS (henceforth termed the *RERA paradigm*) provided an explanation for the hypersomnolence associated with UARS, it did not provide an explanation for the somatic, cognitive, and affective complaints, such as insomnia, fatigue, body pain, depression, anxiety, cognitive dysfunction, and gastrointestinal dysfunction, or for the parasomnias, such as bruxism, sleepwalking, and catathrenia, that have subsequently been associated with UARS.[40,42,43,47-49,51,63,64]

As clinical experience with UARS patients increased, investigators came to postulate that the hypersomnolence of UARS patients is not simply the consequence of sleep fragmentation but also of altered sleep quality that affects its restorative properties. The alpha frequency intrusion into sleep[40,55] and the unstable sleep stages characterized by increased shifts from deeper to lighter sleep[48,54] and CAP,[61] as described earlier, were seen as alternative responses to pharyngeal collapse during sleep that maintain a more patent pharyngeal airway while maintaining sleep continuity. In contrast, OSA patients, whose only response to pharyngeal collapse during sleep is episodic arousals terminating apneas and hypopneas, experience more sleep fragmentation.[35] Bao and Guilleminault[65] have further hypothesized that UARS evolves into OSA over time because of upper airway trauma related to snoring. According to this hypothesis, because of the effect of snoring on the upper airway, UARS patients eventually lose their increased sensitivity to pharyngeal collapse and their

sleep-maintaining response. As a consequence, their sleep deepens and their mild resistive events become hypopneas and apneas terminated by arousal. This proposed *sleep quality* paradigm of UARS provides an explanation for the alpha frequency intrusion into sleep and sleep stage instability characterizing UARS patients; however, it remains focused on nonrestorative sleep leading to hypersomnolence without providing an explanation for the spectrum of somatic, cognitive, and affective disorders also associated with UARS.

A third paradigm of UARS, the *chronic stress* paradigm, builds on the *sleep quality* paradigm of UARS and provides a more complete explanation for the varied symptoms associated with the syndrome.[66] The paradigm postulates that some individuals can become sensitized to upper airway resistance as a stimulus that activates the stress response (activation of the hypothalamic-pituitary-adrenal axis and sympathetic nervous system by the brain's limbic system) as if it were an existential threat. Because upper airway resistance during sleep occurs for at least several hours daily, in these individuals, it constitutes a chronic stress with associated symptoms including sleep onset and sleep maintenance insomnia, headaches, gastrointestinal and bladder irritability, body pain, anxiety, and depression. In addition to these symptoms, so prevalent among UARS patients, chronic stress is associated with hypertension, type 2 diabetes mellitus, gonadotrophic hormone deficiency leading to sexual dysfunction (erectile dysfunction in men and polycystic ovarian syndrome in women), and growth hormone deficiency leading to diminished growth in children. These are all prominent medical conditions associated with OSA. According to such a chronic stress paradigm, the sleep fragmentation by arousals and altered sleep quality caused by alpha frequency intrusion and sleep stage instability observed among UARS patients is not a direct effect of upper airway resistance on sleep continuity, but an adaptive response of the brain to the existence of a disturbance or threat. Having sleep continuously interrupted, or having a state of vigilance maintained during sleep through alpha frequency intrusion and sleep stage instability theoretically enables the individual to respond more quickly to a danger, an apparent survival advantage.[59] This advantage, however, is accompanied by the disadvantages of parasomnias and daytime sleepiness resulting from the chronically altered sleep. The chronic stress paradigm of UARS explains not only the hypersomnolence associated with UARS but also the somatic complaints, affective disorders, cognitive dysfunction, and parasomnias observed among UARS patients. A more complete discussion of this paradigm can be found in the review by Gold.[66]

In summary, the pathophysiologic and associated clinical paradigm of UARS has evolved from sleep fragmentation by RERAs through altered sleep quality as a direct response to upper airway resistance, leading to milder resistive events than occur among OSA patients, to recent consideration of upper airway resistance, provoking chronic stress with sleep-related, somatic, cognitive, and affective consequences. The pathophysiologic paradigms of UARS will continue to evolve as new data accumulate. However, the recognition that altered sleep *quality* contributes to the hypersomnolence and fatigue of UARS patients supports the idea that UARS also exists below the RDI threshold for a diagnosis of OSA—an important possibility when one contemplates making the diagnosis of idiopathic hypersomnolence.

Treatment

The treatment of UARS uses the same treatments that have been discussed earlier for snoring. Chief among these treatments is nasal CPAP, which is highly effective and can be precisely titrated by the prescribing physician to eliminate IFL during sleep. To titrate nasal CPAP for UARS patients, one must titrate to convert IFL during sleep into non-flow-limited breathing, as illustrated in Figures 112-2 and 112-3. In a large, published clinical series of sleep-disordered breathing patients all titrated in this manner (using only nasal masks), mean therapeutic level of nasal CPAP for 22 UARS patients was found to be 7 cm H_2O with a range of 4 to 9 cm H_2O.[3] Although autotitrating positive airway pressure has not been studied specifically in UARS, the algorithms used attempt to eliminate IFL during sleep and should be acceptable for treatment of UARS as they are for OSA. For patients unable (or unwilling) to breathe with the mouth closed or to wear a nasal mask, alternative forms of treatment such as mandibular advancement appliances or tongue-retaining devices, weight loss, and surgical procedures may be considered as previously described. A growing body of literature suggests that applying positive airway pressure through an oronasal mask is not a reliable method for eliminating IFL during sleep[67,68] and anesthesia.[69] Among pediatric patients, rapid palatal expansion performed by an orthodontist has been used effectively to treat UARS (e.g., the patients in Figures 112-5 and 112-6[48]) and mild OSA.

CLINICAL PEARLS

- Silent inspiratory airflow limitation (IFL) during sleep is characterized by either an inspiratory airflow plateau or an increase in the ratio of inspiratory time to the respiratory cycle time with a prolongation of the time near maximal inspiratory airflow.
- In a patient consulting the clinician for habitual snoring that disturbs his or her bed partner, with normal alertness, no somatic or metabolic disorders, and no known cardiovascular disease, a polysomnogram will likely reveal either isolated snoring or asymptomatic OSA. Consider evaluating the results of a carotid ultrasound, looking for evidence of atherosclerosis, before foregoing specific OSA treatment in this setting.
- For patients with functional somatic syndromes complaining of insomnia, fatigue, headache, body pain, gastrointestinal or bladder irritability, anxiety and depression, with or without audible snoring, consider performing polysomnography to diagnose UARS (OSA by ICSD3 criteria) because prevention of IFL during sleep may be an effective treatment not only for fatigue and insomnia but also for somatic symptoms.

SUMMARY

Our understanding of pathologic pharyngeal collapse during sleep has progressed from recognizing obstructive apneas and hypopneas associated with arousal from sleep and oxygen desaturation (clinically, obstructive sleep apnea) to recognizing the mildest IFL without audible snoring, arousal, or oxygen desaturation. At the same time, our understanding of the consequences of pathologic pharyngeal collapse during sleep has expanded from hypersomnolence and cardiovascular

and metabolic disorders to include associations with somatic syndromes, affective disorders, and carotid artery atherosclerosis independent of metabolic syndrome. Underlying this evolution is a new paradigm of *sleep related breathing disorders* (often referred to as "sleep-disordered breathing") in which pharyngeal collapse during sleep acts not only directly, causing oxygen desaturation and arousal from sleep, but also indirectly, with even the mildest IFL during sleep serving as a chronic activator of the body's stress response. In this context, one can appreciate the evolving understanding of what constitutes clinically significant sleep related breathing disorders associated with sleep-related upper airway pathophysiology.

Obstructive Sleep Apnea: Phenotypes and Genetics

Susan Redline

Chapter Highlights

- There is clear evidence that a positive family history of obstructive sleep apnea (OSA) is an important risk factor for an elevated apnea-hypopnea index (AHI) and associated symptoms such as snoring, daytime sleepiness, and apneas. Patients with OSA often have relatives—parents, siblings, and children—who have similar symptoms, a diagnosis of OSA, or both. The familial aggregation of OSA has been quantified through use of twin and cohort studies, which conservatively estimate that risk for OSA is increased by 50% in individuals with an affected first-degree relative.
- Overall heritability estimates (the proportion of the variance in a trait attributable to genetic factors) for the AHI are 0.30 to 0.40. Although there is a strong correlation between OSA and obesity, only 35% of the genetic variance in the AHI may be accounted for by genes that influence obesity (with 65% of the genetic variance likely due to genetic variants in other etiologic pathways). Other potentially inherited risk factors for OSA include craniofacial structural traits that influence upper airway patency; body fat distribution, including propensity for airway fat deposition; chemoreflex ventilatory control; and arousability to ventilator stimuli.
- Pedigree studies analyzed using linkage analysis have identified several areas where biologically plausible candidate genes are located, including candidates for ventilatory control and obesity. A number of association studies and emerging meta-analyses of candidate and genome-wide association studies also provide evidence for increased susceptibility to OSA in persons who inherit variants for genes in pathways implicated in ventilatory control, inflammation, body fat distribution, and craniofacial structure.

DEFINITION OF THE OBSTRUCTIVE SLEEP APNEA PHENOTYPE

As is the case with many other complex disorders, variable definitions have been used to characterize obstructive sleep apnea (OSA) in genetic analyses. Clinically, OSA is recognized by the occurrence of repetitive episodes of complete or partial upper airway obstruction during sleep that result in oxygen desaturation or arousal and that are usually accompanied by symptoms of loud snoring and daytime sleepiness. However, there can be substantial variability in identification and characterization of OSA because of variations in how specific respiratory events are identified and defined, the threshold level for frequency of events during sleep considered pathologic, and to what extent other clinical and polysomnographic data are thought necessary for characterizing disease status.

Most family and genetic studies of OSA have used the apnea-hypopnea index (AHI) to define phenotype. The advantages of using the AHI include its ability to be readily calculated from data obtained from overnight sleep apnea tests with moderate to high night-to-night reproducibility[1] and from widespread clinical use. In addition, it is often followed as a key outcome in OSA treatment research studies. Because the AHI has been shown to be moderately correlated with other indexes of OSA severity, such as nighttime oxygen desaturation and sleep fragmentation, it may provide information about several correlated traits that are important in disease expression. All genetic studies of OSA that use the AHI as the outcome measure have demonstrated significant familial aggregation, suggesting that this measure captures useful information for quantifying genetic associations. All candidate gene studies conducted to date also have defined "case" and "controls" on the basis of threshold levels of AHI (either >5 or >15/hour of sleep).

Additional metrics of OSA that provide more specific information on patterns of respiratory disturbances during sleep have been reported to be heritable and thus have potential for use in genetic studies. These include measures of AHI specific to rapid eye movement (REM) and non–rapid eye movement (NREM) sleep, average levels of nocturnal oxygen desaturation, and average duration of sleep-related respiratory disturbances. The latter metric, which is related to respiratory arousability, has been reported to have a heritability of almost 0.60[2] (indicating as much as 60% of the variance in this trait is explained by familial factors acting additively) and thus may be useful for identifying genes influencing ventilatory control.

A multidimensional OSA phenotype can be derived by combining polysomnographic data with information related to symptoms, signs, and outcome data. In the Cleveland Family Study, a stronger relationship between familial risk and OSA was observed when OSA was defined by an AHI greater than 15/hour plus reported daytime sleepiness than when disease was defined by AHI alone.[3] Additional power may be gained in future genetic studies of OSA that use multidimensional phenotypes. For example, alternatives to the AHI, such as indexes of flow limitation during sleep and critical airway closing pressure, may prove to be superior markers for genetic studies. However, a phenotype must be feasible for use in the large numbers of subjects who are needed for genetic epidemiologic studies of complex traits. The choice of phenotype for use in genetic and other research studies will be influenced by the cost, degree of invasiveness, and individual burden required for identifying and quantifying the phenotype and by applicability across the spectrum of age and body mass index (BMI), as well as by its accuracy and reliability.

INTERMEDIATE DISEASE PATHWAYS AND PHENOTYPES

OSA is a complex disorder that is defined using a combination of clinical and physiologic measures, such as symptoms and data from overnight sleep apnea testing. However useful such an approach may be for clinical diagnosis, such definitions may be insufficiently specific for use in genetic analyses. An alternative approach for studying the genetic basis of OSA is to study intermediate traits that confer increased risk for the disorder. Such intermediate traits may be more closely associated with specific gene products and may be less influenced by environmental modification than more complex (and downstream) phenotypes (Figure 113-1).

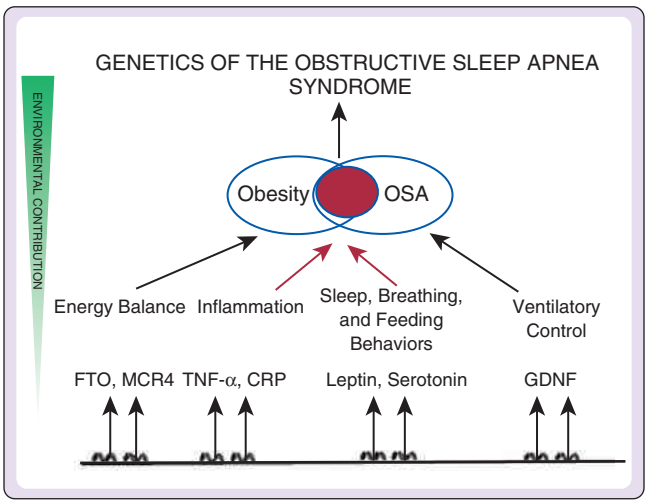

Figure 113-1 Schema showing the influence of genes on obstructive sleep apnea (OSA) from four intermediate pathways (energy balance, inflammation, sleep-feeding overlap, and ventilatory control) may be influenced by specific genes, and individually or together may influence obesity and/or OSAH. CRP, C-reactive protein gene; FTO, fat mass and obesity–associated gene; GDNF, glia-derived growth factor; Leptin: leptin or leptin receptor genes; MCR4, melanocortin-4 receptor gene; Serotonin: genes in the serotonin pathways (e.g., *HTR2A*); TNF-α, tumor necrosis factor-α gene. As one moves from the gene to the complex phenotype, the relative influence of specific genes decreases while the influence of environmental factors increases.

A number of risk factors likely interact to increase propensity for the repetitive upper airway collapse that occurs during sleep in patients with OSA. In a given person, the relevant attributes may be determined by anatomic and neuromuscular factors that influence upper airway size and function. Strong OSA risk factors are obesity and male gender. Although it has been argued that the genetics of obesity cannot be separated from the genetics of OSA, careful statistical modeling of AHI and BMI indicates that only about 35% of the genetic variance in AHI is shared with BMI, suggesting that a substantial portion of the genetic basis for OSA is in fact independent of obesity.[4] Other pathogenic pathways include those that influence upper airway size, ventilatory control mechanisms, and possibly elements of sleep and circadian rhythm control.

Thus it is useful to consider at least four primary intermediate pathogenic pathways through which genes might act to increase susceptibility to OSA: obesity and body fat distribution and related metabolic syndrome and inflammatory phenotypes, craniofacial and upper airway morphology, control of ventilation, and control of sleep and circadian rhythm[5]; these are discussed in more detail in the following sections. The limitation of this approach is that the genes so identified might not be sufficient to describe the clinically important phenotype, which might only occur in the context of other genetic and environmental factors. Specifically, susceptibility genes for intermediate traits associated with OSA might not be equivalent to the susceptibility genes for OSA.

Obesity and Body Fat Distribution

Obesity increases risk for OSA by 2- to 10-fold, with the strongest associations observed in middle age.[6] There are several pathways through which obesity predisposes to OSA. Fat deposition in the parapharyngeal fat pads may directly narrow the upper airway and predispose it to collapse when neuromuscular activation of upper airway muscles declines with sleep (see Chapters 17 and 111). Fat deposition in the thorax and abdomen (i.e., visceral fat) can increase the mechanical work of breathing, which can produce hypoventilation and reduce lung volumes, which in turn reduces parenchymal traction on the trachea, making the airway more collapsible. Reduced lung volumes also can increase propensity for oxygen desaturation to occur, increasing the likelihood that any given reduction in airflow may be classified as a "hypopnea," thus operationally increasing the severity of the adjudicated AHI, as well as physiologically increasing the severity of a hypopnea-associated disturbance. In addition, low lung volumes can reduce oxygen stores and alter "loop gain," which in turn can promote ventilatory instability. Finally, adipose tissue secretes hormones such as leptin that can influence ventilatory drive (see later).

Heritability estimates for obesity-associated phenotypes such as BMI, skinfold thickness, regional body fat distribution, fat mass, and leptin levels range between 40% and 70%, consistent with moderate to strong influences of genetic factors on these traits.[6-8] Approximately 7% of cases of early-onset obesity have been estimated to be attributable to the effects of mutations in a small number of genes involved in the leptin-melanocortin signaling pathway (i.e., melanocortin-4 receptor, leptin, leptin receptor, and pro-opiomelanocortin [POMC]), which are believed to influence weight largely through alterations in appetite regulation.[7] Mutations in melanocortin-4

receptor, the most common mutation, increase risk for severe childhood obesity by approximately 30% and also have been implicated in 0.5% to 1% of adult cases of obesity.[8]

The genetic etiology of obesity in the general population has been studied intensively in large populations that have undergone genotyping. Meta-analyses of genome-wide association studies, which examine the variation of frequency of thousands of alleles with disease status, have led to the discovery and replication of 36 genetic loci that associate with BMI.[9] However, all risk alleles together explain only 6% to 11% of the phenotypic variation.[10] The locus with the largest effect size is in the *FTO* (fat mass and obesity–associated gene),[11] which explains 0.34% of the variation in BMI among adult populations. An association between *FTO* and BMI has been replicated across populations and indicates that homozygotes for the risk allele weigh on average 3 to 4 kg more than persons without the risk allele and have an associated 1.67-fold increased risk for obesity compared with persons without the allele. Although the functioning of this gene is not well understood, *FTO* is expressed in the hypothalamus, and there is some evidence that it confers a risk for increased obesity through regulation of food intake and possibly through mechanisms that influence stress responses. Distinct genetic variants have been associated with waist-to-hip ratio,[12] which may be particularly relevant to OSA given the strong association between central obesity and OSA.

Craniofacial Morphology

Craniofacial morphology, which encompasses both bony and soft tissues, predisposes to OSA by reducing upper airway dimensions. Soft tissue structures that vary with OSA include elongation of the soft palate, macroglossia, and hypertrophy of adenoids and tonsils. Magnetic resonance imaging (MRI) has specifically shown that the lateral pharyngeal wall and tongue are larger in OSA patients compared with matched controls.[13] Cephalometry also has shown that patients with OSA compared with those without OSA have reduction of the anterior-posterior dimension of the cranial base, increased lower facial height, mandibular retrognathia or micrognathia, and inferior displacement of the hyoid[14-16] (see Chapters 111 and 143). A brachycephalic head form, measured by anthropometry, is often found in association with reduced upper airway dimensions. This head form is associated with a small but significant increased risk for OSA in those of European ancestry, and it also identifies families at risk for both OSA and sudden infant death.[17] In African Americans, this head form is uncommon and does not appear to increase risk for OSA. It is possible that a brachycephalic head form may contribute to increase risk for OSA among individuals of Asian ancestry.

In the Cleveland Family Study, both hard tissue (e.g., head form, intermaxillary length) and soft tissue (e.g., soft palate length, tongue volume) factors predicted the AHI level in European Americans. In African Americans, soft tissue factors also predicted AHI levels, but hard tissue anatomic features appeared to be only weakly associated with OSA.[18] These data support the importance of structural features in increasing susceptibility to OSA, but they also suggest that the anatomic underpinnings and the genes for upper airway anatomy might differ among ethnic groups.

Facial morphogenesis and patterning are complex processes that involve multiple signaling pathways. In humans, the genetic basis for craniofacial features is supported by both twin and family studies.[19,20] Heritability estimates (the proportion of the variance in the trait explained by additive genetic factors) for facial features such as facial height and mandibular position have been reported to be high as 0.80. A genome-wide association study has identified loci in five genes associated with facial morphology,[21] the most robust of which was in the paired box 3 gene (*PAX3*), which encodes a developmentally important transcription factor expressed in neural crest cells. There are also at least 50 syndromes in which congenital malformations of mandibular and maxillary structure occur, many of which also are associated with respiratory impairment and upper airway obstruction. These include Pierre-Robin syndrome and Treacher Collins syndrome.[22,23] Studies of various syndromes and genetic defects suggest potential roles of genes belonging to the fibroblast growth factor (e.g., *FGFR1, FGFR2, FGFR3*), transforming growth factor-β (e.g., *TGFBR1, TGFBR2*), homeobox (e.g., *MSX1, MSX2*), and sonic hedgehog (e.g., *PTCH, SHH*) pathways. Other potentially relevant candidate genes are those that have been implicated in craniofacial development, including genes on the endothelin pathway (e.g., *ECE1, EDN1, EDNRA*),[24-26] and *TCOF1*, the cause of Treacher Collins syndrome.[27] Further understanding of homeobox genes and genes controlling growth factors might contribute to our clarifying the origins of craniofacial dysmorphisms found in OSA.

Inherited abnormalities of craniofacial structure appear to explain at least some of the familial aggregation of OSA. Relatives of patients with OSA have been shown to have a more retropositioned mandible and smaller posterior-superior airway space compared with normative data.[28] Relatives of OSA probands also have been shown to have decreased total pharyngeal volume and glottic cross-sectional area, retropositioned maxilla and mandible, and a longer soft palate compared with relatives of controls.[29] In subjects both with and without OSA, acoustic reflectometry has demonstrated that more than 30% of the variance in the minimal cross-sectional area of the pharynx is heritable.[30] MRI has further demonstrated significant heritability for both the volume of soft tissue airway structures (including the tongue and lateral pharyngeal walls)[20] and hard tissue craniofacial dimensions (e.g., mandibular length and width).[31]

Although MRI precisely describes anatomic characteristics, its cost limits its utility for large-scale genetic epidemiology studies. Future research needs to assess the ability of reproducible and noninvasive techniques to identify subgroups of persons who inherit polymorphisms associated with genes relevant to craniofacial compared with other etiologic OSA pathways. There is also a need to further investigate how anatomic measurements performed awake and in the sitting position predict collapsibility during sleep and how anatomy interacts with physiology to influence susceptibility to OSA. Anatomic compromise may also be inferred from measurement of the pharyngeal critical closing pressure (Pcrit),[32] an index that can be derived during attended polysomnography with measurement of airway responses to progressive decreases in the delivery of therapeutic continuous positive airway pressure.

Ventilatory Control

Potentially inherited abnormalities of ventilatory control may predispose to OSA or central sleep apnea by affecting

ventilation, ventilatory drive, and upper airway patency. These inherited ventilatory control abnormalities may include neuromuscular responses to the influences of state (sleep-wake), chemical drive (e.g., ventilatory response to hypoxia and hypercapnia), sensitivity of ventilatory load compensation (the degree to which an individual defends the tidal volume or minute ventilation in the presence of an imposed mechanical load to breathing such as an increased resistance or elastance), and arousal threshold. They can result in different ventilatory responses to sleep-related stresses and shape both the magnitude of ventilation and ventilatory pattern and the propensity for respiratory oscillations in sleep. The relative contribution of these ventilatory control factors varies among individuals, and such variability likely contributes to genetic heterogeneity in OSA. According to a multiple-risk factor model, OSA is likely to manifest as severe anatomic compromise, regardless of nonanatomic risk factors. In the presence of a lesser degree of anatomic compromise, OSA occurs when there are coexistent abnormalities in arousal threshold, loop gain (sensitivity of the ventilatory control system to feedback loops, such as due to changes in CO_2), or muscle responses.

Experimental data indicate that there is substantial interindividual variation in the contributions of these physiologic factors to OSA.[33] Further, the magnitude of ventilatory chemoresponsiveness appears to be subject to major genetic control; for example, heritability estimates for chemoresponsiveness to oxygen saturation levels range from approximately 30% to 75%.[34] Ventilatory responses are more strongly correlated between monozygotic than dizygotic twins.[35-37,38] Population differences in ventilatory patterns and hypoxic sensitivity have been identified for populations that have adapted to living at high altitude.[39,40] Abnormalities in hypoxic or hypercapnic ventilatory responsiveness have been described in the first-degree relatives of probands with unexplained respiratory failure,[41] chronic obstructive pulmonary disease,[42,43] and asthma.[44] There is a growing understanding of the molecular bases for ventilatory responses, with identification of a number of respiratory chemoreceptors in the carotid body and lower brainstem, including the nucleus solitaries, retrotrapezoid nucleus, locus coeruleus, and raphe.[45]

Although the contributions of the previously noted population and genetic data to OSA-related phenotypes are not clear, there is some evidence that absence of the retrotrapezoid nucleus causes severe central apneas in congenital central hypoventilation syndrome.[46] Additionally, a potential role for inherited impairments of ventilatory control in influencing susceptibility to OSA has been suggested by several studies of carefully characterized families of OSA patients, which have demonstrated blunted hypoxic responses and impairment in load compensation compared with controls.[47-51]

As referred to earlier, the potential impact of deficits in ventilatory control on OSA susceptibility is likely magnified in persons with anatomically compromised upper airways. With sleep onset, the central inspiratory drive to upper airway motor neurons, a major determinant of airway patency, is reduced or fluctuates.[52,53] Any given reduction in central inspiratory drive results in greater increases in upper airway resistance in persons with anatomically compromised airways than in others.[54] Conversely, persons with greater degrees of upper airway resistance (due to craniofacial or obesity risk factors) can require a high level of compensatory drive to overcome sleep-associated airway collapse, and thus they may be especially vulnerable to the influence of genetically determined ventilatory control deficits.

These observations underscore the potential importance of considering the interaction of genetic risk factors that influence more than one etiologic pathway. Similarly, systematic characterization of ventilatory control pathophysiology and clinical phenotypes could accelerate discovery of genes that influence specific mechanistic pathways in humans, similar to mouse models which have allowed genes to be identified that determine respiratory timing, frequency, awake ventilation, chemosensitivity, and load responses. Clear strain differences have been observed for many of these phenotypes, with evidence of quantitative trait loci near plausible candidate genes. Knockout and transgenic mice also have helped identify the role of specific proteins and receptors in ventilatory chemoreception, neuromuscular transmission, and neural integration. Candidate genes identified from such studies include genes that sense O_2[55-57] and CO_2[58,59]; genes that modulate serotonin signaling[60]; genes on the endothelin pathway,[61,62] which also are important in craniofacial development; and genes that regulate neural crest migration, including *PHOX2B,* mutations of which are associated with congenital central hypoventilation.[63,64]

Control of Sleep and Circadian Rhythm

Given the effect of sleep-wake state on respiratory motor neuron activation, insights into the susceptibility of upper airway muscles to collapse during sleep may require delineation of the genetics of sleep-wake control. Orexins, neuropeptides that play a fundamental role in the regulation of appetite and sleep-wake states,[65,66] also influence arousal and muscle tone.[65] Orexin A levels are reported to be reduced in OSA.[67] Thus abnormalities in orexin genes may be relevant to OSA because of their influence on arousal, muscle tone, ventilatory control, and weight.

It may similarly be useful to consider how respiratory motor neuron control is influenced by genetic processes that determine circadian clocks, which are known to drive important metabolic and behavioral rhythms. Genes influencing circadian rhythm have been identified in animal models and in humans[68] and have been shown to influence metabolism, inflammation, and aging.[69] The relevance of these findings to OSA is unclear. However, genetic variation in circadian rhythm determination may influence apnea number and duration by affecting the distribution of REM and NREM sleep and the associated neuromuscular responses across the sleep period. Genes that influence regulation of sleep-wake rhythm may also influence the phenotypic expression of OSA (e.g., ability to compensate for sleepiness in response to recurrent apneas and sleep disruption).

FAMILIAL AGGREGATION OF OBSTRUCTIVE SLEEP APNEA

In addition to the specific heritability and genetic associations of OSA discussed to this point, significant familial aggregation of AHI or of symptoms of OSA have been observed in studies from the United States, Finland, Denmark, the United Kingdom, Israel, and Iceland.[28,29,70-72] Such studies have used a variety of designs, including cohorts, small and large pedigrees, twins, and case-control studies; they have included adults and children; and they have employed varying

Table 113-1 Familial Correlations for Apnea-Hypopnea Index

approaches for assessing phenotype. Despite study design and population differences, these studies have consistently shown familial aggregation of the AHI level and symptoms of OSA in children and adults and in obese and nonobese subjects. These studies have provided clear evidence that a positive family history of OSA is an important risk factor for an elevated AHI and for associated symptoms such as snoring and daytime sleepiness, although the estimated magnitude of effects has varied greatly.

Several large twin studies have shown that concordance rates for snoring, a cardinal symptom of OSA, were significantly higher in monozygotic twins than in dizygotic twins.[71,73,74] A study of adult male twins has shown significant genetic correlations for daytime sleepiness as well as snoring, with models consistent with common genes underlying both symptoms.[71] A subsequent report from this cohort showed significant heritability for objectively measured AHI levels in this twin population.[75] A large Danish cohort study showed that the age, BMI, and comorbidity-adjusted risk for snoring were increased threefold when one first-degree relative was a snorer and were increased fourfold when both parents were snorers.[76]

The prevalence of objectively measured OSA among first-degree relatives of OSA probands has been reported to vary from 22% to 84%.[28,29,70-72] Among the studies that included controls, the odds ratio, which relates the odds of a person with OSA in a family with affected relatives to that for someone without an affected relative, has varied from 2 to 46.[3,28,29,70] Pedigree studies from the United States and Iceland have shown consistent associations; the overall risk for OSA in a family member of an affected proband compared with an individual without affected relatives is approximately 2. This is lower than that reported from case-control studies, which may be subject to biases depending on the appropriateness of the selection of cases and controls. Heritability estimates for the AHI from both pedigree[77,78] and twin studies[75] are approximately 35% to 40%. Similar parent-offspring (correlations of approximately 0.20) have been observed, and they are greater than spouse-spouse correlations.[3]

OSA has been described as occurring more commonly as a multiplex (affecting at least two members) than as a simplex (occurring in a single family member) disorder. Further evidence for a genetic basis for OSA is derived from the observation that the odds of OSA syndrome, defined as AHI greater than 15/hour and self-reported daytime sleepiness, increases with increasing numbers of affected relatives.[3] Table 113-1 show the odds for OSA syndrome given one, two, or three affected relatives with these findings, adjusted for age, gender, ethnicity, and BMI, compared with OSA patients who have no affected relatives, These results support the utility of ascertaining family history as part of the evaluation of the patient for OSA. Information on snoring, apneas, and sleepiness among first-degree relatives can be used to refine the likelihood of OSA in a given patient. Such information can also be used to help identify the need for other family members to seek sleep evaluations.

Several studies have reported a coaggregation of OSA with sudden infant death syndrome (SIDS) and acute life-threatening events.[70,79,80] Members of families with both OSA and SIDS cases have been reported to have a relatively increased prevalence of brachycephaly, an anatomic feature that is associated with upper airway narrowing, as well as reduced hypoxic ventilatory responsiveness.[80] These observations suggest that the two sleep-related breathing disorders have a shared genetic predisposition acting through ventilatory control or craniofacial structure pathways. The demonstration of widespread serotoninergic brainstem abnormalities in SIDS victims and the putative role of this pathway in respiratory drive[81] suggest a biologic basis for the potential genetic link between these disorders.

In children, both OSA and adenotonsillar hypertrophy (the chief risk factor for pediatric OSA) have been elevated in the siblings of children with OSA.[82] Pedigree studies show that the disease is transmitted across generations,[83] suggesting that common risk factors might influence OSA susceptibility in children and adults. Although hypertrophy of the tonsils is a major risk factor for childhood OSA, children of OSA probands more often have residual OSA after tonsillectomy compared with the offspring of adults without OSA,[84] suggesting the importance of underlying genetic susceptibility as a determinant of treatment response as well.

GENETIC ANALYSES

Candidate Gene Studies

The molecular genetics of OSA have been investigated using candidate gene approaches. In these association studies, the frequency of genetic variants thought to relate to disease susceptibility are compared in groups with and without OSA or are assessed in relationship to the severity of a quantitative phenotype (e.g., AHI). A number of plausible candidate genes are also found in pathways that influence the intermediate traits of obesity, craniofacial structure, and ventilatory control (Box 113-1). Candidate genes that have been examined in relationship to OSA in humans include those for apolipoprotein E (*APOE*), angiotensin-converting enzyme (*ACE*), serotoninergic pathways, leptin pathways, obesity, and inflammation. The largest single multiple-candidate gene

study analyzed more than 1000 single nucleotide polymorphisms (SNPs) from 53 candidate genes representing key intermediate pathways in approximately 1500 individuals of European or African ancestry.[85] In European Americans, variants within the C-reactive protein (*CRP*) and glia-derived neurotrophic factor (*GDNF*) were significantly associated with OSA, with suggestive associations observed for several SNPs in the 5-hydrotrypamine receptor 2A (*5-HTR2A*) gene and endothelin-1 (*EDN1*) gene. In African Americans, a variant in the serotonin receptor 2a (*5-HTR2A*) gene was associated with approximately twofold increased odds of OSA, with suggestive associations observed for variants in the leptin receptor and hypocretin receptor 2. Genetic associations frequently reflect false-positive findings and require replication in independent samples. However, smaller candidate gene studies, summarized later, provide additional support implicating serotoninergic, leptin signaling, and inflammatory pathways.

Serotoninergic Pathways

Serotonin (5-hydroxytryptanmine [5-HT]) receptors are found in the carotid body and in the brainstem near ventilatory control centers important for chemoreception, as well as in hypoglossal neurons. Research in animals suggests that serotoninergic neurotransmission, through peripheral actions at the level of the carotid body or hypoglossal nerve, or centrally, at medullary respiratory control centers, influences a wide range of functions relevant to OSA, including upper airway reflexes, ventilation, and arousal, as well as sleep-wake cycling.[60] Although the pharmacology is complex, with at least 14 receptor subtypes, this pathway has been implicated in the pathogenesis of SIDS, which, as discussed earlier, might share common genetically determined risk factors with OSA.

Polymorphisms in three genes—*5-HTT* (5-hydroxytryptamine transporter; encoding a serotonin transporter protein that clears serotonin from the synaptic space), *HTR2A* (encoding the 5-HT_{2A} receptor), and *HTR2C* (encoding the 5-HT_{2C} receptor)—each have been studied in relationship to OSA.[86-88] Several meta-analyses have been conducted that have pooled data on variants in these genes for approximately 500 to 700 cases and controls, each from three to six studies conducted in Japan, China, Turkey, and Brazil.[89-91] These analyses indicate than an approximately twofold increased OSA risk is associated with a variant in *5-HT2A* (an allele of 5-HT2A 148G/A) and 20% and 200% increased risks are associated with variants in the *5-HTT* gene (intron-2 variable numbers of tandem repeats and *5-HTT* gene–linked polymorphic region, respectively). Although requiring further replication, these findings are noteworthy given that the HTR2A receptor appears to be the predominant excitatory receptor subtype at the hypoglossal motor neuron and thus is a strong biologic candidate for an association with OSA.

Leptin Signaling

Animal and human studies suggest that leptin, an adipose-derived circulating hormone that influences appetite regulation and energy expenditure, not only influences body weight but also has important effects on central ventilatory drive mediated by brainstem receptors in the nucleus tractus solitarius and hypoglossal motor nucleus.[92,93] Mice homozygous for a knockout mutation in leptin hypoventilate and have a blunted ventilatory response to hypercapnia. Leptin replacement improves the ventilatory responses to hypercapnia in both wakefulness and sleep in leptin-deficient mice.[94] In obese women, increases in circulating levels of leptin have been shown to correlate with the magnitude of compensatory upper

airway neuromuscular responses to experimental airway occlusion.[59] The stimulatory effects of leptin on hypercapnic ventilatory response appear to be mediated through melanocortin, which is produced from a precursor polyprotein, POMC. As described earlier, the Cleveland Family Study reported suggestive evidence for linkage to an area on chromosome 2p that houses the POMC locus,[77] an area also reported by others to be strongly linked to serum leptin levels.[95] An association of OSA with the leptin receptor LEPR also has been reported in candidate gene studies.[85,91] Thus hypothalamic and pituitary pathways involved in leptin signaling may influence OSA susceptibility.

Inflammatory Pathways

Genes in inflammatory pathways may contribute to OSA by influencing upper airway patency through effects on pharyngeal edema, tonsillar hypertrophy, and pharyngeal neuropathic changes[96] or through effects of adipokines such as leptin that influence central respiratory drive. Given the reported associations between tumor necrosis factor-α (TNF-α) levels and OSA severity and sleepiness, a functional polymorphism in the TNF-α gene has been examined in several case-control studies of OSA[97,98] (including one study that compared genetic variants in affected and unaffected sibling pairs[98]) that have reported an elevated risk for OSA in association with a variant associated with higher TNF-α levels. A more recent population-control study by some of the same investigators did not report a significant difference between controls and subjects with OSA in the frequency of that single nucleotide polymorphism of TNF-α or other alleles of TNF-α.[98a] Other studies have reported associations with variants in genes for interleukin-6 and CRP.[85,99] Variants in the nitric oxide synthase (*NOS*) and endothelin (*EDN*) pathways have been reported to be elevated in children with OSA compared with snoring controls.[100] These genes have been implicated in cardiovascular disease, which is common in OSA. These findings suggest that either there are common genetic mechanisms which predispose to both OSA and cardiovascular disease or that individuals with OSA who harbor these variants may be at increased risk for cardiovascular disease.

Apolipoprotein E. An allele of the apolipoprotein E ε4 gene (*APOE*) gene associated with increased risk for both cardiovascular disease and Alzheimer disease was reported to be associated with OSA in two cohort studies of predominantly white subjects.[101,102] Two other studies, however, did not replicate this finding.[103,104] The Cleveland Family Study reported evidence for linkage to AHI near the *APOE* locus on chromosome 19.[86] However, the *APOE* genotype did not explain the linkage findings and was not associated with OSA status. These findings suggested that the susceptibility locus for OSA is not to *APOE* but another locus close to it. A candidate gene in this area is hypoxia-inducible factor 3, which plays a role in oxygen sensing.

APOE ε4 has also been examined as a disease-modifying risk factor. Several studies have shown that individuals with moderate to severe OSA who carry one or more *APOE ε4* variants have greater cognitive impairment than individuals with OSA without such a risk allele.[87,88] It has been hypothesized that the *APOE ε4* allele increases the likelihood of brain injury to oxidative or other stresses.

Angiotensin II Converting Enzyme. Angiotensin II, an important vasoconstrictor, also appears to modulate afferent activity from the carotid body chemoreceptor and thus might influence ventilatory drive.[105] Angiotensin II levels are regulated by the actions of ACE, which is encoded by the *ACE* gene. Several studies of Chinese cohorts have reported an association between polymorphisms in the *ACE* gene and OSA, particularly in persons with hypertension.[106-110] Data from the Wisconsin Sleep Cohort and the Cleveland Family Study did not show an association between ACE genotype and OSA but did show an association between hypertension and OSA severity, which varied in strength by ACE genotype.[111,112]

Linkage Analysis

Linkage analysis quantifies the cosegregation of a disease locus and a marker locus among family members. Typically, the strength of genetic associations is expressed as an LOD score (the log-odds quantifying the probability of receiving alleles at two loci). A LOD score of 3 or more is considered strong evidence for linkage. By identifying alleles that cosegregate in related individuals, areas of the genome are identified that have an increased probability of harboring risk alleles for a given trait. Although linkage analysis has limited resolution to identify specific genetic variants, linkage signals can help prioritize areas of the genome likely to harbor risk variants, and this information can then be integrated into tests of genetic association to increase the statistical power for discovering genetic variants. Linkage analysis can also be used to identify families likely to carry risk alleles, particularly rare mutations that may have large effects. A whole-genome screen for OSA-related traits has been performed in the Cleveland Family Study.[77,78] In one set of analyses including 1275 members of 237 families, linkage analysis was used to identify genetic regions that were uniquely associated with OSA (modeling the AHI) and other regions that associated with AHI through genetic associations with BMI.[113] Several areas of significant linkage to AHI were identified that were not associated with coincident linkage for BMI. Notably, significant linkage was observed on chromosome 6 for the BMI-adjusted AHI level (LOD score of 3.5). A linkage peak on chromosome 13 near the serotonin 2a receptor was observed in African Americans for both AHI and BMI, providing supportive evidence that variants in *HTR2A* may influence both OSA and obesity.

Genome-Wide Association Analyses

Marked advances in technology permit dense mapping of genetic markers across the genome, with some assays providing coverage of more than 1 million genetic variants (SNPs), providing the opportunity to discover genetic variants for a trait without prior knowledge of candidate genes. Such whole-genome scans can be applied to family members and analyzed with linkage analysis. The first study to report a broad analysis of genetic variants for OSA used an assay ("chip") that contained 45,237 SNPs from more than 2000 genes selected to be relevant to heart, lung, blood, and sleep phenotypes.[114] In 3551 participants from three cohort studies, significant associations were identified for several novel loci with OSA. Evidence of replication in independent cohorts was found for a variant in the lysophosphatidic acid receptor (*LPAR1*), a gene expressed in the embryonic cortex with proinflammatory

effects. Craniofacial abnormalities have been observed in an *LPAR1* knockout mouse. Another replicated association was in the prostaglandin E_2 receptor (*PTGER2*), which also is expressed in neuronal tissues and previously was associated with hypertension. Preliminary findings from more recent genome-wide studies of more than 20,000 individuals studied with assays of more than 500,000 SNPs have been reported. It is expected that, as such findings are replicated, genetic loci and their corresponding pathophysiologic pathways, relevant in the pathogenesis of OSA, will be identified.

CLINICAL PEARL

A positive family history of OSA (or of related symptoms) is useful in identifying patients at increased risk for the disorder. Craniofacial abnormalities and obesity can each have a genetic basis and are risk factors for OSA. Clinicians should ask about OSA symptoms in family members, including offspring. Individuals from families with more than one affected member may harbor genetic variants for OSA and may benefit from close follow-up after interventions to ensure their OSA is adequately treated.

SUMMARY

Despite the challenges in studying an inherently complex trait, there is strong evidence from clinical and epidemiologic studies supporting the importance of familial, and specifically genetic, factors in influencing OSA susceptibility. The largest pedigree and twin studies consistently estimate heritability for the AHI to be between 35% and 40%, with recurrent risk factors of approximately 2. Although obesity is the strongest risk factor for OSA and has a clear genetic basis, causal modeling suggests that only 35% of the genetic variance in the AHI of persons with OSA is shared with pathways that determine body weight. Thus most of the genetic variance for the AHI is likely due to the influence of genes that influence other pathways, including those that influence craniofacial structure, ventilatory control, and possibly sleep-wake patterns. Molecular studies of OSA still lag behind those of other chronic diseases. However, data from candidate gene studies, linkage analyses, and emerging genome-wide association analyses implicate variants in genes in the serotonin and leptin pathways, as well as genes in novel inflammatory and development pathways, relevant to the pathogenesis and possible treatment of OSA. Further investigations of the genetic etiology of OSA should provide a means of better understanding its pathogenesis, with the goal of improving preventive strategies, diagnostic tools, and therapies.

Obstructive Sleep Apnea: Clinical Features, Evaluation, and Principles of Management

Harly Greenberg; Viera Lakticova; Steven M. Scharf

Chapter Highlights

- Obstructive sleep apnea (OSA) is the most common respiratory disorder of sleep, with a high prevalence that is linked to the increase in obesity.
- OSA is frequently comorbid with cardiovascular, cerebrovascular, and metabolic diseases and is commonly observed in populations with these comorbidities. The relationship of OSA with these multisystem disorders may be bidirectional.
- The pathogenesis of OSA is complex, with contributions from mechanical factors that increase collapsibility of the upper airway as well as factors that lead to instability of ventilatory control during sleep.
- Clinical assessment, in addition to various screening questionnaires, is useful to identify patients at risk for OSA. However, accurate diagnosis requires monitoring of sleep.
- In-laboratory polysomnographic testing for OSA, as well as various technologies for ambulatory or out-of-center-sleep testing, are presented. The utility and limitations of these techniques are discussed.
- Various treatment modalities for OSA are described. An individualized treatment approach that emphasizes chronic disease management that improves sleep-related health outcomes is necessary to optimize care.

DEFINITION

Obstructive sleep apnea (OSA) is a common disorder that is recognized as a major risk factor for a number of important chronic medical conditions and is responsible for poor quality of life. Ample evidence exists that patients with untreated OSA consume more health care resources than matched patients without OSA, leading to considerably increased health care use costs.[1,2] Most studies agree that treatment reduces health care use to that of matched controls. Further, estimates are that OSA remains underdiagnosed.[3]

The classic signs and symptoms of OSA include excessive daytime sleepiness (EDS), loud snoring, snorting, and gasping at night (associated with apnea termination). Physical signs commonly associated with OSA include obesity, large neck circumference, and crowding of the oropharynx (Table 114-1).

BRIEF HISTORY

Burwell and colleagues are often given credit for the first medical description of a patient with probable OSA.[4] These authors described an obese, sleepy, hypercapnic patient, demonstrating periodic breathing, who reminded them of the character Joe in the Charles Dickens 1836 novel *The Posthumous Papers of the Pickwick Club* (see also Chapter 120). However, others used this term previously to describe similar patients.[5] Although the prevailing thought was that hypoventilation, possibly owing to excess weight, contributed to somnolence, Kuhl and associates described breathing cessations at night during polysomnography (PSG) and attributed sleepiness to the resultant sleep fragmentation.[6] As a result of these findings, the world renowned neurologist Gastaut added measurements of airflow and chest wall motion to other PSG measures to document obstruction of the upper airway (UA) at night.[7,8] The Bologna group of Lugaresi and Coccagna demonstrated large swings in arterial and pulmonary pressures during apneas, thus documenting that nocturnal breathing disorders had major adverse consequences and required treatment.[9] Following the observation of Kuhl and associates, the Bologna group reported that tracheostomy improved symptoms in a group of "pickwickian" patients.[10,11] In 1981 Sullivan and colleagues published their seminal paper demonstrating that nasally applied continuous positive airway pressure (CPAP) could alleviate UA obstruction in OSA.[12] Shortly thereafter, Rapoport and associates demonstrated that the "pickwickian syndrome" could be reversed with long-term use of nocturnal CPAP.[13] Additional therapies for the disorder, now termed OSA, including UA surgeries, mandibular advancement, and even stimulation of the hypoglossal nerve, have evolved and allow the physician to offer a variety of therapies tailored to the individual patient.

PHYSIOLOGIC EFFECTS

It is now well established that OSA has a number of acute physiologic effects that are thought to contribute to adverse multisystem consequences. These include intermittent hypoxia

Table 114-1 Signs and Symptoms of Obstructive Sleep Apnea

Severe snoring, snoring, gasping, or choking in sleep
Witnessed apneas in sleep
Excessive daytime sleepiness; tendency to fall asleep in inappropriate situations (e.g., while driving, attending lectures)
Lack of energy
Morning headaches
Large neck size: 17 inches in men, 16 inches in women
Crowding of the oropharynx: Mallampati score of 3 or greater, large tonsils, large tongue, elongated uvula
Facial abnormalities: retrognathia, midface deformities
Obesity (body mass index >30)
Nocturnal gastroesophageal reflux
Impotence; erectile dysfunction

Note: Male gender and postmenopausal state in women confers increased risk.

Table 114-2 Medical and Mental Health Conditions for Which There Is Evidence of Association with Obstructive Sleep Apnea*

Hypertension[155] (25% to 50% all hypertension; as high as 83% in drug-resistant hypertension)
Myocardial infarction[156] (as high as 70%)
Stroke[157] (as high as 68%)
Depression[158]
Congestive heart failure[159] (as high as 76%)
Asthma[51]
Chronic obstructive pulmonary disease[48] (as high as 50%)
Atrial fibrillation (and other dysrhythmia)[38] (49%)
Type 2 diabetes[46] (as high as 48%)
Traffic and industrial accidents[83] (as high as fivefold increase)
Overall mortality[160] (increased risk by 46%)

*Approximate risks listed where available.

(IH) occurring as a result of apneas and hypopneas, exaggerated negative swings in intrathoracic pressure (ITP), and terminal arousals. In animal models, IH leads to increased sympathoadrenal tone, a feature well demonstrated in humans with OSA.[14,15] Further, IH leads to oxidant stress in the brain[16] and in the myocardium, a finding associated with poor left ventricular function, apoptosis of myocardial cells,[17,18] and endothelial dysfunction.[19] Further, arousals associated with termination of apneas, hypopneas, and periods of inspiratory flow limitation contribute to heightened sympathetic tone.[20] In animal models, IH has been shown to be associated with release of pro-inflammatory mediators, at least partially mediated by NF-κB–related pathways.[21,22] Exaggerated swings in ITP, primarily during inspiration against an occluded airway, lead to increased venous return and stress on the right ventricle.[23] The latter appears to be primarily responsible for pulmonary hypertension, a common finding in OSA.[24] Sleepiness is thought to be, at least in part, a result of the terminal arousals and associated sleep fragmentation.

OSA is an independent major risk factor for a number of associated medical conditions (Table 114-2). Chief among these are cardiovascular disease, including hypertension, stroke, myocardial infarction, and congestive heart failure. Heightened sympathoadrenal tone, oxidant stress, and pro-inflammatory cytokines appear to be involved in the pathogenesis of these conditions.

EPIDEMIOLOGY

There are varying estimates of the prevalence of OSA, largely owing to differences in diagnostic methods, definitions of disease, and differences in age, gender, and body mass index (BMI). As reviewed by Young and colleagues in 2002, prevalence estimates range from 2% to 26% depending on gender, definition of "disease," and population studied.[25] These prevalence rates were mostly derived from epidemiologic studies performed in the 1990s. Data from the Wisconsin Sleep Cohort were used to derive the estimate that symptomatic OSA affected 2% to 4% of middle-aged adults in the United States.[26] However, the increase in prevalence of obesity necessitated revision of these initial estimates. Using data from the National Health and Nutrition Examination Survey on BMI in U.S. populations, as well as data from the Wisconsin Sleep Cohort, Peppard and associates now estimate that among adults 30 to 70 years of age, approximately 13% of men and 6% of women have an apnea-hypopnea index (AHI) of more than 15/hour, whereas 14% of men and 5% of women have an AHI of more than 5/hour with symptoms of daytime sleepiness.[27] Both definitions meet *International Classification of Sleep Disorders*, third edition (ICSD3) criteria for OSA.[28] In the U.S. working age population, males have a twofold to threefold greater prevalence of OSA than females. A meta-analysis of community and sleep center referral–based cohorts showed that male gender is more common among patients with diagnosed OSA (odds ratio, 3.1; 95% confidence interval [CI], 2.5 to 3.8). However, among women, postmenopausal status is associated with an increased risk for OSA that equals that observed in men.[29,30] The prevalence of OSA in the United States also increases with advancing age, from about 35 to 60 years, after which there is less of an age-related increase.[31]

OSA prevalence has also been assessed in many regions of the world other than the United States and among various ethnic groups. Estimates of OSA prevalence in white European and Australian populations are similar to those observed in North America. Further, comparable OSA prevalence rates have been found in studies of Korean, Chinese, and Indian populations. Most studies have also shown similar OSA prevalence between North American white, African American, and Hispanic cohorts.[32]

PREVALENCE IN DISEASE-SPECIFIC COHORTS

Because OSA is associated with cardiac, cerebrovascular, pulmonary, metabolic, and other comorbid diseases, it is worthwhile to consider the prevalence of OSA in relevant disease specific cohorts. The pathophysiologic features of OSA, including IH, increases in sympathoadrenal tone, large swings

in ITP, and sleep fragmentation, with associated increases in oxidative stress, systemic inflammation, and endothelial dysfunction, among other factors, may contribute to many of these associated comorbid conditions. It is also worthwhile to consider that the relationship of OSA with some of these diseases may be bidirectional.

One of the most studied cardiovascular comorbidities of OSA is systemic hypertension. Most observational studies have shown that up to 50% of patients with systemic hypertension have OSA.[33] Further, OSA is a common cause of "resistant" hypertension, with a prevalence of 64% in one cohort of patients with difficult-to-control hypertension.[34] Atrial fibrillation (AF) is another cardiac disorder associated with OSA. Data from the Sleep Heart Health Study (SHHS) demonstrated a higher prevalence of AF in subjects with OSA than in those without such sleep-disordered breathing (4.8% vs. 0.9%; $P = .003$).[35] Conversely, a high prevalence of OSA (32% to 49%) has been demonstrated in various cohorts of patients with AF.[36] The association between these disorders is further documented by data that demonstrate an increasing prevalence of AF with increasing severity of OSA as assessed by the nocturnal oxygen desaturation index.[37] Other studies have shown that OSA is associated with development of AF after cardiac surgery and with an increased risk for recurrence of AF after cardioversion or ablation therapy.[38] OSA is also common in congestive cardiomyopathy and may adversely affect outcomes in this disease. Eleven percent of a cohort of patients with cardiomyopathy (defined as left ventricular ejection fraction <45%) was found to have OSA, although central sleep apnea (CSA) was more frequently observed in this group.[39] In another cohort of systolic heart failure patients, 61% were found to have a sleep related breathing disorder; approximately half had OSA, whereas CSA was present in the remainder.[40] OSA is also an independent risk factor for cerebrovascular disease with a threefold to fourfold increased odds of incident stroke in moderate to severe OSA (AHI >20/hour).[41,42] In accord with this finding, the prevalence of OSA in post–cerebrovascular accident cohorts is notably high, ranging from 38% to 74%.[43,44] The relationship of these cardiovascular and cerebrovascular disorders with OSA may be bidirectional. The adverse consequences of OSA may contribute to the development of these conditions; conversely, cardiac and cerebral dysfunction may contribute to OSA by promoting pathophysiologic factors that promote apneas and hypopneas during sleep. The association of OSA with type 2 diabetes and the metabolic syndrome is also well described. Data from the SHHS, for example, demonstrated that a remarkable 58% of subjects with type 2 diabetes had an elevated AHI.[45] A study of obese adults with type 2 diabetes showed that 87 % of that cohort had OSA, with a mean AHI in the moderate range.[46]

Although some studies have suggested that the occurrence of OSA in chronic obstructive pulmonary disease (COPD) patients is not greater than expected based on the prevalence of each disease in the population,[47] others have shown an increased prevalence of COPD among OSA patients compared with matched controls.[48] A case-control study of 1497 patients with PSG-proven OSA compared with 1489 age- and gender-matched controls showed that COPD was more prevalent in the OSA group (7.6 vs. 3.7 %; $P < .0001$).[49] OSA was also found to be highly prevalent among a cohort of patients moderate to severe COPD referred for pulmonary rehabilitation.[50] Regardless of whether the concomitant prevalence of COPD and OSA is greater than can be expected by chance occurrence, the coexistence of these disorders, termed the *overlap syndrome*, is associated with more severe nocturnal hypoxemia, hypoventilation, pulmonary hypertension, comorbid obesity, and diabetes than that which is observed in isolated OSA or COPD (see Chapter 119).

Recent studies have also suggested an association between OSA and asthma.[51] Although most data regarding a possible link between these two diseases comes from cross-sectional studies performed in asthma clinic cohorts, results consistently demonstrate that the prevalence of OSA is approximately double in these cohorts compared with the general population. Asthma severity, BMI, gastroesophageal reflux, and female gender have all been associated with increased OSA risk in asthma. An analysis of data from the Wisconsin Sleep Cohort showed that a diagnosis of asthma was associated with increased risk for incident OSA.[52] Whether these disorders are mechanistically linked and whether OSA treatment alters asthma outcomes remains to be investigated.

OSA is also frequently observed in patients with chronic kidney disease, with prevalence rates reported to be as high as 50% in patients with end-stage renal disease (ESRD).[53] An increasing prevalence of OSA has been associated with declining kidney function, ranging from 41% in patients with chronic kidney disease to 48% in those with ESRD.[54] The relationship between renal dysfunction and OSA may also be bidirectional. OSA might contribute to renal dysfunction by exacerbating hypertension, diabetes, endothelial dysfunction, sympathetic neural activity, systemic inflammation, and oxidative stress.[55,55a] Conversely, renal dysfunction may contribute to OSA, possibly owing to fluid overload that may increase UA edema as well as other factors. Support for the possibility of such a bidirectional relationship comes from data that demonstrate improvement in the AHI with intensive nocturnal hemodialysis in ESRD.[56] In addition, removal of fluid by ultrafiltration, without affecting uremia, was shown to improve the AHI in association with a decline in fluid volume of the neck.[57]

It is clear from these studies that OSA is frequently comorbid with several important and common diseases. Whether treatment of OSA alters disease-specific outcomes when coexistent with other major medical disorders remains a matter of ongoing investigation for most of these conditions.

RISK FACTORS

Anatomy

OSA is associated with anatomic risk factors that narrow the UA. As mentioned previously, the most widely recognized factor is central obesity, with a direct relationship observed between BMI and apnea severity. OSA is attributable to obesity in up to 58% of subjects.[58] Further, weight loss typically results in improvement in OSA. Linear regression modeling from the Wisconsin Sleep Cohort showed that in individuals with OSA, after adjustment for sex, age, and cigarette smoking, an approximate 1% increase or decrease in body weight was associated with a corresponding 3% increase or decrease in the AHI.[59] Obesity can contribute to airway narrowing by depositing adipose tissue around collapsible segments of the UA, increasing the size of the parapharyngeal fat pads and increasing fat content and volume of the base of

the tongue.[60,61] Obesity may also indirectly contribute to UA collapsibility by reducing lung volume. Lower lung volume is associated with reduced tracheal caudal traction on the UA, which decreases stiffness of the lateral pharyngeal walls and promotes airway collapse.[62]

In addition to deposition of adipose tissue, overall increases in UA soft tissue volume contribute to pharyngeal narrowing and predispose the UA to collapse during sleep. Numerous imaging studies have demonstrated that the UA lumen is narrower in patients with OSA compared with control subjects. Such narrowing is largely due to an increase in volume of the surrounding soft tissues. Although the cross-sectional dimension of the OSA airway is smaller at several levels, the greatest difference compared with controls is typically in the retropalatal or velopharyngeal region.[61] Magnetic resonance imaging volumetric analyses have demonstrated increased volume of the lateral pharyngeal walls, soft palate, tongue, and parapharyngeal fat pads that compromise the airway lumen. In addition, differences in the shape and length of the UA are evident. Although the UA is normally largest in its lateral dimension, its anterior-posterior dimension is greatest in OSA; this decreases efficiency of UA dilator muscles. Further, UA length is increased in OSA, which contributes to its collapsibility.[61] In addition to soft tissues, decreased size of the maxilla, with a narrowed and high palatal arch and a small retropositioned mandible can also narrow the UA.[62,63]

Other factors that contribute to a narrow airway lumen in OSA include edema and inflammation of UA soft tissue. Histologic studies of resected palatal tissue showed edema and lymphocytic infiltration of mucosal as well as muscular layers in OSA, possibly owing to vibratory trauma from snoring.[64] In addition, rostral shift of blood volume and edema fluid from the lower extremities when subjects with lower extremity edema assume a recumbent position during sleep has been associated with increased neck circumference, UA resistance, and increased AHI.[65]

Relationship of Upper Airway Anatomic Factors to Development of Inspiratory Flow Limitation and Obstruction

The UA can be modeled as a collapsible tube through which air flows (Figure 114-1). The propensity of the airway to collapse is determined by the elastic properties of the airway structure itself as well as activity of the UA dilator muscles. During inspiration, pressure in the pharyngeal lumen is negative relative to atmospheric pressure; otherwise air could not flow in the inspiratory direction. With increased inspiratory effort or narrowing of the pharyngeal lumen, pressure becomes more negative within the UA. This can lead to obstruction in collapsible segments of the UA if airway luminal pressure decreases to a value below what is termed the critical closing pressure (Pcrit) and the UA dilator muscles do not respond sufficiently. At this point, inspiratory flow ceases and an *obstructive apnea* occurs. Intraluminal pressure downstream (toward the thorax) of the closed segment is equal to intrathoracic pressure during no-flow conditions. Because the

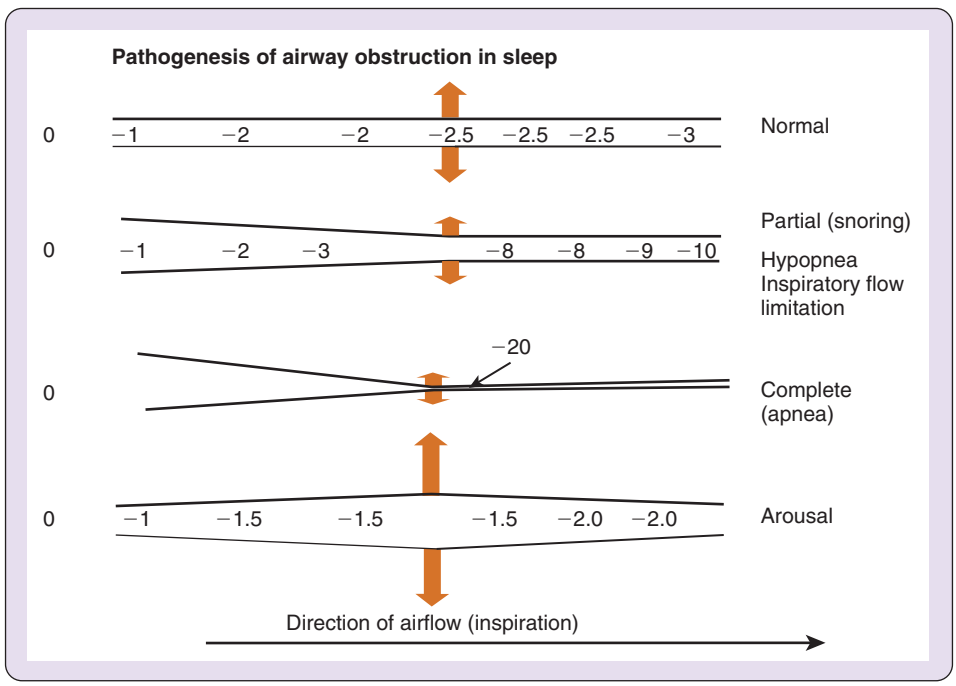

Figure 114-1 Pathogenesis of upper airway closure in OSA. The upper airway (UA) is depicted as a tube. With inspiration, there is a small gradient of pressure in the direction of flow (*upper panel*). Even though pressure is slightly negative, the airway is held open by UA dilator muscles (*orange arrow*, force represented by length of the arrow). With narrowing of the UA and some decrease in abductor force, the gradient of airway pressure is greater; flow may become limited. Vibrations in the airway produce snoring. With complete closure of the UA, no air can flow. Pressure in the airway is negative and will be equal to intrathoracic pressure (no flow condition). Closure of the UA occurs because of decreased activity of UA dilator muscles. When brainstem and other appropriate receptors sense no airflow, with hypoxia and hypercapnia, UA dilators are activated and open the airway (*bottom panel*).

patient typically generates increased inspiratory efforts against the occluded UA, exaggerated negative swings in intrathoracic pressure occur that may be quite large. If UA collapse is partial, further decreases in intraluminal pressure may not be able to overcome the increased resistance and do not result in increases in inspiratory flow, resulting in a condition of *hypopnea* or *inspiratory flow limitation* (see Chapter 112). After complete airway closure or flow limitation occurs, inspiratory flow can only be restored if UA dilator muscles respond by increasing luminal diameter, thereby decreasing resistance and restoring flow.[66]

Pcrit of the passive oropharynx varies widely among individuals. The mean value for Pcrit in a group of normal subjects has been found to be −4.35 ± 4.15 cm H_2O, whereas it was near atmospheric pressure for subjects with mild to moderate OSA (0.56 ± 1.54 cm H_2O) and above atmospheric pressure for those with severe OSA (2.23 ± 2.96 cm H_2O), although there was considerable overlap among groups.[66] For subjects with a Pcrit at or above atmospheric pressure, pharyngeal dilator muscle activity is required to maintain airway patency during wakefulness and sleep.

If anatomic and mechanical characteristics of the UA were the sole factors responsible for the occurrence of obstructive apneas and hypopneas, a strong linear relationship should exist between Pcrit and the severity of OSA as measured by AHI. However, the correlation between Pcrit and AHI is moderate at best. This indicates that factors other than mechanical or structural properties of the UA contribute to the occurrence and severity of OSA.[66,67] Primary among these nonanatomic factors is unstable or inadequate ventilatory drive during sleep to the UA dilator and ventilatory pump muscles, which can contribute to the development and perpetuation of apneas.

CLINICAL IDENTIFICATION AND ASSESSMENT

Daytime Symptoms and Functional Consequences

EDS, which is associated with persistent somnolence that may cause inappropriate or unintentional sleep episodes, is one of the most frequent symptoms of OSA, and one that adversely affects daytime function and quality of life. The presence and impact of EDS may be subtle, such as drowsiness occurring during periods of relative inactivity, or it may be more severe, with episodes of falling asleep during activities such as driving. EDS is considered to be a consequence of sleep fragmentation and has been associated with loss of vigilance. However, EDS is not universally present in all patients with OSA.[68] Further, the correlation between severity of EDS and the AHI is relatively weak.[68,69] Other factors such as nocturnal IH, autonomic dysregulation, and OSA related comorbidities such as obesity, cardiovascular disease, diabetes, and depression may also contribute to EDS.[70-73] It is worth emphasizing that the absence of a complaint of EDS does not reliably discriminate between patients with and without OSA.[74] Sleepiness may not be directly recognized by many patients who instead perceive their symptoms as fatigue. In clinical practice, EDS is often subjectively quantified using the Epworth Sleepiness Scale.[75]

EDS increases the risk for cognitive dysfunction, poor performance, injury, and motor vehicle accidents (MVAs). Despite objective evidence of EDS, some patients might not recognize impairment of performance, including driving ability, because of sleepiness.[76] It is worth noting that the term *excessive daytime sleepiness* (EDS) is somewhat of a misnomer because excessive somnolence can be very problematic in night-shift workers, with similar adverse consequences as somnolence during the day.

OSA is also associated with reduced quality of life as measured by general and disease specific QOL scales. The Functional Outcomes of Sleep Questionnaire is a QOL assessment tool sensitive to the impact of sleep disorders and excessive sleepiness and is often used to measure the impact of OSA and its treatment.[77] Objective evidence of sleepiness, including reduced sleep latency on the Maintenance of Wakefulness Test or the Multiple Sleep Latency Test, may also be demonstrated, especially in patients with moderate to severe OSA.[78]

Deficits in Cognition, Vigilance, and Executive Function

Impairment of cognitive function may occur in OSA, possibly owing to cortical arousals, sleep fragmentation, excessive somnolence, and nocturnal IH. Deficits have also been observed in sustained attention, or vigilance, which is important for prolonged complex tasks such as driving a motor vehicle.[79-81] Further, monitoring of information, reaction time, distractibility, and processing capacity are impaired in OSA.[82] These deficits may, in part, be responsible for the twofold to sevenfold increased risk for MVAs observed in OSA.[83] Crashes, or near misses, may be caused by sleepiness, inattention, fatigue, or micro-sleep episodes that result in failure to respond rapidly and appropriately.[84,85] Some studies have found a dose-response relationship between the severity of OSA and MVA risk. However, prediction of driving risk in individual patients is not precise.[85] Deficits in cognitive function, vigilance, somnolence, and other sequelae of OSA may also contribute to poor performance in the workplace (absenteeism, presenteeism) and work-related injuries.[86]

Executive function, which encompasses cognitive processes responsible for problem solving, flexibility, decision making, and initiating appropriate responses and actions, may also be impaired in OSA. In addition, deficits in memory have been associated with OSA, although not all studies have demonstrated such an effect. The underlying mechanisms responsible for impairment in executive function and memory may be related to sleepiness and attention deficits as well as to neuronal damage from oxidant stress related to IH in the prefrontal cortex and hippocampus.[87] Improvements in memory, attention, and executive function observed after CPAP therapy for OSA have been correlated with increases in gray matter volume in these regions.[87]

Mood Disorders

A higher than expected prevalence of mood disorders has been observed in OSA. A Veterans Administration study showed that 21.8% of OSA patients had major depression, whereas 16.7% had anxiety disorder.[88] Newly diagnosed OSA patients are twice as likely to develop depression within 1 year compared with controls.[89] Conversely, investigations of patients with major depression demonstrated an increased prevalence of OSA. The association between OSA and depression is strengthened by studies which showed that CPAP therapy results in sustained improvement in depression scores, particularly in patients with moderate to severe OSA.[90,91] However, cross-sectional studies have generally not

demonstrated an association of measures of apnea severity with depressive symptoms.[92]

Sleep-Related Signs and Symptoms

The classic sleep-related sign of OSA, as observed by a bed partner, is loud snoring alternating with periods of silence, associated with paradoxical movement of the chest and abdomen, terminated by a loud gasp or snort. A meta-analysis of community and sleep center cohorts with documented OSA showed that a complaint of gasping or choking during sleep was the most useful clinical predictor of OSA (likelihood ratio, 3.3; 95% CI, 2.1 to 4.6).[74] Snoring is also very common, with a prevalence of 35% in a population-based survey of persons 30 to 70 years old in Spain; importantly, an isolated complaint of snoring is not a useful predictor of OSA.[93] In contrast, the absence of snoring makes OSA less likely. Other common symptoms of OSA include awakening with a dry mouth, which may reflect mouth breathing, restless sleep, and nocturnal diaphoresis.

Nocturia may also be seen in OSA.[94] A cross-sectional analysis of the SHHS demonstrated an independent association between the AHI and prevalence of nocturia. Nocturia was also associated with disturbed sleep and with subjective complaints of daytime somnolence.[95] Increased intraabdominal pressure during obstructive apneas, confusion associated with arousals, and increased secretion of atrial natriuretic peptide are proposed mechanisms contributing to nocturia and nocturnal enuresis.[96]

Complaints of nocturnal gastroesophageal reflux (GER) are often reported in OSA. In support of an association between GER and OSA, 24-hour esophageal pH monitoring demonstrated episodes of decreased esophageal pH in 80% of OSA subjects during sleep; CPAP therapy reduced reflux events.[97] The common association of OSA with GER may be a result of large decreases in intrathoracic pressure occurring during obstructed inspiratory efforts, with increases in intraabdominal pressure, that may contribute to GER; alternatively, obesity, which increases risk for hiatal hernia, may be the primary factor leading to this association.[98]

Morning headaches are sometimes reported in OSA. The International Classification of Headache Disorders II describes OSA-related headaches as "bilateral, with a pressing quality, not accompanied by nausea, photophobia or phonophobia."[99] Headache is present on awakening and usually resolves within 30 minutes; morning headaches are eliminated with effective treatment of OSA.[99] A recent study demonstrated that 11.8% of OSA patients had morning headache. However, morning headache without OSA is also common, with a prevalence of 4.6% in this cohort.[100]

Physical Findings

As previously mentioned, obesity is the most commonly observed risk factor for OSA. Suspicion for OSA should be raised if the BMI is more than 30 kg/m^2.[101] Patients with OSA have a larger neck circumference that those without this disorder. The average neck circumference (measured at the superior border of the cricothyroid membrane in the upright position) was 43.7 ± 4.5 cm in a series of patients with OSA and 39.6 ± 4.5 cm in those without OSA (P = .0001).[102] A neck circumference at least 40 cm has a sensitivity of 61% and a specificity of 93% for OSA regardless of gender.[103] Neck circumference, as well as neck circumference corrected for height, is a correlate of increased visceral fat, which is associated with OSA.

Physical examination should assess nasal patency, oropharyngeal anatomy, and craniofacial structure. Increased nasopharyngeal resistance, due to nasal septal deviation, turbinate hypertrophy, polyps, or other obstructing lesions, is associated with OSA.[104] The soft palate, uvula, base of tongue, and tonsils should be observed with attention to their size, length, and overall volume in relation to the oropharynx. A low-lying or redundant soft palate and uvula, often with edema or erythema due to vibratory trauma and inflammation from snoring, are frequently present in OSA. Both the Mallampati classification, which assesses oropharyngeal anatomy with the tongue protruded, and the Friedman classification, which is a similar assessment but without tongue protrusion, are commonly used to stage oropharyngeal crowding.[105] These scoring systems provide a numeric scale that grades the size of, and relationship among, the soft palate and uvula, lateral tonsillar pillars, and base of tongue. In addition, tonsil size should also be assessed. Anatomic crowding of the oropharynx has been shown to be related to the presence and severity of OSA, but this finding in and of itself has limited value for predicting presence of OSA (likelihood ratio range, 1.4 to 1.6).[103]

It is also important to assess craniofacial anatomy. In particular, mandibular retrognathia, or retrusion of the mandible, narrows the posterior air space and can increase the propensity for airway collapse during sleep. A high arched and narrow hard palate may also predispose to OSA. Assessment of dentition may also be useful to identify a narrowed posterior air space. In particular, the presence of *overjet*, defined as displacement of the mandibular teeth posteriorly compared with the maxillary teeth, is indicative of a small oral cavity that may result in posterior displacement of the base of the tongue, which narrows the retroglossal airway.[106]

ASSESSMENT

In-Laboratory or Full Polysomnographic Sleep Testing

The diagnosis of sleep apnea should be confirmed objectively by sleep testing. The "gold standard" test is PSG, a multichannel assessment of physiologic variables performed in a laboratory equipped with proper sensors, trained personnel, and a standardized way of recording results, with a qualified individual to interpret the study. Recorded variables usually include electroencephalogram (EEG), electromyogram (EMG) of the submentalis muscle, electrooculogram (EOG), a measure of airflow (usually sensors by the nose and mouth), a measure of respiratory effort (chest wall and abdominal movement, EMG of parasternal muscles, or changes in esophageal pressure), a measure of oxygen saturation (pulse oximetry), pulse rate, electrocardiogram (ECG), body position, EMG of legs (anterior tibialis muscle, for leg movements), and snoring (usually by microphone). Many laboratories also record continuous video imaging of the patient both for medical-legal reasons and to observe parasomnias. Table 114-3 contains a list of some of the most common variables recorded during in-laboratory PSG testing; a typical PSG epoch with recordings of these parameters is presented in Figure 114-2. More recently, efforts have been made to simplify the use of PSG for the diagnosis of sleep related breathing disorders. These systems measure fewer variables and are

Table 114-3 Commonly Recorded Parameters During In-Laboratory Polysomnography

Parameter Recorded	Purpose	Other
EEG (several channels) EMG of submentalis (other facial as indicated) EOG	Sleep staging	Usually standard 10 to 20 system for EEG—may also be used for seizure detection (EEG) if suitable montage used
Oronasal airflow Tidal swings in CO_2 measured at the mouth Respiratory effort (rib cage and abdominal movement)	Sleep-related abnormal breathing events	Nasal cannula pressure for hypopnea and flow limitation detection Thermistor for apnea detection
Pulse oximetry	O_2 saturation, pulse	Some definitions of DBEs depend on saturation, quantifies oxygenation at night
Microphone	Snoring	Some systems use perturbation in airflow
Body position sensor	Body position	
EMG: submental and pretibial	Sleep onset, REM onset, abnormal limb movements	
ECG	Rate and rhythm abnormalities	Usually precordial only; may detect rate of rhythm disturbances or changes in ST-T segments
CO_2: end-tidal, transcutaneous	Changes in alveolar ventilation	

DBE, Disordered breathing event; ECG, electrocardiogram; EEG, electroencephalogram; EMG, electromyogram; EOG, electrooculogram. Other variables often recorded during in-laboratory sleep studies include audio-videography and actigraphy.

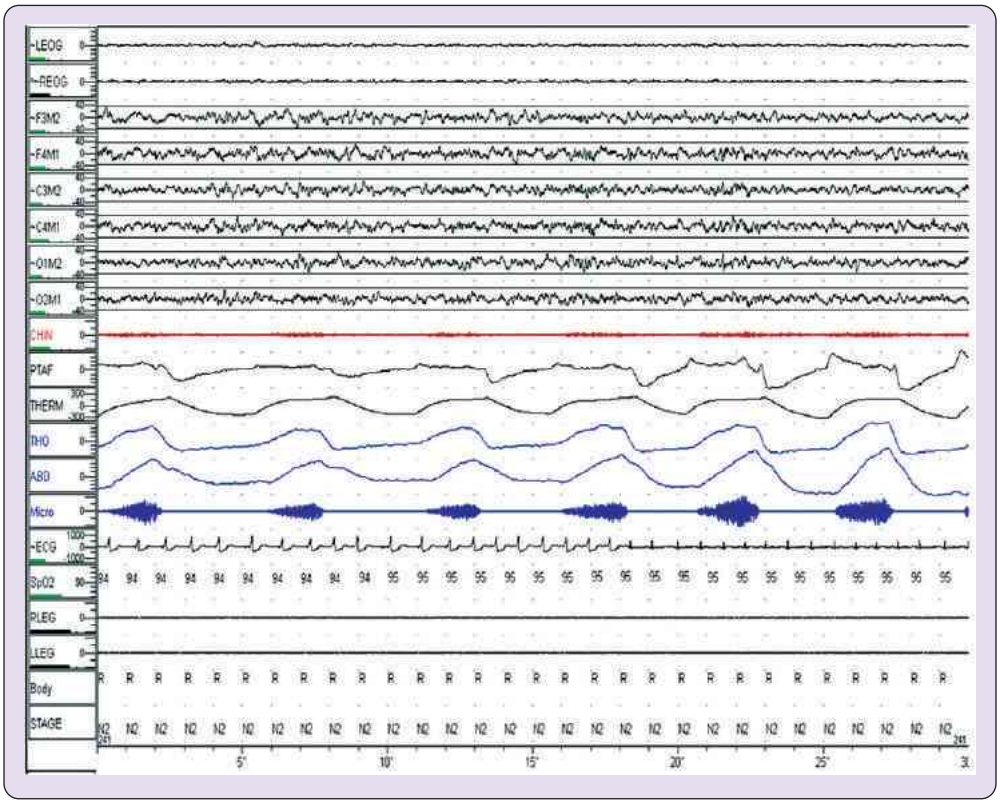

Figure 114-2 Sample montage for polysomnography. There are timing marks at the bottom; this is a 30-second epoch.

suitable for portable or out-of-center sleep testing (OCST) under certain conditions.

Technical specifications and acceptable derivations for in-laboratory PSG testing are specified in the American Academy of Sleep Medicine (AASM) scoring manual,[107] as well as elsewhere in this volume, as are the visual rules for sleep staging, respiratory events, limb movement events, and other "events" of note. We briefly review some of the specifications for recording respiratory "events" during PSG. Airflow is usually recorded using oronasal thermistor and nasal air pressure. Nasal air pressure, measured using small cannulas in the nose, is a more accurate approximation of airflow.[108] Thermistors placed by the nose and mouth do not measure flow but indicate airflow as a change in temperature. Thus they cannot quantify flow and instead record the presence or absence of airflow. In addition, if the thermistor moves toward or away from the nose and mouth, it will record changes in the signal that do not reflect actual flow. Tidal CO_2 is also sometimes used to assess flow. It is possible to get a true quantitative measurement of airflow with a tight-fitting facemask with a pneumotachograph. However, because of discomfort, this technique is not useful on a routine basis. Further, detection of respiratory events called respiratory event–related arousals (RERAs; discussed later; see Chapter 112) depends on detection of inspiratory flow limitation. As can be seen in Figure 114-3, this is not possible with thermistors or any other sensor that simply records the presence or absence of flow (e.g., tidal CO_2 monitoring). Therefore preference should be given to using nasal air pressure recording. Alternatives to measurement of airflow include the summed chest and abdomen signal from respiratory impedance belts, use of the mask pressure signal during positive airway pressure (PAP) titrations, and various indexes of respiration derived from pulse and finger plethysmographic techniques for OCST.

The AASM scoring manual[107] recommends that the primary means for detecting apnea is absence of the oronasal thermistor signal, although alternates are suggested. The manual recommends that the primary method for identifying hypopnea should be nasal pressure, although alternates are also suggested. During PAP titrations, it is recommended to use the change in PAP mask pressure as the primary flow signal. The manual recommends the use of esophageal manometry or respiratory impedance plethysmography thoracoabdominal belts as the primary measure of respiratory effort, although belts that measure changes in resistance are also acceptable. For detection of snoring, microphones, piezoelectric sensors, or perturbations in nasal air pressure are all considered acceptable. The reader is referred to this publication for more detailed analysis.

The severity of sleep apnea is usually defined in terms of frequency of respiratory "events" (see later). This implies that counting discrete occurrences adequately characterizes the severity of disease. In general, a greater frequency of such events per hour of sleep is associated with a more severe clinical syndrome. However, this is not a tight correlation because many patients with a "severe" respiratory event index have minimal symptoms, whereas many with a "mild" index have severe sleepiness. In general, severity of OSA as estimated

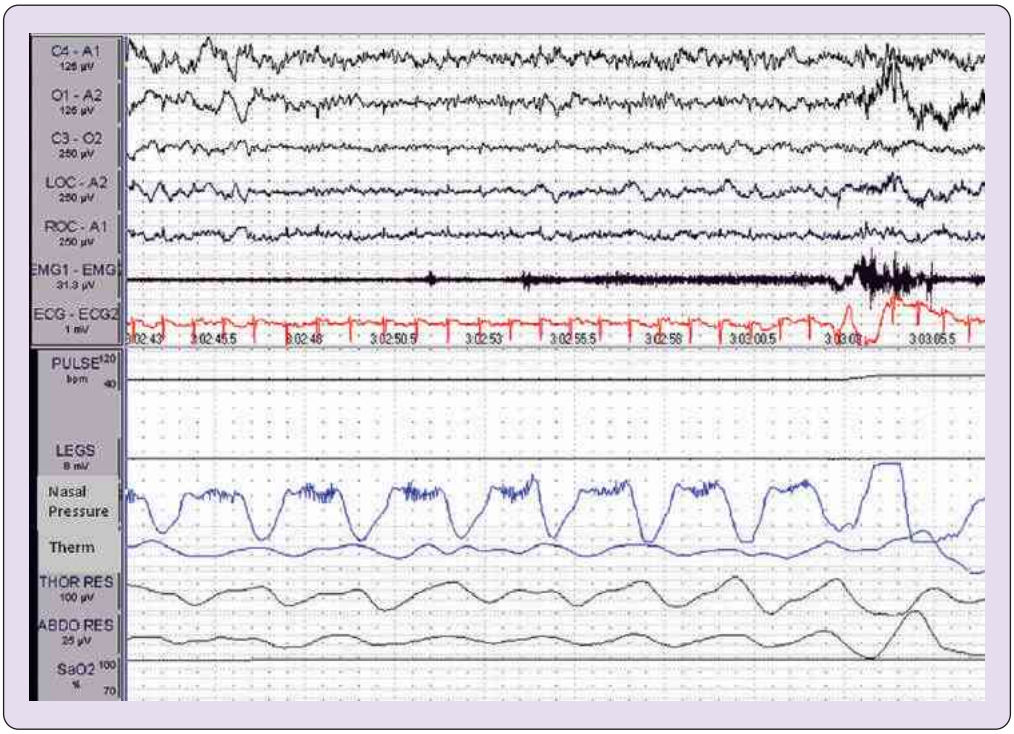

Figure 114-3 Respiratory event–related arousal (RERA). Comparison of airflow measured by oronasal thermistor (Therm) with that measured by nasal pressure (NP). For the nasal pressure signal the inspiratory direction is up, expiratory direction down. Note that with the nasal pressure transducer, inspiratory flow limitation (flattening of the signal and snoring) is readily detected. Note the arousal following this event (electroencephalogram [EEG] and electromyogram [EMG]). The first three channels are EEG, left EOG (LOC), and right EOG (ROC). EMG1-EMG; submentalis EMG; ECG, electrocardiogram; pulse is derived from the pulse oximeter; Legs, pretibial EMG.

Table 114-4 Definitions of Disordered Breathing Events in Sleep[107]

Duration	Event Type	Change in Airflow	Respiratory Effort	Associated Phenomena	Other
10-second duration measured from nadir preceding the first reduced breath to beginning of first breath approximating baseline	Obstructive apnea	Decrease ≥90%	Continues or increases throughout the entire period	NA	Oronasal thermistor (diagnostic study), PAP device (titration)
	Central apnea		Absent inspiratory effort throughout the entire period		
	Mixed apnea		Absent inspiratory effort initially with resumption in latter part of DBE		
	Hypopnea	Decrease by 30% to 90%	Continues	AASM: 3% desaturation *or* terminal arousal CMS: 4% desaturation	May score as: "Obstructive" = snoring, inspiratory flattening of flow (nasal pressure), thoracoabdominal paradox "Central" = none of above obstructive criteria
	RERA (AASM only)	Inspiratory flattening (<30%)	Increased effort	Terminal arousal	Crescendo snoring common
NA	Hypoventilation	NA	NA	NA	Increased P_{CO_2} to >55 torr for ≥10 minutes *or* ≥10 torr increased in P_{CO_2} c/w awake to >50 torr for ≥10 minutes
NA	Cheyne-Stokes breathing	NA	NA	NA	≥3 consecutive central apneas/ hypopneas separated by crescendo/ decrescendo change in airflow with cycle length >40 seconds *and* ≥5 central apneas/ hypopneas per hour sleep with crescendo/ decrescendo pattern over ≥2 hours monitoring

AASM, American Academy of Sleep Medicine; CMS, Centers for Medicare and Medicare Services; DBE, disordered breathing event; PAP, positive airway pressure; P_{CO_2} measured from arterial line, end-tidal, or transcutaneously; RERA, respiratory event–related arousal.

from accepted techniques of respiratory event indexes appears to be a reliable predictor of neurocognitive changes such as sleepiness and vigilance.

Sleep-related respiratory events have been defined in various ways. In adults, a respiratory event must last at least 10 seconds. This follows the definition of the original workers in the field who reasoned that this interval would encompass at least two breaths for the average adult.[4-11] There are other requirements for scoring specific types of sleep-related respiratory events. Table 114-4 summarizes the criteria for scoring disordered breathing events in adults as elaborated by the current version of the AASM scoring.[107] Table 114-5 lists commonly used definitions of OSA severity. The definitions are those of the Centers for Medicare and Medicaid Services.[3] Examples of PSG recordings of disordered breathing events are presented in Figure 114-3 (RERAs), Figure 114-4

Table 114-5 Severity Criteria for Obstructive Sleep Apnea*

Severity Definition	Apnea-Hypopnea Index	Coverage (CMS)
Mild	5–14	With comorbidities and symptoms†
Moderate	15–30	Yes
Severe	>30	Yes

*Definitions per Centers for Medicare and Medicaid Services (CMS).[3]
†Comorbidities that allow for coverage of "mild" disease in Medicare recipients include documentation of excessive sleepiness, impaired cognition, mood disorders, insomnia, hypertension, ischemic heart disease, history of stroke.
Note: Medicare will cover treatment for OSA when the diagnosis and severity classification were determined by home sleep testing as well as in-laboratory testing.

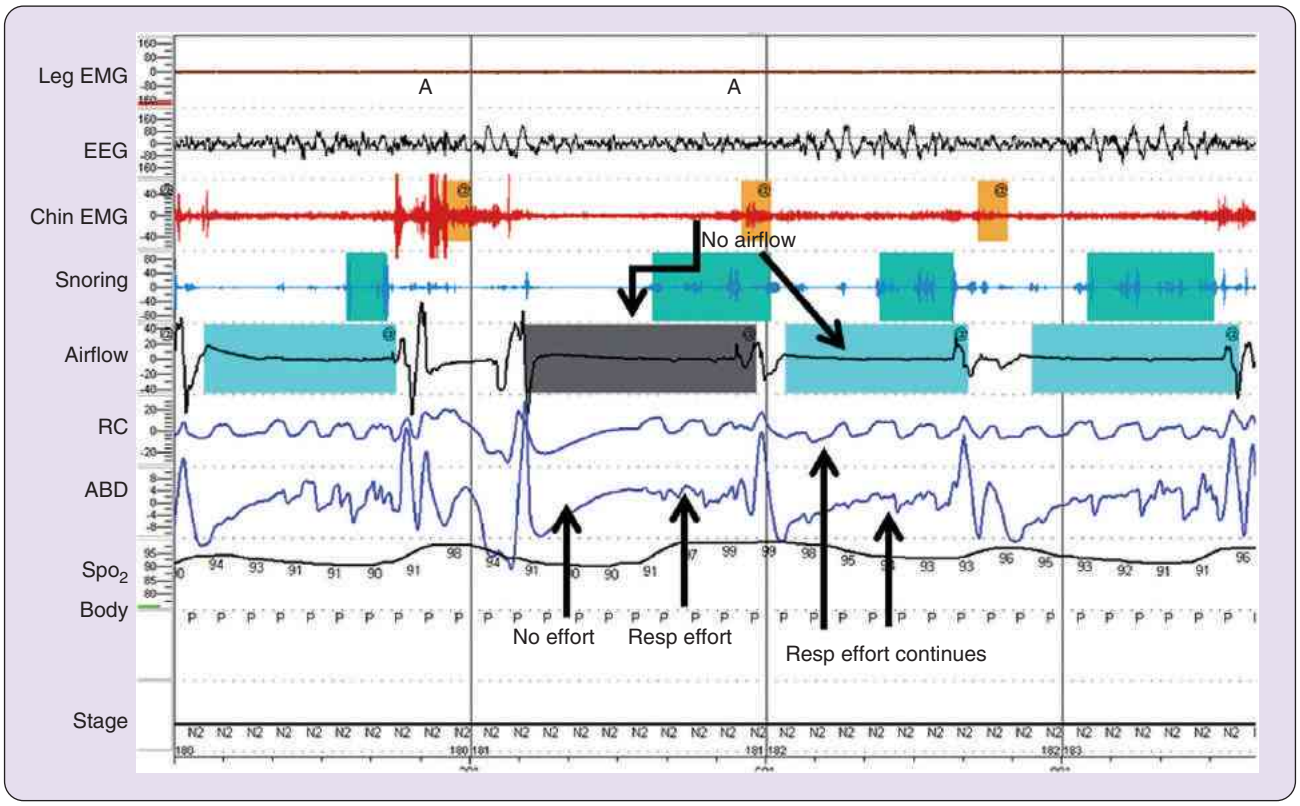

Figure 114-4 Obstructive and mixed apneas. Three obstructive apneas are outlined in blue-green, one mixed apnea in gray. Note for the obstructive apneas and the latter part of the mixed apnea, there is total cessation of airflow but chest wall movement continues. Note that the initial part of the mixed apnea shows no chest wall movement and resembles a central apnea (see Figure 114-5). Postapnea arousals are clearly seen (A). Airflow is measured by nasal air pressure. RC/ABD, Rib cage and abdominal movement by respiratory impedance pneumography; Spo_2, oxygen saturation of hemoglobin (pulse oximeter); Body, body position; Stage, stage of sleep. *Vertical lines* represent 30-second epochs.

Out-of-Center Sleep Testing

Although the previous parameters for assessing sleep-related respiratory events primarily pertain to in-laboratory, technologist attended PSG, a number of techniques have been developed to optimize the detection of sleep-related respiratory events outside of the laboratory, usually using a limited number of recording channels. Out-of-center sleep testing (OCST) offers a number of advantages compared with in-laboratory PSG. First, the initial costs are generally less than those of the state-of-the-art in-laboratory study, and primarily for this reason numerous insurance carriers require OCST for reimbursement in the initial evaluation of many patients with suspected OSA. Further, OCST offers a more rapid method of assessing the many patients with undiagnosed OSA who have limited access to, or who are reluctant to undergo, in-laboratory PSG.[109] However, Chervin and colleagues[110] performed a careful cost utility analysis, comparing in-laboratory PSG, OCST, and no testing (with treatment based on clinical characteristics). Their outcomes were based on costs per quality-adjusted life years over 5 years. These authors concluded that standard in-lab PSG provides greater quality-adjusted life years over 5 years than either OCST or no testing. Reuveni modeled costs of in-laboratory PSG versus OCST, accounting for the published technical failure rate of OCST and the published European costs for PSG.[111] They demonstrated that there was no long-term cost saving using OCST versus in-laboratory PSG.

Recent studies have directly compared health outcomes between OCST and in-laboratory PSG in selected patients. In 2010, Skomro and colleagues performed a randomized clinical trial of OCST compared with in-laboratory PSG in diagnosis and management of OSA in patients with a high clinical suspicion for the disorder.[112] All patients were evaluated and treated by physicians facile in interpretation of sleep studies as well as in clinical identification and management of sleep disorders. Exclusion criteria included concomitant cardiopulmonary morbidities and suspicion of other sleep disorders. Clinically relevant outcomes included quality of life, CPAP treatment adherence, blood pressure, and sleep quality after 4 weeks of therapy. There were no significant differences in any of these outcomes between OCST and in-laboratory PSG.

Overall, the relative advantages and disadvantages of OCST compared with in-laboratory testing in the evaluation and management of OSA require further definition. Approximately one third of OSA patients have a concomitant sleep disorder, of which approximately two thirds require treatment.[113] Thus patients need to be evaluated by a professional skilled in the evaluation and management of sleep disorders,

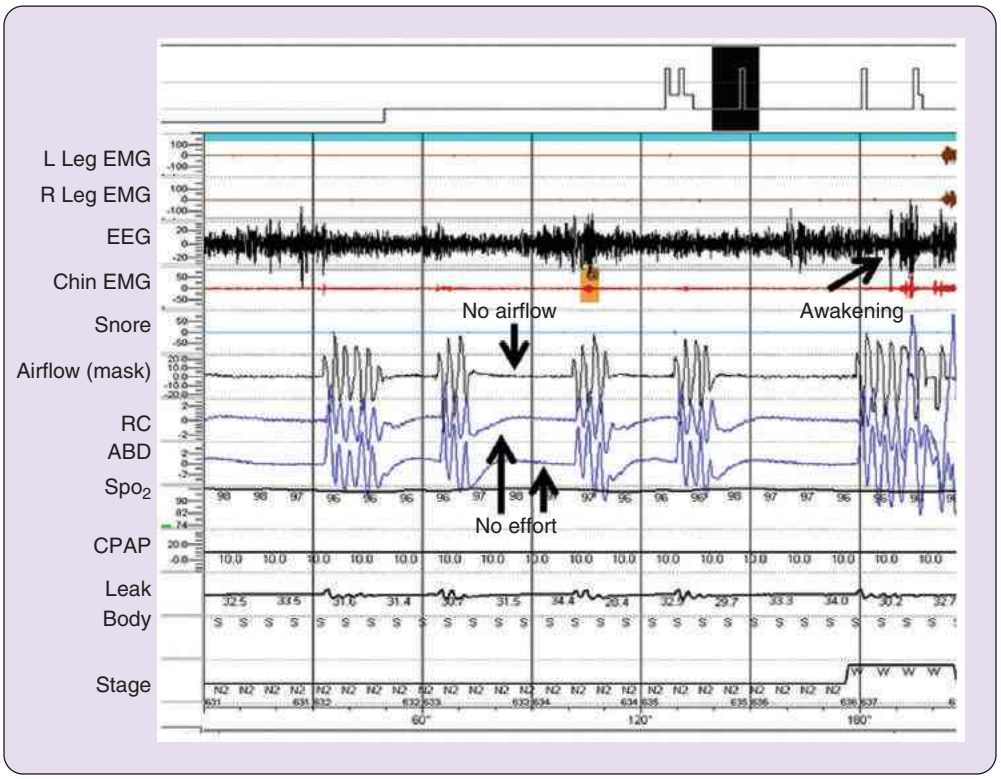

Figure 114-5 **Central apneas.** Central apneas developed during titration of continuous positive airway pressure (CPAP). Note absence of airflow (measured from the CPAP mask) and absence of respiratory effort (rib cage, abdominal movement measured by respiratory impedance pneumograph belts). RC, Rib cage signal; ABD, abdominal signal, snoring (absent here) measured from a microphone taped to the neck; Spo_2, oxygen saturation of hemoglobin measured from a pulse oximeter; Leak, estimation of leak from the CPAP mask; Body, body position; Stage, stage of sleep (hand scored). The *vertical lines* represent 30-second epochs. Note that after the series of central apneas, there is an arousal, and respiration resumes.

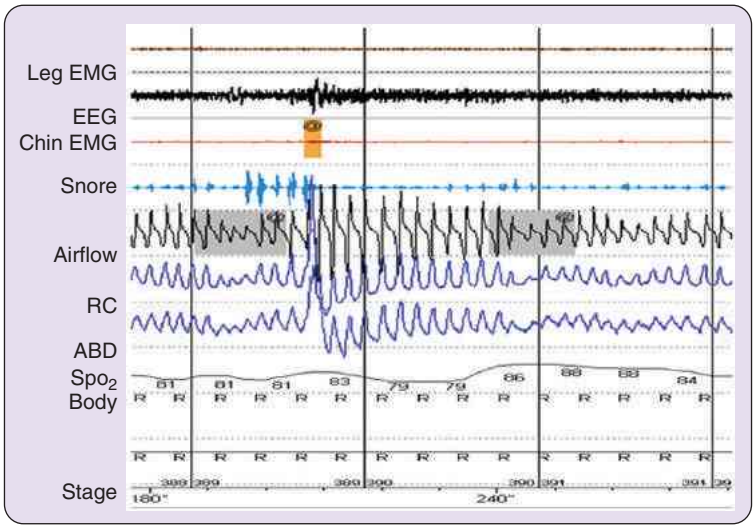

Figure 114-6 **Hypopnea.** In this diagnostic study airflow is measured using a nasal pressure cannula. The hypopneas are outlined in gray on the airflow signal. The first event shows a terminal arousal and 4% O_2 desaturation (the nadir of the event-associated desaturation is seen approximately 25 seconds after the arousal). The second event does not show an arousal, but there is an O_2 desaturation of 4%. The patient is in REM sleep. Body, Body position; RC/ABD, rib cage and abdominal movement by respiratory impedance pneumography; Spo_2, oxygen saturation of hemoglobin (pulse oximeter); Stage, stage of sleep. *Vertical lines* represent 30-second epochs.

whether OCST, in-laboratory PSG, or both are used in the diagnostic assessment. Incorporation of test results into a complete evaluation and management plan that encompasses all sleep-related complaints is essential. The clinician should also be aware that sleep testing is currently rated into levels of complexity. Type 1 is the classic in-laboratory full PSG as discussed previously, including measures of airflow, respiratory effort, oxygenation, EEG, EOG, and EMG to allow for sleep staging. Type 2 is an out-of-laboratory portable study essentially equivalent to the in-laboratory study (minimum of seven parameters). Type 3 is an unattended portable recording measuring at least four channels: heart rate, oxygen saturation, respiratory airflow, respiratory effort, but no sleep staging. Type 4 is an unattended portable study, measuring a minimum of three channels such as heart rate, oxygen saturation, and respiratory analysis. Appropriate documentation from a regional Medicare carrier should be consulted for details regarding coding, and the policies of specific insurance carriers should be consulted regarding requirements for allowing classical in-laboratory PSG versus portable OCST.

Even with the advent of reliable OCST, such testing still requires a relatively high level of instrumentation and analysis. Prescreening for OSA has the potential to improve sensitivity and specificity of both OCST and in-laboratory PSG, or even eliminate the need for such testing, taking into account pretest probability accruing from the previously noted demographic, physiologic, and clinical symptoms, signs, and conditions associated with OSA. A number of workers have therefore attempted to develop screening tools and techniques, some assessing physiologic parameters and some using self-administered questionnaires, with or without inclusion of key physical traits.

Early attempts at physiologic screening for OSA were based on simple pulse oximetry.[114] These devices generally relied on estimating the number of 3% or 4% drops in oxygen saturation. However, problems with validity and sensitivity remained. Newer techniques make use of the known coupling between cardiovascular (pulse, autonomic function, arterial tone) and respiratory phenomena. For example, Liu and colleagues used a sophisticated transform to analyze signals from a single ECG lead to detect breathing and sleep-related disordered breathing events.[115] Their analyses resulted in acceptable sensitivity and specificity (area under the receiver-operator curve of 0.79) for OSA screening using a single ECG electrode. An index called the temporal variability of the dominant frequency was well correlated to AHI and could distinguish among sleep-related breathing events of various severities.

Peripheral arterial tonometry (PAT) has also been developed as an OSA screening tool. Bar and colleagues evaluated such a device (WatchPAT, Itamar Medical, Caesarea, Israel) placed on the finger that measured pulse oximetry and volume of the finger.[116] The abrupt arousals associated with termination of the obstructive events are associated with bursts of sympathetic discharge causing vasoconstriction that decreases volume of the digit. In addition to PAT and standard oximetry, the device recorded pulse rate and movement (actigraphy). The respiratory disturbance index (RDI) measured using PAT was highly correlated with RDI measured during in-laboratory PSG (the area under the receiver-operating curve was 0.82 and 0.87 for thresholds of RDI = 10/hour and RDI = 20/hour, respectively).

Another device that relies on measures of pulse, oxygen saturation and peripheral digital volume is the photoplethysmograph (PPG; Morpheus Ox, WideMed, Herzliya, Israel). Digital volume, pulse, and oxygenation signals are recorded and imputed into proprietary algorithms that generate clinically relevant respiratory waveforms and approximation of the sleep-wake state. A recent study using the AASM 2012 apnea-hypopnea detection scoring parameters validated this device against standard in-laboratory PSG.[117] A unique feature of the study was that among the 65 subjects, 19 had significant cardiopulmonary comorbidities. There was excellent correlation between the PPG- and PSG-derived AHI. For AHI of more than 5/hour, sensitivity was 80%, specificity 86%, and positive likelihood ratio 5.9. For AHI of more than 15/hour, sensitivity was 70%, specificity 91%, and positive likelihood ratio 7.83. Further, results in patients with cardiopulmonary morbidities were not different from the rest of the subjects.

Numerous questionnaires have also been designed in an attempt to use patient symptoms to improve the pretest probability for OSA. The Harvard sleep apnea screening questionnaire was one such attempt.[118] Subjects with essential hypertension were screened. No one symptom was found to be predictive of an AHI greater than 10/hour, although loud snoring was predictive of oxygen desaturation in sleep. Numerous OSA screening questionnaires have been developed that incorporate symptoms (e.g., snoring, snorting, witnessed apneas, excessive sleepiness), demographics (e.g., gender, age), physical traits (e.g., BMI, crowding of the oropharynx, neck circumference), and important c-morbidities (e.g., hypertension). Clinical prediction formulas, some requiring sophisticated calculations and even computer assistance, have been developed that assign weights to the various factors. Questionnaires that have been validated in specific populations include the Berlin Questionnaire, designed for use in primary care settings,[119] and the STOP-BANG questionnaire, designed for preoperative screening.[120] Other such instruments include the Wisconsin questionnaire[121] and the questionnaire of Haraldsson and colleagues.[122] Overall, it appears that such questionnaires have the greatest potential to screen patients at high risk for OSA. Further, validation studies indicate that the applicability of any such questionnaire is limited to the specific populations studied.

The predictive value of the clinical examination has also been assessed in an attempt to identify features on the clinical examination with the greatest value for predicting a "positive" PSG.[73] No one single symptom or sign appears sufficiently predictive of OSA, if defined as AHI greater than or equal to 10/hour, including snoring, subjective sleepiness, and morning headache. Rather, a combination of signs and symptoms, including neck circumference, habitual snoring, systemic hypertension, and bed partner report of nocturnal gasping or choking appears to optimally identify patients most likely to have sleep-study documented OSA.[123]

PRINCIPLES OF MANAGEMENT

The adverse consequences of OSA pose an enormous health and economic burden.[124,125] Effective treatment requires a patient-centered chronic disease management approach that goes beyond initial diagnosis and therapy prescription. Monitoring and enhancing adherence to therapy, providing

alternative therapeutic modalities when needed, and managing comorbid sleep disorders are necessary to optimize long-term sleep-related health outcomes.

CPAP, which pressurizes the UA to prevent its collapse during sleep, remains the mainstay of therapy for OSA. Initiation and prescription of CPAP is usually accomplished by in-laboratory PSG CPAP titration, which determines CPAP pressure requirements during all stages of sleep in all sleep positions. Autotitrating positive airway pressure (APAP) devices assess inspiratory airflow and adjust positive airway pressure automatically to maintain normal inspiratory flow patterns. Data supporting noninferiority of APAP for initiation of CPAP therapy are limited.[126] Patients with comorbid cardiopulmonary disorders, especially those with obesity hypoventilation syndrome, central sleep apnea, Cheyne-Stokes breathing, or COPD, are not candidates for APAP therapy.

Multiple studies have evaluated the effect of CPAP on EDS. Most placebo-controlled studies demonstrated improvement in subjective measures of daytime somnolence, whereas data are mixed with regard to objective measures. A randomized placebo-controlled study with more than 1000 participants demonstrated that CPAP improved both subjective and objective measures of daytime sleepiness, especially in severe OSA (AHI >30/hour).[127] Similarly, clinical trials of the effects of CPAP on neurobehavioral and cognitive performance, as well as on overall quality of life, are mixed, with some studies demonstrating benefit.[128] A recent randomized placebo-controlled clinical trial evaluated the effects of CPAP on daytime sleepiness and quality of life in patients with mild to moderate OSA with a complaint of daytime somnolence, a patient type that represents a large portion of the OSA population. CPAP resulted in greater improvement in functional outcomes, including quality of life, subjective daytime sleepiness, and mood, compared with sham CPAP.[127] The optimal duration of nightly CPAP use necessary to achieve improvement in functional outcomes has also been a matter of investigation. In a multicenter effectiveness study that used both subjective and objective measures of daytime somnolence and quality of life as outcome measures, a greater percentage of patients achieved improvements in outcomes with longer nightly duration of CPAP use, up to 7 hours/night. Although the mean nightly duration of CPAP use in this trial was 4.7 $\pm$ 2.2 hours, a substantial minority of patients demonstrated benefit with a shorter duration of nightly CPAP use (even <2 hours/night), whereas some subjects exhibited residual sleepiness with more than 7 hours of use per night. Thus assessment of optimal CPAP use should rely not only on hours of nightly use but also on assessment of relevant treatment outcomes.[128]

The efficacy of CPAP is limited by suboptimal adherence. Many studies have evaluated measures to improve adherence to CPAP therapy. Technologic improvements in CPAP delivery, such as APAP, expiratory pressure reduction, heated tube humidification, and other modalities that adjust the contour of the pressure waveform, have contributed somewhat to improvements in comfort but have not solved the overall adherence problem with CPAP.[129] Other measures to enhance adherence include educational and supportive efforts as well as cognitive behavioral therapy, that may help to acclimatize patients to CPAP and encourage nightly use. A recent review indicated that these interventions can improve CPAP adherence.[130]

The identification of *treatment emergent central sleep apnea*, which is a form of sleep breathing disorder in which central apneas emerge during CPAP therapy disrupting sleep, may also limit efficacy and tolerability of CPAP. Although the pathophysiology of this form of central sleep apnea has not been fully elucidated, it may occur as a result of ventilatory instability during sleep. Cheyne-Stokes breathing, which is not well treated with CPAP, is common in patients with systolic heart failure and may contribute to failure of CPAP therapy in this population. However, while effective in reducing disordered breathing events, the newer modality of adaptive servo ventilation is no longer recommend in patients with heart failure and predominantly central sleep apnea due to an observed increase in mortality with this therapy.[132]

Mandibular advancement oral appliance therapy can be considered either as first-line therapy for mild to moderate OSA or as an alternative to CPAP. Improvement in somnolence, vigilance, and neurocognitive performance has been observed with this modality. Interestingly, the improvement in functional outcomes achieved with oral appliances is similar in magnitude to that seen with CPAP, despite persistence of mild degrees of OSA.[133,134] It is important to perform follow-up PSG to assess efficacy of the appliance because subjective reports of improvement may not reliably predict the AHI with therapy. In a study of patients with mild to severe OSA, only 65% of the cohort who had subjective symptomatic improvement with oral appliance therapy achieved an AHI of 10/hour or less on follow-up PSG. The degree of mandibular advancement was then increased in the incomplete responders. An additional 30% of the cohort achieved an AHI of 10/hour after this secondary adjustment, indicating the importance of the follow-up PSG.[135] Better predictors of response to oral appliances, as well as accurate determination of the optimal degree of mandibular advancement, may improve utility and efficacy of this modality. Remotely titratable appliances have been developed, in which the degree of mandibular advancement can be titrated during PSG, that may help to identify patients who respond to this modality and accurately determine the optimal degree of mandibular advancement.[136] In addition, recent data suggest that response to oral appliance therapy may be predicted by visualization of velopharyngeal widening with mandibular advancement during awake nasopharyngoscopy.[137]

Nasal expiratory positive pressure (nEPAP) is another alternative therapy for OSA that provides positive pressure during end expiration when the cross-sectional area of the UA and dilator muscle activity are at their nadir. By increasing expiratory airflow resistance using a small valve taped to the nostrils, nEPAP is created that prevents airway collapse. In addition, increases in lung volume have been observed with nEPAP, which may reduce UA collapsibility by increasing caudal traction on the UA. Significant decreases in the AHI have been observed in efficacy trials, although tolerability and compliance remain to be fully established.[138,139]

UA surgery, including nasal septoplasty, uvulopalatopharyngoplasty (UPPP), tonsillectomy, and tongue advancement procedures, as well as maxillomandibular advancement surgery, are alternative therapeutic modalities for OSA. In addition to patient preference and consideration of medical comorbidities, UA anatomy should be evaluated when assessing suitability of a surgical approach. A clinical staging system, based on observation of the oropharynx, such as that offered by

Friedman,[105] which classifies palate position, tonsil size, and BMI, can be a useful predictor of outcome of UPPP and tonsillectomy. These authors showed that the best response is achieved when the inferior border of the palate is above the base of the tongue, with enlarged tonsils and BMI of 40 kg/m^2 or lower.

Imaging with nasopharyngoscopy can more directly assess UA anatomy than clinical observation of the oropharynx. Dynamic behavior of the UA can also be observed during a Müller maneuver. Although identification of a velopharyngeal site of collapse during a Müller maneuver was originally shown to predict response to UPPP, subsequent studies demonstrated a low predictive value.[140,141] Recently, drug-induced sleep endoscopy has been introduced in which the UA is evaluated during propofol-induced sedation in an operating room setting. The relationship of drug-induced sleep endoscopy findings to UA behavior during sleep and their relevance to UA surgical operative planning and outcomes has not been established.[142,143]

Clinical experience has shown that although nasal surgical procedures including septoplasty and turbinectomy usually do not achieve resolution of OSA, they may be useful to improve tolerability of CPAP in patients with nasal obstruction. Although response to a single UA surgical procedure may be limited, a multilevel approach to the UA, including UPPP followed by genioglossal suspension or advancement with hyoid myotomy, has achieved improved success rates.[144] Modifications of current UA soft tissue surgical procedures, as well as development of new approaches, may ultimately improve outcomes. Maxillary-mandibular advancement osteotomy is also performed in the surgical management of OSA with reported high success rates. The resultant increase in volume of the UA has been correlated with reduction in the AHI. Surgical planning using three-dimensional UA imaging may also improve the success of these surgical procedures.[145,146]

Positional therapy may also be useful in selected patients in whom disordered breathing events occur predominantly during supine sleep. Avoidance of supine sleep can lead to reduction in the AHI in such cases, particularly with use of positioning devices, which are typically worn around the chest and prevent inadvertent supine sleep.[147]

Because OSA severity is sensitive to weight loss, weight reduction programs and bariatric surgery are valuable treatment modalities. Although most studies have shown that bariatric surgery is associated with resolution or improvement of OSA in most cases, it is important to recognize that OSA can persist in some cases after substantial weight loss. Because the correlation of subjective daytime sleepiness with AHI severity is relatively weak, follow-up PSG, rather than reliance on symptoms, is important to determine whether further OSA therapy is needed despite weight loss.[148,149]

Electrical stimulation of the hypoglossal nerve is a recently introduced modality that was developed in response to the observation that inadequate neural activation of the UA dilator muscles is a key factor in the pathophysiology of OSA. The stimulator can deliver phasic electrical pulses to the hypoglossal nerve at the onset of inspiration augmenting genioglossal inspiratory activity. Efficacy trials have included patients with moderate to severe OSA with BMI of less than 40 kg/m^2. Some of the studies excluded patients with concentric retropalatal collapse. Most of the trials demonstrated more than 50% improvement in the AHI, which was sustained during long-term follow-up.[150-152] Although experience remains limited, hypoglossal nerve stimulation may be a useful alternative for selected patients.

Future approaches to treatment may be developed based on identification of individual "phenotypes" of OSA. Recent studies have demonstrated interindividual differences in the pathophyphysiology of OSA. In some patients, instability of ventilatory control during sleep, measured as elevated "loop gain," is a predominant factor. Loop gain is a dimensionless value that quantifies response of the ventilatory system to decrements in ventilation such as those induced by UA obstruction. High loop gain is associated with an excessive ventilatory response to apnea (or hypopnea) that contributes to ventilatory instability and perpetuates recurrent apneas. A low arousal threshold, which destabilizes sleep, has also been shown to contribute to ventilatory instability during sleep. In other patients, inadequate activation of UA dilator muscles in response to obstruction is a predominant pathophysiologic feature. Anatomic factors, with a highly collapsible UA, indicated by a high (less negative or positive) Pcrit, is identified as the major factor contributing to OSA in other patients.[151]

Understanding OSA phenotypes may help to individualize treatment. Mechanically based therapies including CPAP, mandibular advancement oral appliances, or surgical interventions are the best therapeutic options for patients in whom anatomic factors, with a highly collapsible UA, play a major role. Patients with high loop gain, or a low arousal threshold, in whom ventilatory control instability is the predominant factor, may respond to novel therapeutic measures to stabilize sleep and ventilatory control. Approaches that increase UA dilator muscle activity during sleep, such as hypoglossal nerve stimulation, may be most useful in patients that have reduced UA dilator muscle responsiveness to UA collapse. Thus thinking about OSA as a heterogeneous disorder with multiple "phenotypes" might facilitate development of new and individualized therapies.[153,154]

SUMMARY

OSA is a highly prevalent disorder and is overrepresented in populations with cardiovascular, cerebrovascular, and metabolic disease. The pathophysiologic basis of OSA is complex, with contributions from anatomic factors that narrow the UA as well as ventilatory control instability that affects neural drive to the UA and ventilatory pump muscles during sleep. The acute, repetitive physiologic perturbations during sleep that occur as a result of obstructive apneas and hypopneas include sleep fragmentation, large swings in intrathoracic pressure, increased sympathoadrenal tone, and intermittent hypoxia and reoxygenation. OSA is associated with multiple adverse systemic consequences, including excessive sleepiness, impairment of cognitive function, mood, vigilance, and performance, including driving ability. OSA is also associated with multiple cardiovascular, cerebrovascular, and metabolic disorders as well as other medical conditions. The relationship between OSA and these comorbidities may be bidirectional. Although clinical presentation can identify patients at risk for OSA, diagnosis requires objective monitoring of sleep. In-laboratory PSG testing remains the gold standard for accurate identification of OSA; however, OCST using ambulatory technology is useful in selected patients. Skilled assessment and management of this chronic disorder are necessary to

ensure optimal long-term outcomes. Most studies have demonstrated improvement in daytime somnolence and quality of life with CPAP therapy for OSA. Other therapeutic modalities, including mandibular advancement oral appliances and surgical approaches to the UA, are useful alternative modalities in selected patients. Newer approaches such as hypoglossal nerve stimulation, nasal expiratory positive pressure devices, and other treatments require further investigation to establish their clinical utility. Investigational approaches that define an individual's predominant OSA phenotype may ultimately guide treatment decisions.

CLINICAL PEARL

OSA is highly prevalent, particularly in patients with comorbid cardiovascular, cerebrovascular, and metabolic disease. Because OSA independently contributes to morbidity and mortality, with multisystem consequences, clinical suspicion for OSA should be a priority for clinicians, especially in patients with these comorbidities. Clinical assessment, as well as sleep testing with in-laboratory PSG, or OCST in appropriately selected and managed patients, is necessary for accurate diagnosis. Effective treatment of OSA and any comorbid sleep disorders requires a focus on optimizing sleep-related health outcomes with a chronic disease management approach.

Positive Airway Pressure Treatment for Obstructive Sleep Apnea

Chapter 115

Neil Freedman

Chapter Highlights

- Continuous positive airway pressure (CPAP) therapy is indicated for patients with moderate to severe obstructive sleep apnea (OSA) with or without symptoms and for patients with mild OSA with associated symptoms or comorbid illnesses.
- CPAP consistently improves or resolves respiratory events across the spectrum of disease severity and improves symptoms of daytime sleepiness, especially for patients with moderate to severe OSA. Improvements in blood pressure are relatively small, with reductions in blood pressure tending to be greatest in patients with untreated hypertension and in those with better compliance with therapy. Improvements in other outcomes are inconsistent across the spectrum of disease severity.
- Compliance with positive airway pressure (PAP) therapy is far from perfect. Systematic education through several approaches, with or without behavioral therapy, have been the only interventions that have been associated with consistent improvements in compliance with PAP therapy. The roles of other interventions, including heated humidification, prescription hypnotics, telemedicine, and sleep specialist care, for most patients with OSA are not clear.
- Advanced PAP technologies, including bilevel PAP and expiratory pressure relief devices, have not been associated with better compliance or improvements in other important outcomes compared with standard CPAP therapy. The roles for bilevel PAP and devices with expiratory pressure relief technology in the management of most patients with OSA are not clear.
- Autotitrated positive airway pressure (APAP) used in an unattended setting, either to determine a fixed CPAP pressure or as a primary treatment, is reasonable therapy for most patients with uncomplicated moderate to severe OSA syndrome. APAP therapy has been shown to result in similar compliance and improvements in other important outcomes compared with conventionally titrated CPAP therapy. In appropriate OSA patients, an ambulatory approach using portable testing and APAP therapy should lead to reductions in the cost of management of OSA while not adversely affecting patient outcomes.

Treatment with positive airway pressure (PAP) remains the primary therapy for most patients with obstructive sleep apnea (OSA), especially those with moderate to severe OSA. This chapter reviews various forms of PAP therapy for the treatment of OSA, highlighting the indications for treatment, methods for determining an effective pressure prescription, treatment outcomes, and methods that may improve compliance with therapy. The initial part of the chapter focuses on continuous positive airway pressure (CPAP) therapy, and the later portion of the chapter emphasizes the technologic advancements in the delivery of PAP therapy, including autotitrating positive airway pressure (APAP), bilevel PAP, and expiratory pressure reduction (EPR) technologies.[1]

CONTINUOUS POSITIVE AIRWAY PRESSURE TREATMENT

CPAP therapy was initially described as a treatment for OSA by Sullivan and colleagues in 1981.[1a] Since its initial description, CPAP has become the predominant therapy for the treatment of patients with OSA because it has been demonstrated to resolve sleep-disordered breathing events and improve several clinical outcomes.[2,3] Treatment with CPAP is typically indicated for patients with moderate to severe OSA by apnea-hypopnea index (AHI) of 15 or more events/hour with or without associated symptoms or comorbid diseases and for patients with mild OSA (AHI ≥5 to ≤14 events/hour) with associated symptoms or comorbid diseases (Box 115-1).

CPAP is conventionally delivered through a nasal mask at a fixed pressure that remains constant throughout the respiratory cycle. The proposed mechanism of action of CPAP therapy is that it acts as a pneumatic splint that maintains the patency of the upper airway in a dose-dependent fashion. It does not exert its effects by increasing upper airway muscle activity[4] and acts only as a treatment, and not a cure, for the disorder. Several studies have demonstrated that withdrawing CPAP therapy in patients with OSA across the spectrum of disease severity results in the recurrence of OSA and associated daytime symptoms in most patients within 1 day to several days.[5-7]

Box 115-1 TYPICAL INDICATIONS FOR CONTINUOUS POSITIVE AIRWAY PRESSURE THERAPY FOR OBSTRUCTIVE SLEEP APNEA

- Moderate to severe obstructive sleep apnea (≥15 events per hour of sleep) with or without associated symptoms or comorbid diseases
- Mild obstructive sleep apnea (≥5 to ≤14 events per hour of sleep) with symptoms or associated comorbid diseases:
  - Symptoms: excessive daytime sleepiness, impaired cognition, mood disorders, or insomnia
  - Comorbid diseases: hypertension, ischemic heart disease, or history of stroke

Determining the Optimal Setting

The optimal CPAP settings for home use may be defined as the minimal pressure required to resolve all apneas, hypopneas, snoring, and arousals related to these events in all stages of sleep and in all sleep positions.[2,8-10] Simply, the optimal CPAP setting should resolve all sleep-disordered breathing in supine rapid eye movement (REM) sleep to account for the effects of gravity and changes in muscle tone that may occur in different sleep stages and positions.[8] The optimal pressure should also maintain oxygen saturation at or above 90% and should minimize mask leak, allowing and maintaining only mask leak that that is appropriate for the given pressure. The most current American Academy of Sleep Medicine (AASM) Practice Parameters recommend a full night of CPAP titration based on the criteria outlined previously.[9,10] A repeat CPAP titration need only be performed if symptoms of OSA reappear despite compliance with CPAP therapy, if a patient sustains a significant weight loss either through diet or bariatric surgery, or if CPAP compliance and benefits remain suboptimum by current standards.

A "split-night" sleep study, in which the initial portion of the study is used to objectively document an individual's sleep related breathing disorder followed by a CPAP titration during the second portion of the night, may be indicated in certain situations.[8-10] A split-night sleep study may be considered when the following criteria have been met: (1) an AHI of 40 or more events/hour is recorded during the initial 2 hours of the polysomnography (PSG) study and (2) at least 3 hours remain during the PSG study to conduct an adequate CPAP titration. A second full night of CPAP titration should be considered if an optimal CPAP pressure setting could not be achieved during the second portion of the split-night study. Split-night studies can also be considered for individuals who demonstrate less severe OSA, with an AHI of 20 to 40 events/hour, during the initial 2 hours of a sleep study, although data suggest that CPAP titrations in this subgroup of patients may be less accurate when performed in the split-night protocol setting. Although split-night studies potentially reduce waiting times to initiate home CPAP therapy, especially in areas with long sleep laboratory waiting times, a significant portion of patients with OSA may undergo suboptimal CPAP titrations using this format.[11]

The use of home sleep testing (HST) is currently not recommended for the titration of CPAP or other PAP therapies because there are few data on the reliability of HST for this indication. Given the absence of data regarding HST for CPAP titration, the Centers for Medicare and Medicaid Services and commercial insurance companies in the United States typically will not reimburse providers who use HST for this indication.

Table 115-1 Adequacy of Continuous Positive Airway Pressure Titration Definitions

Optimal	Reduces the RDI <5 for at least a 15-minute duration and should include supine REM sleep at the selected pressure that is not continually interrupted by spontaneous arousals or awakenings
Good	Reduces the RDI ≤10 or by 50% if the baseline RDI <15 and should include supine REM sleep that is not continually interrupted by spontaneous arousals or awakenings at the selected pressure
Adequate	Does not reduce the RDI ≤10 but reduces the RDI by 75% from baseline (especially in severe OSA patients), or in which the titration grading criteria for optimal or good are met with the exception that supine REM sleep did not occur at the selected pressure
Inadequate	Does not meet any one of the above grading criteria

RDI, respiratory disturbance index, which accounts for apneas, hypopneas, and respiratory effort–related arousals.
Adapted from Kushida CA, Chediak A, Berry RB, et al. Clinical guidelines for the manual titration of positive airway pressure in patients with obstructive sleep apnea. *J Clin Sleep Med* 2008;4:157–71.

Although there are current recommendations to help guide clinicians on how to manually titrate CPAP therapy in an attended laboratory-based setting, these recommendations largely serve as guidelines because they are principally based on the consensus of expert opinion and not on randomized trials demonstrating their superiority over other methods of manual titration.[8] The AASM guidelines classify the adequacy of a CPAP titration as delineated in Table 115-1. The AASM guidelines currently recommend considering a repeat titration study for patients who do not achieve an optimal or good PAP titration.

There are actually few data on the quality or efficacy of CPAP titrations, as defined by the AASM clinical guidelines, in clinical practice. Specifically, few data exist on how often patients actually achieve an optimal PAP titration, despite having their PAP pressures determined in an attended setting. Furthermore, there are few data examining the outcomes of patients who are initiated on CPAP therapy after undergoing PAP titrations that are less than optimum. Many of the randomized controlled trials evaluating the effect of CPAP on various outcomes have shown a mean residual AHI or respiratory disturbance index (RDI) of 5 or greater, indicating that more than 50% of these patients underwent CPAP titrations that did not achieve optimal results. Of the limited existing data from clinical settings, approximately only 50% to 60% of patients with OSA achieve an "optimal" titration and up to 30% to 40% achieve only an "adequate" or "inadequate" titration.[12,13] Thus many patients on CPAP therapy, even those who undergo attended in-laboratory titrations, may currently

be treated with suboptimal pressures settings. More data are needed to better define the optimal clinical and physiologic benchmarks for the various levels of PAP titration adequacy as well as to determine the outcomes and proper management for patients who do not achieve optimal or good PAP titrations during an in-laboratory titration study. The important point is that the clinician should not assume that a given patient is on an adequate CPAP setting simply because the patient's CPAP pressure was determined during an in-laboratory titration study.

Although current recommendations warrant that CPAP titrations occur during a full overnight in-laboratory PSG study, some data suggest that a fixed-pressure CPAP can be successfully initiated in an unattended home setting using various approaches.[14-21] Specifically, several studies confirm that CPAP therapy initiated in an unattended home setting (without HST or PSG monitoring to confirm the efficacy of treatment) can be successful in many patients with uncomplicated OSA (OSA without associated chronic obstructive pulmonary disease [COPD], congestive heart failure [CHF], or hypoventilation syndromes) when CPAP settings are determined by a clinical prediction formula,[20] by CPAP self-adjusted to resolve snoring and daytime symptoms,[17,18] or APAP therapy[14-16,21] (Table 115-2).

It is important to note that all of these methods typically offer only a starting pressure for initiating CPAP therapy. As observed in several of the study protocols, many patients may require pressure adjustments based on symptoms and problems with therapy. Because results from several studies continue to support the efficacy of PAP titrations in unattended nonlaboratory settings for patients with uncomplicated OSA, specifically with the use of APAP devices, PAP therapy may potentially be initiated in the home for many patients with uncomplicated OSA. It is possible that in the future, in-laboratory attended CPAP titrations may be reserved for patients with OSA and concomitant cardiac or respiratory disease, those with obesity hypoventilation syndrome, and those who are having difficulty with CPAP initiated in an unattended setting. If such an approach to CPAP treatment comes to fruition, patients with OSA may benefit by realizing shorter waiting times for CPAP therapy, and health care dollars should be saved by reducing the need for unnecessary PSG studies.[15,16,18,19,22]

Table 115-2 Clinical Prediction Formulas Used to Determine an Effective Continuous Positive Airway Pressure Setting

Study	Clinical Prediction Formula
Miljeteig & Hoffstein, 1993[166]	P(eff) = 0.13 (BMI) + 0.16 (NC) + 0.04 (RDI) – 5.12
Lin et al, 2003[167]	P(eff) = 0.52 + 0.174 (BMI) + 0.042 (AHI)
Stradling, 2004[168]	P(eff) = 2.1 + 0.048 (ODI) + 0.128 (NC)
Hukins, 2005[169]	BMI < 30 = 8 cm H_2O BMI 30–35 = 10 cm H_2O BMI > 35 = 12 cm H_2O
Loredo, 2007[170]	P(eff) = 30.8 + RDI (0.03) – nadir SaO_2 (0.05) – mean SaO_2 (0.2)

AHI, Apnea-hypopnea index; BMI, body mass index; NC, neck circumference; ODI, oxygen desaturation index; P(eff), effective continuous positive airway pressure; RDI, respiratory disturbance index.

Benefits of Therapy

It is the perception of many non–sleep practitioners and the lay public that CPAP treatment consistently resolves or improves several important outcomes, including sleep architecture, daytime sleepiness, neurocognitive function, mood, quality of life, and cardiovascular disease in all patients with OSA. When titrated appropriately, CPAP therapy has been demonstrated to resolve most sleep breathing disorder across the spectrum of disease severity and has been demonstrated to be superior to placebo, conservative management, and positional therapy with regard to this outcome.[9,23] Randomized controlled trials have also shown CPAP therapy to be superior to placebo at increasing the percentage of time and total time in stages N3 (non–rapid eye movement [NREM] sleep stage 3) and REM sleep. The effects of CPAP on other sleep parameters, including stages N1 and N2 sleep, total sleep time, and the arousal index, have been inconsistent across studies.[9,23]

Effect on Daytime Sleepiness

Several randomized controlled studies have shown that CPAP therapy significantly improves or resolves subjective symptoms of daytime sleepiness in OSA patients who suffer from this complaint, predominantly in those who suffer from severe OSA (AHI >30 events/hour).[18,21,24-31] The minimal and optimal amounts of nocturnal use necessary to improve symptoms of daytime sleepiness are, however, not well defined because even partial nocturnal use (as little as 2 hours per night) has been associated with significant improvements in daytime symptoms in some patients.[32,33] Although the minimal amount of time required on a nightly basis to improve symptoms of daytime sleepiness is not well established, it is clear that CPAP therapy is required for a least a portion of each night because symptoms of daytime sleepiness reappear when CPAP therapy is discontinued for as little as one to two nights.[6,34,35] Reoccurrence of daytime symptoms on CPAP withdrawal has been observed across the spectrum of OSA severity. As mentioned previously, a specific threshold for nightly use of CPAP, in terms of improvements in symptoms of daytime sleepiness, does not exist and is likely dependent on the individual.[32,33] In general, greater adherence to CPAP therapy on a nightly basis has been associated with greater improvements in symptoms of daytime sleepiness.

The data regarding the effects of CPAP on more objective measures of daytime sleepiness are more inconclusive across the spectrum of disease severity.[23,24] A large meta-analysis of randomized controlled trials comparing CPAP therapy with placebo or conservative management demonstrated only a small, although statistically significant, improvement in the mean sleep latency as measured on either the Multiple Sleep Latency Test (MSLT) or Maintenance of Wakefulness Test (MWT). Across all studies, the mean sleep latency improved by 0.93 minutes ($P = .04$). Whether this small improvement in objective sleepiness is clinically significant is unclear.

Although most patients with daytime sleepiness related to OSA will achieve significant improvements in symptoms after CPAP therapy has been instituted, this is not the case for all patients. There remains a subgroup of OSA patients who continue to suffer from symptoms of residual daytime

sleepiness despite adequate compliance with CPAP therapy,[32,33,36,37] although the actual prevalence of residual daytime sleepiness in CPAP-compliant patients remains undefined. Prospective observational data have demonstrated that as many as 20% to 30% of patients who are compliant with CPAP therapy for 7 hours or longer per night may still complain of subjective sleepiness (Epworth Sleepiness Scale score of >10) after 3 months of treatment.[32,33] In addition, many patients also may not achieve a normal level of objective alertness (as defined by the MSLT or MWT) or associated functional outcomes (as defined by the Functional Outcomes of Sleep Questionnaire [FOSQ]), despite seemingly adequate nightly use of CPAP therapy. The mechanisms responsible for this syndrome of residual daytime sleepiness also remain unclear but may in part be related to the oxidative injury effects of long-term intermittent hypoxemia on the sleep-wake cycle–promoting regions in the brain.[38]

Effect on Neurocognitive Function, Mood, and Quality of Life

Numerous studies have assessed the effects of OSA on neurocognitive functioning, mood, and quality of life.[9,30,39-50] Most randomized controlled studies demonstrate inconsistent improvements in several neurobehavioral performance parameters across the spectrum of disease severity.[23,30,31,35,39-41,51] For example, large-scale randomized controlled trials have demonstrated mild, transient improvements in several measures of executive function in patients with severe OSA, but similar improvements have not been consistently demonstrated in patients with less severe disease.[31] The data regarding the therapeutic effects of CPAP treatment on mood and quality of life are also variable and inconsistent, with many randomized trials demonstrating no clear benefits of CPAP therapy compared with placebo or conservative treatments in these parameters.[23]

One reason for the inconsistent improvements in neurocognitive function demonstrated with CPAP therapy is that the impact of OSA on neurocognitive function for most patients with OSA may be relatively small across the spectrum of disease severity. The Apnea Positive Pressure Long-Term Efficacy Study (APPLES) trial demonstrated that most patients with OSA did not have significant neurocognitive deficits and that the degree of deficit was only weakly associated with the degree of oxygen desaturation and not associated with the AHI.[52] Another possible explanation for the inconsistent effect of CPAP in improving outcomes associated with neurocognition, mood, and quality of life is the use of multiple, different measures of function to assess similar parameters. For example, there is nearly universal use of the Epworth Sleepiness Scale when assessing improvements in subjective sleepiness, yet there are multiple tests that are used across several studies to assess for improvements in mood, neurocognitive function, and quality of life. Further research is required to better define the role of CPAP therapy in alleviating these symptoms and deficits in susceptible OSA patients.

Despite the inconsistent data regarding improvements in neurocognitive function with CPAP use, several observational studies support a significant reduction in the incidence of motor vehicle accidents in patients with OSA following the initiation of CPAP therapy.[53] Although the actual time course to improved driving performance in real-life situations is not clear, driving simulator performance can improve in as little as two to seven nights of therapy. Similar to other aspects of neurobehavioral performance that may be adversely affected by OSA, many patients with OSA may continue to demonstrate impaired driving simulator performance despite several months of high adherence to CPAP therapy.[54] The explanation for this last finding is not completely clear, although it is likely that many patients may still not be adhering to PAP therapy enough on a nightly basis or achieving enough sleep on a regular basis to normalize their driving skills. Unfortunately, there is no specific threshold of CPAP use or duration of treatment that can accurately predict a given individual's fitness to safely drive a vehicle. Because the severity of OSA alone is not a reliable predictor of motor vehicle accident risk, the clinician must take into account several factors, including improvements in subjective symptoms and compliance with therapy, before determining a driver's ability to safely operate a motor vehicle.

Effect on Cardiovascular Disease

Although untreated OSA has been associated with an increased risk for hypertension and other cardiovascular diseases in certain populations, the literature and outcomes data supporting the beneficial effects of CPAP on cardiovascular outcomes have been inconsistent.[9,23,55,56] Several randomized clinical trials and meta-analyses have assessed the effects of CPAP on blood pressure.[57-59] Overall, CPAP treatment appears to attenuate the adverse effects of untreated OSA on daytime and nocturnal systolic and diastolic blood pressure and on 24-hour mean blood pressure. These data demonstrate that, compared with placebo, sham CPAP, or supportive therapy alone, CPAP treatment is associated with small (–1.8 to –3.0 mm Hg) but statistically significant improvements in diurnal mean arterial systolic and diastolic blood pressures. When considering pooled data, improvements in systolic and diastolic blood pressures have been observed both during the daytime (2.2 ± 0.7 mm Hg and 1.9 ± 0.6 mm Hg, respectively) and nighttime (3.8 ± 0.8 mm Hg and 1.8 ± 0.6 mm Hg, respectively).[57] In general, improvements in blood pressure with CPAP therapy have been associated with greater severity of baseline OSA (higher AHI), the presence of subjective daytime sleepiness, younger age, and greater adherence with CPAP use on a nightly basis.

One of the main limitations of the current studies evaluating the effect of CPAP use on blood pressure in patients with OSAS is that although these studies evaluated blood pressure as an outcome measure, several of the studies either did not include patients with hypertension or included patients with hypertension who were already adequately controlled on antihypertensive medications. More robust reductions and clinical improvements in blood pressure with CPAP therapy have been observed when evaluating data from studies that included patients with uncontrolled hypertension.[60] In patients with uncontrolled hypertension at baseline, the use of CPAP has been associated with significantly greater reductions in awake systolic and diastolic blood pressure (7.1 mm Hg and 4.3 mm Hg, respectively) compared with placebo or sham PAP therapy. These improvements have been observed even after controlling for several potential confounders, including severity of disease, daytime sleepiness, patient demographics, use of antihypertensive medications, CPAP adherence, and duration of CPAP therapy.

Few studies have compared the effects of CPAP and antihypertensive medication on blood pressure reduction in patients with OSA and hypertension. In one randomized controlled trial, medical treatment with valsartan (160 mg daily) alone without CPAP therapy reduced several parameters of blood pressure significantly more than CPAP therapy alone over an 8-week period.[61] Specifically, valsartan therapy demonstrated superior reductions in 24-hour mean arterial pressure (–2.1 ± 4.9 mm Hg with CPAP vs. 9.1 ± 7.2 mm Hg with valsartan; $P < .001$) as well as mean arterial blood pressures during the daytime and throughout the night compared with CPAP therapy. The addition of CPAP therapy to antihypertensive medication does appear to improve blood pressure control in some patients with resistant hypertension and moderate to severe OSA.[62] Based on limited data, the addition of CPAP therapy to a regimen of several antihypertensive medications improved 24-hour mean blood pressure (3.1 mm Hg; 95% confidence interval [CI], 0.6 to 5.6; $P = .02$) and 24-hour diastolic blood pressure (3.2 mm Hg; 95% CI, 1.0 to 5.4; $P = .005$), but did not result in a significant improvement in 24-hour systolic blood pressure (3.1 mm Hg; 95% CI, –0.6 to 6.7]; $P = .10$) compared with the control group. In addition, CPAP therapy resulted in a greater proportion of patients demonstrating a normal nocturnal "dip" in blood pressure compared with controls (35.9% vs. 21.6%; adjusted odds ratio [OR], 2.4; 95% CI, 1.2 to 5.1; $P = .02$). Similar to other studies, there was a significant dose-response effect, with greater nightly CPAP use being associated with greater improvements in 24-hour mean blood pressure, systolic blood pressure, and diastolic blood pressure. Although reductions in nocturnal blood have been observed more consistently in his patient population, improvements in daytime blood pressure with CPAP therapy have been less consistent.[63]

As noted previously, the presence of subjective daytime sleepiness has generally been associated with a more robust improvement in blood pressure with CPAP therapy. There is some bias in these data because most of the studies that have evaluated various outcomes have in fact predominantly assessed patients with OSA and such associated daytime sleepiness. Because more than half of all patients with OSA, including those with severe disease (AHI ≥30 events/hour) do not have associated daytime sleepiness, it would be important to determine whether treating patients with OSA who do not complain of subjective sleepiness improves blood pressure or reduces the incidence of hypertension and other cardiovascular morbidities. One large randomized controlled trial assessing CPAP therapy compared with conservative therapy in patients with moderate to severe OSA without daytime sleepiness found that CPAP therapy did not result in a statistically significant reduction in incident hypertension or cardiovascular events (nonfatal myocardial infarction or stroke, transient ischemic attack, congestive heart failure, or cardiovascular death) over a period of 4 years of follow-up.[64] When the data were stratified by CPAP adherence, however, patients using prescribed CPAP therapy for more than 4 hours per night did demonstrate a small but statistically significant ($P = 0.04$) reduction in the incidence of hypertension over the 4-year study period. Thus the benefit of treating patients with moderate to severe OSA who do not have symptoms of daytime sleepiness or cardiovascular disease remains to be better defined regarding the risk for future cardiovascular morbidity and mortality. In fact, however, the role of CPAP therapy in reducing the incidence of hypertension and other cardiovascular morbidity in OSA patients even with daytime sleepiness is also unclear because there are no large-scale long-term prospective data addressing this at this time.

The role of CPAP therapy in resolving or reducing the occurrence or reoccurrence of cardiac arrhythmias is uncertain. Several observational studies have demonstrated an association between OSA and atrial fibrillation as well as a higher risk for recurrence of atrial fibrillation after electrical cardioversion or catheter ablation therapy. These studies also have shown an association between increased adherence with CPAP therapy and a lower reoccurrence rate of atrial fibrillation after these procedures.[65-68] Because all of the current data regarding CPAP therapy and atrial fibrillation are based on observational studies, the role of CPAP as an adjunct treatment to improve atrial arrhythmia control remains uncertain. Although there may be an increased risk for ventricular arrhythmias (tachycardia and fibrillation) in some patients with untreated OSA, there are limited data on the effect of PAP therapy for reducing the incidence and prevalence of these events.[69] Thus the role of PAP therapy in reducing ventricular arrhythmias in patients with OSA is not clear.

There are several possible explanations for why CPAP therapy has not been demonstrated to result in more consistent and greater improvements in blood pressure and other cardiovascular outcomes in patients with OSA. First, most of the literature assessing the effects of CPAP on blood pressure has been based on small trials of relatively short duration (≤3 months). This duration of treatment, even in patients with underlying hypertension, may not be a long enough treatment time to improve blood pressure. Second, as mentioned previously, although several of the studies used blood pressure as an outcome measure, many of the studies enrolled patients without hypertension at baseline. Thus one would not necessarily expect to observe a change in blood pressure if hypertension was not present at the initiation of the studies. Also, most of the patients who had hypertension at enrollment were on antihypertensive medications during most of the studies, which is likely to attenuate the effect of CPAP on blood pressure decreases. Third, although improvements in blood pressure tend to be associated with better CPAP adherence, overall adherence in most studies have typically averaged between 4 and 5 hours per night. Thus inadequate nighttime CPAP use may limit the beneficial effect of therapy on blood pressure in those with and without hypertension. Fourth, even though OSA is found to be an independent risk factor for hypertension in many populations, hypertension is typically associated with several comorbid conditions that are also related to OSA. Thus treating OSA without treating the other comorbid conditions may not result in significant improvements in blood pressure or other cardiovascular outcomes. Fifth, it is possible that many patients with longstanding hypertension have fixed disease that CPAP therapy may not improve. Sixth, many studies use different definitions for hypopneas (i.e., associated with a 4 percentage-point oxygen saturation, 3 percentage-point oxygen desaturation, or 3 percentage-point oxygen desaturation with or without an associated electroencephalogram arousal), and it is difficult to compare such studies because changing the definition of the hypopneas also changes the definition of OSA as well as the severity of disease for many patients. Finally, not all untreated OSA patients are necessarily at similar risk for the development of hypertension.

Thus trials that are unable to stratify patients deemed to be at higher risk for hypertension may only demonstrate mean results across a given population. When, and if, biomarkers are discovered that may identify patients at higher risk for hypertension and other cardiovascular diseases, therapies such as CPAP may be targeted to at-risk populations that would be deemed to derive greater benefits from therapy.

Aside from the one randomized controlled trial evaluating the effects of CPAP on incident hypertension and cardiovascular disease in patients with moderate to severe OSA without daytime sleepiness, there are currently limited long-term randomized controlled data evaluating the effect of CPAP on any cardiovascular outcomes, including mortality. The most convincing long-term data regarding the potential beneficial effects of CPAP therapy on cardiovascular outcomes comes from Marin and colleagues,[70] who followed a large group of male OSA patients with a spectrum of OSA severity and associated daytime sleepiness in a prospective observational study over a period of 10 years. Their results demonstrated two important findings: (1) Compared with normal nonsnoring controls, patients with untreated severe OSA (defined as an AHI >30 events/hour) had a significantly increased incidence of both fatal and nonfatal cardiovascular events; and (2) CPAP treatment (>4 hours/night) in patients with severe OSA (AHI ≥30 events/hour) reduced the incidence of adverse cardiovascular outcomes and improved survival, demonstrating outcomes similar to normal controls. Similar improvements in outcomes with CPAP therapy were not observed in OSA patients with less severe disease because untreated mild to moderate OSA was not observed to be associated with increased risk for cardiovascular morbidity or mortality in this study. Another observational study also demonstrated improvements in cardiovascular mortality across a spectrum of OSA severity, although the data are limited by absence of a control group.[71]

Given the inconclusive nature of CPAP therapy on cardiovascular outcomes in general, the AASM Practice Parameters recommend CPAP therapy only as an adjunctive therapy to lower blood pressure in hypertensive patients with OSA.[9] Several other authorities and professional societies have recommended that further supporting data are required to better determine the role of CPAP therapy on improving cardiovascular outcomes before making recommendations for its use in various populations.[55,56]

Effect on Mild Obstructive Sleep Apnea

Most of the literature assessing the effects of CPAP on various outcomes has predominantly evaluated OSA patients with moderate to severe disease. Although approximately 28% of patients with mild disease (AHI = 5 to 14 events/hour) complain of subjective daytime sleepiness,[72] it remains unclear whether treating this group of patients with CPAP therapy improves their daytime symptoms. Results from the CPAP Apnea Trial North American Program (CATNAP) demonstrated that CPAP therapy significantly improved daytime symptoms as measured by the FOSQ compared with sham CPAP therapy in patients with mild to moderate OSA over an 8-week period of follow-up.[73] APPLES was a large multicenter randomized controlled trial comparing the neurocognitive effects of therapeutic CPAP with sham CPAP across the spectrum of OSA severity.[31] As expected, subjective daytime sleepiness and objective alertness as assessed by the MWT was improved by CPAP therapy at 6 months, but significant improvements in both of these parameters were only observed in patients with severe OSA (AHI ≥30 events/hour). In patients with moderate disease (AHI = 15 to 29 events/hour), improvements in subjective sleepiness, but not objective alertness, were observed after 6 months of therapy. In patients with mild disease, there were no significant improvements in objective alertness or subjective sleepiness after 2 and 6 months of CPAP therapy. Thus the role of CPAP therapy for this indication in patients with mild disease remains unclear based on the current data. It appears reasonable to initiate CPAP therapy in patients with daytime symptoms, but the decision to continue chronic therapy in this patients group should be based on a response to therapy. For patients with mild disease without daytime symptoms, it is not clear that treating these patients is beneficial or should be recommended based on the current data.

Effect on REM-Predominant Obstructive Sleep Apnea

The prevalence of REM sleep–related or REM-predominant OSA is unclear, in part because of the absence of a standard definition for this entity. This OSA variant tends to be more common in women, although it may affect adult patients of both genders across the age spectrum.[12,74] The association of this OSA variant with daytime or nighttime symptoms is not clear, but it appears that a subgroup of patients are affected. For patients who demonstrate this type of OSA and complain of daytime symptoms or nighttime sleep disturbance, it is unclear whether treatment with CPAP consistently improves daytime or nighttime symptoms. Limited observational data of CPAP therapy in symptomatic patients with such REM-predominant OSA have demonstrated significant improvements in daytime sleepiness, fatigue, and the FOSQ. These improvements with CPAP therapy were similar to those in patients with OSA not limited to REM sleep.[12] However, there are no randomized controlled data assessing any outcomes in this subgroup of patients, including cardiovascular disease outcomes.

Effect on Obstructive Sleep Apnea and Comorbid Diseases

CHF is a common disease with an estimated prevalence of concomitant OSA of approximately 33%. Two small randomized controlled trials demonstrated a beneficial effect of CPAP therapy on left ventricular ejection fraction (LVEF) in patients with concomitant OSA and CHF with systolic dysfunction.[75,76] Compared with optimal medical management alone, CHF patients with moderate to severe OSA showed left LVEF improvements of 5% to 9% over 1 to 3 months.[75,76] Since these earlier studies, several additional randomized controlled studies have assessed the effects of CPAP therapy on LVEF in CHF patients with and without systolic dysfunction.[77] Overall, CPAP therapy has shown statistically significant improvements in LVEF in patients with OSA and concomitant systolic dysfunction, with an average improvement in LVEF across studies of approximately 5%. In patients with diastolic CHF and concomitant OSA, CPAP therapy has not been associated with significant improvements in LVEF (1%). For patients with CHF and systolic dysfunction, one would expect this degree of improvement in LVEF to be associated with improvements in other outcomes based on trials of medical therapies for CHF. However, it is uncertain

whether the improvements in LVEF in patients with OSA and concomitant CHF translate into improvements in other important outcomes, such as reductions in hospitalizations and mortality. Most of the studies evaluating this patient population have been limited by small sample sizes and relatively short durations of follow-up (typically 12 weeks or less). Currently, two large randomized trials are evaluating the role of advanced PAP therapies in this population to determine whether PAP treatment can be used to enhance these important outcomes. Until these studies are completed, the role of CPAP therapy in patients with CHF and OSA to improve important outcomes beyond LVEF remains unclear. Patients with severe heart failure may also have concomitant central and obstructive sleep apnea. An interim analysis of this therapy suggests that advanced PAP therapies (such as adaptive servo ventilation) may have a negative effect on cardiovascular mortality in heart failure patients with predominantly Cheyne-Stokes breathing and a left ventricular ejection fraction of 45% or less (see Chapters 123 and 129).[78]

The *overlap syndrome* refers to the coexistence of OSA with COPD (see Chapter 119). The prevalence of OSA in patients with COPD appears to be similar to that of the general population. Prospective observational and retrospective studies have shown that untreated OSA in this patient group is associated with an increased risk for death and severe COPD exacerbations leading to hospitalizations compared with groups of COPD patients without concomitant OSA.[79,80] Observational data have shown that CPAP therapy in OSA patients with COPD has been associated with significant reductions in both acute exacerbations of COPD requiring hospitalizations and death, with outcomes similar to COPD patients without OSA. Increased adherence to CPAP therapy has been independently associated with reduced mortality in this patient population, whereas decreased CPAP adherence and increased age have been independently associated with increased mortality.[80] Observational data suggest that adherence to CPAP therapy for as little as 2 hours per night has been associated with a reduction in mortality in this group of patients. Given the current observational data, it is reasonable to recommend CPAP therapy in patients with the overlap syndrome, although given the absence of randomized controlled data in this patient population, the role of CPAP therapy to reduce exacerbations or improve mortality remains undefined.

The role of CPAP therapy in improving important outcomes associated with diabetes mellitus (short-term and long-term glucose control) in patients with concomitant OSA is unclear because most of the trials evaluating the use of CPAP in this patient population have yielded inconsistent results.[81,82] The role of CPAP as an adjunct therapy to improve weight loss is also uncertain, and adequate treatment of OSA has not been observed to result in enhanced weight loss in most studies.[83]

Comparison with Other Obstructive Sleep Apnea Treatments

Oral appliances (nonadjustable mandibular advancement devices and tongue-retaining devices) are typically recommended for patients with mild to moderate OSA as well as for patients with severe disease who fail or do not tolerate CPAP therapy. In general, CPAP therapy results in greater improvements in the AHI and degree of oxygen desaturation compared with oral appliance treatment. Despite these findings, improvements in daytime sleepiness tend to be similar between the two therapies. This may be related to greater overall compliance with oral appliance therapy compared with CPAP.[84,85] Comparisons of CPAP with oral appliance therapy for improvements in blood pressure are difficult. Although most of the pooled data suggest a favorable effect of oral appliance therapy on many parameters of blood pressure, most of the studies have been observational, with few head-to-head comparisons between the two treatments.[86,87] Thus, based on the current data, is it difficult to draw conclusions or make recommendations between the two therapies concerning the outcome of blood pressure control.

Oxygen Therapy

The risk for cardiovascular disease related to untreated OSA is dependent on numerous factors, including the severity of disease, as defined by the AHI, and the degree of associated oxygen desaturation. Several small studies have shown that nocturnal oxygen therapy alone can in fact improve both the AHI and degree of oxygen desaturation, although such therapy may be associated with a prolongation of apneas and hypopneas. CPAP, however, has been associated with greater improvements in the AHI compared with nocturnal oxygen therapy alone.[88] Further, a short-term (12 weeks) randomized controlled trial has shown that CPAP results in greater reductions in 24-hour mean arterial blood pressure compared with nocturnal oxygen (2 liters/minute) or supportive therapy without CPAP in patients with moderate to severe OSA and cardiovascular disease or multiple cardiovascular risk factors. Similar to other studies, decreases in blood pressure with CPAP therapy were relatively small compared with baseline or the control group (–2.4 mm Hg).[89] Oxygen therapy alone was not associated with any changes in blood pressure compared with baseline or the control group over the study period.

Outcomes Summary

CPAP consistently improves or resolves OSA events across the spectrum of OSA severity and improves symptoms of daytime sleepiness predominantly in patients with moderate to severe OSA. Improvements in other outcomes are inconsistent. Treatment with CPAP has been associated with small reductions in blood pressure, with greater reductions being observed in patients with poorly controlled or resistant hypertension. The role of CPAP therapy in reducing long-term cardiovascular risk or mortality in OSA is uncertain based on the current data. Finally, the role of CPAP in patients without daytime symptoms, cardiovascular disease, or cardiovascular risk factors across the spectrum of OSA severity is undefined.

ADHERENCE AND PROBLEMS WITH CONTINUOUS POSITIVE AIRWAY PRESSURE TREATMENT

In a perfect world, all patients with OSA would use their CPAP therapy all night, every night. Unfortunately, just like many therapies associated with other chronic diseases, adherence with CPAP therapy for OSA is far from perfect. Although there are no formal definitions of what constitutes adherence with CPAP therapy, most studies have arbitrarily defined adherence as use of CPAP greater than or equal to 4 hours

per night for 70% of the observed nights.[90] Using this definition, subjective adherence ranges between 65% and 90%, whereas objective measures of CPAP adherence have demonstrated use in the range of 40% to 83%.[91] Most studies have shown that patients usually overestimate their CPAP use by approximately 1 hour per night, a pattern that is observed in both new and long-term OSA patients.[90,92]

Short-term follow-up of OSA patients demonstrates that CPAP use patterns typically fall into two groups: (1) use of CPAP on more than 90% of the nights, with an average use time of greater than 6 hours per night, and (2) use of CPAP intermittently, with an average use of less than 3½ hours per night.[93] Early follow-up for patients newly initiated on CPAP therapy is important because these patterns of use can typically be identified within the first several days to several months of CPAP therapy.[86-89] Long-term objective follow-up has demonstrated that approximately 68% of OSA patients continue to use their CPAP therapy after 5 years.[92]

Some studies have suggested certain parameters that may predict greater short- and long-term adherence to therapy. Improved adherence has been associated with symptoms of subjective sleepiness (Epworth Sleepiness Scale score of >10), severity of OSA (AHI >30 events/hour), and average nightly adherence within the first 3 months of therapy. Reduced short- and long-term adherence has been observed in patients reporting problems during their initial night with CPAP therapy in the sleep laboratory.[92,94] Interestingly, although one might expect higher levels of CPAP pressure to predict poorer adherence, neither high nor low CPAP pressures have been shown to reliably predict CPAP use. Several studies have also associated African American race and lower socioeconomic status with poorer adherence with CPAP therapy, even in patients with standardized access to care and treatment.[95-97] The reasons for this last observation are not clear.

Role of Objective Adherence Monitoring and Limitations with Current Technology

Unfortunately, when taken together, most studies have not been able to identify factors that consistently predict short- or long-term adherence with CPAP therapy.[26,90,98-101] Because adherence with PAP therapy tends to be suboptimal, subjective adherence tends to overestimate objective PAP use, there are no consistent early predictors of PAP adherence, and PAP adherence patterns tend to be determined early in most patients, professional societies currently recommend, and many payer policies require, objective adherence data review to document adherence with therapy and identify problems that can be addressed.[3] Although most randomized controlled trials have used objective adherence data to monitor outcomes related to PAP therapy, the overall effect of assessing objective compliance data for all patients on PAP therapy is uncertain.

Most of the PAP manufacturers have developed sophisticated online software programs for monitoring several parameters of PAP therapy, including nightly adherence, efficacy of therapy (residual AHI), and problems with mask fit (primarily amount of air leak). Although there are several potential advantages to these programs, the technologies also have several potential limitations. To improve the effect of these technologies on meaningful patient outcomes, several improvements will be required, including (1) standardization of respiratory event and leak definitions among manufacturers as well as validation of the device outputs compared with PSG; (2) improved access of PAP adherence data for frontline providers, including determining ways to more easily integrate PAP adherence data into the various electronic medical record software programs; and (3) education of non–sleep specialists on interpretation of the available adherence information.

Interventions to Promote Adherence

Typical problems that may lead to reduced adherence with CPAP therapy include claustrophobia, nasal congestion, and poor mask fit, leading to leaks and skin irritation. Several interventions have been proposed and instituted in an attempt to improve adherence with CPAP therapy (Table 115-3).

The most consistent intervention that has been associated with improved CPAP adherence in most PAP-naïve patients is systematic education. Several approaches, including provider and home-based education of the patient and spouse, supportive care at therapy initiation or follow-up, phone calls, home-based videos, and daylong educational programs, have been associated with improved adherence, although no one intervention has been demonstrated to be consistently beneficial in all patient groups. In general, increased intensity of patient education or frequency of health provider contact have been associated with improved CPAP adherence.[9,23] Overall these educational interventions tend to improve CPAP adherence by approximately 35 to 50 minutes per night,[102] although the effects of these interventions on other important outcomes such as daytime sleepiness, quality of life, and cardiovascular disease and risk are unclear. Several behavioral approaches have also been associated with improved adherence. In general, these behavioral approaches, including motivational interviewing and cognitive behavioral therapy delivered in individual or group settings, have been associated with an average improvement in adherence of 1.5 hours per night. The overall effect of these behavioral approaches on CPAP adherence is not well defined because the data supporting these approaches are of lower quality than the data supporting the previously discussed educational interventions.

The data evaluating the effects of heated humidification on adherence to CPAP therapy remain controversial. Although there are some studies that demonstrate that the addition of heated humidification can improve adherence to CPAP therapy, there are several studies demonstrating no improvement in adherence with this intervention.[9,103-106] Patients who tend to benefit the most from the addition of heated humidification are those with symptoms of nasal congestion or rhinitis. Limited data evaluating the role of heated tubing have shown no improvements in adherence in patients with and without nasopharyngeal complaints.[107] The role of nasal steroids with or without heated humidification therapy, especially in unselected CPAP-naïve patients with OSA, remains unclear because many studies have demonstrated little benefit of this intervention in improving CPAP use.[106,108]

CPAP delivery interfaces, or masks, come in several shapes and sizes, including nasal masks, full-face (oronasal) masks that cover both the nose and the mouth, nasal pillows that fit into the nostrils, and oral interfaces that fit into the mouth. Some studies have observed a negative effect of oronasal masks on CPAP compliance, whereas other studies have not confirmed these findings.[109] Oronasal masks may be better for patients with chronic nasal congestion or obstruction, for those patients who are predominantly mouth breathers, and

Table 115-3 Effects of Interventions on Positive Airway Pressure Adherence

Intervention	Effect on PAP Adherence	Comments
Education and supportive care	Beneficial	Various approaches helpful, including phone calls, office and home visits, and individual and group sessions Best intervention, or combination, unclear
Behavioral therapies	Beneficial	Various therapies helpful, including motivational interviewing and CBT Most interventions studied in addition to education Best intervention, or combination, unclear
Heated humidification	Beneficial	Some data support improved adherence Most helpful for patients with nasal congestion or rhinitis Addition of nasal steroids not helpful
Advanced PAP (bilevel, EPR, and APAP)	No benefit	Not associated with improved compliance BiFlex may be the exception in CPAP noncompliant patients
Mask type	Unclear	Best mask type unclear Changing masks may alter effective PAP pressure
Hypnotics	Unclear	Eszopiclone may improve PAP titration efficacy and 6-month compliance Data do not support other hypnotics
Telemedicine	Unclear	Limited data suggest benefit, whereas other data do not support approach
Adherence monitoring	Unclear	Objective adherence monitoring recommended, but no clear data that the intervention itself improves compliance
Sleep specialist care	Unclear	Observational studies support approach RCTs show no advantage in uncomplicated OSA

APAP, Autotitrated positive airway pressure; CBT, cognitive behavioral therapy; EPR, expiratory pressure relief; OSA obstructive sleep apnea; PAP, positive airway pressure; RCT, randomized controlled trial.

for patients requiring higher CPAP pressures when mask leak is an issue. Nasal pillows have typically not been recommended for CPAP settings of more than 12 cm H_2O owing to the potential for interface leak, although more recent data show that select patients may do well with a nasal pillows interface even with higher PAP settings.[110] Overall, although proper mask fit may be crucial to the initial and ongoing acceptance of CPAP therapy, the optimal form and type of CPAP delivery interface remain unclear.[111,112] In general, the best interface for a given patient (which tends to correlate to the best adherence with therapy) is the one that the patient is most comfortable wearing.

Changing interfaces after a problem has developed has not been shown to consistently improve long-term adherence in various studies, although from a clinician's standpoint attention to mask complaints and changing masks when problems arise can improve adherence in select patients. The provider should be aware that changing the mask type from nasal to oronasal or vice versa might change the necessary effective treatment pressure that was initially identified during an in-laboratory titration.[113] Thus, for patients on fixed PAP therapy, the clinician should consider the need to adjust the pressure or to have the patient perform an in-laboratory PAP titration if problems that could result in reduced adherence with therapy persist after a mask change has been instituted.

Because many patients may complain of sleep disruption or difficulty initiating sleep during the first few days to weeks of CPAP therapy, several studies have evaluated the use of prescription hypnotics to improve adherence to CPAP treatment either in the sleep laboratory during a PAP titration study or during the first few weeks of therapy. Although some studies have demonstrated that, in newly diagnosed patients with severe OSA, treatment with eszopiclone 3 mg before an overnight titration study or during the first 14 days of PAP therapy has been associated with improved quality of CPAP titrations (greater proportion of patients with optimal or good titrations) or improved adherence to CPAP therapy over the first 6 months of treatment, respectively, these results are not typical of most of the literature regarding the use of hypnotics as adjunctive therapies to improve adherence to PAP therapy.[13,114] When compared with placebo or usual care, other randomized controlled studies have demonstrated no significant benefits, but no significant adverse effects of other hypnotic therapies (zaleplon or zolpidem), on CPAP adherence.[115,116] As with most studies, the data evaluating the effects of hypnotics on CPAP adherence have looked at relatively short-term adherence in specialized centers of care. The ability to generalize these data to a typical clinical population and office setting is uncertain based on the current literature, and care should be used when applying this approach to a given patient or population. Given the limited data in patients with OSA, the use of short-term or chronic hypnotics should generally be avoided in patients with OSA.

Role of the Sleep Specialist in Improving Adherence

Several retrospective and observational studies have shown that sleep specialist consultation, before an in-laboratory sleep study or during the initiation and follow-up of CPAP therapy, has been associated with improved CPAP adherence and other important outcomes, such as patient satisfaction and timeliness of care.[91,117] Alternatively, three randomized controlled trials in symptomatic patients with a high clinical suspicion of uncomplicated moderate to severe OSA demonstrated that management by either a specially trained nurse, nurse–primary

care physician team, or primary care physician resulted in outcomes (CPAP adherence and improvements in daytime sleepiness) that were similar to management by sleep specialists.[118-120] In addition to similar CPAP adherence, all of these studies demonstrated a significant cost savings in the non–sleep specialist group. Thus the data supporting the role of the sleep specialist in the treatment and overall management of all patients with uncomplicated moderate to severe OSA is not well defined based on the current literature. More research is necessary to better determine which groups of patients with OSA may receive the most benefit from sleep specialist management of CPAP therapy.

Current recommendations, based predominantly on expert opinion, suggest that patients should have initial office follow-up during the first few weeks of prescribed CPAP therapy. Thereafter patients using CPAP should be followed on an annual basis and as needed to troubleshoot problems as they arise.[9,23] Centers for Medicare and Medicaid Services has defined its own rules regulating how and when patients on CPAP should have office follow-up, and commercial payers have also adopted their own policies on CPAP follow-up and adherence monitoring. Based on the current outcomes literature, the optimal method or schedule for short- or long-term follow-up is not clear. Clinicians must determine appropriate follow-up based on a given patient's response to therapy as well as payer policies that may guide requirements to continue treatment.

Technology to Improve Adherence

In addition to technologic advancements in the delivery of PAP therapy that are discussed later in this chapter, several applications of technology have been employed in an attempt to improve PAP adherence. Interventions include the use of online PAP adherence monitoring software as described earlier, telemedicine, and patient interactive technologies. As noted previously, most patients overestimate their compliance with therapy and thus objective monitoring of CPAP therapy has been recommended by the AASM.[3,9] Although the literature supports the concept that CPAP use can be reliably determined by CPAP tracking systems, the role of objectively measuring PAP adherence and its effect on improving adherence in all patients are uncertain.[121] Limited data suggest that online monitoring of PAP adherence and the use of a telemedicine management strategy may be associated with improved adherence, although more data are required to better define the role of this approach.[122] Finally, although several PAP device manufacturers have developed software (smartphone and computer-based applications) aimed at improving patient involvement with their CPAP therapy, there are currently no randomized trials that have objectively evaluated the effect of this approach on adherence or, in fact, any outcomes.

TECHNOLOGIC ADVANCEMENTS IN THE DELIVERY OF POSITIVE AIRWAY PRESSURE THERAPY FOR OBSTRUCTIVE SLEEP APNEA

Although CPAP remains the mainstay of therapy for OSA, there are several other methods of delivering PAP therapy. This section of the chapter focuses on technologic advancements in the delivery of positive pressure therapy, including bilevel PAP, EPR devices, and APAP.

Bilevel Positive Airway Pressure Therapy

The potential benefits of bilevel PAP in treating patients with OSA were first described in 1990.[123] As opposed to CPAP, which delivers a fixed pressure throughout the respiratory cycle, bilevel PAP therapy allows the independent adjustment of the expiratory positive airway pressure (EPAP) and the inspiratory positive airway pressure (IPAP). In its initial description, bilevel PAP therapy demonstrated that obstructive events could be eliminated at a lower EPAP compared with conventional CPAP pressures.[123] Bilevel PAP is typically titrated during an attended in-laboratory sleep study. As is the case for CPAP titrations, the current guideline recommendations for bilevel PAP titration strategies are based on consensus opinion.[8] Although intuitively one would predict that bilevel PAP would increase adherence by reducing expiratory pressure–related discomfort and side effects, there are in fact no objective outcomes studies that show that bilevel PAP improves adherence and daytime sleepiness compared with CPAP in patients with uncomplicated OSA.[9,23,124]

Newer bilevel PAP systems have been introduced by several companies. The BiFlex device (Respironics, Murrysville, Pa.) differs from conventional bilevel systems in two major respects. First, the inspiratory pressure is reduced slightly near the end of inspiration, and the expiratory pressure is slightly reduced near the beginning of expiration. Second, the amount of pressure relief change of the EPAP during expiration is proportional to patient effort. Although the data regarding the use of traditional bilevel and BiFlex therapies do not demonstrate any advantages over CPAP therapy in patients with newly diagnosed OSA, one study has demonstrated a potential role for BiFlex therapy in patients who are noncompliant with CPAP therapy.[125] Ballard and colleagues studied a large group of OSA patient who were noncompliant with CPAP therapy despite significant education, attention to proper mask fitting, and the addition of heated humidification. After 3 months of therapy, those patients randomized to BiFlex therapy demonstrated significantly better nightly adherence (P =.03) compared with those who were randomized to continuing on standard CPAP therapy. Importantly, because BiFlex technology provides PAP through its own unique algorithm, these findings are specific to the BiFlex devices and cannot be generalized to other non-bilevel PAP therapies.

Overall, bilevel PAP therapy remains a reasonable option for CPAP-intolerant patients, patients with OSA with concurrent respiratory disease (e.g., COPD), and patients with obesity hypoventilation syndrome.[2,9,23] The role of bilevel PAP therapy, and its variants, in otherwise uncomplicated OSA remains unclear.[3,126]

Expiratory Pressure Relief Systems

A common complaint in many patients with OSA using CPAP is the uncomfortable feeling of exhaling against positive pressure. This consequence is one potential barrier to the long-term acceptance of CPAP therapy. Several PAP manufacturers have developed EPR systems in an attempt to remedy this potential problem. EPR device technologies allow pressure relief during exhalation with the goal of making CPAP therapy more comfortable. EPR technologies briefly reduce the CPAP pressure, between 1 and 3 cm H_2O, during exhalation and then return the pressure to its set CPAP setting before the initiation of inspiration. Certain EPR technologies monitor the patient's airflow during exhalation and reduce the

expiratory pressure in response to the airflow and patient effort. The amount of pressure relief varies on a breath-by-breath basis, depending on the actual patient's airflow, and is also dictated by the patient's preference setting on the device.

Although several PAP manufacturers have developed EPR devices for the marketplace, only the Philips Respironics (Respironics, Murrysville, PA) technology (C-Flex) has been evaluated in the peer-reviewed literature.[120-128] Several randomized controlled trials have evaluated the role of C-Flex technology compared with standard CPAP therapy in patients with uncomplicated, predominantly moderate to severe OSA. Overall, the use of such C-Flex technology at fixed pressure relief settings between 1 and 3 cm H_2O has not been associated with improved adherence in either parallel or crossover trials.[129] In addition, improvements in other commonly measured outcomes (subjective sleepiness, objective alertness, vigilance, or residual OSA) were similar to, but not better than, standard CPAP therapy. C-Flex therapy has not been shown to offer significant benefits in that subgroup of patients who require CPAP pressures of 9 cm H_2O or greater. Based on these data, the routine use of C-Flex technology is not recommended as a method to improve compliance or other major outcomes compared with fixed CPAP therapy. Further randomized controlled trials are necessary to determine whether this technology offers any objective advantages over fixed CPAP therapy in select groups of patients.

Autotitrating Positive Airway Pressure

APAP (also known as auto-, automated, autoadjusting, or automatic positive airway pressure) incorporates the ability of the PAP device to detect and respond to changes in upper airway flow and resistance in real time.[130] This section focuses on the literature related to APAP in the treatment of patients with previously diagnosed OSA because there is currently little evidence to support the use of APAP technology for the diagnosis of OSA.[131]

Currently available APAP devices use proprietary algorithms to noninvasively detect and respond to variations in patterns of upper airway inspiratory flow or resistance. Most APAP machines monitor a combination of changes in inspiratory flow patterns, including inspiratory flow limitation, snoring (indirectly measured through mask pressure vibration), reductions of airflow (hypopnea), and absence of flow (apneas), using a pneumotachograph, nasal pressure monitors, or alterations in compressor speed. Most units detect flow limitation through proprietary algorithms using flow-versus-time profiles to determine a flattening index. The other less commonly used technology uses the forced oscillation technique method, which is an alternative method that detects changes in patterns of upper airway resistance or impedance.[132-134] Because the forced oscillation technique method measures changes in upper airway resistance that are independent of patient activity and ventilatory effort, this technology has the potential advantage of better differentiating central apneas from obstructive apneas or mask leak. There are currently no peer-reviewed data to substantiate efficacy of such detection, or clinical outcomes, with such technology.

When upper airway flow or impedance changes have been detected, the APAP devices use proprietary algorithms to automatically increase the pressure until the flow or resistance has been normalized. After a therapeutic pressure has been achieved, the APAP devices typically reduce pressure until flow limitation or increases in airway resistance resume. Most devices have a therapeutic pressure range between 4 and 20 cm H_2O, giving the clinician the ability to adjust the upper and lower pressure limits based on the clinical conditions and the patient's response to therapy. This should be differentiated from bilevel PAP or autobilevel PAP (discussed later), in which a separate IPAP and EPAP are set with changes in pressure across each respiratory cycle. Similar to CPAP, expiratory relief and other pressure delivery modifications are available for APAP technologies, although these additional pressure modifications have not be shown to consistently improve several APAP-related outcomes, including in-laboratory titration success, PAP adherence, or daytime sleepiness.[135-137] Because pressures changes occur throughout the sleep period, some have postulated that APAP devices may actually increase sleep fragmentation.[138] This concern has not been substantiated in studies evaluating changes in sleep structure or in clinical trials that have measured subjective sleepiness as a main outcome. Specifically, the frequency of microarousals and sleep fragmentation induced by APAP devices appears to be small,[139] and clinical outcomes related to subjective sleepiness also show no significant differences compared with conventional CPAP therapy.[18,140-143]

Currently available APAP machines have several potential limitations. Most flow- and pressure-based APAP devices are somewhat limited in their ability to distinguish between central and obstructive apneas as well as large mask leaks.[144-147] These flow patterns are "interpreted" by these types of devices as an absence of flow, which in the cases of central apneas and leaks may erroneously lead to increases in pressure and worsening of the central events or leaks. Newer APAP algorithms appear to be better at differentiating obstructive from central events as well as compensating for large mask leaks. Also, the ability of the APAP devices to respond to sustained hypoventilation in the absence of upper airway obstruction is unclear because most APAP studies have excluded patients at high risk for hypoventilation, including patients with obesity hypoventilation syndrome or chronic respiratory diseases. Given these potential limitations in technology, as well as the exclusion of patients with many comorbid diseases from the randomized trials comparing APAP to in-laboratory titrated CPAP therapy, the current AASM Practice Parameters regarding the use of APAP recommend that APAP devices only be used for patients with uncomplicated moderate to severe OSA.[131,148,149] APAP devices typically should *not* be used in the patients with comorbid medical conditions that could potentially affect their respiratory patterns (complicated OSA), including patients with CHF, patients with lung diseases such as COPD; and patients expected to have nocturnal arterial oxyhemoglobin desaturation due to conditions other than OSA (e.g., obesity hypoventilation syndrome and other hypoventilation syndromes). Patients who do not snore (either because of palatal surgery or naturally) should not be titrated with an APAP device that relies on vibration or sound in the device's algorithm.[131,148,149] Finally, APAP devices are not recommended for split-night titrations given the lack of data to support such a practice.

There have been several randomized controlled trials that have compared APAP technology to conventionally titrated CPAP therapy for the treatment of uncomplicated OSA.[18,19,126,134,140-143,150-159] Compared with standard fixed CPAP therapy, APAP devices as a group are almost always

associated with a reduction in mean pressure across a night of therapy in the range of 2 to 2.5 cm H_2O, although peak pressures through the night tend to be higher than fixed CPAP therapy. Aside from these differences, APAP and standard CPAP are similar with regard to improvements in several outcomes, including objective adherence, ability to eliminate respiratory events, and subjective daytime sleepiness as measured by the Epworth Sleepiness Scale.[160] There are few data regarding improvements in blood pressure with APAP therapy and no long-term data regarding any cardiovascular outcomes. These findings have been consistently demonstrated for APAP therapy used as a primary chronic therapy and for APAP used for a short therapeutic trial to determine a fixed CPAP setting for ongoing CPAP therapy.

Most of the literature concerning APAP technology as a treatment for OSA has evaluated patients with uncomplicated predominantly moderate to severe OSA (AHI ≥15 events/hour), and therefore the results and recommendations that have been reviewed predominantly apply to this group of patients. The data comparing efficacy of APAP versus attended in-laboratory titrated CPAP in patients with mild OSA (AHI = 5 to 14 events/hour) are more limited.[159,160] Based on the available information, there appear to be similar improvements in important outcomes, including resolution of sleep-disordered breathing and daytime sleepiness and adherence with therapy between APAP and CPAP, even in patients with more mild disease, although it is difficult to make reliable recommendations concerning the use of APAP for this subgroup of patients.

Although the use of APAP as a therapy with or without changing the patient to a fixed CPAP device has also been well described, the optimal method for determining treatment success is controversial. Most of the newer PAP devices calculate several parameters, including device use time, an AHI, and leak data. Compliance with PAP therapy can be reliably determined using the various PAP tracking systems, but the validity of the PAP-calculated AHI data are not as easy to interpret because the various PAP manufacturers define respiratory events differently from each other and differently from the standard scoring definitions used by the AASM. In general, most studies comparing the APAP-calculated AHI to a PSG-determined AHI show that the PAP-calculated AHI tends to overestimate the AHI, especially at the lower end of the AHI spectrum.[161,162] In general, PAP-calculated AHIs of less than 10 events/hour tend to correlate with adequately treated sleep-disordered breathing events and have been associated with improved outcomes in randomized controlled trials.[121] This is especially true when these findings are associated with the resolution of nighttime snoring and daytime symptoms. Because the various proprietary APAP algorithms are far from perfect for detecting and resolving all sleep-disordered breathing events, the clinician should consider an in-laboratory attended PAP titration study when a patient is having difficulty with unattended APAP therapy or when residual daytime symptoms persist even if the APAP-calculated parameters suggest adequately treated OSA syndrome.[163]

Autobilevel Therapy for Obstructive Sleep Apnea

Autobilevel therapy has also been developed that, using proprietary algorithms, automatically adjusts both the EPAP and IPAP in response to sleep-disordered breathing events. Limited data indicate that, compared with CPAP, autobilevel therapy results in similar compliance and other important outcomes in patients who have had poor initial experiences with CPAP therapy.[164,165] There is currently no peer-reviewed literature evaluating outcomes with autobilevel therapy for OSA in PAP-naïve patients. Thus, unlike non-autobilevel PAP therapy, no recommendations can be made for autobilevel PAP therapy for treating patients with OSA.

In summary, APAP technologies appear to be as effective as conventional fixed CPAP therapy when used for treatment in attended and unattended settings in patients with moderate to severe uncomplicated OSA.[131] Although APAP technologies as a group reduce the mean treatment pressure across the night, they appear to result in similar objective adherence and improvements in other important clinical outcomes compared with in-laboratory titrated CPAP therapy. Although APAP therapy has demonstrated some shortcomings in the peer-reviewed literature, the technology is rapidly advancing. The main benefits of APAP technology in the future will likely be the ability to provide more rapid treatment to patients with uncomplicated OSA and possibly the saving of health care dollars by eliminating some attended in-laboratory sleep studies that are typically required for CPAP titrations.[18,19,141]

CLINICAL PEARLS

- CPAP is the first-line therapy for patients with moderate to severe OSA, especially for those with daytime symptoms.
- CPAP therapy consistently resolves sleep-disordered breathing events and improves symptoms of daytime sleepiness in symptomatic patients, especially for patients with moderate to severe disease. There are inconsistent data concerning the benefits of CPAP therapy with regard to neurocognitive function, mood, quality of life, and cardiovascular outcomes across the spectrum of disease severity. The data regarding the benefits of CPAP therapy in patients with more mild disease are even more controversial, especially in those without daytime symptoms or underlying cardiovascular disease.
- The role of CPAP therapy for patients without associated daytime symptoms across the spectrum of OSA severity is unclear based on the current data. Most randomized controlled trials in this patient group have failed to demonstrate improvements in important outcomes, including blood pressure control, cardiovascular morbidity and mortality, neurocognitive function, and quality of life.
- Adherence with CPAP therapy is suboptimal for many patients, although improvements in adherence have been consistently associated with systematic education with and without behavioral therapy. The roles of other interventions, including heated humidification, hypnotics, and telemedicine, to improve adherence to CPAP therapy are unclear based on limited or inconsistent outcomes data from observational and randomized controlled trials.
- The roles of advanced PAP technologies, including EPR and bilevel PAP pressure devices, are not clear because they have typically not been associated with improved adherence, daytime sleepiness, or quality of life in patients with OSA.
- APAP used in an unattended setting, either to determine a fixed CPAP setting or as a primary treatment, is reasonable therapy for patients with moderate to severe OSA without underlying comorbidities. Most of the data on APAP therapy have been limited to patients with daytime sleepiness; thus the role of APAP therapy in patients without associated daytime sleepiness is not clear.

SUMMARY

CPAP therapy remains the mainstay of treatment of patients with moderate to severe OSA, especially those patients with daytime sleepiness. The role of PAP therapy in patients with OSA in the absence of daytime sleepiness is not clear. Despite its potential to improve several clinical outcomes including daytime sleepiness, neurocognitive dysfunction, quality of life, and blood pressure, long-term adherence with therapy remains suboptimum. Newer technologies such as APAP have the potential to improve the treatment of OSA, with most data demonstrating that this technology is as effective as in-laboratory titrated CPAP in patients with uncomplicated moderate to severe OSA. Although the role of APAP in the treatment of OSA is still not well defined, it has the potential to improve the delivery of PAP therapy by replacing laboratory-based PAP titrations in patients with uncomplicated OSA, thus reducing the current sleep laboratory waiting times and potentially reducing health care spending on in-laboratory studies. Other technologic advancements such as EPR and bilevel PAP devices are supported by limited data and appear to offer no advantages over conventionally titrated CPAP therapy in most patients with OSA.

Medical and Device Treatment for Obstructive Sleep Apnea: Alternative, Adjunctive, and Complementary Therapies

Susheel P. Patil; Ephraim Winocur; Luis Buenaver; Michael T. Smith

Chapter Highlights

- Medical treatments for obstructive sleep apnea (OSA) can be categorized on the basis of the pathophysiologic mechanisms (i.e., anatomic, neuromuscular, and neuroventilatory control) that the interventions generally target. Stratifying treatments by pathophysiologic target may be particularly useful in personalizing therapy for patients with OSA.
- The current and emerging medical and device therapies available for the treatment of OSA generally are indicated as alternative therapies when traditional therapies for OSA are poorly tolerated, or as adjunctive treatment to more standard therapy.
- Therapeutic interventions and strategies such as weight loss, positional therapy, hypoglossal nerve stimulation, use of expiratory nasal resistors, and oral pressure therapy can successfully treat OSA in the appropriate patient. Other approaches such as myofunctional therapy, nasopharyngeal stenting, high nasal flow therapy, application of compression stockings, and pharmacotherapy are not proven as efficacious treatment for OSA and currently should be considered as experimental, possibly alternative, or at times adjunctive therapies.
- Oxygen therapy alone has not been shown to improve outcomes in OSA. In fact, use of supplemental oxygen has been associated with increased duration of apneic episodes and the development of hypercapnia.
- A limited number of complementary and alternative medicine approaches also have been studied for the treatment of OSA.
- Even with otherwise effective treatment for OSA, some patients may experience persistent sleepiness despite adequate sleep time and may be appropriate candidates for adjunctive stimulant pharmacotherapy.

Obstructive sleep apnea (OSA) is a highly prevalent disorder that increases cardiovascular and metabolic disease–related morbidity and mortality, contributes to the risk of motor vehicle and occupational accidents, and reduces occupational productivity. The recurrent episodes of upper airway obstruction that characterize OSA have been attributed to both anatomic loads (e.g., retrognathia, micrognathia, excess pharyngeal muscosal tissues, large parapharyngeal fat pads) on the upper airway and impairments in neuromuscular responses.[1] Potential treatments for OSA can be considered in light of the mechanisms identified to be important in its pathogenesis (Figure 116-1).

Therapy for OSA traditionally has targeted reductions in anatomic loads on the upper airway using continuous positive airway pressure (CPAP) therapy, oral appliances, upper airway surgery, and weight reduction. However, therapeutic approaches for OSA targeting neuromuscular (e.g., muscle responsiveness) and neuroventilatory (e.g., arousal threshold, apnea threshold, and loop gain) mechanisms have also been investigated; these include electrical stimulation of the hypoglossal nerve, myofunctional therapy, and pharmacotherapy. Given known difficulties with adherence to conventional therapies, particularly CPAP and use of oral appliances, for OSA,[2] active investigation of alternative and adjunctive therapies continues.

This chapter presents an overview of medical and device treatments for OSA based on the pathophysiologic mechanisms (i.e., anatomic, neuromuscular, and neuroventilatory control) that the interventions target. Stratifying treatments based on pathophysiologic targets may be useful in personalizing optimal therapy for patients with OSA. Patient preference also plays an important role in therapy decisions.[3] Such treatments may be considered in three categories: primary, alternative, and adjunctive. In this chapter, *primary treatment* or *therapy* is defined as a treatment that should be considered as a first-line therapy. *Alternative treatment* or *therapy* refers to a therapy that should be considered when a primary therapy is poorly tolerated or ineffective. *Adjunctive therapy* is defined as a treatment that should be used in conjunction with a primary or alternative therapy. *Investigational treatment* or

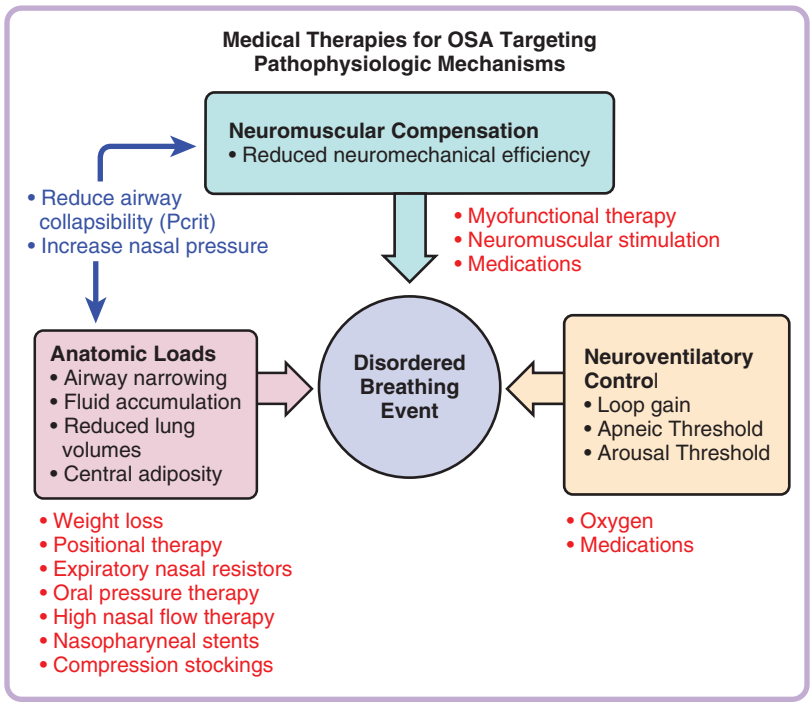

Figure 116-1 Medical Therapies for Obstructive Sleep Apnea (OSA), Stratified by Mechanisms Targeted. Certain therapies can be considered on the basis of the pathophysiologic mechanisms targeted. OSA is thought to occur as a consequence of increases in anatomic loads on the upper airway, impairments in neuromuscular compensation, or alterations in neuroventilatory control. Traditional therapies such as continuous positive airway pressure (CPAP) use nasal pressure to overcome anatomic loads. By contrast, upper airway surgery or weight loss result in reduced airway collapsibility (Pcrit). Other therapies that may relieve anatomic loads on the upper airway include positional therapy, use of expiratory nasal resistors, oral pressure therapy, nasopharyngeal stenting, and application of compression stockings. Therapies that address impairments in neuromuscular function include myofunctional therapies, use of certain medications, and neuromuscular stimulation. Therapies that may affect neuroventilatory control include use of medications to increase the arousal threshold and supplemental oxygen, which can affect loop gain.

therapy is defined as a treatment that cannot be currently recommended except in the setting of clinical research. Another important term, *complementary and alternative medicine* (CAM) *therapy*, is used in the current literature to refer to treatments that are not part of allopathic medical treatment for OSA. Recommendations regarding whether a specific current or emerging alternative medical or device therapy for OSA should be considered primary, alternative, adjunctive, or investigational are provided, with the recognition that this is not without controversy for some treatments. Furthermore, many of the treatments discussed may be classified in more than one category, depending on the specific clinical context. Concluding the chapter is a section on management of residual excessive sleepiness in patients with otherwise adequately treated OSA and good adherence to therapy, with a focus on use of pharmacologic stimulants.

THERAPIES PRIMARILY TARGETING UPPER AIRWAY ANATOMIC LOADS

Increases in upper airway anatomic loads may be incurred through several mechanisms, including (1) airway narrowing due to complex interactions between pharyngeal soft tissues and the bony enclosure within which the upper airway resides, (2) central adiposity–mediated increases in airway collapsibility (Pcrit) through reductions in lung volume and tracheal stiffness, and (3) fluid accumulation within pharyngeal soft tissues. Primary treatment options targeting reduction in anatomic loads have included CPAP therapy (see Chapters 115 and 116), upper airway surgeries (Chapter 149), and oral appliance therapy (see Chapter 147). However, a number of other medical and device therapies aimed at relieving anatomic loads imposed on the upper airway have been explored, including weight loss, positional therapy, expiratory nasal resistance therapy, oral positive-pressure therapy, and use of compression stockings. These therapeutic interventions have been studied as primary, adjunctive, and alternative OSA treatments.

Medical and Surgical Weight Loss

Excess weight has long been recognized as a major risk factor for the development of OSA. The attributable risk of OSA in overweight individuals (BMI ≥ 25 kg/m^2) is estimated to be 41%.[4] Obesity-related impairments in upper airway function appear to be mediated through several mechanisms that affect upper airway anatomy. First, obesity may alter pharyngeal airspace geometry. Data from imaging studies of the human upper airway demonstrate that increases in the lateral pharyngeal fat pads are seen in patients with OSA compared with weight-matched control subjects.[5-7] Enlarged lateral pharyngeal fat pads alter the airway geometry from a horizontal elliptical orientation to an anterior-posterior orientation, which can increase susceptibility of the airway to collapse.[8,9] Second, external mass loads imposed on the upper airway

increase airway collapsibility. In early studies using isolated animal upper airway preparations, application of external loads to the anterior neck and submandibular space led to elevations in Pcrit.[10] In more recent studies, investigators have demonstrated that lateral pharyngeal fat pad pressure fluctuations correlate with cyclic pharyngeal pressure changes, supporting the role of cervical fat depositions in increasing airway collapsibility.[11,12] Peripharyngeal fat deposits are clinically evident as enlarged neck circumference, with studies demonstrating a correlation between increasing neck circumference and increasing airway collapsibility.[13,14] Obesity also may indirectly impose upper airway anatomic loads through mechanical modulation of lung volumes. Central adiposity decreases functional residual capacity (FRC), reducing tracheal traction and thereby increasing upper airway collapsibility. This pathomechanism has been shown experimentally through manipulation of end-expiratory lung volumes in human volunteers, in whom reductions in lung volumes resulted in increases in Pcrit.[15,16]

Medical and surgical weight reduction has long been studied and implemented as a treatment for OSA[17-24]; however, randomized clinical trials have been published only in the past decade.[25-27] Early nonrandomized intervention studies of medical weight loss demonstrated that modest weight loss in the range of 10 to 20 kg in moderately to severely obese men with severe OSA resulted in an apnea-hypopnea index (AHI) reduction of 47% to 50%. A small subset of patients reduced their AHI below 20 (i.e., nighttime occurrence of fewer than 20/hour).[17,19]

More recent randomized, controlled studies in different patient populations have confirmed that medical weight loss decreases OSA severity. Collectively, these studies demonstrate that reductions in OSA severity with weight loss interventions are dose-dependent and sustained over a 1- to 4-year period despite a 30% to 50% weight regain. Furthermore, patients with more severe OSA at baseline demonstrate the greatest improvements in AHI,[25,26] with men tending to experience the greatest benefits.[26]

Tuomilehto and associates[27] studied obese patients with predominantly mild, positional OSA who undertook a 3-month program of a very-low-calorie diet (VLCD) and subsequent lifestyle modification. Patients in the intervention group, with a mean weight reduction of 10.7 kg at 12 months, exhibited a reduction in mean OSA severity (evidenced as occurrence of 4.0 fewer nighttime events/hour), whereas the control group subjects, with a mean weight reduction of 2.4 kg, showed no significant mean change in OSA severity (0.3/hour). Similar reductions in supine AHI were seen in the intervention and control groups (apopnea-hypopnea rate reduced by 6.5/hour and 5.9/hour, respectively). Despite the modest reduction in AHI, 61% of participants in the intervention group experienced resolution (AHI less than 5) of their OSA, compared with 32% in the control group. Improvement as evidenced by a decrease in mean OSA severity was sustained for an additional year despite a mean weight regain of 32% after termination of the supervised program.[28]

Johannson and colleagues[25] randomly assigned obese men with moderate to severe OSA either to a group managed with dietary intervention—VLCD combined with lifestyle counseling—or to a control group with no weight intervention. With a mean 18-kg weight reduction achieved after 9 weeks of intervention in the VLCD group, mean OSA severity decreased, with improved AHI as evidenced by 21 fewer events/hour during nighttime sleep, with 17% demonstrating resolution of their OSA. OSA-related symptomatic improvement was sustained (mean AHI reduction by 17 events/hour) at 1 year despite a 31% weight regain.[29]

Additionally, the Sleep AHEAD (Sleep Apnea in Look AHEAD [Action for Health in Diabetes]) study investigators randomly assigned overweight and obese patients with type 2 diabetes mellitus and OSA to either an intensive lifestyle intervention (ILI) for weight loss or to diabetes support and education (DSE). At 1 year, the ILI group achieved a mean 10.8-kg weight reduction with a concomitant mean decrease in AHI of 5.4; the DSE group demonstrated an increased mean AHI of 4.2, despite no significant change in weight. OSA resolved (for an AHI of less than 5) in 36.3% of those receiving ILI, compared with 10.7% in the DSE group. The improvement in AHI persisted at 4 years despite a 50% weight regain. At year 4, 44% of participants demonstrated an improvement in OSA severity category, compared with only 18% of participants given DSE. Moreover, nearly 21% of ILI participants exhibited complete remission of OSA, to achieve an AHI below 5, compared with only 3.6% of DSE participants.[30]

Surgical weight loss, in contrast with medical weight loss, can result in more dramatic weight reduction that is more likely to be sustained over time (see also Chapter 121). Current National Institutes of Health (NIH) consensus guidelines for surgical weight loss recommend that patients with a BMI of 40 kg/m^2 or greater, or with a BMI of 35 kg/m^2 or greater associated with an obesity-related comorbid condition, including OSA, with previous unsuccessful attempts at medical weight loss, can be considered as potential candidates for surgical weight loss.[31] Bariatric surgeries can include restriction-based techniques such as laparoscopic adjustable gastric banding (LAGB) or vertical sleeve gastrectomy. More dramatic weight loss can be achieved when such techniques are combined with malabsorptive interventions such as the Roux-en-Y bypass or biliopancreatic diversion surgery (see Chapter 121).

Data regarding the effects of bariatric surgery on OSA are predominantly from uncontrolled case series or nonrandomized studies. A large meta-analysis of data for more than 20,000 patients from 134 studies that were predominantly uncontrolled case series reported outcomes from various bariatric surgical procedures. The analysis found that patients on average lost 61.2% of their excess weight, with 85.7% achieving resolution of their OSA.[32] However, resolution of OSA was adjudicated on the basis of patient self-report, rather than postoperative polysomnography, in most of these studies. A meta-analysis that examined only studies in which polysomnography was used before and after surgery reported reductions in mean OSA severity as evidenced by a decrease in AHI (apnea-hypopnea rate of 15.8 events/hour down from 54.7 events/hour) in association with a 17.9 kg/m^2 reduction in BMI.[33] This observation of reduction in severity but incomplete resolution of OSA was confirmed by Dixon and coworkers,[34] who conducted a randomized, controlled trial comparing LAGB with medical weight loss therapy in patients with severe OSA over a 2-year period. Patients in the LAGB group lost more weight compared with the medical weight loss group (mean weight loss of 27.8 kg versus 5.1 kg, respectively). With this weight reduction, the LAGB group

had a tendency to greater reduction in OSA severity as reflected in mean AHI, although the difference was not statistically significant (apnea-hypopnea rate reduction by 25.5 events/hour versus 14.0 events/hour, respectively). In contrast with the medical weight loss studies, which demonstrated dose-dependent improvements in OSA severity with weight loss, this study demonstrated a nonlinear reduction in AHI with weight loss, with a plateau in AHI reduction after 10 kg of weight loss. Thus, although some patients will experience resolution of their OSA to achieve an AHI below 5/h with surgical weight loss, the vast majority will continue to have some level of OSA that may necessitate continued treatment other than weight loss after surgery.

For several reasons, some overweight and obese patients may not experience symptomatic improvement or resolution of OSA with weight loss. Responsible factors include insufficient weight loss, persistent anatomic defects from craniofacial morphology or nasopharyngeal obstruction, or continued disturbances in neuromuscular or neuroventilatory control that contribute to increased airway collapsibility (high Pcrit). For example, obese patients who lost approximately 20% of their baseline weight demonstrated a reduction in Pcrit. However, resolution of OSA occurred only in participants for whom Pcrit fell below a threshold of –4 cm H_2O.[35]

In summary, weight loss, whether by medical therapy or surgical intervention, generally reduces OSA severity and may be curative in certain patients. Unfortunately, those subsets of patients with OSA who are most likely to benefit from these interventions have yet to be defined. Furthermore, the potential success of weight loss in mitigating OSA severity is tempered by the substantial weight regain that occurs in many if not most patients over time, particularly in the setting of medical weight loss. In addition, the risk of a major adverse outcome (e.g., perioperative death, abdominal operation, venous thromboembolism, endoscopy, extended hospitalization) with surgical weight loss interventions is approximately 4% in the first 30 days after surgery.[36] Careful consideration of the risks and benefits of surgical weight loss interventions for OSA must be individualized.

Nevertheless, given the role of obesity in the pathogenesis of OSA, medical providers should advocate weight loss in all patients with OSA who are overweight or obese. Lifestyle interventions for weight loss not only have the potential to reduce OSA severity but may decrease morbidity and mortality from other obesity-related diseases such as metabolic syndrome, hypertension, cardiovascular disease, and diabetes mellitus.[37] Whether a weight loss program should be a primary, adjunctive, or alternative therapy depends on the patient's circumstances. For example, any overweight or obese patient treated for OSA with a primary therapy (e.g., CPAP, use of an oral appliance, upper airway surgery) should be prescribed weight loss as an adjunctive therapy. In patients with mild to moderate OSA associated with minimal daytime symptoms, weight loss could be recommended as a potentially primary therapy, provided that the patient is monitored for success with weight loss over a limited time frame. If a patient is unsuccessful with weight loss, then other primary therapies should be recommended. Patients with symptomatic OSA, however, should not be prescribed weight loss as a sole primary therapy; for example, symptoms of sleepiness may pose a safety risk and must be addressed using other traditional, primary OSA therapies. In patients who are motivated to pursue weight loss, referral to weight management programs that involve a multidisciplinary team, when available, may lead to sustained benefits over those achievable with a traditional weight loss program.[38]

Positional Therapy for Obstructive Sleep Apnea

Positional OSA typically is defined as that associated with an overall AHI less than 5, with a supine AHI that is at least twice the nonsupine AHI. The prevalence of positional OSA in affected patients overall is estimated to be approximately 56%, and it is more common among less obese patients and in those with mild to moderate OSA.[39-41] In view of the marked differences in AHI seen in these patients, positional therapy has been evaluated as a primary or alternative therapy for OSA. Many case series have demonstrated marked improvements in AHI with positional therapy in patients with positional OSA; however, randomized, controlled trial data on use of positional therapy as primary therapy are limited.[42] In one 4-week study, patients with positional OSA (mean AHI of 20.9) were randomly assigned to either a control group (lifestyle education for one session discussing exercise, weight loss, and sleep in the lateral position) or an active group (lifestyle education and the use of a tennis ball position modification device). There was a 46% versus 23% reduction in AHI in the active group versus the control group, respectively, which correlated with reduced supine sleep time in the active group. However, no difference between the groups was found for improvements in sleepiness, mood, or quality of life. Additional small randomized, controlled crossover trials have been performed comparing positional therapy with CPAP over 3 nights to 9 weeks.[43-45] In aggregate,[46] positional therapy has been less effective than CPAP in normalizing the AHI (mean posttreatment apnea-hypopnea rate of 6.2 events/hour versus 2.0 events/hour, respectively). The higher posttreatment AHI in the positional therapy groups in the data noted earlier was due to residual, nonsupine OSA, rather than to an inability to maintain the nonsupine position. Nevertheless, positional therapy improved sleep quality and quality of life measures similarly to CPAP in these studies, despite the higher posttreatment AHI.[43-45]

With most positional therapy techniques, an object is strapped to the back (tennis balls, squash balls, special vests), preventing the patient from sleeping in the supine position. This interventional strategy may disturb sleep architecture and sleep quality owing to arousals precipitated on turning from the right lateral position[47] to the left, resulting in poor long-term treatment adherence.[48] Alternative forms of positional therapy recently have been developed in attempts to improve longer-term adherence. For example, a new neck-worn device delivers a vibration when the patient moves supine, to provide feedback to the patient to shift to a non-supine position without significantly reducing total sleep time.[47,49] Other devices include sleep position trainers worn as a strap around the chest, which similarly vibrates when the supine position is detected,[50-52] and specially designed pillows to improve cervical positioning[53] The limited data available suggest that long-term adherence to positional therapy over 6 months may be comparable to or better than that reported for CPAP[51] but may be specific to the type of positional device used. Additional randomized, controlled studies are needed to demonstrate longer-term improvements in OSA severity status and OSA-related outcomes, as well as long-term adherence, before

positional therapy is considered as a primary treatment for positional OSA. Positional therapy should, however, be considered as adjunctive therapy added to primary therapies in patients with positional OSA. For example, positional therapy could be used in combination with an oral appliance to minimize the extent of mandibular advancement needed to normalize the AHI, or to improve the AHI when the appliance is already at maximum advancement and residual disordered breathing persists. Positional therapy also could be used as an adjunct to CPAP, to increase adherence by lowering the CPAP level in patients intolerant of such settings. Finally, use of positional therapy as an alternative modality in patients with positional OSA, particularly if the nonsupine AHI is near normal, could be considered when other primary therapies are not tolerated or if the patient is traveling without primary therapy appliances or devices. These decisions ideally should be guided by objective data from a sleep study, the patient's preferences, and the clinical response.

Expiratory Nasal Resistors

An expiratory nasal resistor (ENR) is a device containing a one-way valve that is superficially placed in the nares and is secured to the skin of the nose with an adhesive. The valve allows inspiration to occur unimpeded but partially closes during expiration (Figure 116-2). Closure of the valve creates expiratory nasal resistance that results in expiratory positive airway pressure (EPAP) within the pharynx, which is thought to stabilize the upper airway during subsequent inspirations.

Several mechanisms of action have been postulated for EPAP production with use of an ENR, aimed primarily at relieving mechanical loads on the upper airway.[54] First, expiratory pharyngeal airway dilation could reduce subsequent inspiratory airway narrowing. Dynamic imaging of the upper airway suggests that airway caliber is most narrow at end-expiration, when pharyngeal muscle tone is dependent on tonic muscle activity. Using fiberoptic endoscopy, investigators have reported significant expiratory narrowing of the pharyngeal airspace before the development of an apnea.[55] Thus, an increase in end-expiratory airway size has been hypothesized to prevent pharyngeal collapse during the subsequent inspiration. Second, similar to CPAP, ENR may increase lung volumes, thereby increasing tracheal traction and reducing upper airway collapsibility. Investigators, using MRI-based techniques to measure FRC, demonstrated that FRC increases by 47% during wakefulness in association with increases in nasal EPAP between 4 to 17 cm H_2O. The effect of ENRs on lung volumes, however, was mitigated when subjects breathed through the mouth, thus bypassing the ENR.[56] Finally, use of an ENR may improve OSA through indirect chemoresponsive mechanisms by inducing hypercapnia by means of ENR-induced hypoventilation. End-tidal CO_2 measurements have been shown to increase by approximately 2 to 6 mm Hg during ENR application with sleep.[56,57] Increases in CO_2 may then reduce airway collapsibility through recruitment of genioglossal muscle activity.[58,59]

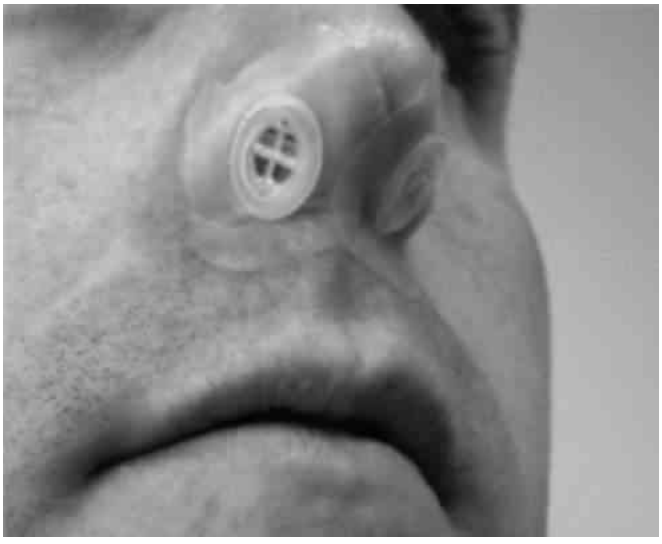

Figure 116-2 An Expiratory Nasal Resistor. This device generates end-expiratory positive airway pressure within the pharynx. (From Walsh JK, Griffin KS, Forst EH, et al. A convenient expiratory positive airway pressure nasal device for the treatment of sleep apnea in patients non-adherent with continuous positive airway pressure. *Sleep Med* 2011;12:147-52.)

Clinical trials of the effectiveness of ENRs have been performed[60-63] since the initial observation by Mahadevia and associates[64] that selective EPAP reduced apnea severity. Initial, uncontrolled studies demonstrated an approximately 50% reduction in AHI in patients with mild to moderate OSA, and 32% reduction in those with severe OSA.[60,61] Subsequently, a 3-month randomized, double-blinded clinical trial was conducted in patients with a new OSA diagnosis.[62] Participants were predominantly obese male patients with mild positional OSA. At 3 months, application of ENRs resulted in a 61% reduction in AHI, compared with 19% in the sham ENR group. The subgroup of patients with severe OSA also demonstrated a 61% reduction in AHI. Although improvements in sleep architecture were not observed with ENR use, decreases in subjective sleepiness based on the Epworth Sleepiness Scale (ESS) score were statistically significant. These effects appeared to be sustained with continued ENR use at 12 months in a follow-up study of a subset of adherent participants in whom ENR therapy reduced AHI by 50%, with decrease in number of events/hour to less than 10.[63] In contrast, in a study of ENR versus sham ENR therapy for 2 weeks in patients with severe OSA undergoing CPAP withdrawal, investigators demonstrated that ENR use did not lessen OSA severity.[65] Side effects reported with use of ENRs include headache, dry mouth, breathing discomfort, nasal itching, sleep maintenance insomnia, and vertigo and resulted in 7% discontinuing therapy.[62]

As indicated by the available evidence, ENR therapy should be considered an alternative therapy for the treatment of OSA in patients who are intolerant of traditional therapies such as CPAP or use of oral appliances. Patients with mild to moderate OSA, particularly positional OSA, appear to be most likely to respond, although in some situations patients with severe OSA also may respond. Patients with symptoms of nasal obstruction are less likely to tolerate ENR therapy, owing to increased nasal resistance, and are not good candidates for this therapy. Efficacy of ENR use in reducing OSA severity should be determined through objective sleep testing before long-term prescription of this therapy. For patients in whom use of ENRs has demonstrated efficacy, the ENR technique could be used as an alternative therapy during travel—for example, if the available electrical source is unreliable or if the equipment for CPAP therapy is perceived as too cumbersome. Additional research is necessary to confirm effectiveness

of this therapy, including whether use of ENRs reduces excessive sleepiness and cardiovascular risk similar to that seen with CPAP or oral appliances, before ENR should be considered a primary therapy.

Oral Pressure Therapy

Oral pressure therapy (OPT) represents another alternative therapy for OSA that aims at reducing upper airway mechanical loads. The OPT system consists of a customized mouthpiece, which is worn nightly, connected by flexible tubing to a console that generates a vacuum of approximately −50 cm H_2O that is applied to the oral cavity[66-68] (Figure 116-3). The negative pressure is isolated to the oral cavity as a consequence of the natural seal created between the soft palate and the tongue.[66] MRI studies performed during wakefulness indicate that OPT increases retropalatal airspace in the lateral and anterior-posterior dimensions through movement of the soft palate (anterior and superior) and the tongue (anterior-superior segment only). The retroglossal airspace is reduced, however, primarily owing to the resting position of the device. OPT may potentially reduce OSA severity through other mechanisms, including vacuum-mediated attenuation of airway collapse during inspiration, and through activation of upper airway negative pressure reflexes, which stabilize the upper airway through increased pharyngeal muscle activity during inspiration.[66]

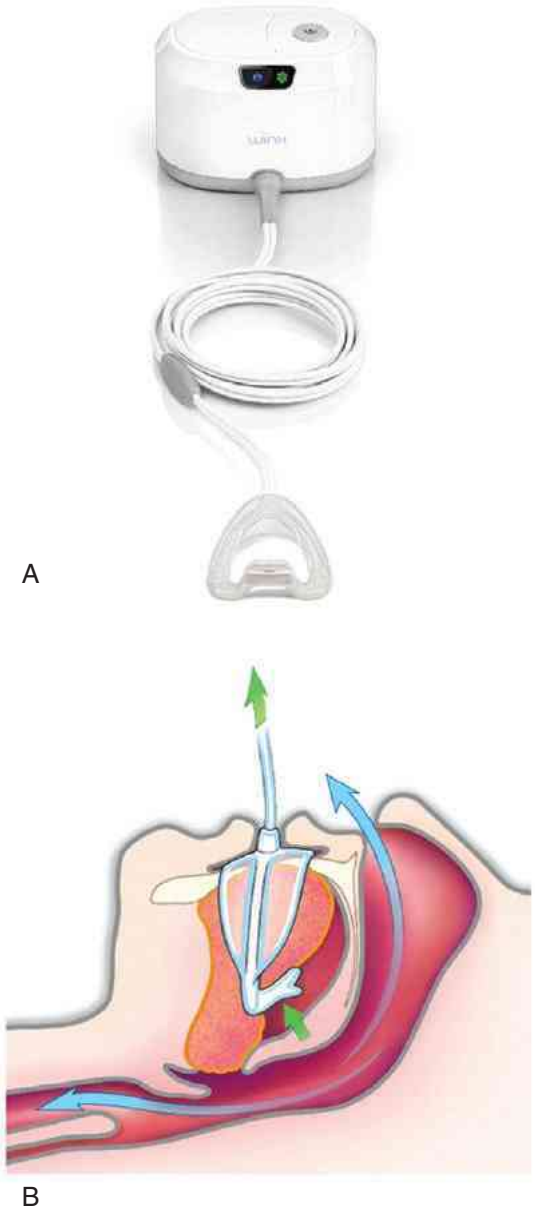

Figure 116-3 Oral Positive-Pressure Therapy Device. **A,** The device sits in the mouth and applies a gentle suction to keep the tongue and soft palate forward during breathing, while the patient lies supine. **B,** The effect of the suction pressure on tongue and palate position. (Images provided and reproduced with permission from Apnicure, Inc.)

Several clinical trials have been performed to assess the efficacy of OPT. Initial studies were uncontrolled and tested OPT in patients with OSA for one night compared with a baseline sleep study.[67,68] These preliminary studies demonstrated that in patients with an AHI of approximately 35, OPT reduced their AHI by 36% to 40%. AHI was reduced to less than 10 in 38% to 48% of the patients with OSA. A subsequent study performed a randomized, cross-over, first-night order study of OPT compared with control conditions, which was followed by an open-label, 4-week trial period.[69] Participants were naive to any OSA treatment, intolerant of CPAP, or actively using CPAP but electing to participate in the study. The pre-OPT mean AHI was 27.5 and was reduced by 51%, to 13.4 on OPT, which was sustained with use of OPT during sleep at the end of 4 weeks, with a mean AHI of 14.8. Thirty-two percent of patients were considered responders, defined as achieving an AHI below 10 and at least a 50% decrease in AHI from baseline. Baseline OSA severity, however, did not predict response to therapy. As in the initial studies, improvements in sleep architecture were demonstrated, characterized by reductions in stage N1 sleep, stage N1 shifts, overall sleep stage shifts, awakenings, arousal index, and by increases in stage R (rapid eye movement [REM]) sleep. In participants who were naive to any OSA treatment, improvements in subjective sleepiness and sleep-related quality of life were reported. However, participants who were actively using CPAP before the study did not demonstrate a reduction in sleepiness, presumably owing to the efficacy of CPAP in improving sleep status. Common side effects reported with OPT included oral tissue discomfort or irritation, dental discomfort, and dry mouth, with 5% of patients ($n = 3$) discontinuing therapy during the trial.

OPT is approved by the U.S. Food and Drug Administration (FDA) for primary treatment of OSA; in view of the limited available data, however, it should be considered an alternative therapy for OSA in patients intolerant of traditional therapies such as CPAP or use of oral appliances. Efficacy of the therapy in reducing OSA severity should be determined through sleep testing before this modality is prescribed. Randomized, controlled trials and comparative effectiveness studies need to be performed to demonstrate whether OPT decreases OSA-related morbidity similar to traditional OSA therapies.

High Flow Nasal Therapy

Several small studies have investigated the effects of high-flow-rate (20 to 30 L/minute), humidified air administered by nasal cannula for treating OSA (Figure 116-4). Such *high flow*

Figure 116-4 An Example of a High-Flow Nasal Therapy Device. This device administers warm, humidified air by nasal cannula at high flow rates. Although the system is "open" compared with the "closed" system inherent in continuous positive airway pressure (CPAP), a positive airway pressure (PAP) of approximately 2 cm H_2O can be generated. (Images provided and reproduced with permission from TNI-Medical.)

nasal therapy (HFN) is hypothesized to improve mechanical loads on the upper airway in a manner similar to that for CPAP, by increasing end-expiratory pharyngeal pressure by approximately 2 cm H_2O.[70] In addition, HFN may prevent pharyngeal collapse through neurally mediated mechanisms. HFN reduces ventilatory drive through reductions in the inspiratory duty cycle and respiratory rate, thereby improving mean inspiratory airflow with each breath.[70,71]

In a study of 11 adult participants with mild to moderate OSA, the mean AHI was reduced by 64% (from mean of 28/h to 10/h) with HFN.[70] In 8 participants, the AHI fell below 10. HFN also has been studied in 10 patients who had experienced a recent acute ischemic stroke (mean, 4.8 days).[72] HFN in this patient population with severe OSA had more modest effects, with an AHI reduction by 24% (mean of 30.8 down from 40.4). In the largest case series of 56 patients, modest reduction in OSA severity were seen with a mean AHI reduction from 22.6 to 17.2, with similar reduction seen for separate hypopnea and apnea indices. A therapeutic response, defined by an AHI of less than 10, with a 50% reduction in AHI from baseline, was seen in 27% of patients. In a separate study using the respiratory disturbance index, patients with predominantly obstructive hypopneas, respiratory effort–related arousals, or REM-related events appeared to be most likely to respond to HFN. By contrast, the nightly occurrence of more than 10% central apneas or more than 90% obstructive apneas predicted a poor response to HFN.[73] Although these initial results are promising, additional clinical trials are needed before HFN can be recommended as a primary or alternative therapy.

Nasopharyngeal Stents

Use of nasopharyneal stents, sometimes referred to as nasal trumpets, has been studied as a potential treatment for OSA since the 1970s.[74-76] Traditionally, such devices are used in the emergency setting to maintain an airway until intubation or tracheostomy can be performed. The stents are inserted into the nose and extend into the nasopharynx, protecting the airway from obstruction. If long enough, the stent may prevent obstruction of the oropharynx. The stents also prevent obstruction of the internal and external nasal valves and may decrease nasal resistance in some patients.[76] To date, no randomized, controlled trials have been performed demonstrating efficacy of nasopharyngeal stenting in improving OSA severity. A systematic review of nasopharyngeal stents identified five noncontrolled studies testing the efficacy of these devices in reducing the AHI in settings that included the sleep laboratory, the postoperative setting, and the home.[74] Overall, the AHI decreased by 49%, from a mean of 44.1to 22.7, and the minimum oxygen saturation improved from 66.5% to 75.5%. The tolerability of nasopharyngeal stenting on a night-to-night basis, however, remains to be established. Until controlled studies are performed, use of nasopharyngeal stents cannot be recommended as a primary or alternative therapy for OSA, except on an emergent basis in the hospital setting to mitigate active airway obstruction in patients with known OSA or suspected OSA based on snoring, witnessed apneas, and oxygen desaturation in an attempt to prevent respiratory failure and the need for emergency intubation.

Venous Compression Stockings

Investigations have examined the use of compression stockings in the treatment of OSA based on the observation that fluid displacement from the legs in awake, healthy subjects without OSA results in an increased neck circumference, pharyngeal narrowing with increased pharyngeal resistance, and increased airway collapsibility.[77-79] Furthermore, increases in OSA severity correlate with the amount of fluid displaced from the legs to the neck when patients were sleeping supine.[80] Subsequently, several studies have examined the effects of venous compression stockings on OSA severity.[81,82] One randomized, crossover study recruited 12 nonobese patients with chronic venous insufficiency and OSA and assigned them in random order to 1 week of wearing compression stockings and 1 week of no stockings. Compared with control conditions, the use of stockings resulted in a 62% reduction in leg fluid volume and a 60% increase in neck circumference that was associated with a 36% reduction in AHI (from 48.4 events/hour to 31.3 events/hour).[81] More recently, the effects of compression stockings were studied in a sample of 57 patients with OSA, who were randomly assigned to a control condition or the use of compression stockings for 2 weeks. Subjects who wore compression stockings demonstrated greater reduction in overnight decrease in leg fluid volume, which correlated with a higher morning upper airway cross-sectional area and a greater AHI reduction compared with

control data (reduction of 8.6 events/hour versus 0.9 event/hour, respectively).[83]

These results, although intriguing, do not support the use of compression stockings as primary therapy for the treatment of OSA. However, the use of compression stockings may have an adjunctive role in combination with primary therapies such as CPAP in treating OSA, particularly in patients who are in states of volume overload such as congestive heart failure, chronic venous stasis, or chronic kidney disease.

THERAPIES TARGETING PRIMARILY NEURAL AND NEUROMUSCULAR MECHANISMS

Pharyngeal obstruction has long been postulated to occur in part by disturbances in neuromuscular function during sleep.[84] OSA subjects have impaired dynamic responses to upper airway obstruction and have reduced tonic genioglossal muscle activity compared with age-, sex-, and BMI-matched healthy control subjects.[1,85] Furthermore, studies of motor unit potential morphology suggest signs of neurogenic remodeling of the genioglossus in persons with OSA.[86] Treatments for OSA thus aimed at relieving impairments in upper airway neuromuscular function or augmenting upper airway neuromuscular responses have been and continue to be investigated. Examples of such interventions are electrical stimulation of the hypoglossal nerve, myofunctional therapy, and pharmacotherapy, as discussed next.

Hypoglossal Nerve Stimulation

Hypoglossal nerve stimulation (HGNS) has been developed as a potential therapy for OSA, with at least one proprietary HGNS system approved by the FDA (see also Chapter 149).[87] HGNS stimulates the hypoglossal nerve, which in turn stimulates the genioglossus muscle, an upper airway dilator muscle. Early studies in animal models demonstrated the potential success of extrinsic electric stimulation of the genioglossus muscle in maintaining upper airway patency during sleep.[88-90] This initial success led to pilot human studies using submental stimulation of the genioglossus[91-93] or direct fine-wire stimulation of the genioglossus or hypoglossal nerve.[94-97] These studies, in addition to demonstrating increases in airflow during sleep in the obstructed airway (Figure 116-5), provided important lessons for the design of the most recent generation of HGNS systems. First, distal placement of electrodes along the hypoglossal nerve to provide selective stimulation of tongue protrusors, or in combination with tongue retractors, improved airway patency.[98] However, proximal nerve stimulation of tongue retractors alone led to airway obstruction.[99] Second, nerve stimulation synchronized with inspiration demonstrated the maximal benefit in airflow improvements and provided secondary benefits of extending battery life and minimizing neuromuscular fatigue.[97,99]

Several HGNS systems have now been developed using either synchronous, closed-loop stimulation or continuous, open-loop stimulation. These systems contain an implanted pulse generator similar to a cardiac pacemaker, which is connected to a respiratory sensing lead (Figure 116-6). A stimulus burst output is delivered and synchronized with inspiration to a cuff that is implanted around the hypoglossal nerve, immediately increasing inspiratory airflow. The continuous, open loop system uses an array of electrodes arranged within the electrode cuff. Stimulation is performed at a set duration, irrespective of the respiratory cycle, in a manner targeting different nerve fibers and minimizing stimulation of the duty cycle.[100,101]

Studies testing the current generation of HGNS systems have predominantly enrolled obese, male patients with moderate to severe OSA that had difficulties "tolerating" CPAP. The studies generally have excluded patients with moderate to severe obesity and some degree of central sleep apnea (greater than 5% or 25% of the AHI events are central or mixed apneas). One system, Inspire (Inspire Medical Systems, Maple Grove, Minnesota), uses drug-induced sleep endoscopy (DISE) as an exclusion criterion based on earlier studies suggesting that concentric airway collapse during DISE predicted greater chance of therapeutic failure.[102] Despite differing eligibility criteria, the studies in aggregate have demonstrated a mean AHI reduction of 50% to 70%, from a mean baseline rate of 32 to 45 events/hour.[100,103,104] Furthermore, in the Stimulation Therapy for Apnea Reduction (STAR) trial, patients who received the HGNS system demonstrated improvements in subjective sleepiness based on ESS scores and in sleep-related quality of life as assessed by the Functional Outcomes of Sleep Questionnaire (FOSQ).[103]

Adverse events related to HGNS have been reported. Short-term surgical risks include wound infections requiring removal of hardware, hematomas, and nerve palsy. Longer-term risks associated with repetitive tongue stimulation include soft tissue abrasions, discomfort with electrical stimulation, and dry mouth.[87,103] In addition, the need for DISE may carry additional risks, such as oxygen desaturation or hypoventilation, that may necessitate bag-mask ventilation or prolonged recovery from sedation due to enhanced drug sensitivity, which warrants careful monitoring by trained professionals.

The Inspire device recently has been FDA-approved. Given that roughly one third of patients in trials of this device were considered to be nonresponders (response was defined as an AHI reduction of at least 50%, with a residual AHI below 20) and had persistent OSA, even after correct application of inclusion and exclusion criteria, additional research is needed to refine optimal patient selection criteria. Further work also is needed to determine how HGNS stimulus settings can be optimized and managed over the long term. Finally, long-term effects on OSA severity and patient safety beyond 18 months remain to be reported. At this time, HGNS should not be considered a primary therapy for OSA until results of additional studies are available. HGNS is available only through specialized centers whose personnel have undergone the appropriate training with the device manufacturer. HGNS, however, should be considered as an alternative therapy in patients with significant difficulties in adhering to or benefiting from CPAP or other primary therapies who meet the inclusion-exclusion criteria defined in the study.

Myofunctional Therapy

The term *myofunctional therapy* is used to describe oropharyngeal exercises used to improve nasal breathing, facial appearance, and mandibular growth.[105] More recently, myofunctional therapy has been studied in the treatment of OSA, using specific voice lessons, musical instruments, and oropharyngeal exercises. An early, uncontrolled study of self-reported chronic snorers found that after a single voice lesson and practice of singing daily for 20 minutes at maximum volume and control

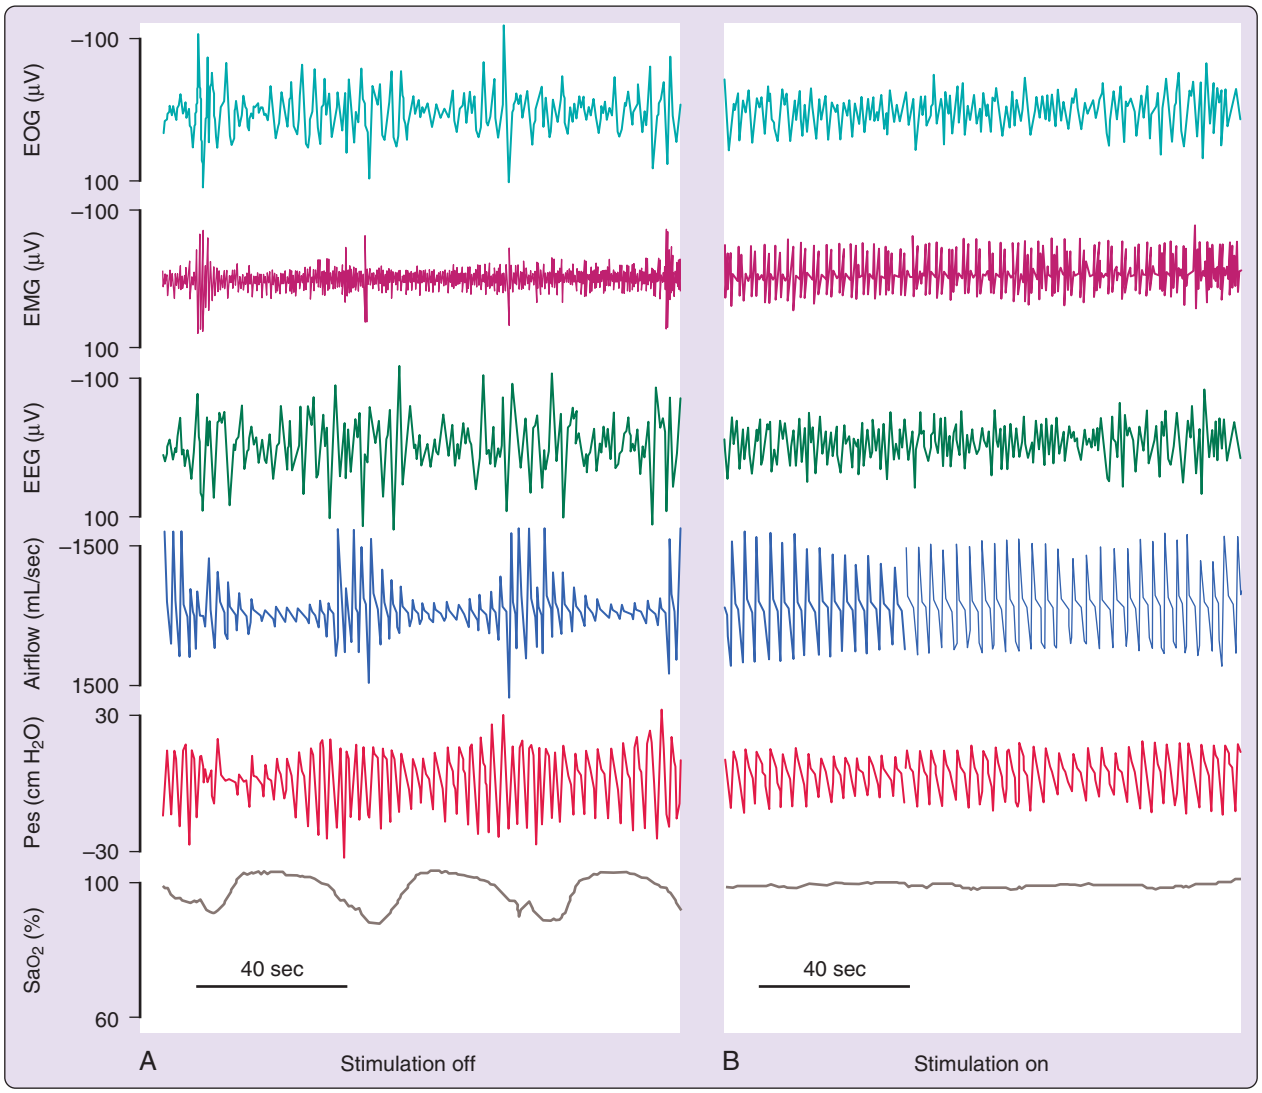

Figure 116-5 Effects of Hypoglossal Nerve Stimulation. **A,** Breathing pattern during non–rapid eye movement (NREM) sleep with hypoglossal stimulation off. **B,** Breathing pattern during NREM sleep with hypoglossal stimulation on. EEG, C3-A2 electroencephalogram; EMG, electromyogram; EOG, electrooculogram; Pes, esophageal pressure; Sa_{O_2}, oxyhemoglobin saturation. (From Schwartz AR, Bennett ML, Smith PL, et al. reduced the duration of loud snoring after 3 months. Training included instruction in the proper use of the diaphragm and the production of sounds and scales, which cause the soft palate to rise and fall.[106] Subsequently, a cross-sectional study of orchestra musicians completing a Internet-based survey found that double-reed woodwind musicians, in comparison with those who play other wind or non-wind instruments, had a reduced prevalence of OSA risk based on the Berlin questionnaire. Although the proportion of women in the double-reed instrument group was higher, which might have explained this association, the relation persisted after adjustments for sex. Practice duration with a double-reed instrument also was associated with a reduced OSA risk score based on the Berlin questionnaire[107] In another web-based survey study of orchestra members also using the Berlin questionnaire to assess OSA risk, wind instrument players were found to have a greater odds of OSA risk; however, this was no longer significant after adjustments for BMI.[108] Potential explanations for the discrepant findings could include that the latter study did not distinguish between wind instrument type (i.e., single-reed versus double-reed), and that double-reed instruments require both a relatively unique lip placement and a high degree of air resistance. Furthermore, statistical overadjustment for obesity by including this as a covariate may have occurred, because BMI is part of the Berlin questionnaire.

Overcoming such limitations of correlational design and the use of questionnaires to assess OSA risk, findings in at least three preliminary randomized, controlled trials provide promising support for the efficacy of oropharyngeal exercise training for OSA in selected patients. In the first of these studies, investigators performed a controlled trial and randomly assigned 25 participants with moderate OSA (with an AHI between 15 and 30)[109] either to receive digeridoo lessons,

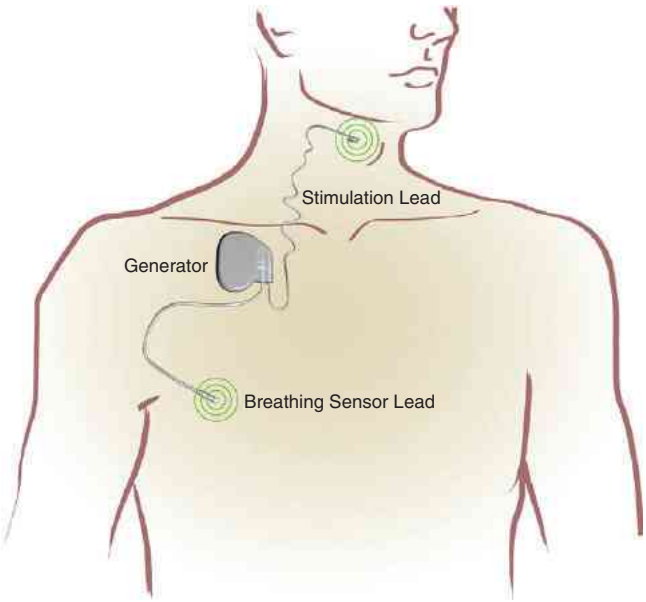

Figure 116-6 General Design of a Closed-System Hypoglossal Nerve Stimulator. (Image provided and reproduced with permission of Inspire Medical Systems, Inc.)

a traditional instrument of the aboriginal Australian culture, with daily practice or to a waitlist for lessons and followed the participants for 4 months. After 4 months of playing the digeridoo for at least 5 days/week for 20 minutes per day, patients in the digeridoo group achieved an AHI reduction of 10.7, compared with 4.5 in the control group participants. Decreases in subjective daytime sleepiness as measured by the ESS also were observed in the digeridoo group.

A more recent randomized, controlled trial of speech therapy–derived oropharyngeal exercises in patients with recently diagnosed moderate OSA studied the effects of isometric and isotonic exercises of the tongue, soft palate, and lateral pharyngeal wall compared with sham exercises performed over a 3-month period. Exercises were observed weekly by a speech therapist, and participants performed exercises for 30 minutes daily for 3 months. Adherence to exercises was monitored using a diary. The investigators found that the oropharyngeal exercise group demonstrated a mean AHI reduction of 38%, compared with 6% in the sham exercise group, for a mean reduction in AHI of 8.7 events/hour versus a mean increase of 1.5 events/hour, respectively; the pretreatment mean AHI was 22.4 for both groups.[110] Significant reductions in neck circumference were found in the oropharyngeal exercise group compared with the sham group (a decrease of 1.1 cm versus a gain of 0.2 cm, respectively) and correlated with the AHI reduction. As in the didgeridoo study, significant reductions were noted in ESS score, a measure of subjective daytime sleepiness.

Myofunctional therapy also has been successfully applied to treat residual symptoms of OSA after adenotonsillectomy (AT) in children.[111] Thirty children with an AHI greater than 1 after AT were randomly assigned to either an exercise regimen targeting nasal breathing, labial seal, lip tone, and tongue posture or no treatment (control group). Children practiced three times per day for 3 months. Oropharyngeal training significantly reduced the post-AT AHI by 58%, compared with 7% for the control group. With the recognition that a majority of children who have undergone AT continue to display at least mild residual OSA symptoms, oropharyngeal training has the potential to become an important adjunctive postsurgical therapy.

These preliminary studies of oropharyngeal muscle training are promising and support continued research in this area. The studies reported to date, however, generally are small and highly selective, with inclusion of only subjects with mild to moderate OSA; thus whether similar reductions in AHI would be observed in patients with severe OSA is unknown. Furthermore, the longevity of the effects is unknown beyond the initial 3-month training period. Further elucidation of the specific types of training exercises that are most strongly associated with decreased airway collapsibility during sleep is needed. Although myofunctional therapy cannot be currently recommended as a primary therapy for OSA, it may be a useful adjunctive modality for use with other OSA therapies or as an alternative therapy in patients who refuse or otherwise cannot benefit from primary treatments for OSA.

Pharmacotherapy for Obstructive Sleep Apnea Targeting Neuromuscular Control

Selecting and studying pharmacologic targets that might successfully treat OSA in humans constitute a challenging endeavor owing to the complexity of respiratory control, the multiple neurochemical pathways that drive respiration, interactions with the sleep state, and limitations in animal models of OSA.[112,113] An ideal pharmacologic agent for the treatment of OSA would need to possess multiple properties including the ability to achieve (1) maintainance of normal airway patency and respiratory drive during both non-REM (NREM) and REM sleep and (2) mitigation of the effects of intermittent arousals and hypoxemia.[114] No such pharmacologic intervention currently exists, although various drugs have been studied in this context. Current pharmacologic approaches for the management of OSA might best be described as alternative therapy in patients for whom other primary or even alternative OSA therapies have not been of benefit. In view of the current evidence, however, such an alternative therapy approach should be considered investigational, with perhaps a few exceptions, until appropriate clinical trials have been completed. Pharmacotherapies used as adjuncts to primary treatment modalities for OSA, including PAP, oral appliance therapy (OPT), surgical treatments, and weight loss, however, also have received attention. Agents that have been evaluated include REM-suppressing agents and drugs that improve airway patency (e.g., serotoninergic, cholinergic, and cannabinoid agents). Overall, the results of these approaches for OSA treatment to date generally have been disappointing, as reviewed next (see Table 116-1 for a summary of the findings).

Serotoninergic Agents

Serotoninergic neurons are known to regulate upper airway motor output, and several studies have investigated the possible beneficial effects of serotoninergic agents in patients with OSA. Serotoninergic control of respiration, however, is complex and remains poorly understood. Whereas some serotoninergic inputs are excitatory and facilitate respiration,[115] others inhibit upper airway motor neuron function.[116] Systemically administered agents that augment or attenuate

serotonin levels, therefore, might be expected to either decrease OSA severity or exacerbate the condition, respectively.[117]

Several clinical trials have tested serotoninergic medication–based regimens for OSA. Mirtazapine, an antidepressant with both 5-HT_1 agonist and 5-HT_3 antagonist effects, has been more widely investigated as a medication for OSA treatment. On the basis of an animal study in which mirtazapine was found to be effective in reducing central apneas in rats,[117] investigators conducted a randomized, double-blind, placebo-controlled, threeway crossover study of mirtazapine in 12 patients with OSA.[118] The results were positive in that the daily administration of 4.5 to 15 mg of mirtazapine for 1 week reduced the AHI by approximately 50% in adult patients with OSA, from a pre-treatment mean AHI of 22.3 to an on-treatment mean of 11.4. A subsequent randomized, controlled trial, however, demonstrated no significant benefits of mirtazapine (in a dose of 7.5 to 45 mg for 2 weeks) compared with placebo in moderating OSA severity: Compared with the pre-treatment mean AHI of 24.1, on-treatment mean AHI increased to 26.7 to 39.2, depending on the dose of mirtazapine.[119] Use of this medication was associated with a mean weight gain of approximately 1 kg. Relatively common side effects of mirtazapine include both sedation and weight gain, two problems linked with OSA itself.

Subsequently, investigators compared placebo, fluoxetine (a central 5-HT_2 agonist), odansetron (a peripheral 5-HT_3 antagonist), and combined fluoxetine and ondansetron in a randomized, controlled 4-week trial in 35 adults with mild to severe OSA. Combined high-dose therapy with fluoxetine and ondansetron showed some efficacy: This regimen reduced the mean AHI significantly compared with baseline at days 14 and 28 for the second half of full-night polysomnography, in contrast with no significant changes in AHI with placebo.[120] However, no subsequent confirmatory trials have been performed. Common side effects reported with use of these medications include headache, constipation, dry mouth, and hypersomnolence, although such effects were not seen during this 4-week clinical trial.

Protriptyline, a nonsedating tricyclic antidepressant, acts as a serotonin and norepinephrine reuptake inhibitor and also has been shown to have partial treatment effects in OSA at doses up to 30 mg. Mechanisms which contribute to improvements in OSA severity include reduction in REM sleep duration,[121] and increased hypoglossal and recurrent laryngeal nerve activity with increased upper airway motor tone.[122] In at least two small clinical trials, use of protriptyline for treatment of severe OSA (mean AHI range, 71 to 75) was associated with reductions in AHI by 21% to 33%,[121,123] predominantly as a consequence of reductions in apnea frequency and duration. Furthermore, subjective improvements with respect to sleepiness were reported by most patients despite significant residual disordered breathing, suggesting that protriptyline may have independent alerting effects.[121] Documentation of significant residual disordered breathing and hypoxemia, however, has diminished enthusiasm for this treatment when more effective therapies are available. Side effects of protriptyline include dry mouth, urinary hesitancy, constipation, confusion, and ataxia, all of which also may limit the use of medications of this class.[124]

Thus, as a group, serotoninergic medications have modest effects on OSA severity status. In light of the availability of more effective treatments for OSA and potentially significant side effects for some of these drugs, these medications should not be used for primary therapy for OSA but rather are best considered as adjunctive therapy with other OSA treatments. Use of serotoninergic medications also could be considered an alternative therapy in patients with OSA intolerant of other forms of OSA treatment, particularly in patients in whom these medications are already planned to be used for comorbid disorders such as depression (mirtazapine or protriptyline), anorexia (mirtazapine), migraine (protriptyline), and cataplexy (protriptyline or fluoxetine). Reductions in OSA severity with

these medications should not be assumed on the basis of decreased symptoms, and the patient's OSA status should be monitored by sleep testing.

Cholinergic Agents

Acetylcholine, a cholinergic neurotransmitter active primarily during REM sleep, is involved in the modulation of upper airway motor tone. Preliminary investigations of acetylcholinesterase inhibitors have been performed on the basis of findings in preclinical studies, which demonstrated that injection of physostigmine into cholinergic neurons located in the rostral ventrolateral medulla of anesthetized and vagotomized cats was followed by increased hypoglossal and phrenic nerve activity. This increased activity resulted in prolonged hypoglossal to phrenic nerve firing interval with consequent improvement in respiratory drive.[125] On the basis of such data, a double-blind, placebo-controlled trial was conducted in 12 men with moderate to severe OSA.[125] Physostigmine or placebo was injected intravenously on separate nights followed by an overnight sleep study. Comparison of sleep recordings for the physostigmine night and the placebo night demonstrated a slightly lower mean AHI (apnea-hypopnea rate of 41 events/hour and 54 events/hour, respectively), with the greatest reduction occurring during REM sleep (mean AHI of 54 versus 30, respectively).

Donepezil, a reversible inhibitor of the acetylcholinesterase enzyme often used to treat memory impairment in Alzheimer disease (AD), also has been tested as a potential agent for treatment of OSA in patients with and without AD. An initial study was performed in 23 patients with AD and mild to moderate OSA. This randomized, double-blind, placebo-controlled trial demonstrated that at 3 months, donepezil improved the mean AHI from 20.0 to 9.9 compared with placebo, for which the mean AHI did not change (23.2 versus 22.9). As would be expected with a cholinergic medication, increased REM sleep was observed in the donepezil group at 3 months.[127] Another double-blind, placebo-controlled trial of donepezil was conducted in 21 male patients with OSA but no AD. This study also found donepezil to improve mean AHI at 1 month, although the effects were more modest, with a mean AHI reduction of 23% (pretreatment mean of 42.2 versus posttreatment mean of 32.8) versus a mean AHI increase of 14% (pretreatment mean of 26.4 versus posttreatment mean of 31.0) in the placebo group.[128] This study found no differences in REM sleep between the groups. Side effects reported with donepezil included dizziness, nausea, headaches, vivid dreams, and nightmares. Although these results are promising, further confirmatory studies are needed in larger samples to determine if donepezil has a role in the treatment of OSA. For now, there may be a role for donepezil in patients with AD with comorbid OSA, when donepezil is already being considered for memory-related conditions and other primary or alternative OSA therapies are not tolerated.

Cannabinoids

Cannabinoid agonists have recently been investigated as a candidate target for OSA therapy. Preclinical data suggest that dronabinol, a nonselective cannabinoid type 1 (CB1) and type 2 (CB2) receptor agonist, increases phasic genioglossal activity and attenuates serotonin-induced apneas in rats when injected in the nodose ganglion.[129] Dronabinol is hypothesized to inhibit afferent vagal nerve activity, which may thereby result in disinhibition of upper airway motor neurons.[130] In an initial proof-of-concept human clinical trial,[131] participants with moderate OSA treated with CPAP were withdrawn from their CPAP regimen for 1 week. Participants were then given dronabinol in an escalated dose over 3 weeks, up to 10 mg. Pretreatment AHI was reduced by 29% from a pretreatment mean AHI of 48.8. Side effects noted during the study included somnolence and increased appetite without weight increase. Although these findings are of interest, controlled studies are needed on the potential effects of dronabinol in OSA, and this treatment should be considered investigational at present.

THERAPIES TARGETING PRIMARILY NEUROVENTILATORY MECHANISMS

Neuroventilatory mechanisms play an influential role in the expression of OSA severity. Physiologic parameters such as the arousal threshold, apnea threshold, CO_2 reserve, and circulatory time determine the subject's response to reduced ventilation from any cause whether mediated centrally (central hypoventilation) or peripherally (obstruction). Globally, these measures determine the degree of ventilatory instability (loop gain) and whether disordered breathing will be mitigated or perpetuated. Neuroventilatory mechanisms, therefore, present a potential therapeutic target for OSA treatment. Examples of such interventions are oxygen therapy and pharmacotherapies and are discussed next.

Supplemental Oxygen

Many of the consequences of OSA are attributable to nocturnal hypoxemia. Studies done before the widespread use of CPAP reported that supplemental oxygen administration during sleep in patients with OSA could significantly increase oxygen saturation of hemoglobin (Sao_2) but could also lengthen apneic spells, potentially leading to hypercapnia and respiratory acidosis.[132-134] These early studies found no improvement in subjective or objective measures of daytime sleepiness with nocturnal oxygen treatment.[135] However, reduction in OSA severity with oxygen therapy alone may depend on whether the patient has stable or unstable ventilatory control (low or high loop gain, respectively). In a study of subjects with severe OSA, oxygen reduced the AHI by 53% in the high loop gain group, compared with 8% in the low loop gain group.[136] A randomized clinical trial comparing oxygen administration alone with CPAP in patients with OSA and comorbid cardiovascular disease or multiple cardiovascular risk factors found that CPAP, but not nocturnal oxygen therapy, significantly reduced 24-hour mean blood pressure.[137] Thus oxygen therapy alone during sleep is not recommended as a primary or alternative therapy for most patients with OSA.

However, subgroups of patients with OSA who might benefit from oxygen therapy are recognized. Patients with significant cardiovascular disease (e.g., coronary artery disease or cerebrovascular disease) and an only marginally elevated frequency of abnormal breathing events during sleep, but who experience severe oxyhemoglobin desaturation during those events, might benefit in terms of reduced risk of myocardial ischemia with oxygen supplementation.[138,139] The use of supplemental oxygen also could be considered as alternative therapy in patients with OSA and significant intermittent

hypoxemia who are intolerant of a primary therapy such as CPAP, to minimize potential cardiovascular and metabolic risks. In the absence of any high-grade evidence, such use should be considered controversial, particularly because oxygen administration is not without risks (e.g., hypercapnia, fire risk). The clinician in this situation should consider titration of oxygen in an attended sleep study setting to document the optimal minimum oxygen dose for efficacy in patients with OSA in preventing hypoxemia and minimizing hypercapnia.

Oxygen also may be added as adjunctive therapy to PAP in patients in whom CPAP or bilevel PAP regimens are effective in treating their OSA, but in whom hypoxemia persists owing to ventilation-perfusion mismatching or hypoventilation.[140] This may occur in patients with severe obesity or a so-called overlap syndrome (see Chapter 119). Patients with OSA who require supplemental oxygen therapy during wakefulness almost always will require supplemental oxygen during sleep, even if PAP therapy maintains a patent upper airway.[141] However, it should be determined if persistent oxygen desaturation in patients on CPAP is related to hypoventilation,[10] because use of bilevel positive pressure in patients who are hyperventilating despite adequate control of OSA may obviate the need for added oxygen.

Transtracheal Oxygen Delivery

Several reports have described the use of transtracheal oxygen administration in patients with OSA who are intolerant of CPAP.[142-144] One study described the use of this modality as salvage therapy in a patient with overlap syndrome and in a patient with persistent hypoxemia despite CPAP and in-line oxygen.[145] These data are too limited to recommend this mode of oxygen delivery; accordingly, transtracheal oxygen use in OSA as either an alternative or adjunctive therapy should be considered investigational.

Pharmacotherapy for Obstructive Sleep Apnea Targeting Neuroventilatory Control

Several drugs have been studied targeting neuroventilatory control mechanisms such as a high loop gain state and a low arousal threshold. Although more often considered as potential treatments for central sleep apnea (see Chapter 110), some of these pharmacologic approaches have been examined in the setting of OSA. With the possible exception of acetazolamide, these approaches should be considered either as alternative therapies for use in patients who have demonstrated intolerance to primary therapies or as investigational therapies.

Carbonic Anhydrase Inhibitors

Acetazolamide, a carbonic anhydrase inhibitor that induces a metabolic acidosis, thereby increasing ventilation, has been studied primarily in patients with central sleep apnea secondary to high altitude exposure or heart failure, who often have unstable ventilatory control (i.e., high loop gain). Similarly, some patients with OSA also have been shown to have an elevated loop gain.[146] In one study of patients with OSA treated with CPAP, administration of acetazolamide for 7 days reduced the mean loop gain by 41% and the mean AHI by 41%.[147] However, difficulties with tolerability of acetazolamide may preclude its long-term use, because patient-reported side effects have included paresthesias, altered taste, nocturia, and hypokalemia (when it is used in combination with a diuretic), with the need to monitor serum bicarbonate levels over time. Currently, use of acetazolamide should be considered only as alternative or adjunctive therapy for OSA.

Methylxanthines, Opioid Antagonists, and Dopamine Agonists

A randomized, crossover, placebo-controlled trial in 1987 assessed the efficacy of infusion of aminophylline, a methylxanthine derivative known to have respiratory stimulant properties, in male subjects with moderate OSA.[53] Aminophylline decreased the frequency of central and mixed apneas but did not affect the frequency or duration of obstructive apneas. Mean and minimum arterial oxygen saturation values in sleep also were unchanged, and sleep architecture was markedly disturbed.

In recognition of the effects of opiate agonists on respiratory depression, another early investigation tested multiple medications including naloxone (an opioid antagonist), theophylline, and bromocriptine mesylate (a dopamine agonist). None of these agents had any significant beneficial effects on the frequency or duration of obstructive apneic and hypopneic spells or on oxygen desaturation indices.[148] Thus none of these medications are appropriate for use as as primary agents in the treatment of OSA.

Sedatives and Hypnotics

The use of sedatives and hypnotics in the treatment of OSA appears to be counterintuitive, on the basis of concerns regarding worsening of OSA secondary to the myorelaxant and central nervous system sedative effects of many of these medications.[149] However, a low arousal threshold in a patient with OSA may result in a premature arousal before compensatory neuromuscular mechanisms have sufficient time to restore complete upper airway patency. A premature arousal when combined with an underlying state of ventilatory instability may result in persistent disordered breathing during sleep. One study[146] demonstrated that 37% of patients with OSA have a low arousal threshold, raising the possibility that increases in the arousal threshold, as may be achieved with sedative-hypnotics, may represent a therapeutic target for this population.

Initial clinical studies testing this possibility have looked at the use of eszopiclone, a nonbenzodiazepine sedative, or trazodone, an antidepressant medication with serotoninergic, antihistaminic, and antiadrenergic effects. One study randomly assigned 17 subjects with OSA with a nadir Sao_2 greater than 70% to receive one night of eszopiclone 3 mg or one night of placebo.[150] The arousal threshold, quantified by degree of nadir epiglottic pressure level associated with electroencephalogram arousal, was observed to increase by 18% in stage N2 (NREM stage 2) sleep , whereas the mean AHI was reduced by 23% (rate decrease from 31 events/hour to 24 events/hour) in the eszopiclone group compared with the placebo group. No significant difference in hypoxemia severity was seen between the two groups. In another, more rigorous study of double-blind, placebo-controlled cross-over design, however, participants with mild to moderate OSA were randomly assigned to receive either eszopiclone or placebo for two consecutive nights. No significant difference in AHI was seen between the groups.[151] Several studies have examined the use of trazodone to treat OSA.[152-154] Trazodone given at

100 mg for one night was reported to increase the arousal threshold by 32% but did not reduce the AHI[153] A subsequent study of 15 patients with severe OSA given trazodone 100 mg or placebo had conflicting results, demonstrating no significant changes in arousal threshold but mild improvements in AHI with trazodone compared with placebo (reported rate of 28.5 events/hour vs. 38.7 events/hour, respectively).[154] These data suggest that at the very least, certain sedatives and hypnotics may not exacerbate OSA and could be used in patients with comorbid insomnia when indicated. In view of the noted conflicting results, however, the use of sedatives and/or hypnotics to treat OSA, whether as adjunctive or alternative therapy, currently should be considered investigational.

Complementary and Alternative Medicine Therapy for Obstructive Sleep Apnea

The term *complementary and alternative medicine* (CAM) typically is used to refer to treatments that are not part of allopathic medical training.[155] Such treatments are not restricted to medications and typically lack a clear and compelling mechanism of action that targets known pathophysiology. In the following discussion, the concept of *CAM therapy* is differentiated from *adjunctive* and *alternative therapy* as described earlier in the chapter. CAM therapies may potentially be used as adjunctive or alternative treatments for OSA. In view of the well-established cardiovascular, cerebrovascular, and metabolic consequences of OSA and the neuromechanical nature of the disease, the role for CAM treatments, if not specifically contraindicated, is expected to be minimal. As noted earlier, however, PAP, the "gold standard" treatment for OSA, is difficult to adhere to for many patients.[2] Recent surveys suggest that a majority of patients with OSA are actively interested in CAM approaches.[156] Setting aside the general absence of well-controlled studies evaluating complementary interventions for OSA, we present a brief review of preliminary studies of acupuncture therapies, considered a form of CAM.[157,158] In general, however, other CAM-designated treatments such as use of herbal and dietary supplements and manipulative therapies (e.g., tai chi) have been studied in a very limited and uncontrolled fashion and consequently are not further discussed here. With the possible exception of acupuncture, reports of CAM treatments are of insufficient scientific quality to support their use. Placebo effects and manipulation of presleep expectancies,[159,160] which represent potential mechanisms by which some of these interventions could improve sleep parameters, have been shown to persist into and alter sleep-related physiologic measures. Indeed, some work demonstrates that REM sleep may play a role in the persistence of next-day placebo analgesia effects.[159]

Acupuncture

Most studies of CAM therapies for OSA have not used randomized, placebo-controlled experimental designs. Acupuncture is a notable exception. One single-blind study of acupuncture randomly assigned 36 patients with previously untreated OSA for 10 weeks to either an acupuncture group, a sham acupuncture group, or a control group (in which sleep hygiene and weight loss counseling was provided).[161] Weekly acupuncture significantly improved the mean AHI by approximately 50%, from a recorded rate of 19.9 events/hour to 10.1 events/hour, compared with the sham acupuncture or control group, for which mean AHI was unchanged or significantly worsened, respectively.[161] The acupuncture group also demonstrated improvement in subjective measures of sleepiness based on the ESS and in some quality of life domains based on the short form 36 health survey questionnaire (SF-36). A more recent randomized, controlled study by the same group of investigators compared manual acupuncture and electroacupuncture for one session with no treatment (control condition) in 40 patients with previously untreated, moderate OSA. Both manual acupuncture and 10-Hz electroacupuncture administered just before sleep significantly reduced the mean AHI by approximately 50% (apnea-hypopnea rate for manual acupuncture: 21.9 events/hour reduced to 11.2 events/hour; rate for 10-Hz electroacupuncture: 20.6 events/hour reduced to 10.0 events/hour), compared with 2-Hz electroacupuncture and no treatment (control condition) (both groups: no significant change in mean AHI).[162]

A randomized, controlled trial of auricular plaster therapy, a form of acupuncture administered only to the ear, compared this treatment against vitamin C supplementation in the control group.[163] Forty-five participants with severe OSA were randomly assigned to receive either auricular acupuncture three to five times per day or vitamin C three times daily for 10 days. Patients in the auricular acupuncture group demonstrated modest, but statistically significant, improvement in the mean AHI (pretreatment apnea-hypopnea rate of 72.4 events/hour versus posttreatment rate of 59.2 events/hour), in contrast with the control group (pretreatment rate of 73.5 events/hour versus posttreatment rate of 72.0 events/hour).

Although the mechanisms by which acupuncture may modulate OSA severity, and the longevity of such effects, are unknown, these preliminary studies are promising and merit further research. Acupuncture should not replace established primary treatments in current use, but if this modality is added, it should be performed using published protocols by professionals trained in this discipline to promote standardization of effects.

PHARMACOLOGIC MANAGEMENT OF "RESIDUAL" EXCESSIVE DAYTIME SLEEPINESS WITH ADEQUATELY TREATED OBSTRUCTIVE SLEEP APNEA

Even with objectively documented successful treatment of OSA, including acceptable adherence to therapy, it has been estimated that as many as 10% of patients with OSA continue to report significant excessive daytime sleepiness (EDS).[164] The significance of EDS cannot be overstated in view of its role in contributing to motor vehicle accidents, impaired psychological functioning, and reduced work performance.[45] The cause of such "residual" EDS, however, can be difficult to definitively ascertain. Data from mouse models suggest that intermittent hypoxia may result in irreversible oxidative injury to brain centers associated with sleep.[165]

As part of the clinical management of patients with appropriately treated OSA but persistent EDS, other contributing factors and conditions such as insufficient sleep time, insomnia, medication-related side effects, or other comorbid sleep disorders should be carefully ruled out. Successful treatment of OSA should be documented by objective measures of adherence to therapy and a normal AHI with the prescribed

CPAP regimen as confirmed by a sleep study. Objective documentation of EDS with a Multiple Sleep Latency Test (MSLT) or Maintenance of Wakefulness Test (MWT) could be considered, although this is not a requirement for most third party payers, and such testing typically is performed when the possibility of a primary CNS hypersomnolence disorder such as narcolepsy is a concern. If EDS persists despite adequate OSA treatment, nonsympathomimetic stimulants (e.g., caffeine) can be used, as well as psychostimulant medications (i.e., nonamphetamine or amphetamine derivatives). Such regimens should be considered as part of an overall management strategy to improve daytime alertness.[166]

Traditionally, amphetamine-class medications have been used to treat residual EDS in patients with OSA, on the basis of data for subjects with narcolepsy and sleep-restricted persons (Chapter 90). The potential for harmful cardiovascular consequences and potential negative mood- and sleep-related effects with this class of medications has led to investigational use of pharmacologic agents other than amphetamines, for which these effects seem less likely to occur. Comparative effectiveness studies of different stimulants in the treatment of residual EDS in patients with OSA are needed because many of the amphetamine derivatives are considerably less expensive than the nonamphetamine medications. The use of these medications is not discussed further here owing to the absence of data regarding their use in the treatment of residual EDS in patients with OSA.

Modafinil and armodafinil, the *R*-isomer of modafinil, are nonamphetamines currently FDA-approved for the treatment of residual hypersomnolence in patients with OSA considered to be otherwise adequately treated with PAP.[167] The wake-promoting effects of the medication are incompletely understood but are reported to be due primarily to dopaminergic-mediated pathways.[168] Several relatively large randomized, placebo-controlled clinical trials have demonstrated that modafinil[148,149,169,170] and armodafinil[167,171-174] can safely reduce EDS, as indicated by subjective and objective measures,[175] and can improve quality of life in patients with OSA adequately treated with CPAP.[176,177] For example, an initial 4-week randomized, double-blind, placebo-controlled, parallel group study[169] of modafinil versus placebo reported normalization of the ESS score in 51% of the modafinil group versus 27% in the placebo group. Although the mean sleep latency on an MSLT was decreased in the modafinil group compared with the placebo group, normalization of the mean sleep latency (to less than 10 minutes) was similar in both groups (29% versus 25%, respectively). A subsequent randomized, controlled trial[170] performed over 12 weeks evaluated the effects of placebo versus modafinil at a 200-mg or 400-mg dose. Improvements in ESS scores and mean sleep latency on the MWT were reported, with similar improvements for the 200-mg and 400-mg modafinil dose groups. Improvements in sleep-related quality of life and global function as assessed by the FOSQ and Clinical Global Impression of Change questionnaires were observed to a similar degree in both modafinil groups compared with placebo. No change in CPAP adherence was reported in these two studies.[169,170] However, in a separate 12-week open label continuation of modafinil from the initial study,[169] mean CPAP use was observed to decline from 6.3 hours/night to 5.9 hours/night,[178] suggesting that such agents may in fact reduce adherence to CPAP. Accordingly, clinicians should continually remind their patients to be adherent to CPAP, to maximize the wake-promoting effects of both therapies.

A similar literature base is available regarding the efficacy of armodafinil for residual EDS in patients with treated OSA.[167,171-174] Armodafinil has a duration of action that is 10% to 15% longer than that of modafinil. Data from a pooled analysis[172] of two 12-week multicenter, double-blind, placebo-controlled, parallel group clinical studies[176,179] found that adjunctive treatment with armodafinil in CPAP-adherent participants with OSA coupled with residual EDS significantly improved wakefulness, long-term memory, and ability to engage in activities of daily living. Armodafinil also reduced patient-reported fatigue, evaluated separately from sleepiness, and was well tolerated in terms of side effects.[172] Treatment with armodafinil showed no effect on subsequent CPAP adherence, but active monitoring of CPAP adherence by the clinician is advocated in this setting.[174] A multicenter, flexible-dose, open-label study found that armodafinil remained effective for more than 12 months in patients with residual EDS and treated OSA.[173]

The most commonly reported adverse events in the studies that were associated with both medications included headache (occurring in approximately 15% to 20% of subjects), nausea (in 10% to 20%), insomnia (in 5% to 10%), and anxiety (in 5% to 15%). Up to 15% of patients in one study discontinued medications owing to such adverse events. A rare but serious adverse event that clinicians should be aware of is the occurrence of serious rashes, including Stevens- Johnson syndrome and toxic epidermal necrolysis, which typically occur within 5 weeks of the initiation of therapy but in rare cases may appear later than that. Rare cases of multiorgan hypersensitivity manifesting as fever, rash, and organ system dysfunction have been reported with modafinil and armodafinil, as well as anaphylactoid reaction with armodafinil. Modafinil and armodafinil may decrease the effectiveness of hormonal birth control systems, so women should be advised of this possibility, with consideration given to use of nonhormonal contraceptive approaches.

In summary, the use of pharmacologic stimulants in patients with OSA should be considered as adjunctive therapy for the management of residual EDS in patients with OSA adequately treated with CPAP, with documentation of acceptable adherence to CPAP, and after exclusion of other causes of EDS. More controversial is whether stimulants should be considered as an alternative therapy for patients with EDS due to OSA who are intolerant of treatments for their OSA. At least two studies suggest that use of modafinil during a 2-day CPAP withdrawal period or for 2 weeks in patients with mild to moderate untreated OSA resulted in significant improvements in driving performance in a driving simulator, decrease in subjective sleepiness, and better scores for attention and vigilance on the psychomotor vigilance test.[180,181] In patients in high-risk situations in which alertness and performance are critical (e.g., professional drivers, military personnel) and those for whom use of primary PAP therapy is interrupted (such as with an unreliable electrical source during travel), there may be a role for stimulants as sole treatment for brief periods. However, continued reinforcement of adherence to the patient's prescribed OSA treatment, as well as monitoring for medication side effects, is necessary to avoid potential long-term adverse effects of stimulants.

CLINICAL PEARLS

- Despite the efficacy of traditional primary treatments such as CPAP, oral appliance therapy, and upper airway surgery for OSA, patient factors such as suboptimal adherence or poor tolerance of a therapy may lead to incomplete treatment.
- In such situations, alternative therapies should be considered, either alone or as adjunctive treatment with other OSA treatment options (e.g., use of positional therapy with supplemental oxygen in a patient with positional OSA and persistent hypoxemia).
- In patients with OSA and residual sleepiness, adjunctive pharmacologic stimulant therapy can be considered, but only after ensuring that OSA treatment and sleep time are adequate, and that no other sleep disorders are present that may explain the residual sleepiness.

SUMMARY

In light of the fact that traditional primary treatment modalities for OSA, including CPAP, use of oral mandibular advancement devices, and upper airway surgery, often have poor adherence rates and/or insufficient long-term outcomes (e.g., upper airway surgery for OSA), adjunctive and alternative treatment options for OSA should be considered in nonadherent patients and those who are otherwise not fully benefiting from primary and adjunctive therapies. Furthermore, OSA treatments can be individualized in accordance with the known pathophysiologic basis for OSA in a particular patient, and with the patient's personal preferences. Treatment measures such as weight loss, positional therapy, HGNS, ENRs, and OPT have been studied and shown to successfully treat OSA in appropriate, sometimes selected patients. Other potential therapies such as myofunctional therapy, nasopharyngeal stenting, highnasal-flow therapy, use of compression stockings, and pharmacotherapies do not have proven efficacy and should currently be considered as adjunctive or investigational therapy, rather than primary therapy, for OSA. Oxygen therapy alone has not been shown to improve outcomes in OSA, although treatment of severe hypoxemia with supplemental O_2 alone or in combination with PAP can be considered a reasonable adjunctive or alternative treatment option in some patients, including those who cannot maintain adherence to or benefit from primary therapies, or who need supplemental O_2 with PAP to adequately ameliorate sleep-related hypoxemia. Promising preliminary data are available for the use of acupuncture, a form of CAM therapy for OSA, as an adjunctive or alternative therapy, but this modality requires further investigation before it can be recommended for use in OSA. Even with effective treatment for OSA, some patients may experience persistent sleepiness despite adequate sleep time and may be appropriate candidates for adjunctive stimulant therapy. In view of the difficulties that some patients experience with primary therapies for OSA, continued investigation into alterative and adjunctive OSA treatment options can be expected.

Obstructive Sleep Apnea and the Central Nervous System: Neural Adaptive Processes, Cognition, and Performance

Ivana Rosenzweig; Terri E. Weaver; Mary J. Morrell

Chapter Highlights

- Patients with obstructive sleep apnea (OSA) demonstrate variable degrees of cognitive, emotional, and performance deficits.
- OSA is increasingly recognized as one of the potentially modifiable risk factors for dementia; its multiple effects on the central nervous system are acknowledged, albeit their nature and prognosis are yet to be fully understood.
- During nocturnal apnea-hypopnea episodes and sleep fragmentation, both maladaptive and adaptive pathways are likely initiated in the brain of patients; the net result likely depends on the chronicity of process and idiosyncratic characteristics of each patient.
- Treatment of OSA with continuous positive airway pressure results in consistent improvement in cognition and performance, although the magnitude of improvement is variable.
- The role of continuous positive airway pressure and its long-term effectiveness with regard to cognitive and performance deficits need further study.

Obstructive sleep apnea (OSA) is one of the potentially modifiable risk factors for dementia,[1-4] and it is commonly associated with serious cardiovascular and metabolic comorbidities.[5-7] Nocturnal episodes of complete or partial pharyngeal obstruction in patients with OSA result in intermittent hypoxia, reoxygenation, hypercapnia, and sleep fragmentation.[8,9] An increase in respiratory effort, in association with hypoxemia or hypercapnia, triggers the frequent sleep arousals, which usually terminate the apneic episodes but also contribute to abnormal sleep architecture and lighter and less restorative sleep.[10] Progressive changes in sleep quality and structure, changes in cerebral blood flow, neurovascular and neurotransmitter changes, and the cellular redox status and neural regulation in OSA patients all may constitute contributing factors to cognitive decline.[8,11-13]

Increased road traffic accidents, reduced quality of life, excessive daytime sleepiness, labile interpersonal relationships, and decreased work and school efficiency have all been documented in OSA patients.[13] These impairments and deficits are not always reversed with treatment.[14] Beneficial effects of treatment on cognitive performance, sleepiness, and neural injury in OSA (Figure 117-1) are, however, documented in recent meta-analyses[15,16] and a meta review.[17] Two studies also suggest beneficial effects of continuous positive airway pressure (CPAP) therapy in minimally symptomatic, and older OSA patients, respectively.[18,19] In a recent study of a well-characterized longitudinal cohort (the Alzheimer's Disease Neuroimaging Initiative cohort), the self-reported presence of untreated sleep-disordered breathing, including "obstructive sleep apnea" and "sleep apnea," was associated with an earlier age at cognitive decline, up to a decade.[4] This association was found to be significant even when accounting for possible confounding factors such as sex, apolipoprotein ε4 status, diabetes, depression, body mass index, cardiovascular disease, hypertension, age at baseline, and education of participants. Moreover, this link appeared significantly attenuated in patients who used CPAP, suggesting that use of CPAP may delay progression, or onset, of cognitive impairment.[4] However, the effect of CPAP on delay in age at Alzheimer disease dementia onset was not demonstrated in this study.[4]

The current dearth of fully effective treatments for the central nervous system (CNS) sequelae of OSA is likely to be a reflection of an as yet poorly understood intricate interplay of both adaptive and maladaptive processes with the hypoxemia, reoxygenation, hypercapnia or hypocapnia, and sleep fragmentation that occur in the CNS of OSA patients.[13] The overall net result of ongoing neuroinflammatory processes and ischemic preconditioning for each particular patient depends on the stage of this OSA-induced dynamic process, effects on other body systems, cognitive reserve, and idiosyncratic susceptibility.[11,13,20,21] Thus, different therapeutic approaches might benefit different stages and conversely might aggravate damage in some patients.[11,13,20] This chapter addresses recent clinical and translational findings regarding the effects of intermittent hypoxia and sleep fragmentation on the CNS, describes the known cognitive and psychological deficits

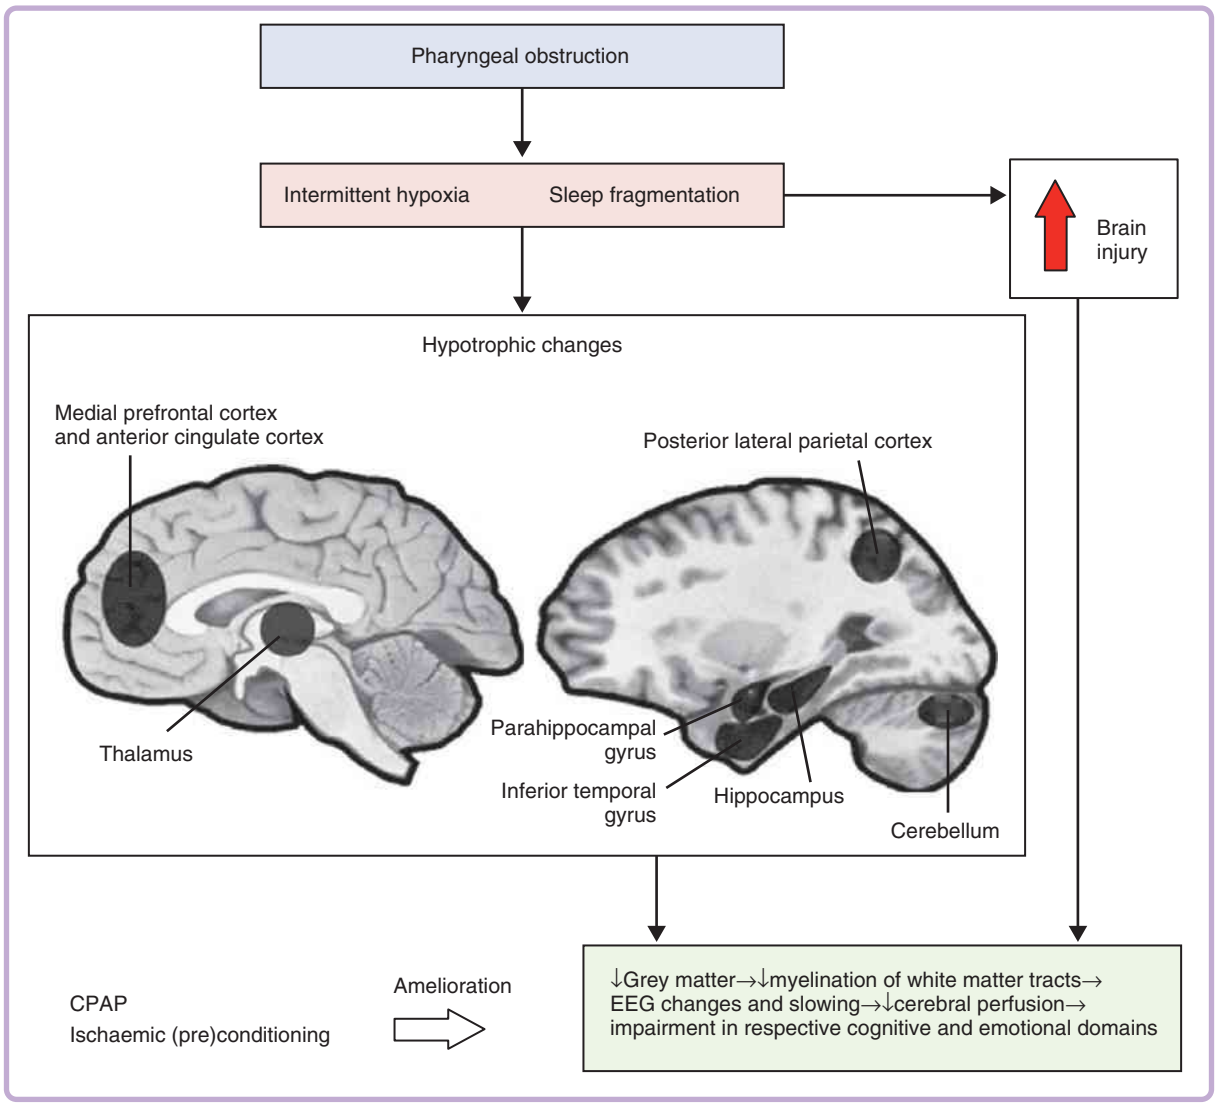

Figure 117-1 Brain regions and mechanisms involved in sleep apnea injury. The nocturnal episodes of complete or partial pharyngeal obstruction result in intermittent hypoxia and sleep fragmentation. Both intermittent hypoxia and sleep fragmentation can aggravate brain injury (*red arrow*) and cause hypotrophic changes in several brain regions shown.[128] Ensuing neurophysiologic and neurochemical changes can also manifest in cognitive and emotional deficits that can be ameliorated (*white arrow*) with continuous positive airway pressure therapy (CPAP) and/or ischemic preconditioning. EEG, Electroencephalography. (From Rosenzweig I, Glasser M, Polsek D, et al. Sleep apnoea and the brain: a complex relationship. *Lancet Respir Med* 2015;3:404–14.)

in patients with OSA, and proposes etiologic mechanisms behind the complex relationship between OSA and the CNS.

NEUROPATHOLOGY OF OBSTRUCTIVE SLEEP APNEA

Changes in cerebral blood flow that occur during obstructive apneas[22] and apnea-induced hypoxemia, combined with reduced cerebral perfusion, likely predispose patients to nocturnal cerebral ischemia.[23,24] In addition, an altered resting cerebral blood flow pattern in several CNS regions has been shown in OSA, along with hypoperfusion during the awake states.[25] Numerous clinical studies have demonstrated changes in the electroencephalogram of OSA patients compared with healthy individuals, including aberrant cortical excitability[26-28] and an associated array of neurocognitive deficits.[10] Taken collectively, such studies have also delineated a putative neurocircuitry "fingerprint" of OSA-induced brain injury and have suggested a disconnection of the frontal regions (Figure 117-2) and a disruption of the (cerebellar)-thalamocortical oscillator, with involvement of the hippocampal formation.[9,10] It has been previously suggested that the constellation of symptoms frequently encountered in OSA patients, such as depression, disturbances in attention, dysmetria of thought and affect, and executive and verbal memory deficits,[29-31] point to similarities with two other recognized neurologic clinical syndromes, frontal lobe syndrome and the cerebellar cognitive affective syndrome.[10,32]

The prefrontal model posits that the sleep disruption, intermittent hypoxemia, and hypercapnia experienced by OSA

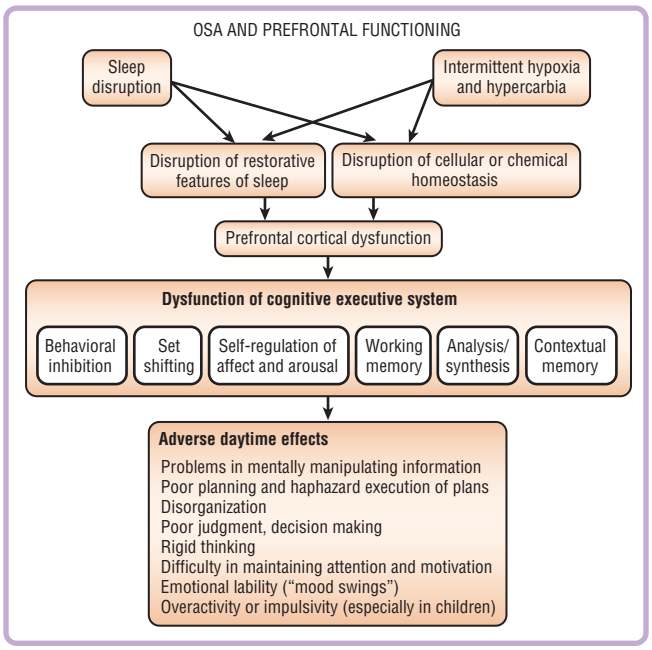

Figure 117-2 The proposed prefrontal model. In this model, obstructive sleep apnea–related sleep disruption and intermittent hypoxemia and hypercarbia alter the efficacy of restorative processes occurring during sleep and disrupt the functional homeostasis and neuronal and glial viability within particular brain regions, particularly the prefrontal regions of the brain cortex. (From Beebe DW, Gozal D. Obstructive sleep apnea and the prefrontal cortex: towards a comprehensive model linking nocturnal upper airway obstruction to daytime cognitive and behavioral deficits. *J Sleep Res* 2002;11:1–16.)

patients alter the normal restorative process that occurs during sleep, generating cellular and biochemical stresses that result in disruption of functional homeostasis and altered neuronal and glial viability within certain brain regions, primarily the prefrontal regions of the brain cortex.[33,34] This model has been proposed as a theoretical framework for the relationship between sleep fragmentation and nocturnal hypoxemia and predominantly frontal deficits (see Figure 117-2).[34] OSA-induced neuropathologic alterations can lead to destabilization of the executive system, causing behavioral disturbance in inhibition, maintenance of performance, self-regulation of affect and arousal, working memory, analysis and synthesis, and contextual memory.[33,34] Alterations in the executive system can adversely affect cognitive abilities, resulting in maladaptive types of behavior as depicted in Figure 117-2.[33,34] Nonetheless, unlike some other neurologic disorders, the impairments associated with OSA are more likely to produce inefficient performance rather than inability to perform.[34] For example, when memory- or divided attention–related neuronal circuitry is incapacitated, other CNS systems and circuitries likely get recruited in an effort to compensate.[33,34] However, if such systems are themselves affected by sleep fragmentation or hypoxemia, their compensatory contributions might be suboptimal. This may account for the increased activation of the prefrontal cortex under conditions of sleep deprivation documented by functional magnetic resonance imaging.[33,34] Impairments in performance of OSA patients can be further explained by deficits in elementary cognitive functions, specifically, sensory transduction, feature integration, and motor preparation and execution, which are required, even in simple response-time tasks.[34,35] Corresponding to the listed deficits in OSA patients, the neuroanatomic regions that have most commonly been reported in clinical and animal studies as affected in OSA suggest that both the cerebellar modulation of neural circuits and the normal state-dependent flow of information between thalamus (and basal ganglia) and frontoparietal cortex are likely to be affected in susceptible patients (see Figure 117-1).[10,36-41]

Some clinicians have argued against such a reductionist approach to OSA-induced brain injury and point out that emerging research indicates that the relationship between OSA disease severity and cognitive dysfunction is the product of a multitude of susceptibility and protective factors and that sleep fragmentation, hypoxemia, and cognitive reserve are only three such aspects.[9,10,16] Other commonly overlooked factors are duration of the disease, role of the blood-brain barrier, presence of hypertension, metabolic dysfunction, and systemic inflammation, levels of cerebral blood flow, and genetic vulnerability.[16] Further research is necessary to provide a clear understanding of the risk for neurocognitive dysfunction and the benefit and optimization of treatments.

Affected Neurocognitive Domains

Despite contradictory results and ongoing polemics in the field, most studies to date agree that patients with OSA can have significant deficits in attention and vigilance, long-term visual and verbal memory, visuospatial and constructional abilities, and executive function.[13,17,29] Several associations have been recognized, including the association between worsening global cognitive functioning and the severity of hypoxemia as well as the association between attention and vigilance dysfunction and the degree of sleep fragmentation.[13,17] Consensus is less strong on the effects of OSA on working memory and short-term memory.[17] In some studies, language ability and psychomotor functioning have been shown to be largely unaffected by OSA,[17] whereas others have pointed to psychomotor slowing as the most vulnerable cognitive domains and also the least responsive to treatment with CPAP.[42] Similarly, several studies showing impairments in language abilities in patients with severe OSA have not shown agreement on whether phonemic or semantic domains have the greatest effect.[43] Neurodevelopmental stages of adolescents and children with OSA appear to dictate a higher risk for this deficit.[44]

In children with OSA, the results of studies assessing cognitive performance and effects of treatment are similarly divergent.[45,46] In a recent study of children 7 to 12 years of age with sleep-disordered breathing (SDB), who were followed for 4 years, treatment of the SDB led to improvements in several aspects of neurocognition, collectively categorized as performance IQ.[45] Performance IQ represents fluid intelligence that is reflective of incidental learning, and it describes one's ability to adapt to new situations.[47] In this study, improvements were recorded in tasks associated with spatial visualization, visuomotor coordination, abstract thought, and nonverbal fluid reasoning.[45] However, overall improvements in academic ability or behavior were less clear. Furthermore, tendency to worsening of verbal IQ, which, unlike performance IQ, is more likely to be affected by formal education and learning experiences, was noted in a treated group.[45] A definitive explanation for this finding was not provided, and no statistically significant association between the reduction

in verbal IQ performance and treatment was demonstrated.[45] Conversely, in another influential study, younger children with SDB followed for 12 months of treatment showed significant improvements in academic performance.[46] The different neurodevelopmental ages of children and different test parameters used provide for a complex clinical data set, against which no finite conclusions can be drawn. Nonetheless, particular patterns and associations seem to be emerging from this and earlier work, among which the association between performance IQ and slow wave activity (SWA) during non–rapid eye movement (NREM) sleep is perhaps the strongest one.[45,48] It has been argued that cognitive improvements in treated OSA patients may reflect increased stability of brain activity during sleep, allowing crucial synaptic repair and maintenance to occur and counteracting toxic effects of arousal and hypoxic effects of OSA.[45,49] This argument is concordant with findings showing that the neurochemical and gene environments of sleep and sleep activity patterns present crucial window periods during which the brain can restore cellular homeostasis, increase signal-to-noise ratio, and reinforce neuronal circuitry for subsequent cognitive processing demands.[12,50,51]

PROPOSED MECHANISTIC ROLE FOR PERTURBED SLEEP IN PATIENTS WITH OBSTRUCTIVE SLEEP APNEA

Sleep and sleep deprivation alter molecular signaling pathways that regulate synaptic strength, plasticity-related gene expression, and protein translation in a bidirectional manner.[51] Moreover, sleep deprivation can impair neuronal excitability, decrease myelination, and lead to cellular oxidative stress and misfolding of cellular proteins.[51,52] Frequent brief awakenings lead to fragmented sleep that negatively affects the next day's cognitive and emotional functioning, in a manner similar to that of total sleep deprivation.[2] Several studies have attempted to assess whether OSA patients are more vulnerable to sleep-loss-induced performance deficits, with special emphasis on driving performance variables, with varied results.[53-56] From the practical point of view it is of major interest to develop reliable and practical bedside tests to help clinicians advise patients on their individual risk for traffic accidents.[13] Preclinical animal studies suggest that sleep fragmentation independently affects similar brain regions to those affected by intermittent hypoxia, as occurs in OSA.[8] Also, clinical studies of the effects of sleep deprivation on cognition in the general population suggest comparable cognitive impairments to those seen in OSA.[57] Frequent partial arousals during sleep in OSA patients contribute to abnormal sleep architecture and symptoms of excessive daytime somnolence (i.e., sleepiness).[8,9] An independent association between excessive daytime somnolence and cognitive impairment has been demonstrated, and several prospective studies have shown that excessive daytime somnolence is associated with an increased risk for cognitive decline and dementia.[1] Further, in a prospective cohort study of Japanese American men in the Honolulu-Asia Aging Study, lower nocturnal oxygenation and reduction in stage 3 (slow wave) NREM sleep were associated with the development of microinfarcts and brain atrophy.[58] Conversely, men with longer slow wave sleep time showed slower cognitive decline.[58]

The relationship between OSA and its effect on selected sleep stages merits particular attention, given that each of the sleep stages, with its attendant alterations in neurophysiology, is associated with facilitation of important functional learning and memory processes[12] (also see Chapter 22). In OSA patients, the proportion of stage 2 NREM sleep (N2) has been shown to be increased, whereas proportions of stages 1 and 3 NREM sleep (N1, N3) and rapid eye movement (REM) sleep are decreased.[43] Limited experimental studies conducted to date have shown specific impairments of sleep-dependent consolidation of verbal declarative information in patients with OSA.[59] Furthermore, several recent clinical studies suggest disturbed spatiotemporal evolution of sleep spindles in patients with OSA during the night.[60,61]

However, dynamic analysis of sleep architecture is required to fully gauge the neurophysiologic effect of sleep fragmentation on sleep in OSA patients.[13] For example, in one study of mild OSA the exponential decay function of SWA was demonstrated to be significantly slower in OSA patients compared with controls.[62] This was due to the more even distribution of SWA throughout the night, without significant decrease in total slow wave and REM sleep time. These results show that mild sleep fragmentation can alter the dynamics of SWA, without significantly decreasing the amounts of slow wave and REM sleep, and emphasize the need to perform SWA decay analysis in sleep fragmentation disorders.[62] In the same study, a decrease in spindle activity was observed in N2 and N3 sleep that was not attributed to an increase of SWA.[60,62] Such a reduction in total spindle density has also been reported in sleep maintenance insomnia and is likely to be related to sleep fragmentation.[60-62]

The model proposed by Landmann and colleagues[63] suggests an integrative framework for the qualitative reorganization of memory during sleep.[63] It further builds on studies that have shown that sleep facilitates the abstraction of rules and the integration of knowledge into existing schemas during slow wave sleep.[50,51,63] REM sleep, on the other hand, has been shown to benefit creativity that requires the disintegration of existing patterns.[63] Both respective sleep stages have been commonly reported as reduced or fragmented in patients with OSA, and their dysregulation could underlie some of the frequently reported cognitive and performance deficits in OSA patients.[27,43] In line with this argument, one study that investigated the neurocognitive deficits in OSA found that the number of microarousals during the night was the best predictor of episodic memory deficit.[64] Traditionally, obstructive events during NREM sleep have been viewed as associated with greater cognitive deficits or impaired quality of life, whereas REM sleep events have been shown to be associated with greater sympathetic activity, arterial hypertension, and cardiovascular instability in patients with OSA.[65,66] Recently, the role for fragmented REM sleep in spatial navigational memory in OSA patients has been addressed with a physiologically relevant stimulus.[67] During this study, patients spent two different nights in the laboratory, during which they performed timed trials, before and after sleep, on one of two unique three-dimensional spatial mazes.[67] Normal consolidation of sleep was achieved with use of therapeutic CPAP throughout the first night, whereas during the second night CPAP was reduced only during the REM stages. Patients showed improvements in maze performance after a night of normal sleep, but those improvements were significantly reduced following a night of isolated REM disruption, without changes in psychomotor vigilance. Noted cognitive

improvements were positively correlated with the mean REM run duration across both sleep conditions.[67]

It has been argued that the sense of excessive daytime sleepiness and of feeling unrefreshed in the morning in some OSA patients could be due to the inability to augment NREM SWA or REM sleep. Moreover, in some OSA patients, reduction of REM sleep can lead to dissociation of REM traits with other sleep stages, further affecting critical sleep windows for memory formation and consolidation.[12] Equally, it has been shown that when high homeostatic demands are not fully met during sleep, in the subsequent wake period microsleeps can occur in highly active regions of the brain[68] and can lead to concomitant disability for the function subserved by that region.[50,68] To what degree this takes place in OSA patients and whether this also contributes to attention-vigilance dysfunction and the higher frequency of traffic accidents noted for this patient group are yet to be fully defined.[13] Previously reported retarded SWA decay throughout the night, even in patients with mild OSA, further supports the notion of nonrestorative sleep in OSA.[62]

Several recent studies have aimed to discern the role of sleep in cognition and cognitive decline, with potential effect on the way we consider sleep in patients with OSA. For example, as depicted in Figure 117-3, *A*, it has been suggested that the amount of atrophy in the medial prefrontal cortex (mPFC), predicts the extent of disrupted slow wave (N3) sleep in older people, and consequent impaired overnight episodic hippocampal memory consolidation.[51,69] The mPFC area has been shown to be independently affected by OSA (see Figure 117-1) and has been known to be involved in the generation of slow waves.[13,69] It has been proposed that improving slow wave sleep in older adults (irrespective of their OSA status) may represent a novel treatment for minimizing cognitive decline in later life.[69]

The importance of sleep spindles in cognition has also gained interest over the past several years.[13,70] It has been shown that, during the night, OSA patients, unlike healthy controls, display a significant proportion of slow spindles in the frontal, central, and parietal regions.[60] One recent study has shown that older adults who express fewer prefrontal fast sleep spindles also exhibit a proportional impairment in hippocampal functioning during the subsequent wake periods and, with that impairment, a deficit in the ability to form new episodic memories.[71] Fast sleep spindles represent part of a coordinated NREM sleep–dependent memory mechanism, and it is thought that hippocampal sharp-wave ripples provide feedback excitation, which initiates neuroplasticity in spindle-activated cortical neurons.[51] Relative to slow sleep spindles, fast sleep spindle activity is associated with greater hippocampal activation and greater hippocampal-cortical functional connectivity.[2,71] The sleep architecture of even mild OSA patients shows a high degree of sleep fragmentation, which results in a different time course of SWA and a decreased sleep spindle index compared with controls.[62] Whether this deregulated spindle formation and activity present another contributory facet to cognitive complaints in patients in OSA, however, remains a conjecture at this point. Nonetheless, taken together, these studies suggest a possible role for OSA-induced brain injury in the acceleration, or even initiation, of cognitive decline in older adults (see Figure 117-3, *A*).[1-3,31,69] The exact pathophysiology of such an association remains elusive.[13]

Mental Health and Sleep Associations in Obstructive Sleep Apnea Patients

A bidirectional relationship between sleep and the function of the brain circuitry involved in emotions is increasingly supported by studies that further build on long-standing clinical observations of co-occurring mood and sleep disorders.[13,72] Unsurprisingly, then, a variety of mental health issues, such as affective disorders, emotional lability, and depression, have been reported as highly prevalent in individuals with OSA, with some studies reporting that up to 63% of OSA individuals are so affected[73] despite considerable heterogeneity and a high risk for bias in these studies.[13] Evidence from various studies is particularly suggestive of a role for REM sleep in selective emotional memory processing and sleep-dependent emotional memory depotentiation (see Figure 117-3, *B*).[72] Moreover, REM sleep is suggested to play a role in recalibrating the sensitivity and specificity of the brain's response to emotional events, both positive and negative.[72] This recalibration effect likely occurs, at least in part, as a result of modulation of noradrenergic brainstem activity and the responsive profiles of the amygdala and mPFC, two regions critically involved in detecting emotional salience.[13,72]

Of the psychiatric disorders, the evidence for increased prevalence of OSA is particularly strong in major depressive disorder and posttraumatic stress disorder (PTSD),[74,75] both independently associated with REM sleep disturbance.[13] Even though the causal relationship between these affective disorders and OSA is unclear and is likely to be multifactorial, the potential sleep mechanics of their interaction is worthy of further consideration.[13] PTSD is independently associated with decreases in the total time spent in REM sleep. It is also associated with marked fragmentation of REM sleep, indicative of arousal-related awakenings from REM sleep linked to adrenergic surges.[72] CPAP adherence has been shown to be reduced in veterans with PTSD and comorbid OSA.[74] Based on the current knowledge of OSA-induced sleep deficits, it can be argued that in PTSD patients with comorbid OSA, the additive effect of sleep disturbances associated with the OSA can further impair the quantity and quality of REM sleep. This would likely also affect the REM noradrenergic "housekeeping" function because it has been shown that REM sleep reduces, and thus likely restores, concentrations of CNS noradrenaline to baseline, allowing for optimal awake state functioning.[13,72] More specifically, several studies suggest that quiescence of locus coeruleus activity, a brainstem structure that is a source of noradrenergic input, during REM sleep throughout the night restores the appropriate next-day tonic-phasic response specificity within the emotional salience network (e.g., locus coeruleus, amygdala, mPFC).[72] It is hence feasible that OSA-induced REM fragmentation could further aggravate the hyperadrenergic state of some PTSD patients and lead to decreased connectivity between the PFC and amygdala and thus exaggerated amygdala reactivity.[72] The functional outcome may be an aggravated disease course and worse prognosis.[13,72] Of note, in the prospective Honolulu-Asia Aging Study, in which men (n = 3801) aged 71 to 93 years at baseline (1991) were followed until their death, higher nocturnal oxygenation during REM sleep was associated with less gliosis and neuronal loss in the locus coeruleus.[58]

Major depression, on the other hand, is associated with exaggerated REM sleep qualities and deficiency in

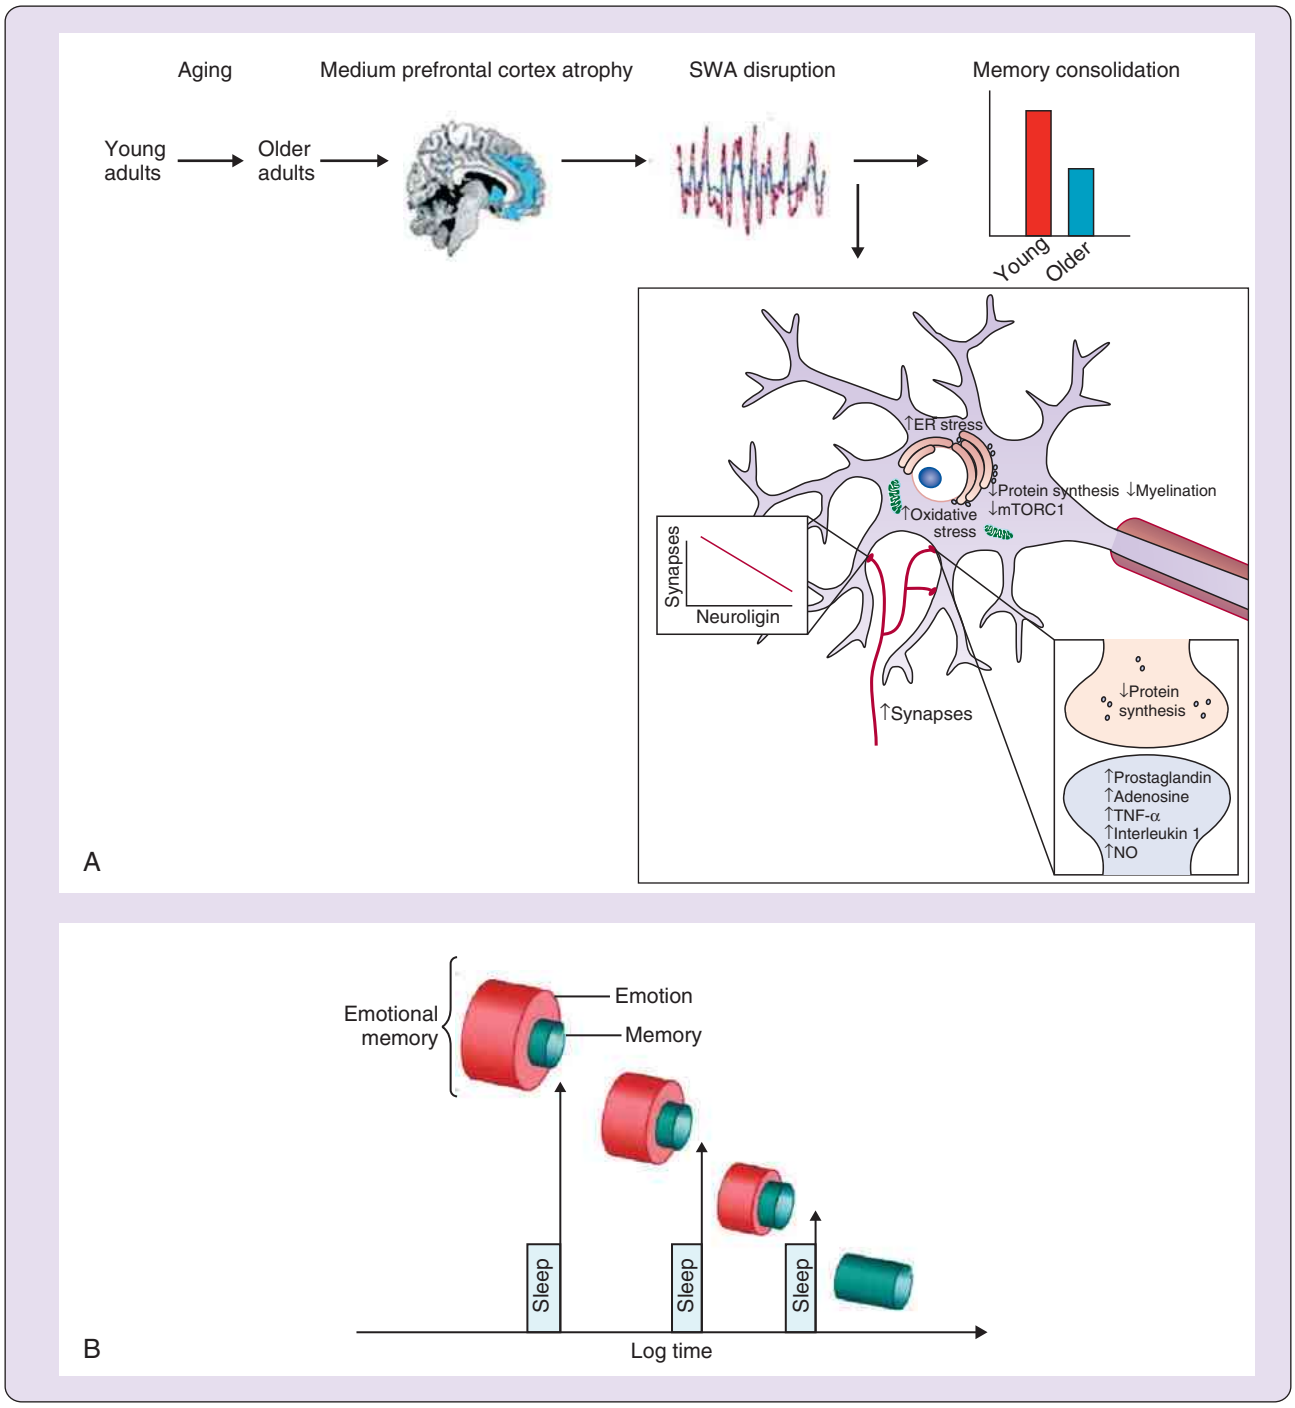

Figure 117-3 The proposed role for sleep in cognition and emotions. **A,** *Cognitive sleep:* Sleep apnea and aging can independently cause gray matter atrophy in the prefrontal cortex. Atrophy can mediate the degree of slow wave activity (SWA) disruption, whereas SWA in turn can mediate the degree of impaired memory retention.[69] SWA activity disruption likely also leads to cellular stress.[52] **B,** *Emotional sleep:* Conceptual schematics of "the sleep to forget and sleep to remember" model are shown, as described by Goldstein and Walker.[72] Over one or several nights and numerous repetitions of this REM mechanism, sleep transforms an emotional memory into a memory of an emotional event that is no longer emotional.[72] ER, Endoplasmic reticulum; IL-1, interleukin-1; mTORC1, mammalian target of rapamycin contact 1; NO, nitric oxide; TNF-α, tumor necrosis factor-α. (From Rosenzweig I, Glasser M, Polsek D, et al. Sleep apnoea and the brain: a complex relationship. *Lancet Respir Med* 2015;3:404–14.)

monoamine activity.[72] The bidirectional-dual relationship between major depression and OSA has been suggested by findings of several studies.[31] In some OSA patients, fragmented REM sleep can precipitate a vicious cycle of impaired REM regulation and rebound REM augmentation.[13] This, along with concomitant changes in neurotransmitter systems caused by hypoxemia, could further lead to reduced monoamine activity, with associated increased negative rumination and ensuing depression, in genetically predisposed individuals.[13] Through its effects on REM sleep, comorbid OSA might

also lead to dysfunctional consolidation and depotentiation of emotional memory from prior affective experiences.[13,72] It has been proposed that this may result in a condition of chronic anxiety within autobiographic memory networks (see Figure 117-3, *B*).[72] In support of this recent meta-analysis of randomized controlled trials of treatment of OSA, a significant improvement in depressive symptoms was reported.[76]

Even though the previously argued theoretical constructs of a bidirectional relationship between fragmented or disturbed sleep in OSA and psychiatric disorders are indirectly supported by animal and neuroimaging studies of sleep,[72] the underlying mechanics are likely to be more complex and, as such, require further well-designed studies.[13]

NEUROINFLAMMATION AND ISCHEMIC PRECONDITIONING

Cognitive and emotional complaints of OSA patients may also be explained by oxidative and neuroinflammatory effects of OSA on the CNS emotional salience network.[10,13,31] In OSA, repetitive occlusions of the upper airway lead to intermittent hypoxia and recurrent hypoxemia, typically characterized by short cycles of hypoxemia and reoxygenation.[20] However, the patterns vary greatly among patients, and, depending on the idiosyncratic characteristics of each individual, the end results might be either adaptive or maladaptive.[20] The outcome will likely depend on the dynamic interplay between the specific type and amount of reactive oxygen-nitrogen species produced, duration and frequency of such production, the intracellular localization, and microenvironmental antioxidant activity.[11] Additional interplay depends on factors such as genetic makeup, nutrition, and other lifestyle-related variables, all of which affect the redox status.[11,20] A variety of studies to date suggest that the severity of hypoxia, its duration, and its cycle frequency are fundamental determinants of outcomes (Figure 117-4, *A*).[77,78] For example, it has been generally acknowledged that short, mild, and lower cycle frequencies of intermittent hypoxia may generate beneficial

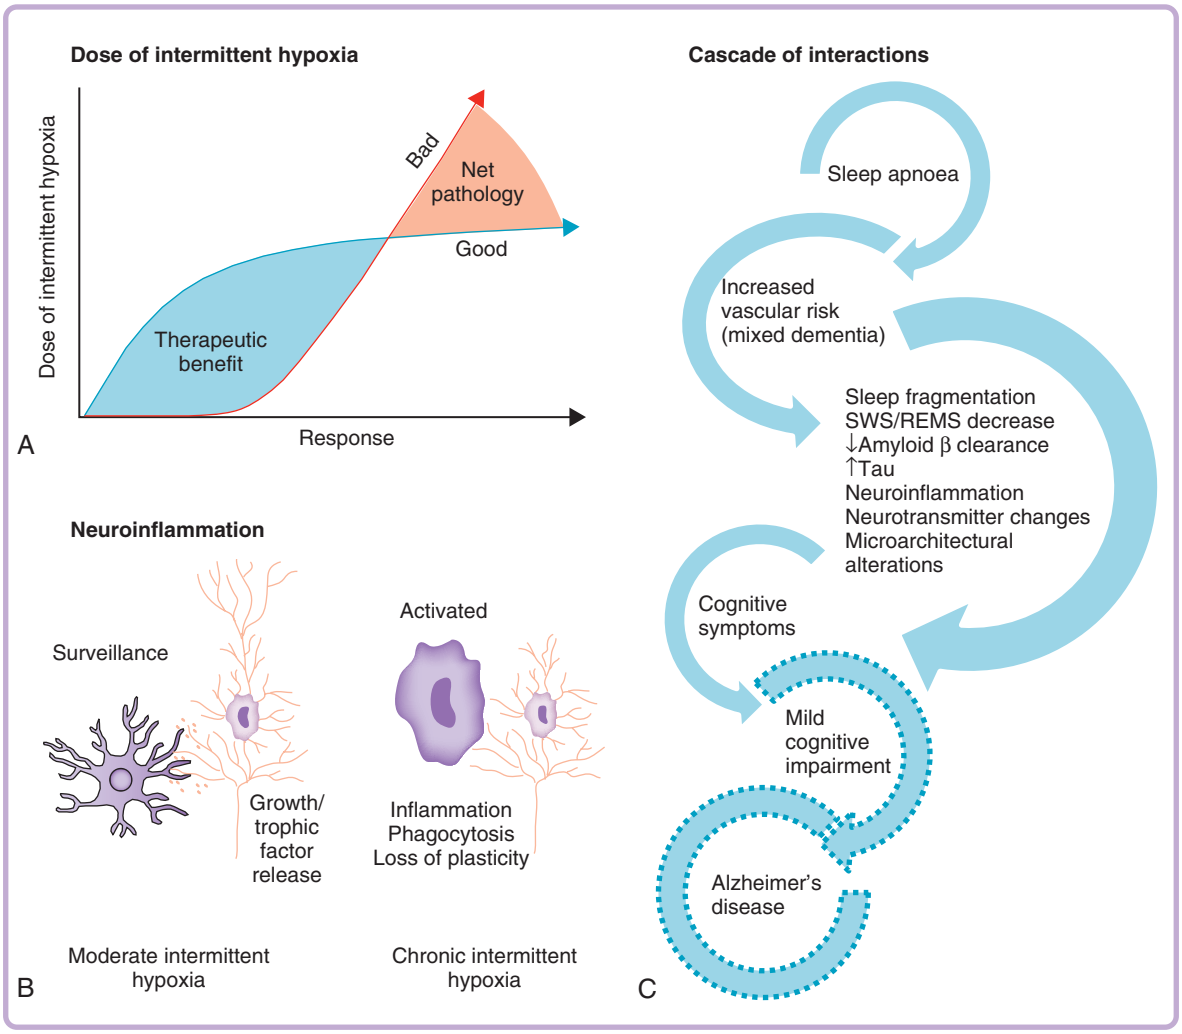

Figure 117-4 Adaptive and maladaptive processes induced by intermittent hypoxia. **A,** Conceptual presentation of the net effect of cycles of intermittent hypoxia, of varied length and frequency, over a period of time (minutes to days to weeks), as described by Dale and colleagues.[78] High doses still elicit neuroadaptive mechanisms, but the balance is shifted and maladaptive processes such as neuroinflammation **(B)** are likely to be instigated. Finding an optimal dose is key to developing effective treatment.[78] **C,** Possible cascade of interactions between sleep apnea and Alzheimer disease. (From Rosenzweig I, Glasser M, Polsek D, et al. Sleep apnoea and the brain: a complex relationship. *Lancet Respir Med* 2015;3:404–14.)

and adaptive responses in the brain, such as ischemic preconditioning.[20] Conversely, chronic, moderate to severe, and high-frequency intermittent hypoxia can induce maladaptive disruption of homeostatic mechanisms, leading to dysfunction and sterile neuroinflammation.[11,20]

Ischemic preconditioning represents a generalized adaptation to ischemia by a variety of cells.[21,79] In OSA, induction of ischemic preconditioning is thought to be due to the activation of several gene programs, including the hypoxia inducible factor-1, vascular endothelial growth factor, erythropoietin, atrial natriuretic peptide, and brain-derived neurotrophic factor.[80,81] Various end mechanisms and pathways have been shown to play a role in preconditioning, including those of long-term facilitation of phrenic motor output, chemoreflex activation, vascular remodeling, neo-angiogenesis, productive autophagy, reactive gliosis, various synaptic alterations, and modulation of adult hippocampal neurogenesis.[11,82,83] CPAP treatment of OSA has been shown to partially reverse structural imaging changes in gray matter of hippocampal regions and to ameliorate some of the associated cognitive deficits, possibly also by modulating adult neurogenesis.[84] In a recent neuroimaging study, coexistence of hypotrophic and hypertrophic changes in the brain of OSA patients was taken to reflect the evolving nature of OSA-associated brain injury.[36] It has been proposed that at any given time ongoing maladaptive neuroinflammatory processes likely exist alongside adaptive mechanisms of increased brain plasticity and ischemic preconditioning.[13] As a corollary to these findings, in a recent study that compared the cognitive performance of patients with high and low levels of OSA-related hypoxemia, controlling for demographic factors and other aspects of OSA severity, an unexpected advantage of higher levels of hypoxemia on memory was demonstrated in a carefully matched clinical cohort.[85]

Several studies also suggest that, under certain conditions, intermittent hypoxia can increase immune defenses without exacerbating inflammation.[11,20] Moreover, in animals, short-lasting hypoxic exposures mimicking OSA have been associated with recruitment of bone marrow–derived pluripotent stem cells, which exhibited upregulation of stem cell differentiation pathways, particularly involving CNS development and angiogenesis.[20]

Another powerful central neuroprotective adaptive mechanism for ischemic events has been demonstrated following the activation of the intrinsic neurons of the cerebellar fastigial nucleus.[86] Neurostimulation of these nuclei appears to provide "protective" reduced excitability of cortical neurons during subsequent ischemic episodes and to lead to reduced immunoreactivity of cerebral microvessels.[10] Also, a "compensatory" entraining of cerebellum by hypertrophic hippocampi has been proposed to occur in some younger patients with mild OSA.[36] Although there are no direct monosynaptic anatomic connections between hippocampi and cerebellum, their connectivity is thought to be important for the control of movement under states of heightened emotion and novel conditions and for associative learning.[10,13] Failed adaptation of cerebellar networks to injury, of any etiology, has been shown to lead to cognitive deficits and hyperactivity, distractibility, ruminative behaviors, dysphoria, and depression in some patients.[10,32]

Neuroinflammation in Obstructive Sleep Apnea

There are, however, relevant maladaptive effects of intermittent hypoxia.[13] These include neuroinflammation, and although the exact neurocellular sources for associated processes are still incompletely defined, activation of astroglia is likely to be important.[11,13,78] In addition, oligodendrocytes, myelin-producing cells of the CNS, have been shown to be selectively sensitive to hypoxia and sleep fragmentation.[87,88] The subsequent loss of buffering functions can ultimately contribute to pathologic processes, such as increased glial proliferation and microglial activation (see Figure 117-4, *B*).[13,78] Astroglial and microglial cells play critical roles in regional blood flow regulation and inflammatory processes in the brain, as well as critical coordination of bioenergetics through lactate transport.[78] Under normal conditions, microglia in the healthy CNS exhibit a surveillance phenotype that synthesizes and releases neuroprotective growth and trophic factors.[78] However, severe and prolonged hypoxia can activate microglia toward a toxic, proinflammatory phenotype that triggers pathology, including hippocampal apoptosis, impaired synaptic plasticity, and cognitive impairment.[78] Neuroinflammation has been shown to independently increase the brain's sensitivity to stress, resulting in stress-related neuropsychiatric disorders, such as anxiety and depression.[13,89] Dynamic changes in transcription of inflammatory genes have been demonstrated following exposure to intermittent hypoxia.[13,78] Increased prostaglandin E_2 neural tissue concentrations have also been demonstrated in hippocampal and cortical regions accompanied by lipid peroxidation of polyunsaturated fatty acids.[78] Similarly, it has been shown that increased carbonylation- and nitrosylation-induced oxidative injury emerges in susceptible brain regions following exposure to intermittent hypoxia and promotes excessive daytime somnolence.[11,78] Recently, toll-like receptor 4 (TLR4) expression and activity have been demonstrated to be increased on monocytes of patients with OSA.[90] Similarly, ligands for TLR4 have been shown to be increased in the serum of children with OSA.[13,90] The microglia of the cortex and brainstem exhibit TLR4 expression after chronic intermittent hypoxia, when it is postulated to play a region-specific and differential (adaptive or maladaptive) role.[13,90] This finding is of particular interest because TLR4 has also been strongly implicated in several inflammatory and neurodegenerative disorders, including vascular dementia and Alzheimer disease.[90] In cognitively healthy adults, intermittent hypoxia has been correlated with increases in phosphorylated and total tau and amyloid β^{42} concentrations in cerebral spinal fluid, key components of Alzheimer pathology.[1,13] Similarly, cerebral amyloidogenesis and tau phosphorylation, along with neuronal degeneration and axonal dysfunction, have been demonstrated in the cortex and brainstem of animals exposed to intermittent hypoxia.[2] Taken together, these findings support the role for neuroinflammatory processes in cognitive and emotional deficits of OSA patients. They further suggest a close association between hypoxemia-induced maladaptive processes and dementia (see Figure 117-4, *C*).[13]

NEUROLOGIC DISORDERS AND COGNITIVE AND PERFORMANCE DEFICITS ASSOCIATED WITH OBSTRUCTIVE SLEEP APNEA

Several neurologic disorders have been associated with OSA.[10] For example, adults with epilepsy appear at increased risk for OSA.[91] Conversely, OSA is a recognized independent risk factor for stroke.[10] OSA has been associated with seizure

exacerbations in older adults with epilepsy, and treatment with CPAP may represent an important avenue for improving seizure control in this population.[10,92,93] OSA-induced brain injury is believed to exacerbate neural damage during incident stroke as well as to increase the risk for a subsequent stroke.[94,95]

Additionally, an increasing body of evidence from animal studies suggests that cerebral amyloidogenesis and tau phosphorylation, two cardinal features of Alzheimer disease, can be triggered by intermittent hypoxia.[2] Intermittent hypoxia and associated generation of reactive oxygen species, known to occur during nocturnal apneic episodes, have been shown to initiate neuronal degeneration and axonal dysfunction in the cortex and brainstem of animals.[2,10] Also, oligodendrocytes, myelin-producing cells of the CNS, are selectively sensitive to hypoxia and sleep fragmentation.[10,88] However, it is not clear to what extent this particular vulnerability contributes to the widely reported hypotrophic white matter changes in the brains of some OSA patients, including the fornices and corpus callosum.[10,96,97] Impaired learning capabilities have been documented in children with OSA, along with increased hyperactivity and incidence of attention deficit disorders.[8] On the other end of the age spectrum, as noted earlier, several clinical studies have suggested that older patients with OSA might suffer accelerated brain atrophy, cognitive decline, and the onset and severity of dementia.[77,98,99]

It has been estimated that approximately 80% of OSA patients complain of both excessive daytime sleepiness and cognitive impairment, and half also report personality changes.[34] However, the exact prevalence of neurocognitive deficits in patients with OSA remains unknown. One in four patients with newly diagnosed OSA has appreciable neuropsychological impairments.[34,100] Various studies suggest that memory impairments can be found in up to 9% of OSA subjects; 2% to 25% have problems with sustained attention, and 15% to 42% demonstrate difficulties with executive functioning.[34,101] Moreover, the increased frequency of work-related and traffic accidents in OSA patients may be taken as a surrogate indicator of neurobehavioral performance deficits.[34,102,103] Patients with OSA are 37 times more likely to complain of sleepiness compared with nonsnoring healthy controls. Work limitation in terms of difficulties with time management, mental tasks, interpersonal relationships, and work output have all been associated with excessive daytime sleepiness.[34] OSA patients are 7.5 times more likely to have difficulties with concentration at work, have a ninefold increase in difficulty learning new tasks, and are 20 times more likely to have problems performing monotonous tasks.[34,104] In addition, occupational accidents have been reported to occur in 50% of male OSA patients, whereas the risk for occupational accidents in women with OSA has been reported as six times greater than in controls.[34,102,105]

Of particular note is the finding that motor vehicle drivers, regardless of OSA status, do not always perceive their impairment and continue to drive while sleepy.[34,106] Overall, compared with normal controls, OSA patients are 2 to 13 times more likely to experience a driving-related traffic accident.[107] Such accidents are more likely to occur in those who manifest greater daytime sleepiness.[34,107] However, OSA has also been associated with motor vehicle crashes independent of daytime sleepiness.[108] Sleepiness due to work schedules and sleepiness due to OSA are independent risk factors for accidents.[34]

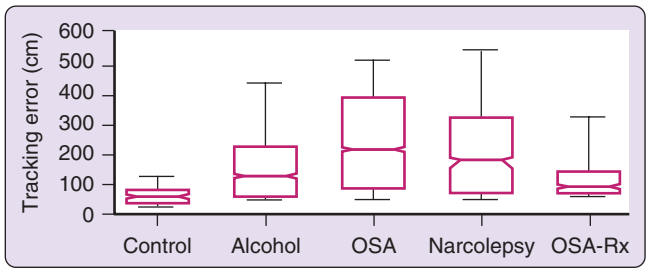

Figure 117-5 Summary of tracking errors in different groups on the Divided Attention Driving Task. OSA, Obstructive sleep apnea. (From George CF. Vigilance impairment: assessment by driving simulators. *Sleep* 2000; 23[Suppl. 4]:S115–18.)

For example, in commercial vehicle drivers, in whom both of these sleepiness-promoting conditions coexist, those with the highest level of sleepiness have a twofold increase in multiple accidents.[109] The data for OSA and automobile crashes are numerous and consistent: as a group, OSA patients' risk for motor vehicle collisions is increased twofold to fourfold (Videos 117-1 and 117-2).[34] On driving simulators, OSA patients hit more obstacles, have increased error in tracking and visual search, have increased response time to secondary stimuli, and drive out of bounds more times compared with non-OSA control subjects (Figure 117-5).[110] Still, not all OSA patients who drive have accidents, and as many as two thirds never have a collision.[106,110] A means to identify OSA patients at greatest risk for motor vehicle collisions is still not clear based on available literature, and this complicates decision making from a medical and legal perspective.[34]

ASSESSMENT OF COGNITIVE AND NEUROBEHAVIORAL PERFORMANCE DEFICITS IN OBSTRUCTIVE SLEEP APNEA

To understand the cognitive and neurobehavioral performance deficits that affect patients with OSA, it is helpful to consider these from a categorical perspective.[34] The effects of sleep loss on performance include changes in cognitive performance, difficulty with working memory, slowing of response or inability to sustain attention across the duration of the task, declines in best effort or fastest response, lapses, and false responses.[34,111] As noted earlier, in OSA, hypoxemia-reoxygenation cycles with attendant biochemical and cellular alterations cause dysfunction of the prefrontal cortex, among other CNS regions.[34] This results in impaired executive function manifesting as false responses, problems with working memory and contextual memory, problems with cognitive processing in addition to deficits in the pattern of responses, and self-regulation of affect and arousal.[33,34] A description of the performance deficits and commonly used assessment techniques in OSA patients is given in Box 117-1.[34] Tests that can readily be performed in the clinical setting include the Digit Symbol Substitution Task (90-second test) to assess cognitive processing and the Psychomotor Vigilance Task (10-minute task) to evaluate the ability to sustain attention.[34] Summary information regarding the neurobehavioral tests may be found elsewhere.[112] The effects of OSA on cognitive processing, memory, sustained attention, and executive and motor functioning are further shown in Figure 117-6, which reports the effects of OSA in patients relative to healthy adults.[34]

Box 117-1 DEFINITION AND ASSESSMENT OF COGNITIVE AND NEUROBEHAVIORAL DEFICITS ASSOCIATED WITH OBSTRUCTIVE SLEEP APNEA

Cognitive Processing

Behavior

Decreased ability to digest information
- Slowing on task
- Increased errors
- Decline in total number correct and/or completed per unit of time

Measures Commonly Used to Assess Deficit

Self-paced tasks of short duration (1 to 5 minutes), including arithmetic calculations, communication, or concept attainment
- Paced Auditory Serial Addition Task (PASAT)
- Trail Making Test Parts A and B: sequencing numbers (A) or letters and numbers (B)
- Category Test: six sets of items organized around different principles with a seventh set comprising previously shown items
- Digit Symbol Substitution Test: supplying matching symbol given the corresponding number
- Digit Backward: stating verbally provided numbers in reverse order
- Letter Cancellation: cancellation of target alphabets from presentation of randomized alphabets

Memory

Behavior

Decreased ability to register, store, retain, and retrieve information

Measures Commonly Used to Assess Deficit

Short-term memory: timed tasks of up to 10 minutes that require free recall of words, numbers, paragraphs, or figures
- Probed, Recall Memory Task (words)
- Digit Span Forward (numbers)
- Wechsler Memory Scale Story Task (paragraph)
- Rey Auditory-Verbal Learning Test (figure)

Long-term memory: presenting the subject with lists of items that are longer than the seven-item memory capacity
- California Verbal Learning Test

Procedural memory: gradual acquisition and maintenance of motor skills and procedures
- Mirror Tracing Task
- Rotary Pursuit Task

Sustained Attention or Vigilance

Behavior

Inability to maintain attention over time.
- Slowing of response time (time on task)
- Increased errors
- Reduction in the fastest optimal response times
- Periods of delayed or no response (lapses)
- Response to stimuli when none presented (false responses)

Measures Commonly Used to Assess Deficit

Short-duration tasks (30 minutes)
- Psychomotor Vigilance Task (PVT)
- Four Choice Reaction Time Test
- Steer Clear
- Continuous performance tests

Divided Attention

Behavior

Inability to respond to more than one task or stimuli, such as with driving

Measures Commonly Used to Assess Deficit

Divided Attention Driving Test (DADT): mimics vigilant-related behavior essential to driving
- Tracking (the ability to stay within the driving lane)
- Visual search (looking for and avoiding obstacles, traffic lights, etc.)

Executive Functioning

Behavior

Problems with manipulating and processing information
Inadequate planning and execution of plans
Disorganization: poor judgment, decision making
Inflexible: emotional liability
Impulsivity
Difficulty maintaining motivation

Measures Commonly Used to Assess Deficit

Volition component or intentional behavior
- Assessed by asking the patients' preferences, what they like to do, or what makes them angry

Planning component
- Porteus Maze Test
- Tower Tests: Tower of London, Tower of Toronto, Tower of Hanoi
- Wisconsin Card Sorting Test

Purposive action
- Tinkertoy Test

Effective performance
- Random Generation Task

Modified from Dinges D. Probing the limits of functional capability: the effects of sleep loss on short-duration tasks. In: Broughton R, Ogilvie R, editors. *Sleep, arousal, and performance*. Boston: Birkhauser; 1992. p. 177–188.

An additional issue to consider when assessing patients with OSA is their subjective cognitive and emotional complaints.[13] A detailed analysis of important studies in the field has suggested only a weak correlation between (subjective) cognitive complaints in patients with OSA and their objective cognitive functioning.[13,113] Divergent results of subjective versus objective complaints have been recognized in other medical populations, and several possible explanations for this in OSA patients have been suggested.[13] For example, an insufficient specificity of current tests for deficits documented in OSA is evident and largely acknowledged. Currently used and validated objective tests for cognition are frequently designed to assess deficits found in patients with traumatic brain injury and as such do not specifically assess impairments in OSA-induced brain injury.[13,113] Cognitive domains are not unitary constructs, and only the carefully deconstructed analysis of

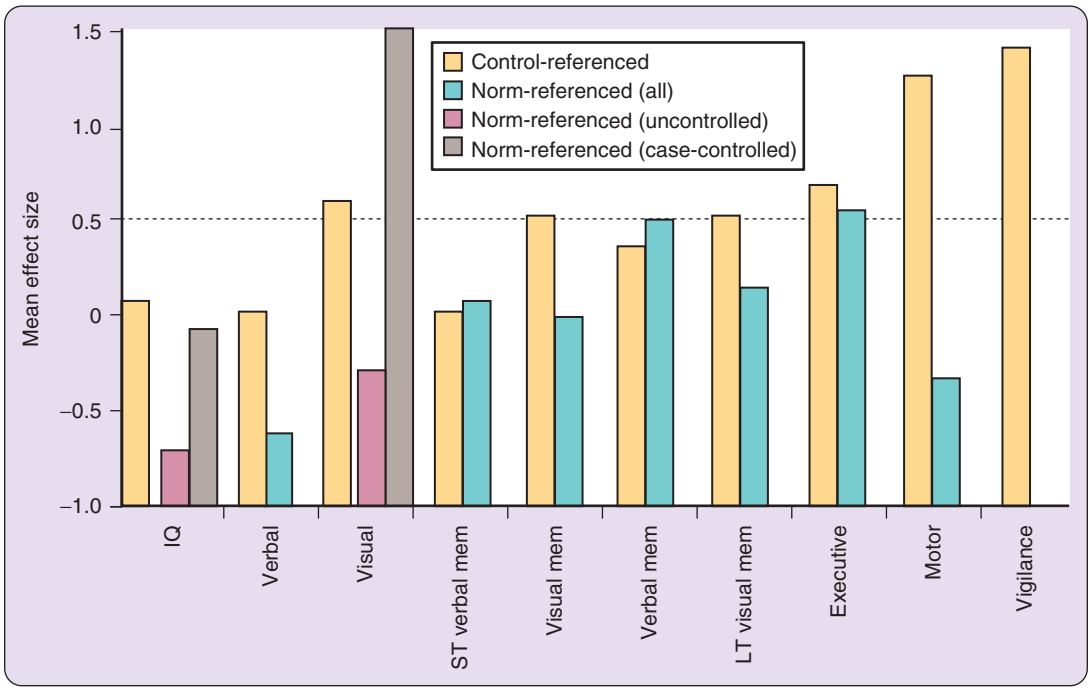

Figure 117-6 **Summary of mean effect sizes across domains and data sets.** Positive values indicate deficits relative to healthy adults, and negative values indicate strengths relative to healthy adults. The data set for moderate intelligence and visual functioning is split into case-controlled and uncontrolled samples for domains where study design (case-controlled versus uncontrolled) moderated the data. ST Mem, Short-term memory; LT Mem, long-term memory. (Modified from Beebe DW, Groesz L, Wells C, et al. The neuropsychological effects of obstructive sleep apnea: a meta-analysis of norm-referenced and case-controlled data. *Sleep* 2003;26:298–307, p. 302.)

their different subcapacities and their vulnerabilities to a range of risks and protective factors specific to OSA can provide a more realistic assessment of an individual's disability.[13,16] Similarly, a number of impairments may be secondary to other symptoms of OSA, such as sleepiness itself, or they can be a sign of psychological distress.[113,114]

To date, subjective cognitive complaints have been largely ignored in randomized controlled trials of treatments for OSA patients. However, given that subjective cognitive complaints are linked to the quality of life, work productivity, and health care utilization of patients, it is important that future studies account for these.[113]

EFFECT OF OBSTRUCTIVE SLEEP APNEA TREATMENT ON ASSOCIATED NEUROCOGNITIVE DEFICITS AND DISORDERS

Nonpharmacologic and pharmacologic treatments for OSA have been shown to improve cognitive outcomes in OSA patient subpopulations, as described in Chapter 114. The results of several meta-analyses suggest that CPAP treatment reduces sleepiness complaints and mood problems and that it improves objective cognitive functioning in OSA patients.[14,15,113,115,116] However, many questions regarding treatment with CPAP, the most pivotal of which are to whom, when, and for how long should CPAP treatment be administered, remain to be clarified.[13] The optimal treatment protocols, likely in combination with other lifestyle or pharmacologic approaches, may only be achieved once the full spectrum of the neuropathology of OSA and its dynamic fingerprinting are understood.[9,10,13] For example, it has been shown that in some treatment-compliant patients, the beneficial effect of CPAP on symptoms of sleepiness and sleep quality can be obtained after only few days of treatment. On the other hand, the effects on other subjective and objective cognitive symptoms are less well defined, and in to provide similar therapeutic effects, much longer duration of treatment may be required.[110,117] Two recent studies suggest that prolonged treatment might in fact be required in patients with severe OSA.[118,119] In one of these, an almost complete recovery of white matter tract pathology in patients with severe OSA was demonstrated in association with significant improvement in memory, attention, and executive functioning, only when 1 year of CPAP adherence was achieved.[118] The functional neuroanatomy of OSA has been highlighted in a study that documented that 3 months of treatment with CPAP improved cognitive function in several domains that corresponded to gray matter volume increases in frontal and hippocampal regions.[84] Most studies investigating treatments for OSA, however, fail to account for incomplete reversal of tissue damage or deficits in cognition, suggesting that early initiation of a prolonged treatment regimen might be necessary to optimize improvements in the neurocognitive disease process associated with OSA.[120-122]

The need for a longer duration of treatment with CPAP in elderly patients compared with younger patients has been suggested by the findings of a small pilot study that found that treatment of severe OSA in Alzheimer disease patients of mild to moderate severity was associated with significantly slower cognitive decline over 3 years.[119] Further, 1 year of CPAP treatment has been shown to improve sleepiness and quality of life in older people with OSA.[19]

Although less striking, limited evidence with drugs such as donepezil, physostigmine, and fluticasone also points to better cognitive outcomes in treated patients, likely necessitating longer treatments.[123,124] Pharmacologic treatment may also be required in patients with OSA who, despite adequate CPAP use, continue to complain of residual sleepiness.[125] It has been suggested that, among the most common explanations for persistent sleepiness in OSA patients, low CPAP compliance, inadequate CPAP titration leading to residual respiratory events and sleep fragmentation, mask or mouth leaks, treatment emergent central sleep apnea, behaviorally induced insufficient sleep syndrome, comorbid psychiatric disorders, sedative medication use, and undiagnosed coexisting sleep disorders predominate.[126] However, it has been recognized that some compliant CPAP users can still experience excessive daytime somnolence even after sleep hygiene improvement, optimization of CPAP treatment, and comorbid disorders management, and those patients are then considered as suffering from true residual sleepiness.[126] Although its pathophysiologic mechanisms remain unclear based on retrospective studies, the prevalence of such residual sleepiness can be estimated at approximately 10%.[126]

In clinical cases in which sleepiness is deemed severe enough to require treatment with an alerting drug, an objective evaluation at baseline should be done. This will allow for proper assessment of vigilance on treatment.[126] Of alerting drugs commonly used in other sleep disorders, modafinil and armodafinil have been shown to have some effects on CPAP-resistant sleepiness[126] (see also Chapter 43). A recent meta-analysis of the effect of modafinil and armodafinil in patients with residual sleepiness suggested improved objective and subjective measures of sleepiness, wakefulness, and patients' perception of disease severity, with overall good tolerance and minimal side effects.[125] Moreover, a trend toward decreased CPAP after treatment with these agents was also observed.[125] Methylphenidate,[126] dexamphetamine, venlafaxine, and atomoxetine are yet to be tested specifically for this indication. Clinical trials of residual sleepiness treatment with histamine-3 receptor agonists are underway and may provide a useful alternative in countries where modafinil and armodafinil are not approved for the treatment of residual sleepiness.[127] Future large prospective studies are required to better define predictive baseline characteristics and possible causal mechanisms for residual sleepiness as well as to inform and guide clinicians in choosing the most appropriate pharmacologic treatments.

CLINICAL PEARLS

OSA is increasingly recognized as one of the potentially modifiable risk factors for cognitive and performance deficits and dementia in adults. During untreated apnea-hypopnea episodes, intermittent hypoxemia, reoxygenation, and hypercapnia or hypocapnia occur, along with sleep fragmentation and changes in cerebral blood flow. These may, independently and in combination, result in cognitive deficits and reduced daytime performance, with functional consequences for work and school efficiency. Clinician awareness of these impairments and their prompt treatment will reduce the burden of illness on the individual patient with OSA as well as the public health risk.

SUMMARY

Patients with OSA demonstrate variable degrees of cognitive and performance deficits. Such deficits are more easily identified in those with more severe OSA.[34] The long-term effectiveness of CPAP with regard to reducing cognitive and performance deficits in patients with mild OSA remains undetermined and needs further exploration.[34] The disruption of normal sleep physiology by OSA has been increasingly recognized as an underappreciated factor regarding such deficits, which, together with hypoxemia and other already recognized factors, may further aggravate age-related memory deficits in patients with OSA.[2,3,69,71] Clinically, this dynamic interplay underscores numerous subjective and objective cognitive and emotional complaints in some patients.[13,31,72] An understanding of the proportional effect of these factors in each individual OSA patient is a major challenge because they typically occur simultaneously and, in all likelihood, target similar neurocircuitry.[13] Persistent deficits, even after prolonged treatment with CPAP in some patients, suggest that early detection of the CNS sequelae in OSA is vital so that appropriate treatment can be administered before irreversible atrophic and metabolic changes occur. However, the optimal timing and duration of treatment and the optimal treatment population are still unclear and must be addressed in future prospective randomized controlled trials.[13] Studies discussed in this chapter strongly suggest that tapping into the therapeutic potential of ischemic preconditioning, while working on ameliorating the acute and chronic effects of neuroinflammation, may offer legitimate therapeutic targets in OSA.[2,11,78] Similarly, although they are in their infancy, studies of clinical approaches that target the sleep disturbance factors of this intricate equation advocate a significant future treatment intervention potential.[13]

Despite the need for more evidence regarding cognitive and performance deficits in community-acquired samples in sham CPAP–controlled studies, there is significant documentation that untreated and CPAP nonadherent OSA patients are at risk for traffic and occupational accidents.[34] Recent findings also raise valid questions about the mechanics of associations between OSA and dementia and further highlight the public health importance of detecting and targeting patients with OSA at highest risk for cognitive decline.

Obstructive Sleep Apnea and Metabolic Disorders

Mary Sau-Man Ip

Chapter 118

Chapter Highlights

- With the common risk factor of obesity, obstructive sleep apnea (OSA) and metabolic disorders often coexist. Obesity itself is considered a metabolic disease. With global escalation of obesity trends, the current and future health care burdens of these conditions are of immense concern.
- OSA produces intermittent hypoxia and sleep disruption, with evidence for downstream cascades of sympathetic activation, oxidative stress, and inflammation—pathways that align with the pathogenetic mechanisms in metabolic disorders.
- Growing epidemiologic and clinical evidence suggests that OSA may modulate metabolic outcomes. The confounding effects of obesity on metabolic disorders have, however, been difficult to dissect. Of greater clinical relevance may be potential synergistic effects between OSA and obesity, mediated partly through exacerbation of adipose tissue dysfunction.
- Animal and cell-based studies, mostly using intermittent hypoxia regimens as a surrogate model of OSA in humans, have provided evidence for deleterious effects on various tissues and cells in the pathogenesis of metabolic dysfunction and have elucidated relevant molecular pathways.
- Despite suggestive data from human observational studies, no definitive evidence has yet emerged to indicate that controlling OSA would result in improvement in metabolic function of significant clinical impact. Future studies need to address the challenges of small heterogeneous samples, diverse methodology for metabolic evaluation, and issues regarding withholding treatment for symptomatic OSA for substantial periods in longitudinal cohort follow-up or in randomized controlled studies.

Sleep modulates body metabolism, and sleep restriction or disturbance can have negative metabolic effects. Although each metabolic disorder has specific pathogenetic pathways, all share common grounds of engagement of hormones, oxidative stress, and inflammation, with obesity as a prevalent phenotypic feature.[1,2] Recurrent obstructed breathing events in obstructive sleep apnea (OSA) characteristically result in repeated cycles of hypoxia-reoxygenation with consequent disruption of sleep architecture, which may trigger downstream cascades that align with the mediating mechanisms for cardiometabolic dysfunction.[3,4] Hence, beyond the common link of obesity in the close partnership between OSA and metabolic disorders, great interest has focused on the potential role of OSA in the causation or aggravation of metabolic dysfunction per se, or in concert with other factors.

The metabolic network is one of intricate cross-talk among various organs, tissues, and cells and their respective signaling pathways. Thus the relationship between OSA and metabolic disorders is unlikely to comprise a set of discrete, one-to-one unidirectional connections but rather can be depicted as a complex network with interplay of various organs and tissues, along with multiple positive or negative feedback mechanisms.[1,2,5] Furthermore, metabolic function is subject to genetic as well as behavioral influences such as dietary intake and physical exercise, and these factors contribute to individual metabolic outcomes in persons with and without OSA.

OBSTRUCTIVE SLEEP APNEA AND METABOLIC DYSREGULATION: PATHOGENESIS AND MECHANISMS

Obesity and Adiposity

With advances in the understanding of adipose tissue biology, fat tissue, which traditionally has been viewed as a storage depot of energy, is now known as an active system with autocrine, paracrine, and endocrine functions, propagating signals to entrain metabolic cooperation of other organs and tissues.[2,5] Under conditions of positive energy balance, fat accumulates, and its distribution is crucial to health outcomes. Visceral fat in particular becomes dysfunctional, with altered nonesterified free fatty acid metabolism which may contribute to hepatic insulin resistance, dyslipidemia, and altered release of adipocytokines which are mediators of dysmetabolism.[2,6] The expansion of adipose tissue with hypertrophied adipocytes may cause cellular hypoxia, and oxidative stress and inflammation, initiating adipose tissue dysfunction.[6] Obesity is thus characterized by a state of chronic low-grade systemic and adipose tissue inflammation, fueling cardiometabolic dysfunction.[5,6,7]

Adiposity holds a unique role in the consideration of links between OSA and metabolic disorders. It is well established that obesity is a major risk factor for various metabolic disorders and a key component of the metabolic syndrome.[2,7]

Furthermore, obesity is now considered a metabolic disease in itself, with many systemic manifestations.[8] Obesity carries major public health impact, and its prevalence is escalating globally.[9] Obesity is the most common risk factor for OSA, although BMI accounts for only a small part of the variability of OSA severity as reflected in the apnea-hypopnea index (AHI), implying a multifactorial nature of OSA pathogenesis.[10] OSA and its severity have been reported to be associated with central obesity (involving the neck, trunk, and abdomen) and abdominal visceral fat, more so than with BMI, particularly in men.[10-12] Apart from affecting breathing mechanics predisposing to upper airway collapse, abdominal fat is a source of the adipokine leptin, which may modulate ventilatory control and upper airway function (see Chapter 120). In parallel, obesity also is the predominant risk factor for metabolic dysfunction. In clinical practice, abdominal obesity, as measured by waist circumference, is recommended as a useful screening tool for metabolic disorders.[13] The accumulation of visceral fat may result in lipid overflow, with further ectopic fat deposition in sites such as skeletal muscle and liver, and promote insulin resistance, whereas in the pancreas, lipid excess may impair insulin secretion.[2]

In OSA, neck fat deposition is considered to be of importance in upper airway dimensions and function, promoting structural narrowing and functional collapse.[10] Neck circumference, an established predictor of OSA, also has been shown to be a novel measure of cardiometabolic risk in the Framingham data.[14] Open to speculation, however, is whether neck circumference was a surrogate marker for OSA in those data in terms of cardiometabolic risk.

Inasmuch as obesity is a common and strong risk factor for both OSA and metabolic disorders, it is not surprising that patients with OSA not uncommonly have metabolic comorbid diseases. The ongoing enigma is whether and to what extent OSA per se is involved in the causation and/or aggravation of various metabolic disorders, including obesity. It is hypothesized that OSA exerts systemic effects on different end organs and tissues, with adipose tissue as one of the targets. With its strategic position in the metabolic network, dysfunctional adipose tissue is likely to play an important role in further metabolic dysfunction in OSA.[15] Additional evidence points to a more adverse metabolic profile even in lean subjects with OSA, compared with those without OSA.[16-18] It is not known, however, if OSA may act as a factor to convert presumably metabolically healthy adipose tissue in nonobese subjects to metabolically unhealthy tissue—a mechanism that has been proposed in metabolic dysgenesis.

It has been speculated that patients with OSA are inherently predisposed to weight gain and may experience difficulty in losing weight compared with subjects without OSA,[19] possibly relating to selective differences in body metabolism regulated by hormones such as insulin, leptin, or ghrelin. Repeated apneic spells and arousals during sleep are associated with excessive daytime sleepiness, which may reduce motivation to engage in physical activity and thereby predispose affected persons to weight gain over time. Furthermore, OSA may promote abdominal obesity through increasing insulin resistance, and/or disturbing sleep quality and quantity. The presence of sleep apnea in men with central obesity was found to attenuate metabolic improvement in response to a lifestyle intervention program, compared with men without OSA.[20]

Insulin Resistance and Glucose Metabolism

The body maintains glucose homeostasis mainly through the action of insulin on various tissues. In type 1 diabetes mellitus (DM), pancreatic beta cell failure of insulin secretion is the key defect, whereas in type 2 DM, which accounts for more than 90% of cases of DM globally, insulin resistance in muscle and liver is the primary pathophysiologic defect. Insulin is secreted in response to an increase in glucose concentration and reduces glucose levels by suppressing hepatic gluconeogenesis and promoting glucose uptake in skeletal muscle and fat. With increasing insulin resistance, pancreatic beta cells respond with a compensatory increase in insulin secretion such that glucose homeostasis and a constant blood glucose level can be maintained. When this compensatory mechanism is deficient or overwhelmed, impaired glucose tolerance and overt DM ensue.[21] Although the origins of insulin resistance can be traced to genetic background, the epidemic of DM is related to the parallel epidemic of obesity and physical inactivity. Insulin resistance is closely but not exclusively linked to visceral obesity, and worsening insulin resistance may further stimulate fat accumulation and encourage ectopic fat deposition.[2]

Insulin also regulates glycogenesis, lipogenesis, and protein synthesis, and insulin resistance may occur in many cells and tissues, within which there may be selective hormone resistance for different pathways.[22] In concert with other mechanisms, insulin resistance predisposes affected patients to endothelial dysfunction, which underlies many cardiometabolic diseases.[23]

In keeping with the common factor of obesity, it is not surprising that OSA is strongly associated with the spectrum of insulin-glucose dysmetabolism. OSA may contribute independently to insulin resistance and glucose dysmetabolism through its pathophysiologic profile of intermittent hypoxia, sympathetic activation, oxidative stress, and inflammation.[3] Such data, are, however, subject to accuracy and variability of research methodology. A variety of methods for the evaluation of glucose metabolism have been deployed in sleep research[24,25] (Table 118-1). To accurately measure insulin sensitivity, it is necessary to use a method that observes in some fashion the metabolic effect of insulin given intravenously. Other methods are simpler to perform, but the results are affected by any degree of beta cell failure.[26,27] Furthermore, findings from epidemiologic or clinical studies are subject to the adequate control of the confounding factors. that are not easy to accurately identify or quantify.

Lipid Metabolism and Dyslipidemia

Lipids, including cholesterol, triglycerides, and others, are transported in the body as lipoprotein complexes in body fluids (plasma, interstitial fluid, and lymph) passing into and out of tissues, and metabolized through exogenous and endogenous pathways. The exogenous pathway operates for dietary lipids absorbed through the gastrointestinal tract, transporting them to the liver and other peripheral tissues, especially fat and muscles. The endogenous pathway refers to hepatic secretion and metabolism of lipoproteins, and their transport to peripheral tissues. As noted earlier, under conditions of positive energy balance, excess fat accumulates in adipose tissue and other organs as ectopic fat.[2,15] Lipid metabolism is regulated by both genetic and nongenetic factors. Secondary changes in plasma levels of lipids occur in a variety of diseases

Table 118-1 Assessment Tools for Glucose Metabolism in Clinical Practice and Research

Test	Brief Methodology	Parameter(s) Measured	Comments
Blood glucose	Fasting venous blood sample for plasma glucose level	Fasting glucose level	Conventional test for diagnosis of DM/impaired fasting glucose
Hemoglobin A_{1c} (HbA_{1c})	Spot venous blood sample for glycated hemoglobin level	Glycemic status over past 2–3 months	Used in clinical practice to assess glycemic control in past 2–3 months in DM HbA_{1c} ≥6.5% is used for diagnosis of DM (ADA/WHO); HbA_{1c} of 5.7%–6.4% is used for diagnosis of prediabetes (ADA) Higher levels predict worse diabetic complications
Oral glucose tolerance test (OGTT)	Oral glucose loading (75 g) followed by evaluation of 2-hour post–blood glucose loading	Impaired glucose tolerance (IGT)	2-hour glucose ≥11.1 mmol/L for diagnosis of DM 7.8–11 mmol/L for diagnosis of IGT
	Oral glucose loading followed by evaluation of glucose every 30 minutes; simultaneous insulin levels measured	Insulin sensitivity	May be reflecting insulin secretion in response to glucose loading rather than insulin sensitivity Poor test reproducibility due to variability of gastrointestinal absorption and other factors
Hyperinsulinemic euglycemic clamp	A dose-response curve for data on exogenous insulin is generated by measuring the variable infusion rate of glucose required to maintain euglycemia	Insulin sensitivity	Gold standard for assessing insulin sensitivity The steady-state rate of peripheral glucose utilization (M value) is measured as milligrams of glucose used per kilogram of body weight per minute Labor-intensive investigation
Homeostasis model assessment (HOMA)	Fasting venous blood sample with glucose and insulin measurements		First derived from epidemiologic studies
	HOMA-IR: insulin (μU/mL) × glucose (mmol/L)/22.5	Insulin resistance: HOMA-IR	Measures basal insulin resistance and insulin secretion
	HOMA-β: [20 × insulin (μU/mL)]/[glucose (mmol/L) − 3.5]	Insulin secretion: HOMA-β	Reflects mainly hepatic insulin resistance
Frequently sampled intravenous glucose tolerance test (FSIGT, FSIVGTT)	Fasting baseline blood glucose (and insulin), followed by frequent sampling after glucose injection (for insulin sensitivity, insulin is injected 20 minutes later) for 3 hours. A computer model describing plasma dynamics (minimal model) is applied for deriving metabolic parameters	Assesses both pancreatic beta cell secretory capacity and peripheral glucose uptake in response to the bolus IV glucose Additional information on insulin sensitivity is gained by administration of insulin 20 minutes after the glucose load	Validated for insulin sensitivity against hyperglycemic euglycemic clamp No need for on-line measurements or external control of infusion Reflects whole-body insulin sensitivity
Short insulin tolerance test (SITT)	Administration of exogenous insulin followed by monitoring of fall in blood glucose over the next 30 minutes, to derive the glucose disappearance rate	Insulin sensitivity	Validated for insulin sensitivity against hyperglycemic euglycemic clamp No need for on-line measurements or external control of infusion

and clinical conditions, including obesity, smoking, insulin resistance, DM, and liver disorders. Obesity is frequently, although not invariably, accompanied by hyperlipidemia. An increase in fat mass is associated with increased release of free fatty acids to the liver, where they are reesterified in hepatocytes to form triglycerides, which are then packaged for secretion back into the circulation.[2] Obesity is a predisposing factor for development of fatty liver, in which disruption of hepatic biosynthesis of lipids occurs.[15]

Dyslipidemia is a major risk factor for atherosclerosis. In the clinical setting, lipids usually are classified as total cholesterol, high-density lipoprotein cholesterol (HDL cholesterol) and low-density lipoprotein cholesterol (LDL cholesterol), and triglycerides. The levels of these parameters have different implications regarding vasculopathy and cardiovascular disease (CVD). Multiple epidemiologic studies have demonstrated a strong relationship between serum cholesterol levels and coronary heart disease, and randomized controlled trials (RCTs) have unequivocally demonstrated that lowering cholesterol reduces clinical events due to atherosclerosis. LDL cholesterol is considered deleterious, whereas HDL cholesterol is believed to be protective, although in fact little evidence exists regarding the benefit of raising HDL cholesterol.[28] Elevated fasting triglyceride levels have not been correlated with significant CVD risk, but it has been suggested that postprandial hypertriglyceridemia may be a bigger CVD risk factor than fasting triglyceride levels.[29]

In the context of these biologic pathways and clinical outcomes, it is clear that the pathophysiology of OSA holds biologic plausibility regarding causation and/or promotion of dyslipidemia through modulation of fat or liver metabolism.

Liver Injury and Related Metabolic Dysregulation

As discussed previously, the liver plays a pivotal role in the regulation of both lipid and glucose metabolism. Obesity is known to result in liver injury as nonalcoholic fatty liver disease (NAFLD), which is another recently proposed addition to the list of disorders for inclusion in the metabolic syndrome.[30] Obesity causes intracellular accumulation of lipids in the liver, designated *hepatic steatosis* in light of the associated histopathologic changes observed. NAFLD ranges in severity from hepatic steatosis (presence of fat in more than 5% of hepatocytes), to steatohepatitis (i.e., nonalcoholic steatohepatitis [NASH]), to liver fibrosis and cirrhosis, and it may be a risk factor for hepatocellular cancer.

Obesity and insulin resistance are major risk factors for NAFLD; conversely, fat accumulation in the liver may cause hepatic insulin resistance with enhanced hepatic glucose production.[30] The reported prevalence of NAFLD varies, ranging between 30% and 100% in obesity and between 10% and 75% in type 2 DM.[31]

Obesity alone, however, does not appear to account for all cases of NAFLD. Although weight loss can significantly improve NASH histologic activity scores, the potential triggers for progression of NAFLD are not fully understood. OSA, possibly through the pathomechanism of intermittent hypoxia may promote the progression of simple steatosis to the more severe forms of NAFLD.[31]

Neurohumoral Activation

The hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system play important roles in energy balance, body metabolism, and the pathogenesis of obesity.[32] Other than exerting a prominent regulatory function on blood pressure, cortisol is an anabolic hormone that promotes insulin resistance and dyslipidemia, whereas catecholamines upregulate hormone-sensitive lipase and increase circulating free fatty acid levels, induce beta cell apoptosis, and adversely affect adipokine profile.

Recurrent asphyxia from obstructed breathing, as occurs in OSA, poses a potent stress to the body, resulting in the so-called "fight or flight" phenomenon. Stress-related neurohumoral activation is a potential mechanistic pathway for metabolic dysregulation in OSA. Animal models of chronic intermittent hypoxia (CIH) demonstrate sympathetic activation contributing to CIH-induced hypertension.[33] Experimental studies in healthy subjects subjected to short-term sleep deprivation, sleep fragmentation, or intermittent hypoxia have demonstrated alterations in hormonal profiles in association with altered glucose metabolism.[34] Sleep fragmentation induced by acoustic stimuli without hypoxia in healthy volunteers resulted in alterations in insulin-glucose metabolism, which were accompanied by alterations in daytime heart rate variability as a marker of sympathetic activation.[35,36] CIH may potentially sensitize the carotid body, contributing to increase in sympathetic nerve activity and increase in blood pressure.[37]

Studies of patients with OSA consistently demonstrate increased muscle sympathetic nerve activity even in the awake state, as well as increased output of urinary catecholamines, although the extent to which obesity itself contributes to such sympathetic activation remains unclear.[38,39] Robust data show that CPAP treatment of OSA can rapidly reduce sympathetic activity, indicating that OSA itself induces sympathetic activation.[40] In a study of subjects undergoing sleep study to investigate suspected OSA, the independent determinants of serum adiponectin levels included insulin resistance and urinary catecholamine levels but not the presence or severity of OSA, suggesting a complex relationship among these pathophysiologic parameters.[41]

The associations between OSA and other hormones from the HPA axis, such as cortisol, are not clear. In a study of obese subjects, despite a lack of difference in baseline cortisol levels between those with and those without OSA, the subjects in the OSA group showed a reduction in heart rate and greater cortisol suppression with dexamethasone after 3 months of CPAP treatment, suggesting that untreated OSA may lead to abnormally high activation of the sympathetic nervous system and HPA axis.[42] Overall, the literature on cortisol status and associated dysmetabolism in OSA has not been abundant or consistent.[43]

Intermittent Hypoxia

Recurrent apneas and hypopneas in OSA generate intermittent hypoxia, which appears to hold a pivotal position in the pathogenesis of metabolic dysfunction in OSA. The chronic if intermittent oxygenation deficit in OSA results in systemic tissue and cellular hypoxia, with a plethora of downstream effects. Mounting evidence suggests that intermittent hypoxia simulates ischemia-reperfusion and can activate oxidative stress and inflammation, which are key pathogenetic pathways in cardiometabolic dysfunction.[1,4]

Intermittent hypoxic exposure in animals in vivo or in cell cultures in vitro allows the controlled interrogation of cellular and molecular mechanisms that may occur in various tissues,

organs, and cells under different conditions. Exposure to intermittent hypoxia for 6 to 8 hours in the 24-hour time clock over days or weeks, termed *chronic intermittent hypoxia* (CIH), as noted earlier in association with OSA in humans, often is used in experimental settings. A wide array of intermittent hypoxia regimens is used in different laboratories, which may partly explain the sometimes discrepant results. Different tissues and organs in murine models demonstrate individualized oxygenation profiles[44] and oxidative stress responses[45,46] to intermittent hypoxia challenge. For example, intermittent hypoxic exposure has been shown to cause oxygen partial pressure swings in the liver, whereas such fluctuations were found to be attenuated in muscle and markedly so in fat, which instead showed steady hypoxia.[44] Compared with lean mice, obese mice had lower baseline liver oxygen tension but similar fat and muscle tissue oxygen tensions, whereas both obese and lean mice exhibited similar tissue partial pressure changes with intermittent hypoxic exposure.[44] Another caveat regarding this mechanism as a pathogenetic trigger is the likely presence of adaptive mechanisms, and the balance or imbalance of these various otherwise poorly delineated factors probably determines eventual health outcomes.[47,48]

Intermittent hypoxia–induced upregulation of nuclear factor kappa B (NF-κB), the master transcriptional switch of inflammation, has been demonstrated in a variety of cells and tissues—leukocytes, vascular cells, fat cells, cardiovascular tissue, and liver tissue, with increased production of inflammatory gene products downstream of activation of NF-κB, such as tumor necrosis factor alpha (TNF-α), interleukin 6 (IL-6), and C-reactive protein (CRP).[44,45,49-53] Data have been controversial regarding intermittent hypoxia induction of hypoxia-inducible factor-1 (HIF-1), a transcription factor critical to physiologic responses to hypoxia, including erythropoiesis, angiogeneis, and glucose metabolism.[48] Severe, but not moderate, intermittent hypoxia has been found to elicit HIF-1 activation in PC12 pheochromocytoma cells,[54] whereas moderate intermittent hypoxia has been found to elicit preferential activation of NF-κB, but not HIF-1, in HeLa cells.[49]

In a lean mouse model of CIH (at 12 weeks), liver histologic examination showed marked accumulation of glycogen in hepatocytes, with evidence of increased hepatic levels of oxidative stress biomarkers and activation of NF-κB, and these changes were followed by sensitization to acetaminophen-induced liver toxicity.[52] Exposure to CIH in a mouse model of high-fat, high-cholesterol diet–induced obesity, compared with similar dietary manipulation alone, caused liver oxidative stress and hepatic inflammation in addition to hepatic steatosis.[53]

Taken collectively, animal and cell data indicate that CIH may act independently, or in concert with obesity, alcohol, or drugs, to promote oxidative stress, inflammation, and dysmetabolism. In rigorously controlled experimental settings, human volunteers have been exposed to intermittent hypoxic regimens to investigate specific metabolic responses. In some studies involving patients with OSA, dysmetabolism arising from OSA has been inferred to be due specifically to sleep hypoxemia, when the metabolic parameter studied showed significant correlations with deoxygenation parameters such as oxygen nadir, oxygen desaturation index, or duration of oxygen desaturation.

In a mouse model of intermittent hypoxia, insulin resistance increased in lean and genetically obese mice, as well as those with dietary obesity, and was dependent on the disruption of the leptin pathways.[55,56] With exposure to intermittent hypoxic regimens of increasing severity, progressively elevated insulin resistance and leptin levels were found in lean mice, whereas increase in leptin levels plateaued in obese mice, suggesting that adiposity may have overwhelmed the effect of the hypoxia on adipokine production.[44] Insulin resistance persisted in intermittent hypoxia–exposed mice that were subjected to pharmacologic denervation of the sympathetic and parasympathetic nervous systems,[56] which did not support the hypothesized mechanistic role of sympathetic activation on glucose dysmetabolism in OSA. Lean rats exposed to different regimens of CIH demonstrated "dose-related" increases in serum insulin, probably reflecting augmented beta cell secretion in response to increased insulin resistance, alongside a commensurate circulating adipocytokine profile with increases in leptin, IL-6, and TNF-α and a decrease in adiponectin.[50] Lean or obese mice exposed to CIH demonstrated evidence of oxidative stress in liver tissue, with upregulation of inflammatory markers; this line of evidence has given rise to the speculation that intermittent hypoxia may contribute to hepatic insulin resistance through the pathophysiologic changes of NASH.[52,53] However, one study of CIH exposure for 4 weeks demonstrated exacerbation of insulin resistance and induction of steatohepatitis in mice with diet-induced obesity, but not in lean mice.[57]

Intermittent hypoxia–induced alterations in adipose tissue and cell metabolism pave the way for adverse downstream effects on insulin resistance and glucose metabolism. In vitro studies of 3T3-L1 adipocytes have demonstrated hypoxic exposure dose–dependent upregulation of proinflammatory activities, represented by the profile of NF-κB, HIF-1, glucose transport factor-1, TNF, IL-6, leptin, and adiponectin.[50] Synthetic sympathomimetics also could suppress adiponectin gene expression in preadipocyte cell lines independently of the intermittent hypoxia mechanism.[58]

Intermittent hypoxia may modulate pancreatic beta cell function. Lean mice exposed to CIH and glucose infusion demonstrated pancreatic beta cell replication with increased insulin secretion,[59] whereas another study of CIH reported associated beta cell proliferation and enhanced cell death, which was mediated by oxidative stress.[60] Other than induction of insulin resistance and hepatocyte glucose output, intermittent hypoxic exposure for 14 days in lean mice increased oxidative stress in the pancreas and impaired beta cell function, and cessation of hypoxic exposure could not fully reverse observed changes in glucose metabolism.[61]

Intermittent hypoxia also has been shown to be a key factor in the upregulation of genes responsible for hepatic lipid biosynthesis, promotion of oxidation of serum lipids, and modulation of the neurohormonal axes that influence signaling pathways in lipid transport and synthesis.[62] Exposure to CIH has led to increase in circulating levels of triglycerides, total cholesterol, and LDL and VLDL cholesterol in a hypoxic dose-dependent manner in both lean and obese murine models.[63] CIH exposure in a mouse model of dietary obesity exacerbated diet-induced dyslipidemia, with evidence of atherosclerosis in the aorta.[64] At a molecular level, insulin's effects on lipogenesis were mediated predominantly by the transcription factor sterol regulatory element–binding protein (SREBP)-1c, which controls the expression of genes required for cholesterol, fatty acid, triglyceride, and phosopholipid

synthesis.[65] Mechanistic studies focusing on the liver have further demonstrated that intermittent hypoxia induces increased lipolysis with free fatty acid flux into the liver, with sequential upregulation of the master transcriptional factors HIF-1 and NF-κB, SREBP-1, and stearoyl coenzyme A desaturase-1 (SDC-1).[64,65] The outcomes are hepatic steatosis, aggravation of hepatic insulin resistance, and disruption of hepatic lipoprotein biosynthesis and secretion. A murine model of severe CIH was shown to result in poor clearance of triglyceride-rich lipoproteins, attributed to reduced lipoprotein lipase activity, which was decreased by 80% in adipose tissue.[66] These results resonate with the finding of postprandial hyperlipemia in subjects with OSA, which could be decreased with CPAP treatment.[67]

In human studies, intermittent hypoxia simulating that seen in OSA has been induced by altering inspired oxygen concentrations. Young healthy men exposed to 8 hours of intermittent hypoxia (through inhalation of "air" with 5% oxygen alternating with 21% oxygen) demonstrated impairment of insulin sensitivity, glucose disposal, and pancreatic islet cell function.[68]

Derangement of Sleep Quality and Quantity

The impact of sleep quality and sleep derangement on metabolism is discussed in Chapter 20. Recurrent obstructed breathing gives rise to cerebral arousals and disturbs sleep architecture, posing another trigger for metabolic dysregulation in OSA. Several epidemiologic studies have found a curvilinear relationship between sleep duration and obesity or glucose dysmetabolism, and subjects who reported shorter sleep durations, compared with those averaging more than 7 to 8 hours of sleep per night, exhibited greater degrees of obesity and glucose dysmetabolism.[69] Alterations in energy-regulating hormones including leptin and grhelin have been implicated.[70] Healthy subjects who were subjected to experimental sleep restriction demonstrated abnormal glucose metabolism[71] and impairment of insulin signaling in their subcutaneous adipocytes,[72] compared with after normal sleep. Studies using acoustic stimuli to induce sleep fragmentation,[36] with reduction of slow wave and REM sleep and preserved total sleep time,[35] showed that sleep disruption without hypoxia could lead to a decrease in insulin sensitivity, as well as impaired non–insulin-dependent glucose disposal and inadequate compensatory increase in insulin secretion.

In a study of 226 children, both obesity and OSA, and to a greater extent the combination of the two, were associated with reduced circulating levels of G protein–coupled receptor 120 (GPR120), a long-chain free fatty acid receptor protective against insulin resistance and systemic inflammation.[73] GPR120 levels correlated with insulin resistance, but not with dyslipidemia or CRP levels. Among the sleep parameters, GPR120 levels showed the strongest independent association with respiratory arousal index, which provoked the query of whether sleep curtailment or disruption, rather than the other pathophysiologic disturbance of OSA, was the etiologic mechanism.

Oxidative Stress

Oxidative stress is a state caused by imbalance between the production of reactive oxygen species (ROS) highly damaging to cells and the antioxidant activity that counteracts ROS. Oxidative stress activates redox-sensitive transcription factors that regulate inflammatory processes and downregulate nitric oxide synthase, with consequent reduced nitric oxide in endothelial cells, leading to microvascular and macrovascular endothelial dysfunction. These cellular mechanisms also may be operative in other tissues and organs and may underlie the development of insulin resistance, dyslipidemia, arterial hypertension, and other cardiometabolic derangements.[6,74] The recurrent hypoxia-reoxygenation cycles in OSA (i.e., intermittent hypoxia and particularly CIH, as described previously) are thought to be analogous to ischemia-reperfusion injury known to produce ROS in the reperfusion phase. Evidence for occurrence of increased oxidative stress in OSA is not consistent, however. A majority of studies have found that subjects with OSA have increased biomarkers of oxidative stress compared with control subjects without OSA, which decreased after CPAP treatment of OSA, whereas a few studies reported reduced antioxidant activity.[4,75,76] For example, subjects with OSA were found to have an increase in lipid peroxidation, glycated end products of oxidation, serum or urinary reactive oxygen metabolites, ROS production from leukocytes or monocytes, and reduction of circulating nitric oxide, although there have also been negative studies.[4] Discrepant findings for the presence of oxidative stress in OSA may be related to the difficulty of assessing oxidative status accurately.[77] Furthermore, obesity itself has been associated with enhanced oxidative stress systemically and locally in adipose tissues, constituting a confounding factor in the study of oxidative stress potentially due to OSA.[6,15,75]

Inflammation and Alteration of the Adipocytokine Profile

Obesity and metabolic syndrome are known as proinflammatory states, with elevated circulating levels of proinflammatory mediators, often referred to as adipocytokines (see earlier under Obesity and Adiposity).[7] Adiopokines are produced predominantly from adipose tissues, whereas cytokines are released by a variety of cells and tissues. Collectively, adipocytokines function as key mediators linking obesity and metabolic disorders. [7] It is hypothesized that OSA may modulate the expression and release of adipokines to favor adverse metabolism.[11] Intermittent hypoxia, oxidative stress, and sympathetic activity are capable of modulating release of proinflammatory adipocytokines from a variety of cells and tissues, including adipose tissues.[15,44,49-54] Investigation of alterations of adipocytokine regulation in subjects with OSA, however, have yielded highly variable results, which may be attributed to the presence of confounding factors, in particular obesity.[24]

OBSTRUCTIVE SLEEP APNEA AND METABOLIC DYSREGULATION: CLINICAL ASSOCIATIONS AND TREATMENT

Obesity

It has been estimated that a range of 15% to 90% of obese subjects have OSA, depending on age, gender, and BMI.[78] Generally, OSA prevalence is higher among persons with morbid obesity, and OSA severity is greater in obese than in leaner subjects.[10,78] Longitudinal data of the Wisconsin cohort indicated that a 10% gain in body weight increased the chance of developing moderate to severe OSA by a factor of 6, and that every 1% increase in body weight was associated with a 3% increase in AHI.[79] Conversely, weight loss reduced OSA

severity but to a less substantial degree than that seen with exacerbation with weight gain. If OSA alters energy balance to promote obesity, it follows that treatment of OSA should mitigate obesity. However, studies on the impact of treatment of OSA on body weight or adiposity have not been supportive of a beneficial effect on body composition. In an RCT of CPAP treatment for OSA, therapeutic CPAP decreased daytime sleepiness and promoted physical activity over a 3-month period, but no change in body weight was seen.[80] Studies on the impact of CPAP treatment on abdominal fat have yielded conflicting data,[15] with randomized, sham-controlled trials for 8 and 12 weeks, respectively, showing no change in abdominal fat quantified by imaging.[81,82] In fact, a recent meta-analysis of data from randomized trials suggests that CPAP treatment of OSA may promote increase in BMI and body weight.[83] On the other hand, interventions including lifestyle modifications, antiobesity medications, and bariatric surgery (also termed metabolic surgery) can produce weight loss and have undoubted metabolic benefits as well as resulting in symptomatic improvement in obese subjects with OSA, although the relative impact of various weight reduction regimens in this regard remains underinvestigated.[84] In a controlled trial of surgical versus conventional therapy in severely obese subjects with OSA, greater weight loss in the surgical group did not translate to significantly greater reduction in AHI than that achieved with conventional weight loss approaches.[85] A daunting challenge is to find the optimal weight control measure that not only is effective in improving anthropometric aspects and various health outcomes but also is acceptable to the individual patient and sustainable in real-life situations.

Insulin and Glucose Metabolism

The clinical relationship between OSA and a range of glucose dysmetabolism disorders ranging from insulin resistance to overt diabetes has been extensively investigated and regularly reviewed.[3,86,87] Several population-based studies from the United States, Hong Kong, Korea, Brazil, and Europe consistently found that OSA was associated with increased insulin resistance or evidence of impaired glycemic status including DM, despite adjustment for obesity and other confounders.[17,88-93] The Sleep Heart Health Study (SHHS) cohort of 5874 subjects in the United States did not show an independent relationship between OSA and DM,[94] although in a subgroup of overweight, middle-aged men in the SHHS, an independent association was found between OSA and insulin resistance/glucose intolerance.[89] In 2014, the European Sleep Apnea Database (ESADA) reported its cross-sectional analysis of data on 6616 participants and found that increasing OSA severity was associated with increased likelihood of type 2 DM and worse glycemic control in the diabetic subjects despite adjustment for confounding variables.[93] The Wisconsin Sleep Cohort, which found an independent association between severity of untreated OSA and prevalence of DM at baseline, did not find any increase in incident DM at a 4-year follow-up evaluation.[88] Other longitudinal follow-up cohort studies from the United States[95] and Japan[96] have found associations between baseline OSA and incident diabetes over 3 to 4 years, as did another study from Australia, although the incidence of DM was very low in that cohort.[97] A historical cohort of 8678 patients undergoing diagnostic study for OSA in a single clinical center in Toronto showed that DM developed in 1017 subjects with OSA (11.7%) over a median follow-up period of approximately 67 months.[98] With full adjustment for confounders, subjects with AHI greater than 30 had a 30% higher hazard of developing DM than those with AHI below 5. Adjusted odds ratios for the incidence of DM in moderate to severe OSA compared with those without OSA in different studies have ranged from 1.31[98] to 13.45.[87]

Conversely, a high prevalence of OSA has been reported among diabetic populations[94,99-104] (Figure 118-1). Several studies in diabetic subjects suggest that severity of OSA is associated with worse glycemic control,[93,102] although this correlation is not universally seen.[103]

A majority of studies analyzing nondiabetic subjects have reported independent associations between OSA and insulin resistance or sensitivity and/or other measures of glycemic health, with dose-dependent effect of OSA on such measures of metabolic impairment.[86] However, some studies found that such a relationship was confounded by obesity, such that the association was abolished after adjustments for BMI and/or other measures of adiposity.[86] The ESADA cohort study found that OSA severity independently predicted glycemic health assessed by HbA_{1c} in nondiabetic subjects.[92] Nonobese subjects with OSA, compared with BMI-matched or BMI-adjusted counterparts without OSA, also had more insulin resistance or glucose dysmetabolism.[16-18,105,106]

It has been proposed that excessive daytime sleepiness may be a phenotypic marker for insulin resistance in OSA. Associated abdominal or visceral obesity in OSA could contribute to sleepiness in OSA through hypercytokinemia.[107] Waist circumference and visceral fat have demonstrated high correlations with insulin resistance[13] and also with OSA prevalence[10,15] or severity.[12,15] Excessive daytime sleepiness was reported to be a useful indicator of moderate or severe OSA in white diabetic subjects,[108] but this was not the case in a Chinese diabetic population.[103] In a case-control study of nondiabetic subjects with similar BMI and AHI, those with excessive daytime sleepiness (as defined by a mean Epworth Sleepiness Scale [ESS] score of 16) had higher scores on homeostasis model assessment for insulin resistance (HOMA-IR) than those without sleepiness (mean ESS score of 4), and indices of insulin resistance were improved with CPAP treatment only in the group with baseline excessive sleepiness.[109]

Despite abundant positive data supporting an independent association of OSA and disturbance of glucose homeostasis, cross-sectional studies cannot be considered definitive for a causal link. Reported data on the effect of treatment of OSA, usually with CPAP, on insulin-glucose metabolism remain highly controversial.[86,87,110] A number of observational studies in either diabetics or non-diabetics with OSA suggested improvements in insulin resistance or glycemic status with CPAP treatment, but such results are by no means consistent, and most of the RCTs did not provide definitive evidence for an improvement in insulin-glucose metabolism in response to CPAP.[40] Several RCTs of CPAP treatment for OSA without DM ranging from 1 to 12 weeks in duration did not find consistent improvement in insulin resistance measured by HOMA-IR, or insulin sensitivity using OGTT or a hyperinsulinemic clamp.[111-113] Data from subset analysis or open continuation phase of these RCTS, and from observational studies, suggest that severity of OSA,[112] BMI,[111,114] CPAP adherence,[115] sample size, and/or treatment duration[113] may contribute to the determination of metabolic effects. Reported

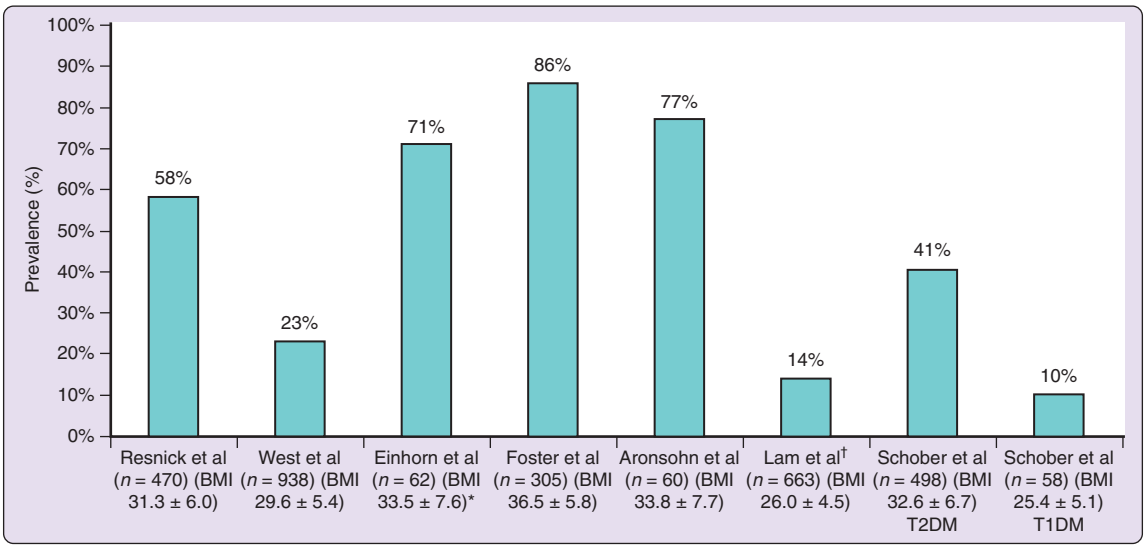

Figure 118-1 Prevalence of obstructive sleep apnea (OSA) in subjects with diabetes mellitus.*BMI available only in a bigger cohort of *n* = 279. †Chinese (Asian criteria for obesity: BMI greater than 25 kg/m^2). T1DM, Type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus. (Data from referenced studies: Resnick et al., 2003[94]; West et al., 2006[99]; Einhorn et al., 2007[100]; Foster et al., 2009[101]; Aronsohn et al., 2010[102]; Lam et al., 2010[103]; Schober et al., 2011—both cohorts.[104])

data on the confounding influence of obesity are controversial, with conflicting evidence that either obese (Chinese)[111] or nonobese (non-Asian white) subjects[114] can show more improvement in insulin sensitivity in response to CPAP. A rigorously conducted RCT that investigated the effects of CPAP alone versus weight reduction alone versus both interventions in a cohort of obese subjects with severe OSA showed that weight reduction but not CPAP alone over 24 weeks improved insulin sensitivity.[116] The beneficial effect was not further enhanced in the group receiving both interventions, suggesting that obesity has a more dominant impact than OSA on insulin resistance in persons with OSA. Because weight loss also may lead to changes in OSA, however, the absence of information on sleep-disordered breathing after the treatment period in those data disallows definitive analysis of the complicit interactions of multiple risk factors and conditions that occur in this patient population.[117]

In diabetic subjects with OSA, data from observational studies on treatment of OSA tend to be favorable regarding improvement in indicators of glycemic status.[86] In the only randomized sham-CPAP controlled study reported to date, neither HbA_{1c} nor insulin sensitivity measured with the hyperinsulinemic euglycemic clamp showed any improvement with CPAP over a 3-month period,[118] but the low average CPAP use of 2.5 hours per night in the "therapeutic" CPAP group is considered inadequate to produce any change in OSA-related sequelae. Rapid eye movement (REM)-related event frequency, as indicated by REM-AHI, but not NREM-related event frequency, was found to be associated with worse glycemic control in type 2 DM, suggesting potential treatment implications regarding the need for adequate inclusion of REM sleep periods in overnight CPAP usage.[119]

Recently, an RCT of CPAP in 39 subjects with prediabetes and OSA found that 8 hours of CPAP use every night for 2 weeks, documented by nightly in-laboratory sleep monitoring, could reduce glucose response to oral glucose tolerance testing and improve insulin sensitivity.[120] As with a previous 1-week RCT in nondiabetic men,[111] these findings can be regarded as proof-of-concept for an adverse effect of untreated OSA on glucose metabolism, which is reversible with control of OSA, but the relevant clinical impact remains elusive.

In the face of increased insulin resistance, compensatory increase in insulin secretion occurs, but this homeostatic mechanism of beta cell function may be lost with chronic insult, ageing or pre-diabetic state. In clinical subjects or experimental human models of OSA, studies have shown conflicting data: pancreatic insulin secretion may be enhanced or impaired. In a study of 118 nondiabetic subjects with OSA evaluated with an intravenous glucose tolerance test (FSIVGGT), despite "OSA dose–dependent" impairment of insulin sensitivity, no increase in pancreatic beta cell insulin output was seen.[121] By contrast, in a study of 26 lean young men free of cardiometabolic disease, the presence of mild to moderate OSA was associated with insulin resistance and an increase in insulin secretion,[106] and a study of 45 severely obese adults also found that OSA was associated with increased beta cell function in those with normal glucose metabolism.[122]

Additional data indicate that coexistence of obesity, pregnancy, and OSA may well pose a conglomerate predisposition to gestational DM. Despite adjustment for pre-pregnancy BMI, a diagnosis of gestational DM has been strongly associated with a diagnosis of OSA.[123]

The diverse results regarding the effect of OSA or its treatment on glucose metabolism as illustrated above may be due to the use of different investigative tools that are not directly comparable, and to different sample characteristics. Host factors, intrinsic or extrinsic, play important roles in the determination of insulin-glucose metabolism in OSA, including age, BMI and adiposity, duration of OSA, prevailing glycemic status, genetic susceptibility, and variable exposures to external factors such as diet and exercise. Adherence to and duration of treatment for OSA also must be considered in the appraisal of any potential metabolic response. An overview of the

literature indicates that assessment tools, sample size, patient characteristics, and treatment duration and adherence are factors that need to be carefully addressed in the design of future clinical studies.

Although current investigative data are dominated by studies of the action of OSA towards glucose homeostasis and DM, the possibility of diabetic autonomic neuropathy as a predisposing factor toward sleep-related pharyngeal collapse and OSA has been raised.[124] In subjects with type 1 DM in particular, who usually are not overweight or obese, a higher prevalence of OSA than in the general population raises the possibility of contribution by autonomic neuropathy,[104] although data are very limited in this regard.[124]

Dyslipidemia

Clinical data regarding the relationships of OSA and lipids and the effect of treatment of OSA on lipids are mostly gleaned from studies that include several metabolic parameters as end-points, and relatively few which specifically investigated dyslipidemia as the primary measure of interest. Epidemiologic studies comprising relatively large numbers of subjects have identified an association between OSA and dyslipidemia independent of confounding variables. In the American SHHS cohort with mean age of 62 years, stepwise regression models identified that the respiratory disturbance index was independently determined by higher total cholesterol levels in men, and lower HDL cholesterol levels in women.[125] The European SYNAPSE study of 846 participants with mean age of 68 years showed that severe OSA was independently associated with low HDL cholesterol.[126] Oxygen desaturation index and AHI were independent predictors of HDL cholesterol levels, and the relationships were more pronounced in those not receiving lipid-lowering agents.[126] The Brazilian San Paola sleep cohort found that an AHI of 15 or less and a longer duration of oxygen saturation below 90% were independently associated with elevated fasting glucose and triglyceride levels and HOMA-IR.[91] By contrast, no independent association was identified between OSA (defined by AHI of 5 or less) and cholesterol or triglyceride levels in community-dwelling middle-aged Chinese residents of Hong Kong.[90]

Clinical studies of patients with OSA have reported various adverse lipid profiles, including elevations of total cholesterol, triglycerides, LDL cholesterol or lower HDL cholesterol levels.[62] Apart from promoting a dyslipidemic profile of cholesterol or triglycerides, subjects with OSA have been shown to have higher levels of oxidized or dysfunctional lipids which are more atherogenic, ascribed to increased oxidative stress.[127,128]

Observational intervention studies and RCTs regarding the effect of OSA treatment on dyslipidemia profiles have demonstrated variable changes in lipid parameters,[15,40] although some studies with short treatment durations may not have allowed adequate time for changes in circulating lipid levels. In a single-center longitudinal follow-up study of 127 patients with OSA, positive airway pressure treatment for 6 months significantly increased HDL cholesterol levels.[129] Pooled data from two RCTs on metabolic profile in OSA suggested that CPAP treatment of OSA results in a lowering of serum total cholesterol.[130] In a randomized controlled cross-over trial with dyslipidemia as the primary end point, therapeutic CPAP treatment for 2 months compared with placebo CPAP in 30 subjects with severe OSA (defined as mean AHI of 41) reduced postprandial hypertriglyceridemia and also lowered fasting and postprandial total cholesterol levels.[67] However, in the Icelandic Sleep Apnea Cohort, a 2-years follow-up assessment of CPAP treatment outcomes in 199 subjects with newly diagnosed OSA compared with 118 nonusers did not show any change in fasting lipid levels with CPAP treatment.[131] A recent systematic review of randomized controlled studies did not show any alteration in lipid levels with CPAP treatment of OSA.[40]

Hepatic Dysfunction and Nonalcoholic Fatty Liver Disease

A number of reports of liver enzyme elevations in adults and children with OSA have been published.[31,132,133] The National Health and Nutrition Examination Survey (NHANES) data between 2005 and 2010 for 10,541 adults reported that 15% had NAFLD and 7.2% had sleep disorders, identified as sleep apnea in 64.7% of those affected, and sleep apnea was independently associated with NAFLD with an odds ratio of 1.39 (95% confidence interval, 0.98 to 1.97).[134] Definitive evidence of liver injury in OSA was mostly derived from findings in morbidly obese subjects who underwent liver biopsy during bariatric surgery.[15] As with other metabolic dysfunction, the association of fatty liver with OSA is substantially confounded by obesity, and an independent relationship has not been firmly established.[31]

In studies of obese subjects, those with moderate or severe OSA and severe sleep-related hypoxemia exhibited more significant changes in indices of hepatic inflammation than those with mild OSA,[135,136] and in a series of subjects undergoing bariatric surgery, the absence of OSA was found to be an independent predictor of normal findings on liver histologic analysis.[137] Patients with severe OSA (AHI greater than 50) were found to have more insulin resistance and to have higher percentage of steatosis, as well as higher prevalence of necrosis and fibrosis, than patients with milder OSA with similar BMI.[138] In a study of 65 consecutive children with biopsy-proven NAFLD, 60% were shown to have OSA on polysomnography, and the presence and severity of OSA were associated with features of NASH and fibrosis, independently of BMI, abdominal adiposity, metabolic syndrome, and insulin resistance.[139] This relationship held in the nonobese children with NAFLD. Of note, the duration of oxyhemoglobin saturation below 90% correlated with increased hepatocyte apoptosis and fibrogenesis.

Despite the concern that OSA may worsen NAFLD, the major causes of premature death in subjects with NAFLD have been identified as type 2 DM and CVD, rather than the liver disease itself.[140] This correlation serves, however, as a reminder of the potential role of additional liver injury from OSA as a pathway to greater cardiometabolic burden.

Inflammation and Alteration of Adipocytokines

Multiple studies have addressed the profile of proinflammatory mediators in OSA, and results have been diverse and confounded by obesity.[24] A meta-analysis of 51 studies found higher levels of CRP, TNF-α, IL-6, and other molecules in patients with OSA than in control group subjects.[141] The Icelandic cohort study of 454 subjects with untreated OSA showed that OSA severity, as reflected by the degree of nocturnal oxygen desaturation, but not AHI, correlated significantly with levels of IL-6 and CRP.[142] An association of

BMI with IL-6 was found only in obese participants, and an independent association of OSA severity and CRP levels was found for minimum oxygen saturation only. Although a meta-analysis found that treatment of OSA with CPAP improved levels of CRP, TNF-α, and IL-6, the studies pooled for this analysis generally were small, nonrandomized trials,[143] and well-designed studies have failed to demonstrate that CPAP alters inflammation markers in OSA.[24,40]

Leptin regulates appetite and energy intake, and hyperleptinemia in obesity reflects leptin resistance. Hyperleptinemia is associated with increased insulin resistance and cardiometabolic morbidities. Subjects with OSA have consistently been found to have elevated plasma leptin levels compared with healthy subjects, although whether the increase is related independently to OSA or is simply due to the concomitant adiposity remains controversial.[24] Some studies have suggested that nocturnal hypoxemia, rather than AHI itself, is a better indicator of the effect of OSA on leptin levels. The Icelandic Sleep Apnea Cohort study of 452 patients with untreated OSA (mean BMI, 32.7 kg/m^2) showed that the dominant determinants of leptin levels were still obesity and gender, although OSA severity as measured by AHI explained a significant variance (3.2%) in leptin levels in the nonhypertensive group, with the relationship strongest in nonobese, nonhypertensive subjects.[144] Adiponectin has insulin-sensitizing, antiinflammatory, and antiatherogenic properties, and hypoadiponectinemia is associated with reduced insulin sensitivity, type 2 DM, and the metabolic syndrome. A majority of relevant studies in OSA have found that hypoadiponectinemia strongly correlates with obesity and insulin resistance as in general populations, but the relationship of adiponectin levels and OSA is heavily confounded by obesity.[24] One study suggested that the degree of sympathetic activation, rather than sleep-disordered breathing indices, contributed to the determination of adiponectin levels.[41] Another study found that nonobese men with severe OSA, compared with nonobese control subjects who did not have OSA, demonstrated more impaired insulin resistance (higher HOMA-IR) and a profile of higher 24-hour levels of leptin, CRP, IL-6, and TNF-α but similar levels of adiponectin.[18]

Obstructive Sleep Apnea and Metabolic Syndrome

Although the considerable disagreement in the medical community over terminology and diagnostic criteria has yet to be resolved, *metabolic syndrome* is conceptually accepted as a clustering of multiple metabolic risk factors for CVD and DM.[13] The key features of metabolic syndrome are abdominal obesity, insulin resistance, atherogenic dyslipidemia, a prothrombotic state, and an inflammatory profile. This constellation of metabolic aberrations often is accompanied by arterial hypertension and/or type 2 DM, in keeping with the relevant genetic or exogenous predispositions.[2] Different sets of clinical criteria for definition of metabolic syndrome have been reached by various expert panels,[13] and one widely used set of criteria from the National Cholesterol Education Program Adult Treatment Panel III is presented in Table 118-2[145,146] for reference. Besides the core components, an increasing number of conditions are proposed to be included in the metabolic syndrome "family," and OSA is one such condition because of its strong associations with other core factors and its potential role in causing CVD and glucose dysmetabolism.[146,147]

Table 118-2 Definition of Metabolic Syndrome of the National Cholesterol Education Program Adult Treatment Panel III (NECP-ATIII)

Risk Factor	Defining Level
Abdominal obesity (waist circumference)	
Men	>102 cm
Women	>88 cm
Triglycerides	≥150 mg/dL
High-density lipoprotein cholesterol (HDL cholesterol)	
Men	<40 mg/dL
Women	<50 mg/dL
Blood pressure	≥130/≥85 mm Hg
Fasting glucose	≥110 mg/dL
Asian criteria for abdominal obesity*	
Men	≥90 cm
Women	≥80 cm

As illustrated in previous sections of this chapter, strong and probably independent associations of OSA with various individual clinical components of the metabolic syndrome are likely. Studies have demonstrated a 5- to 7-fold increase in the association of OSA with this phenotypic entity, compared with those without OSA, and the association was independent of BMI and age; a similar association has been found in subjects with versus those without metabolic syndrome.[3,11] Of a total of 228 patients referred for OSA evaluation, 146 patients proved to have OSA, of whom 60% had metabolic syndrome, whereas of those without significant OSA, only 40% had metabolic syndrome.[148] The presence of OSA in subjects with classical metabolic syndrome as defined by current international guidelines may add to the associated inflammatory and cardiometabolic burden.[149] To date, definitive evidence that treating OSA reduces the occurrence of conventionally defined metabolic syndrome is lacking. With respect to clinical impact, this may be just a matter of threshold—if indeed treatment of OSA can produce adequate improvement in individual components of the metabolic syndrome, it is reasonable to anticipate improvement in the adverse cardiometabolic outcomes predicted by metabolic syndrome. However, despite increasing research focus in this area, treatment of OSA has not yet been associated with consistent and clinically important improvement in the metabolic components of obesity, insulin-glucose dysmetabolism, dyslipidemia, or systemic inflammation.[40,150]

CONCLUSIONS AND PERSPECTIVES

The strong association between OSA and metabolic disorders has received intense interest, against the background of a

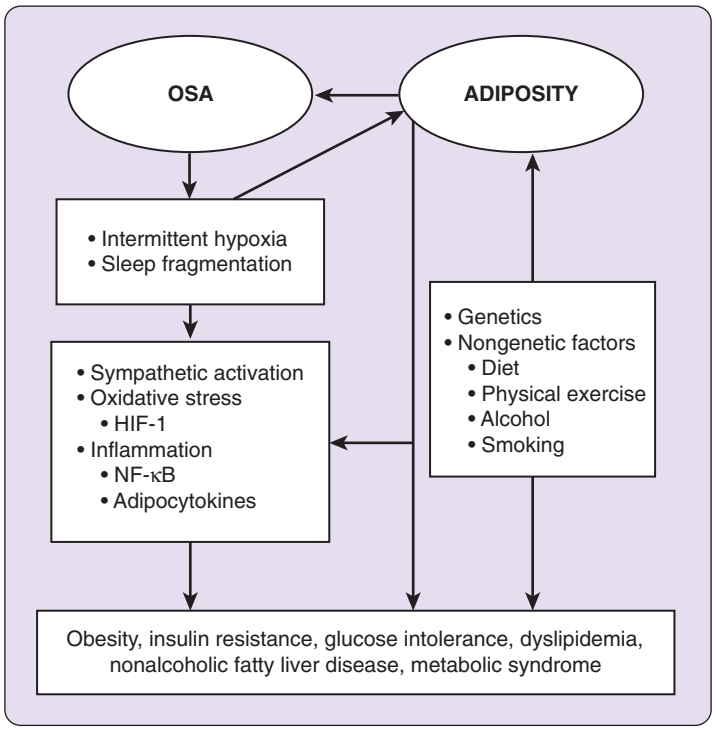

Figure 118-2 Proposed mechanistic links of obstructive sleep apnea (OSA) and metabolic disorders. HIF-1, Hypoxia-inducible factor-1; NK-κB, nuclear factor kappa B.

global epidemic of obesity and obesity-related diseases, and the modern lifestyle of sleep curtailment. In human disease, despite growing evidence for an independent or additive adverse effect of OSA on metabolic function, the relationship remains controversial owing to the strong potential confounding effect of obesity and the unaccounted influence of numerous intrinsic or exogenous factors that may affect body metabolism. Furthermore, the influence of OSA and metabolic dysfunction may be bidirectional, and the putative alterations of metabolic function by OSA, such as increased insulin resistance with promotion of visceral adiposity, may in turn aggravate OSA, allowing a vicious circle to be established (see Figure 118-2). The demonstration of a beneficial metabolic effect of treatment of OSA, moreover, has been elusive. Overall, many studies are of limited sample size and/or heterogeneous sample characteristics, and because of the need for symptomatic treatment in this condition, conducting RCTs or longitudinal follow-up studies of untreated disease with adequate duration is inherently difficult. Treatment results for children, young adults, and a range of middle-aged to elderly adults can hardly be directly compared; obese subjects may behave differently from lean subjects metabolically, and the difference may not be adequately resolved with adjustment for BMI. Furthermore, factors such as the duration of OSA before sleep study diagnosis are not possible to define accurately, owing to the nonspecific and insidious onset of symptoms in most cases, and the prevailing metabolic status in the individual patient influence whether "reversibility" could still be attained with treatment of OSA even if it is the culprit for dysmetabolism. Finally, any metabolic benefits that are demonstrated in the study setting, especially in short-term studies, need to be reproducible in real life, where lifestyle factors and treatment adherence interpose.

Animal and cellular studies using intermittent hypoxia or other surrogate models for OSA allow manipulation of experimental conditions to provide insights into the physiologic or molecular mechanisms that may be at play in the human disease. Accordingly, such studies can be expected to pave the way for extension into translational work in humans.

SUMMARY

In view of the many factors that may influence metabolic health and disease, it is unrealistic to expect that one unifying path applies to all. Although any demonstrated adverse impact of OSA on metabolic function may be of limited clinical effect, the economy of scale would translate such effect into an enormous health care burden when coupled with the sweeping epidemic of obesity and anticipated escalation of rates of related morbidity in the coming decades. Meanwhile, holistic care mandates a multidimensional approach, in both clinical practice and research, to the management of patients presenting with either OSA or a metabolic disorder. Strong evidence suggests that controlling body weight is of pivotal importance in improving metabolic health, including in subjects with OSA. OSA is gaining professional recognition as a serious comorbid condition to be accorded appropriate attention in the management of cardiometabolic disorders.[151,152] Recent clinical practice guidelines note that OSA should be identified and appropriately treated in the comprehensive care of patients with DM.[152] It is of pivotal importance that both the medical profession and the public be aware of the clustering of OSA and metabolic disorders, with the consequent need for determination of optimal methods of prevention, early recognition, and relevant clinical management.

CLINICAL PEARL

Strong associations are recognized between OSA and various metabolic disorders, notably obesity, type 2 DM, dyslipidemia, and NAFLD. Despite abundant suggestive evidence for independent associations between OSA and metabolic dysfunction, a causal or aggravating role for OSA in dysmetabolism is not yet delineated, and treatment of OSA has not been definitively shown to prevent or improve metabolic dysfunction. A reasonable holistic clinical approach mandates high vigilance regarding the clustering of these conditions, with relevant screening and specific management considered accordingly. The need for appropriate body weight control measures is particularly relevant in this regard.

Overlap Syndromes of Sleep and Breathing Disorders

Chapter 119

Jose M. Marin; Santiago J. Carrizo

Chapter Highlights

- Sleep depresses the central control of breathing and muscle tone. These changes have no health effects in healthy subjects. However, in patients with pulmonary diseases such as chronic obstructive pulmonary disease (COPD), asthma, and interstitial lung diseases, these changes may aggravate gas exchange abnormalities and induce significant hypoxemia and hypercapnia, especially during rapid eye movement sleep.
- As COPD, asthma, and obstructive sleep apnea (OSA) are prevalent disorders in adults, overlap of OSA and either COPD or asthma is frequent in clinical practice. Such overlap, termed overlap syndrome, carries an excessive risk for worsened sleep- and awake-related outcomes than any one of these conditions alone, including increased risk of COPD exacerbations and mortality.
- Practitioners should identify the coexistence and severity of OSA in patients with COPD or asthma and the presence and severity of the overlap syndrome, and they should establish a personalized treatment in each case. A sleep study should be considered in any patient with COPD or asthma with signs and symptoms of OSA, such as snoring and excessive daytime sleepiness, or with inappropriate awake hypoxemia.
- Noninvasive ventilation (continuous positive airway pressure, bilevel positive airway pressure), with supplemental oxygen if necessary, should be prescribed after an appropriate titration process.

OVERVIEW

Sleep is associated with adaptive changes of the airways, lungs, and chest wall mechanics. In patients with chronic pulmonary diseases, such physiologic changes as well as the pathophysiologic changes of sleep breathing disorders, such as obstructive sleep apnea (OSA), may result in acute and chronic adverse effects, including precipitation or worsening of hypoxemia, hypercapnia, and bronchoconstriction, which in the long term can contribute to worsened outcomes in these chronic pulmonary disorders. This chapter reviews the clinically imperative concepts of overlap syndromes, defined as the coexistence in the same patient of OSA and one or more of the following chronic respiratory conditions: chronic obstructive pulmonary disease (COPD), asthma, and pulmonary hypertension (PH). The clinical relevance of identifying the coexistence of a primary sleep disorder such as OSA in patients with these chronic respiratory disorders lies not only in the diagnosis of an overlap syndrome; it involves a worse prognosis for these coexistent respiratory diseases and the need for specific treatment of the concomitant sleep-disordered breathing (SDB). Physicians who care for patients with such respiratory disorders should recognize these associations.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

According to the latest version of the Global Initiative for Chronic Obstructive Lung Disease (GOLD) strategy document,[1] COPD is defined as a preventable and treatable disease, characterized by persistent airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles or gases. A clinical diagnosis of COPD should be considered in any patient with dyspnea, chronic cough, or sputum production and a history of exposure to risk factors for the disease. Spirometry is required to make the diagnosis in this clinical context; a postbronchodilator forced expiratory volume in the first second of expiration to forced vital capacity (FEV_1/FVC) ratio of less than 0.7 confirms the presence of persistent airflow limitation and thus of COPD.

Sleep disturbance is common in COPD without other coexistent primary sleep disorders. In a large survey conducted in North America and Europe, 40% of patients reported problems with their sleep.[2] In a European survey, 78.1% of patients with COPD reported some degree of nighttime symptoms, including one or more of the following: dyspnea, cough with increased sputum production, wheezing, and difficulty with maintenance of sleep. The prevalence of such nighttime symptoms was positively correlated with the severity of spirometrically measured airflow obstruction.[3] Polysomnography (PSG) studies show that these patients have problems initiating or maintaining sleep, reduced rapid eye movement (REM) sleep, and frequent microarousals. This poor sleep quality increases in parallel with the frequency of nocturnal respiratory symptoms, like cough and wheezing,[4] and COPD severity.[5]

In COPD patients, sleep is associated with reduced rib cage contribution to breathing, diaphragmatic inefficiency, and increased accessory muscle contribution to breathing.[6] The result is a reduction in functional residual capacity, which may augment ventilation-perfusion mismatching and hypoxemia. More than 50% of COPD patients with daytime arterial oxygen saturation of hemoglobin (Sao_2) above 90% on breathing room air, and without concomitant OSA, experience significant oxygen desaturation during sleep, defined as spending at least 30% of the night with Sao_2 below 90%.[7] Daytime gas exchange abnormalities are, however, somewhat predictive of sleep oxygen desaturation among COPD patients.[8] Given the shape of the oxyhemoglobin dissociation curve, patients on the steep portion of the curve (e.g., Pao_2 < 60 mm Hg on breathing room air during the daytime) would be expected to have a greater fall in Sao_2 during sleep, particularly during REM sleep. Accentuated physiologic hypoventilation in COPD is also the consequence of decreased central respiratory drive response to chemical and mechanical inputs,[9] increased upper airway resistance due to a loss of tone in the upper pharyngeal muscles,[10] and reduced efficiency of diaphragmatic contraction due to lung hyperinflation.[11] The consequences of nocturnal hypoxemia and hypercapnia are well known and include arrhythmias and PH. In addition, recent data suggest that disturbed sleep is an independent risk factor of COPD exacerbations and mortality.[12]

Chronic Obstructive Lung Disease and Obstructive Sleep Apnea Overlap Syndrome

Definitions and Classifications

The GOLD definition of COPD also underlines that "exacerbations and comorbidities contribute to the overall severity in individual patients."[1] OSA is recognized as one of these comorbidities. OSA is characterized by sleep-related pathologically increased upper airway resistance, repetitive decrease or absence of inspiratory and expiratory airflow, sympathetic activation, and intermittent oxyhemoglobin desaturation and hypercapnia.[13] The diagnosis of OSA requires a PSG study, with five or more apneas or hypopneas per hour of sleep (i.e., the apnea-hypopnea index [AHI]) consistent with OSA.[14] The consensus definitions of severity in OSA, mild (AHI ≥5 and <15 episodes/hour), moderate (AHI ≥15 and <30 episodes/hour), and severe (≥30 episodes/hour), are in part based on published literature that has found an association between such severity definitions of OSA and risk of excess mortality in this sleep-related breathing disorder.[15-19]

The coexistence of COPD and OSA was first described as the overlap syndrome by David Flenley 30 years ago.[20] He pointed out that PSG should be considered in COPD patients with obesity, snoring, or morning headache associated with nocturnal oxygen therapy to assess for the presence of associated OSA. He believed that the clinical course and prognosis of such "overlap patients" were worse than for patients suffering from COPD or untreated OSA alone. These opinions remain valid today. Nevertheless, at present, the term *overlap syndrome* is not a formal diagnostic designation for patients suffering from OSA and COPD. In the individual patient, it is better to describe the underlying lung disease and the associated abnormality of the sleep disorder. A classification of severity for this entity is not available, and health outcomes appear to depend on the severity of OSA and COPD independently.

Epidemiology of COPD/OSA Overlap Syndrome

In pulmonary clinics, OSA and COPD are two of the most prevalent chronic respiratory disorders. It is estimated that 10% of the general population has moderate to severe COPD as defined by an FEV_1/FVC ratio of less than 0.7 plus an FEV_1 of less than 80% predicted.[21] The prevalence of COPD increases with age and is directly related to the prevalence of tobacco smoking, but outdoor and indoor air pollution are also major COPD risk factors. The prevalence and burden of COPD are projected to increase in the coming decades because of continued exposure to COPD risk factors and the aging of the world's population.

Among men and women between the ages of 30 and 60 years, 20% and 9%, respectively, had an AHI of at least 5 events/hour in the Wisconsin Sleep Cohort Study.[22] Since this report was published 20 years ago, data from the same ongoing cohort provide prevalence estimates of moderate to severe SDB of the sleep apnea type (AHI ≥ 15 events/hour), thus showing a substantial increase during the last 2 decades.[23] The sex disparity of OSA ends at around the age of 55 years, with a sharp rise among postmenopausal women.[23-25]

There are, however, no studies that directly assess the prevalence of the OSA/COPD overlap syndrome. Because COPD and OSA are each increasing throughout the world in association with an aging population, presumably the overlap syndrome is becoming more prevalent. In clinical series, it has been noted that approximately 11% of patients with at least moderate OSA, as defined by an AHI of more than 20 events/hour, have airflow limitation on spirometry.[26] In a European population study of patients with predominantly mild COPD, the coincidence of OSA syndrome (AHI > 5 events/hour accompanied by excessive daytime sleepiness) occurred in 1% of the total population.[27] The Sleep Heart Health Study, a community-based cohort study that included 5954 participants who had PSG and spirometry at baseline, found that 19% had airway obstruction (defined as FEV_1/FVC < 0.7) that was predominantly mild. The prevalence of OSA, defined as a respiratory disturbance index of more than 10 events/hour, was not higher in subjects with airway obstruction (defined as FEV_1/FVC < 0.7) compared with the nonobstructed population.[28] There were 254 participants (4.3%) who had both characteristics: obstructive airways disease and sleep apnea. As expected, respiratory disturbance index increased with higher body mass index (BMI) in participants with and without airway obstruction. Age effect was not specifically addressed in this study. In short, the few available population studies of the association between COPD and OSA (i.e., overlap syndrome) show great variability in the prevalence of this association. It does appear that the world's adult population is affected in a range between 1% and 4%. This range likely reflects, at least to some extent, differences in the criteria used to define OSA and the age and weight of the subjects studied.

Sleep in Patients with COPD/OSA Overlap Syndrome

In the Sleep Heart Health Study, patients with OSA/COPD overlap syndrome had a lower total sleep time, lower sleep efficiency, and higher daytime sleepiness as assessed by the Epworth Sleepiness Scale[29] than did patients with COPD alone. They were also more likely to have greater sleep-related

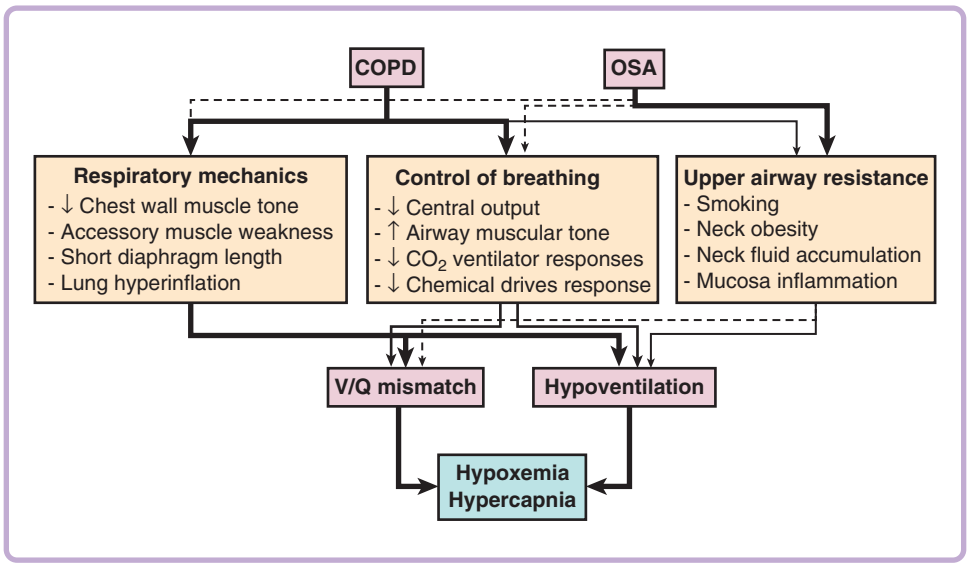

Figure 119-1 Pathways involved in producing sleep-related hypoxemia and hypercapnia in chronic obstructive pulmonary disease (COPD) and obstructive sleep apnea (OSA) overlap syndrome.

oxygen desaturation compared with participants with OSA or airway obstruction alone.[28] Most important, patients with overlap syndrome, compared with patients with either COPD or OSA alone, display more profound oxygen desaturation during sleep as well as worse daytime hypoxemia and hypercapnia.[26]

Risk Factors for COPD/OSA Overlap Syndrome

Patients with COPD can incur specific OSA risks, including obesity irrespective of airflow obstruction severity,[30] active smoking,[31,32] and both pharyngeal and lower extremity edema associated with episodic use of oral corticosteroids and impaired cardiac output.[33] There is also evidence that patients with advanced COPD who lose weight may show reduced diathesis for upper airway obstruction.

Sleep and Breathing Pathophysiology of COPD/OSA Overlap Syndrome

Because obesity also reduces functional residual capacity during sleep, overweight and obese patients with COPD/OSA overlap syndrome are particularly subject to a reduction of alveolar volume and greater gas exchange abnormalities during sleep apneas and hypopneas (Figure 119-1). Further, respiratory control center output is reduced during sleep, especially during REM sleep,[34] including blunted ventilatory responses and mouth occlusion pressure responses to CO_2.[35] During obstructive apneic episodes, to overcome the upper airway resistance and to maintain adequate airflow to the lung, increased diaphragmatic and abdominal muscle effort is required. This can be particularly difficult in COPD patients who already have increased intrathoracic airway resistance and lung hyperinflation at baseline. When COPD patients develop such obstructive apnea episodes, the compensatory response of the respiratory center is slower, apneas are longer, and changes in Pao_2 and Pco_2 are more intense compared with non-COPD subjects. Patients with COPD/OSA overlap syndrome who have awake hypoxemia are especially prone to nocturnal oxygen desaturation by being on the steep portion of the oxyhemoglobin dissociation curve.

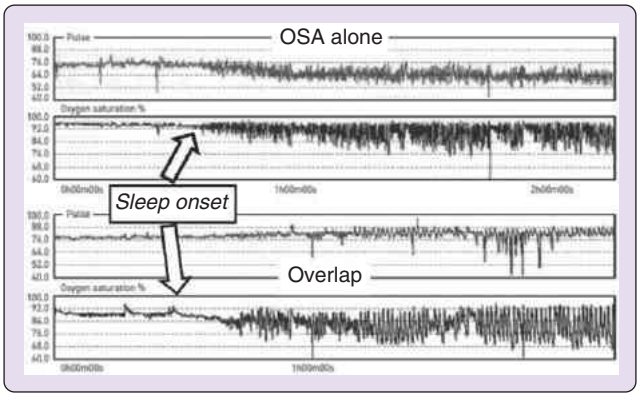

Figure 119-2 Typical pattern during sleep of a patient with obstructive sleep apnea (OSA) alone (*upper panel*) and chronic obstructive pulmonary disease (COPD)/OSA overlap syndrome (*lower panel*). Note the pattern of persistent O_2 desaturation in overlap patients; in contrast to the OSA patients, O_2 saturation does not return to baseline between apnea episodes.

Clinical Features of COPD/OSA Overlap Syndrome

Compared with patients with COPD alone or OSA alone, overlap patients of similar ages tend to be more obese and to have more comorbid conditions.[36] They also report more daytime sleepiness[28] and poorer quality of life[37] than either COPD or OSA patients without overlap syndrome. Sleep recordings of patients with COPD/OSA overlap show a lower total sleep time, lower sleep efficiency, and greater sleep fragmentation than those with COPD or OSA alone. More severe nocturnal O_2 desaturation is also a characteristic feature in COPD/OSA overlap patients compared with either condition alone. Subjects with OSA alone return to a normal O_2 saturation (Sao_2) in sleep between obstructive events (i.e., intermittent hypoxemia), whereas in COPD alone, as a result of the diathesis to sleep-related hypoventilation and ventilation-perfusion mismatch as noted before, nocturnal O_2 saturation characteristically decreases more evenly throughout sleep and at the termination of an apnea or hypopnea episode tends not to return to the initial baseline level (Figure 119-2).

A typical patient with COPD/OSA overlap syndrome has a reduced awake and asleep baseline Sao_2, a lower mean sleep-related Sao_2, and a longer time in hypoxemia than patients with OSA or COPD alone.

The majority of patients with OSA alone do not develop significant sleep-related hypercapnia because of interapnea hyperventilation. However, if the patient also has COPD, the abnormal mechanical and chemical ventilatory responses as noted before may result in postapnea CO_2 levels that do not return to baseline. Over time, a progressive desensitization of the respiratory center in response to OSA-related hypoxic-hypercapnic episodes develops, such that patients with COPD/OSA overlap syndrome can remain hypercapnic during sleep.[38] Of note, continuous positive airway pressure (CPAP) treatment for the OSA (see Diagnosis and Management of COPD/OSA Overlap Syndrome) can partially reverse this phenomenon.[39] Although daytime hypercapnia can develop in OSA without COPD, awake hypercapnia is much more frequent in the patient with overlap syndrome.[40] Both daytime hypoxemia and hypercapnia have been found to be predictors of right-sided heart failure in COPD patients,[41] and therefore these should be considered potentially treatable markers of otherwise poorer prognosis in COPD/OSA overlap.

Excessive sleepiness in patients with OSA alone is associated with decrements in school and work performance.[42] Further, there is also a strong association between OSA severity, as measured by the AHI, and the risk of traffic accidents.[43] It is reasonable to expect that in patients with COPD/OSA overlap syndrome, such performance decrements and risks reflect the sum of the severity of the sleep disorders of both entities, but such consequences of the COPD/OSA overlap syndrome have not been evaluated specifically. Similarly, whereas OSA is considered an independent risk factor for insulin resistance, with OSA severity predicting risk for incident diabetes,[44] neither COPD alone nor COPD/OSA overlap has been specifically linked with risk of metabolic disorders.

Both OSA and COPD alone are associated with an increased risk of cardiovascular morbidity and mortality. For example, epidemiologic data show a strong association between OSA and incident arterial hypertension,[45] particularly refractory hypertension. In COPD alone, however, arterial hypertension prevalence is similar to that of the general population, and patients with COPD/OSA overlap appear to have the same prevalence rates as patients with OSA alone.[36] Untreated OSA patients are also particularly susceptible to development of atrial fibrillation,[46] as are patients with COPD alone, likely related to nocturnal O_2 desaturation.[47,48] A community-based retrospective cohort analysis, including data collected on 2873 patients older than 65 years, confirmed an increased risk of new-onset atrial fibrillation in COPD/OSA overlap syndrome compared with OSA or COPD alone.[49]

Epidemiologic data indicate that incidence of coronary artery disease, stroke, and heart failure is increased in OSA[15,16,50] and COPD[51]; no such incidence data are available for COPD/OSA overlap. However, Chaouat et al[26] demonstrated that patients with COPD/OSA overlap syndrome have increased daytime pulmonary vascular resistance compared with patients with OSA alone, whereas Sharma et al[52] recently documented a higher right ventricular mass and

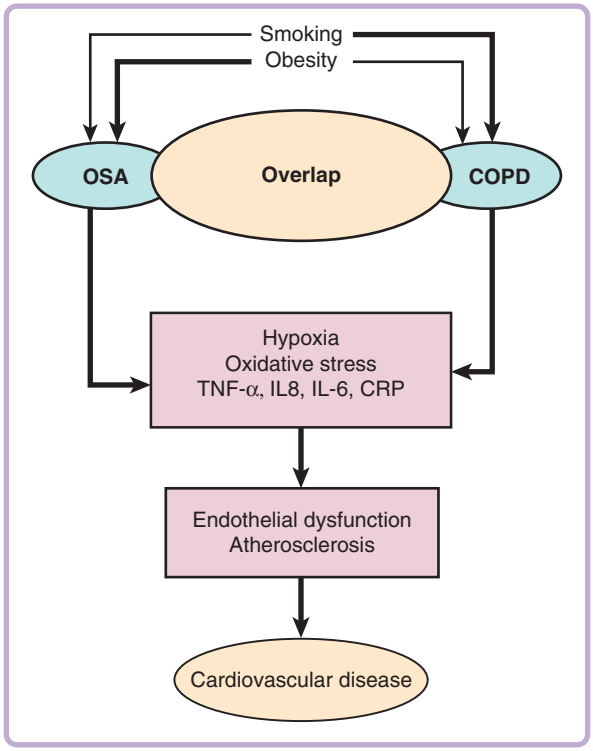

Figure 119-3 Schematic illustrating potential pathways involved in producing accelerated cardiovascular disease as a result of obstructive sleep apnea (OSA), chronic obstructive pulmonary disease (COPD), and COPD/OSA overlap syndrome. COPD, Chronic obstructive pulmonary disease; CRP, c-reactive protein; IL, interleukin; TNF-α, tumor necrosis factor-alpha.

remodeling indices in overlap syndrome compared with patients with COPD alone. In addition, arterial stiffness, a surrogate marker of subclinical atherosclerosis, has also been found to be significantly higher in subjects with COPD/OSA overlap than in those with OSA alone.[53] Finally, whereas increased oxidative stress is associated with both COPD and OSA, with evidence of increased circulating proinflammatory cytokines and leukocytes in both disorders, no specific data exist regarding COPD/OSA overlap syndrome and risk and prevalence of such oxidative stress compared with COPD or OSA alone. Potential key risk factors for endothelial dysfunction, atherosclerosis, and ultimately cardiovascular diseases are depicted in Figure 119-3.

In both COPD alone and OSA alone, the risk of excess all-cause mortality increases in association with increasing severity of these disorders. The excess of mortality is most marked in younger individuals with OSA[54] and in more elderly patients with COPD.[55] Overall, evidence indicates that mortality is increased in COPD/OSA overlap patients. For example, in OSA patients studied at sleep clinics, the coexistence of COPD has been found to increase the risk of death compared with patients with OSA alone.[56] We have recently confirmed this in a large cohort of patients with an average age of 57 years, referred with suspected SDB. In addition to PSG, all patients underwent spirometry as a routine procedure.[36] During a median follow-up period of more than 9 years, all-cause mortality was higher in the overlap group untreated for OSA (42.2%) than in the COPD-only group (24.2%) (Figure 119-4). In the COPD patients, comorbid untreated OSA remained a risk factor for death even after

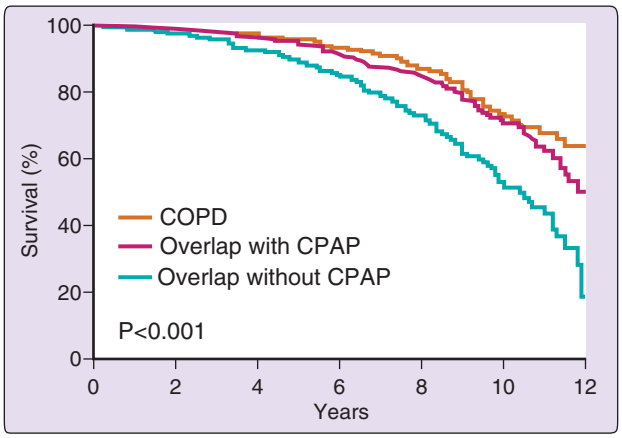

Figure 119-4 Kaplan-Meier survival curves of chronic obstructive pulmonary disease (COPD) patients without obstructive sleep apnea (OSA), patients with COPD and coexisting untreated OSA (overlap group), and patients with overlap syndrome treated with continuous positive airway pressure (CPAP). The differences in survival for COPD alone and COPD/OSA overlap syndrome treated with CPAP are statistically different compared with patients with untreated overlap syndrome ($P < .001$). Outcomes in patients with chronic obstructive pulmonary disease and obstructive sleep apnea: the overlap syndrome. *Am J Respir Crit Care Med* 2010;182:325–31. Official Journal of the American Thoracic Society.)

adjustment for FEV_1 percentage predicted as a surrogate of COPD severity. There was a significantly higher number of cardiovascular deaths in patients with COPD only and untreated overlap syndrome compared with overlap patients treated appropriately for their OSA with CPAP. Interestingly, the second most frequent cause of death was cancer in patients with both OSA and COPD alone.[57,58]

Nocturnal death risk appears to be increased in COPD compared with the general population, mainly during COPD exacerbations.[59] Nocturnal hypoxemia, an important pathophysiologic feature of OSA, is associated with sudden cardiac death (SCD). Gami et al[60] reported on 10,701 consecutive adults undergoing diagnostic PSG and sought to identify the risk of SCD associated with OSA. During an average follow-up of 5.3 years, 142 patients had resuscitated or fatal SCD. Independently of well-established risk factors, SCD was best predicted by age older than 60 years, AHI above 20, mean nocturnal Sao_2 below 93%, and nadir nocturnal Sao_2 below 78%. No data are available in this study regarding the risk of nocturnal death in patients with COPD/OSA overlap versus COPD or OSA alone. Nevertheless, the report by McNicholas and FitzGerald[59] documented that nocturnal death was higher among patients admitted for acute exacerbation of chronic bronchitis or emphysema than in patients admitted for other causes. It is possible that an increased sympathetic activity along with a reduction in the perfusion of oxygen to the myocardium can increase the risk of arrhythmias and mortality during nighttime hours in COPD patients. Whether the coexistence of OSA (i.e., COPD/OSA overlap) increases this risk remains unknown.

Diagnosis and Management of COPD/OSA Overlap Syndrome

There are no specific guidelines for the diagnosis or treatment of COPD/OSA overlap syndrome. In the appropriate clinical context, PSG and spirometry should be performed to confirm the existence of the syndrome and to establish its severity. It has been appropriately stated that PSG should be considered in patients with COPD "when OSA is suspected because of either symptoms or the development of hypoxemic complications—cor pulmonale and polycythemia—with daytime Pao_2 greater than 60 mm Hg."[61]

The therapeutic management of identified COPD/OSA overlap syndrome patients should, in general, be based on optimizing treatment for both conditions (COPD and OSA) following corresponding clinical recommendations.[1,43] The goal of such therapy includes improvement in subjective outcomes, such as sleep fragmentation, sleep quality, and daytime sleepiness, as well as optimization of more objective data regarding daytime alertness and function and COPD- and OSA-specific cardiopulmonary outcomes, such as frequency of COPD exacerbation. Correction of hypoxemia and hypercapnia during sleep is considered especially important to reduce cardiovascular complications and to increase survival.

Noninvasive ventilation (NIV), currently typically applied as positive airway pressure (PAP) delivery thorough a nasal or face mask, is the most effective treatment for OSA. Continuous PAP (CPAP) is the optimal PAP therapy for most patients with OSA; bilevel PAP, which delivers a higher pressure during inspiration than during expiration, may also be used if a pressure gradient that increases alveolar ventilation is necessary, effective, and tolerated.

In COPD, NIV in a specifically ventilatory mode (usually bilevel PAP) is consistently shown to be highly effective in the setting of acute and acute-on-chronic hypercapnic respiratory insufficiency. In contrast, data regarding the effects of NIV on quality of life, lung function, gas exchange, and long-term survival have been contradictory when it is used in the chronic setting in COPD patients, in part because of the absence of studies of sufficient power and duration.[62] In the United States, NIV is reimbursed for patients with severe COPD and all the following criteria: (1) OSA has been ruled out; (2) awake $Paco_2$ is 52 mm Hg or higher; and (3) sleep oximetry shows Sao_2 of 88% or less for 5 minutes or more while breathing supplemental O_2 at 2 liters/minute or at the patient's prescribed FIo_2.[63]

Data have now accrued specific to OSA/COPD overlap syndrome regarding nocturnal NIV, specifically CPAP. In a long-term cohort study, overlap syndrome patients not treated with CPAP demonstrated both an increased risk of death from any cause and an increased risk of hospitalization for COPD exacerbation compared with overlap patients who were treated with and adhered to CPAP.[36] In another observational study, the use of CPAP added to long-term oxygen therapy improved survival among overlap patients with chronic respiratory failure.[64] Finally, a retrospective analysis of 227 patients with COPD/OSA overlap syndrome treated with CPAP revealed that a greater time on CPAP was associated with a reduced risk of death after controlling for common risk factors.[65]

The choice between CPAP and bilevel PAP can be determined during the titration session, based on the pattern of SDB. In cases in which OSA predominates and there is no coexistent consistent sleep-related hypoventilation, CPAP may be most appropriate to treat the OSA component. In cases in which there is evidence of any degree of nocturnal hypoventilation in addition to the apneic episodes, bilevel

PAP may be more appropriate. Nevertheless, there is no specific evidence in the literature of the superiority of CPAP or bilevel PAP for the treatment of patients with OSA/COPD overlap syndrome regarding long-term outcomes. Supplemental oxygen should be added to the mask or the PAP circuit if the otherwise optimal-appearing PAP regimen (whether CPAP or bilevel PAP) alone fails to provide satisfactory oxygenation. The ideal setting in which to adjust these parameters is the sleep laboratory, and such "titrations" should be conducted by well-trained technicians with the design, guidance, and interpretation of clinicians with sleep breathing expertise.

In most patients with COPD alone, nocturnal hypoxemia, when present, is corrected with supplemental O_2 through a nasal cannula. Nevertheless, alveolar ventilation of such patients is particularly dependent on the peripheral stimulant effect of hypoxemia. Therefore, to minimize the tendency toward CO_2 retention, particularly during sleep hours, such O_2 supplementation should be titrated carefully. The emergence of morning headache after O_2 initiation in patients with COPD is an indication to perform a PSG study to exclude the coexistence of OSA or to investigate the development of CO_2 retention. In OSA, supplemental oxygen treatment without PAP can eliminate or reduce nocturnal hypoxemia, but it does not reduce the AHI, daytime hypersomnolence,[66] or nocturnal blood pressure.[67] The role of oxygen supplementation as a solo nocturnal therapy in COPD/OSA overlap syndrome has not been sufficiently explored, and at present it is recommended that nocturnal O_2 be used as a complement to NIV in patients with COPD/OSA overlap syndrome.

No specific studies have been conducted on sleep quality, SDB, or long-term clinical outcomes to evaluate the effects of pharmacologic treatment in patients with COPD/OSA overlap syndrome. Potential use of pharmacologic therapy in overlap syndrome can therefore only be extrapolated from limited existing data about such treatment in OSA and COPD alone. There is in fact currently no established role for pharmacologic treatment of OSA alone, whereas patients with COPD alone receive pharmacologic treatment according to current recommendations.[1] The most common drugs currently prescribed in stable COPD, such as long-acting anticholinergics and long-acting beta agonists, have been shown to improve nocturnal O_2 saturation but not quality of sleep.[68,69] Theophylline, potentially useful for patients with COPD and SDB as a central respiratory stimulant with enhancement of the activity of the respiratory muscles,[70] is currently not clearly shown to be efficacious in improving COPD-related sleep breathing disorders or perturbed quality of sleep. Inhaled corticosteroids used in patients with stable COPD have not been specifically linked with either enhanced or decreased sleep continuity. Benzodiazepine sleep aids are typically avoided in patients with COPD and with OSA because of concerns that they may decrease the arousal response to hypercapnia, induce hypoventilation, and decrease upper airway muscle tone. There is evidence that nonbenzodiazepine hypnotics do not decrease respiratory drive and do not cause daytime drowsiness[71]; however, the indications for and contraindications to any type of sleep aid in these conditions, whether OSA or COPD alone or COPD/OSA overlap syndrome, remain to be better established.

The role of surgery in the treatment of COPD/OSA overlap as well as the need for special precautions regarding preoperative and postoperative evaluation and care in such patients undergoing surgery for treatment of their COPD or OSA, including lung transplantation, lung volume reduction, upper airway surgery, and bariatric surgery, also remains to be established.

ASTHMA

According to the Global Strategy for Asthma Management and Prevention of the Global Initiative for Asthma (GINA), asthma is defined by a history of respiratory symptoms such as wheeze, shortness of breath, chest tightness, and cough that vary over time and in intensity, together with variable expiratory airflow limitation.[72] It is typically recognized as a heterogeneous disease, usually characterized by chronic airway inflammation. Current asthma prevalence across all ages in the United States is 8.2%.[73]

Sleep has a deep impact on the morbidity and mortality of patients with asthma. Classical studies linked nocturnal asthma to an increased risk of mortality, with 70% of deaths and 80% of respiratory arrests caused by asthma occurring during nocturnal hours.[74] The normal physiologic changes that affect the lung during sleep and how those changes may contribute to nocturnal asthma have recently been reviewed in depth.[75]

Nocturnal asthma is characterized by coughing, wheezing, or dyspnea that interrupts and disturbs sleep, with such patients complaining of frequent arousals and poor sleep quality.[76] Nocturnal asthma generally indicates poor control of asthma and the need to modify overall asthmatic treatment.[72] Sleep studies done when current asthma treatment was not available showed a lower sleep efficiency, more awakenings, and less stage 3–4 sleep in asthmatics compared with nonasthmatic subjects.[77] Cognitive performance, as tested by psychometric testing, has also been shown to be impaired in patients with nocturnal asthma.[78] Circadian peak expiratory flow variation of 20% or more, a surrogate parameter of asthma instability, has been associated with poorer daytime cognitive performance compared with healthy control subjects.[79] Effective asthma treatment resulted in the recovery of cognitive impairment to a level of performance comparable to that of the healthy control subjects, paralleled by a reduction of circadian peak expiratory flow variation below 10% and by the resolution of nocturnal asthma symptoms.

Asthma and OSA Overlap Syndrome

Epidemiology

In adults, diseases with a known association with asthma include gastroesophageal reflux disease, rhinosinusitis, obesity, mental disorders, and OSA. The GINA initiative recommended investigation for the coexistence of OSA (i.e., asthma/OSA overlap syndrome) in all patients with asthma, especially in those with severe asthma, difficult to control asthma, and asthma with associated obesity.[72]

There are, however, few population-based data to identify the prevalence or severity of OSA in adult asthmatics. In a U.S. academic institution, patients in the asthma clinic and internal medicine clinic were surveyed for OSA risk with the Berlin Questionnaire, a validated instrument with a positive predictive value of 0.89.[80] OSA risk, as determined by the Berlin Questionnaire, was higher in the asthma group (39.5%) than in the internal medicine group (27.2%; $P = .004$). In a

Canadian cohort of patients with asthma, whose severity was established in accordance with the American Thoracic Society criteria,[81] OSA as defined by an AHI of 15 or more events per hour of sleep was present in 88% of patients with severe asthma, 58% of patients with moderate asthma, and 31% of controls without asthma.[82] From these limited data and in the absence of robust population-based studies, it appears that the prevalence of asthma/OSA overlap syndrome, defined as the coexistence of both entities in the same patient, likely is high in asthmatics, especially those with the most severe forms of asthma.

In patients with nocturnal asthma whose quality of sleep does not improve with proper antiasthma treatment, the coexistence of OSA (i.e., asthma/OSA overlap syndrome) should be excluded. Whereas there are no specific studies regarding the effect of coexistent OSA on the quality of sleep and daytime function in asthmatics, it is rational to expect an additive adverse effect of OSA on these outcomes.

Pathophysiology and Risk Factors for Asthma/OSA Overlap Syndrome

Numerous pathophysiologic and clinical factors contribute to an increased diathesis for OSA in patients with treated and untreated asthma; similarly, there are many pathophysiologic and clinical factors that increase the diathesis for asthma, including nocturnal asthma, in patients with OSA. Such factors, therefore, not only constitute risk factors for the presence and severity of asthma/OSA overlap syndrome but also thus represent the adverse clinical manifestations of asthma/COPD overlap. Obesity is a risk factor for both asthma and OSA and therefore for asthma/OSA overlap syndrome. There is a "dose response" effect of increasing BMI on increasing risk of incident asthma, especially in women.[83]

Many patients with nonatopic asthma and most atopic asthmatics suffer from nasal obstruction due to rhinitis and chronic sinusitis, which cause nasal congestion and airflow resistance, and nasopharyngeal polyps, which reduce airway caliber. These lead to increasing intrathoracic and pharyngeal negative pressure, which promotes upper airway collapse during inspiration, snoring, and obstructive apnea.[84] Similarly, in patients with chronic asthma, persistent mucosal inflammation affects the upper airway by decreasing cross-sectional area of the pharynx, promoting upper airway collapse.[85]

Inhaled corticosteroids are the most effective and most widely used drugs in asthma. Their long-term effects on the collapsibility of the pharynx remain unknown. However, the effects of oral corticosteroids on the upper airway are well known and are generally adverse, including myopathy of the muscles of the pharynx, fatty infiltration of the pharyngeal wall, and accumulation of liquid in the neck. In asthma clinics, asthmatics requiring frequent bursts or consistent use of oral corticosteroids were found to have a high prevalence of OSA (>90%) after adjustment for BMI and neck circumference.[86]

Factors potentially effective in reducing the risk and severity of OSA in patients with asthma include the same factors as in the case of patients with COPD/OSA overlap: weight loss, sleep in the lateral decubitus position, and smoking cessation. The effect of adjusting asthma medications to improve concomitant OSA has not been studied. In nonasthmatic patients with OSA, there is both molecular and clinical evidence of the ability of inhaled corticosteroids to reduce upper airway inflammation and to improve AHI in a subgroup of patients with concomitant allergic rhinitis.[87] In clinical practice, nasal inhaled corticosteroids and oral antileukotrienes may be beneficial for reducing snoring and obstructive apneas in children with asthma and OSA, but such an effect has not been proved in adults. These noted factors, both predisposing to and protective against OSA in patients with asthma, are shown in schematic form in Figure 119-5.

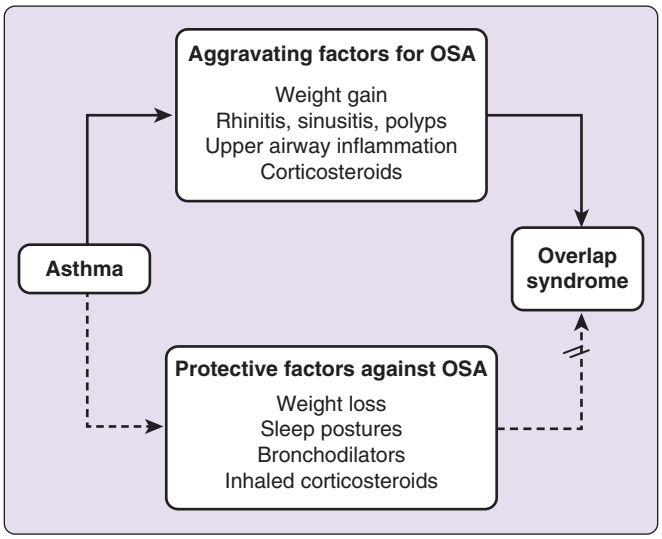

Figure 119-5 Interactions between asthma and obstructive sleep apnea (OSA) contributing to asthma/OSA overlap syndrome.

The potential mechanisms by which OSA may worsen asthma are also multifactorial. Obstructive apneic episodes are associated with repetitive arousals from sleep, perturbations in autonomic activity, and intermittent hypoxemia.[43] Increased vagal tone during obstructive apnea episodes can contribute to nocturnal asthma through stimulation of muscarinic receptors of the central and upper airways. Negative intrathoracic pressure during obstructive events leads to intermittent loss of lower esophageal sphincter tone; associated gastroesophageal reflux is associated with bronchial microaspiration of gastric acid, potentially promoting nocturnal asthma.[88] By stimulation of carotid body receptors, intermittent hypoxia can enhance bronchial responsiveness through vagal pathways.[89] Chronic intermittent hypoxia in OSA may also induce a low-grade systemic inflammation characterized by the elevation of serum proinflammatory cytokines and chemokines. Local inflammatory changes of the upper airways similar to those noted in asthma are also prominent in OSA. Such inflammatory changes may reduce airway caliber and at the same time increase underlying bronchial hyperresponsiveness, thus representing a potential asthma trigger.

Clinical Outcomes and Treatment in Asthma/Overlap Syndrome

In contrast to COPD/OSA overlap syndrome, there are no long-term studies that have evaluated asthma outcomes, either nocturnal or awake, among patients with comorbid untreated OSA or OSA outcomes in OSA patients with comorbid asthma. Consequently, there are currently no guidelines specific to the management of asthma/OSA overlap syndrome. However, in asthma/COPD overlap patients, OSA treatment with CPAP has important potential pathophysiologic

beneficial effects for asthmatics, including reducing gastroesophageal reflux, airway and systemic inflammation, and airway smooth muscle contractility.[89] Therefore, CPAP appears to have significant potential clinical benefit in the treatment of the asthma/OSA overlap syndrome, and data do exist documenting that CPAP treatment for comorbid OSA improves asthma symptoms, decreases use of rescue medication, and improves asthma-specific quality of life.[90-93] Further, in a short-term randomized trial, CPAP use decreased airway reactivity in asthmatics without OSA, possibly through reducing bronchial inflammation.[94] Longer term studies are needed to determine the optimal application of CPAP in patients with and without asthma/OSA overlap in improving asthma symptoms, medication need, and overall cardiorespiratory and quality of life outcomes.

Second-line treatments for OSA, such as mandibular advancement devices and upper airway surgery, have not been prospectively evaluated in patients with asthma/OSA overlap. However, bariatric surgery for patients with OSA and morbid obesity may be effective not only for OSA resolution but also for improving asthma.[95] There are no studies assessing clinical outcomes related to the use of asthma medications in asthma/OSA overlap syndrome. At this time, therefore, it appears that asthma in patients with OSA should be treated according to current asthma treatment guidelines[72] in addition to optimizing treatment of the comorbid OSA.

INTERSTITIAL LUNG DISEASE

Diffuse parenchymal lung disease, also known as interstitial lung disease (ILD), represents more than 200 nonmalignant, noninfectious entities characterized by inflammatory and fibrotic changes affecting alveolar and air spaces. ILD is characterized by progressive dyspnea, hypoxemia, and restrictive-ventilatory limitation. It should be suspected in the appropriate clinical context when there is evidence of impairment of gas exchange or restrictive lung function deficit. Confirmation comes when there is a pattern of usual interstitial pneumonia on lung biopsy or on computed tomography scan.[96] The incidence of ILD appears to be increasing mainly because of improvements in the ability to diagnose the condition due to advances in chest imaging.[97]

Sleep is often disturbed among patients with ILD, which contributes to daytime fatigue in this population.[98] Compared with control subjects, Perez-Padilla et al[99] reported worse sleep quality in patients with ILD, with more time in stage N1 (33.7% of total sleep time versus 13.5%), less time in REM sleep (11.8% versus 19.9% of total sleep time), and more fragmentation of sleep. In this study, patients with awake hypoxemia (Sao_2 < 90%) had greater abnormalities in sleep structure than did those with Sao_2 above 90%. Potential mechanisms that contribute to sleep fragmentation include hypoxemia, hypercapnia, and cough. Most patients report nocturnal cough as an important cause of nocturnal awakenings. Esophageal dysmotility and reflux, also prevalent in ILD, and the pulmonary fibrotic process itself are the main intermediate mechanisms that explain nocturnal cough.[100]

Hypoxemia during sleep is also common and tends to be worse in those with more severe daytime hypoxemia.[99] During REM sleep, O_2 desaturation is often more severe than that occurring during exercise.[101] The role of nocturnal desaturation on health outcomes in patients with ILD has been evaluated retrospectively in a large cohort of patients with ILD.[102] In this study, desaturation index was defined as the number of desaturation events above 4%/hour. Desaturation was present in 37% of patients, and 31% of them had PH on echocardiography. Increased desaturation index was associated with higher mortality independent of age, gender, BMI, and PH. These data indicate the need to conduct sleep studies in patients with ILD. If nocturnal hypoxemia is detected, it is reasonable to treat these patients with oxygen therapy, at least until randomized trials are available.

ILD and Obstructive Sleep Apnea Overlap Syndrome

OSA is prevalent in ILD but clearly underrecognized. In a sample of 50 patients with stable ILD, OSA was confirmed with PSG in 88%.[103] Of those, 68% were moderate to severe (AHI >15 events per hour of sleep). It appears that severity of OSA, as indicated by AHI, inversely correlates with total lung capacity and, interestingly, poorly correlates with BMI.[103] The mechanistic relationship between OSA and ILD and the impact of comorbid OSA on the natural history of ILD remain unknown. Nevertheless, clinicians should evaluate the potential coexistence of SDB in patients with ILD as the appropriate treatment can improve the patient's quality of life and may improve survival.

PULMONARY HYPERTENSION

PH is defined as a mean pulmonary artery pressure higher than 25 mm Hg.[104] The current classification of PH consists of five categories: (1) primary pulmonary arterial hypertension (PAH); (2) PH due to left-sided heart disease; (3) PH associated with chronic pulmonary diseases, such as COPD and OSA; (4) chronic thromboembolic PH; and (5) PH due to various disorders, such as sarcoidosis or systemic vasculitis.[104] The mechanisms by which OSA can lead to the development of PH as a potential long-term complication are reviewed in Chapter 127.

Pulmonary Hypertension and Sleep-Disordered Breathing Overlap Syndrome

SDB overall can be considered a spectrum of ventilatory disorders during sleep that include OSA, central sleep apnea, and sleep-related hypoventilation. The prevalence of SDB/PH overlap is not known. One study conducted to determine the prevalence and significance of nocturnal oxygen desaturation in patients with PH, using home oximetry studies, showed that 69.7% of patients spent more than 10% of sleep time with Sao_2 below 90%.[105] Nocturnal hypoxemia correlates with advanced PH and right ventricular dysfunction. Interestingly, 60% of this subgroup with nocturnal hypoxemia had no exertional hypoxemia. In a small study of patients with idiopathic PH who had full PSG, Schulz et al[106] found that 30% of these patients had periodic breathing, defined as a crescendo-decrescendo pattern of hyperventilatory phases alternating with central apneas or hypopneas of at least three consecutive cycles. Most of these patients, however, had normal nocturnal oximetry. In another study of 38 PH patients who had ambulatory cardiorespiratory sleep studies, 45% had 10 or more apnea-hypopnea events per hour.[107] A subgroup of 22 patients also had in-laboratory PSG. Among patients who underwent both studies, home sleep studies accurately predicted an AHI of 10 events or more during PSG (area under the

receiver operating characteristic curve, 0.93; $P = .002$). The corresponding value for pulse oximetry was 0.63 (P = not significant). Therefore, when SDB is suspected among patients with PH, evaluation should include full PSG or modified cardiorespiratory sleep studies rather than pulse oximetry alone.

In the largest series of patients with confirmed PH by right-sided heart catheterization,[108] home cardiorespiratory sleep studies demonstrated that among 169 patients, 26.6% had an AHI above 10 events. Of these, 27 patients (16%) had OSA and 18 patients (10.6%) had central sleep apnea. Despite these limited data, it seems that the prevalence of SDB/PH overlap appears to be higher in PH patients than in the general population.

The extent to which SDB contributes to the PH patient's symptoms and disease progression is unclear. In a retrospective review of 52 consecutive patients with PAH referred for assessment of possible SDB, 71% had SDB (56% of these had primarily OSA and 44% primarily central sleep apnea).[109] There were no differences in cardiopulmonary hemodynamics at baseline assessed by right-sided heart catheterization between patients with PAH only and those with SDB/PH overlap. After a median follow-up of 4.7 years, no differences in survival between those with and without SDB were observed. In this study and in the other studies commented on before,[105,107] there was a lack of subjective daytime sleepiness as assessed by the Epworth Sleepiness Scale in the PAH population with or without coexistent SDB, similar to that found in patients with heart failure with and without SDB; such a phenomenon could be explained by elevated sympathetic nervous activity in both heart failure and PH[110,111] that can act as an adrenergic cortical alerting mechanism. Predictors of SDB in patients with PH do not differ from those of the general population, being mainly older age and BMI.[105-109]

Coexistent OSA may contribute to worsening of underlying PAH. During obstructive events, negative intrathoracic pressures result in right ventricular overload.[112] This is aggravated by intermittent hypoxia and elevated sympathetic nervous activity. Together, these mechanisms contribute to right ventricular hypertrophy and ultimately cardiac failure. Conversely, patients are more predisposed to development of OSA if they accumulate fluid in the neck during sleep.[113] Such rostral shift of fluid from the legs during the daytime to the neck at night has been demonstrated in patients with left ventricular failure[114] (Figure 119-6).

Because of the absence of long-term studies, the prognosis of SDB/PH overlap remains unknown. Similarly, no studies have systematically evaluated the effect of SDB treatment on SDB/PH overlap syndrome outcomes. However, the presence of PH may have prognostic importance in patients with OSA; for example, an observational study of 83 patients with OSA (AHI > 5) who underwent pulmonary artery catheterization for unspecified reasons documented 1-, 4-, and 8-year survival rates that were lower among patients with PH (mean pulmonary artery pressure > 25 mm Hg at rest) than among those without PH.[115]

We believe that at the present time, patients with PH should be evaluated by PSG when presenting with symptoms that suggest the coexistence of SDB, such as daytime hypoxemia or heart failure. Treatment with CPAP, supplemental oxygen, or both is ideally titrated in the sleep laboratory to customize the treatment as in the other overlap syndromes described before.

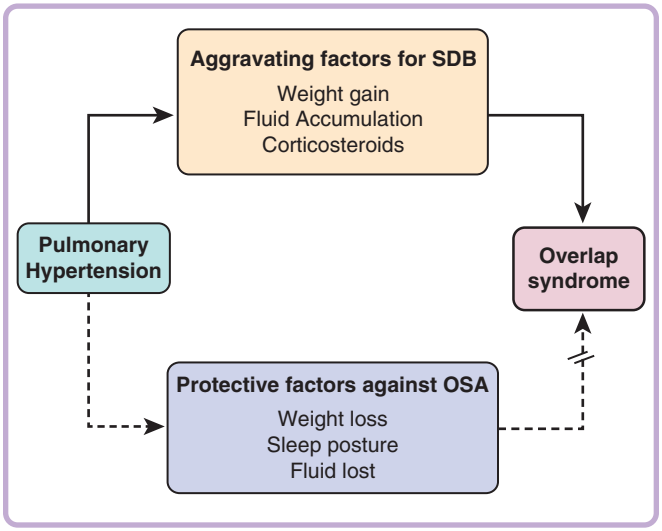

Figure 119-6 Interactions between pulmonary hypertension and sleep disordered breathing (SDB).

INSOMNIA IN PULMONARY DISEASES

Chronic insomnia is a major health problem that leads to worse quality of life and decreased productivity.[116] It is estimated that approximately 10% of the general population is insomniac.[117] There has been little interest in the study of insomnia in pulmonary disorders. Specifically, there are no data on the prevalence and burden of insomnia in patients with PH or ILD. In COPD, relatively older studies reported a high prevalence of self-reported insomnia compared with non-COPD subjects that appears related to the severity of the respiratory symptoms.[118] According to the American Academy of Sleep Medicine, insomnia is defined as history of frequent difficulty in initiating or maintaining sleep and significant disruption of daytime functioning for at least 1 month.[119] Recently, using the American Academy of Sleep Medicine criteria, Budhiraja et al[120] interviewed 183 patients with COPD about sleep complaints. Insomnia was present in 27.3% of participants. Severity of COPD as assessed by pulmonary function test (FEV_1 < 50% predicted) or by the Medical Research Council dyspnea scale was not different among participants with insomnia or without insomnia. Interestingly, the presence of insomnia was associated with increased daytime sleepiness and worse quality of life. There are no studies that have evaluated the causality of factors associated with insomnia in patients with COPD or that have evaluated the insomnia as a determinant of health outcomes in COPD.

Because of this high prevalence of insomnia, it is common that COPD patients request medicines to improve their quality of sleep. Benzodiazepines are prescribed for non-COPD insomniacs because they shorten sleep latency, improve sleep efficiency, and decrease arousal frequency. Nevertheless, these agents should be avoided if possible in COPD patients because they reduce alveolar ventilation, diminish arousal response, and increase apnea frequency, and therefore they can worsen hypoxemia and hypercapnia.[121]

Some nonbenzodiazepine hypnotics, such as zolpidem,[122] and melatonin receptor antagonists, such as ramelteon,[123] have been reported to have no adverse effects on gas exchange in patients with COPD. Recently, the safety profile of suvorexant, an orexin receptor antagonist approved for treatment of insomnia in the United States, was evaluated in COPD. Suvorexant, at up to twice the maximum recommended dose, did not cause SBDs in a multicenter, randomized, double-blind, placebo-controlled, crossover study in patients with mild to moderate COPD.[124] At the present time and in the absence of comparative studies, we consider that physicians caring for COPD patients with insomnia should preferably use nonbenzodiazepine hypnotics with which they are most familiar.

Sleep disturbances in patients with asthma relate to the occurrence of nocturnal asthmatic crisis. The prevalence of insomnia symptoms was significantly higher among asthmatics than among nonasthmatics (47.3% versus 37.2%) in a postal questionnaire sent to a random sample of 45,000 adults in Sweden.[125] In this study, the risk of insomnia increased with the severity of asthma. In another recent online survey of adolescents from the general community, it was reported that almost twice as many adolescents with severe asthma had clinically significant insomnia than adolescents with mild or no asthma.[126] Daytime sleepiness was frequent in this population, and 28% of its variance was accounted for by insomnia severity, whereas only 2% was accounted for by asthma severity. Insomnia remains a common problem among asthmatics that should be addressed in any patient as part of his or her comprehensive treatment.

CLINICAL PEARLS

- Overlap of OSA with COPD, the COPD/OSA overlap syndrome, affects more than 1% of adults. The prevalence of OSA overlap with asthma, the asthma/OSA overlap syndrome, and the prevalence of SDB overlap with PH, the SDB/PH overlap syndrome, are not well defined. Nevertheless, the coexistence of OSA in asthma and PH increases with increasing severity of both pulmonary disorders.
- Obesity increases the risk of OSA in both COPD and asthma populations.
- Untreated OSA in OSA/COPD overlap is associated with worsened clinical outcomes for both the OSA and the comorbid pulmonary disorder. Conversely, effective identification and treatment of OSA reduce diurnal and nocturnal symptoms and improve clinical outcomes in patients with OSA/COPD.

SUMMARY

OSA and COPD, each a prevalent and clinically important condition in adults, carry numerous common risk factors, including obesity and smoking. It is estimated that the coexistence of OSA and COPD, the COPD/OSA overlap syndrome, affects more than 1% of the general population. The presence of such overlap, when the OSA is untreated, carries a risk of more adverse diurnal and nocturnal physiologic and clinical outcomes, including greater sleep fragmentation, more severe nocturnal hypoxemia, and increased overall mortality, than is documented for COPD alone and OSA alone. Effective identification and treatment of the comorbid OSA and the other features of SDB in the COPD/OSA overlap syndrome improve overall clinical outcomes in the condition.

Asthma, ILD, and PH are also linked with OSA and, in the case of PH, other types of SDB, such as central sleep apnea and sleep-related hypoventilation, by common risk factors and mutually exacerbating pathophysiologic and clinical features. The prevalence of asthma overlap with OSA and PH overlap with SDB is not well defined but increases as the severity of both asthma and PH increases. As with COPD and OSA overlap, effective treatment of the comorbid OSA, using well-established therapy with CPAP, improves asthma-related and overall pathophysiologic and clinical outcomes of the asthma/OSA overlap syndrome, including airway and systemic inflammation, asthma control, and asthma-specific quality of life.

Chapter 120

Obesity-Hypoventilation Syndrome

Babak Mokhlesi

Chapter Highlights

- Obesity-hypoventilation syndrome (OHS) has been conventionally and to some extent arbitrarily defined by the combination of obesity and daytime hypercapnia during wakefulness occurring in the absence of an alternative neuromuscular, mechanical, or metabolic explanation for hypoventilation. This syndrome is also invariably accompanied by sleep disordered breathing (e.g., obstructive sleep apnea or sleep hypoventilation), and therefore sleep disordered breathing is included as one of the diagnostic criteria in some definitions of OHS.
- During the last 3 decades, the prevalence of extreme obesity has markedly increased in the United States and other countries. With such a global epidemic of obesity, the prevalence of OHS is likely to increase.
- Patients with OHS have a lower quality of life with increased health care expenses and are at higher risk for development of pulmonary hypertension and early mortality due to cardiopulmonary complications compared with eucapnic patients with obstructive sleep apnea.
- OHS often remains undiagnosed until late in the course of the disease. Early recognition is important as these patients have significant morbidity and mortality if they are left untreated. Effective treatment can lead to significant improvement in patient outcomes, underscoring the importance of early diagnosis.

HISTORICAL PERSPECTIVE

The association between obesity and hypersomnolence has long been recognized. Of historical interest, obesity-hypoventilation syndrome (OHS) was described well before obstructive sleep apnea (OSA) was recognized in 1969.[1-3] In 1955, Auchincloss et al[4] described in detail a case of obesity and hypersomnolence paired with alveolar hypoventilation. One year later, Bickelmann et al[5] described a similar patient who finally sought treatment after his symptoms caused him to fall asleep during a hand of poker, despite having been dealt a full house of aces over kings. Although other clinicians had made the comparison some 50 years earlier,[6] Bickelmann popularized the term *Pickwickian syndrome* in his case report by noting the similarities between his patient and the boy Joe (Figure 120-1), Mr. Wardle's servant in Charles Dickens' *The Posthumous Papers of the Pickwick Club*.

DEFINITION

OHS has been conventionally and to some extent arbitrarily defined by the combination of obesity (body mass index [BMI] ≥ 30 kg/m^2) and daytime hypercapnia (partial pressure of arterial CO_2 [$Paco_2$] ≥ 45 mm Hg at sea level) during wakefulness occurring in the absence of an alternative neuromuscular, mechanical, or metabolic explanation for hypoventilation. This syndrome is also invariably accompanied by a sleep breathing disorder (SBD), and therefore SBD is included as one of the diagnostic criteria in some expert definitions of OHS.[7] Approximately 90% of patients with OHS have OSA, defined by an apnea-hypopnea index (AHI) of 5 events/hour or more. The remaining patients have nonobstructive sleep hypoventilation. The American Academy of Sleep Medicine has arbitrarily defined sleep hypoventilation in adults by the following criteria: the $Paco_2$ (or surrogate, such as end-tidal CO_2 or transcutaneous CO_2) is above 55 mm Hg for more than 10 minutes or there is an increase in the $Paco_2$ (or surrogate) above 10 mm Hg (compared with an awake supine value) to a value exceeding 50 mm Hg for more than 10 minutes.[8] This point is relevant because although the definition suggests a diurnal pathologic process, overnight polysomnography is required to determine the pattern of nocturnal SBD including hypoventilation (obstructive or nonobstructive) and to individualize therapy, particularly the optimal mode of positive airway pressure (PAP).

OHS is a diagnosis of exclusion and should be distinguished from other conditions that are commonly associated with awake hypercapnia (Box 120-1).

EPIDEMIOLOGY

Nearly 1 of 3 adults in the world are overweight (BMI ≥ 25 kg/m^2), and almost 1 in 10 adults are obese (BMI ≥ 30 kg/m^2). This "obesity epidemic" is associated with myriad comorbidities including OHS. Between 1986 and 2005, the prevalence of morbid obesity (BMI ≥ 40 kg/m^2) increased by fivefold in the United States, affecting 1 in every 33 adults. Similarly, the prevalence of BMI of 50 kg/m^2 and higher has

Figure 120-1 Joe the "fat boy." (Detail from "Mr. Pickwick in Chase of His Hat." Illustration by Robert Seymour. In: Dickens C. *The posthumous papers of the Pickwick Club*. Published in serial form. Box 120-1 DIAGNOSTIC FEATURES OF OBESITY-HYPOVENTILATION SYNDROME

Obesity

Body mass index ≥ 30 kg/m^2

Chronic Hypoventilation

Awake daytime hypercapnia (sea-level arterial Pco_2 ≥ 45 mm Hg)

Possible role of serum venous bicarbonate or calculated bicarbonate >27 mEq/L from capillary blood gas

Sleep Breathing Disorder

Obstructive sleep apnea (apnea-hypopnea index [AHI] ≥ 5 events/hour)

Nonobstructive sleep hypoventilation (AHI <5 events/hour, $Paco_2$ above 55 mm Hg for more than 10 minutes or an increase in the $Paco_2$ [or surrogate] above 10 mm Hg [compared with awake supine $Paco_2$] to a value >50 mm Hg for >10 minutes during sleep, or sustained hypoxemia with oxygen saturation ≤88% without obstructive respiratory events)

Exclusion of Other Causes of Hypoventilation

Severe obstructive airways disease (e.g., chronic obstructive pulmonary disease)

Severe interstitial lung disease

Severe chest wall disorders (e.g., kyphoscoliosis)

Severe hypothyroidism

Neuromuscular disease

Congenital hypoventilation syndromes

increased by 10-fold in the United States, affecting 1 in every 230 adults.[9] With such epidemic obesity, the prevalence of OHS is likely to increase.

Thirteen studies have reported a prevalence of OHS between 8% and 20% in patients referred to sleep centers for evaluation of SBD.[10-12] A meta-analysis of 4250 outpatients with obesity and OSA (mean BMI range between 30 and 44 kg/m^2 and mean AHI range between 40 and 60 events/hour) who did not have chronic obstructive pulmonary disease reported a 19% prevalence of awake hypercapnia.[13] On the basis of these data, approximately 19% of obese patients with OSA have OHS. East Asian populations are known to have OSA at a lower BMI compared with other populations, probably because of cephalometric differences.[14] Therefore, in these populations, OHS may be more prevalent at a lower BMI range than in non-Asian populations.[11,14-16] The prevalence of obesity-associated hypoventilation among consecutive patients with BMI higher than 35 kg/m^2 hospitalized on medical wards (excluding critical care units) has been reported to be 31%.[17] Although it remains unclear why the prevalence of obesity-associated hypoventilation in this hospitalized cohort was higher than the reported prevalence in outpatient obese patients with OSA, it may be related to the facts that the investigators enrolled subjects with a higher BMI (>35 kg/m^2 as opposed to >30 kg/m^2) and there was high prevalence of diuretic use (64% of the patients).

Prevalence estimates for OHS vary significantly across studies, owing partly to differences in sample characteristics, disease definitions, and assessment procedures.[10] In populations of patients with concomitant OSA, as the degree of obesity increases, the prevalence of OHS increases (Figure 120-2).[10] Laaban and Chailleux[18] reported an OHS prevalence of 11% in a cohort of 1141 patients with OSA with a mean BMI of 30 kg/m^2, whereas Mokhlesi et al[19] reported a prevalence of 24% in patients with OSA and a mean BMI of 44 kg/m^2. Among non-Asian populations, the prevalence of OHS is 8% to 11% among patients with OSA with BMI of 30 to 35 kg/m^2 and increases to 18% to 31% among patients with OSA with BMI of 40 kg/m^2 and higher.[18-21] The prevalence of OHS in the general population is unknown but can be estimated. The most recent report from the Centers for Disease Control and Prevention has estimated that approximately 6.4% of the general U.S. adult population has morbid or severe obesity (BMI ≥ 40 kg/m^2), and the prevalence is substantially higher at 12.2% amongst non-Hispanic blacks.[22] If we conservatively estimate that half of patients with this degree of obesity have OSA and that approximately 20% of these OSA patients have OHS, the prevalence of OHS can be estimated as roughly 0.6% (approximately 1 in 160 adults in the U.S. population). OHS may be more prevalent in the United States than in other nations because of its obesity epidemic. With such an epidemic, the prevalence of OHS is likely to increase, and therefore there is a need for a high index of suspicion on the part of clinicians to optimize early recognition and treatment of this syndrome.

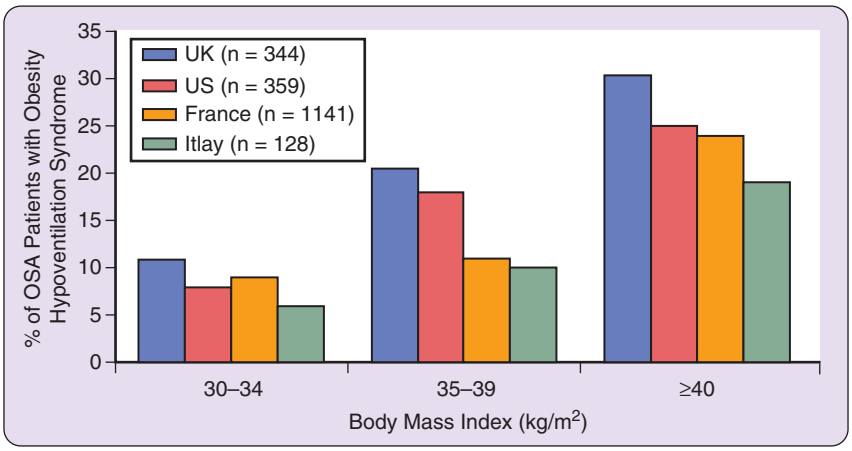

Figure 120-2 Prevalence of obesity-hypoventilation syndrome in patients with obstructive sleep apnea (OSA), sorted by body mass index (BMI). In the U.K. study,[21] the mean BMI was nearly 40 kg/m^2, and 38% of subjects had a BMI higher than 40 kg/m^2. Similarly, in the U.S. study,[19] the mean BMI was 43 kg/m^2, and 60% of subjects had a BMI higher than 40 kg/m^2. In contrast, the mean BMI in the French study[18] was 34 kg/m^2, and only 15% of subjects had a BMI higher than 40 kg/m^2. Italian data[30] were provided by Professor Onofrio Resta (personal communication).

CLINICAL PRESENTATION AND DIAGNOSIS

OHS is typically diagnosed either when an afflicted patient reaches a high state of acuity, in the form of acute-on-chronic hypercapnic respiratory failure,[23] or, alternatively, when ambulatory care is escalated to include evaluation by pulmonary or sleep specialists.[20] Unfortunately, a delay in diagnosis is common; the diagnosis typically occurs during the fifth and sixth decades of life, and during this delay, OHS patients use more health care resources than comparably obese normocapnic patients.[17,23-25] In one study, 8% of all admissions to a general intensive care unit met diagnostic criteria for obesity-associated hypoventilation (BMI > 40 kg/m^2; $Paco_2$ > 45 mm Hg; and no evidence of musculoskeletal disease, intrinsic lung disease, or smoking history). All of these patients presented with acute-on-chronic hypercapnic respiratory failure.[26] Of these patients, nearly 75% were misdiagnosed and treated for obstructive lung disease (most commonly chronic obstructive pulmonary disease) despite having no evidence of obstructive physiology on pulmonary function testing.

Patients with OHS tend to be morbidly obese (BMI ≥ 40 kg/m^2), have severe OSA (≥30 obstructive respiratory events/hour of sleep), and are typically hypersomnolent. Compared with patients with eucapnic OSA and similar BMI, patients with OHS are more likely to report dyspnea and to manifest cor pulmonale. Box 120-2 provides the typical portrait of an OHS patient based on the clinical features of a large combined cohort of OHS patients reported in the literature.[16-19,25,27-35] Whereas severe obesity (BMI ≥ 40 kg/m^2) is a predominant risk factor for OHS, not all patients with severe obesity develop OHS. There are significant physiologic differences between obese patients who have OHS and similarly obese patients without OHS as summarized in Box 120-3.[36]

Although the definitive test for alveolar hypoventilation is a room air arterial blood gas analysis, an elevated serum bicarbonate level due to metabolic compensation of respiratory acidosis is supportive of OHS.[19] Mokhlesi et al[19] first demonstrated that a venous serum bicarbonate threshold of 27 mEq/L, suggestive of chronic respiratory acidosis, could be used for OHS diagnosis in obese patients with diagnosed OSA. Their data demonstrated that among obese patients with OSA and normal renal function, serum bicarbonate level below 27 mEq/L had a 97% negative predictive value for excluding a diagnosis of OHS. Macavei et al[21] assessed ear

Box 120-2 CLINICAL FEATURES OF PATIENTS WITH OBESITY HYPOVENTILATION SYNDROME*

Clinical Features	Mean (Range)
Age (years)	52 (42–61)
Male (%)	60 (49–90)
Body mass index (kg/m^2)	44 (35–56)

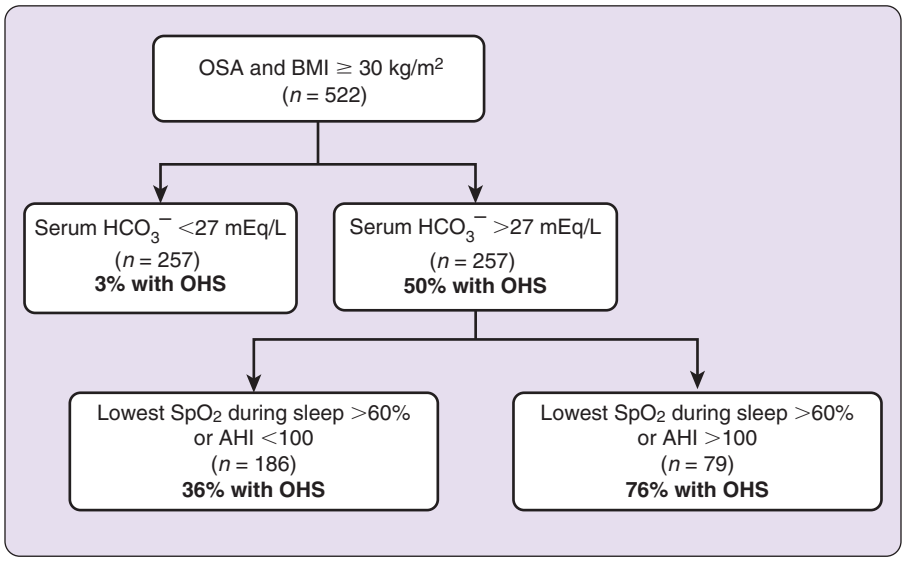

Figure 120-3 Decision tree to screen for obesity-hypoventilation syndrome (OHS) based on observation in 522 obese patients with OSA (BMI ≥ 30 kg/m² and AHI ≥ 5). Among those with a venous serum bicarbonate level above 27 mEq/L, OHS was present in 50% of patients. Very severe OSA (AHI > 100 events/hour or Spo_2 nadir during sleep < 60%) increased the prevalence of OHS to 76%.[19] OSA, Obstructive sleep apnea; AHI, apnea-hypopnea index; BMI, body mass index.

lobe capillary blood gas samples from patients referred to a sleep center and determined that bicarbonate values calculated from the Henderson-Hasselbalch formula have similar predictive values. A calculated serum bicarbonate level of 27 mEq/L and higher had a sensitivity of 85% and a specificity of 89% for the diagnosis of OHS among their patient sample. Two additional studies have confirmed serum bicarbonate to be an independent and reliable predictor of OHS.[12,37] Figure 120-3 shows the prevalence of OHS in obese patients with OSA (BMI ≥ 30 kg/m² and AHI ≥ 5) using a serum bicarbonate level combined with other readily available measures, such as severity of OSA.[19] Indeed, several investigators have suggested incorporating serum venous bicarbonate (HCO_3^-) levels into the definition of OHS, particularly because using a single measurement of arterial Pco_2 for OHS diagnosis is susceptible to a number of confounding factors, including the impact of the patient's periprocedural anxiety leading to hyperventilation.[38]

In addition to blood gas sampling and serum venous bicarbonate assessments, daytime finger pulse oximetry (Spo_2) may be a valuable tool for clinicians in screening for possible OHS.[39] Resting hypoxemia during wakefulness is not a typical feature of either patients with OSA or patients with obesity. Therefore, abnormal resting pulse oximetry during wakefulness should increase the suspicion for OHS among obese OSA patients.[19,40,41] Similarly, significant sleep-associated hypoxemia, defined as oxygen saturation below 85% for more than 10 continuous minutes, in an obese patient with OSA should raise suspicion for presence of sleep hypoventilation and possibly OHS.[42] In a meta-analysis, the mean difference of percentage of total sleep time with Spo_2 spent below 90% was 37.4% (56.2% for OHS, 18.8% for eucapnic obese OSA

patients) with very little overlap in the 95% confidence intervals.[13]

Ultimately, a rise in carbon dioxide levels (≥45 mm Hg) during wakefulness is necessary to define hypoventilation. There are a variety of techniques to measure carbon dioxide, such as daytime arterial blood gases, arterialized capillary blood gases, venous blood gases, and end-tidal carbon dioxide and transcutaneous carbon dioxide monitoring. Each of these techniques has its advantages and disadvantages.[43,44] The most reliable and practical method for identifying sleep hypoventilation is to measure carbon dioxide levels continuously during sleep by end-tidal or transcutaneous monitoring.[41] Improving technologies should greatly expand our ability to identify and to quantify nocturnal hypoventilation in sleep laboratories or even at home.

MORBIDITY AND MORTALITY

The majority of OHS patients are severely obese and have severe OSA.[18] Although severe obesity[45] and severe OSA are independently associated with increased risk of mortality,[46-50] OHS may contribute further.[51] A retrospective study reported that 7 of 15 patients with OHS (46%) who refused long-term noninvasive PAP therapy died during an average of 50 months of follow-up.[32] A prospective study by Nowbar et al[17] observed a group of 47 severely obese patients after hospital discharge. The 18-month mortality rate for patients with untreated OHS was higher than for the control cohort of 103 patients with obesity alone (23% versus 9%) despite the fact that the groups had similar BMI, age, and number of comorbid conditions. When adjusted for age, sex, BMI, and renal function, the hazard ratio of death in the OHS group was 4.0 in the 18-month period. Only 13% of the 47 patients were treated for OHS after hospital discharge. The difference in survival was evident as early as 3 months after hospital discharge. In contrast, Budweiser et al[34] conducted a retrospective analysis of 126 patients with OHS who were highly adherent to noninvasive ventilation (NIV) during sleep, with the NIV modality initiated in pressure support mode and after an adaptation period switched to pressure-cycled assist control mode, finding the 1-, 2-, and 5-year survival rates to be 97%, 92%, and 70%, respectively. Similarly, in a large retrospective study, 110 patients with OHS treated with NIV in the form of bilevel PAP (mean inspiratory PAP of 18.5 ± 2.5 cm H_2O and mean expiratory PAP of 8.4 ± 1.9 cm H_2O) were matched with 220 patients with OSA treated with continuous PAP (CPAP; mean pressure of 8.9 ± 1.7 cm H_2O).[51] Despite similar rates of adherence to PAP therapy (mean bilevel PAP use of 6.2 ± 3.0 hours/night vs. mean CPAP use of 5.8 ± 3.2 hours/night; $P = .29$), the 5-year mortality rates were 15.5% in the OHS cohort and 4.5% in the OSA cohort ($P < .05$). Patients with OHS had a twofold increase (odds ratio, 2; 95% confidence interval, 1.11-3.60) in the risk of mortality compared with those with OSA. Using bilevel PAP less than 4 hours/night emerged as the strongest independent predictor of mortality in patients with OHS.[51] Together, these studies suggest that treatment with NIV may lower the short-term mortality of patients with OHS (Figure 120-4).[7,34] Accumulating evidence from prospective cohort studies suggests that long-term survival may be better in OHS patients treated chronically with home NIV (most commonly in the form of bilevel PAP therapy) compared with CPAP therapy.[52]

The morbidity associated with a diagnosis of OHS can be varied, as illustrated by Jennum et al,[53] who evaluated 755 patients with a diagnosis of OHS (using *International Classification of Diseases, Tenth Revision* diagnostic codes) from a Danish national patient registry; in the 3 years before OHS diagnosis, these patients were more likely than age- and sex-matched controls to be diagnosed with a variety of medical conditions, including cellulitis, carpal tunnel syndrome, type

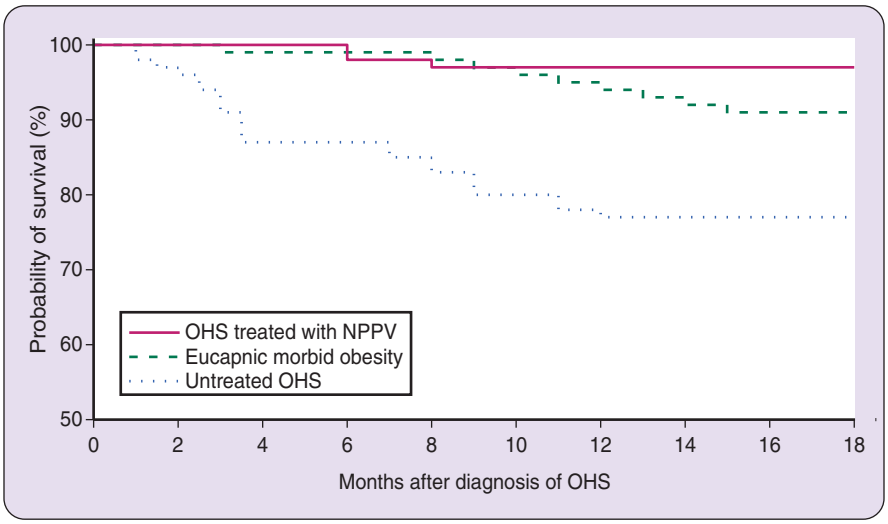

Figure 120-4 Survival curves for patients with untreated obesity-hypoventilation syndrome (OHS; $n = 47$; mean age, 55 ± 14 years; mean body mass index [BMI], 45 ± 9 kg/m^2; mean $PaCO_2$, 52 ± 7 mm Hg) and eucapnic obese patients ($n = 103$; mean age, 53 ± 13 years; mean BMI, 42 ± 8 kg/m^2) as reported by Nowbar et al[17] compared with patients with OHS treated with nocturnal positive pressure ventilation (NPPV) therapy ($n = 126$; mean age, 55.6 ± 10.6 years; mean BMI, 44.6 ± 7.8 kg/m^2; mean baseline $PaCO_2$, 55.5 ± 7.7 mm Hg; mean adherence with NPPV of 6.5 ± 2.3 hours/day). 2 diabetes, congestive heart failure, obstructive lung disease, and arthritis of the knee. It remains unclear if these conditions would be more prevalent than in an obese matched cohort with uncomplicated OSA. Furthermore, quality of life ratings among OHS patients appear to be lower than among those with hypoventilatory respiratory disorders such as obstructive lung disease.[54]

Cardiovascular morbidity is of particular concern in OHS.[51] Kessler et al[55] found a pulmonary hypertension prevalence of 58% among a cohort of 34 OHS patients compared with just 9% among a sample of similar OSA patients. Similarly, Berg et al[33] compared 20 OHS patients from a Canadian health registry with obese matched controls. OHS patients in their study were nine times more likely to have a diagnosis of cor pulmonale and nine times more likely to have a diagnosis of congestive heart failure. Moreover, hospitalized patients with obesity-associated hypoventilation are at increased risk of admission to the intensive care unit and need for invasive mechanical ventilation compared with hospitalized patients with eucapnic obesity.[17]

Accordingly, identifying patients with OHS in a timely manner is important, and treatment with PAP therapy should be initiated and monitored without delay to avoid adverse outcomes, such as readmission to the hospital, acute-on-chronic respiratory failure requiring intensive care monitoring, or death. More important, adherence to therapy should be emphasized and monitored objectively.[56]

PATHOPHYSIOLOGY

The partial pressure of CO_2 in the arterial blood ($Paco_2$) is determined by the balance between CO_2 production and elimination. Although the main reason for reduced CO_2 elimination is reduced alveolar ventilation due to an overall decreased level of ventilation (i.e., minute ventilation), maldistribution of ventilation with respect to pulmonary capillary perfusion (i.e., an increase in physiologic dead space) may contribute as well. Further, the rate of CO_2 production in OHS is of particular physiologic concern; severely obese patients, with or without OHS, have increased work of breathing, increased oxygen cost of breathing, and increased CO_2 production compared with lean individuals.[57-59] The majority of individuals with severe obesity maintain homeostasis by increasing alveolar ventilation and associated CO_2 elimination, thereby averting progression to OHS. This is achieved by tight compensatory mechanisms that require an intact integration between respiratory control and acid-base regulatory systems. Ultimately, inadequate elimination of CO_2 relative to CO_2 production leads to chronic hypercapnia in patients with OHS. In addition to the differences as illustrated in Box 120-3, there are a variety of physiologic differences between patients with OHS and those with eucapnic obesity with or without OSA, such as increased upper airway resistance,[60] decreased respiratory system compliance compared with similarly obese subjects without OHS,[61] ventilation-perfusion mismatching secondary to pulmonary edema[62] or low lung volumes/atelectasis,[63] and, most important, impaired central response to hypoxemia and hypercapnia. Although these mechanisms contribute in varying degrees to the gas exchange abnormality observed in patients with OHS, the combination of SBD, a blunted central response to hypercapnia and hypoxia, and renal buffering can explain the progression from sleep hypoventilation to chronic daytime hypoventilation.[64-67]

Severe obesity (BMI ≥ 40 kg/m^2) increases the work of breathing because of the excess weight on the thoracic wall and abdomen.[61,68] However, it is unclear what role, if any, these altered mechanics have in the pathogenesis of OHS. The lung compliance of OHS patients is less than that of equally obese controls (0.122 versus 0.157 L/cm H_2O). This can be explained by the lower functional residual capacity (1.71 versus 2.20 L). There is an even greater difference in chest wall compliance between the two groups (OHS, 0.079 L/cm H_2O; obese controls, 0.196 L/cm H_2O).[61] Patients with OHS also have a threefold increase in lung resistance that has also been attributed to a low functional residual capacity.[61,69] The changes in lung mechanics are frequently demonstrated on spirometry by a low forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1) and a normal FEV_1/FVC ratio. The spirometric abnormalities may be related to the combination of abnormal respiratory mechanics and weak respiratory muscles.[29,30,70,71] The abnormal respiratory system mechanics in subjects with severe obesity imposes a significant load on the respiratory muscles and leads to a significant increase in the work of breathing, particularly in the supine position.[61,68] As a result, morbidly obese patients dedicate 15% of their oxygen consumption to the work of breathing compared with 3% in nonobese individuals.[58]

The maximal inspiratory and expiratory pressures are normal in eucapnic morbidly obese patients but are typically reduced in patients with OHS.[72-74] Patients with mild OHS, however, may have normal inspiratory and expiratory pressures.[75] Further, the role of diaphragmatic weakness in the pathogenesis of this disorder remains uncertain because patients with OHS can generate similar transdiaphragmatic pressures at any level of diaphragmatic activation compared with eucapnic obese subjects.[73] In a study by Sampson and Grassino,[73] patients with OHS were able to generate equivalent transdiaphragmatic pressures as eucapnic obese patients during hypercapnia-induced hyperventilation, suggesting that respiratory muscle weakness may not play a role in the development of OHS. In addition, the OHS group showed no evidence of acute diaphragmatic fatigue (or neuromuscular uncoupling) throughout the hypercapnic trial when measured by the ratio of peak electrical activity of the diaphragm to peak transdiaphragmatic pressure, which theoretically eliminates the variable of the patient's cooperation. Potentially more accurate assessments of diaphragmatic strength (e.g., by cervical magnetic stimulation) have not been performed in patients with OHS.[76]

Patients with OHS are able to voluntarily hyperventilate to eucapnia,[77] evidence for a defective, "blunted" central respiratory drive. Further, patients with OHS do not hyperventilate to the same degree as eucapnic morbidly obese patients when rebreathing CO_2.[71,73,75] This deficit improves in most patients after PAP therapy.[75,78,79] In addition, patients with OHS do not augment their minute ventilation to the same degree as eucapnic obese OSA patients when breathing a hypoxic gas mixture.[75,79] This blunted hypoxic drive also improves with PAP therapy,[75,79] suggesting that such blunted drive is a secondary effect of the syndrome (and necessary for its persistence) but not the origin of it. Obesity, genetic predisposition, SBD, and leptin resistance have all been proposed as mechanisms for the blunted response to hypercapnia. Such

blunted respiratory response to hypercapnia is unlikely to be genetic because the ventilatory response to hypercapnia is similar between first-degree relatives of patients with OHS and control subjects.[80]

Leptin, a satiety hormone produced by adipocytes, stimulates ventilation.[81-84] Obesity leads to an increase in CO_2 production and load.[57,59,81] Therefore, with increasing obesity, the excess adipose tissue leads to increasing levels of leptin to increase ventilation to compensate for the additional CO_2 load. This is likely the reason that most severely obese individuals do not develop awake hypercapnia. Patients with OHS and OSA have significantly higher leptin levels compared with lean or BMI-matched subjects without OSA. Although the independent contribution of OSA or OHS to leptin production remains unclear, the data suggest that excess adiposity is a much more significant contributor to elevated serum leptin levels than the presence of OSA or OHS.[85-88] Patients with OHS, however, have a higher serum leptin level than eucapnic subjects with OSA matched for percentage body fat, and AHI and serum leptin levels each drop after treatment with PAP.[87,89,90] These observations suggest that patients with OHS might be resistant to leptin. For leptin to affect the respiratory center and increase minute ventilation, it has to penetrate the cerebrospinal fluid (CSF). The leptin CSF to serum ratio is fourfold higher in lean individuals compared with obese subjects (0.045 ± 0.01 vs. 0.011 ± 0.002; $P < .05$).[91] Individual differences in leptin CSF penetration may explain why some obese patients with severe OSA develop OHS and others do not.

OSA may well contribute to the ventilatory control defect because treatment with CPAP or bilevel PAP typically improves the response to hypercapnia.[75,78,79] The $P_{0.1}$ response to hypercapnia (a sensitive measure of respiratory drive) improves as early as 2 weeks and reaches normal levels after 6 weeks of therapy with PAP in patients with OHS who demonstrate an awake $Paco_2$ between 46 and 50 mm Hg. The response of minute ventilation to hypercapnia improves by the sixth week of PAP therapy but does not completely normalize,[75] and although such findings are not universal,[78,92,93] OSA appears well established in the pathophysiologic mechanism of OHS by the resolution of hypercapnia in most patients after treatment with either tracheostomy or PAP therapy.[11,27,32,56,75,94-96]

Norman et al[64] have proposed an elegant mathematical model that explains the transition from acute hypercapnia during OSA to chronic daytime hypercapnia. In most patients with OSA, the hyperventilation after an apnea eliminates all CO_2 accumulated during the apnea.[97] However, if the interapnea hyperventilation is inadequate or the ventilatory response to the accumulated CO_2 is blunted, it could lead to an increase in $Paco_2$ during sleep.[65] Even in this acute setting, during sleep the kidneys can retain small amounts of bicarbonate to buffer the decrease in pH. If the time constant for the excretion of the small amount of accumulated bicarbonate is slow, the patient will have a net gain of bicarbonate, which may blunt the respiratory drive and lead to CO_2 retention during wakefulness to compensate for the retained bicarbonate.[64] Further, the combination of a decreased response to CO_2 and a slow rate of bicarbonate excretion will lead to a blunted respiratory drive for the next sleep cycle. Indeed, obese eucapnic individuals with an elevated serum bicarbonate level exhibit a blunted response to hypercapnic and hypoxic stimulation tests compared with equally obese eucapnic individuals with normal serum bicarbonate level.[39] Further research is needed to elucidate whether these individuals represent a subgroup of "early OHS" and whether they are at increased risk of progressing to overt daytime hypercapnia over time.

Many studies have tried to identify risk factors associated with hypercapnia in patients with OSA, but the results have been mixed.[16,18,19,25,28-31,98] In a large meta-analysis of 15 studies, Kaw et al[13] identified three factors that were significantly associated with chronic hypercapnia in nonchronic obstructive pulmonary disease obese patients with OSA: (1) severity of obesity as measured by the BMI, (2) severity of OSA measured by either the AHI or hypoxemia during sleep, and (3) degree of restrictive chest physiology.

TREATMENT

Treatment modalities for patients with OHS are based on different aspects of the underlying pathophysiologic mechanism of the condition: reversal of SBD (OSA and nonobstructive sleep hypoventilation), weight reduction, and possibly pharmacotherapy. Nocturnal PAP therapies are considered first-line treatment and are effective in improving patient outcomes.[99,100] However, treatment strategies that include weight reduction and physical activity should also be offered to patients with OHS to improve their metabolic and cardiovascular risk profiles.[101-103]

Positive Airway Pressure Therapy

PAP, in the form of continuous PAP (CPAP), was first described in the treatment of OHS in 1982.[94] Whereas subsequent studies confirmed its efficacy, failure of CPAP in some cases has led to uncertainty as to whether CPAP should be attempted initially or if NIV (most commonly in the form of bilevel PAP) is a better modality.[18,56,92,94,104] In one prospective study of outpatients with severe OHS, 57% of patients were successfully titrated with CPAP alone. In these patients, CPAP was titrated to treat OSA, and the mean pressure required was 14 cm H_2O.[42] The remaining 43% of patients failed to respond to CPAP titration because of persistent hypoxemia at therapeutic or near-therapeutic pressures that had successfully treated OSA. In these patients, the oxygen saturation remained below 90% for more than 20% of total sleep time. Because this was a single-night titration study, the question of whether residual hypoxemia would resolve with long-term treatment was not evaluated systematically.[105] Even though several studies have described the efficacy of both NIV and CPAP, only one randomized controlled trial has directly compared the two modes.[106] In this study, 45 consecutive patients with OHS underwent a full night of CPAP titration. Nine patients (20%) had persistent hypoxemia (arbitrarily defined as 10 continuous minutes of $Spo_2 < 80\%$ without observed apneas) during the CPAP titration and were excluded from the study. The remaining 36 patients who had a successful CPAP titration night with resolution of OSA and hypoxemia were subsequently randomized to either CPAP or NIV (bilevel PAP in the spontaneous mode without a backup respiratory rate). The two groups were well balanced in terms of body habitus, severity of awake hypercapnia, OSA, and nocturnal hypoxemia at baseline. During titration polysomnography, CPAP was increased in increments of 1 cm H_2O with the aim of preventing obstruction, flow limitation,

desaturation, and arousal. During the bilevel PAP titration, the expiratory PAP (EPAP) was started at 2 cm H_2O below the pressure needed to abolish obstructive apneas during the CPAP titration or at 5 cm H_2O, whichever was higher. The EPAP was then increased in increments of 1 cm H_2O to resolve obstructive apneas. The inspiratory PAP (IPAP) was initially set 4 cm H_2O higher than EPAP and then increased to eliminate hypopneas and to improve oxygen saturation. After 3 months, there was no significant difference between the groups in terms of adherence to PAP therapy or improvement in daytime sleepiness, hypoxemia, or hypercapnia. However, this relatively small clinical trial found benefits in favor of NIV over CPAP, especially in sleep quality. This study confirms that CPAP can be successful in some patients with OHS as long as OSA and nocturnal hypoxemia are effectively treated. On the other hand, the exclusion of patients with severe nocturnal hypoxemia who were not responsive to CPAP therapy suggests that a subgroup of patients with OHS may need more advanced forms of ventilation. Therefore, NIV is not superior to CPAP a priori; rather, treatment should be individualized to each patient.

The American Academy of Sleep Medicine has proposed guidelines for the titration of NIV in patients with chronic alveolar hypoventilation syndromes, although not specifically for OHS.[107] The most common mode of NIV used in clinical practice is bilevel PAP. During in-laboratory titration, EPAP is increased until obstructive apneas are resolved.[108] If hypoxemia is persistent or estimated tidal volumes are lower than expected for the patient's ideal body weight, pressure support needs to be increased.[107] Pressure support is the difference between IPAP and EPAP. Most patients with OHS require a pressure support level of at least 8 to 12 cm H_2O (i.e., an IPAP pressure setting that is at least 8 to 12 cm H_2O above EPAP) to achieve effective ventilation.[27,32,109,110] Some patients with OHS may experience central apneas during NIV therapy. Central apneas could occur in OHS during CPAP or NIV titration because of decreased respiratory drive, heart failure, or unstable ventilatory control (high loop gain).[111] Advanced modes, such as bilevel PAP with a backup rate, can help alleviate central apneas in OHS. In the spontaneous/timed (S/T) or timed mode, a backup respiratory rate of 10 to 12 breaths/minute should be initiated and titrated upward by one or two increments generally not exceeding 16 breaths/minute. The backup respiratory rate should be initiated when a patient with hypoventilation syndrome manifests central apneas or inappropriately low respiratory rate and consequent low minute ventilation. Therefore, to perform an adequate NIV titration during sleep in patients with OHS, it is important to monitor several parameters during polysomnography, such as mask flow, delivered pressure, air leak, estimated exhaled tidal volume, and triggered backup mechanical breaths.[107] Transcutaneous CO_2 monitoring, if it is available, provides useful information about the effectiveness of NIV or CPAP titration. Scoring of respiratory events during NIV titration can be challenging, and a systematic description of these events has been proposed.[112]

In the minority of patients with OHS who do not have OSA, EPAP can be set at 5 cm H_2O and IPAP can be titrated to improve ventilation.[109,110] Switching to NIV should also be considered if the $Paco_2$ does not normalize after 3 months of CPAP therapy with objective evidence of adherence to prescribed therapy.

There is accumulating evidence suggesting that sleep hypoventilation can be better controlled by NIV settings and modes that optimize delivery of nocturnal ventilation with the use of either a higher mandatory backup respiratory rate of the ventilator[113] or pressure-volume hybrid modes.[114] Two of these hybrid modes are "average" volume-assured pressure support (AVAPS) and "intelligent" volume-assured pressure support. These pressure-volume hybrid modes of pressure support, volume-controlled ventilation deliver a more consistent tidal volume with the comfort of pressure support ventilation. With these hybrid modes, the pressure support or assistance delivered during the inspiratory phase aims to ensure a certain tidal volume that is calculated as a function of predicted body weight (usually 8 to 10 mL/kg ideal body weight or at 110% of the patient's tidal volume). The device assesses the preset tidal volume or minute ventilation during a variable time window of 1 to 5 minutes. The operating IPAP (or pressure assist) level is then allowed to fluctuate between a minimum and maximum pressure support level to ensure the target tidal volume. If a patient's tidal volume or minute ventilation decreases below a certain threshold, the device responds by increasing the IPAP and restores the tidal volume to approximately the preselected target volume. Such devices have an EPAP-minimum and EPAP-maximum range that needs to be preset as well. Although higher inspiratory pressures achieved with volume-targeted hybrid modes may also optimally relieve dyspnea, they may be more disruptive to sleep in some patients.[115] Additional settings may include spontaneous or timed respiratory rate settings, and newer technology has automated the respiratory rate selection on the basis of the patient's minute ventilation and proportion of breaths that are triggered versus spontaneous over a period of time. In a randomized controlled trial of 50 patients with OHS, volume-targeted pressure support mode was compared with fixed bilevel PAP S/T mode (with a backup respiratory rate).[116] In this study, there was no significant difference between the two advanced PAP modes after 3 months of therapy. Both PAP modalities significantly improved daytime $Paco_2$, sleep hypoventilation (as measured by transcutaneous CO_2), hypoxemia during sleep, and quality of life. The lack of such demonstrable difference between AVAPS and fixed bilevel PAP S/T in this trial may be due to the carefully "optimized" bilevel PAP S/T setting in these clinical research conditions. There was no significant difference in the levels of PAP delivered between the two groups. Patients randomized to AVAPS received mean pressures of IPAP 22 ± 5/EPAP 9 ± 1 cm H_2O with a backup rate of 14 breaths/minute versus bilevel PAP S/T mode with mean pressures of IPAP 23 ± 4/EPAP 10 ± 4 cm H_2O with a backup rate of 14 breaths/minute.[116] Despite these high-pressure settings, the mean adherence to therapy was reasonable and not different between the two groups (AVAPS, 4.2 hours/day; bilevel PAP S/T, 5.1 hours/day). Comparative post hoc analysis revealed that patients in whom more than 50% of the breaths were delivered as the backup respiratory rate experienced a greater control of nocturnal carbon dioxide by transcutaneous CO_2 monitoring, improved daytime $Paco_2$, and enhanced health-related quality of life at 3 months,[116] which supports the hypothesis that controlled NIV, which minimizes patient ventilatory effort in sleep, may help unload the respiratory muscles and provide optimal nocturnal ventilatory control and improved patient outcomes. In the largest

clinical trial to date, the Spanish Sleep Network investigators performed a randomized controlled trial comparing three treatment strategies in 221 patients with OHS. The treatment strategies consisted of NIV, CPAP, and lifestyle modification (control group). For NIV the 16 centers involved in the study were allowed to use a variety of ventilators all of which were set in the volume targeted pressure support mode (mean IPAP 20 ± 3.3 cm H_2O and mean EPAP 7.7 ± 1.8 cm H_2O; backup respiratory rate of 12–15 breaths per minute and tidal volumes of 550–660 ml). The average CPAP pressure was 11 ± 2.5 cm H_2O. At two months, NIV and CPAP were superior to control group in improving $PaCO_2$, clinical symptoms, and polysomnographic parameters. However, there were no significant differences in the degree of improvement in $PaCO_2$ between NIV and CPAP. Adherence to the PAP modalities was not significantly different (mean adherence to NIV was 5.3 ± 2.3 h/day and CPAP was 5.3 ± 2.1 h/day). Although some health-related quality-of-life assessments, FEV_1, and 6-minute-walk distance improved more with NIV than with CPAP, the long-term significance of these functional improvements requires further investigation. This clinical trial may be able to shed light on the long-term impact of different treatment modalities as the investigators plan to follow these patients for 36 months after randomization.[116a]

There are numerous technical challenges with applying NIV in OHS. Advanced PAP modalities such as volume-targeted pressure support technology rely heavily on and function properly when unintentional air leak from the noninvasive mask remains low.[117] Whereas bench studies have shown that most NIV devices underestimate air leak and exhaled tidal volume, there is significant variability among manufacturers.[118]

The most common reason for persistent hypercapnia and hypoxemia in patients with OHS treated with PAP is lack of adherence to the PAP therapy. In a retrospective study of 75 outpatients with stable OHS, patients who used CPAP or bilevel PAP therapy for more than 4.5 hours/day had a considerably greater improvement in blood gases than less adherent patients ($\Delta Paco_2$ 7.7 ± 5 vs. 2.4 ± 4 mm Hg, $P < .001$; ΔPao_2 9.2 ± 11 vs. 1.8 ± 9 mm Hg, $P < .001$).[56] The degree of improvement in ventilation and gas exchange, which can be seen as early as 2 to 4 weeks after therapy,[56,75,119] may allow discontinuation of daytime oxygen supplementation in many patients with OHS.[56] However, the improvement in chronic daytime gas exchange abnormalities (i.e., hypercapnia and hypoxemia) even in patients who are adherent to PAP therapy is neither universal nor complete.[52,102] Other possibilities behind persistent hypercapnia include inadequate CPAP pressure or insufficient NIV support; CPAP failure in OHS patients who do not have significant OSA; other causes of hypercapnia, such as chronic obstructive pulmonary disease; and metabolic alkalosis due to high doses of loop diuretics. In two studies,[56,106] the $Paco_2$ did not improve significantly in approximately a quarter of patients who had undergone successful PAP titration in the laboratory and were highly adherent (>6 hours/night) with either CPAP or bilevel PAP therapy. It is conceivable that volume-targeted pressure support or higher levels of pressure support with fixed bilevel PAP in the S/T mode would be more effective in normalizing ventilation and gas exchange. Reports of persistent hypoventilation after tracheostomy[27] highlight the need for aggressive nocturnal mechanical ventilation in addition to support of upper airway patency in at least a subset of OHS patients.

Early follow-up is imperative and should include assessment of adherence to PAP therapy; patients with OSA, although not specifically with OHS, frequently overestimate CPAP adherence.[120-122] Changes in serum bicarbonate level and improvements in resting room air pulse oximetry and end-tidal CO_2 measurements during wakefulness could be used as less invasive surrogates of ventilation if the patient is reluctant to undergo follow-up measurement of arterial blood gases.

Oxygen Therapy

In some patients with OHS, oxygen supplementation is necessary after the resolution of apneas and hypopneas during PAP titration, both CPAP and NIV, to keep Spo_2 above 88% to 90%. In two studies, the percentage of OHS patients requiring supplemental oxygen after adequate CPAP titration (i.e., resolution of obstructive apneas and hypopneas) was as high as 43%.[42,56] In contrast, in a relatively comparable group of patients with OHS, only 12% undergoing aggressive NIV titration with relatively high levels of pressure support (~13 cm H_2O above an average EPAP of 10 cm H_2O) required such oxygen supplementation.[116] This finding suggests that higher levels of pressure support during PAP titration must be considered to achieve adequate oxygenation and ventilation during sleep in a large proportion of patients with OHS. Oxygen supplementation as monotherapy without resolution of upper airway obstruction with CPAP or adequate ventilatory support with NIV is strongly discouraged. Two well-controlled clinical trials have reported that in a significant proportion of patients with OHS who were tested during wakefulness and in steady state, supplemental oxygen at high[123] and medium concentrations[124] worsened hypercapnia (because of a drop in tidal volume and minute ventilation). It is plausible that the risk of CO_2 retention is even higher during acute-on-chronic hypercapnic respiratory failure in OHS.[125]

Weight Reduction

Bariatric surgery has variable long-term efficacy in treating OSA.[126] A meta-analysis that included 12 studies with 342 patients who underwent polysomnography before bariatric surgery and after maximum weight loss reported a 71% reduction in the AHI, from baseline of 55 (95% confidence interval, 49-60) to 16 (95% confidence interval, 13-19).[127] Whereas only 38% achieved cure defined by AHI below 5, this drastic improvement in the severity of SBD would likely be enough to normalize daytime blood gases in most patients with OHS. It is also known that in the 6 to 8 years after weight reduction surgery, patients experience approximately 7% weight gain, which may lead to an increase in the AHI.[128,129] Only one study has examined the impact of bariatric surgery in patients with OHS. One year after surgery in 31 patients with OHS, the Pao_2 increased from an awake baseline on breathing room air of 53 to 73 mm Hg and $Paco_2$ decreased from 53 to 44 mm Hg after approximately 50 kg of weight loss (baseline BMI, 56 ± 13 kg/m^2; BMI at 1 year, 38 ± 9 kg/m^2). In the 12 patients in whom an arterial blood gas measurement was available 5 years after surgery, values had worsened, with the mean Pao_2 dropping to 68 mm Hg and $Paco_2$ increasing to 47 mm Hg.[130] The BMI in these 12 patients was 40 ± 10 kg/m^2.

The general perioperative mortality is between 0.5% and 1.0%. Untreated OHS may be associated with higher operative mortality.[131-133] The independent risk factors associated with mortality are intestinal leak, pulmonary embolism, preoperative weight, and hypertension. Depending on the type of surgery, intestinal leak occurs in 2% to 4% of patients and pulmonary embolism occurs in 1% of patients.[132] Ideally, patients with OHS should be treated with PAP therapy before undergoing surgical intervention to decrease perioperative morbidity and mortality. Moreover, PAP therapy using the patient's preoperative settings should be initiated immediately after extubation to avoid postoperative respiratory failure,[133-136] particularly because there is no evidence that PAP therapy initiated postoperatively leads to anastomotic disruption or leakage.[135,137] Such settings, however, may not be optimal for ventilation and/or oxygenation in the immediate postoperative period, particularly with the use of analgesic and/or sedative medication, and must be monitored and adjusted accordingly.

Tracheostomy

Tracheostomy was the first therapy described for the treatment of OHS.[138] In a retrospective study of 13 patients with OHS, tracheostomy was associated with significant improvement in concomitant OSA. However, in seven patients, the AHI remained above 20. Residual respiratory events were associated with persistent respiratory effort, suggesting that disordered breathing was caused by obstructive hypoventilation through an open tracheostomy rather than by central apneas. On occasion, excessive neck skin folds can intermittently obstruct the tracheostomy orifice. However, the overall improvement in the severity of SBD after tracheostomy leads to the resolution of hypercapnia in the majority of the patients with OHS.[139] Currently, tracheostomy is generally reserved for patients who are intolerant of or not adherent to PAP therapy. Patients with tracheostomy may require additional nocturnal ventilation as tracheostomy alone does not treat any central hypoventilation that may be present.[140] Polysomnography with the tracheostomy open is necessary to determine whether nocturnal ventilation is required and to specifically titrate the mode and levels of ventilation necessary.[27]

Respiratory Stimulation

Respiratory stimulants can theoretically increase respiratory drive and improve daytime hypercapnia, but such data in patients with OHS are extremely limited. Medroxyprogesterone acts as a respiratory stimulant at the hypothalamic level.[141] The results of treatment in patients with OHS have been contradictory. In a series of 10 men with OHS who were able to normalize their $Paco_2$ with 1 to 2 minutes of voluntary hyperventilation, treatment with 60 mg/day of oral medroxyprogesterone for 1 month resulted in normalization of the $Paco_2$ (from 51 mm Hg to 38 mm Hg) and improvement in the Pao_2 (49 mm Hg to 62 mm Hg).[142] In contrast, medroxyprogesterone did not improve $Paco_2$, minute ventilation, or ventilatory response to hypercapnia in three OHS patients who remained hypercapnic after tracheostomy.[92] Further, medroxyprogesterone may increase the risk of venous thromboembolism, particularly in this population whose mobility is limited.[143,144] In addition, high doses of medroxyprogesterone can lead to breakthrough uterine bleeding in women and to decreased libido in men.

Acetazolamide induces metabolic acidosis through carbonic anhydrase inhibition, which decreases serum bicarbonate, shifts the CO_2 response to the left, and increases minute ventilation.[92,145] Acetazolamide may also favorably affect OSA by improving loop gain.[146-148]

Most but not all patients with OHS can normalize their $Paco_2$ with 1 minute of voluntary hyperventilation.[77] The inability to eliminate CO_2 with voluntary hyperventilation may be due to mechanical impairment. In one study, the ability to decrease the $Paco_2$ by at least 5 mm Hg with voluntary hyperventilation was the main predictor of a favorable response to respiratory stimulants.[149] Ideally, however, respiratory stimulants should not be used in patients who cannot normalize their $Paco_2$ with voluntary hyperventilation (because of limited ventilation or mechanical impairment); it can lead to an increase in dyspnea or even worsening of acidosis with acetazolamide. Overall, pharmacotherapy with respiratory stimulants cannot be currently recommended as monotherapy in patients with OHS.

Hyperviscosity impairs oxygen delivery and can counteract the beneficial effects of erythrocytosis. Phlebotomy has not been systematically studied in patients with OHS who develop secondary erythrocytosis. In adult patients with congenital cyanotic heart disease, phlebotomy has been recommended if the hematocrit is above 65% only if symptoms of hyperviscosity are present.[150] However, it is difficult to extrapolate this recommendation to patients with OHS because many symptoms of hyperviscosity are similar to the symptoms of OHS. Reversal of hypoventilation and hypoxemia with PAP therapy eventually improves secondary erythrocytosis, and therefore phlebotomy is not needed in patients with OHS.[151]

CLINICAL PEARL

Clinicians should recognize that approximately 8% to 20% of obese patients referred for polysomnography for suspicion of OSA have OHS. The prevalence of OHS is even higher in severely obese patients with OSA. Unfortunately, OHS is typically underrecognized and undertreated. Delay in diagnosis and treatment leads to significant health care resource utilization and increased morbidity and mortality. Therefore, a high index of suspicion is required to diagnose OHS in a timely fashion to improve patient outcomes. Nocturnal PAP therapies are considered first-line treatment and are effective in improving patient outcomes. Whereas significant advances have been made in the delivery of nocturnal PAP therapy, adherence to such therapy remains suboptimal in many patients with OHS. Therefore, comprehensive management should include strategies to improve PAP adherence. Although PAP therapy improves nocturnal and daytime hypoventilation and quality of life, weight reduction and increase in physical activity should be included as part of comprehensive treatment strategies to improve the metabolic and cardiovascular risk profiles of patients with OHS.

SUMMARY

With the current global epidemic of obesity, the prevalence of OHS is likely to increase. Despite the significant morbidity and mortality associated with the syndrome, it is often unrecognized, and treatment is frequently delayed. A high index of suspicion can lead to early recognition of the syndrome and initiation of appropriate therapy. Significant advances have

been made in the delivery of PAP therapy and NIV. Clinicians should encourage adherence to PAP therapy to avert the serious adverse outcomes of untreated OHS.

Chapter 121

Obstructive Sleep Apnea, Obesity, and Bariatric Surgery

Eric J. Olson; Anita P. Courcoulas

Chapter Highlights

- Excessive body weight is a growing global health issue. In the United States, two of every three adults weigh more than their ideal body weight. Obesity (defined as a body mass index of 30 kg/m^2 or greater) predicts increased morbidity and mortality. One of the health conditions that obesity has a significant impact on is obstructive sleep apnea.
- Inconsistent results from dietary, behavioral, and pharmacologic weight loss therapies have led to increasing interest in bariatric surgery, which encompasses a variety of abdominal operations that restrict caloric intake, absorption, or both. The global total number of bariatric procedures performed annually is estimated at more than 300,000.
- Familiarity with the principles and applications of bariatric surgery is emerging as an appropriate requirement for sleep medicine practitioners, in view of the frequency with which coexistent obesity and sleep-related breathing disorders, obstructive sleep apnea and obesity-hypoventilation syndrome, are encountered in clinical practice. The sleep specialist has an important role in a comprehensive perioperative bariatric care program.

DEFINITIONS AND OVERVIEW

The increasing proportion of people who weigh more than their ideal body weight is a worldwide health concern, with significant medical, psychological, and economic ramifications. In adults, overweight and obesity traditionally have been defined by the *body mass index* (BMI), which is the quotient of the weight in kilograms divided by the height in meters squared. Table 121-1 depicts the National Heart, Lung, and Blood Institute's weight classification system for adults, in which *overweight* is defined as a BMI of 25 to 29.9 kg/m^2 and *obese* is defined as a BMI of 30 kg/m^2 or more.[1] Excess abdominal fat, defined by a waist circumference of greater than 40 inches (102 cm) in men and greater than 35 inches (88 cm) in women, is an independent predictor of risk for type 2 diabetes mellitus, dyslipidemia, hypertension, and cardiovascular disease in adults with a BMI between 25 and 34.9 kg/m^2.[1] Overweight and obesity are a result of a complex interplay of genetic and sociocultural forces that lead to long-term positive energy balance.[2] Obesity is associated with myriad complications, including obstructive sleep apnea (OSA).

Obesity is one of the most important risk factors for OSA.[3] Excessive body weight may increase propensity for upper airway narrowing during sleep by altering the function and the geometry of the pharynx.[3] In addition, obesity may alter ventilatory control and respiratory muscle function, leading to obesity hypoventilation syndrome (OHS), which is characterized by the combination of obesity, chronic hypercapnia in the absence of another identifiable cause, and usually some component of sleep-related breathing disorder, most commonly OSA (see Chapter 120).[4] Treatment for OSA includes continuous positive airway pressure (CPAP), oral appliances, upper airway surgeries, and risk factor modifications, including weight loss.

For patients desiring to lose weight, initial interventions include dietary modifications to reduce energy intake, enhanced physical activity to increase energy expenditure, and behavioral therapies to overcome barriers to compliance.[1] Pharmacotherapy may be considered for patients with a BMI of 30 kg/m^2 or more, or for those with a BMI of 27 kg/m^2 or more and obesity-related disease who fail to achieve their weight loss targets after 6 months of diet and lifestyle changes.[1]

Surgical therapy for obesity, or *bariatric surgery,* is indicated for morbidly obese persons for whom other attempts at nonsurgical approaches to weight control have failed. Some bariatric surgery procedures restrict food intake, and others induce malabsorption or maldigestion.[5] The number of bariatric procedures being performed has increased dramatically as a result of the rise in prevalence of severe obesity and refinement of operative techniques.

This chapter considers the epidemiology of overweight and obesity, potential mechanisms linking overweight and obesity with OSA, indications for bariatric surgery, technical aspects of common bariatric procedures, perioperative management of patients with OSA, and outcomes of bariatric surgery, including its impact on OSA.

EPIDEMIOLOGY

Epidemiology of Overweight and Obesity

According to the latest National Health and Nutrition Examination Survey (NHANES), for the year 2011 to 2012, 68.5% of U.S. adults were either overweight or obese, 34.9% were obese, and 6.4% had class 3 obesity, which translates to a total of approximately 15 million adults with a BMI of 40 kg/m^2 or greater.[6] Among U.S. youth, 31.8% were either overweight or obese and 16.9% were obese.[6] Between 1980 and 2007, the prevalence of obesity doubled, and the prevalence of class 3

Table 121-1 Classification of Overweight and Obesity by Body Mass Index

Category	Body Mass Index (kg/m^2)
Underweight	<18.5
Normal	18.5–24.9
Overweight	25–29.9
Obesity	
Class 1	30–34.9
Class 2	35–39.9
Class 3 (extreme)	≥40

Bethesda (Md.): National Institutes of Health; 2000. <http://www.cdc.gov/nccdphp/dnpa/obesity/defining.htm>.

obesity nearly quadrupled.[7] Figure 121-1 shows the prevalence of adult obesity in 2014 per state and territory in the United States.[8] Obesity prevalence also has roughly doubled among Canadian adults, although the overall prevalence of adult obesity in Canada (approximately 25%) remains lower than in the United States.[9] Obesity rates in the United States are highest among non-Hispanic black adults (47.8%), followed by Hispanic Americans (42.5%) and then non-Hispanic whites (32.6%) and Asian Americans (10.8%).[6] Obesity prevalence in Native Americans is similar to that in non-Hispanic blacks.[10] Data from the Framingham Heart Study attribute a reduction in life expectancy of 7.1 years in nonsmoking women and 5.9 years in nonsmoking men at age 40 to obesity,[11] with the increased mortality resulting primarily from cardiovascular disease.[12]

Epidemiologic Association between Overweight/Obesity and Obstructive Sleep Apnea

Cross-sectional analyses of clinical and population samples have demonstrated notable colocalization of OSA and

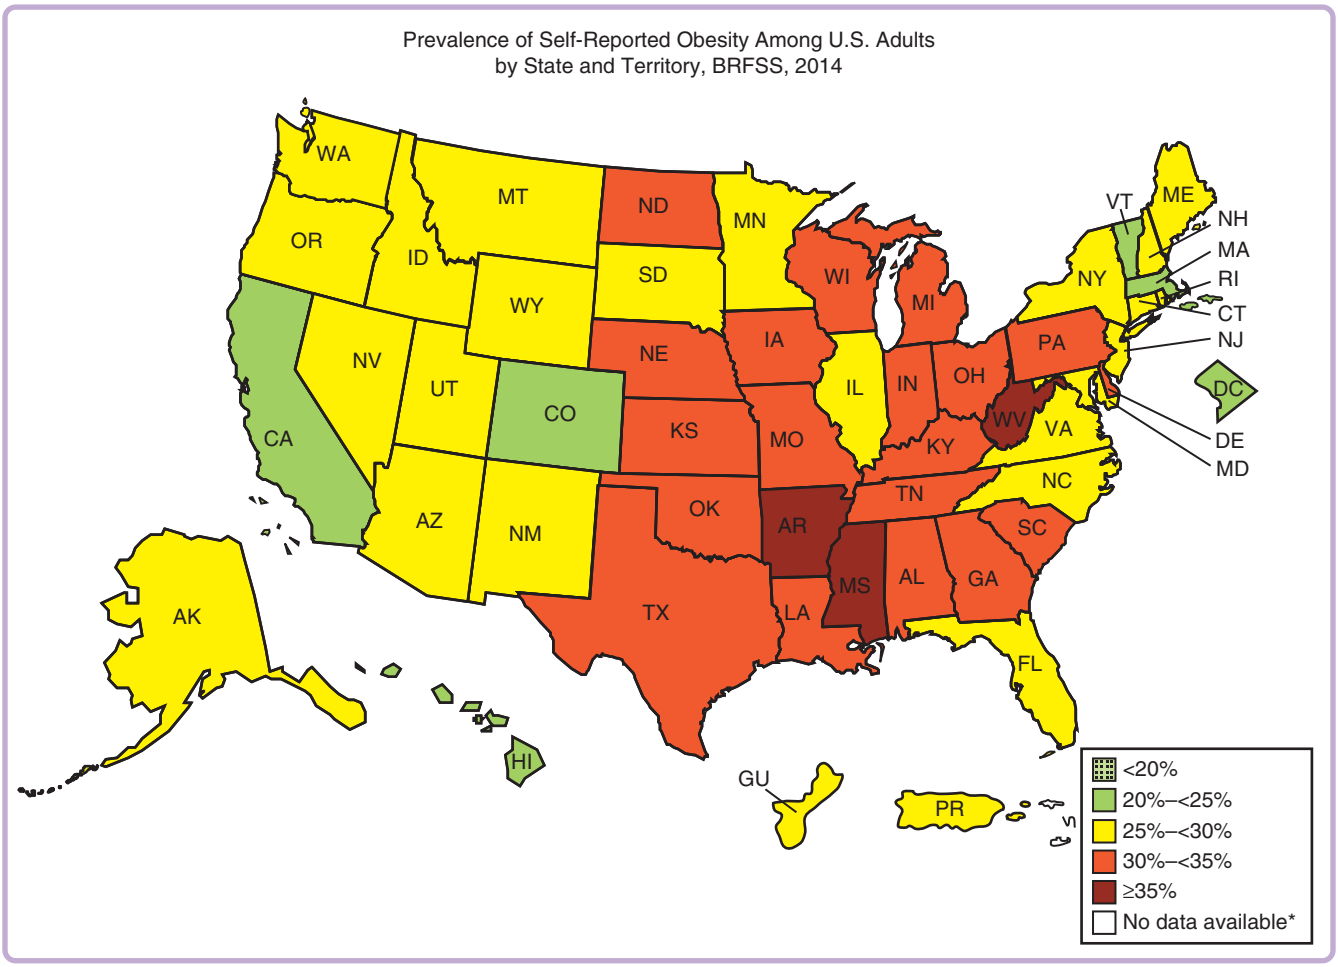

Figure 121-1 Prevalence of self-reported obesity among adults in the United States by state and territory per the Behavioral Risk Factor Surveillance System (BRFSS), 2014. No state has an obesity prevalence of less than 20%. Eighteen states have an obesity prevalence between 30% and less than 35%, and 2 states have an obesity prevalence of 35% or greater. The South has the highest prevalence of obesity, followed by the Midwest, the Northeast, and the West. (From Centers for Disease Control and Prevention. Obesity prevalence maps, 2013. <http://www.cdc.gov/obesity/data/prevalence-maps.html.>)

obesity.[3] OSA has been found in 50% to 80% of obese patients seen in clinical settings,[3] and from 60% to 90% of adults with OSA may be overweight.[13] In the Wisconsin Sleep Cohort, an increase of 1 standard deviation (5.7 kg/m^2) was associated with a fourfold risk of an apnea-hypopnea index (AHI) of 5 events/hour or greater.[14] Furthermore, the Sleep Heart Health Study reported a dose-dependent relationship between increasing BMI and OSA: The prevalence of an AHI of 15 or higher was 10% in the lowest BMI quartile (16 to 24 kg/m^2), as opposed to 32% in the highest quartile (32 to 59 kg/m^2).[15]

Longitudinal population and clinical samples also indicate that weight and AHI change congruently. In the Wisconsin Sleep Cohort, each 1% increase (or decrease) in weight was associated with a 3% increase (or decrease) in AHI, and in patients with mild OSA (AHI of 5 to 15) at baseline, a 10% weight gain led to a sixfold risk for developing moderate to severe OSA (AHI of 15 or higher).[16] In the Sleep Heart Health Study, parallel changes in weight and AHI were similarly found over a 5-year follow-up period, but AHI increased more with weight gain than it decreased with weight loss.[17] Men tend to suffer a greater increase in AHI with weight gain than women,[17] whereas BMI has a greater effect on AHI in postmenopausal women than in premenopausal women.[3] Increasing age may attenuate the association of BMI and AHI.[15]

PATHOGENESIS

Mechanism Linking Obesity to Obstructive Sleep Apnea Risk

Upper airway anatomic and neuromuscular factors may be influenced by parapharyngeal fat accumulation in several ways.[18] In obesity, upper airway size may be compressed by the deposition of adipose tissue, especially in the lateral pharyngeal fat pads, intraluminal structures (tongue, soft palate, uvula), and neck.[19-23] During wakefulness, increased pharyngeal dilator muscle activity provides compensation; the state-dependent attenuation of pharyngeal muscle activity with sleep, by contrast, leaves the upper airway vulnerable to collapse.[24] Accrual of fat around the upper airway may alter soft tissue properties, thereby heightening the propensity to collapse by increasing upper airway compliance,[25,26] or may change upper airway geometry,[3] with a consequent decrease in the ability of pharyngeal muscles to dilate the airway.[27]

Obesity, a chronic inflammatory state itself, may contribute to increasing upper airway tissue inflammation,[28] or upper airway neuropathic damage through the pathophysiologic changes of diabetes mellitus.[29] Abdominal viscera fat accumulation in patients with OSA also is of likely pathogenetic importance, as highlighted by population surveys reporting a twofold to threefold increase in prevalence of symptomatic OSA in men compared with women,[14,30] with a central distribution of fat involving the neck, trunk, and abdominal viscera typical in men, versus fat deposition in the lower body and extremities characteristically seen in women. The interaction of hormonal changes and accompanying increases in central fat deposition may contribute to the increased prevalence of OSA in postmenopausal women.[3] Central obesity–induced reduction in lung volume[31] decreases "tracheal tug," a caudally directed, pharyngeal-stabilizing, lung volume–dependent traction force directed along the trachea.[32] The reduction in lung volumes coupled with globally increased oxygen demand also may promote the oxygen desaturation that accompanies obstructive apneas and hypopneas.

An evolving discussion in sleep medicine concerns the existence of a bidirectional relationship between obesity and OSA. The intermittent hypoxia, sympathetic activation, and sleep fragmentation caused by repeated episodes of obstructive apnea and hypopnea produce metabolic alterations that provide biologically plausible means by which OSA also may exacerbate overweight and obesity (see Chapter 118). The pathogenetic interactions between obesity and OSA, however, are complex and not fully explored, leaving the subject open for active research.[13]

BARIATRIC SURGERY FOR MEDICALLY COMPLICATED OBESITY

Bariatric surgery has emerged in the context of the rising prevalence of severe obesity, heightened concern about associated comorbid medical conditions, and the limited success of traditional weight loss approaches of diet, exercise, and behavior modification. Although the number of bariatric procedures performed had been increasing for many years, only 1% of clinically eligible patients are being treated for medically complicated obesity in this manner.[33] Lack of access to bariatric surgery probably results from many as-yet poorly studied factors, including lack of insurance coverage, poor understanding of the procedures and their effects, and prohibitive costs—facility costs alone for bariatric surgery, for example, range from $10,000 to $15,000 per case.[34]

Patient Selection

Guidelines originally issued by the National Institutes of Health[35] and recently reaffirmed by the American Association of Clinical Endocrinologists, The Obesity Society, and the American Society for Metabolic and Bariatric Surgery (AACE-TOS-ASMBS)[36] state that bariatric surgery is a treatment option for severely obese patients who failed to achieve weight loss on a structured and monitored exercise and diet program and who have a BMI of 40 kg/m^2 or greater, or a BMI of 35 kg/m^2 or greater in conjunction with one or more obesity-related severe comorbid conditions.[1] Such obesity-associated comorbid conditions include diabetes mellitus, arterial hypertension, dyslipidemia, coronary artery disease, pseudotumor cerebri, asthma, venous stasis, severe urinary incontinence, debilitating arthritis, gastroesophageal reflux disease, nonalcoholic fatty liver disease, and OSA.[36] The most recent AACE-TOS-ASMBS clinical practice guidelines also state that bariatric surgery may be offered to patients with a lower BMI of 30 to 34.9 kg/m^2 along with diabetes mellitus or metabolic syndrome, with the acknowledgment that current evidence to support this expansion of potential bariatric surgery candidates is based on limited and short-term data demonstrating benefit and is not universally accepted.[36]

Patients preparing to undergo bariatric surgery must complete nutritional and psychological evaluation screening to rule out untreated depression, substance abuse, or a history of untreated eating disorders. The potential bariatric surgery recipient must demonstrate a complete understanding of the risks and benefits of the operation as a weight loss "tool," recognize the necessity after surgery to limit portion size and food types, and agree to follow a postoperative vitamin supplementation regimen. Patients should be deemed ineligible

Table 121-2 Patient Selection Criteria for Bariatric Surgery

Factor	Criteria
Weight (adults)	BMI of 40 kg/m^2 or greater, with no comorbid conditions BMI of 35 kg/m^2 or greater with obesity-associated comorbidity
Weight loss history	Failure of previous nonsurgical attempts at weight reduction, including nonprofessional programs (e.g., Weight Watchers)
Commitment	Expectation that patient will adhere to postoperative care Follow-up visits with physician(s) and team members Recommended medical management, including use of dietary supplements Instructions regarding any recommended procedures or tests
Exclusion	Reversible endocrine or other disorders that can cause obesity Current drug or alcohol use Uncontrolled, severe psychiatric illness Lack of comprehension of risks, benefits, expected outcomes, alternatives, and lifestyle changes required with bariatric surgery

From Mechanick JI, Youdim A, Jones DB, et al. Clinical practice guidelines for the perioperative nutritional, metabolic, and nonsurgical support of the bariatric surgery patient—2013 update: cosponsored by American Association of Clinical Endocrinologists, The Obesity Society, and American Society for Metabolic and Bariatric Surgery. *Obesity* 2013;21:S1–27.

for surgery if they cannot understand or will not commit to the dietary changes and lifestyle modifications necessary to complement the procedure. In addition, poor surgical or anesthetic risk status (as with advanced congestive heart failure or suboptimally controlled angina), older age (greater than 50 years), reversible endocrine or other disorders that might cause obesity, and active addiction behaviors are contraindications to bariatric surgery. Selection criteria for bariatric surgery are summarized in Table 121-2.[36]

Rationale for Patient Assessment for Obstructive Sleep Apnea before Bariatric Surgery

High OSA prevalence has been reported among patients being considered for bariatric surgery. In a large series of consecutive patients undergoing bariatric surgery ($n = 342$) in whom preoperative polysomnography was performed regardless of suspicion for OSA, the prevalence of OSA (defined as an AHI of 5 or higher) was 77%; 19% had moderate (AHI of 15 to 30) and 27% had severe OSA (AHI higher than 30).[37] In bariatric surgery candidates, many potential reasons to consider the possibility of OSA preoperatively have been documented: Concurrent OSA may complicate the intubation and/or increase the difficulty of mask ventilation in obese patients. Commonly used perioperative drugs have inhibitory influences on central ventilatory drive, protective upper airway reflexes, and arousal mechanisms, which may further jeopardize the airway of the severely obese patient with known OSA. Upper airway edema associated with endotracheal intubation and forced supine positioning also can acutely aggravate OSA risk after bariatric surgery. Spells of desaturation associated with postoperative obstructive apneic episodes or hypoventilation may be exaggerated by the interaction of obesity-related reduction in pulmonary functional residual capacity with factors in the postoperative milieu. OSA may increase risk for and/or destabilize comorbid conditions in the obese patient, such as hypertension, atrial fibrillation, heart failure, and diabetes mellitus, and these conditions may require attention preoperatively or adversely affect the postoperative course. Therefore close collaboration among the sleep specialist, the anesthesiologist, the bariatric surgeon, and the patient is crucial for proper planning to mitigate OSA-related complications perioperatively.

Preoperative Assessment for Bariatric Surgery in the Patient without Known Obstructive Sleep Apnea

The AACE-TOS-ASMBS clinical practice guidelines[36] stipulate that the possibility of OSA should be considered in *all* bariatric surgery candidates. However, uncertainties exist regarding the specifics of the extent of the preoperative OSA evaluation.

Discernment of OSA status begins with a sleep-focused history and physical exam by the bariatric surgery team. The diagnostic features of OSA are discussed in Chapters 113 and 114. No cardinal symptom of OSA, such as snoring or excessive daytime sleepiness, is singularly sufficient to predict the presence of OSA or its severity in bariatric surgery candidates. Furthermore, no a single best metric of body habitus for predicting OSA has been identified.[3] Instead, a combination of symptoms and signs is more discriminatory, so many prediction formulas combining clinical parameters have been created to hone clinicians' detection of OSA. An example of a screening tool for OSA extensively studied in preoperative patients is the STOP-Bang instrument.[38] This questionnaire poses "yes-or-no" questions about **s**noring, **t**iredness, **o**bserved apneas, blood **p**ressure, **B**MI higher than 35 kg/m^2, **a**ge older than 50 years, **n**eck circumference greater than 40 cm, and male **g**ender, with likelihood of the presence of OSA increasing as the number of affirmative responses increases. Sensitivity (proportion of patients with OSA correctly identified by the STOP-Bang to have OSA) and specificity (proportion of patients without OSA correctly identified by the STOP-Bang to not have OSA) for moderate to severe OSA defined by AHI higher than 15 in patients with BMI of 35 kg/m^2 or greater preparing for nonbariatric operations depends on the cutpoints selected: score of 3 or higher: 97% (sensitivity) and 7% (specificity); score of 4 or higher: 86% and 28%; 5 or higher: 65% and 65%; and 6 or higher: 42% and 86%.[39] These figures highlight the tradeoff inherent in creating and implementing OSA prediction tools: As the threshold for the number of required OSA features is increased, those incorrectly labeled as having OSA (false positives) decreases, but detection of patients with OSA (true positives) also decreases. In general, most OSA prediction tools are more sensitive than specific, favoring detection of true positives (presence of OSA in patients identified as having the disorder) and thereby minimizing false negatives, at the expense of false positives (designating many patients as having OSA when in fact they do not). Severe OSA is unlikely to missed by OSA prediction tools, but reported sensitivities and specificities for a given

screening tool have varied in the hands of different investigators, and the ideal preoperative OSA screening instrument has not been identified.[40]

Guidelines emerging from the anesthesiology literature[41-43] recommend incorporating an OSA prediction tool or checklist in the preoperative assessment of patients preparing for any surgery. The STOP-Bang is highlighted in several of these strategies[41,42]; the American Society of Anesthesiologists guideline for the perioperative management of patients with known or suspected OSA contains its own OSA prediction checklist.[43] Those patients judged to be at low risk for having OSA as determined by the screening instrument are cleared to proceed directly to surgery without further sleep testing, whereas those deemed to be at intermediate or high risk should proceed either to a formal sleep assessment or to surgery, with adjustment of their perioperative care for presumptive OSA, depending on the clinical status and the urgency of the surgical issue.

Attempts to create new OSA screening tools[37,44] or to validate existing[45,46] tools in bariatric surgery populations have not yielded powerfully discriminative sensitivity and specificity characteristics for the instruments tested. In the study by Gasa and colleagues,[44] the addition of sleep oximetry data did significantly enhance the sensitivity and specificity of their initial model based on anthropometric and clinical factors alone (age, waist circumference, systolic blood pressure, and witnessed apneas). The latest AACE-TOS-ASMBS bariatric surgery clinical practice guidelines[36] recommend "standardized screening" for OSA, with "confirmatory polysomnography to follow if screening tests are positive," but do not elaborate on the phrase, "screening tests." The guidelines label predictive modeling attempts "encouraging" but not definitive.[36] The current understanding of the role for OSA screening tools in the bariatric population will continue to evolve. At present, incorporation of an OSA screening tool into the preoperative evaluation of all bariatric surgery candidates by the surgical team should be considered as an initial minimum means to consistently ensure that OSA is deliberately contemplated in an organized manner and to enhance detection of the most severe OSA cases. Because the "best" OSA screening tool is not known, the decision about which tool to use must be made locally by the bariatric surgery team, ideally with guidance from their sleep medicine colleagues. The designation of OSA status by the screening tool output must be integrated with other pertinent information, such as collateral observations about the patient's breathing during sleep from the bed partner, history of airway difficulties with previous anesthetics, anticipated surgical approach (open versus laparoscopic), and comorbidity burden.

Laboratory-based, technologist-attended polysomnography remains the diagnostic "gold standard" modality for diagnosis of OSA.[47] A routine role for preoperative sleep testing (polysomnography or home sleep apnea testing) continues to be debated. Proponents for such a practice cite the high prevalence of OSA among severely obese patients, the potential for perioperative complications from unrecognized OSA, and the limited accuracy of clinical impression alone in OSA diagnosis. Opponents point to the lack of data demonstrating improved postoperative outcomes with preoperative initiation of CPAP in patients undergoing bariatric surgery, the uncertainty regarding the relative contribution of OSA to postoperative complications in this population, and potential clinical overuse of such testings in patients deemed to be at low risk by clinical impression or OSA screening tool. The AACE-TOS-ASMBS bariatric surgery clinical practice guidelines[36] are vague: "routine preoperative screening with polysomnography should be considered." Performing sleep studies in all bariatric surgery candidates without exception, however, seems overly rigid. The reality is that if an OSA screening tool is systematically implemented, most patients will face the prospect of sleep testing before bariatric surgery because they will be judged to be at high risk by the OSA screening tool. For instance, in the study examining the performance of STOP-Bang in obese patients,[39] just 5% of preoperative patients with a BMI of 35 kg/m^2 or higher scored less than 2. Additionally, sleep testing may be needed to establish OSA as a weight-related comorbid condition in building justification for bariatric surgery, or if therapy for OSA is desired regardless of whether bariatric surgery is ultimately performed. In those patients without collateral sleep history or who are suspected of downplaying OSA symptoms, overnight oximetry monitoring may be an intermediate step between OSA screening by history and physical examination and a formal sleep study—that is, polysomnography. In bariatric surgery programs in which preoperative polysomnography or home sleep apnea testing is not routinely performed in every patient, preoperative consultation with a sleep specialist about the need for further sleep testing often is appropriate and is specifically recommended in situations of ambiguity about OSA status or its perioperative importance. Private insurers are increasingly mandating home sleep apnea testing in cases of suspected OSA, and the adult bariatric surgery candidate with a high pretest probability of having moderate to severe OSA and without significant comorbid cardiopulmonary disease may be an appropriate candidate for home sleep apnea testing followed by initiation of autoadjusting CPAP.[48] However, laboratory-based polysomnography is indicated and typically is covered by insurance carriers for the very obese suspects with OSA (BMI greater than 45 to 50 kg/m^2) or those with suspected OHS, because of the possible need for attended titration of modalities other than CPAP, such as bilevel (i.e., biphasic) positive airway pressure (BiPAP) and supplemental oxygen.

A high index of clinical suspicion should be maintained for the presence of OHS, because affected patients require more careful presurgical consideration. For several reasons, patients with OHS would be expected to be at higher risk than eucapnic obese patients with OSA during bariatric surgery. The diminished ventilatory responsiveness to hypoxia and hypercapnia in this patient group leads to increased sensitivity to sedatives and opioids, potentially greater problems with weaning from mechanical ventilation, and development of life-threatening obstructive apnea events, as well as acute worsening of hypercapnia with supplemental oxygen therapy unaccompanied by any ventilatory support such as BiPAP.[49] Rates of comorbid conditions such as systemic hypertension, pulmonary hypertension, cor pulmonale, and angina are higher in patients with OHS than in eucapnic obese patients.[50] OHS is a risk factor for development of venous thromboembolic (VTE) disease, which is a leading cause of postoperative death in bariatric surgery.[51]

OHS can be challenging to diagnose before bariatric surgery because patients may not always appear dramatically different than eucapnic obese patients with OSA. Patients

with OHS more commonly have lower extremity edema, report moderate to severe dyspnea on exertion, exhibit higher AHIs and more profound minimum oxyhemoglobin saturations during sleep, spend greater time with an oxyhemoglobin saturation lower than 90% during sleep, have lower awake oxyhemoglobin saturations, are afflicted with higher BMIs, demonstrate greater restrictive changes on pulmonary function testing, and use more health care resources compared with eucapnic obese patients with OSA[4,50] Serum bicarbonate of 27 mEq/L or more (reflecting metabolic compensation for chronic respiratory acidosis) is a sensitive but not specific marker for OHS in the obese patient with OSA.[52] If OHS is suspected on the basis of any or all of these factors, the following tests are recommended: arterial blood gas (hypoventilation manifests as hypercapnia, the severity of which should be determined), pulmonary function tests and chest radiograph (to search for other causes of chronic hypoventilation), echocardiogram (to assess the right heart pressures and function), complete blood count (to detect erythrocytosis), thyroid function tests (to rule out hypothyroidism, if not already done as part of routine testing of the obese patient), and polysomnography[4] (see Chapters 113 and 114).

PAP therapy for moderate to severe OSA (AHI of 15 or higher) should be initiated preoperatively. Case-by-case decisions about CPAP are necessary in milder forms of OSA (e.g., position-dependent OSA); CPAP may be recommended preoperatively for a patient with AHI of 5 to 14 who also is hypersomnolent or in whom the degree of desaturation during obstructive apneas/hypopneas is of greater clinical concern, perhaps in the presence of comorbid conditions such as pulmonary hypertension. The elective nature of bariatric surgery should allow for follow-up assessment of titrated PAP therapy in the patient with newly diagnosed OSA or OHS before surgery. In many bariatric surgery centers, adherence to the preoperative PAP regimen for the candidate with OSA is a mandatory prerequisite; accordingly, failure to comply with this recommended therapy is a deal-breaker, because it points to the likelihood of poor adherence to other postoperative care requirements. The minimal preoperative PAP trial duration for achieving PAP acclimatization and garnering improvement in physical status is not known,[53] but because patterns of PAP use may be established within the first week of therapy,[54] close follow-up monitoring in the first few weeks to document adherence, address problems, and assess response is advised.[55] In the patient with OHS, a repeat measurement of arterial blood gases after 4 weeks of PAP therapy[4] may allow discontinuance of supplemental oxygen with confirmation of an adequate therapeutic response or may indicate the need for tracheostomy with or without ventilation when PAP fails to effect improvement.

Preoperative Assessment for Bariatric Surgery in the Patient with Established Obstructive Sleep Apnea

Patients with a known diagnosis of OSA and who are already on an established PAP regimen at the time they begin to explore the option of bariatric surgery should be asked preoperatively about suboptimal compliance, technical difficulties, persistent symptoms despite PAP, and increases in weight since their last sleep evaluation. Identification of any of these issues should prompt referral to a sleep specialist. Follow-up polysomnography is indicated for patients with substantial weight gain (i.e., 10% of baseline body weight or more) and recurrent OSA symptoms despite PAP adherence.[47] Asymptomatic, PAP-adherent patients generally can proceed to surgery. They should be advised that PAP use will be required postoperatively and that they should bring their equipment to the hospital. Settings for PAP with or without supplemental oxygen usually are maintained postoperatively at preoperative levels, although acute adjustments may be necessary depending on the cumulative effects of factors such as opioid requirements and postoperative pulmonary disorders (e.g., VTE, pneumonia). Those patients with OSA treated previously with upper airway surgery who remain symptomatic, or in whom objective evidence of sleep-disordered breathing resolution is lacking, should be assumed to remain at risk for residual OSA and may benefit from a preoperative evaluation by a sleep specialist before bariatric surgery.[42,56] Such patients should be advised that temporary application of PAP may be necessary in the immediate postoperative period if upper airway obstruction occurs. The possibility of temporary outpatient use of PAP after surgery also should be discussed with bariatric surgery candidates who use an oral appliance for OSA management, because it may not be feasible to use their dental device immediately postoperatively.

Common Bariatric Surgical Procedures

Bariatric surgery procedures have been historically grouped into three categories based on anatomic components: predominately malabsorptive procedures, predominately restrictive procedures, and procedures with both malabsorptive and restrictive components. A majority of these operations are now performed by a less invasive, small-incision, laparoscopic approach. Ongoing research in animal models and human trials is aimed at further elucidation of the underlying mechanisms of action of bariatric surgery, which may ultimately allow a more sophisticated grouping of the surgical procedures based on their impacts on endocrine, neuronal, and behavioral physiologic variables.[57]

Roux-en-Y gastric bypass (RYGB) (Figure 121-2) combines creation of a small gastric pouch with modest intestinal or small bowel bypass. A traditional RYGB consists of transection of a small (15-mL) proximal gastric pouch along the lesser curvature of the stomach from the larger gastric segment, combined with a modest (encompassing 60 to 150 cm) intestinal bypass. The Roux-en-Y configuration allows biliopancreatic secretions and digestive juices to pass through the bile duct into the duodenum and then merge with the alimentary stream passing down from the stomach at the Y-type connection. The lengths of both the Roux and biliopancreatic limbs can be varied to produce more malabsorption. Most weight is lost in the first year, with long-term weight loss stabilizing at 2 to 3 years. Approximately 80% of patients typically experience weight stabilization, usually slightly above weight nadir, approximately 3 years after surgery. The remaining 20% of patients slowly regain excess weight over longer-term follow-up, and they risk becoming surgical failures.

The *laparoscopic adjustable gastric band* is an inflatable silicone prosthetic device that is placed around the top portion of the stomach, just below the esophagus (Figure 121-3), and restricts the upper stomach size to a small volume. The band is attached to a reservoir, with a port placed under the skin on the abdominal wall, and the inner lining of the band is a balloon that is adjustable by the addition or removal of saline

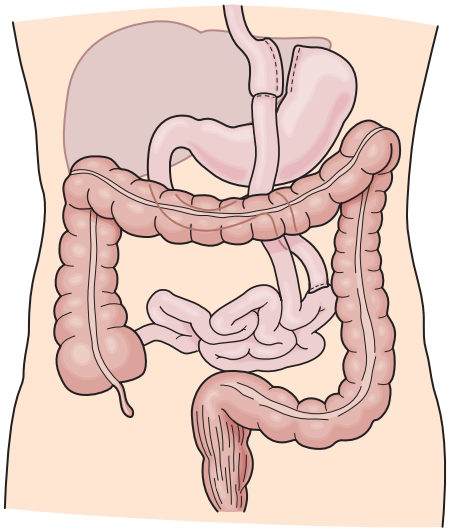

Figure 121-2 Roux-en-Y gastric bypass.

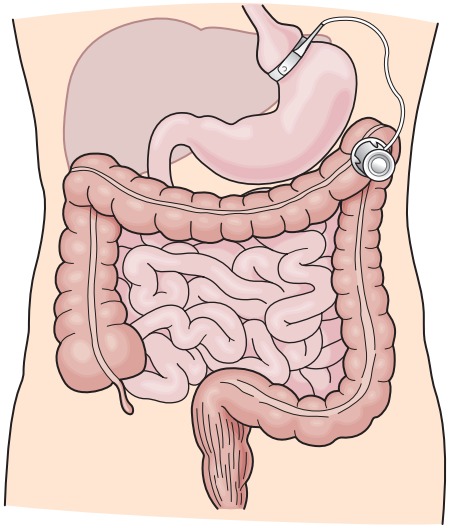

Figure 121-3 Gastric band procedure.

from the reservoir port. Inflation of the band increases the restriction of gastric outlet size and food flow. Postoperative management for patients who have undergone this procedure entails frequent follow-up visits for band adjustments/reservoir fills and strict adherence to dietary guidelines and lifestyle modification to achieve consistent weight loss. The weight loss trajectory after banding procedures is more gradual, with less weight lost than after RYGB. The favorable aspects of this procedure are that it is less invasive and requires less operating time, and that the band is both adjustable and removable. Use of the band procedure is declining with the increase in number of alternative surgical options being offered.[58]

The most recent major bariatric procedure to be introduced and growing in usage is the *vertical sleeve gastrectomy* (VSG).[59] This operation is a 70% vertical gastric resection, creating a long and narrow tubular gastric reservoir with no intestinal bypass. In many ways, VSG is intermediate between bypass and banding in terms of complexity, risk, and weight loss results. Data on long-term results (beyond 1 to 2 years) with VSG are lacking.[60]

The less commonly used *biliopancreatic diversion* (BPD) and *BPD with duodenal switch* (BPDDS) procedures, which result in an extreme degree of malabsorption, are reserved for the treatment of "super-obese" patients. BPD combines a partial, subtotal gastrectomy and a very long Roux-en-Y anastomosis with a short common channel for nutrient absorption. With this procedure, patients can eat much larger quantities of food and still achieve and maintain weight loss. Disadvantages to the procedure include loose and foul-smelling stools, intestinal ulcers, anemia, vitamin and mineral deficiencies, and possible protein-calorie malnutrition. Because of these potential problems, patients who undergo BPD require lifelong dietary supplementation and close follow-up monitoring. With similar weight loss and complications, the BPDDS is a hybrid operation that combines a gastric sleeve resection with a long intestinal bypass in the Roux-en-Y configuration. In this procedure, ulcer rate is reduced, and dumping syndrome (the constellation of nausea, vomiting, abdominal pain or cramping, diarrhea, bloating, fatigue, palpitations, lightheadedness, sweating, and anxiety beginning within 15 to 30 minutes after eating) is eliminated by leaving intact the first portion of the intestine in the alimentary stream. BPD and BPDDS procedures are the most major and technically difficult procedures performed for weight loss and consequently should be offered only by experienced surgeons, and to patients who are able to undertake lifelong follow-up.

Debate continues regarding the selection of a specific procedure type for any given patient, and predictive data to meaningfully guide these decisions are lacking. Patients are provided with general guidelines about the different potential mechanisms of action, percent weight loss over time, and morbidity profile among procedures when making a final decision regarding surgery. The optimal choice of procedure depends in part on the expertise of the surgeon and the clinical facility, patient preference, and risk stratification.[36]

CLINICAL COURSE

Management of Obstructive Sleep Apnea Immediately after Bariatric Surgery

Many details regarding optimal care of the patient with OSA immediately after bariatric surgery remain unclear. The following general recommendations are based on experience, consensus expert opinion for generic surgical care,[41-43,56] and a limited peer-reviewed literature.

Airway extubation after bariatric surgery should be performed only when the patient is fully awake and alert and has demonstrated evidence of return of neuromuscular function (as evidenced by sustained head-lift for more than 5 seconds) and adequate vital capacity and peak inspiratory pressure.[43] Removal of the endotracheal tube should take place in the operating room, postanesthesia care unit (PACU), or special care unit so that airway control can be monitored closely and expertly addressed if lost.[43]

In the PACU, the patient should be maintained in the semiupright or lateral, not supine, position, if possible. Supplemental oxygen typically is provided under continuous pulse oximetry monitoring and titrated to the lowest level to maintain adequate oxygenation, especially in patients with OHS.

Ventilation also must be specifically monitored as supplemental oxygen may maintain adequate oxyhemoglobin saturation despite medication-exacerbated hypoventilation. Ventilation monitoring may include capnography, arterial blood gas testing, and scheduled assessments for respiratory events by PACU staff. In a study of a non–bariatric surgery perioperative patient population, recurrent respiratory events in the PACU powerfully predicted postoperative respiratory complications.[61] Respiratory events were scored during three consecutive 30-minute periods immediately after extubation and were defined as bradypnea (three or more episodes of fewer than 8 breaths/minute), apnea (one or more episodes of 10 seconds or longer of breathing cessation), desaturations (three or more episodes of oxyhemoglobin saturation below 90%), and pain-sedation mismatch (one or more episodes of high pain score and simultaneously high sedation score). Recurrent respiratory events meant that one or more of any of the PACU respiratory events occurred in at least two separate 30-minute time blocks and were associated with an odds ratio of 21 for postoperative respiratory complications.[61] In the PACU, PAP is instituted at the level prescribed before surgery in those patients who were using it preoperatively. In patients whose preoperative CPAP settings are not known or in whom initiation of CPAP is desired to address recurrent respiratory events emerging in the PACU, CPAP in autoadjusting mode can be applied or started at an empirically chosen level of 8 to10 cm H_2O and adjusted as needed, although acute initiation of such therapy in the PACU can be challenging in the PAP-naive patient. BiPAP, usually with oxygen, may be initiated to address acute hypoventilation. PACU staff must be capable of monitoring and managing PAP therapy, including addressing interface leaks and observing diligently for signs of breakthrough upper airway obstruction despite PAP, such as snoring, choking, witnessed apneas, cardiac dysrhythmias, or repetitive oxygen desaturation.

In the first 24 postoperative hours after bariatric surgery, patients are likely to be the most vulnerable to potential OSA-related complications,[62] although OSA propensity may be increased for at least several days after bariatric surgery because of the aggregate effects of ongoing sleep deprivation, rapid eye movement sleep rebound, and medication synergies.[56] Fortunately, the length of hospital stay usually is short (3.5 days and 1.6 days for gastric bypass and restrictive procedures, respectively).[63] Clinicians must consistently keep the possibility of OSA in mind in all patients as they consider postoperative analgesia, monitoring, oxygenation, and patient positioning[43] for the duration of the hospitalization. Systemic opioids should be used cautiously because of their ability to depress the respiratory drive and cause subsequent oxygen desaturation. The use of patient-controlled analgesia is controversial, although it may be an option if used without a basal rate and with restricted dosing. Nonsteroidal antiinflammatory agents may help decrease opioid dosing as recovery progresses but should be used cautiously in the postsurgical patient because of the enhanced potential for bleeding complications. Benzodiazepines should be avoided because of their negative effects on the respiratory control and upper airway musculature. Access to PAP should be available at all times during recovery—a seemingly obvious recommendation but one that may be overlooked by busy house staff, nurses unfamiliar with this ventilatory technique, and patients distracted or impaired by postoperative pain or pharmacologic obtundation. Properly trained health care staff should be readily available to assist patients in PAP device placement, to troubleshoot interface problems, to observe for breakthrough upper airway obstruction, and to reassure patients struggling with a new PAP regimen.

Continuous pulse oximetry monitoring after discharge from the PACU is recommended for all post–bariatric surgery patients for as long as they are deemed to be at increased risk, which may be defined as the duration of intravenous opioid use or an oral opioid dose of greater than 60 mg of codeine every 4 hours.[42] Oximetry data should be continuously observed at the bedside in a critical care or stepdown unit, by telemetry on a hospital ward, or by a dedicated, trained observer in the patient's room. Choosing the optimal monitoring site will depend on the interplay of multiple factors. It is reasonable to consider intensive care unit (ICU) care for the first 24 to 48 hours after bariatric surgery in patients with one or more of the following features: age older than 50 years, BMI greater than 60 kg/m^2, significant comorbid cardiopulmonary disease, brittle diabetes mellitus, severe OSA/OHS with worrisome record of suboptimal PAP compliance, sluggish emergence from anesthesia, and intraoperative complications. In the University HealthSystem Consortium evaluation, a review of the bariatric programs at 29 academic medical centers in the United States, 7.7% of patients undergoing gastric bypass and 1.1% of patients undergoing a restrictive procedure required ICU support postoperatively.[5] Operative approach to bariatric surgery also must be considered. Case series from experienced surgery teams have reported that patients with established and treated OSA undergoing laparoscopic bariatric procedures do not require routine postoperative admission to the ICU.[64,65]

Incentive spirometry should be encouraged. If oxygen desaturations occur despite an appropriate PAP regimen, supplemental oxygen should be added while the provider searches for an explanation, such as transient worsening of upper airway obstruction requiring adjustment of PAP settings, VTE event, atelectasis, aspiration, pneumonia, or anastomotic leak. Caution with the use of supplemental oxygen without PAP during sleep is advised, because this strategy provides no protection against upper airway obstruction and will blunt detection of a disordered breathing event by oximetry monitoring. Postoperative supine positioning also should be avoided; instead, the head of the bed should be kept elevated in a semi-Fowler position (to at least 30 degrees) at all times. All post–bariatric surgery patients should be considered to be at moderate to high risk for VTE events; accordingly, thromboprophylaxis with low-molecular-weight heparin or low-dose unfractionated heparin, along with application of intermittent pneumatic compression stockings, is indicated in all patients.[36,66] The frequency of VTE after bariatric surgery with thromboprophylaxis is low at less than 1%.[66] Because most VTEs occur after hospital discharge, the AACE-TOS-ASMBS advises extended chemoprophylaxis (duration unspecified) for patients at higher risk for such events, such as those with a history of VTE or reduced activity level.[36] Prolonged respiratory failure after bariatric surgery is uncommon, occurring in less than 1% of cases, according to data from the American College of Surgeons' National Surgical Quality Improvement program encompassing approximately 32,000 patients who underwent bariatric surgery between 2006 and 2008; the impact of OSA on the rate of

respiratory failure is not known, because OSA was not a risk factor assessed in the analysis.[67]

Laparoscopic bariatric surgery is performed in some patients in an ambulatory setting. A consensus statement from the Society for Ambulatory Anesthesia[41] warns against use of outpatient surgical procedures in patients with OSA if it is accompanied by a a nonoptimized comorbid condition; if an inability to control pain predominantly with nonopioid analgesic techniques can be anticipated; or if the patient displays unwillingness or inability to use PAP. Patients on PAP should be advised to bring their device to the ambulatory care facility for use during recovery. If the patient experiences recurrent respiratory events while in the PACU, hospital discharge should be delayed until the patient is observed to maintain adequate oxygenation (on PAP if necessary, if used preoperatively) in an unstimulated environment, preferably while sleeping.[43] Patients not on PAP should be advised to sleep exclusively nonsupine, and PAP users should wear their device during all sleep periods, including naps, for "several days" after surgery; all are advised to minimize use of opioids.

Benefits of Bariatric Surgery

Postoperative weight loss typically is reported as the mean percentage of excess weight loss, defined by the following formula:

$$(\text{Weight loss} \div \text{excess weight}) \times 100$$

where excess weight equals total preoperative weight minus ideal weight. In a review of 136 studies involving 22,000 bariatric surgery patients, Buchwald and colleagues[68] reported that the mean percentage of excess weight loss with bariatric surgery was 61.2%: 47.5% for gastric banding, 68.2% for gastric bypass (principally RYGB), and 70.1% for BPD and BPDDS. The mean decrease in BMI was 14.2 kg/m^2, whereas the mean decrease in absolute weight was 39.7 kg, similar to the 20- to 30-kg weight loss reported in the meta-analysis by Maggard and colleagues.[69] Comorbid conditions correspondingly decreased in severity with weight loss. Overall, diabetes mellitus completely resolved in 76.8%, hyperlipidemia decreased in degree in 70%, and arterial hypertension lessened in severity or resolved in 78.5%.[68] Weight loss, improvement with respect to comorbid conditions, and quality of life at 1 year, as well as rates of severe postoperative complications, are similar for RYGB and for VSG, both performed laparoscopically.[70] A retrospective cohort study comparing long-term mortality rates among 7925 patients who underwent gastric bypass and 7925 age-, sex-, and BMI-matched control subjects randomly selected from a state driver's license applicant registry demonstrated a 40% reduction in adjusted long-term mortality with bariatric surgery during a mean follow-up period of 7.1 years.[71]

No large randomized trials have compared bariatric surgery with medical management of obesity. The Swedish Obesity Study[72] was a large, prospective, nonrandomized, controlled trial that compared outcomes for 2010 obese subjects treated with bariatric surgery and for 2037 contemporaneously matched obese control subjects treated conventionally. At 2 years, weight had decreased by 23.4% in the surgery group but had increased by 0.1% in the control group, and after 10 years, weight had increased by 16.1% over presurgical weight in the surgery group but had increased by 1.6% in control subjects ($P < .001$ at both time points). Improvements in clinical indices of diabetes, hypertriglyceridemia, and hypertension were more favorable in the surgery group, and the surgery group exhibited lower 2- and 10-year incident rates of diabetes than those for the control group. Maximal weight loss in the surgery group was assessed after 1 to 2 years, and at 10 years the maximal average losses were 32% for gastric bypass, 25% for vertical banded gastroplasty, and 20% for banding. Overall mortality was lower in the surgery group than in the control group.[73]

Long-term Impact of Bariatric Surgery on Obstructive Sleep Apnea

Weight loss induced by bariatric surgery is consistently associated with reductions in AHI.[74] Buchwald and coworkers' meta-analysis[68] of selected bariatric surgery outcomes reported that OSA resolved or decreased in severity in 83.6%. The weighted (i.e., weighting results by sample size) mean change in the AHI was 40 (events/hour), with a range of 16 to 52.8. Enthusiasm over these results must be tempered by several methodologic concerns. *Improvement* and *resolution* with respect to OSA were not explicitly defined. The studies included in the meta-analysis are not entirely specified, but a review of studies from the inclusion period (1990 to June 2003) revealed that reduction in OSA symptoms probably was sufficient in some studies to assess OSA response (i.e., postoperative polysomnography was not required in all subjects), the timing of polysomnography after surgery was nonuniform, and the results probably were variably reported (e.g., only preoperative and postoperative apnea indices were described, not AHIs).

Studies published since June 2003[75-78] corroborate earlier series reporting that surgically induced weight loss is associated with symptomatic improvement in OSA when reassessment occurs approximately 1 year or longer after surgery. However, many patients have residual OSA. Even though gastric banding resulted in a mean AHI reduction of 23.4 (events/hour), Lettieri and colleagues[79] found that 23 patients (96%) still met criteria for OSA (AHI higher than 5), 20 (83%) continued to experience transient nocturnal hypoxia (oxyhemoglobin saturation below 90%), and 13 (54%) had persistent sleepiness (Epworth Sleepiness Scale scores higher than 10) despite an average weight loss of 54 kg at a mean of 418 days postoperatively. In a metaanalysis of 12 studies involving 342 patients, Greenburg and colleagues[80] found that the pooled mean BMI decreased by 17.9 kg/m^2 and AHI decreased by 38.2, but the residual AHI averaged 15.8. Since that meta-analysis, a small randomized, controlled trial pitting bariatric surgery (laparoscopic adjustable gastric banding) ($n = 30$ patients) against a conventional weight loss program (individualized dietary, physical activity, and behavioral programs) ($n = 30$ patients) demonstrated that although bariatric surgery produced significantly greater mean weight loss at 2 years than that achieved in the nonsurgical program (27.8 kg versus 5.1 kg), the reductions in AHI were statistically similar (25.5 versus 14; $P = .18$).[81] The mean residual AHI in the bariatric group was 39.5, and 73% of the bariatric group continued to have an AHI of 15 or higher. Accordingly, health care providers must remain vigilant for persistent OSA with a systematic postoperative follow-up program, because even dramatic changes in weight and symptoms do not guarantee objective cure of OSA. The optimal timing for postoperative polysomnography is not clear but depends in part on the

patient's weight loss evolution. The CPAP requirement for residual OSA is likely to fall by at least 2 to 4 cm H_2O in the year after surgery.[82] Autotitrating CPAP after surgery may bridge the patient to polysomnography and obviate subjective pressure reductions or serial sleep studies.

The American Academy of Sleep Medicine concluded that bariatric surgery may be adjunctive in the treatment for OSA, but it rates this recommendation as an option, meaning that bariatric surgery is of uncertain clinical use in the management of OSA.[83] This designation is based on the lack of data at the Sackett level of evidence I to III and the potential for perioperative complications.

Risks and Complications of Bariatric Surgery

The Longitudinal Assessment of Bariatric Surgery (LABS) Consortium conducted a prospective, observation study of outcomes of bariatric surgical procedures at 10 clinical sites in the United States from 2005 to 2007. The rate of operative mortality, defined as death within the first 30 days, was 0.3% among 4610 consecutive patients who underwent RYGB or laparoscopic adjustable gastric banding: None of the 1198 patients who had a laparoscopic adjustable gastric band procedure died, 0.2% of the 2975 patients who underwent laparoscopic RYGB died, and 2.1% of the 437 patients who underwent open RYGB died.[84] A composite endpoint of death, deep vein thrombosis or venous thromboembolism, reintervention, and failure to be discharged by 30 days after surgery was reported in 4.1% of patients: 1% in the laparoscopic adjustable gastric banding group, 4.8% in the laparoscopic RYGB group, and 7.8% in the open RYGB group. Factors that were each independently associated with an increased risk of the composite endpoint were a history of venous thromboembolic disease, impaired functional status, and extreme values of BMI. Box 121-1 lists the postoperative adverse events from bariatric surgery, which can be grouped as early and late. A dreaded complication is anastomotic leak: In the University HealthSystem Consortium evaluation,[63] the anastomotic leak rate for gastric bypass procedures was 1.6%.

The extent to which OSA is linked to complications after bariatric surgery is not fully known. In a review of data for more than 3000 patients, OSA, older age, male sex, and revision gastric bypass were found to be independent predictors for anastomotic leak,[85] whereas OSA, hypertension, and less surgeon experience were identified by multivariate analysis as predictors of postoperative complications in a series of nearly 200 patients undergoing laparoscopic RYGB.[86] In the LABS analysis, OSA also was independently associated with increased risk for an adverse outcome, with a composite of such outcomes defined as the endpoint.[84] Accordingly, OSA has been linked to increased cost of postoperative care[87] and higher risk for prolonged postoperative hospital stay.[88] In other studies, however, the investigators have not identified OSA as an independent predictor of complications after bariatric surgery.[89-91] These reports are challenging to interpret and compare because of differences in procedures used and uncertainty over how aggressively OSA was pursued preoperatively and managed postoperatively, and many are single-center and possibly underpowered retrospective reviews, thus providing a lower grade of evidence. PAP initiated immediately after bariatric surgery does not appear to increase risk for anastomotic leaks[92,93]

Box 121-1 COMPLICATIONS OF BARIATRIC SURGERY

Complications Common to All Bariatric Procedures

Early (up to 30 days after surgery)

Venous thromboembolic disease
Bleeding
Anastomotic leaks
Wound infections
Persistent nausea/vomiting, dehydration
Regional abdominal organ trauma
Incisional and internal hernias
Bowel obstruction
Atelectasis
Pneumonia
Cardiac dysrhythmias
Urinary tract infection
Death

Late (beyond 30 days after surgery)

Incisional and internal hernias
Bowel obstruction from adhesions
Nutritional deficiencies
Anastomotic strictures and marginal ulcers or erosions
Cholelithiasis
Anemia
Persistence or recurrence of obstructive sleep apnea
Need for body contouring
Weight regain

Procedure-Unique Complications/Adverse Effects

Roux-en-Y Gastric Bypass

Dumping syndrome

Laparoscopic Adjustable Gastric Banding

Band slippage or erosion
Port or device malfunction

Vertical Sleeve Gastrectomy

Refractory reflux

Biliopancreatic Diversion

Loose, foul-smelling stools
Protein-calorie malnutrition

PITFALLS AND CONTROVERSY

Controversy remains about the impact of OSA on bariatric surgery complications and thus to what extent must OSA be sought and treated preoperatively. Definitive data are not available. Bariatric surgery clinical practice guidelines[36] stipulate that OSA should be considered in all bariatric surgery candidates—but does that mean polysomnography is mandatory and that if it yields a positive result, PAP is required? The answer to both of these questions is likely to be "no." Instead, the history and physical findings pertinent to OSA, perhaps initially organized by a screening tool sensitive to OSA so that the search is consistent and systematized, must be combined with consideration of a host of other factors, both patient-related (comorbidity burden; OSA symptom severity; OHS likelihood) and procedure-related (open versus laparoscopic; inpatient versus ambulatory; anticipated postoperative opioid requirements), in deciding how to proceed. Those patients

judged to be at low risk for having OSA as indicated by the collective clinical information (e.g., STOP-Bang score less than 3) can proceed directly to bariatric surgery without further sleep testing[42] *provided that* postoperative precautions are in place (e.g., careful monitoring in the PACU; minimization of opioid/sedative use; head of bed elevation; incentive spirometry) and the bariatric team is prepared to address OSA should it manifest during the immediate postoperative period. Patients deemed to be at intermediate or high risk for having OSA should proceed to a formal sleep assessment, with the sleep specialist guiding the ordering of sleep testing and the interpretation of findings.[42] PAP is started preoperatively for treatment of moderate to severe OSA (AHI of 15 or higher) and OHS. Preoperative PAP initiation allows the patient to begin accruing its neurobehavioral and cardiovascular benefits while working through other preparatory steps typically required for bariatric surgery. Furthermore, retrospective data suggest that it may decrease the risk of post–bariatric surgery complications[94] and is recommended by the AACE-TOS-ASMBS guidelines.[36]

CLINICAL PEARLS

- The sleep clinician should be mindful that bariatric surgery candidates are likely to have OSA, which requires careful consideration during the preoperative evaluation as well as in the postoperative period.
- Post–bariatric surgery patients should be expected to lose 20 to 50 kg by 1 to 2 years postoperatively, which current studies indicate should be accompanied by a 50% to 75% reduction in AHI and a drop in required PAP levels.
- Autotitrating CPAP may be a useful management modality as weight decreases after surgery.
- Despite dramatic weight loss, OSA may persist in many patients, so follow-up polysomnography is advised to reassess for this condition and to guide decisions about longer-term PAP use.

SUMMARY

The prevalence of obesity, a leading cause of preventable disease and death, is increasing. Nearly 70% percent of Americans currently are overweight or obese. Rates of overweight and obesity are higher among Mexican Americans and non-Hispanic black Americans than among non-Hispanic whites and Asian Americans. Excess weight is the strongest risk factor for OSA because of its adverse impact on upper airway neuromuscular function and anatomy. Bariatric surgery, comprising a variety of procedures that limit food absorption or restrict intake (or both), is indicated for severely obese patients in whom an adequate exercise and diet program has failed to achieve results and who have either a BMI of 40 kg/m^2 or greater or a BMI of 35 kg/m^2 or above in conjunction with one or more obesity-related severe comorbid conditions. The mean percentage of excess weight loss with bariatric surgery is approximately 60%, and in patients with major obesity-related conditions, such as diabetes mellitus and hypertension, consistent improvement in clinical indices is to be expected. Thirty-day mortality rate for bariatric surgery is less than 1%. OSA is almost universally present in bariatric surgery candidates, sometimes in the context of OHS. The immediate post–bariatric surgery setting may exacerbate OSA, whereas OSA and its associated conditions may exacerbate challenges to the patient's immediate postoperative well-being. Systematic screening for OSA should therefore be a required component of preparation for bariatric surgery, with addition of a formal sleep evaluation for patients deemed to be at higher risk for OSA. Symptomatic improvement follows, but the OSA does not usually resolve with bariatric surgery–induced weight loss. The sleep clinician plays an important role in the bariatric surgery process, in preoperatively collaborating with the surgical team to identify OSA and by helping to define its significance, determining which patients need OSA treatment, and initiating or optimizing OSA therapy to postoperatively determine the degree of residual OSA and the need for additional treatment.

Chapter 122

Sleep and Breathing at High Altitude

Vahid Mohsenin; Shahrokh Javaheri; Jerome A. Dempsey

Chapter Highlights

- Exposure to high altitude imposes significant strain on the cardiopulmonary system and the brain. As a consequence, sojourners to high altitude frequently experience sleep disturbances, often reporting restless and sleepless nights.
- At altitudes above 3000 meters, almost all healthy subjects develop periodic breathing, especially during non–rapid eye movement (NREM) sleep.
- Sleep architecture gradually improves after acclimatization to altitude, with increased NREM and rapid eye movement (REM) sleep despite persistence of periodic breathing.
- The primary reason for periodic breathing at altitude is a hypoxia-induced increase in chemoreceptor sensitivity to changes in Pa_{CO_2}—both above and below eupnea, leading to periods of apnea and hyperpnea.
- Acetazolamide improves sleep consolidation and periodic breathing through development of metabolic acidosis and induced hyperventilation, decreasing the plant gain and widening the P_{CO_2} reserve. This widening of the P_{CO_2} reserve impedes development of central apneas during sleep.
- Benzodiazepines and other gamma-aminobutyric acid receptor antagonists such as zolpidem improve sleep without affecting breathing pattern or cognitive function.
- Promising effects of other modalities to improve high-altitude periodic breathing, including noninvasive ventilation and increasing dead space breathing, remain to be further investigated in humans.

EXPOSURE TO HIGH ALTITUDE

Each year several million people worldwide travel from areas of low elevation to altitudes over 2500 meters (8200 ft). Empirically, and because of higher risk for altitude illnesses, 2500 meters has been used as the threshold for high-altitude illnesses. However, polysomnography at altitudes of both 1630 meters (5348 ft) and 2590 meters (8497 ft) shows decreased non–rapid eye movement (NREM) stage N3 sleep (slow wave sleep) and an increased apnea-hypopnea index (AHI) in the form of period breathing compared with the altitude of 490 meters (1608 ft). Interestingly, these healthy male subjects reported no changes in their total sleep time, excessive sleepiness, or acute mountain sickness (AMS) symptoms.[1]

With the increasing popularity of mountain sports such as skiing, climbing, and snowshoeing, and the latest trend in adventure travel to places like the Andes and Himalayas, it is expected that the incidence of high-altitude exposure will continue to grow. These often rapid ascents of nonacclimatized individuals place them at an increased risk for AMS, insomnia, and sleep-disordered breathing.

This chapter focuses on the effect of high altitude on sleep and respiratory control systems, the clinical disorders associated with such effects, and the optimal treatments. Relevant features of acute physiologic adjustment to high altitude are summarized; then the characteristics of the sleep disturbance at high altitude, its pathogenesis, and therapeutic interventions are reviewed. Although much of the focus is on sleep after acute ascent to high altitude, alterations in sleep during long-term altitude exposure are also mentioned. Information in this chapter may also be relevant to the pathophysiology of central sleep apnea at low altitude (see Chapters 15, 16, and 110).

PHYSIOLOGIC RESPONSES TO HIGH ALTITUDE

Primary among the changes in physical environment that attend the ascent to high altitude is a decrease in barometric pressure such that, although the fractional concentration of O_2 is similar to that at sea level, O_2 tension—the product of fractional concentration and barometric pressure—is reduced (Figure 122-1). This decreased O_2 tension of ambient air presents a threat to arterial and tissue oxygenation and elicits a series of responses that act to minimize tissue hypoxia. These responses consist of early increases in ventilation and cardiac output and, during more prolonged exposure, rises in circulating red cell concentration and adaptive changes in peripheral tissue, including increased spatial density of capillaries and mitochondria. Also see Chapter 18 for a detailed review of the physiology related to high altitude.

Increased Ventilation

The earliest, and one of the most important, of these responses is increased ventilation, which acts to minimize the extent of alveolar hypoxia and arterial hypoxemia in the face of a decrease in ambient O_2 tension (Figure 122-2). The acute

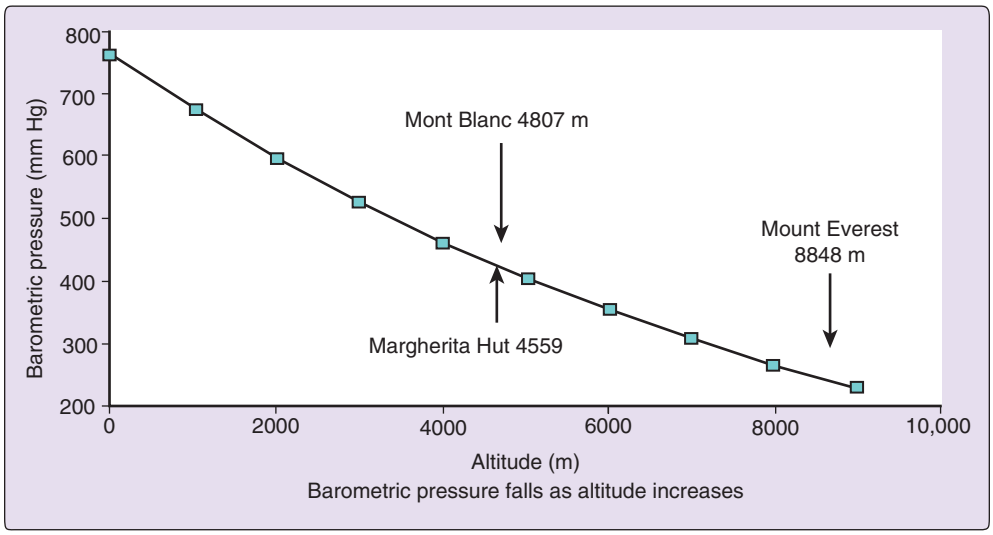

Figure 122-1 Relationship between altitude and barometric pressure. Inspired oxygen pressures at Margherita Hut, Italy, on the summit of Mont Blanc France, and Mount Everest are 84, 82, and 43 mm Hg, respectively.

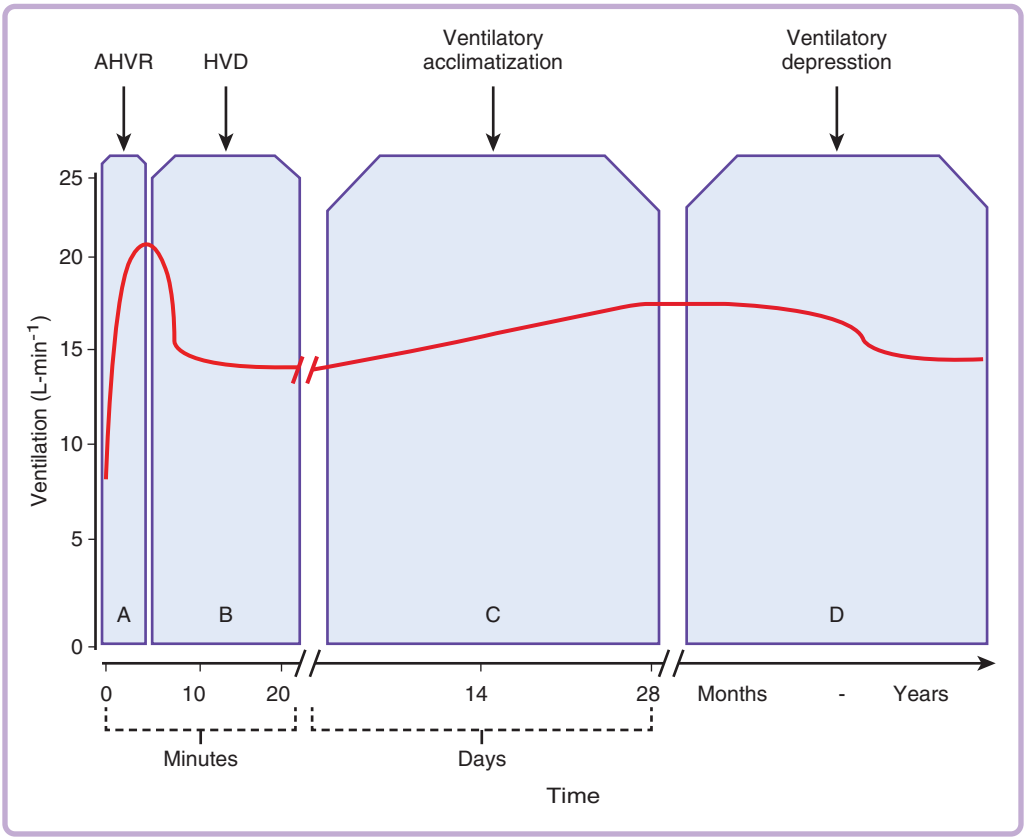

Figure 122-2 Temporal changes in ventilation on acute and prolonged exposure to high altitude. The acute hypoxic ventilatory response (AHVR) is followed within minutes by hypoxic ventilatory decline (HVD) before ventilatory acclimatization to hypoxia occurs. (From Ainslie PN, Lucas SJ, Burgess KR. Breathing and sleep at high altitude. *Respir Physiol Neurobiol* 2013;188:233–256.)

ventilatory response to hypoxia (acute hypoxic ventilator response; AHVR) is followed within minutes by hypoxic ventilatory decline (HVD) before ventilatory acclimatization to hypoxia (VAH) occurs. The exact mechanisms causing HVD are uncertain; however, its occurrence could result from elevations in cerebral blood flow (CBF) increasing CO_2 and hydrogen ion [H^+] washout, resulting in decreased central chemoreceptor sensitivity and/or neural stimulus response.[2,3] The development of HVD has also been attributed, at least in part, to an increased peripheral chemoreflex threshold to the isocapnic hypoxic stimulus.[4] The magnitude of the ventilatory response to hypoxia increases with increasing altitude, but it

also varies considerably among individuals at a fixed altitude. This variability, in part, reflects intrinsic, interindividual differences in the strength of the basal (preascent) ventilatory response to hypoxia.[5]

Ventilation progressively increases over several days after ascent to high altitude (see Figure 122-2). This gradual increase occurs despite the fact that the increasing ventilation is lessening hypoxia, the presumed stimulus to breathing, as well as increasing hypocapnic alkalosis, which is a ventilatory inhibitor. This is the phenomenon of ventilatory acclimatization to high altitude, which is manifested as a progressive decrease in arterial P_{CO_2} (P_{aCO_2}) with increasing ventilation over several days. On restoration of normoxia, hyperventilation continues but slowly dissipates over several days.[6] Although the mechanism of such acclimatization is debated, studies in humans and animals suggest that increased hypoxic sensitivity of the carotid body may be a major contributor.[7] In any case, it is during the early phase of altitude adjustment, shortly after ascent, that sleep disturbances appear to be most marked; they tend to improve during the period of acclimatization.

Periodic Breathing

In the early and mid-nineteenth century, Cheyne and Stokes, respectively, described the crescendo-decrescendo breathing pattern in cardiac patients that now bears their names (see Chapter 129). That periodic breathing is frequent during sleep in normal individuals at high altitude was observed shortly thereafter by Tyndall in 1857, by Egli-Sinclair and Mosso in 1893 and 1894, and by Douglas and colleagues[8] in 1913, and it continues to be a consistent finding in current studies of sleep after ascent to high altitude.[9-14]

The major effects of sleep on ventilatory control include removal of the "wakefulness stimulus"—which is specifically associated with inhibition of motor output to dilator musculature of the pharyngeal airway, resulting in significant increases in upper airway resistance; critical dependence of ventilatory control on P_{aCO_2} and the unmasking of an apneic threshold for P_{CO_2} residing within a few millimeters of mercury (mm Hg) below waking levels of eupneic P_{aCO_2}, and a propensity for periodic breathing in the form of ventilatory overshoot and undershoot.[15] The temporal pattern of periodic breathing and its linkage to sleep stages show night-to-night variation and considerable intersubject differences.[11,13,16-21] Periodicity is usually evident early in sleep, during light sleep stages (NREM sleep N1 to N2), and can persist despite improvement in sleep architecture with increases in slow wave sleep, rapid eye movement (REM) sleep, and a reduction in the arousal index (Figure 122-3).[22] Periodic breathing at high altitude may also occur in wakefulness, especially during periods of drowsiness.[23-25] Periodic breathing at high altitude is different from the typical crescendo-decrescendo pattern in tidal volume observed in heart failure[26] (see later), although has some resemblance to the irregular pattern of breathing associated with opiate use.[27]

Hyperventilation during NREM or REM sleep begins immediately on hypoxic exposure and intensifies with time.[9,28] Within the initial 10 minutes of hypoxia in the sleeping human, tidal volume begins to oscillate, ultimately resulting in cluster-type periodic breathing with a few augmented tidal volumes interspersed with apneas (Figure 122-4). Hypoxemia augments CO_2 chemosensitivity below and above eupnea. Consequently, P_{aCO_2} is closer to the apneic threshold P_{CO_2}, and therefore, a small transient fall in P_{aCO_2} (e.g., after an arousal with hyperpnea) results in an apnea. During these periodic cycles, arterial oxygen saturation (S_{aO_2}) also oscillates and often—depending on the altitude—falls to a point on the steep portion of the oxygen dissociation curve. The periodic breathing pattern characteristically has a short cycle length, ranging from 12 to 34 seconds, which progressively shortens with increasing altitude[29-31] and in this manner differs from the longer cycles of 40 to 90 seconds in patients with heart failure.[32] The relatively shorter cycle length of periodic breathing at high altitude compared with that observed in heart failure is thought to be attributable to the absence of a prolonged circulation time seen in heart failure patients. During the breathing clusters, the most obvious aspect of the periodicity is the oscillation of tidal volume, with a less obvious change in breathing frequency.[29] Like periodic breathing at sea level, periodicity at altitude is often initiated by movement, arousal, or a deeper breath with a resultant transient decrease in the prevailing P_{aCO_2}.

The most striking influence of sleep stage on periodic breathing at high altitude observed in most,[13,22,33] but not all,[20,34] studies is that the breathing periodicity promptly and consistently decreases in REM sleep. This is similar to the relative rarity of periodic breathing and central apnea in heart failure[26] and also in association with opioids.[27] This is attributable to a widening of the P_{CO_2} reserve in REM sleep, making it less likely for the prevailing P_{CO_2} to reach the apneic threshold P_{CO_2}.[26]

Effects of Hypoxia and Hypercapnia

During sleep, ventilation and oxygenation fall below waking values, and these relative changes are similar at high altitude and at sea level.[35] However, the important difference is that at high altitude, basal (awake) oxygenation is lower, chemosensitivity to CO_2 is increased, and P_{aCO_2} is closer to the apneic threshold P_{aCO_2}. Arterial oxygen tensions fall closer to the descending limb of the oxygen dissociation curve, where values are nearer the threshold for stimulation of ventilation. Similarly, because of increased CO_2 chemosensitivity below eupnea, CO_2 tensions fall to values nearer the apnea threshold, below which breathing ceases during sleep.[36] As a result, small variations in gas tensions have much greater effects on ventilation at high altitude, with greater stimulation by hypoxia and greater inhibition by transient hypocapnia.

Central apnea and periodic breathing during sleep occur within minutes of hypoxic exposure (Figure 122-5). As shown in the sleeping sojourner to 4300 meters (14,108 ft), hyperventilation in response to the reduced P_{aO_2} occurs first, followed by oscillations in tidal volume and minute ventilation ($\dot{V}E$) between hypopnea and hyperpnea and then—usually following a single augmented inspiration—full-blown periodic breathing occurs with clusters of large breaths interspersed with apneas at regularly occurring cycle lengths averaging about 20 to 25 seconds. This periodic pattern continues over several nights at high altitude. If normal oxygenation is suddenly restored (via increased inspired oxygen concentration, F_{IO_2}), periodicity continues for a brief period with prolonged apneic length; then, as hyperventilation abates and P_{aCO_2} rises, periodicity resolves, and a rhythmic, stable breathing pattern is restored. The causes of this hypoxia-induced cluster-type periodic breathing pattern involve responsiveness to CO_2 in both the ventilatory overshoot and

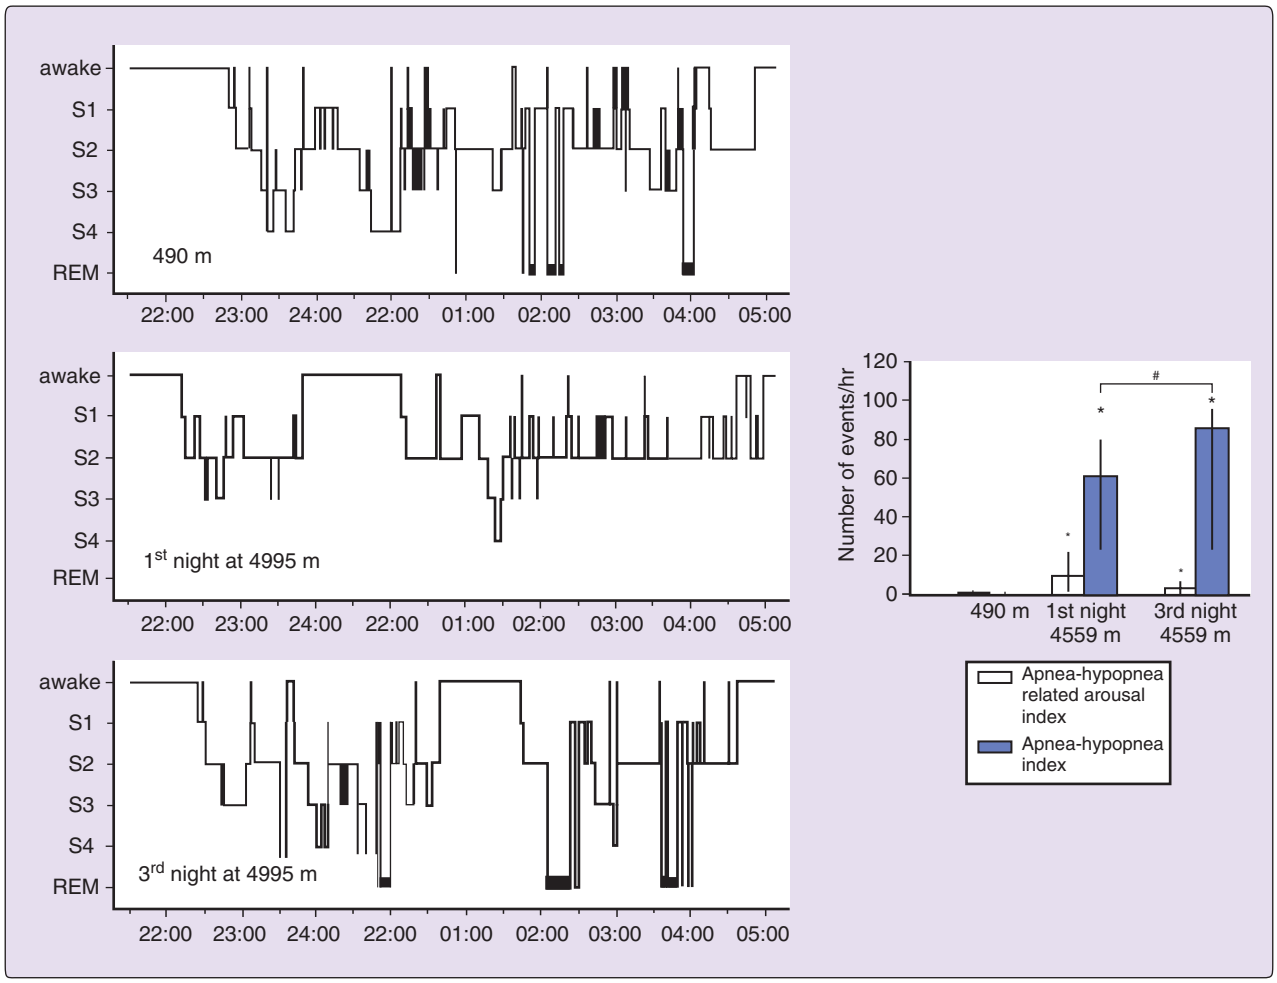

Figure 122-3 A normal subject who climbed to Regina Margherita Hut at 4995 meters (16,388 ft) within 24 hours, who had a reduction in total sleep time, slow wave sleep, and REM sleep and an increased number of arousals on polysomnography during the first night at 4995 meters (16,388 ft) compared with 490 meters (1607 ft). Three days of acclimatization resulted in improvement in sleep architecture, including increases in slow wave sleep and REM sleep and a reduction in the arousal index despite a further increase in apneas and hypopneas (*inset*), suggesting that periodic breathing was not the predominant cause of the sleep disturbances at altitude. (From Nussbaumer-Ochsner Y, Ursprung J, Siebenmann C, et al. Effect of short-term acclimatization to high altitude on sleep and nocturnal breathing. *Sleep* 2012;35:419–23.).

undershoot portions of the periodic pattern. First, as described earlier (see Figure 122-5), variations in $Paco_2$ correlate closely with the development of apnea and periodic breathing with hypoxia and its relief on restoration of normoxia. Second, if inspired fraction of CO_2 ($Fico_2$) is raised at hypoxia onset to prevent hypocapnia, periodic breathing is prevented, and if $Paco_2$ is raised during periodic breathing to elicit 1 to 2 mm Hg increases in $Paco_2$, rhythmic breathing is restored.[9]

The theoretical basis for the importance of $Paco_2$ changes depends on the effect of hypoxia on two types of "gains" that are the key determinants of the tendency toward ventilatory instability[26,37]: chemosensitivity (or controller) gain, defined by the slope of the ventilatory increase or decrease in response to hypercapnia or hypocapnia, respectively ($\Delta\dot{V}E/\Delta PaCO_2$); and plant gain, or the efficiency with which changes in ventilation eliminates CO_2 ($\Delta PaCO_2/\Delta\dot{V}E$) (Figure 122-6). Hypoxic exposure affects these gains in opposite directions; steady-state hypocapnic hyperventilation reduces plant gain, which by itself promotes ventilatory stability; whereas hypoxemia increases CO_2 chemosensitivity both above and below eupnea and narrows the difference between eupneic and apneic threshold $Paco_2$ (see Figure 122-6). The latter mechanism is quite pronounced, overwhelming the former and therefore increasing the likelihood of periodic breathing.

During ventilatory bursts of periodic breathing, the oxygen dissociation curve is shifted to the left, favoring O_2 uptake by the lungs; alternately, during apneas the curve is shifted to the right, favoring O_2 release to the tissues. These findings indicate that satisfactory gas exchange may persist during periodic breathing.

At altitudes above 3000 meters (9842 ft) and with Sao_2 less than 90%, almost all healthy subjects have sufficiently increased chemosensitivity to cause periodic breathing, especially during NREM sleep. With increased duration of hypoxic exposure and ventilatory acclimatization, plant gain is further reduced and chemoreceptor sensitivity further

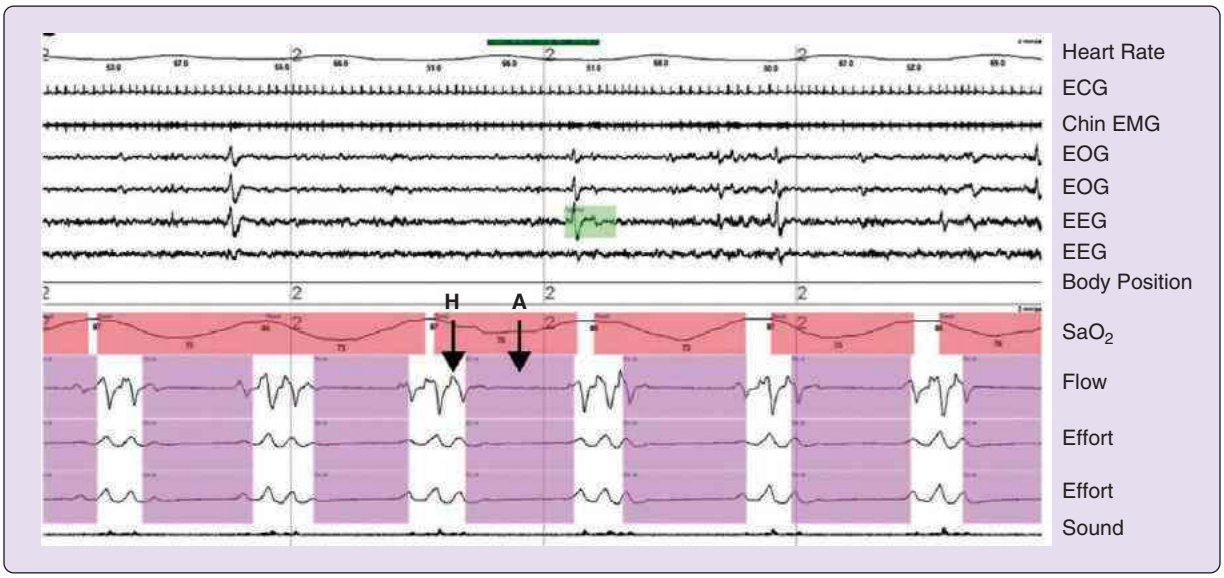

Figure 122-4 A 2-minute epoch from a polysomnogram from one subject during sleep at 5050 meters (16,568 ft) showing periodic breathing with central sleep apnea. *Arrow H* indicates the period of hyperpnea, and *arrow A* the period of apnea. Of note, not all apneas were followed by electroencephalogram (EEG) arousals. Arterial oxygen saturation (Sa_{O_2}) reading showing periods of desaturation. Nasal airflow was measured by pressure transducer. Respiratory effort readings by piezoelectric bands. ECG, Electrocardiogram; EMG, electromyogram; EOG, electro-oculogram. (From Ainslie PN, Lucas SJ, Burgess KR. Breathing and sleep at high altitude. *Respir Physiol Neurobiol* 2013;188:233–256.)

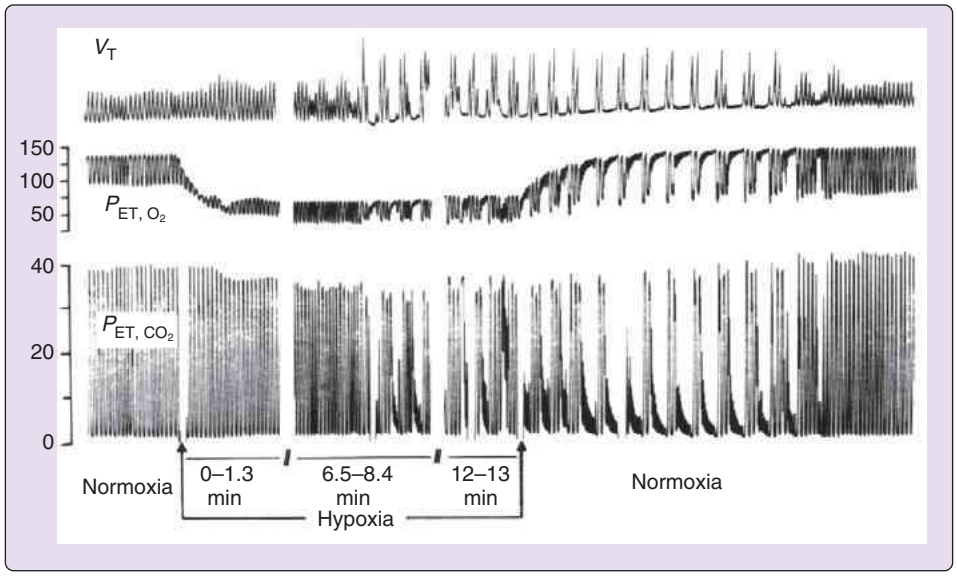

Figure 122-5 Time course of development of periodic breathing on abrupt exposure to simulation of the environmental hypoxia present at 4300 m altitude during NREM sleep and its relief on restoration of normoxia (see description in text). (From Berssenbrugge A, Dempsey J, Iber C, et al. Mechanisms of hypoxia-induced periodic breathing during sleep in humans. *J Physiol* 1983;343:507–24.)

increased. Thus a major—but not the only (see later)—determinant of whether longer durations of hypoxic exposure will result in periodic breathing is the balance struck between further changes in plant versus controller gains. Reports are mixed concerning the question of whether duration of hypoxic exposure increases, decreases, or has no effect on periodicity of breathing.[38] The stabilizing effect on respiratory rhythm of adding F_{ICO_2} in hypoxia—even if P_{ACO_2} is increased by only 1 to 2 mm Hg[9]—is likely attributed to reductions in plant gain,[37] as is the effect of adding such ventilatory stimuli as acetazolamide[39] or progesterone, so long as these added stimuli do not increase chemoreceptor gain.[40] Thus we propose that the net effect of changes in chemosensitivity versus plant gain is the major determinant of periodic breathing in hypoxia

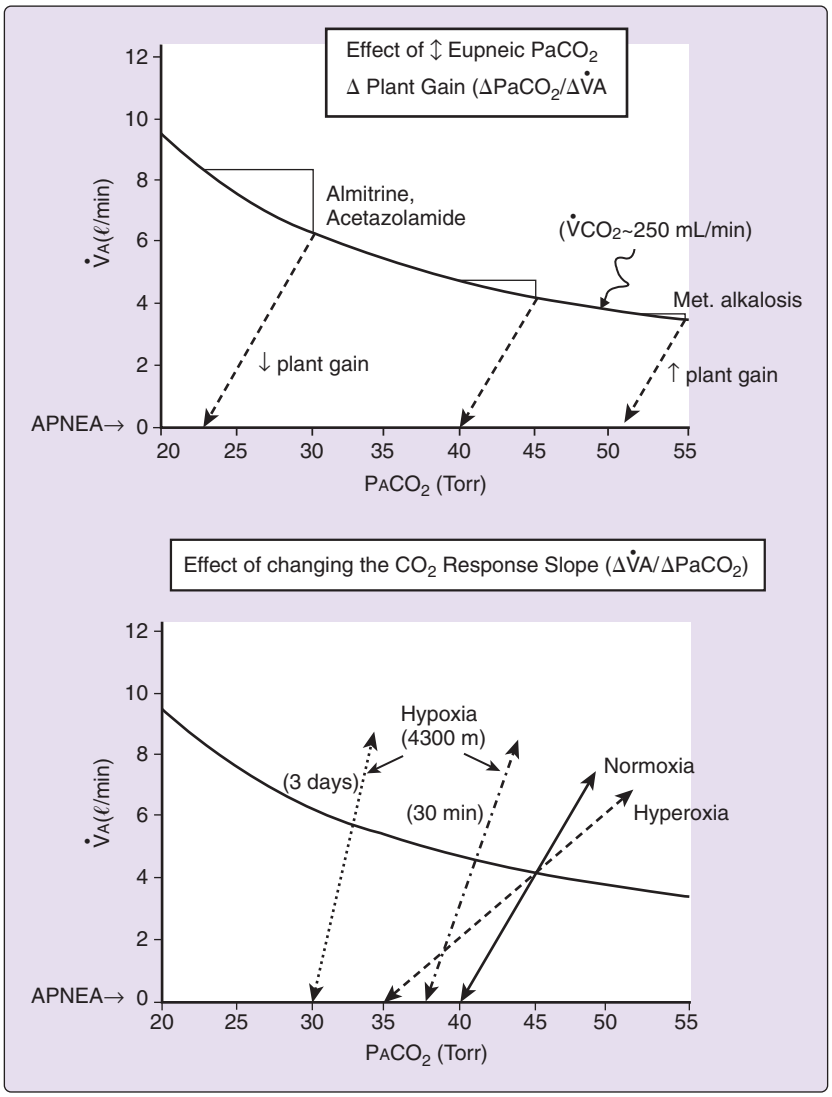

Figure 122-6 Graphic presentation of the relationship of $\dot{V}_A$ to Pa_{CO_2} at a fixed resting $\dot{V}_{CO_2}$ to illustrate how alterations in plant gain or controller gain effect the CO_2 reserve (eupneic Pa_{CO_2} – apneic threshold Pa_{CO_2}) and the propensity for apnea and instability. *Top panel*: changing plant gain by stimulating or reducing eupneic ventilation displaces Pa_{CO_2} along the isometabolic line relating $\dot{V}_A$ to Pa_{CO_2}, thereby altering the $\Delta Pa_{CO_2}/\Delta\dot{V}_A$ ratio and changing the CO_2 reserve and the susceptibility to apnea/periodicity. *Bottom panel*: altering controller gain ($\Delta\dot{V}_A/\Delta Pa_{CO_2}$ slopes) via acute hyperoxia or by acute and chronic hypoxia in normal subjects changes CO_2 reserve and susceptibility to apnea and breathing periodicity. Note that in hypoxia, controller and plant gains will change together. The hyperventilation and increased slope of the CO_2 response observed within the initial 30 minutes of hypoxia are each increased after 3 days in hypoxia. The stabilizing effect of reduced plant gain (decreased eupneic Pa_{CO_2}) is outweighed by the increased controller gain, and the CO_2 reserve is markedly reduced, leading to breathing instability and apnea. $\dot{V}_A$, Alveolar ventilation; $\dot{V}_{CO_2}$, CO_2 production. (From Dempsey JA, Smith CA, Blain GM, et al. Role of central/peripheral chemoreceptors and their interdependence in the pathophysiology of sleep apnea. *Adv Exp Med Biol* 2012;758:343–9.)

at high altitude.[40] However, other important secondary modulators of periodic breathing are also likely to contribute, as outlined later.

Secondary Modulators of Periodic Breathing

Changes occur in CBF in response to hypoxia, and especially in response to transient changes in $Paco_2$ during periodic breathing (averaging ~3% ΔCBF/mm Hg $\Delta Paco_2$) (Figure 122-7).[41] This highly sensitive cerebral vascular reactivity serves to regulate the Pco_2 difference between arterial blood and brain or cerebrospinal fluid, thereby minimizing changes in cerebral extracellular fluid Pco_2 and $[H^+]$ for any given change in $Paco_2$. On arrival to high altitude (5050 meters or 16,568 ft) the CBF velocity increases during NREM sleep compared with before sleep onset, with large oscillations secondary to varying cerebrovascular reactivity to $Paco_2$ and periodic breathing (Figure 122-8).[42] After 2 weeks of acclimatization the mean CBF returns to that seen at sea level but continues to have large oscillations because of the persistent periodic breathing. When the sensitivity of the cerebrovascular response to CO_2 is reduced experimentally (via cyclooxygenase inhibition), the slope of the $Paco_2$ versus

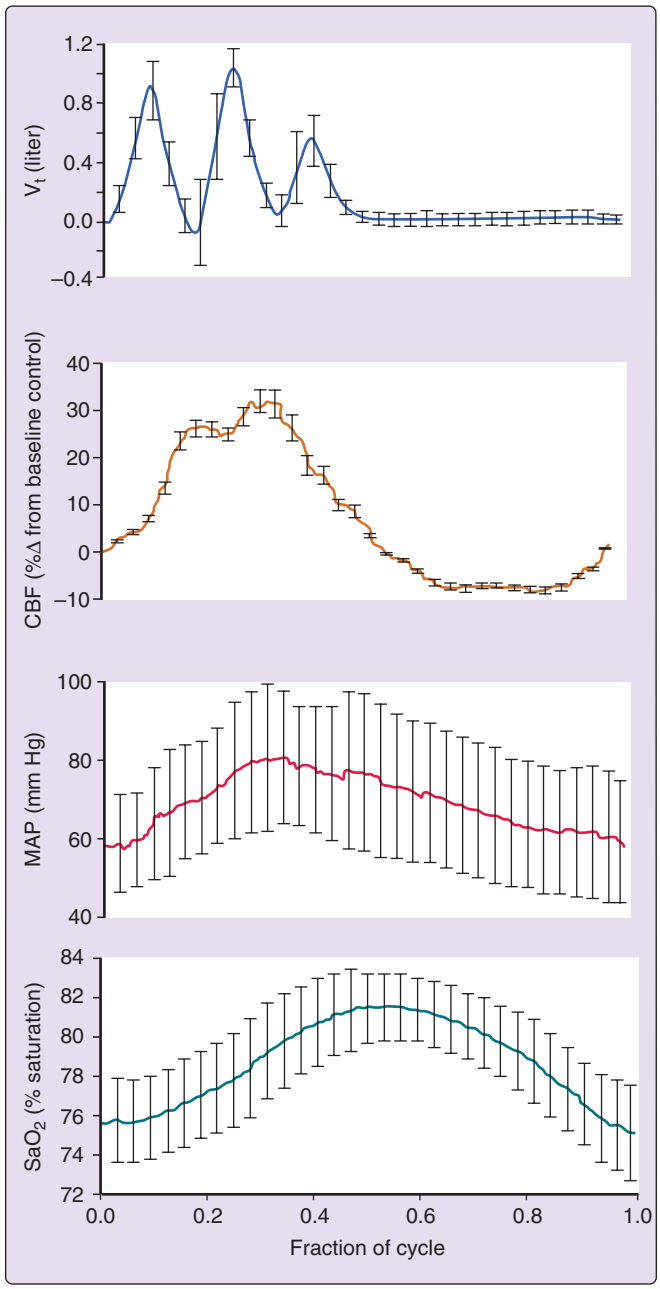

Figure 122-7 The effects of one night of hypoxic exposure (F_{IO_2} = 0.11) on periodic breathing and middle cerebral artery (MCA) blood flow during NREM sleep in the healthy human. Shown are signal-averaged data over 150 periodic breathing cycles in a single healthy subject. These data are representative of those found in six additional subjects. Each periodic breathing cycle averaged 22 seconds in duration and consisted of three hyperpnea tidal breaths followed by an 8- to 12-second apnea. Note the average 30% increase in MCA blood velocity (CBF) as determined by Doppler ultrasound measurements and the increase in mean arterial pressure (MAP), which began at the termination of the apnea and peaked during the ventilatory overshoot phase. Immediately following the ventilatory overshoot, CBF fell 10% below baseline control. (From Dempsey JA, Smith CA, Przybylowski T, et al. The ventilatory responsiveness to CO(2) below eupnoea as a determinant of ventilatory stability in sleep. *J Physiol* 2004;560:1–11.)

$\dot{V}E$ response is increased and the CO_2 reserve reduced[43]; at high altitudes periodic breathing is enhanced.[38] Conversely, acute (via intravenous acetazolamide) elevations in CBF velocity and reactivity to P_{aCO_2} are related to improvements in breathing stability at high altitude during wakefulness[44] and sleep.[42]

Experimental acute increases in left atrial and pulmonary vascular pressures in the naturally sleeping canine model in normoxia will stimulate breathing, enhance the CO_2 response gain and controller gain, and reduce CO_2 reserve.[45] It is not known whether these same influences contribute to ventilatory control instability as pulmonary vascular resistance increases in humans with altitude-related hypoxia.

A powerful stabilizing influence on breathing occurs through the phenomenon of short-term potentiation (STP) of phrenic nerve and respiratory motor output, which occurs following abrupt removal of a chemoreceptor (or other types) of ventilatory stimuli. This results in a gradual dissipation of ventilatory drive back to control levels.[46,47] When apnea occurs during NREM sleep following a transient ventilatory overshoot, this is likely a manifestation of hypocapnic inhibition, including that which is secondary to vagal influences from lung stretch, which has overridden the stimulatory STP effect.[47,48] Acute systemic hypoxemia also has the effect of reducing STP, thereby contributing to apnea and periodicity during sleep in hypoxia.[47]

The modulating roles of sex hormones on sleep-disordered breathing have been suggested by their protective roles against obstructive sleep apnea.[49,50] Sex hormones may directly contribute to ventilatory control through their effects on central respiratory centers, upper airways structure and function, lung dynamics, modulation of chemoreflex sensitivity, and plant gain.[51-53] The potential protective roles of sex hormones on periodic breathing at high altitude were tested in 23 men and 14 premenopausal women who had a sleep study at sea level and then at 3400 meters (11,155 ft) and 5400 meters (17,717 ft). At sea level, a normal breathing pattern was observed in all subjects throughout the night. At 3400 meters (11,155 ft) there was a significant and large difference in the mean AHI between men (AHI = 40/hour: central apneas 77.6%, central hypopneas 22.4%) and women (AHI = 2/hour: central apneas 58.2%, central hypopneas 41.8%). However, with further ascent to the altitude of 5400 meters, AHI increased in both men and women (AHI = 87/hour: central apneas 60.0%, central hypopneas 40.0%; AHI = 41/hour: central apneas 73.2%, central hypopneas 26.8%, respectively). Interestingly, there was no difference in nocturnal S_{aO_2} between the genders in these data despite the large differences in the central respiratory event indexes.[54] In another study, at an altitude of 4559 meters, men more frequently than women exhibited increased nocturnal periodic breathing. Increased periodic breathing directly correlated with heightened hypoxic chemosensitivity that had been assessed at sea level.[55] These data suggest gender differences in hypoxic chemosensitivity and periodic breathing at high altitude, with men being at higher risk for the latter.

In summary, the pathogenesis of periodic breathing in altitude-related hypoxia is clearly multifaceted, although the key element appears to be hypoxia-induced increased chemosensitivity to CO_2, likely involving both primary carotid body stimulation and secondary effects of enhancing the central chemoreceptor CO_2 response.[56,57]

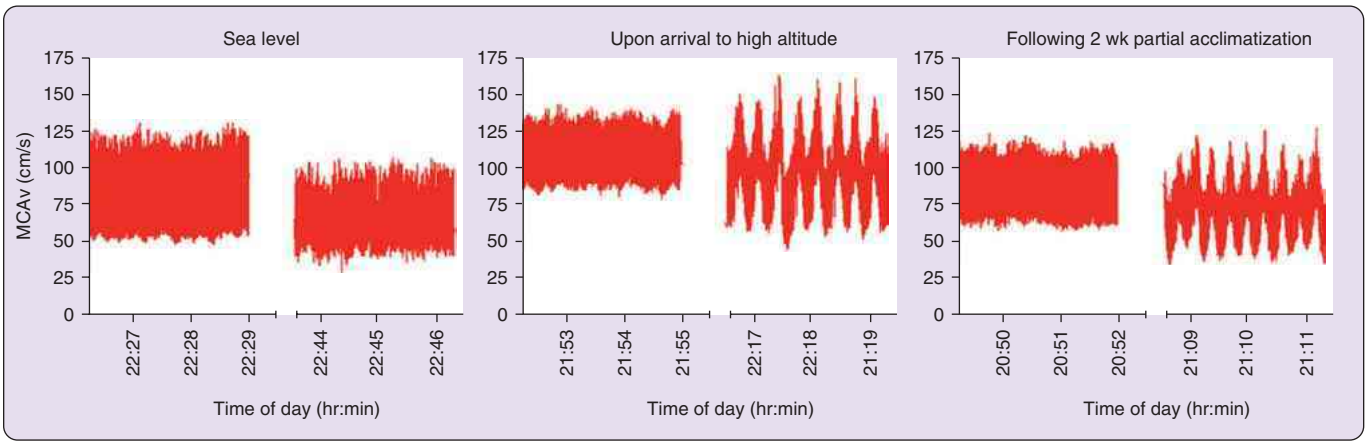

Figure 122-8 The changes in middle cerebral artery blood flow velocity (MCAv) on arrival to high altitude (*middle graph*) and following 2 weeks of partial acclimatization. The decrease in MCAv from wakefulness (left-hand trace) to stage N2 sleep (right-hand trace) was similar on arrival and following partial acclimatization to high altitude compared with sea level (≈10 cm/s). However, both awake and asleep MCAv levels were elevated on arrival to high altitude with marked oscillations compared with sea-level values. (From Burgess KR, Lucas SJ, Shepherd K, et al. Worsening of central sleep apnea at high altitude—a role for cerebrovascular function. *J Appl Physiol* 2013;114:1021–8.)

Sleep at High Altitude

In a comprehensive evaluation of normal subjects ascending to higher elevations (4995 meters, 16,388 ft), altitude-induced hypoxemia during the first night at this altitude was associated with a reduction in total sleep time, N3 sleep, REM sleep, and an increased number of arousals.[22] Breathing during sleep was characterized by increased minute ventilation, periodic breathing, and cyclical oxygen desaturation. Three days of acclimatization resulted in partial improvements of Sao_2 and of alterations in sleep architecture on the third night at 4559 meters, despite a further increase in central apneas and hypopneas, suggesting that periodic breathing was not the predominant cause of sleep disturbances at high altitude (see Figure 122-3). There seems to be no consistent change in the amount of REM sleep at high altitude, which is variably found to be either unchanged (field study),[13,33,58] increased (field study),[59,60] or decreased (hypobaric chamber or field studies).[16,20,22] The inconsistencies of the effect of altitude on REM sleep among these studies are likely related to differences in settings (hypobaric chamber vs. field studies), rate of ascent, and degree of physical exertion (being transported vs. climbing) and sleeping altitude. There is a disparity between subjective evaluation of sleep quality and the objective findings of normal sleep duration. After few nights at high altitude, there is improvement in total sleep time and sleep architecture; however, the subjects continue to complain about sleeplessness. This is most likely due to sleep fragmentation at altitude despite normal cumulative sleep duration that produces the impression of sleeplessness in that setting.[13,61-63]

In summary, on the first two nights following ascent to altitude, sleep is typically of near-normal duration or of decreased duration, with increases in NREM sleep stages N1 and N2 ("light" sleep) and decreases in stage N3 ("deep" sleep). Sleep quality improves after the third night at the same altitude, with increased slow wave sleep and REM sleep. Periodic breathing is present in a substantial proportion of sleep, with frequent arousals and disruption of sleep continuity. Of note, sleep architecture improves over two to three nights at the same altitude but periodic breathing persists, suggesting that periodic breathing is not the predominant cause of sleep disturbances at high altitude.

HIGH-ALTITUDE ILLNESSES

Sleep Apnea in High Altitude

The respiratory pauses and hypopneas in sleep at high altitude are mainly of central origin, unassociated with snoring or other evidence of sleep-related upper airway obstruction, and accompanied by decreased rib cage and abdominal activity.[9,11,33,34,64] One study of subjects with moderate obstructive sleep apnea with AHI of 26/hour at low altitude (60 meters, 197 ft) showed, in fact, that at a simulated altitude of 2750 meters (9022 ft) obstructive events were entirely replaced by central apneas. The authors believed that the obstructive sleep apneas resolved because of an increased respiratory rate and an increase in upper airway tone, whereas central sleep apneas developed because of hypocapnia.[65] However, in a study of patients with moderate to severe obstructive sleep apnea using a randomized crossover design, it was shown that a moderate altitude exposure (up to 2590 meters, 8497 ft) in these untreated patients aggravated hypoxemia and increased the frequency of central apneas and hypopneas, but obstructive apneas persisted.[66] The transformation of obstructive sleep apneas to central type at high altitude in some studies likely reflects an increase in hypoxic ventilatory drive, which may augment the activity of muscles of the upper airway.[67] Conversely, sleep studies of subjects living at moderate altitude (above 2400 meters, 7874 ft) that were conducted at a lower altitude (1370 meters, 4495 ft) in comparison to the altitude of residence, show that at the lower altitude the AHI was reduced. This was likely largely due to a decrease in central events; there was no change in frequency of obstructive apneas, although the latter were more prolonged at a low altitude.[68]

Acute Mountain Sickness and High-Altitude Pulmonary Edema

Rapid altitude ascent is often associated with two well-recognized clinical syndromes of acute altitude maladaptation: (1) AMS manifested by headache, loss of appetite, nausea, vomiting, decreased mental acuity, and insomnia; and (2) high-altitude pulmonary edema (HAPE). The pathophysiology of HAPE is related to acute exposure to high-altitude hypoxia with increased pulmonary artery pressure and increased pulmonary capillary permeability and resultant leakage of plasma proteins and red blood cells into the alveolar air space. Although these are most common in the early post-ascent period when sleep disturbance and respiratory periodicity are also most pronounced, most studies find that the characteristic periodic breathing in sleep is not correlated with the development or severity of these syndromes. Indeed, in subjects with pronounced AMS and HAPE, periodic breathing tends to be replaced by an irregular, nonperiodic pattern.[17,34] However, in one study, periodic breathing was found to be more frequent in those with HAPE than in those with AMS or in control subjects.[69] This suggests that HAPE may be associated with periodic breathing through stimulation of intrapulmonary afferents.[45] In naturally sleeping dogs, increasing pulmonary capillary pressure by inflating a balloon placed in the left atrium resulted in periodic breathing. AMS, conversely, is more closely associated with hypoxemia rather than periodic breathing during sleep, as suggested by a study in trekkers that found a trend toward an association between sleep hypoxemia and severity of AMS.[70] However, the role of sleep-disordered breathing in the symptoms of AMS is questioned by a study of high-altitude expedition members, which found that headache, a common feature of AMS, occurred only 26% of the time in association with sleep or awakening from sleep.[71]

There is evidence for cognitive decline at high altitude in nonacclimatized climbers, as a facet of AMS, which most likely reflects in part the central nervous system effects of hypoxemia compounded by the cerebral vasoconstrictor effects of hypocapnia and sleep fragmentation.[72,73] However, in acclimatized climbers there seems to be no evidence for significant cognitive impairment even at extreme altitudes of 7500 meters (24,606 ft).[74]

SLEEP AT HIGH ALTITUDE AFTER LONG-TERM ADAPTATION

In the Andes, South America, at an altitude of 4330 meters (14,206 ft) healthy natives have sleep duration and distribution of stages comparable to those of subjects at lower altitude.[75] However, these native highlanders have periodic breathing with cyclical oxygen desaturation and elevated hematocrit.[76] Similar observations have been made in Sherpas native to high altitude but not in Sherpas native to low altitude.[64] It is possible that Sao_2 induced by high altitude shifts Sao_2 during sleep to the steeper portion of the dissociation curve and thereby amplifies the influence of ventilatory dysrhythmia on Sao_2. The potential contribution of ethnic or genetic differences is suggested by a study comparing Tibetan and Chinese Han residents of 4000 meters (13,123 ft). Sleep was studied in a hypobaric chamber at simulated altitudes of 2261 (7418 ft) and 5000 meters (16,404 ft). At the higher altitude, Tibetans had more periodic breathing, higher Sao_2, and better sleep structure than did the Han subjects.[77]

Natives and long-term residents of high altitude exhibit chronic mountain sickness or Monge disease, a syndrome of severe polycythemia with headache, dizziness, breathlessness, and sleep disturbance. The pathophysiology of the syndrome is debated, but it likely is induced by increased hypoxemia reflecting the combined effects of altitude, decreased ventilatory drive, and lung dysfunction. Compared with normal subjects, individuals with chronic mountain sickness exhibit exaggerated hypoxemia during sleep without an increase in respiratory disturbance index.[78-80] These subjects also exhibit greater daytime hypoxemia, and thus the role of sleep-associated desaturation remains uncertain.

The adverse effects of high-altitude exposure on physiologic systems are complex but primarily involve the central nervous system and cardiopulmonary regulation. The rate of ascent and hence the degree of hypoxia exposure is the main determinant for the development of AMS, sleep disturbances, periodic breathing, and the risk for HAPE. Acclimatization to high altitude does not completely return the physiologic functions to sea level or low altitudes, even in long-term high-altitude dwellers. With acclimatization AMS and sleep architecture improve but periodic breathing persists with minimal effects on sleep continuity.

PREVENTION AND TREATMENT OF HIGH-ALTITUDE ILLNESSES

The prophylaxis and treatment of sleep abnormalities at high altitude and AMS are similar. Staged, gradual ascent to high altitude is an effective way to blunt sleep-related symptoms and to prevent AMS, but this may be inconvenient or not possible, as in flying to high-altitude research facilities. Pharmacologic approaches include carbonic anhydrase inhibitors and hypnotic agents. Noninvasive positive pressure ventilation or dead space breathing masks have also been evaluated as a possible treatment.[81]

Sleep Disturbances

Acetazolamide, a carbonic anhydrase inhibitor, is the best-studied agent used for amelioration of sleep disturbance at high altitude; it has the advantage of also reducing symptoms of AMS.[82-85] Acetazolamide improves both the mean level and the stability of arterial oxygenation during sleep at high altitude and markedly reduces the proportion of sleep time during which periodic breathing occurs.[14,86,87] Acetazolamide is a respiratory stimulant that causes metabolic acidosis and hyperventilation by increasing renal excretion of bicarbonate.[39] These changes mimic the natural process of acclimatization. An effective prophylactic dose of acetazolamide is 125 mg twice daily to be taken a day before ascent and continued for 2 days after the highest sleeping altitude.

Several studies suggest the safety and potential utility of benzodiazepines for the treatment of sleep disturbance of high altitude.[88-90] Temazepam shortened sleep latency, decreased arousals, increased sleep efficiency, and increased REM sleep, with subjectively better quality sleep in climbers sleeping above 4000 meters (13,123 ft).[89,90] The nonbenzodiazepine sedative agents zolpidem and zaleplon have each been found to be effective in improving sleep architecture and

consolidation at high altitude. A study of these agents at a simulated altitude of 4000 meters (13,123 ft) and another in trekkers at 3613 meters (11,854 ft) showed that, compared with placebo, both agents increased sleep efficiency and decreased wakefulness and that zolpidem increased slow wave sleep. Neither drug, however, had an effect on nocturnal respiratory pattern or Sao_2 nor significantly affected daytime cognitive or physical performance.[91,92]

Periodic Breathing

Acetazolamide improves both the mean level and the stability of arterial oxygenation during sleep at high altitude and markedly reduces the proportion of sleep time during which periodic breathing occurs.[14,86,87] The beneficial effect of acetazolamide on periodic breathing is seen in both men and women but is more pronounced in men.[55] Acetazolamide is a respiratory stimulant that causes metabolic acidosis and hyperventilation by increasing renal excretion of bicarbonate.[39] These changes mimic the natural process of acclimatization. An effective prophylactic dose of acetazolamide is 125 mg twice daily to be taken a day before ascent and continued throughout the ascent and for 2 additional days after the highest sleeping altitude. As mentioned previously benzodiazepines at low doses (temazepam 7.5 mg or 10 mg) improve sleep but have neither beneficial nor adverse effects on breathing at high altitude.

Oxygen supplementation improves periodic breathing by widening the Pco_2 reserve as mentioned earlier. However, the issues with logistics of using oxygen at high altitude preclude its routine use except for the treatment of HAPE and high-altitude cerebral edema. Promising effects of other modalities to improve high-altitude periodic breathing, including noninvasive ventilation and increasing dead space breathing, remain to be further investigated in humans.

CONCLUSIONS

Ascent to high altitude is characterized by frequent awakenings from sleep, which in part reflects sleep fragmentation by respiratory dysrhythmia typically consisting of periodic breathing. Such periodic breathing, an abnormal ventilatory pattern in which central apneas and hypopneas alternate with periods of hyperventilation, is induced by hypoxic stimulation of the peripheral chemoreceptors at high altitude, coupled with enhanced CO_2 chemosensitivity, which facilitates the development of central apneas when $Paco_2$ falls below the eupneic threshold.

Sleep disruption, although not its associated periodic breathing, decreases with time (acclimatization) at moderate altitude but not high altitude. Therapies that have been shown to improve the periodic breathing of high altitude and its associated sleep disruption and clinical syndrome of AMS include pretreatment with acetazolamide, an inhibitor of carbonic anhydrase, which induces metabolic acidosis and widens the Pco_2 reserve, opposing the effects of hypoxia on the peripheral chemoreceptors. Benzodiazepines and other hypnotic agents may improve sleep quality without apparent beneficial or adverse effects on breathing in sleep.[93] Positive airway pressure and increased dead space breathing each also have been used to improve altitude-associated periodic breathing.

CLINICAL PEARLS

- Sleep at high altitude is initially disturbed by the hypoxic stimulation of the peripheral chemoreceptors, resulting in widening of the Pco_2 reserve and proximity of the prevailing Pco_2 to the apneic threshold. This leads to periodic breathing, central apneas, hypopneas, and frequent arousals.
- During acclimatization, sleep architecture improves but periodic breathing persists.
- Effective treatments include acetazolamide, increasing dead space, or blunting of hypoxic stimulation with certain benzodiazepines.

SUMMARY

Exposure to high altitude imposes significant strain on the cardiopulmonary system, including central ventilatory control. As a consequence, sojourners to high altitude frequently experience sleep disturbances, often reporting restless and sleepless nights. Others describe a feeling of suffocation or shortness of breath on awakening from sleep. Objective observations show that sleep stages are generally shifted from deeper toward lighter sleep, along with a characteristic waxing and waning breathing pattern known as periodic breathing that accompanies sleep at high altitude. Such periodicity typically consists of two to four breaths, separated by a central apnea from the next burst of two to four breaths.

The principal reason for apnea and periodic breathing during sleep in hypoxic environments is believed to be elevations in controller or feedback gain, as evidenced by the steep increase in the ventilatory-CO_2 response slope above and below eupnea. Periodic breathing at altitude seems to reflect the respiratory dilemma of acute altitude ascent in which the stimulatory effects of hypoxia are opposed by the inhibitory action of hypocapnic alkalosis. The outcome is respiratory oscillation. With an apnea, Pco_2 rises; this in turn lessens alkalotic inhibition and augments hypoxic stimulation. This triggers hyperpnea, which lessens respiratory stimulation by decreasing hypoxia and increasing alkalosis, leading to recurrent apnea. The occurrence of altitude related apnea with lessening of ventilatory stimuli is enhanced during sleep.

On balance, the poor subjective quality of sleep seems to reflect the fragmentation of sleep by frequent arousals linked to the marked changes in respiratory pattern of periodic breathing. Arousals commonly occur at the transition from the end of apnea to the onset of hyperpnea. Subsequent acclimatization to altitude is associated with lessening of periodic breathing and better-quality sleep.

The most common treatment for periodic breathing of high altitude and its associated syndrome of AMS is prophylactic administration of acetazolamide, an inhibitor of carbonic anhydrase, which likely works by increasing Pco_2 reserve below eupnea. The results of recent studies suggest that benzodiazepines and other sleep-promoting agents may improve sleep quality without apparent beneficial or adverse effects on breathing.

Cardiovascular Disorders

Chapter 123

Sleep and Cardiovascular Disease: Present and Future

Shahrokh Javaheri; Luciano F. Drager; Geraldo Lorenzi-Filho

Chapter Highlights

- Cardiocerebrovascular disorders, including systemic hypertension, coronary artery disease, congestive heart failure, stroke, and transient ischemic attacks, are prevalent and associated with excess morbidity and mortality as well as huge economic costs.
- One of the most significant developments in the field has been the recognition that sleep disorders such as sleep apnea are extremely common among patients with established cardiovascular disease and when present could contribute to a worsening outcome.
- Importantly, sleep disorders are also a potential cause of various cardiovascular diseases. This bidirectional relationship is well established for congestive heart failure and stroke, which can cause sleep disorders such as insomnia and sleep apnea (Figure 123-1). This chapter provides an overview of this section consisting of several chapters of sleep and cardiovascular diseases.

CARDIOVASCULAR DISEASE

Cardiovascular disorders have a high prevalence and are associated with excessive morbidity and mortality and huge economic costs (Table 123-1).[1] Each year, the American Heart Association, in conjunction with the Centers for Disease Control and Prevention, the National Institutes of Health, and other government agencies, updates statistics on the morbidity and mortality of cardiovascular disease. According to the 2014 update,[1] approximately 85 million people—35% of the U.S. population—have some form of cardiovascular disease.

Hypertension alone, a disorder proved to be caused by obstructive sleep apnea (OSA; see Chapter 127), affects 78 million Americans. Many of these patients are erroneously diagnosed as having essential hypertension because of the underdiagnosis of OSA. Congestive heart failure (see Chapter 129) and stroke (see Chapter 93), disorders frequently associated with both central and OSA, are also highly prevalent, each affecting approximately 5.1 to 6.8 million Americans (see Table 123-1).

According to the 2014 update, the actual number of cardiovascular disease deaths per year declined by 16.7%, but cardiovascular diseases still accounted for about 32% or 1 of every 3 deaths in the United States. On the basis of 2010 death rate data, more than 2150 Americans die of cardiovascular disease each day, an average of 1 death every 40 seconds. In fact, since 1900, cardiovascular disease has been the number

Table 123-1 Prevalence, Mortality, and Economic Burden of Cardiovascular and Cerebrovascular Disorders in the United States*

Population Group	Prevalence 2010	Mortality 2010	Hospital Discharges 2010	Cost 2012 (Billion Dollars)
Total	84 million (35% of all adults)	787,650 (32% of all deaths)	5.8 million	315
Women	43 million (34%)	502,200 (54%)	4 million	—
Men	41 million (37%)	390,600 (46%)	3 million	—
Age ≥60 yr	42 million	—	—	—
Hypertension	78 million(33% of Americans)	63,119	488,000	46

one killer every year except 1918. In 2010, the total direct and indirect cost of cardiovascular disease and stroke in the United States was estimated to be $315.4 billion.[1]

Since sleep apnea was recognized as a common medical disorder after the widespread use of full polysomnography, the association of sleep apnea, both obstructive and central, with cardiocerebrovascular disorders is well recognized (see Figure 123-1, Box 123-1, and Video 123-1).[2-7]

SLEEP APNEA

The explosion of basic science and physiologic studies in both experimental animals and humans, as well as epidemiologic and clinical studies, supports the bidirectional linking of sleep apnea to a variety of cardiovascular disorders (see Figure 123-1 and Box 123-1; also see Chapters 127 and 129).[2-7] Although much more research needs to be done in this area, it is interesting to note that cor pulmonale was recognized as a feature of pickwickian syndrome before it became known that the underlying pathologic process of cor pulmonale is a sleep disorder.

There is now evidence that OSA is extremely common among patients with established cardiocerebrovascular and metabolic disease. For instance, among patients with hypertension, coronary artery disease, atrial fibrillation, type 2 diabetes, and metabolic syndrome, the prevalence of OSA ranges from 30% to 87%.[8-12] Moreover, the more severe the underlying cardiovascular disease, the higher the prevalence of OSA. On the other hand, there is also evidence that OSA is largely underdiagnosed and undertreated.[13,14] In addition to the low awareness of the medical community, there is also evidence that the typical symptoms associated with OSA observed in patients referred to the sleep specialist, such as excessive daytime sleepiness, are frequently not present among patients with established cardiocerebrovascular disease.[15]

OSA is associated with a number of biochemical and cellular abnormalities. Obstructive apneas result in neurohormonal activation, release of inflammatory mediators such as

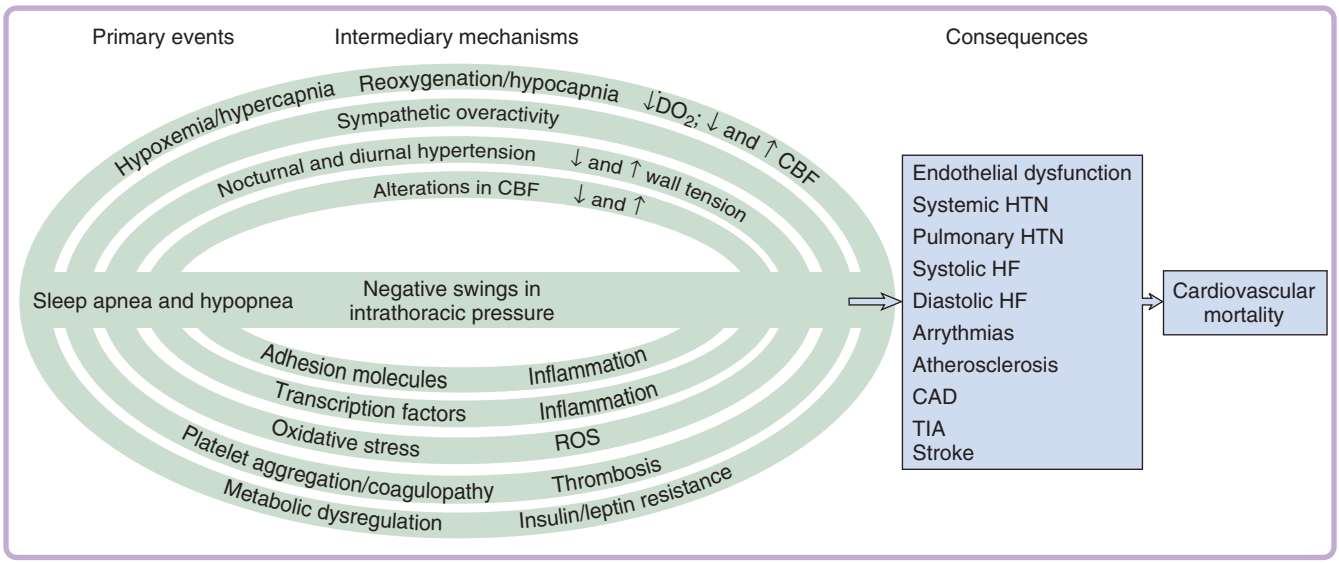

Figure 123-2 The mechanisms by which sleep apnea may result in endothelial dysfunction and cerebrovascular and cardiovascular disorders. CAD, Coronary artery disease; CBF, coronary/cerebral blood flow; $\dot{D}o_2$, oxygen delivery; HF, heart failure; HTN, hypertension; ROS, reactive oxygen species; TIA, transient ischemic attacks; ↑, increase; ↓, decrease. (From McNicholas WT, Javaheri S. Pathophysiological mechanisms of cardiovascular disease in obstructive sleep apnea. *Clin Sleep Med* 2007;2[4]:539–47.)

cytokines, and increased expression of adhesion molecules, resulting in attachment of white blood cells to endothelial cells and their transmigration, as well as oxidative stress. Through increased production of reactive oxygen species,[16] a number of transcription factors are activated, increasing the expression of redox-sensitive genes and resulting in the production of vasoactive and inflammatory proteins. These reactions underlie the pathologic processes involved in endothelial dysfunction syndrome, the underlying pathophysiologic mechanism for atherosclerosis, hypertension, stroke, heart failure, and coronary artery disease (Figure 123-2).[15]

Because of the aforementioned abnormalities, and along with cyclic changes in blood pressure resulting in wall stress, changes in coronary and cerebral blood flow, and diminished oxygen delivery, OSA could play a causative role or contribute to the development of atherosclerosis (see Figure 123-2).[17] In this context, treatment of OSA with nasal continuous positive airway pressure (CPAP) results in reversal of a number of biochemical abnormalities and attenuates surrogate markers of atherosclerosis.[18,19] Furthermore, a number of studies also demonstrate that the treatment of OSA with CPAP results in a reduction in systemic and pulmonary hypertension (see Chapter 127).[4,20,21] Systemic hypertension is the best studied relationship between OSA and cardiovascular disease. Several studies showed that the treatment of OSA with CPAP, even for short periods, is associated with a significant drop in blood pressure. The most beneficial therapeutic effects are observed in patients with severe OSA who are compliant with CPAP[20,21] as well as in patients with resistant hypertension[22-25] (see Chapter 127). Although the fall in blood pressure is frequently small, it has been shown that even small reductions in blood pressure over the long term significantly decrease the incidence of cerebrovascular and cardiovascular diseases.[26] For instance, in prospective studies of 420,000 patients with a mean follow-up of 10 years, drops in diastolic blood pressure of 5, 7.5, and 10 mm Hg were associated with, respectively, at least 34%, 46%, and 56% fewer strokes and at least 21%, 29%, and 37% less coronary heart disease.[26] Therefore, in patients with OSA, even a small drop in blood pressure, which could be maintained with long-term use of CPAP, is clinically, and also from a public health point of view, quite meaningful. Furthermore, treatment of OSA with CPAP may result in additional protection against vascular disorders because OSA may contribute to cardiovascular and cerebrovascular disease by a variety of mechanisms other than hypertension (see Figure 123-2). Regardless of the precise mechanisms, several studies consistently suggest not only that OSA is independently associated with increased cardiovascular mortality but also that the treatment of OSA with CPAP is associated with decreased cardiovascular mortality.[27-30]

METABOLIC SYNDROME

Metabolic syndrome is the clustering of few cardiometabolic risk factors related to abdominal obesity and insulin resistance and not surprisingly a multicomponent risk factor for cardiovascular disease, type 2 diabetes, and also OSA, although the latter is not as well recognized.

With the emergence of metabolic syndrome, a risk factor for incident cerebrovascular and cardiovascular diseases, a new epidemic is evolving.[31-33] Metabolic syndrome goes hand in hand with obesity and is characterized by elevated blood pressure, hyperglycemia, insulin resistance, and hypertriglyceridemia.[34] Metabolic syndrome is a proinflammatory and prothrombotic condition and is associated with increased serum concentrations of high-sensitivity C-reactive protein, fibrinogen, and von Willebrand factor and with increased platelet aggregation. Metabolic syndrome has a high prevalence, affecting one third of all adults.[1,33] Its prevalence increases with age, peaking among those aged 60 to 69 years.[33] Because metabolic syndrome is a precursor of incident cerebrovascular and cardiovascular disorders (relative risk, 1.78; 95% confidence interval, 1.58 to 2.0),[1] its early recognition and targeted therapy have been emphasized by different

medical societies.[34] OSA is also tightly linked to obesity, and OSA itself is associated with a large number of biochemical abnormalities that are markers of metabolic syndrome. As an example, through sympathetic stimulation, OSA contributes to insulin resistance and hypertension. Therefore metabolic syndrome, obesity, and OSA are entangled and are components of a vicious cycle.[15] In concert with the emphasis on early recognition of metabolic syndrome,[33,34] early recognition of OSA as a comorbid condition must be emphasized, particularly because the treatment of OSA with CPAP may reverse some of the abnormalities associated with metabolic syndrome.[35,36] Longitudinal studies should be conducted to determine whether early recognition and treatment of OSA as a companion of metabolic syndrome will prevent incident cerebrovascular and cardiovascular diseases.

SLEEP IN PATIENTS WITH HEART FAILURE

Another major development in the field is the recognition that central sleep apnea (CSA) associated with Hunter-Cheyne-Stokes breathing in patients with congestive heart failure, both with reduced and preserved ejection fraction, is extremely common (see Chapter 129).[37] Interestingly, the discovery of this respiratory pattern of breathing dates back to John Hunter,[38,39] 37 years before John Cheyne's description in 1818. There has been an explosion of physiologic and clinical research studies in this field.[40]

We must emphasize, however, that in addition to CSA, OSA is commonly observed in patients with congestive heart failure,[40,41]

Although some studies have shown that treatment of sleep apnea with CPAP improves mortality in patients with heart failure[42] (see Chapter 129), a major breakthrough in the field has been the advancement in positive airway pressure device algorithms and the development of adaptive servoventilation devices. The most recent generation of devices are equipped with automatic end-expiratory positive airway pressure algorithms that operate to eliminate obstructive disordered breathing events.[43,44] This feature, along with automatic variable inspiratory pressure support and the backup rate, makes these devices very effective for treatment of complex sleep-related breathing disorders.[43,44] As will be reviewed in Chapter 129, a number of studies using servoventilation devices show a reduction in hospital readmission and improved survival in patients with heart failure and sleep apnea. However a recent RCT with ASV showed a negative outcome with treatment.[45] Additionally, a transvenous phrenic stimulator has been developed to treat CSA in heart failure.[45,46] This is quite exciting because the pacemaker is placed intravenously by a cardiologist and primes the phrenic nerve according to a set algorithm to eliminate central apnea during sleep. Adherence should be virtually complete, in contrast to mask therapy with positive airway pressure devices.

IMPACT

The recognition of the association of sleep-related breathing disorders and cardiocerebrovascular diseases is important for several reasons. First, as noted previously (see Table 123-1), these disorders pose a great burden to patients and society. Second, sleep disorders are extremely common among patients with established cardiocerebrovascular disease. Third, recent studies show that treatment of OSA and CSA is associated with improvement in the cardiovascular morbidity, readmission, and probably mortality as well. However, long-term randomized trials that are adequately powered to prove that sleep apnea is a cause of cardiovascular mortality are lacking. Meanwhile, the design of such studies is complicated by a number of factors, such as inclusion and exclusion criteria; for example, should the most severe cases of OSA and excessive daytime sleepiness be excluded because of ethical issues of not treating patients with recognized OSA? This subgroup of patients may be the most compliant with CPAP, and their response to treatment may have the most favorable impact on mortality, the primary end point of the study. Other factors that complicate a long-term randomized clinical trial of OSA include cost, compliance with CPAP (particularly when patients do not feel short-term symptomatic benefit from it), and lack of a perfect placebo for CPAP.

Because of the importance of the relationship between sleep-related breathing disorders (both OSA and CSA) and cardiovascular disorders, this sixth edition devotes a series of chapters to cardiocerebrovascular diseases and sleep. In Chapters 124 and 125, a number of cardiovascular disorders related to sleep but unrelated to sleep apnea are reviewed. The emphasis in Chapter 124 is on nocturnal myocardial ischemia and infarction, and Chapter 125 emphasizes arrhythmias as they relate to changes in autonomic nervous system and sleep stages. The remaining chapters in the section are devoted to OSA and CSA and their relationship to cardiocerebrovascular diseases.

WHERE THE FIELD IS GOING AND WHERE WE ARE

The ability of sleep apnea treatment to reduce cardiovascular morbidity and mortality has not been rigorously demonstrated. Such considerations underscore the importance of well-designed, multicenter, randomized controlled trials (RCTs) to evaluate the impact of sleep apnea treatment on cardiovascular morbidity and mortality. The Spanish Sleep and Breathing Network, started in the mid-1990s, has been very active in conducting clinical trials based on the approach of a central committee that identifies relevant clinical questions, establishes funding streams, and selects participating centers for each project, providing technical support and guidance to researchers and presubmission review of manuscripts. This network has recently concluded an RCT to assess a composite incident cardiovascular disease and hypertension end point in 724 nonsleepy patients with sleep apnea. The Oxford Group reported on the Multicentre Obstructive Sleep Apnoea Interventional Cardiovascular Trial (MOSAIC), which investigated the effects of CPAP on cardiovascular risk score, sleepiness, and quality of life in 391 minimally symptomatic patients.

The largest ongoing RCT, the Sleep Apnea Cardiovascular Endpoints (SAVE) study, has recruited more than 2000 patients with minimally symptomatic OSA and ischemic heart disease or cerebrovascular disease to study the impact of CPAP therapy on combined vascular events and mortality. Reflecting a cautious interest in the area of sleep apnea cardiovascular trials, the U.S. National Institutes of Health have recently funded two planning grants, the Heart Biomarker Evaluation in Apnea Treatment (HeartBEAT) and Best Apnea Interventions in Research (BestAIR), to evaluate

design approaches for a large scale clinical trial of CPAP for cardiovascular risk reduction, including feasibility of recruitment, methods for optimizing adherence, use of control treatments, and use of oxygen as an alternative to CPAP.

There are trials in heart failure and sleep apnea (see also Chapter 129); these include the SERVE-HF study using an adaptive servoventilation device for treatment of sleep-disordered breathing with predominant CSA and the ADVENT-HF trial using a different adaptive servoventilation device for treatment of OSA and CSA in heart failure. The former study was terminated because of negative outcomes with treatment.[47] A third study is using a transvenously placed phrenic nerve pacemaker to treat CSA.[47]

SUMMARY

Cardiocerebrovascular disorders and sleep apnea are common conditions, affecting each other in a bidirectional way. There are many observational studies correlating the impact of both OSA and CSA on cardiocerebrovascular outcomes. Similarly, many studies show that treating sleep apnea with positive airway pressure devices improves the outcome. Most of these studies, except those for systemic hypertension and OSA, have been observational. However, several RCTs are in progress (Table 123-2). Among these are trials using new-generation adaptive servoventilation devices to treat sleep apnea in heart failure.

CLINICAL PEARLS

- Sleep-related breathing disorders are common in patients with cardiovascular disorders and may either play a causative role or contribute to the progression of the cardiovascular pathologic processes. OSA is associated with increased incidence of coronary heart disease, stroke, heart failure, and mortality. Treatment with CPAP improves survival.
- Similarly, CSA and OSA are common in heart failure, with both reduced and preserved ejection fraction. Sleep apnea contributes to excess hospital readmission and premature mortality in patients with heart failure, and effective treatment with CPAP or adaptive servoventilation may increase left ventricular ejection fraction, decrease readmission, and improve survival.

Table 123-2 Ongoing Randomized Controlled Trials Assessing the Effect of Treatment of Obstructive Sleep Apnea on Cardiovascular Outcomes or Intermediate Mechanisms

Acronym	Country	Patient Condition	Intervention	Primary Outcome	Number Enrolled
Cardiovascular Events					
SAVE	Multinational	Stable (>3 mo) cardiovascular or cerebrovascular disease	CPAP vs. conservative treatment	Serious cardiovascular end points or cardiovascular mortality	2500
ISAACC	Spain	Acute coronary artery disease	CPAP vs. conservative treatment	Serious cardiovascular end points or cardiovascular mortality	1864
SERVE-HF*	Multinational	Sleep apnea and congestive heart failure	Adaptive servoventilation vs. conservative treatment	Mortality or hospitalization	1116
ADVENT-HF*	Multinational	Sleep apnea and heart failure	Adaptive servoventilation vs. conservative treatment	Death or hospitalization for a cardiovascular cause	860
RICCADSA	Sweden	Coronary artery disease (with recent percutaneous coronary intervention or coronary artery bypass graft)	CPAP vs. conservative treatment	Serious cardiovascular end points or cardiovascular mortality	510

Table 123-2 Ongoing Randomized Controlled Trials Assessing the Effect of Treatment of Obstructive Sleep Apnea on Cardiovascular Outcomes or Intermediate Mechanisms—cont'd

Acronym	Country	Patient Condition	Intervention	Primary Outcome	Number Enrolled
Intermediate Mechanisms					
BestAIR	USA	Moderate to severe OSA patients with cardiovascular risk factors presenting to a sleep disorders clinic	Active CPAP with RT support vs. active PAP with behavioral modification CPAP vs. conservative medical therapy vs. sham PAP	24-hr systolic blood pressure	150
COMET	USA	OSA and arterial hypertension	CPAP vs. oral appliance	24-hr ambulatory blood pressure monitoring	238
The remedē System Pivotal Trial	Multinational	Central sleep apnea	The remedē System therapy vs. optimal medical management	AHI reduction of 50% in patients with treatment vs. optimal medical management	173
MORPHEOS	Brazil	OSA and uncontrolled hypertension	CPAP vs. nasal strips	Central blood pressure	200
OPTIMAL-HF*	USA	Sleep apnea in chronic heart failure	CPAP vs. ASV vs. nocturnal supplemental oxygen vs. healthy lifestyle and sleep education	Left ventricular ejection fraction	161
OSA and and vasculopathy (no acronym)	China	Men with newly diagnosed severe OSA	CPAP vs. sham CPAP	Vascular reactivity of brachial artery and pulse wave velocity	150
PAC-IC-SAOS	France	OSA in heart failure patients undergoing coronary artery bypass surgery	CPAP vs. sham CPAP	Percentage of ventricular function recovery	69
RAP	France	OSA and resistant hypertension	CPAP vs. CPAP plus physical activity program	Systolic arterial blood pressure assessed by 24-hr home blood pressure monitoring	100
SASS	USA	OSA	CPAP vs. sham CPAP	Oxidative stress	250
Sleep Tight	USA	OSA patients with transient ischemic attack or stroke	Standard CPAP intervention vs. enhanced CPAP intervention vs. usual care	Reduction in five domains of cardiovascular risk markers (inflammatory, autonomic, insulin resistance, endothelial, and atherosclerotic)	255

Chapter 124

Sleep-Related Cardiac Risk

Richard L. Verrier; Murray A. Mittleman

Chapter Highlights

- The brain, in subserving its need for periodic reexcitation during rapid eye movement sleep and dreaming, imposes significant demands on the heart by inducing bursts of sympathetic nerve activity, which reaches levels higher than during wakefulness. In patients with cardiac disease, such neural activity may compromise coronary artery blood flow, as metabolic demand outstrips supply, and may trigger sympathetically mediated life-threatening arrhythmias in response to functional myocardial ischemia.
- An additional challenge is presented by non–rapid eye movement sleep, when hypotension may lead to malperfusion of the heart and brain as a result of a lowered blood pressure gradient through stenosed vessels.
- Impairment of ventilation by sleep-related breathing disorders, including obstructive sleep apnea and central sleep apnea, which afflict millions of Americans, can generate reductions in arterial oxygen saturation and other pathophysiologic sequelae. Obstructive sleep apnea has been strongly implicated in the etiology of hypertension, myocardial ischemia, arrhythmias, myocardial infarction, heart failure, and sudden death in individuals with coexisting ischemic heart disease. Similarly, central sleep apnea has been associated with a variety of atrial and ventricular arrhythmias.
- Atrial fibrillation may be triggered by autonomic or respiratory disturbances during sleep in certain patient populations. Medications that cross the blood-brain barrier may alter sleep structure and provoke nightmares with severe cardiac autonomic discharge.

In healthy individuals, sleep is usually salutary and restorative. Ironically, during sleep in patients with respiratory or heart disease, the brain can precipitate breathing disorders, myocardial ischemia, arrhythmias, and even death. Our observation that 20% of myocardial infarctions (MIs) and 15% of sudden deaths occur during the period from midnight to 6:00 AM projects to an estimated 300,000 nocturnal MIs and 45,000 nocturnal sudden deaths annually in the U.S. population.[1] Thus, sleep is not a fully protected state. Furthermore, the nonuniform distribution of deaths and MIs during the night is consonant with provocation by pathophysiologic triggers. The two main factors implicated in nocturnal cardiac events are sleep state–dependent surges in autonomic activity[2] and depression of respiratory control mechanisms,[3] which affect a vulnerable cardiac substrate. Precise characterization of their interaction in precipitating nocturnal cardiac events is, however, incomplete. Although sudden death during sleep can be presumed to be painless, in many cases it is premature because it occurs in infants and adolescents and in adults with ischemic heart disease, for whom the median age is 69 years. Populations at risk for nocturnal cardiorespiratory events include several large patient groups (Table 124-1). For example, arrhythmias, including paroxysmal atrial fibrillation and nonsustained ventricular tachycardia, during sleep are markedly increased shortly after a sleep-disordered breathing event.[4]

It is an insidious component of the problem of nocturnal risk that many people are unaware of their respiratory or cardiac distress at night and therefore take no corrective action. Thus, sleep presents unique autonomic, hemodynamic, and respiratory challenges to the diseased myocardium that cannot be monitored by daytime diagnostic tests. The importance of nocturnal monitoring of patients with cardiac disease extends beyond identifying sleep state–dependent triggers of cardiac events because nighttime myocardial ischemia, arrhythmias, autonomic activity, and respiratory disturbances carry predictive value for daytime events (Box 124-1).

This chapter discusses the pathophysiologic mechanisms responsible for sleep-related cardiac morbidity and mortality. For a review of mechanisms and treatment of nocturnal arrhythmias, see Chapter 125. Effects of sleep-disordered breathing and apnea on the cardiovascular system are discussed in Chapters 126–129.

AUTONOMIC ACTIVITY AND CIRCULATORY FUNCTION DURING SLEEP

The generalized decrease in mean heart rate and arterial blood pressure at the onset of sleep and throughout non–rapid eye movement (NREM) sleep, which occupies 80% of sleep time, has prompted the assumption that sleep is a period of relative autonomic inactivity. NREM sleep, the initial stage,

Table 124-1 Patient Groups at Potentially Increased Risk for Nocturnal Cardiac Events

Indication (U.S. Patients per Year)	Possible Mechanism
Angina, myocardial infarction (MI), arrhythmias, ischemia, or cardiac arrest at night; 20% of myocardial infarctions (~300,000 cases/yr) and 15% of sudden deaths (~48,750 cases/yr) occur between midnight and 6:00 AM.	The nocturnal pattern suggests a sleep state–dependent autonomic trigger or respiratory distress.
Unstable angina, Prinzmetal angina	Nondemand ischemia and angina peak between midnight and 6:00 AM.
Acute MI (1.5 million)	Disturbances in sleep, respiration, and autonomic balance may be factors in nocturnal arrhythmogenesis. Nocturnal onset of MI is more frequent in older and sicker patients and carries a higher risk for congestive heart failure.
Heart failure (5.3 million)	Sleep-related breathing disorders are pronounced in the setting of heart failure and may contribute to its progression and to mortality risk.
Atrial fibrillation (2.5 million)	Twenty-nine percent of episodes occur between midnight and 6:00 AM. Respiratory and autonomic mechanisms are suspected.
Sleep apnea in patients with coronary disease (5 to 10 million patients with sleep apnea)	Patients with hypertension or atrial or ventricular arrhythmias should be screened for the presence of sleep apnea.
Long QT syndrome	The profound cycle-length changes associated with sleep may trigger pause-dependent torsades de pointes in these patients.
Sudden infant death syndrome (SIDS) (2000-2500 cases or 8% of infant deaths)	SIDS commonly occurs during sleep with characteristic cardiorespiratory symptoms.
Brugada syndrome in Western populations; Asians with warning signs of sudden unexplained nocturnal death syndrome (SUNDS)	SUNDS is a sleep-related phenomenon in which night terrors may play a role. The Brugada syndrome is genetically related to the long QT syndrome.
Patients with epilepsy (2.3 million)	Sudden unexpected death in epilepsy (SUDEP) occurs primarily at night and in patients with a history of nocturnal seizures.
Patients on cardiac medications (13.5 million patients with cardiovascular disease)	Beta blockers and calcium channel blockers that cross the blood-brain barrier may increase nighttime risk because poor sleep and violent dreams may be triggered. Medications that increase the QT interval may conduce to pause-dependent torsades de pointes during the profound cycle-length changes of sleep. Because arterial blood pressure is decreased during NREM sleep, additional lowering by antihypertensive agents may introduce a risk for ischemia and infarction due to lowered coronary perfusion.

is characterized by marked stability of autonomic regulation with a high degree of parasympathetic neural tone and prominent respiratory sinus arrhythmia.[2,5] Baroreceptor gain is high and contributes to the stability of arterial blood pressure and to overall cardiovascular homeostasis.[6] Muscle sympathetic nerve activity is stable, falls with the transition from awake to NREM sleep, and decreases progressively with depth of sleep,[2,7] reaching half the awake value during N3 sleep.[2] Short-lasting increases in muscle sympathetic nerve activity, heart rate, and arterial blood pressure accompany the appearance of high-amplitude K-complexes during N2 sleep.[2,7] Heart rate accelerations may even precede the electroencephalographic arousals of N2 and rapid eye movement (REM) sleep.[8] During transitions from NREM to REM sleep, bursts of vagus nerve activity may result in pauses in heart rhythm and frank asystole. Transitions between REM and NREM sleep elicit posture shifts that are associated with varying degrees of autonomic activation and attendant changes in heart rate and arterial blood pressure.[9] These shifts in body position increase in frequency as individuals age and sleep becomes fragmented.

Autonomic nervous system activity is dramatically altered when REM sleep is initiated (Figure 124-1). REM sleep is marked by profound muscle sympathetic nerve activation, in terms of both frequency and amplitude,[2,6] which attains levels significantly higher than in wakefulness.[2] Sympathetic nerve activity is concentrated in short, irregular periods that are most striking when accompanied by intense eye movements.[2] These bursts trigger intermittent increases in heart rate and arterial blood pressure to levels similar to those in wakefulness, with increased variability.[2,7,8] Significant surges and pauses in heart rate during REM sleep have been described in several species, including humans.[7,8] Cardiac efferent vagal tone and baroreceptor regulation[6] are generally suppressed during REM sleep, and breathing patterns may become highly irregular and may lead, in susceptible individuals, to oxygen desaturation. Thus, while subserving the neurochemical functions of the brain, REM sleep can disrupt cardiorespiratory

Box 124-1 PREDICTIVE VALUE OF NOCTURNAL CARDIORESPIRATORY STATUS

- Because parasympathetic nerve activity is elevated during sleep in healthy individuals, lack of circadian pattern of heart rate variability and baroreflex sensitivity may be readily monitored for increased risk for cardiac events.
- Nondemand nocturnal ischemic episodes may disclose a critical underlying coronary lesion, coronary vasospasm, or transient coronary artery stenosis.
- In elderly subjects, nighttime multifocal ventricular ectopic activity predicts increased mortality from cardiac causes independent of clinically evident cardiac disease.
- Sleep apnea, which may be screened by heart rate variability analysis, conduces to hypertension, left ventricular remodeling, myocardial ischemia, and atrial and ventricular arrhythmias and is a risk factor for lethal daytime cardiac events, including myocardial infarction.
- Hypertensive patients with less than a 10% nocturnal decline in blood pressure (remaining higher than 101/65 mm Hg) are at increased risk for total and cardiovascular mortality and all cardiovascular end points, myocardial ischemia, frequent or complex ventricular arrhythmias, cerebrovascular insult, and increased organ damage, including left ventricular hypertrophy.
- Elevated nocturnal heart rates are associated with increased cardiac mortality.

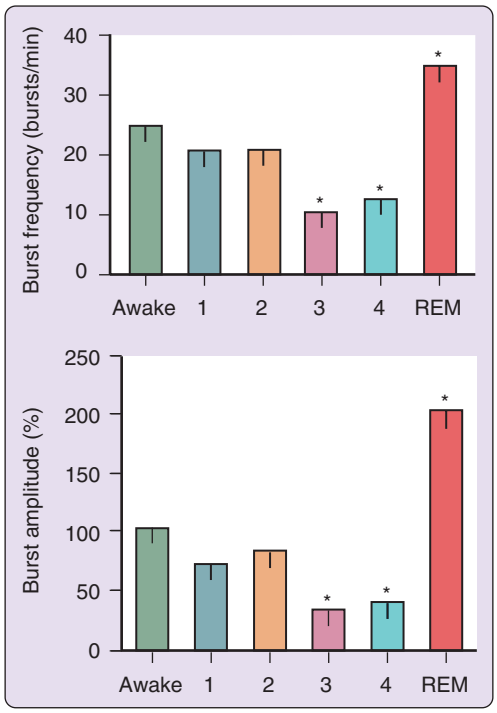

Figure 124-1 Sympathetic nerve burst frequency and amplitude during wakefulness, NREM sleep (eight subjects), and REM sleep (six subjects). Sympathetic nerve activity was significantly lower during stages 3 and 4 ($P < .001$). During REM sleep, sympathetic nerve activity increased significantly ($P < .001$). Values are means ± standard error of the mean. (From Somers VK, Dyken ME, Mark AL, et al. Sympathetic nerve activity during sleep in normal subjects. *N Engl J Med* 1993;328:303–7, with permission from the Massachusetts Medical Society. All rights reserved.)

homeostasis. The brain's increased excitability during REM sleep can also trigger major surges in sympathetic nerve activity to the skeletal muscular beds, accompanied by muscular twitching,[2] which interrupts the generalized skeletal atonia of REM.[9] The peripheral autonomic status characterized by muscle sympathetic nerve recording is compatible with reduced neuronal activity in the brainstem and other regions of the brain and reduced cerebral blood flow during NREM sleep and, during REM sleep, with increased brain activity in several discrete regions to levels higher than waking values.[10]

The decline in autonomic activity during sleep is also evident in peroneal muscle sympathetic nerve activity[2,7] and peripheral levels of epinephrine and norepinephrine and mirrors the generalized sleep-induced decline in heart rate and arterial blood pressure.[11] A nocturnal nadir in plasma catecholamines is evident 1 hour after sleep onset. Plasma cortisol is also depressed during sleep; increased levels are initiated at 5:00 AM.

In the absence of readily achieved, direct measures of cardiac-bound nerve activity, analysis of heart rate variability (HRV) has emerged as a widely accepted method for measuring cardiac sympathetic versus parasympathetic neural dominance. High-frequency (HF) HRV is a general indicator of cardiac parasympathetic tone and includes the effects of respiration. The low- to high-frequency (LF/HF) ratio is widely accepted as an approximation of cardiac-bound sympathetic nerve activity, as validated by studies involving β-adrenergic receptor blocking agents. Decreased HRV, indicating a decline in parasympathetic nerve activity, is an established indicator of risk for sudden cardiac death after MI. HRV analysis reveals a generalized increase in vagus nerve activity and a decrease in cardiac sympathetic nerve activity across the sleep period,[12,13] probably reflecting the dominance of total sleep time by NREM sleep. HRV studies using 5-minute intervals provide results consistent with muscle nerve recording, indicating increased HF and decreased LF (or parasympathetic nerve dominance) in NREM sleep but decreased HF and increased LF (or predominant sympathetic nerve activity) in REM sleep and during wakefulness.[8] In healthy individuals, the increase in HRV measures of cardiac sympathetic nerve activity at onset of REM sleep is initiated before[8,13] the transition from NREM sleep as classically defined from the polysomnographic record.

The typical circadian pattern of decreased nocturnal cardiac sympathetic nerve activity as described by heart rate[14] and HRV studies is altered in patients with coronary artery disease,[15,16] MI,[12,17] and diabetes,[18] suggesting either increased nocturnal cardiac sympathetic nerve activity or decreased parasympathetic nerve activity compared with healthy subjects. The HF component has been observed to decrease approximately 10 minutes before onset of nocturnal myocardial ischemia.[16] In unmedicated patients with a recent MI, the LF/HF ratio was significantly increased during both REM and NREM sleep, in contrast to healthy subjects, in whom this ratio during REM sleep is similar to awake levels and higher than during NREM sleep (Figure 124-2).[12] The conclusions were reached that MI decreases the capacity of the vagus nerve to be activated during sleep, resulting in unbridled cardiac sympathetic nerve activity,[12] and that loss of rise in the HF component is characteristic of patients after an MI and with residual myocardial ischemia.[17]

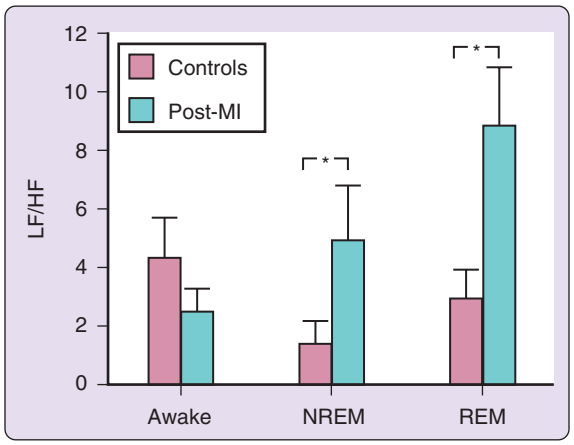

Figure 124-2 Bar graphs indicating low- to high-frequency (LF/HF) ratio of heart rate variability during the awake state (*left*), during NREM sleep (*middle*), and during REM sleep (*right*) in healthy subjects and in post-myocardial infarction (MI) patients ($P < .01$ when comparing control subjects and post-MI patients). Values are means ± standard error of the mean. (From Vanoli E, Adamson PB, Ba-Lin, et al. Heart rate variability during specific sleep stages: a comparison of healthy subjects with patients after myocardial infarction. *Circulation* 1995;91:1918–22, with permission from the American Heart Association.)

These sleep state–dependent profiles of autonomic activity have significant potential to affect coronary function and cardiac electrical stability in patients with ischemic heart disease.

NOCTURNAL CARDIOVASCULAR EVENTS

Nocturnal Myocardial Ischemia and Angina

Accurate assessment and treatment of nocturnal angina has been a subject of concern for more than two centuries. Heberden in 1768 described angina that "will often oblige [the patients] to rise up out of their bed every night for many months altogether." John Hunter, the well-known eighteenth-century surgeon, reported chest pains that "seized him in his sleep so as to awaken him."[19] As early as 1923, MacWilliam[20] postulated that the mechanisms of nocturnal ventricular fibrillation and angina were stimulation of sympathetic nerves and increased arterial blood pressure. He described "reflex excitations, dreams, nightmares, etc., sometimes accompanied by extensive rises of arterial blood pressure (hitherto not recognized), increased heart action, changes in respiration, and various reflex effects" and noted "the suddenness of development of the functional disturbances in arterial blood pressure, heart action, etc., in the dreaming state." He documented greater stress on the circulatory system during dreaming than during wakefulness, with arterial blood pressures reaching 200 mm Hg. In the middle of the twentieth century, the renowned cardiologists Paul Dudley White and Samuel Levine remarked on the frequency of MI and angina in sleep and suggested an association with dreams.

Ischemic activity is an important prognostic marker in patients with cardiac disease, and characteristics of both REM and NREM sleep may conduce to nocturnal myocardial ischemia and angina. The few studies in patients with cardiac disease that have used sleep staging have concluded that in the absence of significant depression of left ventricular function, nocturnal ischemic events occur primarily during REM sleep,[21,22] which is characterized by increased sympathetic nerve activity, metabolic demands, and heart rate surges. In patients with stable coronary artery disease, myocardial ischemia is largely attributable to bouts of sympathetically mediated surges in heart rate and resultant metabolic demands in flow-limited, stenotic coronary arteries.[4,16,22-26] Nowlin and coworkers[22] attributed nocturnal angina to heightened blood pressure after performing detailed, multisession polysomnographic analysis of four patients with advanced coronary artery disease and nocturnal angina pectoris. They established that attacks of nocturnal angina occurred predominantly during REM sleep (32 of 39 recordings) and were associated with heart rate acceleration. Dream content, in patients who could describe it, included awareness of chest pain and involved strenuous physical activity or emotions of fear, anger, or frustration.

Nocturnal myocardial ischemia may be generated by mechanisms in addition to sympathetic nerve activity and unsatisfied metabolic demands. This possibility is suggested by the finding that nighttime ischemic events remain, although they are less frequent, in patients receiving β-adrenergic receptor blockade therapy, the primary therapy that effectively reduces the overall incidence of and suppresses the morning peak in cardiac events by containing sympathetic nerve activity and demand-related myocardial ischemia.[26,27] The main factors that may contribute to nondemand-related myocardial ischemia during NREM sleep are decreased coronary perfusion pressure as the result of hypotension[4,22-29] and increased coronary vasomotor tone.[28] These influences decrease the metabolic threshold for induction of nocturnal myocardial ischemia, which has a nadir between 1:00 and 3:00 AM.[23,28,30] During these hours in patients with stable coronary disease, Benhorin and colleagues[28] observed that myocardial ischemia can be provoked at heart rates of 83 beats/minute, in contrast to 96 beats/minute during midday, and that its incidence was not affected by β-adrenergic receptor blockade. Patel and colleagues[27] noted that nocturnal myocardial ischemia is attended by heart rate elevations of 6 beats/minute or less in patients with unstable angina receiving β-adrenergic receptor blocking agents. Mancia[5] hypothesized that the hypotension of NREM sleep is a major contributor to nocturnal myocardial ischemia and MI because it "reduces the volume and velocity of blood flow, favoring the development of thrombi and embolic and ischemic phenomena before and after arousal." It has also been postulated that myocardial ischemia provoked by transient thrombus formation[31] is attributable to the nocturnal nadir in endogenous fibrinolytic activity[31] as well as to peaks in serum levels of plasminogen activator inhibitor[31] and tissue plasminogen activator antigen, increasing blood viscosity or hypercoagulability at night, and free-radical generation.

Nondemand nocturnal myocardial ischemia is prevalent among patients with more severe coronary disease,[26,30,32] acute coronary syndromes,[17] or diabetes, populations with significant endothelial dysfunction. Indeed, it has been concluded that nondemand nocturnal ischemic episodes disclose a critical underlying coronary lesion, coronary vasospasm, or transient coronary artery stenosis.[27] Patel and colleagues[27] documented a nocturnal peak in ischemic events in their study of 256 hospitalized patients with the acute coronary syndromes of unstable angina and non–Q-wave MI (Figure 124-3). Electrocardiograms were recorded within hours after patients' admission for chest pain to the coronary care unit for

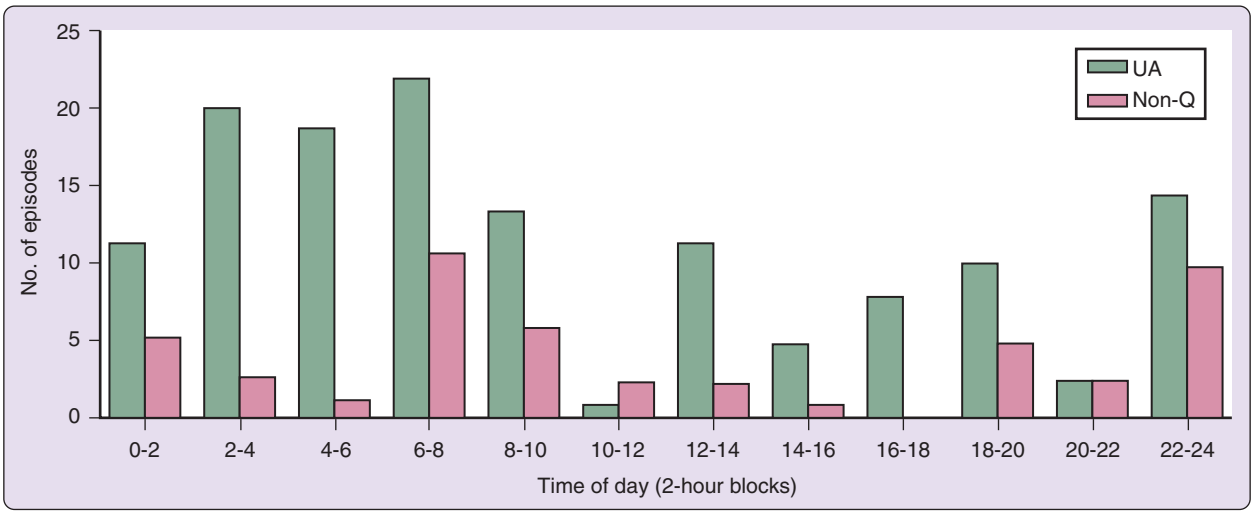

Figure 124-3 The circadian variation of ischemic activity based on 2-hour time blocks for the in-hospital study population. There is a single peak of ischemic activity at night between 10:00 PM and 8:00 AM, and no morning peak in ischemic activity is apparent. More than 64% of episodes occurred during this period ($P < .001$ compared with daytime). The circadian distribution of ischemic episodes in unstable angina (UA) and non–Q-wave myocardial infarction (Non-Q) is similar to the overall pattern of ischemic activity. (From Patel DJ, Knight CJ, Holdright DR, et al. Pathophysiology of transient myocardial ischemia in acute coronary syndromes: characterization by continuous ST-segment monitoring. *Circulation* 1997;95:1185–92, with permission from the American Heart Association.)

new-onset angina, sudden acceleration of previously stable angina, or angina within 1 month of MI. In the hospital, they received optimal medical therapy aimed at containing demand-related myocardial ischemia. It is important to note, however, that the peak in out-of-hospital onset of the syndromes followed the usual circadian pattern, as reported by Cannon and coworkers[33] in the Thrombosis in Myocardial Infarction (TIMI) III Study of 3318 patients. By contrast, in patients with longstanding diabetes or with documented autonomic nervous system dysfunction, there is no nocturnal decrease in myocardial ischemia or onset of acute MI.

Demand-related ischemic episodes can be effectively contained by β-adrenergic receptor blockade,[27] but antihypertensive treatment does not reduce the nocturnal incidence of nondemand-related myocardial ischemia.[34] The use of vasodilators to treat nondemand episodes resulting from endothelial dysfunction is the subject of debate. The lack of sleep staging and arterial blood pressure monitoring in patients with nocturnal myocardial ischemia leaves unidentified any contribution by autonomic and hemodynamic activity dictated by sleep states. Such monitoring would also disclose the prevalence of the established proischemic influences of nocturnal arousal and rising from bed.[15,35]

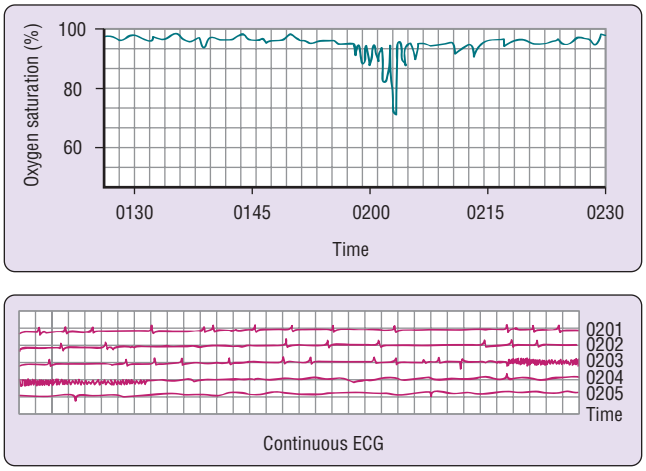

Figure 124-4 Importance of monitoring nocturnal oxygen saturation in patients who have sustained a myocardial infarction. Nonsustained ventricular tachycardia (*bottom*) and hypoxemia measured by pulse oximetry (*top*) occurred simultaneously in a patient on the third night after infarction. The patient died on the following day of cardiogenic shock. ECG, electrocardiogram. (From Galatius-Jensen S, Hansen J, Rasmussen V, et al. Nocturnal hypoxemia after myocardial infarction: association with nocturnal myocardial ischaemia and arrhythmias. *Br Heart J* 1994;72:23–30, with permission from the British Cardiac Society.)

Post–Myocardial Infarction Patients

During the first weeks after MI, sleep is significantly disturbed,[29,36] and nocturnal oxygen desaturation, especially in patients with impaired left ventricular function, may be generalized or episodic and may directly provoke tachycardia, ventricular premature beats, and ST-segment changes (Figure 124-4).[36-39] Both the duration and number of nighttime ischemic events are increased, consonant with increased cardiac sympathetic nerve activity[27,40] or decreased parasympathetic nerve activity (see Figure 124-2),[12] particularly in patients with residual myocardial ischemia.[17] Nocturnal levels of norepinephrine are increased, and nocturnal secretion of melatonin, an endogenous hormone that suppresses sympathetic nerve activity, is impaired.[41] These symptoms become normal over time so that within the first 6 months, ventricular tachycardia during sleep is relatively rare. Improved cardiac function early after MI is associated with decreased sleep apnea.[42]

The most detailed study to date of sleep in post-MI patients was performed in 1978 by Broughton and Baron,[29] who

reported on the sleep and cardiovascular condition of 12 patients, aged 33 to 70 years, after severe MI, first during their stay in the intensive care unit and then in the hospital ward. They noted a "marked disturbance of nocturnal sleep patterns … characterized by high amounts of wakefulness, stage 1, and number of awakenings, and REM density and low amounts of REM sleep, shorter REM periods with prolonged REM latencies. Sleep efficiency was substantially reduced."[29] All of these sleep-quality parameters improved in parallel with time after MI until on day 9 the only remaining abnormal feature was a high content of NREM N3 sleep. REM density peaked on post-MI nights 3 and 4 and NREM sleep on night 4. On subsequent hospital visits after discharge, the patients described terrifying dreams, suggesting that REM suppression was followed by REM rebound more than 2 weeks after the crisis. Importantly, Broughton and Baron observed that NREM sleep provoked nocturnal angina and awakening. They postulated that the hypotension associated with NREM sleep resulted in a diminution in perfusion pressure of the major coronary and collateral vessels supplying the mechanically compromised myocardium. The decreased heart rates typical of NREM sleep, however, were not observed, and heart rates were higher in NREM sleep than in wakefulness on half the nights recorded, indicating enhanced cardiac sympathetic nerve activity even in NREM sleep. In half of the cases, the electrocardiogram amplitude decreased during anginal attacks. In the context of nighttime monitoring, it is of interest to note that T-wave alternans, an electrocardiographic (ECG) phenomenon indicating vulnerability to lethal arrhythmias,[43] was documented in the nighttime electrocardiogram of a patient with left dysfunction enrolled in the ambulatory ECG arm of the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) (Figure 124-5).[44]

Nocturnal Myocardial Infarction

Although only 20% of MIs occur between midnight and 6:00 AM, their nonuniform distribution implicates pathophysiologic triggers.[1] The dynamic perturbations in autonomic nervous system activity both independent of and in conjunction with apnea[45] are likely to constitute important triggers of MI at night. REM-induced surges in sympathetic nerve activity have the potential to provoke tachycardia and hypertension, alterations that carry the potential for inducing MI secondary to coronary artery plaque rupture as well as to inappropriate decreases in the myocardial oxygen supply-demand relationship or α-adrenergically mediated coronary vasoconstriction.

Alternatively, in a starkly opposite manner, the hypotension of slow wave sleep may lead to malperfusion of the myocardium because of reduced coronary perfusion pressure through stenotic vessel segments (Figure 124-6).[46] Several investigators[27,47,48] have attributed nocturnal MI and myocardial ischemia to the relative hypotension of NREM sleep, which "reduces the volume and velocity of blood flow, favoring the development of thrombi and embolic and ischemic phenomena before and after arousal."[5] Mancia therefore advocated avoiding drugs that enhance the hypotension of NREM sleep and prescribing antihypertensive medications only for daytime therapy.[5] He echoed the argument of Floras,[34] who observed that antihypertensive treatment did not reduce the incidence of nocturnal MI and myocardial ischemia. Further evidence of the risk for hypotension-induced infarction has been provided by Kleiman and colleagues,[47] who reported that the incidence of subendocardial MI clustered at 2:00 to 4:00 AM, simultaneously with the nadir in arterial blood pressure. Other factors known to contribute to MI are operative during sleep, including increased ventricular diastolic pressures and volumes caused by the fluid shifts resulting from assuming a supine posture, unfavorable alterations in the balance of fibrinolytic and thrombotic factors,[31] and chronic or episodic oxygen desaturation.[29,36-39]

Specific patient groups experience an increased incidence of nighttime MIs, particularly those with poor ventricular function, advanced age, or diabetes.[49,50] The risk for development of congestive heart failure is higher for nighttime than daytime MIs,[51] potentially because of either the pathologic process or a delay in obtaining high-quality care.

Hypertension

Patients whose nighttime arterial blood pressure declines less than 10% from day to night (called "nondippers") are at increased risk for total and cardiovascular mortality[52] as well as all cardiovascular end points,[53] frequent or complex ventricular arrhythmias,[54] myocardial ischemia,[55] cerebrovascular insult,[56] and increased organ damage, including cardiac

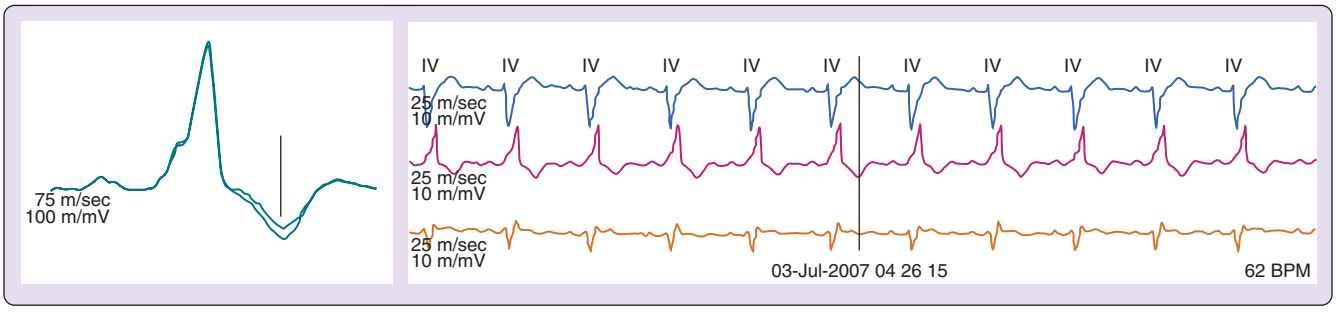

Figure 124-5 High-resolution template showing T-wave alternans (65 μV) in precordial lead V_3 in superimposed electrocardiographic (ECG) waveforms from a nighttime ambulatory ECG recording of a patient with heart failure and left ventricular dysfunction enrolled in the ambulatory electrocardiographic (AECG) substudy of the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS). The associated ECG strip is also provided. (From Stein PK, Sanghavi D, Domitrovich PP, et al. Ambulatory ECG-based T-wave alternans predicts sudden cardiac death in high-risk post-MI patients with left ventricular dysfunction in the EPHESUS Study. *J Cardiovasc Electrophysiol* 2008;19:1037–42, with permission from Wiley.)

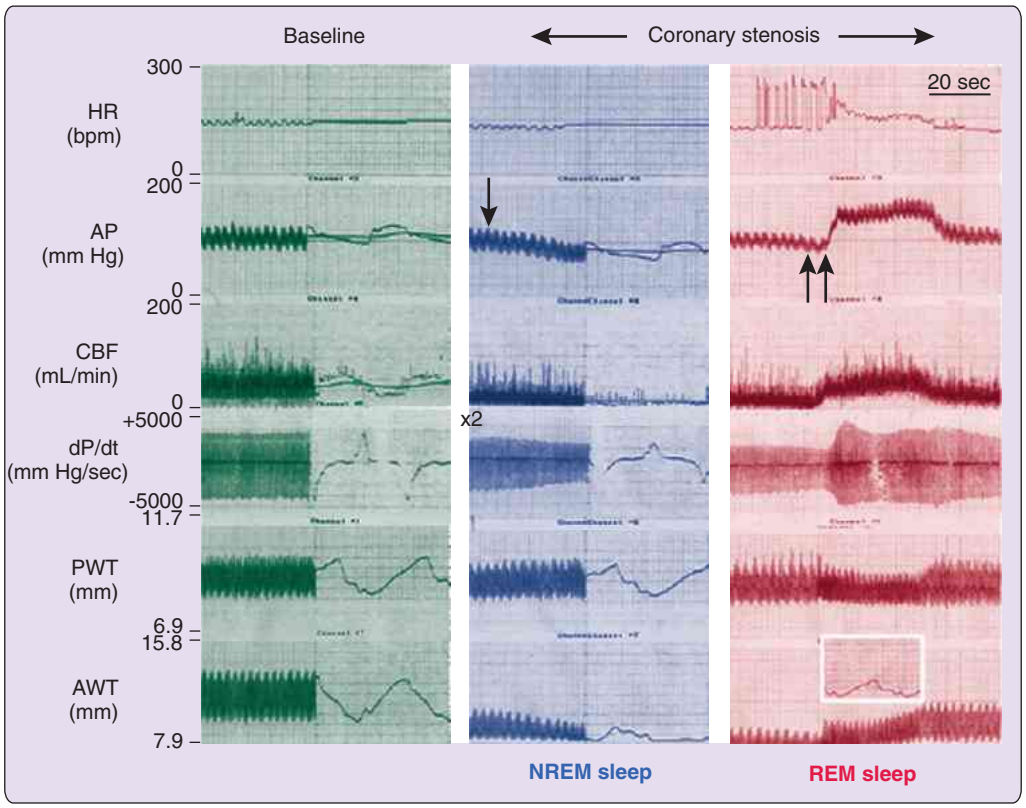

Figure 124-6 Representative tracings for hemodynamic variables at baseline (before stenosis) and during NREM (*single arrow*) and REM (*double arrow*) sleep in the presence of coronary stenosis. NREM sleep initiated a decrease in arterial pressure (AP), resulting in akinesis in the anterior wall (stenotic region). REM sleep induced a rapid increase in heart rate (HR), AP, and dP/dt_{max} (rate of change of left ventricular pressure). The onset of REM sleep increased coronary blood flow, which returned anterior wall function to the poststenotic condition before the onset of NREM sleep. (See expanded tracing in box.) AWT, Anterior wall thickness; CBF, coronary blood flow; PWT, posterior wall thickness. (From Kim SJ, Kuklov A, Kehoe RF, et al. Sleep-induced hypotension precipitates severe myocardial ischemia. *Sleep* 2008;31:1215–20, with permission from the Sleep Research Society and the American Academy of Sleep Medicine.)

hypertrophy.[57] The absence of a nocturnal decline in blood pressure may be an important marker of complications among patients with type 1 diabetes,[58] and it may be reflected in the significant incidence of death at 2:00 to 4:00 AM among hypertensive women reported by Mitler and colleagues (Figure 124-7).[59] Faulty baroreceptor activation may account for the fact that arterial blood pressure during sleep remains significantly elevated in these hypertensive patients, who typically show evidence of central hypersympathetic nerve activity with an increased number of microarousals, a reduced length and depth of NREM sleep, and a shortened REM latency. Blunted endothelium-dependent vasodilation is also implicated.

Heart Failure

Excess mortality risk attends chronic congestive heart failure, particularly among the 40% to 80% of heart failure patients with either obstructive or central sleep apnea. These sleep-related breathing disorders may contribute to the severity of disease, specifically to remodeling of cardiac chambers and left ventricular diastolic dysfunction as well as to T-wave alternans.[43,60] In patients with systolic heart failure, central sleep apnea, smoking,[61] severe right ventricular systolic dysfunction, and low diastolic blood pressure are associated with increased nocturnal ventricular arrhythmias and mortality.[62] Treatment of apnea with continuous positive airway pressure, medications, or devices frequently lessens heart failure symptoms and mortality risk. Diagnostic and treatment strategies are discussed in Chapter 129.

Patients with Epilepsy

Whereas most patients with epilepsy exhibit a low incidence of seizure at night,[63] sudden unexpected death in epilepsy (SUDEP) occurs primarily in patients with a history of nocturnal seizures.[64-66] More than 99% of nocturnal seizures arise in NREM sleep.[67] Sleep disorders are common among patients with epilepsy; sleep apnea worsens seizures, and its treatment improves seizure control.[67,68]

Elderly Patients

Elderly individuals' (particularly women's) reports of daytime sleepiness, suggesting poor quality of sleep, are associated with mortality, cardiovascular morbidity and mortality, MI, and congestive heart failure.[69] Depression, poor health, daytime angina, a limited activity level, and cardiac arrhythmias may accompany disturbed sleep in elderly individuals. Initiating a moderately intense exercise program significantly improves sleep quality[70] and autonomic status[71] in formerly sedentary older people. Nocturnal myocardial ischemia is not uncommon in older patients with vascular disease who experience regular episodes of oxygen desaturation and increased heart

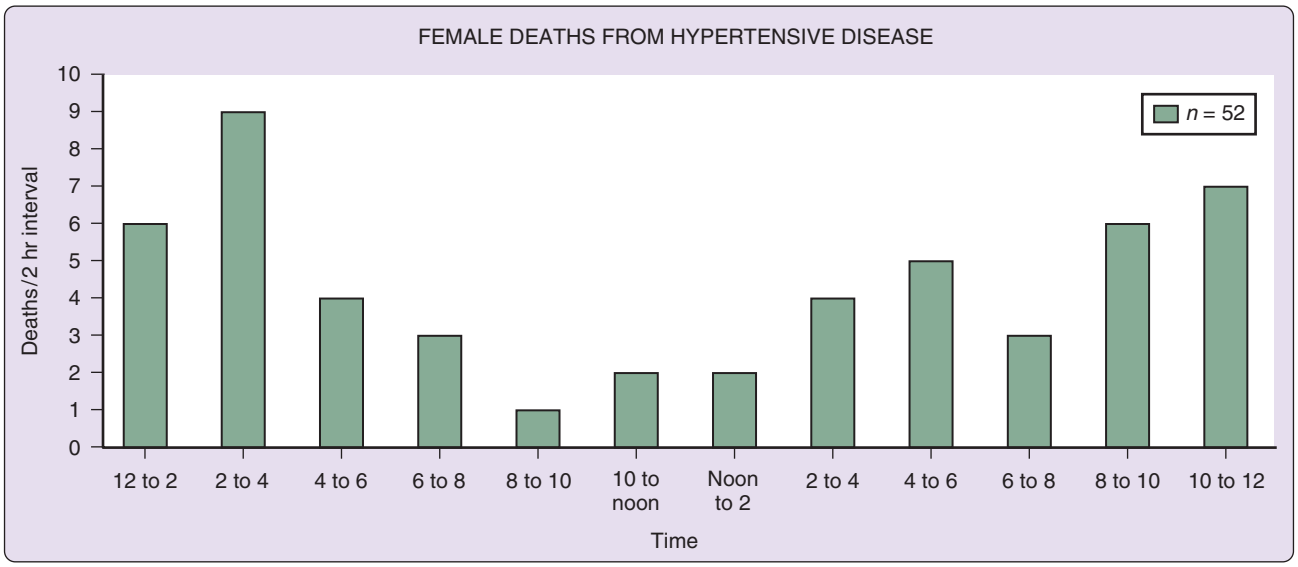

Figure 124-7 The temporal distribution of female deaths attributed to hypertensive disease peaked at 2:00 to 4:00 AM. The temporal concentration was statistically significant ($P < .01$). Data were derived from a 4600-person (>8%) sample of deaths due to disease in New York City in 1979. (Reprinted from Mitler MM, Hajdukovic RM, Shafor R, et al. When people die: cause of death versus time of death. *Am J Med* 1987;82:266–74. Copyright 1987, with permission from Excerpta Medica, Inc.)

rate. Conflicting evidence has been presented of increased risk for nighttime compared with daytime MI and sudden cardiac death in elderly people.[48,49,72] Impaired baroreceptor sensitivity,[73] a measure of the capacity for reflex vagus nerve activation,[6] and increased low-frequency power of HRV[74] are evident at night in susceptible elderly patients. Given this autonomic background, it is not surprising that nighttime multifocal activity in elderly patients is a predictor of cardiac mortality.

CLINICAL PEARLS

- Sleep exerts a major impact on the health of the patient with cardiac disease through both direct cardiovascular influences and sleep-disordered breathing.[75] In a sense, the diseased heart and lungs are unwitting victims of the needs of the sleeping brain, which commands dramatic alterations in autonomic and respiratory activity.
- A sizeable population experiences cardiac events during sleep, with identifiable high-risk groups (see Table 124-1).
- Sleep presents unusual opportunities to monitor the patient with cardiac disease because there is growing appreciation of the fact that nighttime heart rate, blood pressure, myocardial ischemia, arrhythmias, and respiratory disturbances carry predictive value for daytime events (Box 124-1).
- Daytime tests cannot substitute for nighttime monitoring of the patient with cardiac disease because exercise treadmill testing and daytime ambulatory monitoring cannot replicate the autonomic, hemodynamic, or respiratory challenges that uniquely accompany sleep.
- Improved identification of the precise triggers of nocturnal cardiac events may be anticipated when technologies are integrated for monitoring sleep state, respiration, oxygen desaturation, and cardiovascular variables.

SUMMARY

Specific patient groups exhibit elevated sleep-related cardiac risk, including those with a history of cardiac arrhythmias, myocardial infarction, angina, heart failure, or sleep apnea; family members of a person who died from SIDS; and patients with Brugada syndrome, long-QT syndrome, or epilepsy. Improved risk assessment is possible through noninvasive monitoring of autonomic variables and repolarization abnormalities.

Chapter 125

Cardiac Arrhythmogenesis During Sleep: Mechanisms, Diagnosis, and Therapy

Richard L. Verrier; Mark E. Josephson

Chapter Highlights

- The pronounced sleep state–dependent changes in autonomic nervous system activity and respiration can provoke both atrial and ventricular arrhythmias in patients with cardiovascular disease.
- Mortality due to ventricular arrhythmias is most frequent during sleep in the distinct syndromes of sudden infant death, sudden unexplained nocturnal death, and the Brugada syndrome, each of which has been linked to genetic abnormalities.
- The proarrhythmic potential of class III antiarrhythmic agents (potassium channel blockers) for patients with significant heart rate pauses and the sleep-disrupting effect of medications must be considered.

Cardiac arrhythmias are prevalent in the 13.5 million Americans with heart disease, with potentially severe consequences. Approximately 15% of sudden cardiac deaths, which result from lethal ventricular arrhythmias, occur during sleep, and most atrial arrhythmias in patients younger than 61 years have their onset at nighttime. Sleep apnea profoundly alters autonomic nervous system activity and increases risk of arrhythmia, hypertension, and myocardial infarction (see Chapters 126–128). Lack of streamlined technology for concurrent monitoring of sleep state, electrocardiogram (ECG), oxygen saturation, and respiration continues to hamper diagnosis and evaluation of therapy of these arrhythmias. We will review the current state of knowledge regarding epidemiology, risk factors, pathogenesis, and treatment options for each nocturnal arrhythmia type.

VENTRICULAR ARRHYTHMIAS

Malignant ventricular arrhythmias are usually suppressed during sleep, as is evidenced by the nocturnal trough in incidence of myocardial infarction, sudden cardiac death, implantable cardioverter–defibrillator discharge, myocardial ischemic events, and arrhythmias in patients with ischemic heart disease.[1,2] This decrement coincides with lessened metabolic demands during non–rapid eye movement (NREM) sleep, which occupies approximately 80% of sleep time. However, sleep is not entirely free of risk because the nocturnal incidence of sudden cardiac death, which is attributable to ventricular fibrillation, has been calculated at approximately 15%[3] or 45,000 cases annually in the United States alone. Moreover, the nonuniformity of the nighttime distribution of these events (Figure 125-1)[3] suggests physiologic triggering that may be amenable to monitoring for improved diagnosis and therapy.

Surges in cardiac sympathetic nerve activity during rapid eye movement (REM) sleep have been implicated in nocturnal ventricular arrhythmias and myocardial ischemia[4-7] (see Chapter 124). The specific mechanisms of REM-induced cardiac events include direct effects on electrophysiologic status or indirect consequences of heart rate and arterial blood pressure accelerations, which may disrupt plaques and lead to intra-arterial platelet aggregates, releasing proarrhythmic constituents such as thromboxane A_2.[8] Myocardial ischemia or other changes in cardiac substrate and mechanical function resulting from disease,[9] infarction,[10] or aging[11] can amplify nocturnal electrical instability. Oxygen desaturation may trigger nighttime ventricular tachycardia in patients with cardiac disease in the subacute phase after myocardial infarction[10] or in those with heart failure.[9] Hypoxemia and tachycardia frequently occur together during sleep after major surgery and may promote myocardial ischemia.[12] Frequent or complex arrhythmias are also characteristic of hypertensive patients in whom the typical nocturnal trough in blood pressure is not observed.[13] The nocturnal increase in QT-interval dispersion among survivors of sudden cardiac death,[14] acute myocardial infarction,[15] and heart failure[15] provides evidence of their increased vulnerability to cardiac arrhythmias at night.

REM-related nocturnal arrhythmogenesis may have a significant affective component. REM sleep dreams, which may be vivid, bizarre, and emotionally intense, commonly generate the emotions of anger and fear. Because these emotions have been linked in wakefulness to the onset of myocardial infarction and sudden death,[16] it is reasonable to hypothesize that when these affective states are evoked during dreaming, they may trigger lethal events. This possibility is illustrated by a case report of recurrence of ventricular fibrillation in a 39-year-old man with normal coronary arteries and cardiac function while sleeping. A subsequent sleep study determined that ventricular premature beats were substantially increased during REM and that dreams at the same hour that fibrillation had occurred were emotionally charged.[17]

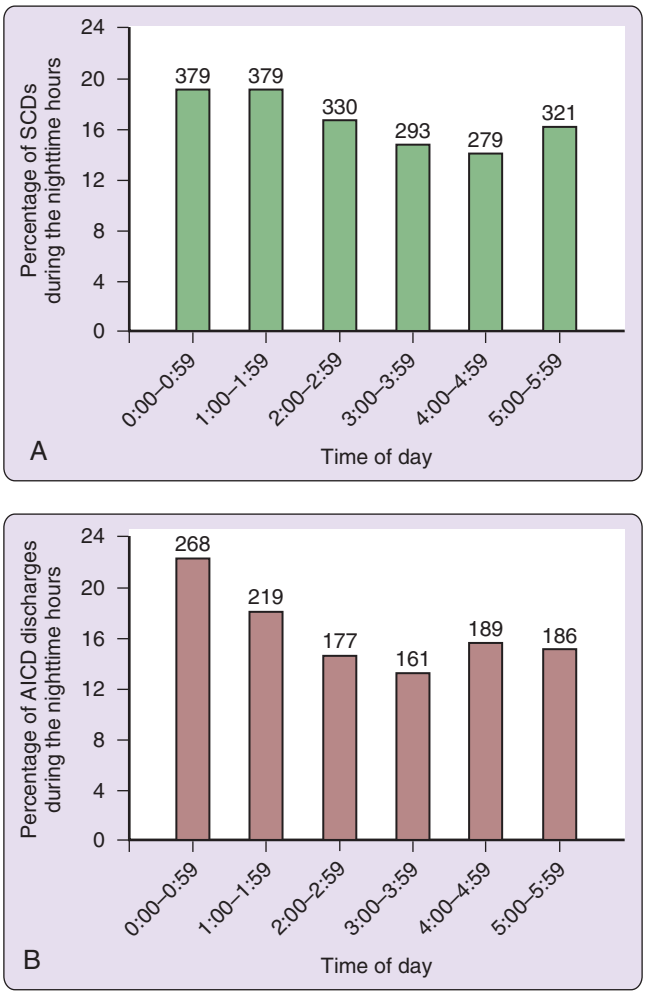

Figure 125-1 A, Hourly incidence of sudden cardiac death (SCD) onset between midnight and 5:59 AM from 12 studies enrolling 1981 patients. The number of sudden cardiac deaths observed each hour is indicated above each bar. **B,** Hourly incidence of automatic implantable cardioverter-defibrillator (AICD) discharge between midnight and 5:59 AM from seven studies enrolling 1197 patients, who experienced 1200 discharges during the nocturnal period. The number of discharges observed each hour is indicated above each bar. (From Lavery CE, Mittleman MA, Cohen MC, et al. Nonuniform nighttime distribution of acute cardiac events: a possible effect of sleep states. *Circulation* 1997;5:3321–7.)

In some cases, arrhythmia frequency may be enhanced during NREM sleep, when latent automatic foci are exposed by the generalized reduction in heart rate after withdrawal of overdrive suppression, or when hypotension exacerbates impaired coronary perfusion.

Therapy

In most cases, an electrically unstable substrate underlies the propensity to develop nocturnal ventricular arrhythmias, and treatment is similar to that for daytime arrhythmias. If surges in sympathetic nerve activity, which typically occur during REM sleep and dreaming, are suspected, beta-adrenergic receptor blockade therapy may prove helpful, with careful attention to avoiding medications that disrupt sleep.[18]

In treating hypertensive patients, it is important to appreciate Mancia's[19] suggestion that pharmacologic therapy that exacerbates the hypotensive effect of NREM sleep may introduce the potential risk of thrombosis and embolism in patients with stenotic lesions in the heart or brain. Floras[20] determined that the nocturnal incidence of myocardial infarction was not diminished in patients treated with antihypertensive agents and suggested that the agents induced nocturnal hypotension. Thus, special attention should be given to the hemodynamic effects of antihypertensive drugs and vasodilators to avoid precipitating cardiac events by inducing profound hypotension. The importance of ruling out "white coat" hypertension is underscored because more than 30% of individuals with elevated blood pressure readings in the physician's office or hospital prove to be normotensive during daily life, as documented by ambulatory blood pressure monitoring.[21]

Nighttime onset of ventricular arrhythmias may also indicate provocation by disturbed breathing, which can be treated by continuous positive airway pressure.[22] For example, sleep-disordered breathing provokes ventricular arrhythmias and appropriate firing of implantable cardioverter–defibrillators, suggesting apnea-screening and therapy to reduce these events.[23] Risk of apnea-induced cardiac events is not limited to the nocturnal period and can be monitored from continuous ECGs by T-wave alternans,[24] a marker of risk for lethal ventricular arrhythmias.[25]

NOCTURNAL ASYSTOLE AND QT-INTERVAL PROLONGATION

Sinus pauses of less than 2 seconds, prolonged atrioventricular (AV) conduction, Wenckebach AV block, and bradycardia are well documented in normal populations during sleep and are attributed to effects of increased parasympathetic activity on AV node conduction.[26,27] These asystoles are more frequent in individuals who are young[28,29] or physically fit, such as athletes[30,31] and heavy laborers.[32] More extreme cases were observed by Guilleminault and colleagues,[32a] who reported periods of sinus arrest of up to 9 seconds during REM sleep in young adults with apparently normal cardiac function. It was concluded that the nocturnal asystoles were the result of exaggerated, if not abnormally elevated, vagal tone, because muscarinic receptor blockers significantly reduced the duration of the nocturnal asystoles but did not prevent them. No further therapeutic intervention was warranted.

However, in patients with cardiac disease, especially those taking class III antiarrhythmic drugs (potassium channel–blocking agents), nocturnal asystolic events can set the stage for ventricular arrhythmias. Such prolongation of cycle length can facilitate the development of early afterdepolarizations and the lethal arrhythmia torsades de pointes. In patients with damaged endothelium resulting from coronary atherosclerosis, the acetylcholine released by surges in vagus nerve activity could result in vasoconstriction rather than vasodilation because of impaired release of endothelium-derived relaxing factor.[33]

Nocturnal heart rate pauses may be particularly arrhythmogenic in subsets of patients with the long QT syndrome, specifically LQT2 and LQT3, who have mutations on the sodium channel, voltage-gated, type V, alpha gene (*SCN5A*).[34] The lethal arrhythmias occur almost exclusively at rest or during sleep, when the QT interval is typically prolonged.[35] (See later section on sudden infant death syndrome.)

Therapy

Ascertaining whether patients exhibit nocturnal heart rate pauses is important when treating individuals for whom class III antiarrhythmic drugs (potassium channel blockers) are the primary option.

ATRIAL FIBRILLATION

In the 2.5 million U.S. patients with atrial fibrillation, which has serious consequences in terms of increased morbidity and mortality,[36] it is likely that 10% to 25% of the arrhythmias are facilitated by vagal influences. This has been termed *vagally mediated atrial fibrillation*. Several investigators have reported nocturnal peaks in onset of paroxysmal atrial fibrillation.[37-39] A significant midnight to 2:00 AM peak in atrial fibrillation onset and a higher average nocturnal incidence were documented by Rostagno and colleagues[37] in their review of records from 10 years of responses by mobile coronary care units staffed by cardiologists in Florence, Italy. This arrhythmia was also found to exhibit a peak in frequency of onset at midnight in a Japanese population of 60 years of age or younger. The maximal duration of the arrhythmia (77±27 minutes per episode) was also greatest between midnight and 6:00 AM (Figure 125-2).[38] Other investigators characterized a 4:00 AM to 5:00 AM peak in onset of paroxysmal atrial fibrillation that was refractory to antiarrhythmic drugs in a 3-month study of 67 patients with implantable cardioverters.[39] The 514 recorded episodes with an atrial rate of greater than 220 beats per minute lasted more than 1 minute before termination by pacing or spontaneous reversion. A potential contribution of sympathetic nerve activity is implicated by the timing of these bouts of atrial fibrillation, which occurred during a period of sleep when REM typically emerges. However, the potential of REM sleep to trigger the arrhythmia was not discussed.

Patients with more frequent atrial tachycardia are more likely to develop atrial tachycardia/fibrillation at night.[40] Records of concurrent monitoring of sleep and nocturnal onset of atrial fibrillation are rare (Figure 125-3).[41] In the case illustrated, disruption of the nocturnal trough in heart rate disclosed sleep-related atrial fibrillation. Available evidence indicates that nocturnal atrial fibrillation is provoked during periods of intense vagus nerve activity, as indicated by heart rate variability studies,[42,43] and the presence of bradycardia,[44] in individuals with structurally normal hearts. Enhanced adrenergic activity may interact in a complex manner with changes in vagal tone to affect atrial refractoriness and dispersion of repolarization and alter intra-atrial conduction, thus increasing the propensity to develop this arrhythmia.[36,44] The high level of vagus nerve tone maintained during slow wave sleep has the capacity to exacerbate atrial fibrillation in patients whose atria are particularly prone to the arrhythmogenic influence of acetylcholine.[36]

Risk of atrial fibrillation is doubled if breathing during sleep is disordered,[45] because apnea can provoke nocturnal hypoxemia, sympathetic nerve activity, and hemodynamic stress.[22,45] Obstructive apnea–induced surges in blood pressure distend atrial chambers and can activate stretch receptors. Incidence of atrial fibrillation is strongly predicted by nocturnal oxygen desaturation in subjects younger than 65 years old

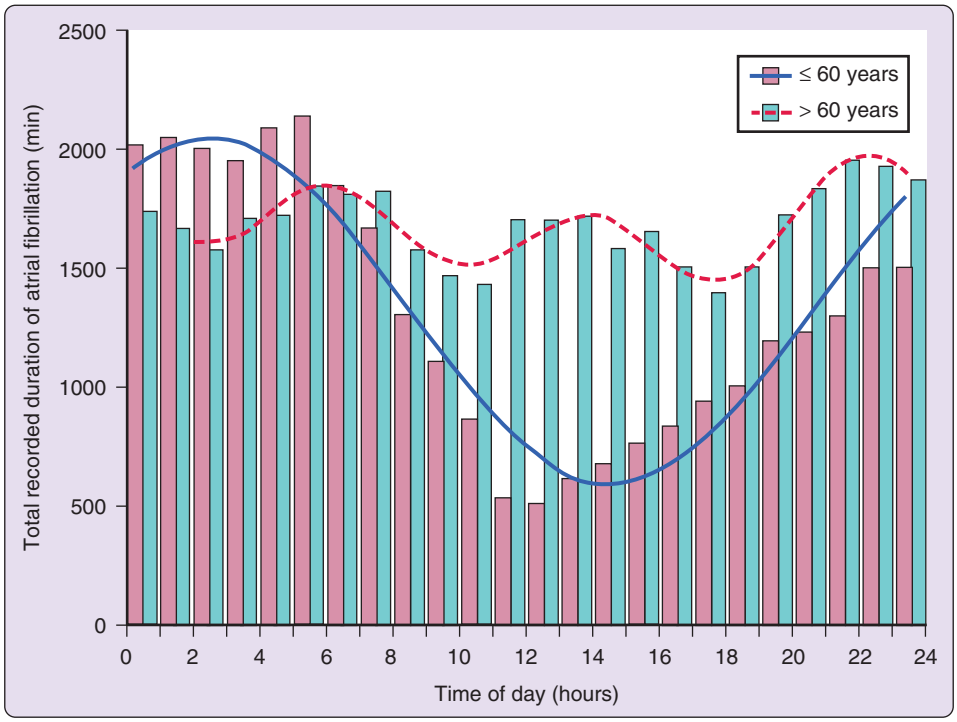

Figure 125-2 Hourly total duration of paroxysmal atrial fibrillation in younger (<60 yr; *red bars*) and older patients (*green bars*). The single harmonic fit of the data from the younger patients is shown by the *unbroken line*. The triple harmonic fit in the older patients is shown by the *broken line*. A prominent monophasic circadian rhythm is present in younger patients, in contrast to a toneless triphasic rhythm in older patients. (From Yamashita T, Murakawa Y, Hayami N, et al. Relation between aging and circadian variation of paroxysmal atrial fibrillation. *Am J Cardiol* 1998;82:1364–7.)

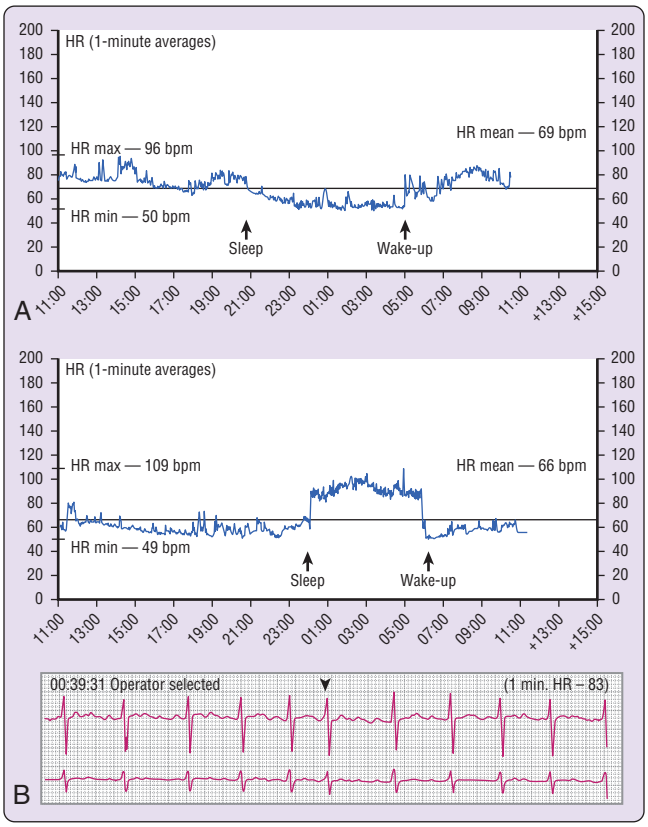

Figure 125-3 **A,** Heart rate (HR) trend from an ambulatory electrocardiogram (AECG) showing a normal circadian rhythm with a sleep-induced decrease in heart rate. **B,** Heart rate trend from an AECG in our patient shows a nocturnal increase in heart rate caused by paroxysmal atrial fibrillation at the onset of sleep and a drop in heart rate after awakening, resulting from spontaneous conversion to sinus rhythm. The ECG (*below*) documents atrial fibrillation during the sleep period. (From Singh J, Mela T, Ruskin J. Images in cardiovascular medicine: sleep [vagal]-induced atrial fibrillation. *Circulation* 2004;110: e32–3.)

and by heart failure in older subjects.[45] Moreover, ablation for atrial fibrillation is effective in patients appropriately treated for sleep-disordered breathing but of limited value in patients whose apnea is not treated.[46] Furthermore, patients with atrial fibrillation and severe sleep apnea are less likely to respond to antiarrhythmic medical therapy.[47]

Therapy

Medical therapy is similar to that for patients whose arrhythmias occur during the day, including therapy to control rate or terminate the arrhythmia pharmacologically or with an atrial cardioverter–defibrillator. Because nighttime atrial fibrillation is classified as *vagally mediated*, anticholinergic agents, such as disopyramide and flecainide, are sometimes helpful to prevent recurrences; adrenergic blocking drugs or digitalis sometimes worsen symptoms.[48] In addition, individuals with nocturnal onset of atrial fibrillation should be monitored for the presence of sleep-disordered breathing, which can be effectively treated by continuous positive airway pressure.

SUDDEN INFANT DEATH SYNDROME

Sudden infant death syndrome (SIDS), the leading cause of mortality in infants between 1 week and 1 year of age, occurs during sleep.[49] The syndrome is a diagnosis of exclusion; that is, it includes all causes that remain unexplained after a thorough case investigation, including an autopsy, examination of the death scene, and review of the clinical history. Thus, SIDS, which took a toll of 2234 infants in 2001 in the United States[50] or 8.1% of infant deaths, may be attributable to a variety of etiologies that challenge the developing cardiorespiratory system. The fatal event in SIDS victims is characterized by hypotension and bradycardia[51] and appears to be attributable to a deficit in the normal reflex coordination of heart rate, arterial blood pressure, and respiration during sleep.[52] This failure to respond to cardiorespiratory challenges during sleep may result from a binding deficit in the arcuate nucleus of SIDS infants,[52] because muscarinic cholinergic activity in this structure at the ventricular medullary surface is postulated to be involved in cardiorespiratory control. Heart rates in infants who later died of SIDS are generally higher and exhibit a reduced range, suggesting altered autonomic control.[53] Autonomic instability has also been documented in NREM sleep in infants with aborted SIDS events.[54]

Repolarization abnormalities have also been observed. Recent evidence from a 19-year, prospective, multicenter observational study of 34,442 infants determined that significant prolongation (35 milliseconds or more) of the QT interval characterized the 24 (0.07%) infants who died of SIDS within the first year of life.[55] These results suggest that some SIDS cases may be attributed to a genetic defect that produces a developmental abnormality in cardiac sympathetic innervation and alters repolarization to increase the risk of ventricular arrhythmia. These repolarization abnormalities typify infants and children with the long QT syndrome genotype linked to chromosome 3 (LQT3). Mutations in the sodium channel gene *SCN5A* are the most common causes of long QT syndrome and are responsible for the arrhythmias and reduced heart rates. The genetic locus of the defect and the length of the QT interval are independent predictors of risk.[56] T-wave alternans, an electrocardiographic indicator of heightened vulnerability to sudden cardiac death,[25] has been reported in infants who became SIDS victims[57,58] or who were successfully treated with pacing[59] or beta-blockade therapy.[60,61] The latter therapy diminished T-wave alternans, indicating antiarrhythmic efficacy.

Among environmental influences, the increased risk of SIDS during the winter season is well documented[62,63] and is not related to bronchiolitis.[64] A genetic susceptibility that may interact with environmental factors has been implicated by a 5.8-fold increase in recurrence of SIDS within families.[65] Tishler and colleagues[66] reported a significant incidence of deficits in ventilatory responses to hypoxia in families with apnea. Conflicting evidence has been provided regarding the relative increase in risk attributable to prone (face-down) sleeping,[67-71] and decreased incidence of SIDS has been attributed to the Back-to-Sleep campaign, which advocates placing infants in a supine position for sleeping.

Passive cigarette smoking is a highly significant modifiable risk factor in SIDS. A reduction of 61% in the number of SIDS deaths has been projected if smoking were eliminated from infants' environments.[66-69,72] A dose-dependent effect has been demonstrated.[67] Maternal smoking during gestation is also implicated.[72-74] Established SIDS risk factors of preterm birth and low birth weight increased risk more than 15-fold

among smokers[74] but not at all among nonsmokers. Illegal drug use increases risk of SIDS by more than fourfold.[75] The mechanisms may include impairment in chemoreceptor responsiveness, resulting from decreased sensitivity to carbon dioxide in infants of substance-abusing mothers.[75] The increase in SIDS due to passive smoking may be attributable to nicotine's adverse effect on chemoreceptor activation of respiration,[76] dulling the arousal response to hypoxia.[77] Nicotine and its metabolites have been found at autopsy in the pericardial fluid of SIDS infants.[78,79] Epicardial nicotine is associated with hypopnea[80] and affects the sinoatrial node and epicardial neural fibers to induce hypotension and bradycardia,[81,82] the documented symptomatology of the final event in SIDS infants.[51]

Therapy

This profile suggests some straightforward opportunities for intervention, including placing infants in a supine (face-up) position for sleeping and avoidance of maternal smoking during gestation and passive smoking during infancy. Theoretically, sodium channel blockade[34] or cardiac pacing[34,59] might be useful in treating infants diagnosed with the long QT3 syndrome, but prospective studies are required. Beta blockade is the current treatment of choice.[34,60,61] Assessment of vulnerability to arrhythmias by QT-interval prolongation has been suggested in a prospective study[55] and by T-wave alternans in multiple clinical reports based on ambulatory electrocardiographic (AECG) recordings.[60,61]

THE BRUGADA SYNDROME AND SUDDEN UNEXPLAINED NOCTURNAL DEATH SYNDROME

The striking phenomenon of sudden death during sleep has been reported in Western adults diagnosed with the Brugada syndrome, which strikes men almost exclusively, and in young, apparently healthy Southeast Asian men with the sudden unexplained nocturnal death syndrome (SUNDS). The latter syndrome is named *lai-tai* ("sleep death") in Laos, *pokkuri* ("sudden and unexpected death") in Japan, and *bangungut* ("to rise and moan in sleep") in the Philippines. These syndromes probably represent the same disorder, which is characterized by right precordial ST segment elevation.[56,83] Deaths are due to lethal ventricular arrhythmias.

The Brugada syndrome is considered responsible for 4% to 12% of all sudden cardiac deaths and for approximately 20% of deaths in patients with structurally normal hearts.[56] The electrocardiographic abnormality is estimated to be present in approximately 5 per 10,000 inhabitants, and, apart from accidents, in geographic regions where it is widespread, this inherited syndrome is the leading cause of death of men younger than 50 years of age. A single sodium channel mutation in the *SCN5A* gene identified in an eight-generation kindred with a high incidence of nocturnal sudden cardiac death, QT-interval prolongation, and Brugada-like ECG characterizes 20% of Brugada patients; other mutations are suspected. Genetic defects in the sodium channel are also associated with progressive conduction system disease attended by bradycardia. A mechanistic link with enhanced presynaptic norepinephrine recycling has been described.[84] Presynaptic sympathetic cardiac dysfunction has been hypothesized, based on abnormal iodine-123 metaiodobenzylguanidine uptake, with bradycardia-dependent QT prolongation, intrinsic sinus node dysfunction, conduction abnormalities, and absence of ventricular ectopy.[85]

In the United States, 117 SUNDS deaths were registered among male Southeast Asian immigrants or their descendants from 1981 to 1988.[86] Autopsies of those who died of SUNDS have established that cardiovascular disease is absent, but, in some instances, conduction pathways are developmentally abnormal.[83] Companions have reported that the immediate symptoms are onset of agonal respirations during sleep along with vocalization; violent motor activity; non-arousability; rapid, irregular deep breathing; perspiration; heart rate surges; and severe autonomic discharge. Several victims revived by vigorous massage reported sensations of airway obstruction, chest discomfort or pressure, and numb and weak limbs. When these symptoms recurred within weeks to months, they culminated in death.[87] Three victims who had been resuscitated from ventricular fibrillation then experienced recurring fibrillation in the hospital during sleep accompanied by similar moaning vocalizations. In these three patients, there was no evidence of atherosclerosis or structural abnormalities and no sleep apnea, but creatine kinase levels were markedly elevated, and potassium was depressed. Vagal tone is lower in SUNDS survivors than in healthy individuals, particularly at night.[88]

The Brugada syndrome is genetically related to the long QT syndrome, which shares risk for lethal nocturnal ventricular arrhythmias,[89] a period when these patients exhibit abnormal levels of T-wave alternans.[25,90]

Therapy

Development of effective therapy for these syndromes has been particularly challenging. Currently, implantation of cardioverter–defibrillators appears to be the most effective approach in patients with Brugada syndrome[56] or risk of SUNDS.[83]

SLEEP-DISRUPTING EFFECTS OF CARDIAC MEDICATIONS

Several important medications that are widely prescribed for patients with cardiac disease, including antihypertensive agents and beta blockers that cross the blood–brain barrier, have the potential to disrupt sleep.[18] In particular, the lipophilic beta blockers (pindolol, propranolol, and metoprolol) increase the total number of awakenings and total wakefulness compared with placebo and with the nonlipophilic atenolol. Penetration of the blood–brain barrier occurs with prolonged therapy, when these distinctions may become less apparent. In addition, pindolol, which has intrinsic sympathomimetic activity, increases REM latency and, as a result, decreases REM sleep time. Sleep disruption may provoke daytime fatigue and lethargy, symptoms widely reported by patients taking beta blockers, which may prompt discontinuation of the medication or noncompliance. It has been postulated that the mechanism of sleep disruption by beta-blocking agents is their well-known tendency to deplete endogenous melatonin,[91] a key sleep-regulating hormone that modulates sympathetic nerve activity. An additional important side effect of these beta blockers[18] is their potential to provoke nightmares. Despite these effects, it is the lipophilic beta blockers (propranolol, metoprolol, carvedilol) that have been shown to reduce the risk of sudden cardiac death. Sleep disturbance has also been documented in conjunction with the widely used

antiarrhythmic agent amiodarone.[92,93] Neurologic side effects were attributed to amiodarone in 20% to 40% of patients. Optimal antiarrhythmic management with this agent to minimize side effects dictates prescription of lower dosages and close patient monitoring and follow-up.

CLINICAL PEARL

Diagnosing and treating patients with nocturnal arrhythmias have been hampered by a paucity of information about concurrent autonomic nervous system activity, cardiac electrical instability, oxygen desaturation, and breathing disturbances. It is now possible to assess autonomic nervous system activity by AECG monitoring of noninvasive markers, such as heart rate variability, a measure of autonomic nervous system tone, and heart rate turbulence, an indicator of baroreceptor function based on the pattern of heart rhythm recovery after a ventricular premature beat.[94] Simultaneous measurement of these indicators, along with clinical history and analysis of cardiac electrical instability with QT-interval dispersion[14,15] or T-wave alternans[25] on continuous ECG monitoring, promises to provide valuable information regarding vulnerability to nocturnal arrhythmias and potential provocation by the autonomic nervous system. Concurrent monitoring of oxygen saturation and respiratory patterns will provide essential information. Increased survival from in-hospital nighttime cardiac arrest can be anticipated with improved monitoring.[95]

SUMMARY

Because the etiology of nocturnal arrhythmias is multifactorial, their management necessitates a comprehensive approach and consideration of a host of cardiovascular and respiratory factors. Treatment must be tailored to contain neurally induced arrhythmias while avoiding exacerbation of hypotension and myocardial ischemia during NREM sleep.

Cardiovascular Effects of Sleep-Related Breathing Disorders

Chapter 126

Virend K. Somers; Shahrokh Javaheri

Chapter Highlights

- The cycle of apnea and recovery causes hypoxemia and reoxygenation, hypercapnia and hypocapnia, changes in intrathoracic pressure, and arousals. These consequences of sleep apnea, both obstructive and central apnea, adversely affect cardiovascular function. The cardiovascular effects of sleep apnea may be mediated by redox-sensitive gene activation, altered autonomic nervous system activity, oxidative stress, and release of inflammatory mediators. Pathophysiologic consequences of sleep apnea elicit acute and chronic cardiovascular changes.
- Hypoxemia has direct (decreased myocardial oxygen delivery) and indirect (activation of sympathetic nervous system, promotion of endothelial cell dysfunction, and pulmonary arteriolar vasoconstriction) cardiac and vascular effects. Reoxygenation may cause additional damage through further production of free radical species. Hypoxemia-reoxygenation, with intermittent and profound alterations in the partial pressure of oxygen (P_{O_2}), may occur hundreds of times during sleep.
- Because of potentiated chemoreflex responses to hypoxemia-hypercapnia, the sympathetic and consequent presser responses to hypoxemia-hypercapnia, particularly in the absence of inhibitory effects of breathing, are marked. Nighttime sympathetic activation carries over into daytime wakefulness.
- Large negative intrathoracic pressures are generated during episodes of obstructive apnea. Negative intrathoracic pressure increases the transmural pressure (pressure inside minus pressure outside) of the intrathoracic vascular structures, including aorta, pulmonary vascular bed, and ventricles.
- Bradycardias may be especially severe and are elicited because of activation of the diving reflex by the combination of hypoxemia and apnea. Episodes of up to 10 seconds or more of sinus arrest may occur because of chemoreflex-mediated vagal activation.
- Sleep apnea has been implicated in systolic and diastolic heart failure, ventricular arrhythmias, and atrial fibrillation. However, whether treating sleep apnea prevents heart failure and arrhythmias or improves survival remains to be determined from randomized controlled trials.

Hemodynamic changes have been most studied in patients with obstructive sleep apnea (OSA), and in these studies, acute apnea-induced hemodynamic changes have been documented. Chronic exposure may also result in left ventricular systolic and diastolic dysfunction and in increased atrial volume. A limited number of studies have shown that treatment of OSA with nasal continuous positive airway pressure (CPAP) devices or tracheostomy can result in reversal of left ventricular dysfunction and arrhythmias. Whether treatment of sleep apnea reduces cardiovascular events or cardiovascular mortality remains to be demonstrated in randomized control trials. However, several observational studies have reported that treatment of sleep apnea improves survival primarily because cardiovascular events are reduced.

Periodic breathing is characterized by cyclic changes in tidal breathing with intervening episodes of obstructive or central apnea or hypopnea. These disordered breathing events result in three basic pathophysiologic consequences: (1) intermittent arterial blood gas abnormalities characterized by hypoxemia-reoxygenation and hypercapnia-hypocapnia, (2) arousals and a shift to light sleep stages, and (3) large negative swings in intrathoracic pressure (Figure 126-1).[1-3] These pathophysiologic consequences of apnea and hypopnea, both obstructive and central, adversely affect cardiovascular function, acutely and chronically.

ARTERIAL BLOOD GAS ABNORMALITIES AND THEIR CONSEQUENCES

Periodic breathing consists of cyclic changes in breathing pattern that include episodes of apnea and hypopnea, resulting in hypoxemia and hypercapnia. After apnea and hypopnea,

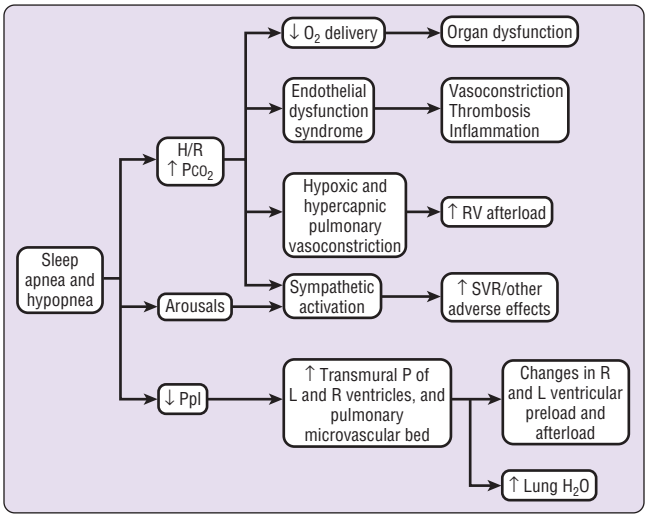

Figure 126-1 Pathophysiologic consequences of sleep apnea and hypopnea. Pleural pressure (Ppl) is a surrogate of the pressure surrounding the heart and other vascular structures. H/R, Hypoxia-reoxygenation; L, left; P, pressure; R, right; RV, right ventricular; SVR, systemic vascular resistance; ↑, increased; ↓, decreased. (Modified from Javaheri S. Sleep-related breathing disorders in heart failure. In: Mann DL, editor. *Heart failure: a companion to Braunwald's heart disease.* Philadelphia: Saunders; 2003. p. 478.)

hyperpnea ensues, resulting in reoxygenation and hypocapnia. These alterations in blood gases affect the cardiovascular system in different ways.

Hypoxemia and Reoxygenation

Hypoxemia has direct (decreased myocardial oxygen delivery) and indirect (activation of sympathetic nervous system, promotion of endothelial cell dysfunction, and pulmonary arteriolar vasoconstriction) cardiac and vascular effects. Hypoxemia with reoxygenation may be analogous to ischemia with reperfusion, and reoxygenation may cause additional damage through further production of free radical species. Biochemical injury due to hypoxemia-reoxygenation has considerable relevance to sleep apnea-hypopnea, where intermittent and profound alterations in the partial pressure of oxygen (Po_2) may occur hundreds of times during sleep.

Direct Effects of Hypoxia on Myocardium

Decreased myocardial oxygen delivery may result in an imbalance between myocardial oxygen consumption and demand, resulting in myocardial hypoxia, particularly if there is already coronary artery disease. At the same time, myocardial oxygen demand may be elevated because of concomitant tachycardia. Potential clinical consequences of myocardial hypoxia include nocturnal angina, nocturnal myocardial infarction,[4] arrhythmias, and even nocturnal sudden death.[5] Hypoxia may also impair myocardial contractility and cause diastolic dysfunction.[6]

Hypoxemia-Reoxygenation and Coronary Endothelial Dysfunction

Coronary vessel endothelial cells play a central role in vasoregulation, coagulation, and inflammation.[7] Blood flow and coagulation are modulated by production and release of vasoactive substances that include vasodilators and platelet deaggregators (e.g., nitric oxide, prostacyclin) and vasoconstrictors and platelet aggregators (e.g., endothelin and thromboxane). The balance between vasoregulatory agents is important in modulating coronary blood flow and coagulation status in both health and disease.

Through activation of certain transcription factors such as hypoxia-inducible factor-1 and nuclear factor-κB,[8,9] hypoxia increases the expression of a number of genes such as those encoding endothelin-1, a potent vasoconstrictor with proinflammatory properties, vascular endothelial growth factor, and platelet-derived growth factor. In contrast, it suppresses the transcriptional rate of endothelial nitric oxide synthase,[10] resulting in decreased production of nitric oxide, which is vasodilatory and has antimitogenic properties. Hypoxia also enhances expression of adhesion molecules and promotes leukocyte rolling and endothelial adherence,[11] and it is involved in induction of endothelial and myocyte apoptosis.[12]

Some of the aforementioned adverse effects of sustained hypoxia have also been observed with intermittent hypoxia (i.e., hypoxia-reoxygenation).[13-23] In this context, intermittent hypoxia has been proposed to be more deleterious than sustained hypoxia.[18,19] Reoxygenation through delivery of oxygen molecules provides a substrate for additional production of oxygen radicals and may contribute to oxidative stress.

The pathophysiologic consequences of hypoxemia-reoxygenation could lead to vascular inflammation and remodeling, similar to atherosclerosis.[7,23] Endothelial dysfunction has been demonstrated in a number of cardiovascular disorders, including hypertension, myocardial infarction, and stroke. Interestingly, these disorders have been also associated with OSA. It is therefore conceivable that endothelial dysfunction caused by sleep-related breathing disorders may contribute to worsening of atherosclerosis, atherothrombosis, and left ventricular dysfunction.[1,24]

The inflammatory and neurohormonal (see Obstructive Sleep Apnea and Systolic Heart Failure, later) consequences of altered blood gas chemistry have been best studied in patients with OSA, which is associated with increased sympathetic activity, high concentrations of endothelin, adhesion molecules, inflammatory cytokines, activation of white blood cells, oxidative stress, endothelial dysfunction, and hypercoagulopathy.[1,22,24-39] These autonomic, biochemical, and functional alterations may be reversed with use of nasal CPAP to treat OSA. However, such systematic studies are lacking for central sleep apnea, with the exception of studies showing increased overnight and morning sympathetic activity and increased concentration of endothelin and brain natriuretic peptide in patients with heart failure with central sleep apnea compared with those without central sleep apnea (for details, see Chapter 129).[40]

Hypoxemia-Hypercapnia and the Autonomic Nervous System

Sleep apneas and hypopneas, both obstructive and central (Figures 126-2 and 126-3), increase sympathetic activity through complex mechanisms. Hypoxemia stimulates the peripheral arterial chemoreceptors in the carotid bodies, triggering reflex increases in sympathetic activity.[41,42] Hypercapnia stimulates the peripheral and the central chemoreceptors located in the region of the brainstem, also increasing sympathetic activity.

Both hypoxemia and hypercapnia increase ventilation, which, acting through thoracic afferents, buffers the increases

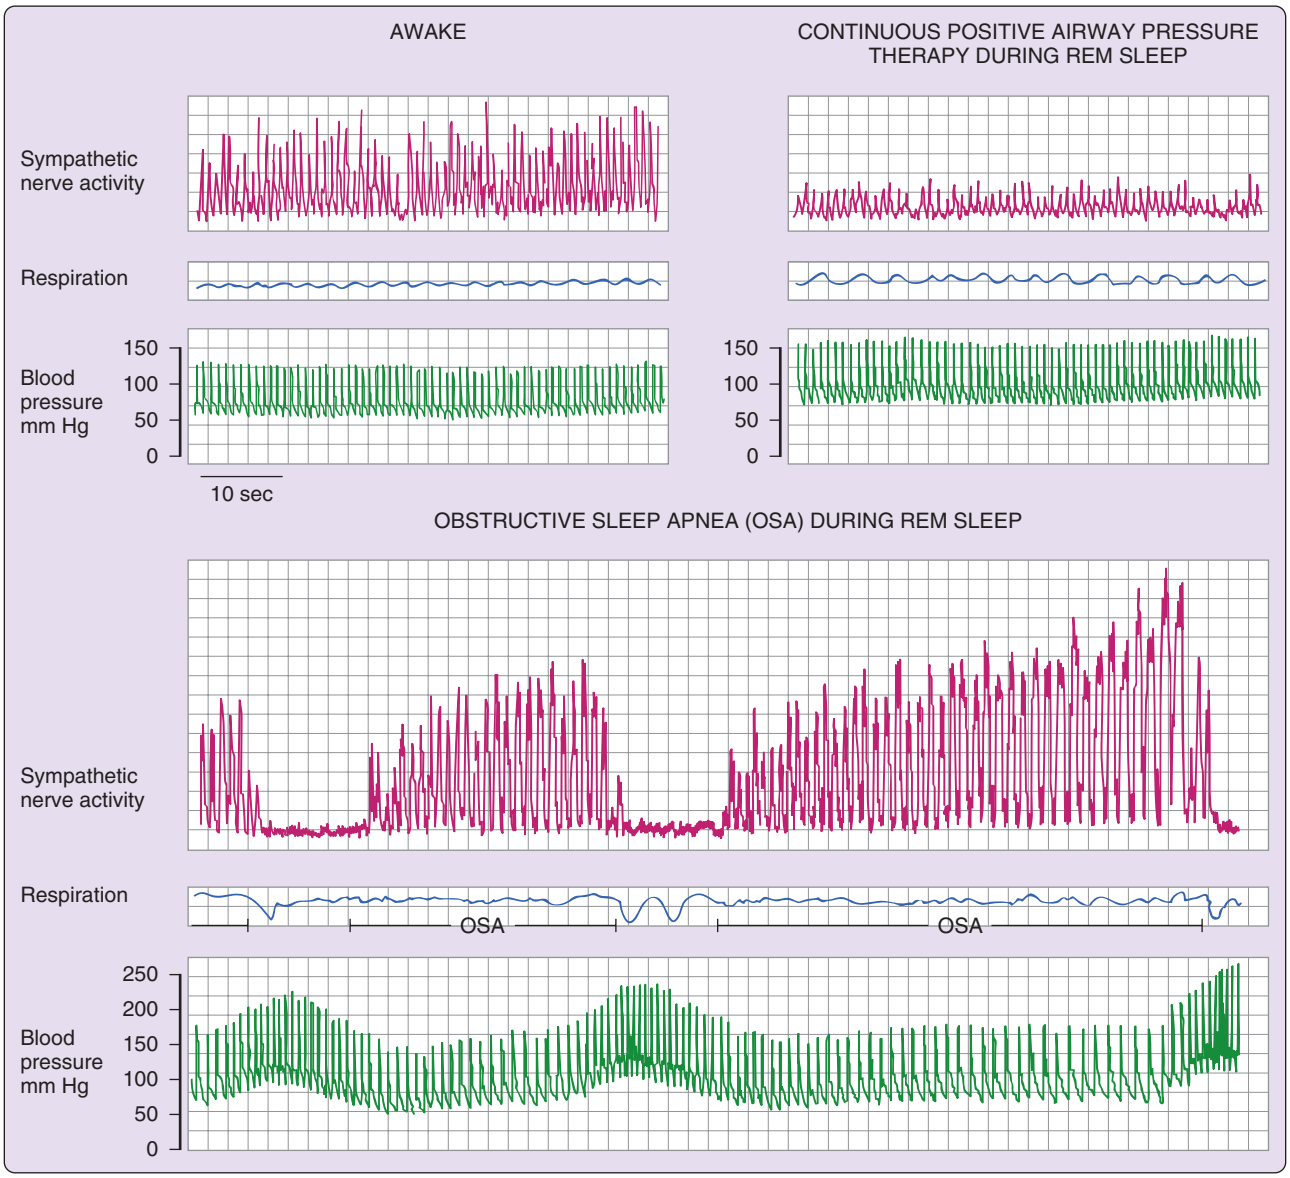

Figure 126-2 Recordings of sympathetic nerve activity, intraarterial blood pressure, and breathing in a normotensive patient with obstructive sleep apnea (OSA) during resting normoxic wakefulness (*top left*). The patient was free of any other overt cardiovascular disease and on no medications. Note the high levels of sympathetic nerve traffic even in the absence of apneic events. During REM sleep (*bottom*), the repetitive hypoxemia and hypercapnia elicit chemoreflex-mediated sympathetic activation and vasoconstriction. At the end of apneas, with increases in cardiac output and severe vasoconstriction, intraarterial blood pressure can reach levels from 130/60 mm Hg during wakefulness to a peak of 220/130 mm Hg during apneas. At the end of apneas, there also is abrupt inhibition of sympathetic traffic because of the increase in blood pressure acting through the baroreflexes and the sympathetic inhibitory effects of the thoracic afferents. After treatment of OSA with continuous positive airway pressure (*top right*), there is a marked reduction in sympathetic traffic and in blood pressure. (From Somers VK, Dyken ME, Clary MP, et al. Sympathetic neural mechanisms in obstructive sleep apnea. *J Clin Invest* 1995;96:1897–904.)

in sympathetic drive during hypoxemia and to a lesser extent during hypercapnia.[41,42] Thus, when hypoxemia or hypercapnia occurs during apnea, the absence of ventilatory inhibition results in a potentiation of sympathetic activation and consequent vasoconstriction and blood pressure surges. In this context, and especially when there are potentiated chemoreflex responses to hypoxemia-hypercapnia,[43,44] the sympathetic and consequent pressor responses to hypoxemia-hypercapnia, particularly in the absence of inhibitory effects of breathing, are marked.

Nighttime sympathetic activation carries over into daytime wakefulness. Repetitive hypoxemia may be implicated because after 2 weeks of chronic intermittent hypoxemia, healthy normal subjects manifested an increase in sympathetic outflow, together with increased chemoreflex gain and blunted baroreflex function.[45]

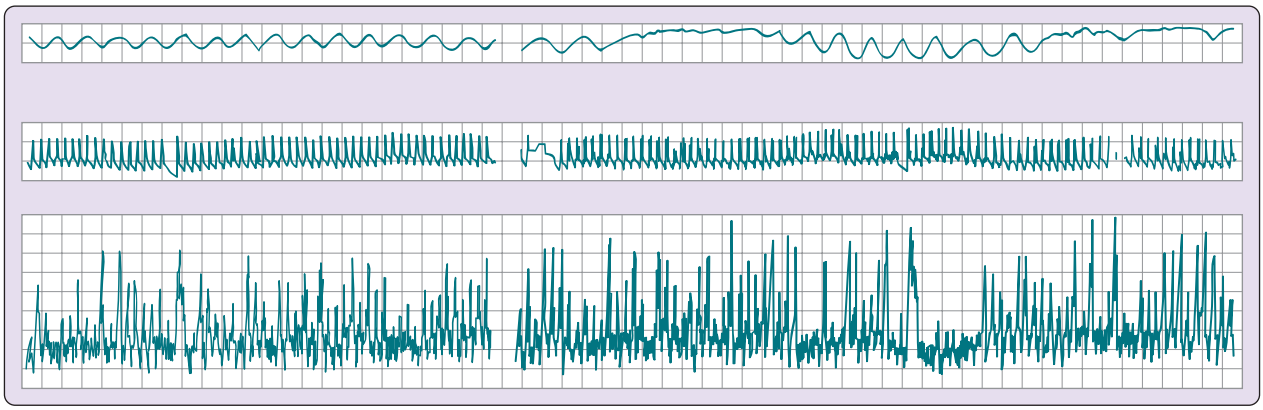

Figure 126-3 Recordings of breathing (*top*), beat-by-beat blood pressure (*middle*), and muscle sympathetic nerve activity (MSNA) (*bottom*) in a patient with severe congestive heart failure, during normal breathing on the *left* and during Cheyne-Stokes breathing on the *right*. Oxygen saturation was 94% during normal breathing and oscillated between 97% and 90% during Cheyne-Stokes breathing. MSNA total burst amplitude increased from 1533 arbitrary units per minute during normal breathing to 1759 arbitrary units per minute during Cheyne-Stokes breathing. Mean blood pressure was 70 mm Hg during normal breathing and peaked at 82 mm Hg during the hyperventilation that followed central apnea. Patients with heart failure have high levels of sympathetic drive even during normal breathing. During central apneas, there is a modest but significant further increase in sympathetic activity. (From Van de Borne P, Oren R, Abouassaly C, et al. Effect of Cheyne-Stokes respiration on muscle sympathetic nerve activity in severe congestive heart failure secondary to ischemic or idiopathic dilated cardiomyopathy. *Am J Cardiol* 1998;81:432–6.)

Alveolar Hypoxia-Hypercapnia and Pulmonary Arteriolar Vasoconstriction

Alveolar hypoxia, in part through release of endothelin, and hypercapnia cause pulmonary arteriolar vasoconstriction and hypertension, which could adversely affect right ventricular function (see Chapter 127).

Hypocapnia

Episodes of hyperpnea after apneas and hypopneas result in hypocapnia. Hypocapnia may impair myocardial oxygen delivery and uptake by coronary artery vasoconstriction[45] and shifting of the oxygen-hemoglobin dissociation curve to the left. Hypocapnia may also contribute to arrhythmogenesis.

Arousals, Shift to Light Sleep Stages, and the Autonomic Nervous System

Compared with wakefulness, the balance of activity of sympathetic and parasympathetic nervous system reverses in normal sleep.[46,47] Normally, there is a progressive reduction in sympathetic nerve traffic, heart rate, and blood pressure during the deepening stages of non–rapid eye movement (NREM) sleep, such that sympathetic activity, heart rate, and blood pressure in stage 4 sleep are substantially lower than during supine resting wakefulness.[46,47] During phasic rapid eye movement (REM) sleep, there is an abrupt increase in sympathetic activity, resulting in intermittent and brief surges in blood pressure and heart rate. On average, blood pressure and heart rate during REM sleep are similar to levels recorded during wakefulness. Thus, during normal sleep, there is a well-regulated pattern of alteration in autonomic and hemodynamic measures, modulated by changes in sleep stage. These organized responses to normal sleep are disrupted in patients with sleep-related breathing disorders, both obstructive and central sleep apnea. Sleep architecture is dramatically altered in patients with OSA-hypopnea and also in patients with heart failure and central sleep apnea. There is a shift to light sleep stages. Most important, however, apneas and hypopneas commonly result in arousals that are also associated with an increase in sympathetic activity and a decrease in parasympathetic activity,[47,48] and increasing blood pressure and heart rate. In OSA, arousals occur at the end of the apnea and with resumption of breathing. In patients with central sleep apnea and Hunter-Cheyne-Stokes breathing pattern, arousals occur at the peak of hyperventilation.

In addition to arousals, sleep-related breathing disorders may increase sympathetic activity by hypoxemia, hypercapnia, and changes in ventilation, as noted previously.

There are multiple adverse cardiac consequences of sympathetic activation. These include increased systemic vascular resistance and left ventricular afterload, venoconstriction with increased right ventricular preload, increased myocardial contractility, hypertrophy, tachycardia, and arrhythmias. Furthermore, increased myocardial norepinephrine may cause myocyte toxicity and apoptosis.[49,50]

Central sleep apnea and OSA increase sympathetic activity as measured by either microneurography or blood and urinary norepinephrine levels.[51-56] Treatment of obstructive[54-56] and central sleep apnea[52,57] decreases sympathetic activity, with important implications. First, with regard to central sleep apnea in heart failure, increased sympathetic activity is associated with poor survival; therefore a reduction in sympathetic activity should have favorable prognostic implications. OSA causes nocturnal increases in sympathetic activity and blood pressure, which carry over into the daytime. OSA is a known cause of hypertension, and in some patients blood pressure decreases relatively quickly with effective treatment of OSA with CPAP (see Chapter 127).

In summary, pathophysiologic consequences of sleep-related breathing disorders, such as increased periods of wakefulness (interruption insomnia), arousals, hypoxemia, and hypercapnia, collectively contribute to increased sympathetic activity.

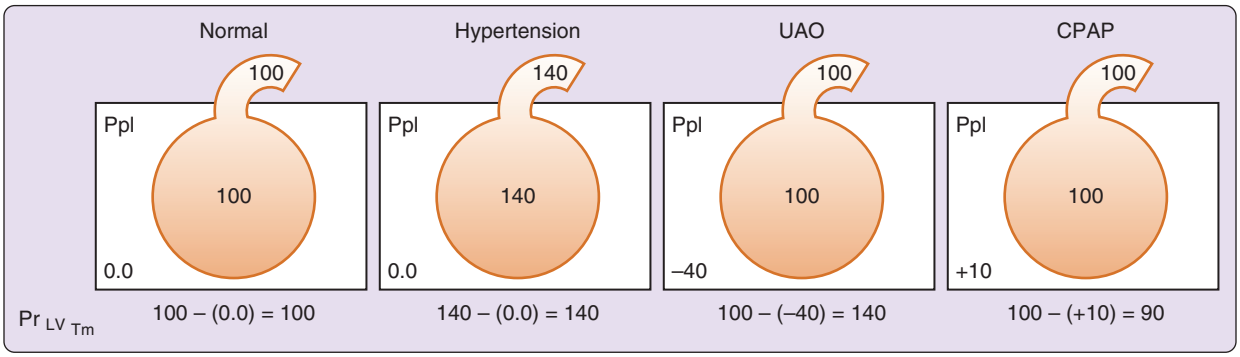

Figure 126-4 Transmural (Tm) pressure (Pr) of the left ventricle (LV) during systole. Because of an obstructive apnea (upper airway occlusion [UAO]), a negative pleural pressure (Ppl) of –40 mm Hg is generated. This increases left ventricular transmural pressure from 100 to 140 mm Hg, which is equivalent to an increase in systolic aortic blood pressure from 100 to 140 mm Hg. Note the reduction in left ventricular transmural pressure with application of nasal continuous positive airway pressure (CPAP). (Modified from Javaheri S. Sleep-related breathing disorders in heart failure. In: Mann DL, editor. *Heart failure: a companion to Braunwald's heart disease.* Philadelphia: Saunders; 2003. p. 480.)

Exaggerated Negative Intrathoracic Pressure and Its Consequences

Large negative intrathoracic pressures are generated during episodes of obstructive apnea. In central sleep apnea, relatively large negative pressure deflections occur during hyperpnea, particularly in the face of less compliant (stiff) lungs (due to heart failure). However, pleural pressure changes are usually more pronounced in obstructive than in central sleep apnea.

A number of studies have addressed the cardiovascular consequences of both negative and positive pressure deflections affecting right and left ventricular function.[58,59] Negative intrathoracic pressure increases the transmural pressure (pressure inside minus pressure outside) (Figure 126-4) of the intrathoracic vascular structures, including aorta, pulmonary vascular bed, atria, and ventricles.

According to Laplace's law, increased transmural myocardial pressure increases wall tension and myocardial oxygen consumption. Furthermore, negative intrathoracic perivascular pressure could increase extravascular lung water by favoring fluid transudation across the pulmonary microvascular bed and by diminishing lymph outflow from the lung.[60] This may account in part for cases of flash pulmonary edema reported in OSA, and sleep apnea may contribute to excess lung water and pulmonary edema in congestive heart failure. In addition, decreased intrathoracic pressure increases venous inflow, resulting in increased right ventricular diastolic filling, which in turn may decrease left ventricular compliance and volume, a phenomenon called ventricular interdependence. Application of nasal CPAP to treat sleep apnea, both obstructive and central, reduces transmural pressure by two mechanisms. First, and most important, it decreases or eliminates apneas, desaturation, and arousals, which as noted previously collectively increase sympathetic activity and result in cyclic surges in arterial blood pressure. Second, nasal CPAP not only attenuates steep surges in intrathoracic pressure but also actually increases the pleural pressure, thus decreasing transmural pressures across intrathoracic structures (see Figure 126-4).

ACUTE HEMODYNAMIC EFFECTS OF SLEEP APNEA

The circulatory responses to individual apneas and hypopneas are governed by the interaction of stresses and physiologic consequences described previously.[61,62] Hemodynamic changes are related to development of hypoxemia, hypercapnia, presence or absence of breathing, changes in intrathoracic pressure, and the consequent mechanical effects.

Hemodynamic changes have been best studied in human OSA.[61,63,64] The evolution of a cycle of apnea and recovery is complex and represents an unsteady hemodynamic state. For these reasons, hemodynamic changes occur during the course of an apnea, and these changes are different from those occurring during the immediate or late postapneic periods. During recovery, arousals and ventilation further affect hemodynamics. Cyclic changes in heart rate and systemic and pulmonary arterial blood pressure paralleling periodic breathing occur commonly.[61,63-66] In some patients, there is a very clear and progressive bradycardia toward the end of apnea, with abrupt development of tachycardia with resumption of breathing, because of the vagolytic effects of lung inflation and arousals. This manifests as a pattern of repetitive bradycardias or tachycardias during sleep, which may be evident on Holter monitoring and may signify the presence of OSA. In experimental sleep apnea, decreases in heart rate are more severe during central than obstructive apnea, reflecting lack of activation of thoracic afferents.[62]

The bradycardias may be especially severe,[65,66] and they are elicited because of activation of the diving reflex by the combination of hypoxemia and apnea. Episodes of up to 10 seconds or more of sinus arrest may occur because of the chemoreflex-mediated vagal activation. The consequent absence of perfusion, because of asystole, may have implications for patients with preexisting severe cerebral or cardiac ischemia.

At the termination of obstructive apneas, there are surges in blood pressure. This cyclic change in blood pressure is one of the most consistent hemodynamic findings in patients with OSA. Multiple mechanisms are involved. During apnea, the

increased hypoxemia and hypercapnia, acting through the chemoreflexes, progressively elicit sympathetic activation and vasoconstriction.[53] With resumption of breathing, because of the inspiratory increase in right ventricular filling, stroke volume may increase. Vagolytic effects of inspiration result in tachycardia. The increased stroke volume and heart rate result in an increased cardiac output entering a vasoconstricted peripheral circulation, with consequent acute increases in blood pressure.[53] However, just after termination of an obstructive apnea, there is abrupt inhibition of sympathetic activity to the peripheral blood vessels, in part because the deep breathing inhibits sympathetic activity through thoracic afferents and in part because of baroreflex inhibition of sympathetic activity secondary to the postapneic blood pressure surge. Nevertheless, despite the interruption in sympathetic nerve traffic, vasoconstriction persists for several seconds after termination of the sympathetic nerve discharge because of the kinetics of norepinephrine uptake, release, and washout at the neurovascular junction.

Another consistent finding is a mild reduction in stroke volume during obstructive apnea, which has been documented using noninvasive techniques for measuring beat-to-beat cardiac output.[61] This probably results from a decrease in left ventricular preload and an increase in afterload. Changes in stroke volume after termination of the apnea depend on where in the recovery cycle it is being measured.[61]

Obstructive Sleep Apnea, Left Ventricular Dysfunction, and Heart Failure

The relationship between central sleep apnea and heart failure is discussed in Chapter 129. In this section, we review OSA as a cause of heart failure.

Obstructive Sleep Apnea and Systolic Heart Failure

In a canine model mimicking severe OSA,[67] within a 1- to 3-month period of exposure to apneas during sleep, left ventricular systolic dysfunction developed. Left ventricular ejection fraction, measured during the daytime, decreased significantly because of an increase in left ventricular systolic volume.

In humans, there are two kinds of studies relating left ventricular systolic dysfunction and OSA—first, studies in which patients with OSA have been assessed for the presence of left ventricular dysfunction,[68-71] and second, studies in patients with established left ventricular systolic dysfunction who have been assessed to determine the prevalence of OSA.[72,73] In some studies,[74-75] changes in left ventricular ejection fraction in response to treatment for OSA have also been described.

Results of studies assessing left ventricular systolic function in OSA patients are conflicting.[68-70] However, in the two studies[69,70] in which technetium-99m was used to assess left ventricular systolic function, OSA was associated with left ventricular systolic dysfunction. Use of radionuclide ventriculography to assess left ventricular function is important because in obese subjects, echocardiography, which has been used in some studies, may be associated with technical difficulties.

Alchanatis and colleagues[69] studied 29 patients with severe OSA (apnea-hypopnea index [AHI] greater than 15/hour; mean AHI, 54/hour; lowest arterial oxygen saturation, 62%) and 12 control subjects (AHI, 9/hour; lowest saturation, 92%). The subjects were without known cardiovascular disease. The mean left ventricular ejection fraction was significantly lower in patients with OSA compared with the control group (53% vs. 61%; $P < .003$). Six months after treatment with CPAP, left ventricular ejection fraction increased significantly to 56% ($P < .001$). Left ventricular diastolic dysfunction also improved significantly (see later).

In a large study[70] of 169 patients with OSA (AHI greater than 10/hour; mean AHI, 47/hour), 13 subjects (8%) had left ventricular systolic dysfunction (range, 32% to 50%). Left ventricular systolic dysfunction was not the result of ischemic disease as evidenced by echocardiography and dipyridamole stress testing. In seven patients who were treated for OSA (six with CPAP and one with upper airway surgery), 1 year after therapy, mean left ventricular ejection increased significantly from 44% to 63%.[70]

In the cross-sectional analysis of more than 6000 patients enrolled in the Sleep Health Heart Study,[71] the presence of OSA increased the likelihood of having a history of heart failure by an odds ratio of 2.5. Furthermore, there was a significant dose-dependent correlation between AHI and the prevalence of heart failure.

In studies of patients with established left ventricular systolic dysfunction undergoing polysomnography (reviewed in Chapter 129), the prevalence of OSA, defined as an AHI of at least 15/hour, ranged from 12% to 32%.[76] This wide range is not particularly surprising. The prevalence depends on a number of factors, including the number of obese patients with heart failure enrolled in each study and the different polysomnographic criteria used by various investigators for diagnosis of OSA. Another important issue is the difficulty in accurately classifying hypopneas into central versus obstructive, which is a determinant of prevalence of the phenotype of sleep-disordered breathing.

In a prospective study[72] of 81 patients with known systolic dysfunction and in whom no question was asked regarding snoring or other symptoms associated with OSA, 11% had OSA, with a mean AHI of 36/hour and a lowest arterial oxygen saturation of 72%. In a retrospective study[73] of 450 patients with systolic dysfunction who were referred for a sleep study because of snoring and other symptoms of sleep apnea, 32% had OSA. From the aforementioned studies, however, it cannot be determined whether OSA preceded heart failure. Yet, as is discussed later, treatment of OSA with nasal CPAP increases left ventricular ejection fraction,[74,75] indicating that OSA contributes to worsening of left ventricular systolic dysfunction.

The mechanisms by which OSA may impair left ventricular systolic function are multiple. Hypoxemia plays a critical role, both by impairing myocardial contractility and through a host of neurohormonal mechanisms. In addition, increases in left ventricular wall stress and transmural pressure occur because of additive effects of the excess negative juxtacardiac pressure (during obstructive apneas) and development of hypertension.

The effects of positive airway pressure therapy on left ventricular ejection fraction in patients with OSA and systolic heart failure have been reported in five randomized clinical trials, two of which were double blind (Table 126-1). In three of the studies in which CPAP was used, including the only two double-blind randomized clinical trials, the rise in left ventricular fraction was minimal or not at all. It should be

Table 126-1 Effects of Positive Airway Pressure Therapy on Left Ventricular Ejection Fraction in Patients with Obstructive Sleep Apnea and Systolic Heart Failure

noted, however, that in at least two of these studies compliance with CPAP was also limited. In the two open studies in which compliance hours with CPAP were more than those in the double-blind studies, ejection fraction increased between 5% and 9%. In one open randomized clinical trial of CPAP versus a bilevel device, the ejection fraction increased significantly only with bilevel therapy.

Obstructive Sleep Apnea and Diastolic Heart Failure

Isolated left ventricular diastolic heart failure with relative preservation of left ventricular systolic function is the most common form of heart failure in elderly subjects. The pathophysiologic consequences of this form of heart failure relate to a hypertrophied, noncompliant left ventricle, shifting the pressure-volume curve upward and to the left. Therefore, for a given left ventricular volume, left ventricular end-diastolic pressure increases, resulting in elevated left atrial and pulmonary capillary pressure and in pulmonary congestion and edema.

As noted previously, hemodynamic studies[63,64] of patients with OSA have documented that pulmonary capillary pressure increases during the course of an obstructive apnea, indicating development of diastolic dysfunction. During obstructive apnea, left ventricular transmural wall tension increases because of an increase in aortic blood pressure and a simultaneous decrease in juxtacardiac pressure. Furthermore, hypoxemia may impair left ventricular relaxation, further impairing diastolic function.[77] Repeated exposure to nocturnal hypertension and hypoxemia and consequent development of OSA-induced systemic hypertension and increased left ventricular mass may also contribute to left ventricular diastolic dysfunction.

Most studies show that OSA is associated with an increase in left ventricular mass,[78-81] and suggest that the OSA-related cardiac structural changes may resolve with CPAP treatment.[80] An early study[78] reported that OSA may cause left ventricular hypertrophy even in the absence of daytime systemic hypertension. This finding was later supported by another study[79] comparing patients with OSA (AHI >20/hour) and those without OSA (AHI <20/hour).

In the largest study,[81] consisting of 2058 Sleep Heart Health Study participants, left ventricular mass was associated with both apnea-hypopnea and hypoxemia indexes after adjustment for age, sex, ethnicity, study site, body mass index, smoking, systolic blood pressure, antihypertensive medication use, diabetes mellitus, myocardial infarction, and alcohol consumption. Although there are considerable data[72,73,82] regarding the prevalence of sleep apnea in patients with systolic heart failure (reviewed by Javaheri[76]), the prevalence of OSA in diastolic heart failure has been studied only in one large systematic study.[83] Bitter and colleagues evaluated 244 consecutive patients (87 women) with heart failure with a preserved ejection fraction (HFpEF). All underwent polygraphy, right heart catheterization, and echocardiography. The two major causes of HFpEF were systemic hypertension (44%) and coronary artery disease (33%). Forty-eight percent had an AHI of 15 or more per hour, a prevalence similar to that seen in patients with heart failure with a reduced ejection fraction (HFrEF). Among patients with an AHI of 15/hour or more, 23% had central sleep apnea. Consistent with the observation in HFrEF, patients with HFpEF and central sleep apnea had lower Pco_2 and higher left ventricular end-diastolic and pulmonary capillary wedge pressure than OSA patients.

As noted earlier, isolated diastolic heart failure is highly prevalent in elderly subjects. Furthermore, elderly subjects have a high prevalence of OSA. It is speculated that OSA could be the cause of diastolic heart failure, or the presence of OSA could contribute to the worsening of left ventricular diastolic dysfunction. In this regard, a preliminary study reported that treatment of OSA improves left ventricular diastolic dysfunction,[69] an observation confirmed by the only randomized, placebo (sham CPAP)-controlled trial[80] showing that after 12 weeks on effective CPAP therapy, there was a significant increase in E/A ratio (the ratio of early to late diastolic filling) and a significant decrease in isovolumic relaxation and mitral deceleration. These observations are similar

to the improvement seen in systolic function when patients with heart failure and OSA are treated with CPAP (see Table 126-1).[74-76]

Arrhythmias in Obstructive Sleep Apnea

Obstructive Sleep Apnea Predisposing to an Arrhythmogenic Substrate

Repetitive nocturnal apneas elicit severe derangements in cardiovascular homeostasis. Hypoxemia, hypercapnia, acidosis, adrenergic activation, increased afterload, and rapid fluctuations in cardiac wall stress would reasonably be expected to be conducive to tachycardia-brachycardia oscillations and atrial and ventricular arrhythmias (Figures 126-5 and 126-6). A variety of atrioventricular arrhythmias, including complete heart block and ventricular asystole during sleep, have been observed in patients with OSA[84-86] and have been eliminated by either tracheostomy or use of nasal CPAP.[84,85] Profound OSA-induced arrhythmias can occur in the absence of any major structural abnormalities in the conduction system.[87]

Although the normal heart would be less likely to manifest malignant arrhythmias in the setting of severe obstructive apnea, the ischemic, hypertrophied, or failing heart may be more susceptible.[88] Nevertheless, activation of the diving reflex[66,89] during apneas can often elicit severe bradyarrhythmias, even in the setting of a normal myocardium and normal cardiac electrophysiologic function.

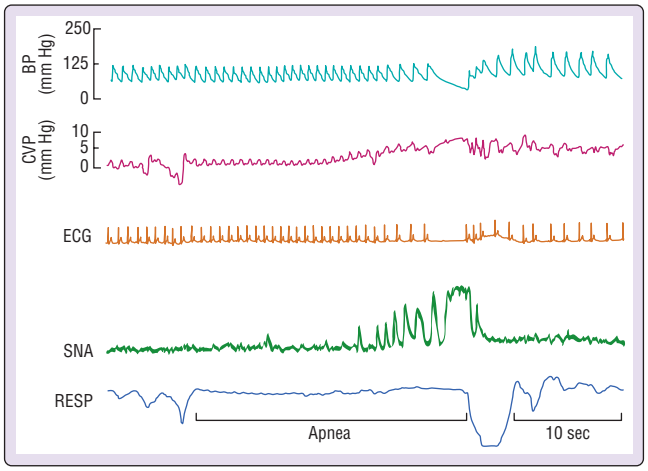

Figure 126-5 Recordings of intraarterial blood pressure (BP), central venous pressure (CVP), electrocardiogram (ECG), sympathetic nerve activity (SNA), and respiratory patterns (RESP) in a healthy subject during voluntary end-expiratory apnea. During apnea, there is a progressive increase in the RR interval on the ECG with eventual sinus pause and atrioventricular block. Accompanying this is increased sympathetic activity. The simultaneous sympathetic activation to peripheral blood vessels and vagal activation of the heart is characteristic of the diving reflex. Note the rapid increase in heart rate and sympathetic inhibition during resumption of breathing. This occurs in part because thoracic afferents activated by inspiration inhibit both sympathetic traffic and vagal cardiac drive. (From Somers VK, Dyken ME, Mark AL, Abboud FM. Parasympathetic hyperresponsiveness and bradyarrhythmias during apnea in hypertension. *Clin Auton Res* 1992;2:171–6.)

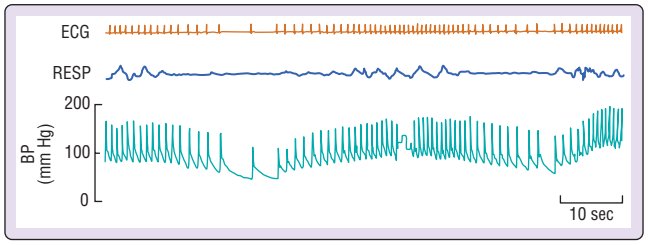

Figure 126-6 A patient with sleep apnea manifesting prolonged and profound bradyarrhythmias with absence of either atrial or ventricular contraction. The beat-by-beat blood pressure (BP) recording confirms the absence of any perfusion during the bradycardia. ECG, electrocardiogram; RESP, respiratory pattern. (From Somers VK, Dyken ME, Mark AL, Abboud FM. Parasympathetic hyperresponsiveness and bradyarrhythmias during apnea in hypertension. *Clin Auton Res* 1992;2:171–6.)

Tachycardia-Bradycardia Oscillations

Patients undergoing Holter monitoring may be noted to have repetitive cyclic episodes of tachycardias and bradycardias during the night.[90,91] These cyclic fluctuations may be attributable to obstructive apneas, although this cannot be confirmed because standard Holter monitoring does not incorporate simultaneous measurements of either breathing pattern or oxygen saturation.

These oscillations in cardiac rate are for the most part explained by changes in cardiac autonomic drive related to breathing pattern. During the course of apnea, incremental hypoxemia elicits the diving reflex so that bradycardia becomes progressively more marked. With termination of apnea, hyperpnea occurs with consequent activation of thoracic afferents, which is vagolytic.[92] Thus, with resumption of breathing, abrupt lung inflation interrupts vagal drive to the heart, resulting in rapid-onset tachycardia. Furthermore, increased cardiac-bound sympathetic drive and withdrawal of parasympathetic activity because of arousals should also contribute to the tachycardia seen with termination of obstructive apnea. It is interesting that tachycardia persists even though blood pressure increases strikingly with termination of apnea. The vagolytic effects of inspiration and the arousal-associated changes in the autonomic nervous system not only interrupt the chemoreflex-mediated cardiac vagal drive but also blunt the expected cardiac vagal drive that would occur secondary to baroreflex activation by the postapneic surge in blood pressure.

Because of the repetitive nature of nocturnal apneas, Holter or other electrocardiographic monitoring at night manifests as a tachycardia-bradycardia pattern. This cardiac rate oscillation is less apparent in patients with autonomic dysfunction, such as patients with long-standing diabetes or cardiac transplant recipients with denervated hearts. Although the changes in cardiac rate are predominantly reflex mediated, breathing-related changes in cardiac filling, as well as rapid changes in cardiac transmural pressures resulting from the Müller maneuver, also modulate heart rate by variations in stretch of cardiac conduction tissue.

Bradyarrhythmias

The primary response to hypoxia is bradycardia.[89] When hypoxia is accompanied by the action of breathing, the bradycardic response is masked because of inhibition of cardiac vagal drive by ventilation.[66] The sympathetic response to hypoxemia, although evident to some extent during breathing, is also attenuated by ventilation and is therefore potentiated during apnea.[93,94] Patients with OSA may be particularly susceptible to hypoxia-induced bradyarrhythmias because their peripheral chemoreflex is heightened, so that even during

voluntary apneas, hypoxemia elicits greater bradycardia than is seen in closely matched control subjects.[95] The arterial baroreflexes serve as an important buffer to diminish chemoreflex gain.[96] Impaired baroreflex sensitivity, such as is seen in hypertension[97] and heart failure,[98] may be associated with further increased chemoreflex drive. Thus patients with hypertension or heart failure who have OSA may manifest even greater sympathetic, and perhaps bradycardic, responses to obstructive apneas.

Profound bradyarrhythmias may have important consequences, particularly in patients with underlying cardiovascular disease. As an example, in the absence of recognition of OSA as a potential cause of the bradyarrhythmia, patients may receive pacemaker implantation, even though their cardiac conduction system may be completely normal and the bradyarrhythmias could be abolished by effective treatment with CPAP.[83,84,99] Second, prolonged episodes of asystole result in absence of perfusion (see Figure 126-6). Absence of perfusion in the setting of apnea-induced hypoxemia, occurring repetitively through the night, may have important implications for ischemic damage to end organs in which there may already be preexisting circulatory compromise.

Ventricular Arrhythmias

There is an extensive literature on sleep apnea inducing nocturnal angina and cardiac ischemia evidenced by ST-segment depression.[100,101] Thus there is a potential contribution of OSA to ventricular arrhythmias through ventricular ectopy during profound bradycardia as well as polymorphic ventricular tachycardia due to cardiac hypoxia-ischemia. These episodes occur primarily with severe desaturation,[83,84] are more common in patients with coronary heart disease,[86] and are virtually eliminated with treatment.[83,84,99] The prevalence of these arrhythmias is low in patients without premorbid cardiorespiratory disease or severe desaturation.[102]

Atrial Fibrillation

In patients cardioverted for atrial fibrillation, those with polysomnographically proven OSA who were not receiving effective CPAP treatment had a 12-month recurrence rate of 82% compared with a 42% recurrence rate in patients with OSA receiving effective CPAP.[103] In patients cardioverted for atrial fibrillation in whom no sleep study had been done, the recurrence rate was 53%. This risk for recurrence in the patients with atrial fibrillation without a previous sleep study suggests that undiagnosed OSA may be present in a large proportion of patients with atrial fibrillation. In addition, among the untreated patients with OSA, those experiencing a recurrence of atrial fibrillation had more severe nocturnal hypoxemia than those without a recurrence. Furthermore, the increased recurrence in patients with untreated OSA could not be explained by factors such as antiarrhythmic medication, body mass index, hypertension, cardiac function, or atrial size.

Mooe and colleagues[104] observed that after coronary artery bypass surgery, patients with OSA were more likely to experience postoperative atrial fibrillation. However, it is not clear whether this was explained by other variables in the patients with OSA.

In a recent longitudinal study of several thousand patients, those with OSA had an increased risk for developing new-onset atrial fibrillation compared with those who did not have OSA. This risk was evident in patients aged 65 or younger, and it was especially marked in those with more severe nocturnal hypoxemia.[105]

There are many reasons that OSA may be conducive to atrial fibrillation. Hypoxemia, presser surges, and sympathetic activation are all potential mechanisms leading to atrial fibrillation. High levels of C-reactive protein may also independently predict the development of atrial fibrillation.[106] Patients with OSA may have increased levels of C-reactive protein.[107-110] Furthermore, abrupt and dramatic changes in intrathoracic negative pressures may especially affect the atria because of their relatively thin walls compared with the ventricles. Increased pressure gradients with consequent increased atrial wall stretch, occurring repetitively through the night, may be expected to induce mechanical and electrical changes that are also conducive to atrial fibrillation.[111-113] Autonomic mechanisms may be pivotal. Animal models suggest that ganglionated plexus ablation may profoundly inhibit the development of atrial fibrillation in response to hypoxemia and apnea.[114]

About 50% of patients presenting for cardioversion have a high risk for sleep apnea compared with 30% of patients from a general cardiology clinic.[115] Even in patients with comorbid OSA undergoing pulmonary vein isolation, recurrence of atrial fibrillation is more than twofold greater in those not treated with CPAP compared with those receiving CPAP therapy.[116]

CLINICAL PEARLS

- Apnea and recovery cycles result in three basic abnormalities: alterations in blood gases, arousals, and changes in intrathoracic pressure.
- Hypoxemia-reoxygenation has deleterious effects on the cardiovascular system. This activates redox-sensitive genes, resulting in synthesis of vasoconstrictor and inflammatory mediators; increases sympathetic activity; and causes oxidative stress. These alterations have been best studied in patients with OSA.
- Untreated OSA may increase the risk for recurrence of atrial fibrillation after cardioversion.
- Sleep apnea can induce severe bradyarrhythmias, including prolonged periods of asystole and heart block, even in the setting of a normal myocardium and cardiac electrophysiologic function.
- OSA should be considered in patients who have ST-segment depression or angina occurring primarily at night.
- Heart failure may be significantly linked to the presence of either central sleep apnea or OSA.

SUMMARY

Sleep-related breathing disorders affect cardiovascular function in a variety of ways. OSA and central sleep apnea act through multiple mechanisms to elicit acute circulatory responses, which have implications for the development of chronic vascular and cardiac dysfunction. The acute responses to apnea are mediated in large part by the effects of apnea on blood gas chemistry, which exerts important cardiovascular effects directly on the myocardium and blood vessels and also acts through reflex mechanisms. Acute neural, circulatory, endothelial, inflammatory, and other responses to repetitive nocturnal hypoxemia and hypercapnia may act to induce

long-term damage to the myocardium and to the coronary and other vascular beds. With the development of functional and structural cardiovascular disease, the consequences of acute apneas are magnified. For example, severe hypoxemia in the setting of sleep apnea is more easily tolerated by an overtly healthy cardiovascular system compared with one in which myocardial ischemia or left ventricular dysfunction is present, with consequent diminished cardiovascular reserve. Small, short-term studies have suggested that effective prevention of recurrent apneas may favorably affect surrogates of cardiovascular disease outcome, such as sympathetic activity, blood pressure, and left ventricular ejection fraction. The importance of large randomized controlled trials in establishing the benefits, if any, of treating sleep apnea in patients with heart failure are highlighted by the results of the recently completed SERVE-HF Study.[117] In patients with stable systolic heart failure (LVEF ≤ 45%) and predominantly central sleep apnea, treatment with adaptive servo-ventilation (ASV) versus usual care was not accompanied by any reduction in the primary endpoint of hospitalization for worsening heart failure or mortality. This was despite a significant improvement in central sleep apnea with ASV. In fact, there was an increase in all cause mortality and in cardiovascular mortality in the treated group. It is important to note that these findings cannot be extended to similar patients with unstable heart failure, to patients with heart failure with preserved ejection fraction, or to heart failure patients with OSA.

Systemic and Pulmonary Hypertension in Obstructive Sleep Apnea

Chapter 127

F. Javier Nieto; Terry Young; Paul E. Peppard; Shahrokh Javaheri

Chapter Highlights

- Cross-sectional and prospective cohort studies in both population and clinical settings show an association between obstructive sleep apnea (OSA) and risk for systemic hypertension that appears to be independent of obesity, age, and other potential confounding factors.
- The strength, consistency, and dose-response relationship shown across studies suggest that the association is causal.
- In support of a causal relationship, recent meta-analysis of randomized trials shows that treatment with positive airway pressure results in a reduction of blood pressure among hypertensive patients with OSA that is likely to be of clinical and therapeutic significance. This effect is most pronounced in patient with baseline elevated blood pressure, those who have severe OSA, and those who are adherent to therapy.
- Using the current definition of pulmonary hypertension, about 10% of patients with OSA have mean pulmonary artery pressure of 25 mm Hg or greater. Mild pulmonary arterial hypertension may occur in patients with OSA without daytime hypoxemia or chronic obstructive pulmonary disease, although pulmonary hypertension could be more severe in the presence of chronic lung disease, heart failure, and obesity hypoventilation.
- Studies, mostly observational, suggest that treatment of OSA improves pulmonary hypertension.

Although the clinical association between obstructive sleep apnea (OSA) and hypertension has long been reported[1-3] in sleep medicine, the potential importance of OSA in patients with elevated blood pressure and cardiovascular disease is gaining recognition beyond the field of sleep research. As early as 1998, a committee of experts gathered by the World Health Organization (WHO) recognized OSA as a likely cause of secondary pulmonary arterial hypertension.[4] A few years later, the increasing evidence that OSA has a causal role in the development of hypertension was discussed in two influential taskforce statements.[5,6] Furthermore, the 2013 guidelines for the management of hypertension by the European Society of Hypertension and the European Society of Cardiology include OSA as one of the "special conditions" that need to be evaluated and treated in hypertensive patients.[7] In the United States, even though OSA was recognized as an identifiable cause of hypertension in the seventh report of the Joint National Committee for the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure,[8] surprisingly, the recently updated eighth report does not include reference to OSA—or any sleep-related disorder—in relation to hypertension management.[9]

An accurate estimate of the fraction of systemic hypertension that can be causally attributed to OSA is lacking, and data on OSA and pulmonary hypertension (PH) are sparse; however, clinical recognition of both the high prevalence of hypertension in people with OSA[10,11] and the high occurrence of OSA in hypertensive patients[12-14] is imperative. The aim of this chapter is to present the epidemiologic and clinical evidence in support of a role of OSA in systemic and PH and to describe the clinical issues in identification and treatment of patients with OSA and hypertension.

SYSTEMIC HYPERTENSION

Epidemiologic Evidence for a Role of Obstructive Sleep Apnea in Systemic Hypertension

The early observations of hypertension in patients with sleep apnea stimulated several cross-sectional clinic- and community-based studies that attempted to determine whether there was an association between OSA and hypertension that was not explained by excess body weight or other factors common to both OSA and hypertension (see Chapter 61).[11] Results were mixed, but many of the studies had methodologic shortcomings, such as inadequate sample size, flawed comparison groups, substantial measurement error, or limited statistical analysis.[15,16] Since then, findings from both population and clinical studies have shed important new light on this association.

Reports from several well-designed epidemiology studies, summarized in Table 127-1, generally show associations of polysomnography (PSG)-determined OSA and hypertension that remain significant after adjustment for potential confounding factors.[17-19] The strongest epidemiologic evidence for a causal association comes from longitudinal analyses of data from the Wisconsin Sleep Cohort Study of middle-aged state employees.[20,21] The incidence of new hypertension, defined as systolic blood pressure of at least 140 mm Hg, diastolic blood pressure of at least 90 mm Hg, or use of antihypertensive medication at follow-up, was significantly dependent on

baseline level of OSA. After considering confounding factors, the odds of developing new hypertension over 4 years was twofold greater for those with an apnea-hypopnea index (AHI) of 5 to 15 events/hour and threefold greater for those with an AHI of greater than 15 at baseline, compared with participants without OSA at baseline (i.e., AHI <1). Longitudinal analyses of OSA as a predictor of 5-year incidence of hypertension in the Sleep Heart Health Study (SHHS)[19] and 7.5-year incidence of hypertension in the Vitoria-Gasteiz (Spain) Cohort[22] did not find the same strong association as was found in the Wisconsin cohort; however, the SHHS findings were consistent with about a 50% increased risk for incident hypertension in persons with severe OSA.

Cross-sectional analyses of baseline data from three population cohorts (Southern Pennsylvania,[23] Spain,[24] and the SHHS[25]) using measurements, definitions, and statistical adjustment models similar to those used in the Wisconsin Sleep Cohort have also shown OSA to be a statistically significant risk factor for hypertension (Figure 127-1; see Table 127-1). Collectively, the relationship between OSA and hypertension has been assessed with state-of-the-art measurements in more than 10,000 men and women from the general population, and results have been generally consistent. Confidence in the validity of the findings is increased as a result of the care taken by investigators to evaluate the effects of methodologic limitations.[20,26] If the epidemiology findings do reflect a causal relationship, as is suggested by most of the population-based data, a harder look must be taken at the importance of preventing OSA or at treating even mild OSA, discussed more fully below.

The largest population study, the cross-sectional examination of OSA and prevalent hypertension of Nieto and colleagues,[22] had sufficient power to describe the strength of the association across a wide spectrum of moderate to severe OSA. The findings suggest a dose-response association between OSA and hypertension up to a moderate level of OSA severity, with the association "flattening" across the severe range (AHI >30). It is possible that a flattening threshold exists, but methodologic limitations may account for it as well. This feature may reflect a survival bias against persons with high-severity OSA and cardiovascular disease, thus potentially missing subjects with the strongest associations from the analysis, as well as greater measurement error of OSA severity at higher AHI levels. Alternatively, a flattening threshold may be due to the presence of pathophysiologic consequences of severe OSA, such as heart failure, that could reduce blood pressure. In regard to heart failure, severe OSA has been associated with left ventricular systolic dysfunction[27]; in the SHHS, there was a dose-dependent relation between AHI and prevalence of heart failure.[28] If left ventricular systolic dysfunction occurs as OSA becomes more severe, adequate left ventricular stroke volume may not be maintained to

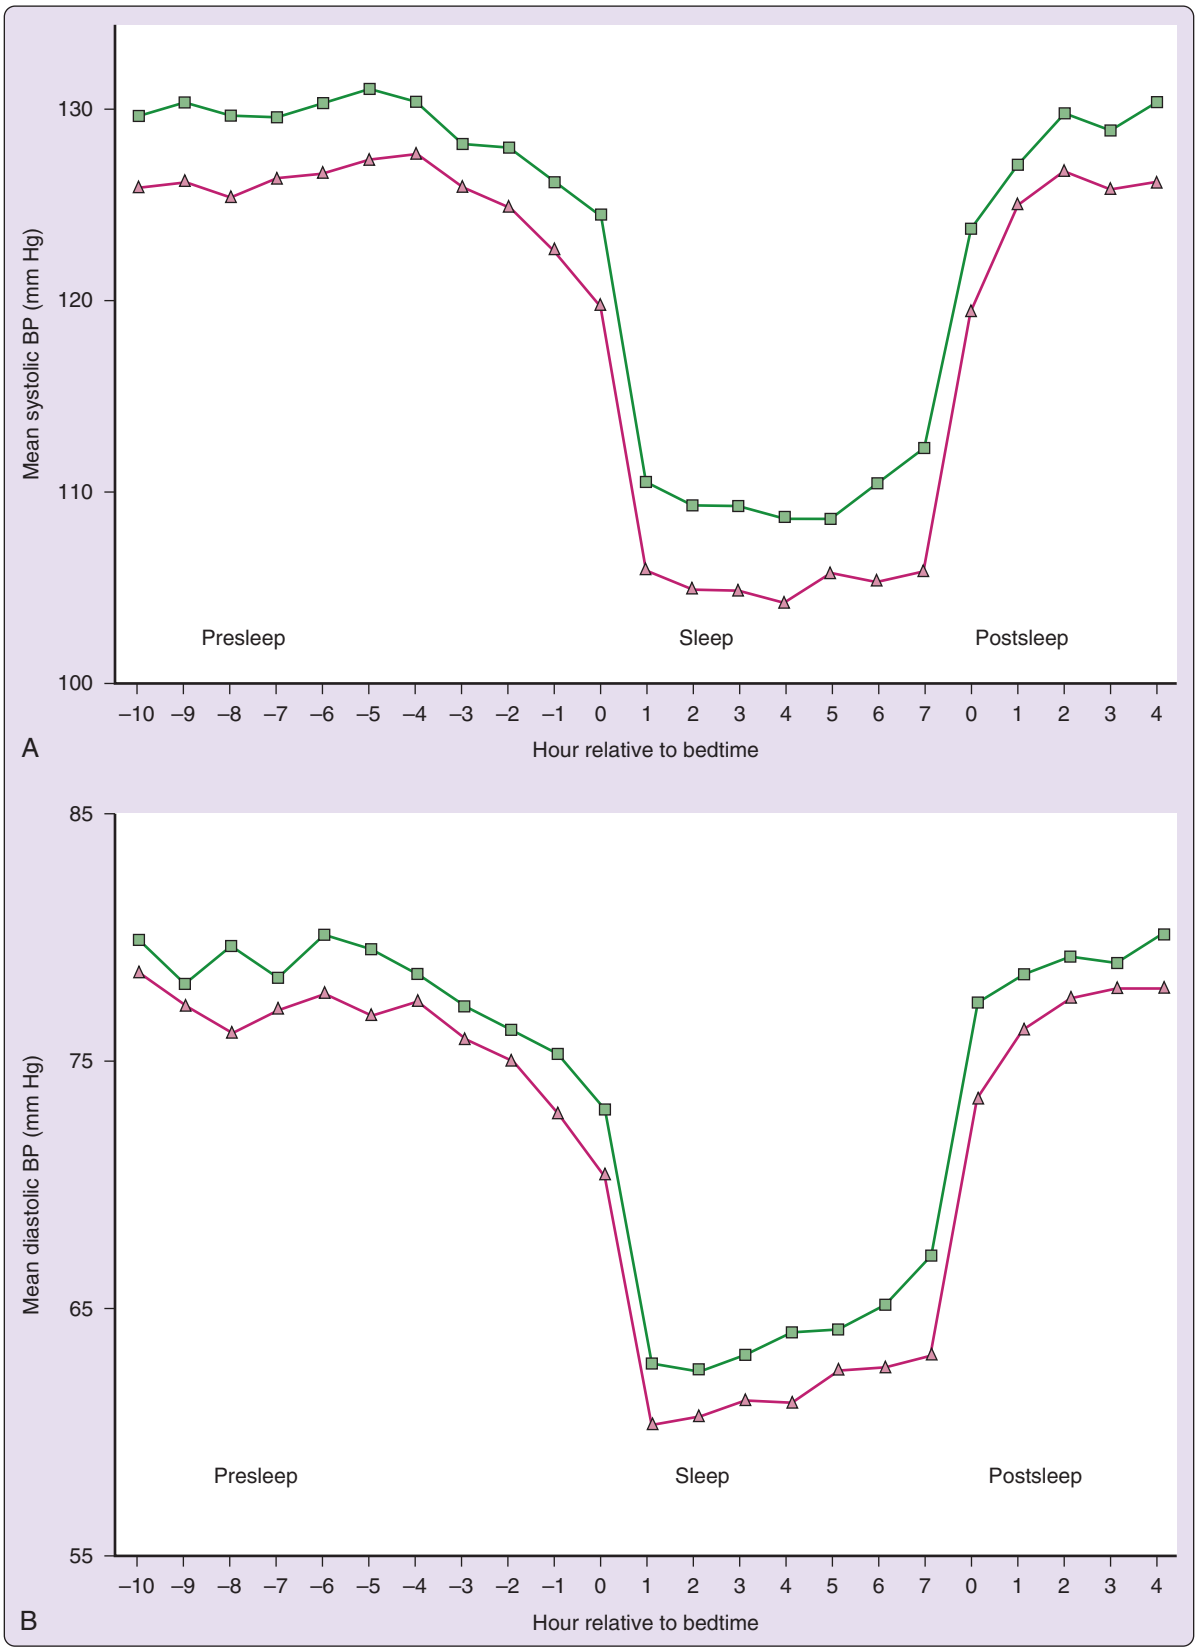

Figure 127-1 Ambulatory blood pressure (BP) during presleep, sleep, and postsleep by apnea-hypopnea index (AHI) category (Wisconsin Sleep Cohort Study). *Triangles:* AHI ≤5 events/hour; number of participants, 537. *Squares:* AHI ≥5, number of participants, 231. **A,** Systolic blood pressure. **B,** Diastolic blood pressure. Mean blood pressure values are adjusted for age, sex, and body mass index.

sustain a high blood pressure. Additionally, mechanisms mediating hypertension in OSA may be become saturated at greater OSA severity levels. In a two-arm study[29] of therapeutic and subtherapeutic positive airway pressure (PAP) in OSA, there were no changes in systemic arterial blood pressure from baseline in the subtherapeutic PAP trial arm despite a decrease in average AHI from 65 to 33. These results are consistent with a flattening of the OSA-hypertension association at greater OSA severity levels.

Obstructive Sleep Apnea and Hypertension in Population Subgroups

Determining the association of OSA with hypertension by subgroups (e.g., sex, age, ethnicity, body habitus) will increase understanding of physiologic mechanisms and may help target health care to appropriate subgroups. Most population cohort studies have reported a lack of sex differences in the association of OSA and hypertension. This message is particularly important because of past underdiagnosis and undertreatment of OSA in women; less-aggressive evaluation and treatment of OSA in women may lead to a relative survival disadvantage for them.[30]

Few studies have included sufficient population diversity to determine whether the association of OSA and hypertension varies by ethnicity. Recent population studies of OSA and hypertension in older adults have expanded the focus beyond OSA in middle age. Cross-sectional regression analyses of two large cohort studies with age ranges that include sufficient older people have suggested a negative interaction between age and AHI with respect to hypertension. Bixler and coworkers found that odds ratios (ORs) for hypertension decreased as age increased when patients with an AHI of 30 or greater were compared with those with an AHI of zero, and there was essentially no risk for hypertension associated with OSA for those 70 years and older.[23] Similar findings were reported by the SHHS: after stratifying their sample with a cutoff age of 65 years, the OR for hypertension with an AHI of greater than 30 versus an AHI of less than 1.5 was lower and not statistically significant for ages 65 years and older (OR = 1.23), compared with ages 40 to 65 years (OR = 1.64).[25] Further analysis of the SHHS data revealed that OSA was not associated with isolated systolic hypertension, the most common form of hypertension in older people.[31]

In contrast, cross-sectional analysis of the Bay Area Sleep Cohort of 129 older adults found a significant association between frequent (10 or more) apnea and hypopnea events during rapid eye movement sleep and diastolic blood pressure greater than 90 mm Hg.[32] This study of adults with a mean age of 72 years also linked occult sleep-disordered breathing to markers of cardiovascular disease. The authors concluded that a role of OSA in cardiovascular disease in older adults should not be ruled out.

Although it is possible that OSA outcomes differ in older versus younger people, methodologic difficulties arising from high comorbidity and survival bias are inherent in studying health effects of OSA in older populations and could cause a spurious age effect. Clinical practice should not be influenced by the notion that health risks of OSA in older people are lower until there are conclusive data—especially considering that even if relative risks relating OSA and hypertension are attenuated in older adults, corresponding absolute risk differences may well not be.

The prevalence of being overweight, a strong risk factor for both OSA and hypertension, is increasing worldwide. Most studies, using multiple regression analysis, have demonstrated that even after consideration of the strong associations of OSA and obesity, they both persist as independent factors in the development of hypertension.[5] However, understanding of specific mechanisms as well as precise effect sizes are limited by many analytic issues, including identification of relevant measures of body habitus, how the variables should be modeled in analyses, and the time course for OSA to have an effect on blood pressure. Adjusting for a marker of obesity (e.g., body mass index [BMI]) in multiple regression analysis of the relationship between OSA and hypertension is justified under the assumption that obesity is a confounder (i.e., obesity is a risk factor for both OSA and hypertension); however, if the relationship between OSA and obesity is bidirectional (e.g., if metabolic changes associated with OSA lead to an increase in body weight), adjustment for obesity in regression models of OSA and hypertension may lead to bias.

Furthermore, the interaction of obesity and OSA with respect to the development of hypertension is not clear. That is, does the strength of the OSA-hypertension association vary by body habitus? Findings from two of the large cohort studies have indicated that OSA is more strongly predictive of hypertension in leaner than in obese individuals: BMI was a significant modifier of the OSA-hypertension association in studies by Young and coworkers[33] and Bixler and coworkers.[23] The OR for hypertension and OSA increased in magnitude with decreasing BMI, indicating that in leaner people, those with OSA compared with those without may be at particularly high risk for hypertension. This finding has clinical implications, particularly in primary care, where sleep apnea is not likely to be suspected in nonobese patients, even in the presence of symptoms.

Obstructive Sleep Apnea and Diurnal Blood Pressure

Hypertension defined by chronic elevated daytime blood pressure is generally considered to be the outcome of interest; however, OSA-related nocturnal perturbations also include repeated spiking of pressures that exceed hypertension cutoff points (blood pressure load) and elevated average nighttime blood pressure as well as a carryover effect resulting in elevated daytime blood pressure.[5] Early studies of hemodynamics in patients with OSA involved invasive blood pressure monitoring; more recent studies of circadian patterns of blood pressure rely on ambulatory monitors that sample blood pressure at 15- to 30-minute intervals with arm cuff inflation–based methods.

Most studies with ambulatory blood pressure monitoring have been conducted on patients with sleep apnea. A Marburg study of 93 OSA patients[34] showed that the number of oxygen desaturation events per hour of presumed sleep was linearly related to both daytime and nighttime systolic and diastolic blood pressures, and it was related more strongly to nighttime pressures. In Great Britain, Davies and colleagues[35] performed ambulatory blood pressure studies on 45 pairs of sleep apnea patients and community controls matched to the patients on age, BMI, and treated hypertension. Sleep apnea patients had significantly higher diastolic pressures during the day and

night, higher systolic pressures during the night, and a notably smaller nocturnal dip.

Data from population studies with PSG and nocturnal blood pressure measures are sparse. In a preliminary study of 147 Wisconsin Sleep Cohort Study subjects,[36] OSA was consistently associated with elevated blood pressure measured by 24-hour ambulatory monitoring. Average systolic and diastolic blood pressures during wake and sleep, and systolic blood pressure load during wake and sleep, were all statistically significantly higher in the participants with mild to more severe OSA. Findings from an update with a much larger cohort sample (n = 768) are shown in Figure 127-1. Blood pressures, adjusted for confounding factors, were higher at every hour before, during, and after sleep for those with an AHI of greater than 5 versus an AHI of less than 5.

Nocturnal blood pressure relative to daytime pressure has been of special interest because studies have shown that the lack of the normal nighttime decline (nondipping) in blood pressure, usually considered to be a nighttime drop of at least 10% of the daytime pressure, is related to adverse cardiovascular outcomes independent of hypertension.[37] Findings from relatively small clinic-based samples do suggest that patients with OSA have a smaller nocturnal decline in blood pressure.[34,35,37-42] Prospective data from the Wisconsin Sleep Cohort study strengthen the evidence that acute effects of apnea and hypopnea episodes lead to a less favorable nighttime pattern of blood pressures.[43] Baseline and 7-year follow-up data from PSG and ambulatory blood pressure on a subsample of 328 participants in the Wisconsin cohort, free of nondipping at baseline, were analyzed. There was a dose-response increase in the odds of developing a pattern of nondipping in systolic blood pressure: Compared with subjects with an AHI of less than 5 at baseline, ORs, adjusted for confounding factors, were 3.1 (95% confidence interval [CI], 1.3 to 7.7) and 4.4 (95% CI, 1.2 to 16) for an AHI of 5 to 14 and for an AHI of 15 or greater, respectively.

Collectively, the ambulatory blood pressure studies do support an association between OSA and elevated blood pressure during both the nighttime and the daytime, and some studies suggest that the effect is greater during nighttime. These findings are particularly important because elevated ambulatory blood pressure has been shown to predict cardiovascular events independently of office-measured blood pressure and other cardiovascular risk factors.[44]

Blood Pressure Changes in Patients with Obstructive Sleep Apnea after Positive Airway Pressure Treatment

Studies of the effect of PAP on blood pressure have evolved from clinical observations of treated patients to sophisticated, randomized, double-blind trials, with sham PAP as the control condition and objectively measured compliance. Results from these studies are important, even though they do not necessarily directly address the basic question of whether OSA caused the initiation (incidence) of hypertension. This is because the effect of OSA on vasculature hemodynamics might be different at different stages in the natural history of OSA and hypertension, both chronic conditions evolving over a lifetime. However, even with this important caveat, clinical trial results generally show that successful treatment of OSA in patients who are also hypertensive tends to result in lower blood pressure levels.

The results of these studies are not uniformly consistent, likely because of differences in study design, sample size, patient populations, treatment regimens, and compliance from study to study. However, as reviewed in the following paragraphs, the pattern emerging from the overall body of literature on the subject, and especially when the most recent and highly powered studies are considered, strongly suggests that treatment of OSA does have a measurable effect in lowering blood pressure.

With respect to observational evidence, a prospective study that followed 55 patients (35 of whom were men) with both OSA and hypertension for 2 years,[45] a significant decrease was shown only for diastolic blood pressure (–2.2 mm Hg [95% CI, –4.2 to –0.1]), but not in systolic or 24-hour mean arterial blood pressure. Subgroup analyses, however, showed that 24-hour mean blood pressure did decrease significantly in patients with incompletely controlled hypertension at entry (–4.4 mm Hg, P = .01) as well as in those with high PAP compliance (–5.3 mm Hg, P = .01).

The predictors of change in blood pressure associated with PAP treatment in patients with OSA were examined in another observational prospective cohort study that recruited 86 patients treated for daytime sleepiness with PAP.[46] After 6 months, the average fall in 24-hour mean blood pressure was 4.9 mm Hg (95% CI, –7.1 to –2.1); the main predictors of blood pressure fall were the change in level of self-reported sleepiness and baseline BMI. These results are consistent with another observational study addressing a slightly different question: whether PAP treatment prevents new-onset hypertension. In this study, the hypertension incidence was assessed among 1889 patients who were referred for a PSG study and were free of hypertension at baseline and followed for up to 17 years (median, 12.2 years).[47] Compared with controls in this study, the adjusted hazard ratio of hypertension was 1.33 in patients with OSA who were not eligible for PAP treatment, 1.96 among OSA patients who declined PAP treatment, and 1.78 among patients not adherent to PAP (all P < .05). In contrast, patients with OSA who received PAP treatment had a statistically significant lower risk for hypertension incidence than controls (hazard ratio, 0.71; 95% CI, 0.53 to 0.94).

Evidence from randomized controlled trials has been growing in recent years, and even though not all the studies are consistent, the evidence supports the notion that PAP treatment results in a moderate but clinically significant lowering of blood pressure. Some of the early studies showed a significant lowering of blood pressure in patients with OSA, even though most of these studies did not select according to hypertension status.[29,48-50] In some of these studies, the effects were stronger or exclusively observed among the PAP-compliant patients.[29,49]

Other randomized trials, however, have shown minimal or nonsignificant effects of PAP in blood pressure.[51-56] Aside from the small sample size and limited statistical power, a potentially important limitation of some of these studies is that many of the patients included in the trial were not hypertensive, and thus there might be limited room for a lowering of blood pressuring effect as well as limited compliance with the treatment.

To address the latter, Hla and coworkers[57] investigated the effect of 3 weeks of PAP on blood pressure in hypertensive subjects with and without OSA to control for effects that PAP

might have on blood pressure independent of an effect from elimination of apnea and hypopnea events. Newly diagnosed, unmedicated hypertensive men from primary care settings were assessed for OSA by laboratory PSG to identify 14 men with an AHI of greater than 5 (mean AHI, 25) and 10 men with an AHI of less than 5 (mean AHI, 1). The OSA group received therapeutic PAP, and the non-OSA group received PAP at a pressure of 5 cm H_2O for 3 weeks. Ambulatory blood pressure monitoring indicated that nocturnal blood pressure in the OSA group dropped significantly with PAP (–10.3 mm Hg systolic, –4.5 mm Hg diastolic) but was essentially unchanged with PAP in the non-OSA group. There was a greater but statistically nonsignificant difference in blood pressure drop in the OSA versus non-OSA group in daytime blood pressure (–2.4 mm Hg systolic, –0.6 mm Hg diastolic).

In a meta-analysis of 16 trials conducted between 1996 and 2006 and including a total of 818 patients,[58] a small but statistically significant mean net change in systolic (–2.5 mm Hg; 95% CI, –4.3 to –0.6) and diastolic (–1.8 mm Hg; 95% CI, –3.0 to –0.6) blood pressures was observed. Net reductions in blood pressure were not statistically different between daytime and nighttime. This meta-analysis had some limitations that might reduce its generalizability (e.g., most studies included predominantly or exclusively obese middle-aged men, some studies were not blinded, and compliance was often limited). Furthermore, the duration of PAP treatment in all these studies was relatively short, ranging from 2 to 24 weeks[58]; longer treatment may be associated with different effects on systemic blood pressure.

These limitations notwithstanding, it is remarkable that a more recent meta-analysis including 28 studies published between 1980 and 2012 (representing 1948 patients) obtained results that were highly consistent with those of the previous study[59]: The weighted mean difference in diurnal systolic blood pressure (–2.58 mm Hg; 95% CI, –3.57 to –1.59 mm Hg) and diastolic blood pressure (–2.01 mm Hg; 95% CI, –2.84 to –1.18 mm Hg) both significantly favored PAP treatment over control arms. The effects were stronger in studies that included patients who were younger, were sleepier, had more severe OSA, and exhibited a higher degree of adherence to PAP.[59] The estimated effects were even stronger (3- to 5-mm Hg decrease in 24-hour blood pressure values) in another meta-analysis focusing on studies of resistant hypertension[60] and in another recent multicenter study in Spain.[61]

In one of the largest and more carefully conducted randomized controlled trials to date, Gottlieb and colleagues recruited 318 patients with cardiovascular disease or multiple cardiovascular risk factors from cardiology practices, that is, patients who were presumably subject to proper blood pressure control.[62] Among the 281 patients who had 24-hour blood pressure data at baseline and 12-week follow-up in this study, mean 24-hour arterial blood pressure was significantly lower in the group receiving PAP than in the control group (–2.4 mm Hg; 95% CI, –4.7 to –0.1; $P = .04$). Remarkably, the estimated reduction in blood pressure achieved by PAP is almost identical to that estimated in the two meta-analyses described previously.[58,59]

The focus of most of the previous studies and meta-analyses was primarily on changes in blood pressure associated with different types and length of PAP treatment in a variety of patient populations (e.g., some with OSA, some with hypertension, combinations of both). The results of one of the few randomized studies looking at the effect of PAP treatment on the *incidence* of hypertension were inconclusive.[63] In this Spanish multicenter study, 725 patients with OSA but without baseline hypertension and symptoms of daytime sleepiness were randomized to PAP treatment or no active treatment and followed up for a median of 4 years; even though a slight reduction (17%) in the combined incidence of hypertension and cardiovascular events was observed in the study, the result was not statistically significant, probably owing to the small number of events and limited statistical power.

A possible mechanism that might explain the putative improvement in blood pressure associated with PAP treatment is an improvement in vascular function. OSA may increase sympathetic activity, which is reversed by therapy with PAP. Other mechanisms are likely to be involved. In a randomized controlled trial including 29 patients with OSA associated with desaturation, compared with placebo, 6 weeks of PAP was associated with an improved forearm blood flow in response to both endothelial and non–endothelium-dependent stimuli.[64] Previous non–placebo-controlled studies have also demonstrated an association between PAP and either biochemical markers of vascular function[65] or forearm flow-mediated dilation measures.[55] Overall, the results of both observational and experimental studies on the effect of PAP therapy are consistent with evidence from both animal and human epidemiologic (particularly longitudinal) studies showing OSA as a possible cause of hypertension (see above). All this evidence, coupled with biologic plausibility studies defining mechanisms linking OSA to hypertension and the reversal of such mechanisms with PAP, support the hypothesis of a contribution of OSA to elevated blood pressure.

Clinical Relevance of the Role of Obstructive Sleep Apnea in Hypertension

In contrast to the state of evidence two decades ago, findings in support of a role for OSA in the development of hypertension are now difficult to dismiss as spurious.[66-68] Translating these findings to clinical settings, however, poses challenges. These findings, as well as new guidelines on hypertension detection and treatment, support case-finding for OSA in patients with hypertension in primary care settings, but what is the next step? Although diagnosis and treatment of a patient with hypertension and symptomatic OSA are priorities, a critical and much-debated question is the course of action that should be taken if a hypertensive patient has mild OSA without daytime symptoms of sleepiness. Is treatment of mild, asymptomatic OSA without complaints of sleepiness warranted on the basis of potential cardiovascular consequences? Arguments against treatment point to the lack of conclusive data. Based on the average effect of PAP on change in blood pressure, the predicted effect on an individual is likely to be small and of uncertain clinical significance and thus would not warrant replacing antihypertensive drugs for controlling blood pressure.[69]

On the other hand, there are arguments for considering PAP treatment in nonsleepy patients with mild, asymptomatic OSA and coexisting hypertension.[70,71] Worsening of mild sleep apnea over time is likely, and cardiovascular consequences that might be attributable to severe OSA could be prevented.[71] Some data suggest that PAP treatment for

patients with OSA and drug-resistant hypertension may be of benefit in lowering blood pressure.[60,72] Also, as noted by Gottlieb and colleagues,[62] even an average reduction of 2 mm Hg in systolic blood pressure—the approximate mean effect of PAP treatment from meta-analyses of OSA treatment trials described previously—might be expected to substantially lower stroke rates (by ~10%) and heart disease mortality rates (by ~7%) in treated populations.[73]

Primary health care providers increasingly recognize markers for OSA, such as snoring, and are becoming more aware of the OSA-hypertension association. Consequently, referrals of patients with mild, asymptomatic OSA for sleep evaluations will very likely increase, heightening the dilemma of whom to treat in the face of limited medical resources. Further understanding of the costs and benefits of OSA treatment in preventing the incidence and progression of hypertension and other cardiovascular diseases is needed before this problem can be satisfactorily addressed.

Meanwhile, clinicians providing care for OSA patients using PAP should underscore the importance of full compliance as well as adequate control of disordered breathing events with PAP, as evidenced by studies showing the importance of treatment adherence in lowering blood pressure.[29,48] As indicated earlier, long-term small changes in blood pressure have major preventive effects. In prospective studies of 420,000 persons, a decrease of 5 mm Hg in diastolic blood pressure lessened the incidence of stroke and coronary heart disease by approximately 34% and 21%, respectively, and there was a dose-dependent reduction in blood pressure and incident cardiovascular diseases.[74] Therefore, in patients with OSA, long-term compliance with PAP may be effective in preventing adverse cerebrovascular and cardiovascular diseases.

PULMONARY HYPERTENSION

Obstructive Sleep Apnea as a Cause of Pulmonary Hypertension

In 1998, the second WHO conference on pulmonary arterial hypertension[4] recognized sleep-disordered breathing as a secondary cause of PH. The classification of PH has been revised by a more recent WHO conference.[75,76] There are five groups, each with a number of subgroups consisting of various causes of PH. The first group, pulmonary arterial hypertension, includes idiopathic pulmonary arterial hypertension. The second class is pulmonary venous hypertension, which is most commonly due to elevated left heart filling pressures such as left ventricular diastolic dysfunction. PH secondary to OSA falls into the third category, which also includes chronic obstructive pulmonary disease (COPD), interstitial lung diseases, and PH chronic exposure to high altitude. The basic pathophysiologic mechanism underlying PH in this group of disorders is hypoxemia. However, as will be emphasized later, OSA can cause PH through left ventricular diastolic dysfunction, as it occurs in group 2. Group 4 is PH due to thromboembolic pathologic disorders, and group 5 consists of miscellaneous disorders that cannot be easily classified in the other four groups.

The gold standard for diagnosis of PH is right heart catheterization. As noted earlier, the WHO defines the presence of PH as resting mean pulmonary artery pressure of 25 mm Hg or greater. Investigators in the field of sleep apnea have mostly used a mean pulmonary artery pressure of 20 mm Hg or greater, a threshold that is lower than that defined by WHO. However, a resting mean pulmonary artery pressure of 20 mm Hg or greater is generally considered abnormal. In this chapter, we defined PH according to the WHO criteria, which have become the rule independent of the cause of the PH. We also emphasized that right heart catheterization is essential for phenotyping PH, assessing its severity and the targeted therapy.

In patients with OSA, the prevalence of abnormal mean pulmonary artery pressure varies considerably, from 15% to 70%.[77-84] This variation in part depends on inclusion in some studies of patients with COPD, hypercapnic OSA (obesity hypoventilation syndrome), and obesity, which contribute to increased frequency, prevalence, and severity of PH in OSA. Meanwhile, in patients with OSA without comorbid disorders, PH is usually mild, although it could also be severe in advanced OSA, resulting in cor pulmonale, a feature of pickwickian syndrome (hypercapnic OSA syndrome).

An early study[1] of 12 patients with OSA who had undergone right heart catheterization showed cyclic changes in pulmonary artery pressure coinciding with episodes of OSA. A marked degree of hypoxemia and hypercapnia was associated with these hemodynamic abnormalities. In some of these patients, systolic pulmonary artery pressure exceeded 60 mm Hg. During wakefulness, four patients had abnormal mean pulmonary artery pressure ranging from 20 to 22 mm Hg. One of these four patients had an elevated pulmonary capillary wedge pressure of 16 mm Hg. With exercise, most of the patients had mean pulmonary artery pressure of about 30 mm Hg. In some of these patients, the wedge pressure increased with exercise, unmasking left ventricular diastolic dysfunction. This study indicated that OSA impaired the physiologic processes that normally operate to enable pulmonary circulation and left ventricular function to maintain pulmonary artery pressure close to normal in the face of increases in cardiac output.

Since the study of Tilkian and colleagues,[1] many studies have demonstrated presence of PH in patients with OSA. Box 127-1 summarizes the four largest studies in which full-night PSG and right heart catheterization, the gold standard for diagnosis of OSA and PH, were performed. In a French study[78] involving 220 consecutive patients with an AHI of greater than 20, 37 patients (17%) had a resting mean pulmonary artery pressure of at least 20 mm Hg (range, 20 to 44 mm Hg), and in 17 patients (8%) the mean pressure was 25 mm Hg or greater. Patients with a resting mean pulmonary artery pressure of at least 20 mm Hg had more severe OSA, a higher $Paco_2$, a higher BMI, and a lower Pao_2 than patients without PH. Furthermore, these patients had higher prevalence of both obstructive and restrictive pulmonary defects. $Paco_2$ and forced expiratory volume in 1 second (FEV_1) were the two major predictors of high resting mean pulmonary artery pressure. When PH was defined as a mean pressure of 30 mm Hg with exercise, virtually all patients met this criterion; in 23 patients (62%) the mean pressure exceeded 40 mm Hg.

In an Australian study[79] of 100 consecutive patients with an AHI of 20 or more, 42% had elevated pulmonary artery pressure, with the mean pressure ranging from about 20 to 52 mm Hg. Some patients had overlap syndrome. In 24% of the patients, the mean pressure was more than 25 mm Hg. In this study, $Paco_2$, Pao_2, and FEV_1 accounted for about 33% of

Box 127-1 STUDIES ON PULMONARY HYPERTENSION IN PATIENTS WITH OBSTRUCTIVE SLEEP APNEA

Chaouat A, Weitzenblum E, Krieger J, et al.[78]

- 220 consecutive French patients with AHI >20 events/hr
- 17% had mean PAP >20 mm Hg
- 8% had PH with mean PAP ≥25 mm Hg; I patient with mean PAP ≥40 mm Hg
- Patients with PAP >20 mm Hg had more severe OSA, higher $Paco_2$ and BMI, lower Pao_2, and a more obstructive and restrictive defect
- $Paco_2$ and FEV_1 were independent predictors of mean PAP

Laks L, Lehrhaft B, Grunstein RR, et al.[79]

100 consecutive Australian patients with AHI >20
42% had mean PAP >20 mm Hg; range, 20 to 52 mm Hg; 24% had PH with mean PAP ≥25 mm Hg
5% had PH with mean PAP >40 mm Hg
$Paco_2$, Pao_2, and FEV_1 accounted for 33% of the variability in PH
Six patients (6%) with mean PAP ranging from 20 to 52 mm Hg had normal Pao_2

Sanner BM, Doberauer C, Konermann M, et al.[80]

92 consecutive German patients with OSA and AHI >10; range, 10 to 100/hr
COPD was an exclusion criterion
20% had mean PAP ranging from 20 to 26 mm Hg; 2 with PH had mean PAP ≥25 mm Hg
Eight patients had increased PCWP; all had systemic hypertension
PCWP and time spent at <90% saturation were independent predictors of mean PAP

Bady E, Achkar A, Pascal S, et al.[81]

44 patients with OSA and AHI >5
COPD (FEV_1/FVC ratio <60%) was an exclusion criterion
27% had mean PAP >20 mm Hg with mean pressure ≥28.5 mm Hg
All with PCWP ≤15 mm Hg
18% had PH with mean PAP ≥25 mm Hg

AHI, Apnea-hypopnea index; BMI, body mass index; COPD, chronic obstructive pulmonary disease; FEV_1, forced expiratory volume in 1 second; PAP, pulmonary artery pressure; PCWP, pulmonary capillary wedge pressure; PH, pulmonary hypertension.

variability in pulmonary artery pressure. Six patients with abnormal pulmonary artery pressure had normal Pao_2.

In a German study[80] of 92 consecutive patients with an AHI of greater than 10 and with COPD as an exclusion criterion, 20% had a mean pulmonary artery pressure of 20 to 25 mm Hg. Only one patient met the current criterion of PH with a mean of 25 mm Hg. Eight patients had increased pulmonary capillary wedge pressure, and all of these patients had systemic hypertension that was presumably causing left ventricular diastolic dysfunction. Pulmonary capillary wedge pressure and time spent with a saturation of below 90% were the independent variables predicting PH.

The presence of PH in patients with OSA but without COPD was also confirmed in another French study (see Box 127-1).[81] In this study, however, COPD was defined by an FEV_1 of less than 70% predicted and a ratio of FEV_1 to forced vital capacity (FVC) of less than 60% predicted. The study involved 44 patients, 12 of whom (27%) had mean pulmonary artery pressure greater than 20 mm Hg, all with pulmonary capillary wedge pressure of less than 15 mm Hg. Importantly, 8 patients (18% of all patients) had PH with mean pulmonary artery pressure of 25 mm Hg or greater. The authors reported that mean pulmonary artery pressure was positively correlated with BMI and negatively correlated with Pao_2. Patients with elevated mean pulmonary artery pressure had significantly lower values for FVC and FEV_1. The mechanisms by which BMI positively correlated with PH could have been multifactorial and related to restrictive lung defect and hypoxemia.

Combining the results of the aforementioned four studies using PSG to determine the presence of OSA, and right heart catheterization to define PH, 51 of the 456 patients (11%) satisfy the current WHO criteria for PH.

In conclusion, mild PH is common in patients with OSA and may occur in the absence of COPD and daytime hypoxemia. However, severe OSA, severe hypoxemia, hypercapnia (obesity hypoventilation syndrome), obstructive or restrictive lung defects, and left heart disease are more commonly associated with PH and contribute to its severity. In addition, as noted, increased pulmonary artery pressure either becomes manifest or is augmented by exercise and can cause dyspnea and exercise intolerance.[82]

Mechanisms of Pulmonary Hypertension in Patients with Obstructive Sleep Apnea

Intermittent nocturnal rises in the pulmonary artery pressure in association with upper airway collapse have been well documented. Multiple mechanisms mediate nocturnal rises in pulmonary artery pressure.[85] These include alterations in blood gases (i.e. intermittent hypoxemia and hypercapnia), cardiac output, lung volume, intrathoracic pressure, compliance of pulmonary circulation, and left ventricular diastolic dysfunction. With time and in the long run, nocturnal PH spills over to diurnal hypertension.

Diurnal PH in patients with OSA could be precapillary, capillary, or postcapillary, depending in part on comorbid disorders that may contribute to the development of PH (Box 127-2). Postcapillary PH (pulmonary venous hypertension) is common and results primarily from elevated left heart filling pressures, specifically owing to their left ventricular hypertrophy and diastolic dysfunction caused by diurnal systemic hypertension and nocturnal consequences of OSA noted

previously. In regard to the latter, left ventricular hypertrophy could be present in patients with OSA even in the absence of daytime systemic hypertension,[86] presumably because of cyclic changes in systemic artery blood pressure and hypoxemia[84] during sleep. In the presence of a hypertrophied or noncompliant left ventricle, end-diastolic pressure increases, resulting in backward passive increase in pulmonary venous, capillary, and pulmonary artery systolic and diastolic pressures. This acute postcapillary PH is reversible, if the etiologic factor (e.g., OSA) is effectively treated. Otherwise, with persistent PH, remodeling of pulmonary vascular bed occurs and vascular resistance increases, which in time may become reversible even if the etiology of left heart disease is effectively treated.

As noted earlier, as a cause of PH, OSA is categorized in group 3 along with COPD and other lung diseases. Here, the underlying pathophysiology is hypoxemia. However, because of intermittent partial or complete pharyngeal collapse during sleep, repeated episodes of hypoxemia and hypercapnia occur, both of which have been shown to acutely induce pulmonary arteriolar vasoconstriction, increasing pulmonary vascular resistance. With time, however, distinct pathophysiologic sequelae ensue that may be irreversible. In any case this is the precapillary PH, which is another potential mechanism of OSA-induced PH. Therefore the combination of hypoxic-hypercapnic pulmonary arteriolar vasoconstriction and pulmonary venous hypertension could result in severe PH in patients with OSA. Similarly, when OSA is comorbid with COPD, which is in the same group with OSA as a potential cause for PH, the combination could result in severe PH.

Detailed molecular mechanisms underlying PH in OSA are beyond the scope of this chapter. However, production of mediators eventually results in endothelial cell damage, vascular cell proliferation, and aberrant vascular remodeling. In addition, with endothelial cell dysfunction, there is reduced nitric oxide production and increased endothelin,[86,87] both of which contribute to further PH. As noted earlier, the initial cascade of events is potentially reversible, emphasizing the importance of early recognition and treatment of OSA.

Loss of vascular surface area, as may occur in patients with COPD, is an important cause of capillary PH, and it may significantly contribute to PH in patients with OSA. Several studies[77-79] have shown that COPD and a low FEV_1 are predictors of PH in patients with OSA. COPD could also contribute to PH by way of arteriolar vasoconstriction due to hypoxemia and hypercapnia as noted previously.

An important mechanism mediating PH in patients with OSA is the presence of factors that cause constriction of pulmonary arterioles, leading to precapillary PH. The best-known stimulus is alveolar hypoxia, and it is not surprising that hypoxemia is an independent predictor of PH in OSA (see Box 127-1). However, hypercapnia could also increase pulmonary arterial blood pressure. The molecular mechanisms of PH in general are complex and multifactorial. Both acquired and genetic factors are involved. Disordered endothelial cell function, in part caused by hypoxia (and reoxygenation) and manifested biochemically by an imbalance between concentrations of local vasodilators (e.g., nitric oxide and prostacyclins) and vasoconstrictors (e.g., endothelin-1, thromboxane, serotonin), as occurs in endothelial dysfunction syndrome, appears to mediate the development of PH.[87,88] It is also conceivable that if OSA is long-standing, pulmonary vascular remodeling similar to that in COPD could occur because a number of mediators such as vascular endothelial growth factor are proliferative and angiogenic.

In summary, the consequence of OSA on pulmonary circulation may vary from those of cyclic nocturnal PH, which occurs in virtually all patients, to daytime PH, right ventricular dysfunction, and eventually cor pulmonale, a feature of pickwickian syndrome. However, even in the absence of cor pulmonale, which is the manifestation of long-standing severe PH, presence of PH increases right ventricular afterload and myocardial oxygen consumption. If PH develops as a result of increases in cardiac output (e.g., with exercise), it may cause dyspnea and exercise intolerance.

Changes in Pulmonary Artery Pressure after Positive Airway Pressure Treatment of Obstructive Sleep Apnea

Because mechanisms of PH in OSA are multifactorial (see Box 127-2), the behavioral response of pulmonary circulation to therapy for OSA probably depends on several factors. For example, if loss of vascular surface area due to the presence of COPD or other comorbid pulmonary disorders is contributing to PH in OSA, this component is irreversible.[89] Similarly, if remodeling of the pulmonary vascular bed has occurred, long-standing effective therapy is necessary to effect any reversal component (reverse remodeling). Therefore, if PAP is used to treat OSA, long-term compliance with therapy is critical and needs to be confirmed by covert monitoring. Large, long-term systematic studies considering these important factors are necessary to determine the effects of treatment of OSA on pulmonary circulation. Lack of such considerations may lead to serious underestimation of effects.

Effective treatment of OSA could improve PH. Here we review the studies that have implemented right heart catheterization both at baseline as well as long term. In an early study when tracheotomy was the best therapeutic option, Fletcher and colleagues[89] studied three groups of OSA patients. Nine patients with hypercapnic OSA and mostly with COPD underwent the operation, and repeat right heart catheterization was performed about 6 months later. Six of nine patients had baseline right heart catheterization, and five of them met the current criteria for PH. The resting mean pulmonary artery pressure was 39 mm Hg in these six patients. About 12 months later, the mean resting pulmonary artery pressure was 25 mm Hg. Mean pulmonary artery pressure decreased in five of the six patients. It did not change significantly in the single patient who had mean pulmonary artery pressure of about 24 mm Hg. Meanwhile there was a significant rise in right ventricular ejection fraction in association with a reduction in the pulmonary artery pressure and vascular resistance. Motta and coworkers[90] also performed tracheostomy on six patients with OSA. However, the mean pulmonary artery pressure did not change significantly in these patients. Importantly, only one patient met the current criterion of PH with a mean pressure of 28 mm Hg.

Another negative study was reported by Sforza and colleagues.[91] The authors treated 54 patients with OSA with CPAP. The mean pulmonary artery pressure did not change significantly. However, similar to the study of Motta and colleagues, none of the patients met the current criterion for PH.

Alchanatis and colleagues[92] studied 29 patients with OSA and without COPD. Three of the 29 patients met the current criterion for PH with baseline values of 30, 30, and 28 mm Hg.

Six months after therapy with CPAP, the mean pulmonary artery pressure had dropped below 25 mm Hg in these 3 patients. Respective values were about 23, 22, and 20 mm Hg.

In another French study of OSA patients who were treated with long-term CPAP, Chouat and associates[92] reported no significant changes in mean pulmonary artery pressure in 44 patients who had undergone right heart catheterization. The mean pulmonary artery pressure at baseline, however, was normal at 16 mm Hg. After an average of 64 months of CPAP use, the mean pressure was 17 mm Hg. The authors reported that in 11 patients whose average value of the mean pulmonary artery pressure was 24 mm Hg at baseline (authors considered a value of 20 mm Hg or greater as PH), the pressure decreased to 20 mm Hg, although this value was not statistically significant. It is not clear how many of the 11 patients met the current criterion for PH. However, if the mean pressure is within normal range it may not be expected to decrease significantly with intervention.

The last a study using right heart catheterization was reported by Sajkov's group[93] who studied 20 patients with OSA (average AHI, 49 or greater) before and 4 months after treatment with PAP. In this study, PAP compliance was objectively monitored, and the average was 5 hours per night. Patients had normal lung function. Five patients who had abnormal pulmonary artery pressure (range, 20 to 32 mm Hg) showed the most dramatic decrease to less than 20 mm Hg after 4 months of effective treatment with PAP. Two of the 5 patients met the current criterion for PH with mean pulmonary artery pressures of 31 and 27 mm Hg. Four months after therapy with CPAP, respective pressures were 18 and 13 mm Hg. Interestingly, the authors showed a time-dependent progressive decrease in mean pulmonary artery pressure with right heart catheterization, which was performed at 1 and 4 months of intervention. In a subject who was not compliant with CPAP, there was no change in pulmonary artery pressure. Although this was a single observation, this finding and those reported for systemic hypertension strongly indicate that effective use of PAP is necessary to lower systemic and pulmonary artery pressures.

We now review relevant randomized clinical trials. Arias and colleagues[94] randomized 23 middle-aged patients with severe OSA (AHI, 44 or greater) to either sham PAP or PAP therapy. In this crossover trial, after 12 weeks of PAP therapy, pulmonary artery systolic pressure decreased significantly from a mean of about 30 to 24 mm Hg. The reduction was greatest (8.5 mm Hg) in patients with PH defined as pulmonary artery systolic pressure of 30 or more determined by echocardiography. In the second randomized study[95] sham CPAP was used as placebo. Arias and colleagues[95] performed a crossover study of 12 weeks' duration in 27 consecutive newly diagnosed men with OSA and abnormal echocardiographic left ventricular filling pattern. Twelve weeks of effective CPAP therapy resulted in significant increases in E/A ratio and reduction in mitral deceleration isovolume relaxation times. We must emphasize that based on the design of this important study, the main and perhaps the only pathologic reason causing left ventricular diastolic dysfunction was OSA; among the exclusion criteria were presence of known hypertension, ischemic or valvular heart disease, diabetes, morbid obesity, and daytime hypoxemia. Therefore the results of this study demonstrate that OSA could be a cause of the reversible diastolic dysfunction. As noted earlier, impaired left ventricular filling could be an important cause of PH in patients with OSA.

The American College of Cardiology and American Heart Association expert consensus document recommends PSG to rule out OSA for all patients with PH. The recommendation is based on the idea that targeted therapy of OSA could either improve or prevent further deterioration in central hemodynamics.

CLINICAL PEARLS

- Epidemiologic studies support a causal role of OSA in systemic hypertension independent of BMI, measures of fat distribution, age, sex, and other possible confounding factors.
- Randomized double-blind placebo (sham PAP)–controlled trials of patients with hypertension demonstrate that effective treatment of OSA with PAP lowers blood pressure. A decrease in blood pressure is most pronounced in those with the most severe OSA and those who are the most compliant.
- Even small decrements in blood pressure, maintained for the long term, have been shown to significantly lessen the incidence of cerebrovascular and cardiovascular diseases. Thus the potential lowering of blood pressure from PAP treatment holds promise for decreasing cerebrovascular or cardiovascular disease. However, adequate control of OSA and compliance with PAP, particularly in patients with severe OSA, are critical.
- Several observational studies show that OSA, particularly when severe, is a cause of mortality. Treatment with PAP decreases mortality risk.
- OSA is a cause of secondary PH, and this has been recognized by international health organizations. PH as defined by a mean pulmonary artery pressure of 25 mm Hg or greater is usually mild, although it could be severe, particularly in the presence of severe OSA or OSA with hypercapnia, obesity, and comorbid disorders such as COPD. Treatment of OSA with PAP may improve or prevent further deterioration in pulmonary pressures. All patients with PH, independent of the cause, should undergo PSG and targeted therapy when indicated. This may halt deterioration in central hemodynamics.

SUMMARY

Findings from investigations based on diverse populations and different study designs support a role for OSA in systemic hypertension and PH. Population-based epidemiology studies have shown that persons with moderate to severe OSA (15 or more apnea or hypopnea events per hour) have greater probability of having or developing hypertension than persons who do not have OSA. These associations are only partly explained by confounding factors such as age or increased BMI. In epidemiologic studies that use 24-hour ambulatory blood pressure monitoring, OSA–blood pressure associations are seen with both sleep and wake blood pressures. PH, too, is prevalent in patients with OSA. Mild pulmonary arterial hypertension may occur in patients with OSA without daytime hypoxemia or COPD, but these comorbidities are more common in patients with severe OSA.

OSA treatment trials also support a causal association between OSA and hypertension, with most studies of

systemic or pulmonary blood pressures before and after PAP therapy demonstrating blood pressure reductions. Intervention trials generally show modest reductions in systemic blood pressure (2 to 10 mm Hg reductions), with the largest effects seen in effectively treated patients with severe OSA. Importantly, small changes in blood pressure, if maintained, have the potential to significantly decrease the population incidence of cerebrovascular and cardiovascular disease.

Chapter
128

Coronary Artery Disease and Obstructive Sleep Apnea

Yüksel Peker; Karl A. Franklin; Jan Hedner

Chapter Highlights

- Obstructive sleep apnea is overrepresented in patients with coronary artery disease and occurs in about 50% (36% to 66%) of such patients, most of them without complaints of excessive daytime sleepiness.
- Sleep apnea is even more prevalent during the presentation of myocardial infarction and may explain a peak incidence of sudden cardiac death during midnight and early morning hours.
- Increased oxygen demand and reduced oxygen supply after obstructive apneas may trigger nocturnal angina in patients with low oxygen reserve because of lack of ventilation.
- Patients with sleep apnea and coronary artery disease have an increased risk for developing stroke, but it is still unclear whether they have an increased risk for early death independent of other comorbidities.
- Obstructive sleep apnea is suggested as an independent risk factor for atherosclerosis because of repeated apnea-induced hypoxemia and reoxygenation-induced oxidative stress with immediate and sustained sympathetic activation, endothelial dysfunction, and inflammation.
- Prospective studies report a reduction of nocturnal ischemia during elimination of obstructive events with continuous positive airway pressure treatment and lowering of the risk for recurrent myocardial infarction, without any reports of adverse events.
- Randomized controlled trials examining the effect of continuous positive airway pressure treatment on long-term cardiovascular outcomes are underway.

Epidemiologic data suggest that obstructive sleep apnea (OSA) is overrepresented in patients with coronary artery disease (CAD). Other studies suggest that the clinical course of CAD is initiated or accelerated by the presence of sleep-related breathing disorders. A rapidly evolving field of experimental data demonstrates that OSA, by phenomena such as hypoxemia and reoxygenation, may trigger a sequence of events involved in the development of atherosclerotic disease.

Development of vascular disease and CAD is influenced by several risk factors that also have been associated with OSA. Sleep apneic events induce a state of increased cardiac oxygen demand but are also often associated with low oxygen reserve because of lack of ventilation. Nocturnal angina can therefore be triggered by sleep apneas in patients with CAD. There is growing evidence that elimination of the sleep disorder can benefit patients with OSA at risk for CAD. Other data suggest that treatment of OSA improves prognosis in patients undergoing coronary revascularization. This chapter reviews the evidence of an association between these two conditions.

EPIDEMIOLOGY

The risk for experiencing angina pectoris or an acute coronary syndrome such as unstable angina, acute myocardial infarction (MI), or sudden cardiac death (SCD) has long been known to be increased during the late hours of sleep or in the hours soon after awakening.[1] This association may be explained in part by occurrence of OSA. A retrospective analysis showed an overrepresentation of peak time in sudden death from the cardiac causes during the sleeping hours in patients with OSA, which contrasted with a nadir in sudden death from cardiac causes in subjects without OSA and in the general population.[2] The same group addressed whether OSA independently increases the risk for SCD in a longitudinal follow-up of 10,701 consecutive adults.[3] During an average follow-up of 5.3 years, 142 patients had resuscitated or suffered from SCD (annual rate, 0.27%). In a multivariate analysis, SCD was associated with an apnea-hypopnea index (AHI) of at least 20 events/hour (hazard ratio [HR] = 1.60), mean nocturnal oxygen saturation of less than 93% (HR = 2.93), and oxygen nadir saturation of less than 78% (HR = 2.60; all $P < .001$). The authors concluded that OSA predicted incident SCD. Another small prospective study addressing the time of onset of MI showed a higher likelihood of having OSA in those with an onset of MI during midnight hours.[4] Moreover, a recent study also demonstrated that the incidence of MI onset between 6:00 AM and 12:00 PM was higher in OSA patients (AHI ≥5) than in control patients (38% vs. 25%; $P = .039$). Moderate to severe OSA (AHI ≥15) significantly enhanced this circadian variation

(odds ratio [OR] = 2.0) after adjustment for age, body mass index (BMI), and comorbidities.[5]

In general, there is a stronger relationship between OSA and CAD in clinical cohorts than in the general population because clinical cohort studies are particularly influenced by comorbidity and confounding factors, including obesity, diabetes mellitus, hypertension, smoking, and hyperlipidemia. This circumstance also suggests that OSA constitutes an additive or synergistic risk factor for development of CAD.

Prevalence of Obstructive Sleep Apnea and Coronary Artery Disease in the General Population

The largest study to date addressing OSA and CAD in the general population is the Sleep Heart Health Study.[6] The investigators performed a cross-sectional analysis of 6132 subjects undergoing unattended full-night home polysomnography. There was a modest risk increase (peaking at an OR of 1.27) for self-reported CAD when the highest and lowest AHI quartiles were compared. The weak association in this general population study may be explained by a proportionally high age and a low median AHI.

Prevalence of Coronary Artery Disease in Patients with Obstructive Sleep Apnea

Clinical studies of CAD in sleep clinic cohorts generally involve patients with OSA and with daytime symptoms. Consequently, compared with studies in the general population, these studies deal with symptomatic patients, those likely to suffer from more severe sleep apnea, and potentially patients with excess comorbidities such as diabetes, obesity, and cardiovascular disorders. Available data are to a large extent based on uncontrolled studies. For example, in a sleep clinic cohort of 386 subjects,[7] CAD was present in almost one fourth of subjects with OSA, and the percentage of patients with CAD was high among those with moderate to severe OSA.

In another study,[8] simultaneous polysomnography and electrocardiographic recordings demonstrated that episodes of nocturnal ischemia were more common in patients with OSA who also had CAD, and mainly so during rapid eye movement (REM) sleep, during periods of high apnea activity, and during sustained hypoxemia. Moreover, ST-segment depression on electrocardiography was not uncommon during sleep in patients with OSA but without a history of CAD, and these changes were eliminated by continuous positive airway pressure (CPAP).[9] Studies using invasive measures, including angiography, verified CAD in more than 20% of investigated subjects with OSA,[10] and an even higher prevalence (68%) was reported in a slightly larger study of unselected patients with OSA.[11] Collectively these data suggest a proportionally high prevalence of CAD in sleep clinic cohorts.

Prevalence of Obstructive Sleep Apnea in Patients with Coronary Artery Disease

Sleep-disordered breathing appears to be common in patients with CAD. An early small study demonstrated OSA or central sleep apnea with Cheyne-Stokes breathing in 13 of 17 male patients with angiographically verified CAD.[12] A subsequent Australian case-control study that investigated middle-aged male survivors of acute MI and age-matched controls provided the first clinic-based epidemiologic evidence of an increased prevalence of OSA in patients with CAD.[13] OSA (apnea index [AI] ≥5 events/hour) was found in approximately one third of the patients, compared with only 4% of age-matched healthy controls, and constituted an independent predictor of MI after adjustment for traditional risk factors.

A larger case-control study provided a similar OSA prevalence (31%), whereas the prevalence in the control group was 20%.[14] In this population, an AHI of 20 was associated with a history of MI (OR = 2.0; 95% confidence interval [CI], 1.0 to 3.8). In a tightly age-, sex-, and BMI-matched Swedish case-control study of 62 patients, OSA, based on an AHI of greater than 10, provided an independent OR of 3.1 (95% CI, 1.2 to 8.3) for CAD adjusted for several cardiovascular risk factors.[15] A recent matched Spanish case-control study found OSA (based on AHI ≥15) in 35% of patients with acute MI compared with 15% in the control group ($P < .001$).[16] The adjusted OR for acute MI was 12.2 (95% CI, 2.0 to 72.6), applying the AHI cutoff value of 15 for OSA diagnosis.

There are also data suggesting that the OSA and CAD association may be influenced by sex and age. In patients with angiographically verified CAD, an AI of greater than 10 was almost twice as common in men,[17] but three times more common in women[18] younger than 70 years, compared with age-matched controls. An uncontrolled study of 50 randomly selected CAD patients demonstrated OSA in 50% based on an AI of greater than 10.[19] Another uncontrolled German study reported an OSA prevalence of 35% applying AHI of 10 or more events/hour as the diagnostic criterion in 74 men with significant stenosis of one or more coronary arteries but failed to establish a significant relationship between AHI and number of coronary vessels involved.[20] A subsequent uncontrolled follow-up study found OSA (AHI ≥10) in 57% of 89 subjects with acute coronary syndrome undergoing percutaneous coronary intervention (PCI).[21] A similar high prevalence of OSA (66%) was reported in another investigation based on AHI of 10 or greater.[22] Two other uncontrolled studies performed in CAD patients undergoing PCI demonstrated OSA (AHI ≥15) in 43% and 66%, respectively.[23,24] One study based on a retrospective chart review of 798 consecutive patients with acute MI demonstrated that OSA was initially suspected only in 12% of the patient records, whereas after overnight polysomnography, 41% of patients presented an AHI of 15 or greater, suggesting that OSA was common but unrecognized in patients with CAD.[25] Moreover, baseline data of a randomized controlled trial (RCT) among 662 revascularized CAD patients in Sweden (the Randomized Intervention with CPAP in Coronary Artery Disease and Sleep Apnoea [RICCADSA] trial) revealed that 64% had an AHI of 15 or greater (Figure 128-1), but most did not report daytime hypersomnolence.[26] Of note, the occurrence of OSA in this cohort was more common than the prevalence of hypertension, diabetes, obesity, and current smoking. Finally, a similar prevalence (64%) of sleep-disordered breathing, defined as an oxygen desaturation index (ODI) of greater than 5 based on a WatchPAT-100 sleep study, was reported recently in prospective evaluation of 180 patients with acute MI.[27] However, no distinction was made between OSA and central sleep apnea or CSR in that cohort.

The possibility that OSA may trigger episodes of nocturnal angina in patients with disabling CAD was addressed in an interventional study.[28] OSA was found in 9 of 10 investigated patients with CAD who had nocturnal angina, and episodes of ischemia were reversed after elimination of the apneic

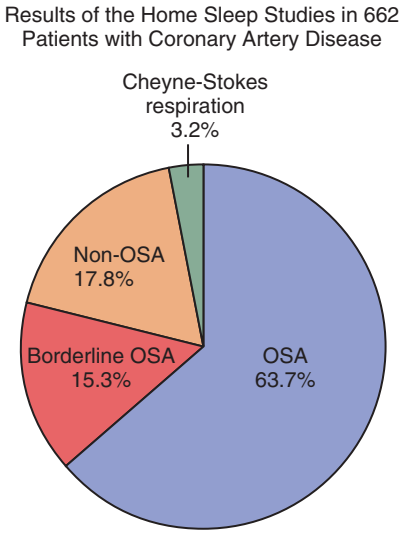

Figure 128-1 Classification of the groups based on the results of the unattended cardiorespiratory sleep recordings in patients with revascularized coronary artery disease. Obstructive sleep apnea (OSA) refers to apnea-hypopnea-index (AHI) of 15 or more events/hr; borderline OSA, AHI 5 to 14.9 events/hr; Non-OSA, AHI <5 event/hr. (Modified from Glantz H, Thunström E, Herlitz J, et al. Occurrence and predictors of obstructive sleep apnea in a revascularized coronary artery disease cohort. *Ann Am Thorac Soc* 2013;4:350–6.)

events with CPAP treatment. A subsequent larger cross-sectional study found signs of silent nocturnal myocardial ischemia in 31% of 226 patients with CAD but failed to demonstrate a general and immediate temporal relationship between OSA and episodes of myocardial ischemia.[29] However, a direct association could be documented in a small subgroup of patients, and, in general, episodes of silent ischemia appeared to be more frequent in those with more severe OSA. A retrospective evaluation of more than 200 patients undergoing electron-beam computed tomography within 3 years of an overnight sleep recording addressed the occurrence of subclinical coronary artery calcification.[30] With multivariate adjustment, the OR for coronary artery calcification was 3.3 in the most severe AHI quartile (mean, 63.4 events/hour).

The effect of OSA on the prognosis of CAD has been addressed in several studies. In a study of patients with CAD who were undergoing elective PCI, concomitant OSA was significantly related to increased late lumen loss and restenosis after an average follow-up time of 7 months.[31] In another study, the incidence of adverse cardiac events (cardiac death, reinfarction, and target vessel revascularization) was reported to be almost 24% among patients with OSA, compared with 5% among those without OSA, during a 6-month follow-up.[21] Moreover, patients with CAD who had concomitant OSA were found to have an increased risk for cardiovascular mortality over a 5-year period.[32,33] Conversely, another study demonstrated no effect of OSA on readmission rate of PCI-treated patients with CAD who had concomitant OSA during a 6-month follow-up period[22] and no significant difference regarding the 10-year survival rate for patients with CAD and with OSA compared with those without OSA at baseline.[34] Moreover, a recent clinical report (mentioned previously)[27] found no association between sleep apnea in the setting of acute MI and adverse clinical outcomes, including death, heart failure, and new MI, during a median follow-up of 68 months. On the other hand, the incidence of stroke was reported to be increased in patients with CAD who had concomitant OSA.[35] Stroke occurred in 18% of patients with CAD and sleep apnea, compared with 5% of those without sleep apnea, during 10 years of follow-up after a coronary angiography was performed. After adjustments for confounders, including hypertension and atrial fibrillation, the patients with sleep apnea had an adjusted HR of 2.9 (95% CI, 1.4 to 6.1) for a stroke.[35]

Hence OSA is common in patients with MI, but their mean AHI is relatively low in most published reports (Table 128-1).[13-15,17-22,27,36] Moreover, the prevalence of OSA is higher in patients with MI than in those with angina pectoris. This finding may be explained by the occurrence of Cheyne-Stokes breathing as a result of reduced ejection fraction.[19] Indeed the definition of the ideal timing for OSA screening after an acute MI remains unresolved. One study reported that 50% of CAD patients had an AHI of 15 or greater at the time of acute presentation in the coronary care unit, whereas 28% had remaining OSA based on the same AHI cutoff at least 6 weeks after hospital discharge.[37] A later study demonstrated occurrence of OSA (AHI ≥10) within the first 2 days after hospital admission in 54% of patients with acute coronary syndromes and preserved left ventricular ejection fraction, whereas 22 of 28 patients (79%) had residual OSA 1 month after the acute event, and only 6 of the 28 patients (21%) were diagnosed as having OSA at 6-month follow-up.[36] Thus OSA may be transient and, to some degree, related to the acute phase of the CAD, to more supine position of patients in the coronary care units, or to medications (sedatives and analgesics). Available studies accumulating some 2324 patients with CAD demonstrated an OSA prevalence of about 47% (see Table 128-1). Despite the differences in the diagnostic procedures (full polysomnography or cardiorespiratory sleep recordings) as well as varying cutoff values of AI, AHI, or ODI for definition of the sleep-disordered breathing, there seems to be enough evidence to advocate for overnight sleep recordings in individuals with MI given that concomitant OSA may worsen long-term outcomes in patients with CAD.

Incidence of Coronary Artery Disease in Longitudinal Studies

The first report on incident CAD data in a sleep clinic cohort was a smaller observational study demonstrating CAD development in almost one fourth of untreated patients with OSA during a 7-year follow-up period.[38] The corresponding numbers in treated sleep apnea patients and nonapneic snorers were 4% and 6%, respectively. Moreover, more than 50% of a normotensive cohort not treated for OSA developed at least one cardiovascular disease during the 7-year follow-up (Figure 128-2).[39] In that cohort, new CAD cases were also found among normotensive patients, suggesting that development of CAD in part may be independent of diurnal systemic hypertension induced by OSA. A larger observational study of a sleep clinic cohort, containing close to 1300 subjects with OSA, with a mean follow-up of 10 years, found a three to four times higher incidence of fatal and nonfatal cardiovascular events in patients with severe OSA compared with simple snorers.[40] Multivariate analysis showed that the risk for fatal cardiovascular events was significantly increased in severe untreated patients with OSA (OR = 3.2; 95% CI, 1.1 to 7.5) compared with healthy controls. Another prospective observational study of a sleep clinic cohort including 1436

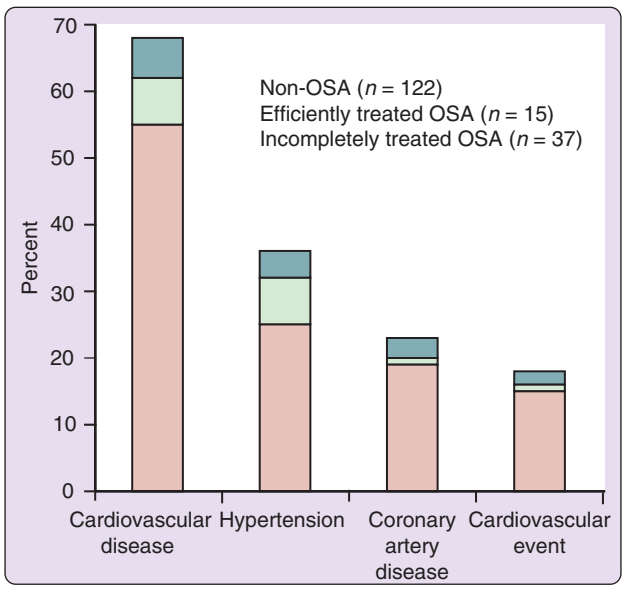

Figure 128-2 Incidence of cardiovascular disease during a 7-year follow-up in middle-aged men otherwise healthy at baseline. The fraction of individuals with incidence of cardiovascular disease, hypertension, coronary artery disease, and cardiovascular event (stroke, myocardial infarction, or cardiovascular death) is shown. Depicted are data from patients without OSA (Non-OSA) as well as from those incompletely or efficiently treated for their sleep and breathing disorder. (Modified from Peker Y, Hedner J, Norum J, et al. Increased incidence of cardiovascular disease in middle-aged men with obstructive sleep apnea: a seven-year follow-up. *Am J Respir Crit Care* 2002; 166:159–65).

consecutive subjects demonstrated that OSA (AHI ≥5) was associated with an increased risk for CAD events or death from cardiovascular causes (adjusted HR = 2.1; 95% CI, 1.1 to 3.9) during a follow-up period of almost 3 years.[41] Moreover, there was a dose-response relationship between AHI and composite outcome of CAD events or cardiovascular death (adjusted HR = 2.8; 95% CI, 1.5 to 5.5) in patients with severe OSA (AHI ≥30) compared with those without OSA (AHI <5).[41] Similarly, the 18-year follow-up study of the population-based Wisconsin Sleep Cohort sample reported an adjusted HR of 5.2 (95% CI, 1.4 to 19.2) for cardiovascular mortality in patients with severe OSA (AHI ≥30) and not using CPAP compared with those without OSA.[42] The longitudinal analysis of the Sleep Heart Health Study, including 1927 men and 2495 women free of CAD and heart failure at baseline, demonstrated a significant but weak association between severe OSA and incident CAD (adjusted HR of 1.7 for those with AHI ≥30 compared with those with AHI <5) in middle-aged men, but not in women.[43] In contrast to this population-based report, a recent observational follow-up study of 1116 women from two Spanish sleep clinic cohorts reported that untreated severe OSA was linked to increased cardiovascular mortality with an adjusted HR of 3.5 for those with AHI of 30 or greater compared to those with AHI of less than 10.[44] Another recent report from the same clinical cohorts demonstrated an adjusted HR of 2.8 (95% CI, 1.4 to 5.6) for the incidence of CAD or stroke in women with untreated OSA (AHI ≥10) compared with the control group without OSA.[45]

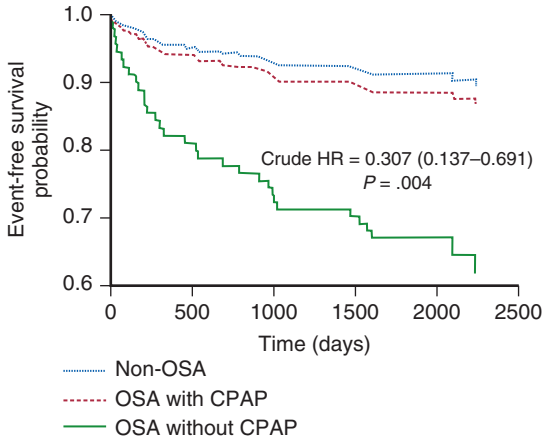
Effect of Obstructive Sleep Apnea Treatment on Coronary Artery Disease

The first-line treatment of OSA is CPAP, which is known to reduce daytime sleepiness and to improve quality of life.[46] A retrospective analysis of 55 subjects and comorbid OSA over an average follow-up time of 7.3 years showed a significantly lower occurrence of the composite end point of cardiovascular death, acute coronary syndrome, hospitalization for cardiac failure, or need for revascularization in those compliant with prescribed CPAP therapy.[47] In another follow-up study over 7.5 years, deaths from cardiovascular disease were less frequent in patients with OSA treated with CPAP compared with those without treatment.[48] Moreover, a review of 371 revascularized patients with OSA with concomitant CAD suggested a significantly lower cardiac death rate (3%) among 175 patients treated with CPAP compared with 10% among 196 untreated patients during a follow-up period of 5 years.[49] In the investigation of the sleep clinic cohort (mentioned earlier),[40] treatment with CPAP significantly reduced cardiovascular risk in men with severe OSA. Similar to that report, adequate CPAP treatment seemed to reduce the risk for composite end point of incident CAD or stroke in women with OSA.[45]

Plenty of evidence suggests that CPAP treatment reduces the number of ischemic events in patients with nocturnal angina and concomitant OSA in the short term.[28] A recent observational study addressed the effect of CPAP on recurrent episodes in patients with acute MI and concomitant OSA.[16] After adjustment for confounding factors, treated OSA patients who were compliant with CPAP had a lower risk for recurrent MI and revascularization (adjusted HRs = 0.16 and 0.15, respectively) than untreated patients and a similar risk to non-OSA patients (Figure 128-3). Of note, some patients with CAD and OSA may not experience daytime sleepiness (i.e., they are asymptomatic), and less is known regarding the adherence to CPAP therapy in these patients. However, a study of a sleep clinic cohort with concomitant CAD suggested a comparable compliance between sleepy and nonsleepy patients.[50] Observational studies might be criticized for potential bias because patients adhering to CPAP may have specific baseline characteristics, may be adhering to other medical therapy, or may otherwise have a healthier lifestyle. Observed benefits of CPAP in an observational study therefore provides a lower scientific evidence value compared with an RCT. Several RCTs examining the effect of CPAP on cardiovascular outcomes are underway.[51-54]

PATHOGENESIS

Obstructive sleep apnea is associated with considerable immediate hemodynamic change (see Chapter 119). During the cycle of the apneic event, there is increased work of breathing, considerable negative intrathoracic pressure swings, recurrent hypoxia and reoxygenation, and fluctuating autonomic activity (see Chapter 119). Heart rate and blood pressure also fluctuate through the cycle, but the relative contribution of each of these changes to development of cardiovascular disease is unknown. Increased oxygen demand and reduced oxygen supply (i.e., hypoxemia) after sleep-disordered breathing may trigger an attack of angina pectoris in patients with CAD, who already have reduced coronary flow reserve.[31] Nocturnal oxygen desaturations have been related to the severity of coronary atherosclerosis in patients with CAD[55] and may be an important contributor to coronary restenosis in patients with CAD who are treated with PCI.[56] Another study reported signs of apnea-induced ischemia predominantly during REM sleep,[8] a finding that may be explained by the often more prolonged and severe apneic events that commonly occur in this sleep stage. OSA is also associated with long-term alteration of cardiac structure, hemodynamic reflex function, and vascular structure or function. A recent report from the baseline echocardiographic investigations of the CAD patients



Patients at risk						
Non-OSA	63	60	59	57	31	12
OSA with CPAP	70	70	67	65	36	19
OSA without CPAP	52	38	35	35	17	9

CPAP, Continuous positive airway pressure; OSA, obstructive sleep apnea. (From Garcia-Rio F, Alonso-Fernandez A, Armada E, et al. CPAP effect on recurrent episodes in patients with sleep apnea and myocardial infarction. *Int J Cardiol* 2013;168:1328–35).

with preserved left ventricular ejection fraction in the RICCADSA cohort demonstrated a poorer diastolic function (OR = 1.9; 95% CI, 1.1 to 3.2) in patients with OSA (AHI ≥15) after adjustment for traditionally recognized risk factors.[57] The OSA is associated with immediate and sustained sympathetic activation.[58] Baroreceptor and chemoreceptor responsiveness is altered,[59] and vascular reactivity in terms of responsiveness to hypoxemia or vasoconstrictors appears to be elevated.[60] A series of studies demonstrated that vascular endothelial function, expressed in terms of nitric oxide vascular dilating capacity, appears to be reduced in OSA.[61] Changes are specific to OSA in the sense that they are reversed by CPAP (see Chapter 119).[62-66]

The mechanisms responsible for endothelial cell damage and dysfunction are not entirely understood. However, investigations have shown that oxidative stress, potentially as a result of periodic hypoxia and reperfusion, is enhanced.[67] Oxidative stress results in compromised nitric oxide bioavailability and leads to an activation of redox-sensitive gene expression. Ensuing steps in this chain of events include increased expression of adhesion molecules by an activated endothelium and leukocytes, which finally leads to acceleration of a vascular inflammatory cascade that promotes atherosclerosis and vascular dysfunction.

This hypothesis (see Chapter 117)[67] is supported by data from patients with OSA demonstrating increased free radical production,[63] increased plasma-lipid peroxidation, increased adenosine and uric acid levels,[67] and increased levels of redox-sensitive gene expression products, including vascular endothelial growth factor[68] and inflammatory cytokines.[69] Interestingly, there was an improvement of endothelial function in patients with OSA following inhibition of xanthine oxidase by allopurinol[70] or supplemental vitamin C.[71] Circulating levels of adhesion molecules[72] as well as adhesion molecule–dependent monocyte to endothelial cell avidity appear to be increased in OSA.[73] Finally, sleep apnea appears to provide an additive stimulus for adhesion molecule expression in patients with CAD.[74] Increased levels of circulating markers of inflammation, including tumor necrosis factor-α,[75] C-reactive protein (CRP),[69,76] and interleukin-6 (IL-6),[69] have been inconsistently found to be increased in OSA. A recent report from the Icelandic Sleep Apnea Cohort containing 454 untreated OSA patients (AHI ≥15) demonstrated that OSA severity was an independent predictor of levels of CRP and IL-6, but this association was found only in obese patients.[77] Another recent report from the RICCADSA cohort demonstrated an association between OSA and elevated CRP and IL-6 also in nonobese patients.[78] This suggests that established CAD may be associated with vascular inflammation in OSA patients irrespective of comorbid obesity and that determinants of these markers are, besides OSA, also influenced by multiple comorbid risk factors for cardiovascular disease.

However, given the knowledge about ischemic preconditioning as a cardioprotective maneuver for reducing experimental myocardial infarct size,[79] it has been proposed that intermittent nocturnal hypoxia in OSA may provide future protection against myocardial ischemic insults by the regulation of critical mechanisms in the coronary endothelium.[80] Indeed, a recent study in patients with acute MI demonstrated a greater mobilization of endothelial progenitor cells and increased endothelial growth factor expression in patients with mild to moderate sleep apnea.[81] Moreover, an observational study of 136 patients with an acute nonfatal MI found lower high-sensitivity troponin-T (hs-TnT) levels in patients with more severe OSA, suggesting a possible cardioprotective role by ischemic preconditioning in OSA.[82] On the other hand, there are data suggesting an independent association between increasing AHI and increasing hs-TnT levels in 1665 individuals without cardiovascular disease.[83] Over a median of 12.4 years' follow-up, hs-TnT was related to risk for death or incident heart failure in all OSA categories, suggesting that subclinical myocardial injury caused by OSA may play a role in the subsequent risk for cardiac disease.[83] Thus the short-term benefits of a possible ischemic preconditioning due to intermittent hypoxemia may be counteracted by other adverse outcomes in the long run.

The tentative association between OSA and CAD is supported by experimental data suggesting oxidative stress, endothelial dysfunction, and acceleration of vascular inflammation as a result of OSA. All these mechanisms facilitate the onset and progression of atherosclerosis. One study found signs of atherosclerosis in large arteries of OSA patients without other risk factors for CAD, and the severity of the signs of atherosclerosis was correlated to the severity of OSA.[84] In another study by the same researcher group, these signs of early atherosclerosis in OSA patients were responsive to CPAP.[85] Finally, a higher atherosclerotic plaque volume in the coronary vessels of the stable CAD patients with OSA was demonstrated using a three-dimensional intravascular ultrasound technique.[86] A more recent study found that the frequency of noncalcified or mixed plaques was much higher in patients with OSA than in non-OSA patients who were investigated by noninvasive coronary computed tomography angiography.[87] Thus atherosclerotic plaque formation may jeopardize coronary flow reserve and generate symptoms of nocturnal angina during periods of increased flow demand. Such episodes occur repeatedly in sleep apnea, and they are associated with hypoxemia that further enhances the vulnerability for ischemia. On the other hand, most heart attacks (i.e., acute MI, sudden cardiac death) stem from sudden rupture of less-obtrusive plaques, which triggers thrombus formation in coronary vessels.[88] As mentioned earlier, it is suggested that sleep-disordered breathing influences the circadian acute coronary event distribution. OSA may lead to a disproportionate number of events that occur during or soon after the sleeping period.

CLINICAL COURSE AND PREVENTION

Early recognition and treatment of OSA may be beneficial in terms of CAD prevention. A retrospective analysis of a sleep laboratory cohort followed over 7 years found a reduction (relative risk, 0.29; 95% CI, 0.10 to 0.82) of incident CAD in patients with effectively treated OSA compared with ineffectively treated or untreated patients.[38] On the other hand, in a group of patients with CAD followed for 5 years, mortality was higher in those with comorbid OSA (38%) than in those with no OSA (9%).[32] Although the higher mortality was in part explained by the presence of other traditional risk factors, there was an independent influence of the breathing disorder. Another study followed 408 patients with stable angina and angiographically verified CAD for 5 years after sleep apnea recordings. The risk for a cerebrovascular event,

including stroke and transient ischemic attack, was tripled in patients with CAD and concomitant OSA.[33,35]

Patients with CAD and nocturnal angina should be considered for sleep recording because nasal CPAP reduces angina attacks and nocturnal myocardial ischemia.[28] In the study of 10 severely disabled patients with a history of frequent nocturnal angina, 9 had sleep apnea.[28] Treatment with CPAP reduced episodes of nocturnal ischemia. There is no evidence to suggest that medication used for treatment of CAD affects the severity of the breathing disorder. A double-blind crossover study of nitrates in patients with OSA with or without CAD found lower oxygen saturation during apnea-associated ischemic episodes than during ischemia not associated with apnea (77.3% vs. 93.1%), and nitrate administration did not reduce the number of ischemic episodes associated with apnea.[89]

Although there is scientific support for a considerable effect of OSA on vascular structure and function, it is likely that development of CAD and other forms of vascular disease is determined by multiple genotypic and phenotypic factors. The absolute role of OSA in this concerted influence should evidently be better clarified. However, with the increasing recognition of OSA as an independent, additive, or even synergistic risk factor for CAD, we are facing a need for early identification of high-risk persons and a consensus on well-defined treatment strategies in such patients. Although more evidence is needed to address CPAP treatment as a useful therapy in patients with CAD and nonsymptomatic OSA, research in this field is growing rapidly, and the results from these ongoing RCTs[51-53] may soon add further insights.

CLINICAL PEARLS

- Recurrent apneas during sleep lead to a sequence of events that independently or in concert with other recognized risk factors are likely to have adverse effects on vascular structure and function.
- Not only may phenomena such as hypoxemia, reoxygenation, and recurrent vascular wall stress induce CAD, but also the events themselves may aggravate already-existing compromised coronary artery flow reserve.
- The adverse health effects of OSA in terms of CAD development, progression, and proneness to complications are likely to depend on genotypic and phenotypic factors. Markers or predictors for identification of high-risk persons in this context are still lacking.
- Almost 50% of patients with CAD have OSA defined according to conventional criteria. A large fraction of these patients do not exhibit daytime sleepiness. Additional data on different phenotypes of OSA as well as compliance with CPAP treatment, especially for nonsleepy patients with OSA and CAD, are needed.
- OSA identifies patients at risk for CAD and may represent a highly prevalent and modifiable risk factor.
- Recognition of the adverse effect of OSA on vascular disease will open a perspective of new primary and secondary prevention models for CAD that involve identifying and eliminating the sleep-disordered breathing.

SUMMARY

Recurrent apneas during sleep lead to a sequence of events that, independently or in concert with other recognized risk factors, are likely to have harmful effects on vascular structure and function. OSA-related phenomena, including hypoxemia, reoxygenation, and recurrent vascular wall stress, may induce CAD, and the events may aggravate already existing compromised coronary artery flow reserve. The epidemiologic support for a causal relationship between OSA and CAD is increasing but is not fully confirmed. This relationship is stronger in clinical cohorts than in the general population, which suggests that comorbid OSA in obese, hypertensive, smoking, and hyperlipidemic patients may provide an additive or synergistic risk factor for development of CAD.

Patients with CAD, including nocturnal angina, should therefore be considered for diagnostic sleep recording because elimination of apneas by nasal CPAP during sleep has been shown to reduce angina attacks and nocturnal myocardial ischemia. Moreover, prospective cohort data point to a reduction of recurrent myocardial infarction and revascularization in CAD patients treated with CPAP. The long-term tentative causal association between OSA and CAD is supported by experimental data suggesting endothelial dysfunction, acceleration of vascular inflammation, and development of atherosclerotic disease as a result of the breathing disorder. Increased recognition of the adverse effect of OSA on vascular disease may open a perspective of new primary and secondary prevention models for CAD that involve identification and elimination of the OSA.

Chapter 129

Heart Failure

Shahrokh Javaheri

Chapter Highlights

- Multiple studies from across the globe showing that about 50% of patients with heart failure, both heart failure with reduced ejection fraction and preserved ejection fraction, have moderate to severe sleep apnea with an apnea hypopnea index ≥15/hour.
- Both obstructive and central sleep apneas may occur concomitantly in the same patient. Therapy will depend, in part, on predominant apnea type, which is determined by polysomnography.
- Multiple studies also indicate that both obstructive and central sleep apneas are independently associated with readmission to the hospital and excess mortality. Furthermore, effective treatment has been shown to decrease the number of readmissions and premature mortality.
- For treatment of obstructive sleep apnea, continuous positive airway pressure therapy is the treatment of choice. Importantly, survival benefits are encountered in only those who are compliant with the device.
- For patients whose sleep apnea is not suppressed by continuous positive airway pressure, including almost 50% of patients with central sleep apnea, we recommend the use of adaptive servo-ventilation if LVEF is greater than 45%. Most of the studies using adaptive servo-ventilation have shown improvement in cardiac biomarkers, and readmission, but the impact on survival may be negative if LVEF is low.

Heart failure has been known for more than 2 centuries to be associated with abnormal breathing patterns, and John Cheyne and William Stokes have been credited for its description—hence the eponym *Cheyne-Stokes breathing*.[1,2] However, 37 years earlier, John Hunter,[3,4] a British physician, was the first to describe this breathing pattern, which is characterized by gradual crescendo–decrescendo changes in tidal volume, commonly with an intervening central apnea (Figure 129-1).[5-9] We therefore refer to this pattern as *Hunter-Cheyne-Stokes breathing* (HCSB). Periodic breathing is a pattern of breathing characterized by cyclic fluctuations in the amplitude of airflow and tidal volume.[10] It consists of recurring cycles of apnea or hypopnea, or both, followed by hyperpnea. The apneas and hypopneas may be obstructive (i.e., the result of upper airway occlusion) or central.[10] Obstructive sleep apnea (OSA)–hypopnea is the most common form of periodic breathing in persons without heart failure. However, in patients *with* heart failure, both obstructive and central periodic breathing are common and frequently occur together, although one phenotype is predominant.

HCSB is a form of periodic breathing with central sleep apnea (CSA) and hypopnea that occurs in patients with heart failure and has a long cycle time.[11] The latter is an important feature of HCSB breathing and reflects the prolonged circulation time that is a pathologic feature of heart failure. HCSB is a subjective description and is not readily quantifiable. For these reasons, the term *central sleep apnea* is preferable, and it also avoids misrepresentation, because credit for the discovery of breathing pattern has not been given to the original discoverer.

CSA observed in awake patients with heart failure has been considered an indicator of a terminal prognosis. However, like obstructive apnea, central apnea occurs primarily during sleep, and polysomnographic studies have reported a high prevalence of this disorder in ambulatory patients with stable heart failure.[8,9,12-14]

EPIDEMIOLOGY OF HEART FAILURE AND SLEEP-RELATED BREATHING DISORDERS

Heart failure has become a major public health problem.[15] In the United States, approximately 5.1 million adults 20 years and older have heart failure, and 0.8 million individuals are newly diagnosed each year.[15] Furthermore, it is projected that the prevalence of heart failure will increase 46% from 2012 to 2030, resulting in more than 8 to 9.5 million people ≥18 years of age with heart failure. It is estimated that heart failure may contribute directly or indirectly to about 280,000 deaths each year.[15] The death rate increases progressively with advanced symptomatology, with a 5-year survival rate approaching 50%.

Heart failure is the largest single Medicare expenditure because it is the leading cause of hospitalization for patients older than age 65 years. Annually, more than 1 million patients with heart failure need hospitalization. In 2012, total cost for heart failure was $30.7 billion dollars (Chapter 123).[15]

Left ventricular (LV) myocardial failure is the most common cause of heart failure in adults, and it could be predominantly diastolic, referred to as *heart failure with preserved ejection fraction* (HFpEF), or manifested by combined systolic and diastolic dysfunction, referred to as *heart failure with*

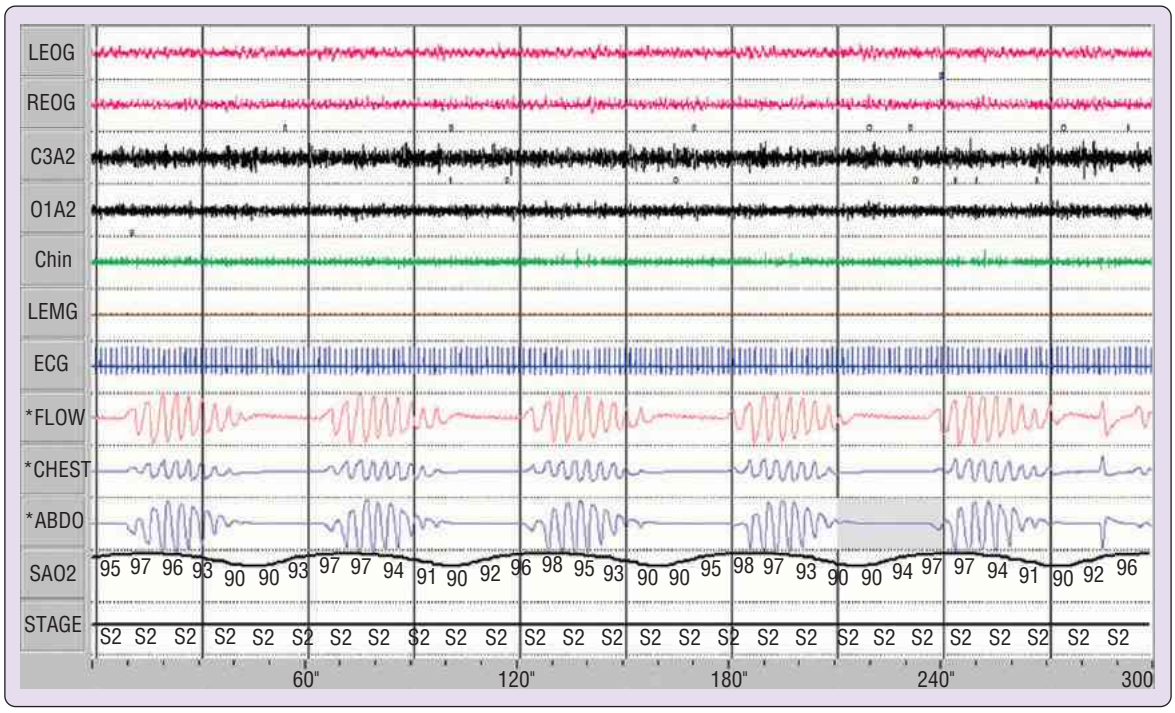

Figure 129-1 A 10-minute epoch of a patient with systolic heart failure and Hunter-Cheyne-Stokes breathing. Note recurrent hypoxia/reoxygenation as a result of central sleep apnea. (From Kryger MH. *Atlas of clinical sleep medicine*. 2nd ed. Philadelphia: Saunders; 2014.)

reduced ejection fraction (HFrEF). The principal hallmark of HFrEF is a depressed left ventricular ejection fraction (LVEF), which is commonly associated with an increase in end-diastolic and systolic volumes. The symptoms, which result from both diminished cardiac output and the concomitant diastolic dysfunction, include shortness of breath, orthopnea, nocturnal dyspnea, nocturia, fatigue, and exercise intolerance. Many of these symptoms overlap with those of sleep apnea, making it difficult to suspect sleep apnea when comorbid with heart failure.

Meanwhile, it is estimated that 20 million people may have asymptomatic LV systolic dysfunction, and, with time, these persons are likely to develop HFrEF. As will be discussed later, overall, about 50% of individuals with LV systolic dysfunction both asymptomatic or symptomatic suffer from moderate to severe sleep apnea.

The other phenotype, HFpEF, is the most common form of heart failure in elderly patients. The pathophysiologic consequence of LV diastolic dysfunction relates to a hypertrophied or a noncompliant left ventricle shifting the pressure volume curve upward and to the left. Therefore, for a given LV volume, LV end-diastolic pressure increases, resulting in elevated left atrial and pulmonary capillary pressures, pulmonary congestion, and edema. Similar to asymptomatic LV systolic dysfunction, which, with time, leads to HFrEF, asymptomatic LV diastolic dysfunction is also independently associated with incident overt heart failure and is predictive of all-cause death.[16]

Sleep Apnea in Heart Failure with Reduced Ejection Fraction

The prevalence of sleep-related breathing disorders has been systematically studied in patients with HFrEF.[5] Polysomnographic studies[6-14,17-25] and studies using respiratory channels[26-29] show a high prevalence of sleep apnea in this population. Most recent large studies of consecutive patients with HFrEF are depicted in Table 129-1.

High prevalence rates have been reported in patients who have HFrEF, HFrEF patients awaiting transplantation,[18] patients with valve heart disease,[19] and those with an implanted cardiac defibrillator.[20]

The most systematic prospective study of HFrEF[17] involved 100 ambulatory male patients with stable, treated heart failure. Using an apnea-hypopnea index (AHI) of 15 events per hour or greater as the threshold, 49 patients (49% of all patients) had moderate to severe sleep apnea–hypopnea, with an average AHI of 44. In comparison, a population study of subjects without heart failure[30] showed that 13% of working men and 6% women ages 30 to 70 years had an AHI of greater than 15. An AHI of 5 or greater has been used to define the presence of a significant number of disordered-breathing events in OSA–hypopnea syndrome.[23] Therefore, with a much higher prevalence of sleep apnea observed in patients with heart failure than in the general population, HFrEF should be the leading risk factor for sleep apnea in the general population. In our studies,[9,17] about 10% of the patients were on beta blockers; however, recent studies continue to show a high prevalence of sleep apnea, both central and obstructive, despite the widespread use of beta blockers. Table 129-1 shows the prevalence of central and OSA in the largest recent studies.[17,23-29] Combining the results of these recent series, which reported an AHI of 15 per hour of sleep as the threshold, 53% of 1607 patients with HFrEF had moderate to severe sleep apnea, 34% had CSA, and 19% had OSA (Figure 129-2). However, there has been considerable variation in the reported prevalence of these two forms of sleep

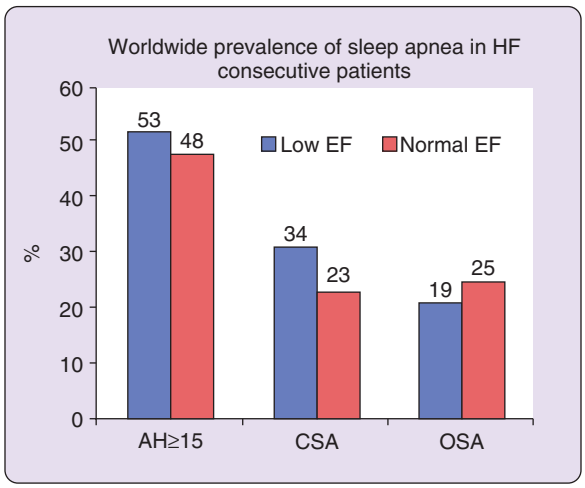

Figure 129-2 Prevalence of sleep apnea in heart failure with reduced ejection fraction (HFrEF) or preserved ejection HFpEF). The data presented combine a series of world sleep studies (see Table 129-1) in consecutive patients with HFrEF, and 244 consecutive patients with HFpEF.[31] AHI, Apnea–hypopnea index; CSA, central sleep apnea; OSA, obstructive sleep apnea. (From Kryger MH. *Atlas of clinical sleep medicine*. Philadelphia: Elsevier; 2014.)

apnea in patients with HFrEF (see Table 129-1), which depends on a number of issues. The major reasons are the criteria used to define hypopnea, the accuracy of classification of disordered-breathing events (obstructive versus central, particularly in regard to hypopneas), the criteria used to define predominant obstructive versus CSA, the number of obese patients with heart failure enrolled, the level of arterial Pco_2, and the severity of LV systolic dysfunction.

Sleep Apnea in Heart Failure with Preserved Ejection Fraction

There is also a high prevalence of sleep apnea in HFpEF.[31,32] The largest prospective study[31] to date evaluated 244 consecutive patients (87 women). All underwent polygraphy, right heart catheterization, and echocardiography. The two major causes of HFpEF were systemic hypertension (44%) and coronary artery disease (33%). Forty-eight percent had an AHI of 15 or more per hour, of whom 23% had CSA. Patients with CSA had lower Pco_2 but higher LV end-diastolic and pulmonary capillary wedge pressure. The latter finding is critical to the development of periodic breathing and CSA because increased wedge pressure and pulmonary congestion decrease the Pco_2 reserve, the major mechanism underlying CSA.[33] We must emphasize that there is a vicious cycle between HFpEF and sleep apnea. Hemodynamic studies show that pulmonary capillary pressure increases during the course of obstructive apnea, indicating the development of LV diastolic dysfunction (see Chapter 120). Chronic repetitive exposure to negative swings in intrathoracic pressure, cyclic nocturnal hypertension and hypoxemia, and diurnal systemic hypertension could eventually result in worsening the LV hypertrophy, dysfunction, and heart failure. In this regard, studies[34,35] suggest that OSA is associated with an increase in LV mass and dysfunction. In the largest study,[36] consisting of 2058 Sleep Heart Health Study participants, LV mass was associated with both apnea–hypopnea and hypoxemia indices after adjustment for age, sex, ethnicity, body mass index, smoking, systolic blood pressure, antihypertensive medication use, diabetes mellitus, prevalent myocardial infarction, and alcohol consumption. Furthermore, in an observational study,[34] treatment of OSA patients with CPAP resulted in a reversal of diastolic dysfunction. In another observational study,[35] an adaptive servo-ventilation (ASV) device was used to treat patients with HFpEF and HCSB and severe CSA. ASV treatment led to a significant decrease in left atrial diameter and early-to-atrial (E/A) filling velocity ratio, whereas the early filling to early diastolic mitral annular velocity ratio increased significantly. It therefore appears that treatment of both OSA and CSA results in remodeling of the left heart structures. These observational findings have been confirmed by a randomized placebo (sham CPAP)–controlled trial,[37] showing that, after 12 weeks on effective CPAP therapy, there was a significant increase in the E/A ratio, a significant decrease in isovolemic relaxation and mitral deceleration time. The results of these studies have important therapeutic implications for HFpEF because, to date, there are no approved therapies to reduce hospitalization or mortality for this disorder, which is on the rise, and the growing elderly population in whom HFpEF is the predominant phenotype of heart failure guarantees additional burden.[38] In addition, similar to asymptomatic LV

systolic dysfunction, which, as noted earlier, will eventually lead to HFrEF, it has been shown that LV diastolic dysfunction is a precursor to HFpEF.[16]

In summary, the prevalence of moderate to severe sleep apnea is about 50% in both forms of heart failure, HFrEF and HFpEF (Figure 129-2), and introduction of beta blockers in the therapeutic armamentarium of heart failure has had no impact on the prevalence of sleep apnea. In contrast to OSA (which is the predominant form of the disorder in the general population with a rare episode of central apnea in the pattern, in heart failure), central and OSA commonly occur together. Sleep physicians reviewing the polysomnogram, therefore, have to determine the predominant form of the disorder for therapeutic options. The predominant phenotype, obstructive versus central, is quite variable and, in large part, depends on the categorization of hypopneas into central or obstructive.

Sex and Sleep-Related Breathing Disorders in Heart Failure

In the general population, the prevalence of OSA is much higher in men than in women. This also holds true for CSA in HFrEF. Combining the results of several studies of patients with HFrEF,[12-14,18,39] 40% of the male patients and 18% of the female patients have CSA (Figure 129-3). A similar trend was found for OSA.

The results of population studies of subjects without heart failure (reviewed by Young and colleagues[40]) suggest that menopause may be a risk factor for OSA, and that the risk is probably reduced by hormone replacement therapy. In women with congestive heart failure and systolic dysfunction, the risk of CSA was six times higher in those ages 60 years and older than in those younger than 60 years.[12] A similar difference was also reported for OSA–hypopnea before and after age 60 years.[12] Thus, female hormonal status plays a role in the development of sleep-disordered breathing in women with and without heart failure.

Progesterone is a known respiratory stimulant, and its effects on the respiratory system may, in part, explain the lower prevalence of central and OSA in menstruating women. Progesterone increases ventilation[41] and the tone of the dilator muscles of the upper airway.[42] Furthermore, premenopausal women have a significantly lower apneic threshold than men.[43] This should decrease the probability of developing central apnea during sleep in female subjects (see the following section on mechanisms of CSA). In contrast to progesterone, administration of testosterone to premenopausal women results in diminution of the P_{CO_2} reserve,[44] which should increase the likelihood of developing apnea during sleep.[32] The results of these two studies suggest that the balance of progesterone/testosterone is critical in determining the P_{CO_2} reserve.

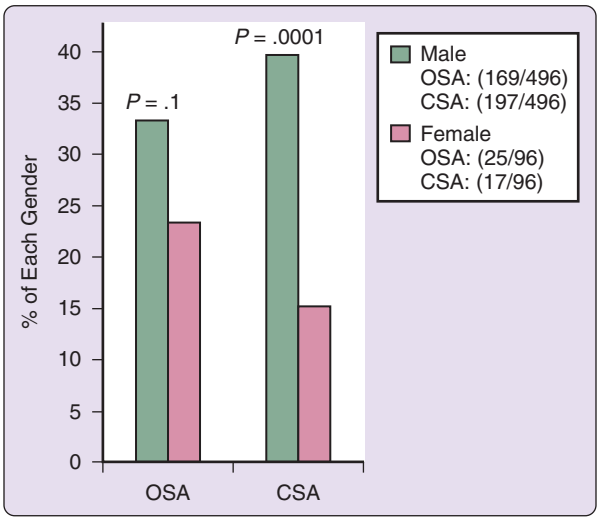

Figure 129-3 Prevalence of obstructive sleep apnea (OSA) and central sleep apnea (CSA) in men and women with systolic heart failure. The prevalence of CSA is much lower in women than in men. A similar trend is found in OSA, although it is not statistically significant. (From Javaheri S. Sleep related breathing disorders in heart failure. In: Mann DL, editor. *Heart failure: a companion to Braunwald's heart disease*. Philadelphia: Saunders; 2004. p. 471–87.)

MECHANISMS OF SLEEP-RELATED BREATHING DISORDERS IN HEART FAILURE

Mechanisms of Central Sleep Apnea in Heart Failure

The mechanisms of periodic breathing and CSA in heart failure are complex and multifactorial (see Chapter 100).[5,33,45,46] In heart failure, alterations occur in various components of the negative feedback system controlling breathing that increase the likelihood of developing periodic breathing, during both sleep and wakefulness. In addition, there are specific sleep-related mechanisms that explain the genesis of CSA and the reason periodic breathing becomes so prevalent during sleep.

Mathematical models of the negative feedback system predict that increased arterial circulation time (which delays the transfer of information regarding changes in P_{O_2} and P_{CO_2} from pulmonary capillary blood to the chemoreceptors, referred to as *mixing gain*), enhanced gain of the chemoreceptors, and enhanced plant gain (e.g., decreased functional residual capacity), which are the three components of the loop gain, collectively increase the likelihood of periodic breathing.[10,11,33,45-48]

Loop gain is the engineering term that defines the tendency of the negative feedback loop toward instability in response to a ventilatory disturbance. As an example, normally, a short pause in breathing, an apnea, or hypopnea causes a compensatory increase in ventilation. If the magnitude of the increase in ventilation is greater than or equal to the magnitude of the preceding respiratory disturbance, that is, loop gain is ≥1, the system becomes unstable and will fluctuate between underventilation and overventilation.

Delay in transfer of information due to prolonged circulation time, that is, increased mixing gain, plays a fundamental role in destabilization of a negative feedback system.[11,33,47] It has the potential to convert a negative feedback system to a positive feedback system. In heart failure, arterial circulation time may be increased for a variety of reasons, including dilation of cardiac chambers, increased pulmonary blood volume, and decreased cardiac output. However, patients with heart failure invariably have increased circulation time. Therefore, although increased circulation time is necessary to develop periodic breathing, it does not explain why only some heart failure patients have periodic breathing. The second component of the loop gain that increases the likelihood of occurrence of periodic breathing (and also central apnea during sleep) is the gain of the chemoreceptors.[8] In persons with increased sensitivity to CO_2 (or hypoxia), the chemoreceptors elicit a large ventilatory response whenever the P_{CO_2} rises (or the P_{O_2} decreases). The consequent intense hyperventilation,

by driving the P_{CO_2} below the apneic threshold, results in central apnea. As a result of central apnea, P_{CO_2} rises (and P_{O_2} falls), and the cycles of hyperventilation and hypoventilation (hypopnea) or central apnea are maintained.[7] Differences in the gain of the chemoreceptors among patients with heart failure may, in part, explain why only some patients with heart failure develop periodic breathing and CSA.

The third component of the loop gain that may contribute to the development of periodic breathing in heart failure is decreased functional residual capacity, which results in underdamping.[5,33,45] This means that, for a given change in ventilation (e.g., a pause in breathing), changes in the controlled variables—namely P_{O_2} and P_{CO_2}—will be augmented (referred to as *increased plant gain*). In turn, the augmented changes in P_{O_2} and P_{CO_2} result in a pronounced compensatory ventilatory response, and overcompensation tends to destabilize breathing. Patients with heart failure may have decreased functional residual capacity for a variety of reasons, including pleural effusion, cardiomegaly, and decreased compliance of the respiratory system. Functional residual capacity may decrease further in the supine position, facilitating the development of periodic breathing in this position.

The aforementioned mechanisms that collectively increase the loop gain and the likelihood of periodic breathing are present during both sleep and wakefulness. However, in the supine position and during sleep, further changes, such as a reduction in functional residual capacity, metabolic rate (another factor in the plant gain), and cardiac output, occur that will augment the likelihood of developing periodic breathing beyond that observed during wakefulness. Furthermore, loop gain, as described previously, differs from the dynamic loop gain during sleep when periodic breathing is present and steady state is absent.[33]

Meanwhile, like obstructive apnea, central apnea usually occurs during sleep or when a subject is awake but dozing. The genesis of CSA during sleep relates specifically to the removal of the nonchemical drive of wakefulness on breathing and to the unmasking of the apneic threshold—the level of P_{CO_2} below which rhythmic breathing ceases.[33] The difference between two P_{CO_2} set points—the prevailing P_{CO_2} minus the P_{CO_2} at the apneic threshold, referred to as *P_{CO_2} reserve*—is a critical factor for the occurrence of CSA. The smaller the difference, the greater the likelihood of occurrence of apnea.

Normally, with the onset of sleep, ventilation decreases and P_{CO_2} increases. As long as the prevailing P_{CO_2} is above the apneic threshold, rhythmic breathing continues. However, in some patients with heart failure, the awake prevailing P_{CO_2} does not significantly rise with onset of sleep.[49,50] Importantly, however, heart failure patients who develop central apnea have increased CO_2 chemosensitivity below eupnea[50] while asleep, as well as above eupnea while awake, as discussed previously.[48] Because of increased CO_2 chemosensitivity below eupnea,[50] the prevailing P_{CO_2} and the apneic threshold P_{CO_2} are close together, increasing the likelihood of developing central apnea during sleep. The increased chemosensitivity above eupnea becomes particularly pathophysiological during arousals occurring following apneas, when excessive ventilatory response lowers the prevailing P_{CO_2} toward or below the apneic threshold.[48]

The reason for the lack of the normally observed rise in P_{CO_2} in some patients with heart failure is not clear. It could result from the lack of the normally observed sleep-induced decrease in ventilation. Conceivably, because of increased venous return in the supine position, and in the presence of a stiff left ventricle, pulmonary capillary pressure could rise. This results in an increase in respiratory rate and ventilation, preventing the normally observed rise in P_{CO_2}. At the same time, the increase in pulmonary capillary pressure increases the chemosensitivity below eupnea and decreases the P_{CO_2} reserve, promoting the likelihood of developing central apnea. This was demonstrated in naturally sleeping dogs in whom pulmonary capillary pressure could be increased to different levels by inflating a balloon placed in the left atrium.[51] The mechanisms remain to be fully elucidated, although vagal afferents have been shown to have significant influences on the responsiveness of both carotid bodies as well as central chemoreceptors.[32] Several studies[52-54] have shown that patients with heart failure and low arterial P_{CO_2} have a high probability of developing central apnea during sleep. Predictive value of a low steady-state arterial P_{CO_2} (<35 mm Hg) is about 80%.[54] The reason for this association lies on the fact that a low arterial P_{CO_2} is caused by increased pulmonary wedge pressure, which, per se, sensitizes carotid bodies and the central chemoreceptors promoting CSA, as noted previously.[48] Meanwhile, although an awake low arterial P_{CO_2} is highly predictive of CSA, it is not a prerequisite. Many patients with heart failure and CSA have a normal awake arterial P_{CO_2}.[55] What is important is the proximity of the apneic threshold to the arterial P_{CO_2}, and an increased CO_2 chemosensitivity below eupnea.

Mechanisms of Obstructive Sleep Apnea in Heart Failure

As noted earlier, OSA and hypopnea are also common in heart failure. The mechanisms are multifactorial.[7,56-59] First, periodic breathing resulting from heart failure predisposes the susceptible subjects to develop upper airway occlusion during the nadir of the ventilatory cycles of periodic breathing.[7,56] For this reason, we observed multiple episodes of upper airway obstruction frequently following central apneas.[7]

Second, increased venous congestion and pressure resulting from right heart failure may diminish upper airway size[57] and facilitate upper airway occlusion. Venous congestion of the upper airway may be worse in the supine (than in the erect) position, and rostral fluid shift, particularly in the presence of edema in the lower extremities and redistribution of fluid into vascular space, may further compound upper airway patency.[58] Third, patients with heart failure and OSA are commonly obese, and obesity may compromise upper airway patency. While currently 35% of patients with HFrEF are obese, almost 53% of those with HFpEF suffer from this disorder[59] for which reason the prevalence of OSA is higher in patients with HFpEF than in HFrEF.[31,32]

In summary, decreased upper airway size resulting from both venous congestion and obesity may predispose patients with heart failure to develop upper airway occlusion during the nadir of the ventilatory cycles of periodic breathing, when the tone of the dilator muscles of the upper airway decreases the most.

PATHOLOGIC CONSEQUENCES AND PROGNOSTIC SIGNIFICANCE OF SLEEP-RELATED BREATHING DISORDERS

The cycles of apnea–hypopnea and hyperpnea, both obstructive and central, are associated with three adverse

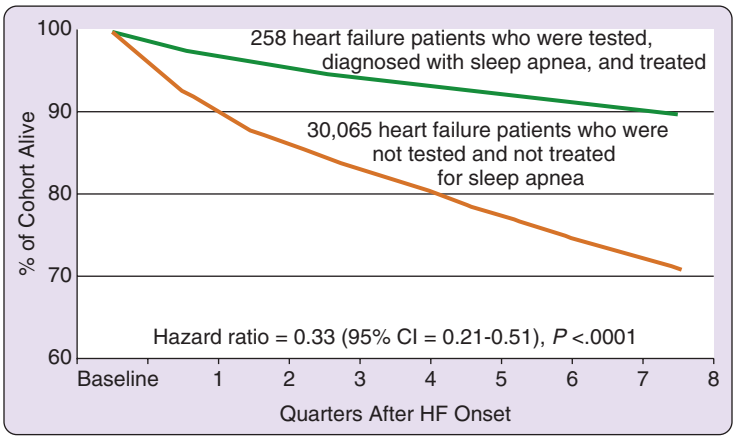

Figure 129-4 Data were from Medicare beneficiaries who were diagnosed with new heart failure. The 2-year survival of the 258 patients who were tested, diagnosed, and treated for sleep apnea was much better than the survival of the 30,065 patients who were not tested for sleep apnea. The survival was adjusted for age, gender, and Charlson Comorbidity Index. (Modified from Javaheri S, Caref B, Chen E, et al. Sleep apnea testing and outcomes in a large cohort of Medicare beneficiaries with newly diagnosed heart failure. *Am J Respir Crit Care Med* 2011;183:539–46.)

consequences. These include arterial blood gas abnormalities characterized by intermittent hypoxemia–reoxygenation and hypercapnia–hypocapnia, excessive arousals and shift to light sleep stages, and large negative swings in intrathoracic pressure (see Chapter 119). The pathophysiologic consequences of obstructive and CSAs and hypopneas are qualitatively similar (but worse in OSA than in CSA), adversely affect various cardiovascular functions, and are potentially most detrimental in the presence of established coronary artery disease and LV systolic and diastolic dysfunction. In the long run, these adverse consequences result in excess morbidity, hospital readmission, and mortality of patients with heart failure.

Effects of Obstructive Sleep Apnea on Sympathetic Activity, Cardiovascular Function, Hospital Readmission, and Mortality

In patients with heart failure, the presence of OSA is associated with increased sympathetic activity[60] and reduced LVEF, which are reversed if sleep apnea is effectively treated with nasal CPAP.[54-57] There are five randomized clinical trials[61-65] of CPAP therapy for OSA in patients with HFrEF. In three of these studies,[61-63] LVEF increased significantly (when compared with the control group) by about 10%, 5%, and 2%. In two[63,64] of these five studies, sham CPAP was used in the control group; in one,[63] LVEF increased significantly but slightly (2%), and, in the other one,[64] ejection fraction did not increase. In the latter study,[64] auto-CPAP was used, and the adherence hours to CPAP were less than in the two previous studies,[61,62] which had demonstrated 10% and 5% increases in ejection fraction. In the most recent study,[64] 45 patients with OSA (mean AHI = 27/hour of sleep) and HFrEF (mean LVEF = 36%) were randomized to CPAP (n = 22) or no CPAP (n = 23) for 6 to 8 weeks. Comparing the two groups, there were no significant changes in LVEF.

In patients with established coronary artery disease, OSA is an independent prognostic factor for recurrent cardiovascular disorders and survival.[66-67] Similarly, in heart failure, OSA is an independent predictor of mortality,[23] and two observational studies (Figure 129-4), one from Japan[68] and the other from the United States,[69] confirm this association and further

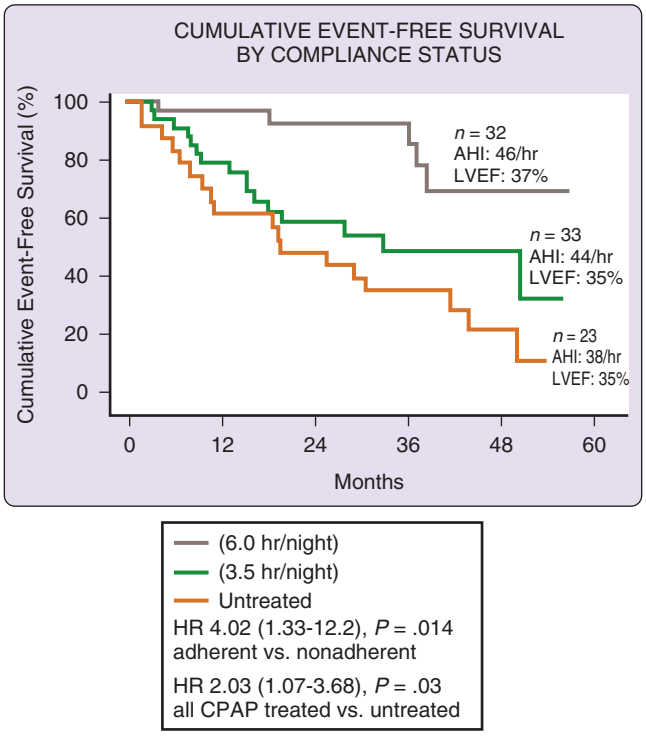

Figure 129-5 Probability for hospitalization and mortality of heart failure patients with obstructive sleep apnea decrease if they are treated with continuous positive airway pressure (CPAP) and adhere to therapy. AHI, Apnea–hypopnea index; HR, hazard ratio; LVEF, left ventricular ejection fraction. (From Kryger MH. *Atlas of clinical sleep medicine*. Philadelphia: Elsevier; 2010; modified from Kasai T, Narui K, Dohi P, et al. Prognosis of patients with heart failure and obstructive sleep apnea treated with continuous positive airway pressure. *Chest* 2008;133:690–6.)

suggest that therapy with CPAP improves survival, particularly in those who are most compliant with it (Figure 129-5).[68] This latter observation in patients with heart failure is similar to that in patients with hypertension, as studies indicate that the reduction in blood pressure is most prominent in those who are most adherent to CPAP therapy

(see Chapter 120). In the U.S. study,[69] a random sample of Medicare beneficiaries newly diagnosed with heart failure was enrolled. Of the 30,719 subjects, only 1263 (4%) were clinically suspected to have sleep apnea. Of these, 553 (2% of the total cohort) underwent sleep study, and some were treated mostly with CPAP. After adjustment for age, sex, and comorbidities, subjects with heart failure who were tested, diagnosed, and treated had a better 2-year survival rate compared with subjects with heart failure who were not tested (hazard ratio, 0.33 [95% confidence interval, 0.21–0.51]; $P = .0001$; Figure 129-4).

One important issue not previously emphasized is that, in patients with heart failure, OSA is independently associated with excess hospital readmission and that treatment of sleep apnea could lower the rate of readmissions. In the United States, Medicare began financially penalizing hospitals with excess readmissions in 2012, and, starting in October 2013, readmission penalties doubled to 2% of reimbursement. In one study from a heart hospital, Khayat and colleagues[70] demonstrated that severe OSA was independently associated with 1.5 times higher readmission when compared to heart failure patients without OSA. Importantly, these authors accounted for a large number of relevant pathologic variables, which otherwise could have associated with excess readmission. Meanwhile, two studies have shown that treatment with CPAP decreases the rate of readmission. In a study of Medicare beneficiaries with congestive heart failure, readmission costs for those treated for sleep apnea (mostly with CPAP) were much lower than for those suspected of having sleep apnea but who were not referred for sleep studies and, consequently, remained untreated.[69,71] Another retrospective study[72] of patients admitted to the hospital for a cardiac cause, including congestive heart failure who underwent polygraphy and found to have sleep apnea (AHI ≥ 5/hour, mostly OSA), hospital readmission or emergency department visit for a cardiac issue within 30 days of discharge was quite high in those who refused or were nonadherent to CPAP compared to those who adhered to CPAP therapy ($P = .025$).

Effects of Central Sleep Apnea on Sympathetic Activity, Cardiovascular Function, Hospital Readmission, and Mortality

Like OSA, CSA is associated with increased sympathetic activity and reduced LVEF, which is reversed by effective therapy with CPAP[73] and oxygen.

Several studies,[21,29,74-86] but not all,[84,85] have suggested that presence of CSA decreases survival among patients with HFrEF. In one[84] of the two studies[84,85] noted, there was a tendency for excess mortality in heart failure patients with CSA, although this was not significant, probably because of the small number of patients.

We followed 88 heart failure patients with ($n = 56$) or without ($n = 32$) CSA with a median follow-up of 51 months.[81] After controlling for 24 confounding variables, CSA was associated with excess mortality (hazard ratio, 2.14; $P = .02$; Figure 129-6). The average survival of heart failure patients without CSA was 90 months compared with 45 months for those with CSA. That CSA contributes to excess mortality in heart failure is supported by the observation that effective treatment of CSA with CPAP in HFrEF[80] and with ASV in HFpEF[87]

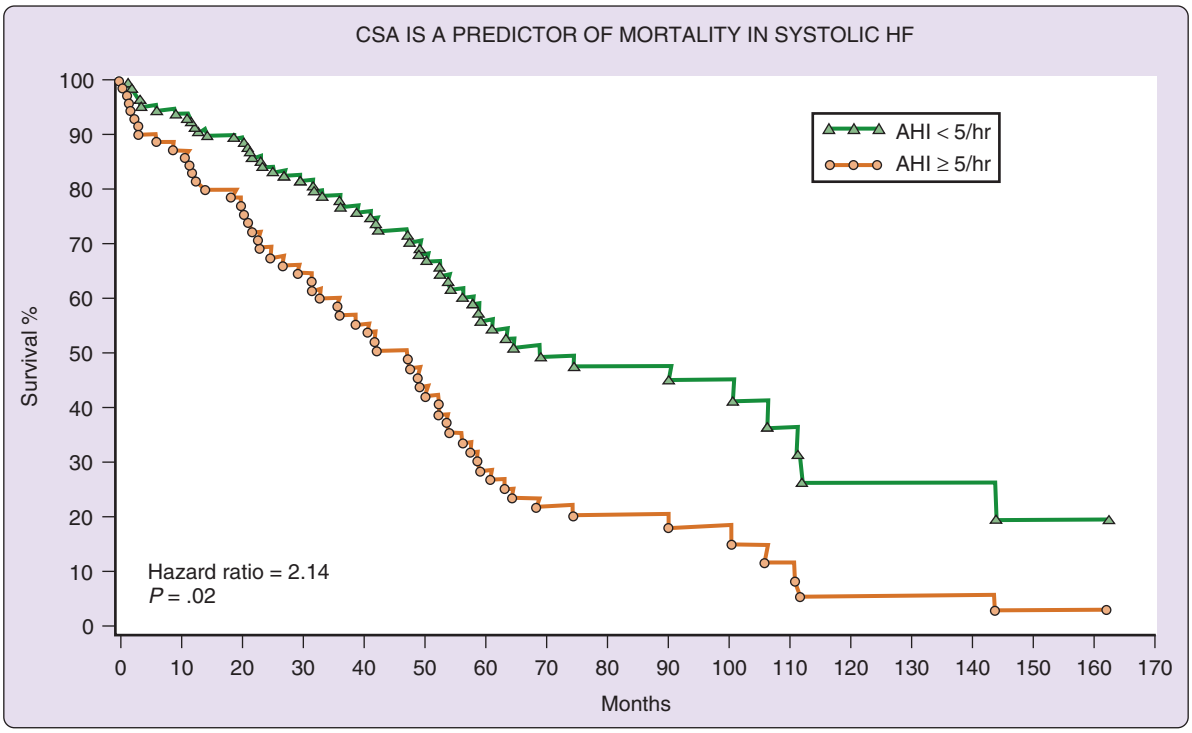

Figure 129-6 Probability of survival in patients with systolic heart failure (HF) according to the presence or absence of central sleep apnea (CSA). AHI, Apnea–hypopnea index. (From Kryger MH. *Atlas of clinical sleep medicine.* Philadelphia: Elsevier; 2010; modified from Javaheri S, Shukla R, Zeigler H, Wexler L. Central sleep apnea, right ventricular dysfunction, and low diastolic blood pressure are predictors of mortality in systolic heart failure. *J Am Coll Cardiol* 2007;49:2028–34.)

improves survival. The first study[80] was based on the post-hoc analysis of the Canadian randomized clinical trial, and the second one was a randomized trial involving the small number of patients with HFpEF.[87] The results of a relatively large observational study[29] of patients with predominantly CSA who agreed to use ASV are consistent with those of the aforementioned randomized trials.[81,87]

Similar to findings in OSA, CSA has been found to be an independent predictor of hospital readmission within 30 days after discharge. Khayat and colleagues[70] performed a prospective observational study of consecutive patients with HFrEF (LVEF = 22%), 165 with CSA and 139 without sleep apnea. In patients with CSA, the rate ratio for cardiac readmission within 1 or 6 months was 1.5 (P = .03) higher than patients without sleep apnea. The authors accounted for age, gender, body weight, blood pressure, coronary artery disease, hemoglobin, serum sodium and creatinine concentration, diabetes mellitus, and length of stay. Further, treatment of CSA has been shown to be associated with decreased hospital readmission.[88-91] Virtually all of these studies[88-91] are from Japan, are observational, the end points were a combination of premature mortality and readmission due to heart failure, and ASV devices were used to treat CSA, or when mixed with OSA.

CLINICAL PRESENTATION OF OBSTRUCTIVE AND CENTRAL SLEEP APNEAS IN PATIENTS WITH HEART FAILURE

Obesity is an important risk factor for development of OSA in patients with heart failure,[9,12,16] as it is for patients without heart failure.[29] Patients with HFrEF and OSA are significantly heavier and snore habitually (Figure 129-7). They may also have a higher systemic arterial blood pressure than subjects with CSA.[9,12] Aside from obesity and habitual snoring, it is often difficult to clinically suspect the presence of sleep apnea in patients with heart failure because (1) the prevalence of sleepiness is similar in heart failure patients with and in those without sleep apnea[9,16] (see Figure 129-7), and (2) the symptoms of heart failure and sleep apnea overlap. The overlapping symptoms of sleep apnea and heart failure include sleep-onset and maintenance insomnia, nocturia, waking up with shortness of breath (orthopnea, paroxysmal nocturnal dyspnea, hyperpnea due to periodic breathing), unrefreshed sleep, and daytime fatigue. The overlapping of the symptoms of heart failure and sleep apnea undoubtedly contributes to the underdiagnosis of sleep-related breathing disorders in patients with heart failure. CSA, in particular, is most difficult to diagnose,[8] because obesity and habitual snoring, which are the two hallmarks of OSA (see Figure 129-7), are commonly absent in heart failure patients with CSA.[8,9] However, there are some clues that, when present, should increase the probability of the presence of CSA. These include a high-numbered class in the New York Heart Association classification, low LVEF, and steady-state arterial Pco_2, atrial fibrillation, and nocturnal ventricular arrhythmias (Figure 129-8).[9]

Indications for Polysomnography in Heart Failure

As noted, patients with heart failure and sleep apnea do not generally present with symptoms that distinguish them from heart failure patients without sleep apnea. Furthermore, because heart failure is common, it is not possible to perform sleep studies on all patients with heart failure. However, there are a number of clinical and laboratory findings that, when present in patients with heart failure, should increase clinical suspicion for sleep apnea. These markers are different for obstructive and CSA.

Risk factors for OSA–hypopnea in patients with heart failure are similar to those in patients without heart failure. They include obesity, increased neck size, habitual snoring, and hypertension. These risk factors and others, such as

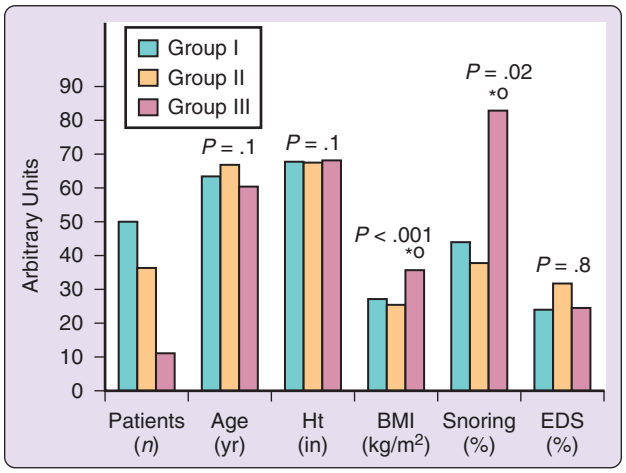

Figure 129-7 Demographics, historical data, and physical examination findings in heart failure patients without sleep apnea, with central sleep apnea (CSA), and with obstructive sleep apnea (OSA). Patients with OSA were more obese and had a higher prevalence of habitual snoring than patients with CSA. There was no difference in prevalence of excessive daytime sleepiness between the patients with heart failure and the patients without sleep apnea. BMI, Body mass index; EDS, excessive daytime sleepiness; Ht, height. (From Kryger MH. *Atlas of clinical sleep medicine*. Philadelphia: Elsevier; 2010; modified from Javaheri S. Sleep disorders in systolic heart failure: a prospective study of 100 male patients—the final report. *Int J Cardiol* 2006;106:21–8.)

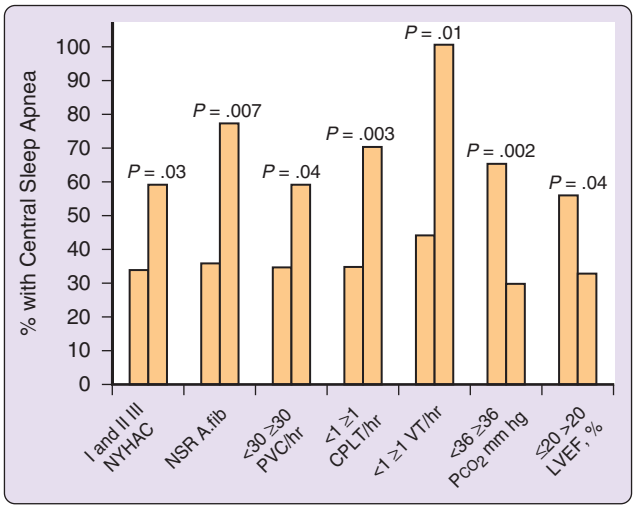

Figure 129-8 Clinical and laboratory characteristics that are more likely to be associated with central sleep apnea. A. fib, Atrial fibrillation; CPLT, couplets; LVEF, left ventricular ejection fraction; NSR, normal sinus rhythm; NYHAC, New York Heart Association Class; PVC, premature ventricular contractions; VT, ventricular tachycardia. witnessed apnea, waking up unrested, and excessive daytime sleepiness, when present, should increase the level of suspicion for the presence of OSA. The following are symptoms that should alert the clinician to the possibility of apnea in heart failure patients:

Nocturnal angina—substernal chest pain that awakens the patient—should increase suspicion for sleep apnea in the general population and for patients with coronary heart disease and heart failure.

Paroxysmal nocturnal dyspnea characteristically awakens the patient with shortness of breath, which is relieved with resumption of an erect position. However, this symptom may be a perception of shortness of breath occurring during the hyperpneic phase of periodic breathing, suggesting presence of sleep apnea.

Restless sleep, maintenance insomnia, and *leg movements* may reflect periodic arousals and movements after apneas and hypopneas. Periodic limb movement, however, is also found in patients with systolic heart failure.[16,92,93]

Patients with heart failure and progressive ventricular systolic or diastolic dysfunction or patients who remain in New York Heart Association classes III or IV, despite intensive medical therapy, should have a diagnostic sleep study.

The prevalence of sleep apnea is high in patients with an implanted cardioverter or defibrillator,[20] and those awaiting cardiac transplantation.[17] The waiting period for transplantation is long, and a large number of patients succumb to the consequences of heart failure while waiting. It is conceivable that survival of these pretransplant patients may improve if their sleep apnea is diagnosed and appropriately treated. If so, the chance of receiving cardiac transplantation may increase.

As noted earlier, several studies[52-54] have shown that heart failure patients with low arterial Pco_2 have a high prevalence of CSA. The predictive value of low Pco_2 (<35 mm Hg) is about 80%.[54] However, many patients with heart failure have CSA apnea without daytime hypocapnia.[54,55]

Several studies have shown that heart failure patients with sleep apnea have a higher prevalence of atrioventricular arrhythmias, especially atrial fibrillation[9,12,16,94] and nocturnal ventricular arrhythmias.[9,16,95] Presence of these arrhythmias should increase suspicion for the presence of CSA.

In the presence of the aforementioned risk factors for obstructive and CSA, polysomnography should be performed for diagnosis and response to therapy. Such an approach has been shown to decrease hospital readmission and improve survival, as discussed previously.

TREATMENT OF SLEEP-RELATED BREATHING DISORDERS IN PATIENTS WITH HEART FAILURE

The choice of therapy for obstructive or CSA is based on the type of sleep apnea.[96]

TREATMENT FOR OBSTRUCTIVE SLEEP APNEA

In general, treatment of OSA–hypopnea is similar in patients with and without heart failure, although there are some differences (Box 129-1). In the presence of cardiovascular disease, every attempt should be made to treat OSA with positive airway pressure devices.

Box 129-1 TREATMENT OF OBSTRUCTIVE SLEEP APNEA IN PATIENTS WITH HEART FAILURE OPTIMIZATION OF CARDIOPULMONARY FUNCTION

- To eliminate or improve periodic breathing
- To decrease right atrial and central venous pressure upper airway congestion/edema, which may increase upper airway size
- To improve functional residual capacity, which may increase upper airway size as lung volume increases
- Avoidance of benzodiazepines, opioids, alcoholic beverages, and Viagra
- Weight loss if applicable
- Nasal positive airway pressure devices:
  - Continuous positive airway pressure (CPAP)
  - Bilevel positive airway pressure (see Chapter 107)
- Oral appliances (see Chapter 109):
  - Supplemental nocturnal nasal oxygen to minimize desaturation and to decrease periodic breathing
- Upper airway procedures:
  - Uvulopalatopharyngoplasty (see Chapter 108)
  - Laser surgery (see Chapter 108)
  - Radiofrequency volume reduction (see Chapter 108)

Optimization of Cardiopulmonary Function

Optimal treatment of heart failure by improving both periodic breathing and lower extremity edema may decrease the likelihood of developing upper airway occlusion. Upper airway narrowing and occlusion may occur at the nadir of the ventilatory cycle of periodic breathing,[56] and, in some patients with heart failure, the first few breaths after central apneas are obstructed.[7] Furthermore, in biventricular heart failure, elevated right atrial and central venous pressure may result in pharyngeal congestion and edema, which along the fluid from lower extremities translocated cephalad in supine position could result in narrowing of the upper airway. Therefore, therapeutic measures to decrease the lower extremity edema and venous pressure[57,58] are advisable. Also, optimal treatment of heart failure to decrease lung water and pleural effusion could increase lung volumes, which should increase upper airway size, which is dependent on lung volume.

Weight Loss

In the general population, obesity is a major risk factor for OSA, and weight reduction improves OSA (see Chapter 106). Similarly, obesity is associated with increased risk of a new onset cardiovascular disease, including heart failure.[97,98] In spite of these aforementioned relationships between obesity, OSA, and heart failure in the general population, studies of patients with heart failure have consistently demonstrated an obesity paradox, indicating that obesity is a strong independent predictor of improved outcomes for patients with chronic heart failure. However, many patients with heart failure and OSA are obese,[9,12,16] and OSA per se has been shown to be a risk factor for the development of heart failure.[99] For this reason, we generally advise weight loss for obese patients with OSA, irrespective of heart failure. However, studies are needed to determine optimal body weight and whether purposeful weight loss in congestive heart failure comorbid with OSA improves cardiac function.

Avoidance of Alcoholic Beverages, Benzodiazepines, and Phosphodiesterase-5 Inhibitors at Bedtime, and Smoking

The use of alcoholic beverages and benzodiazepines may increase the likelihood of upper airway occlusion by promoting the relaxation of the muscles of the upper airway. We also advise patients that phosphodiesterase inhibitors used to treat erectile dysfunction (e.g., sildenafil [Viagra], vardenafil [Levitra], and tadalafil [Cialis]) may worsen OSA. In a randomized double-blind placebo-controlled study,[100] it was shown that 50 mg of sildenafil significantly increased the obstructive AHI and desaturation in a group of patients with OSA.

Smoking, via mechanisms mediated by nicotine, the active chemical in tobacco, increases efferent sympathetic activity (at least, in part, due to stimulating peripheral chemoreceptors in the carotid bodies, which contain excitatory nicotinic receptors) and plasma catecholamine resulting in increases in blood pressure, heart rate, and myocardial oxygen consumption.[101] In addition, nicotine decreases oxygen availability and causes coronary vasospasm, all promoting ventricular tachyarrhythmia. In a recent study[101] of 87 patients with HFrEF, smoking was associated with nocturnal ventricular tachycardia with an odds ratio of about 10. This is not surprising because excessive adrenergic overactivity is the underlying mechanism of arrhythmias and heart failure, in particular, when comorbid with sleep apnea is already a hyperadrenergic state.

Positive Airway Pressure Devices

Positive airway pressure devices are the treatment of choice and have been most successfully used to treat OSA in the general population and in patients with heart failure. First-night application of nasal CPAP results in a significant decrease in disordered breathing, arterial oxyhemoglobin desaturation, and arousals.[102] Short-term use of CPAP in patients with heart failure and OSA improves LVEF, blood pressure, and ventricular systolic volume,[61-63] but adherence to CPAP is a critical factor. For CPAP-noncompliant subjects who complain of a high expiratory pressure, bilevel pressure devices should be tried. As noted earlier, two recent observational studies[68,69] of patients with heart failure have shown that effective treatment of OSA with CPAP improves survival, particularly in those who are compliant with CPAP (see Figures 129-4 and 129-5).[68]

Supplemental Nasal Oxygen

For subjects with heart failure who cannot tolerate positive air pressure devices, oxygen is an alternative for treating OSA. The rationale for use of nocturnal supplemental nasal oxygen is to improve both hypoxemia and periodic breathing. Minimizing desaturation and hypoxemia–reoxygenation may have important therapeutic implications. Furthermore, as noted earlier, improvement in periodic breathing may decrease in obstructive disordered-breathing events that occur at the nadir of ventilation. We emphasize, however, that there are no systematic studies treating OSA of patients with heart failure with oxygen.

Upper Airway Surgical Procedures

Upper airway surgical procedures are performed for treatment of OSA in the general population, but there are no data in patients with heart failure.

Oral Appliances

Oral appliances are used to treat OSA, particularly in patients who cannot tolerate CPAP (see Chapter 109). Limited data are available in heart failure.[103] We speculate that efficacy of these devices in heart failure patients with OSA is similar to that in the general population. After application, a sleep study is recommended to ensure effectiveness.

TREATMENT FOR CENTRAL SLEEP APNEA

Figure 129-9 shows our approach to treatment of patients with CSA in heart failure.

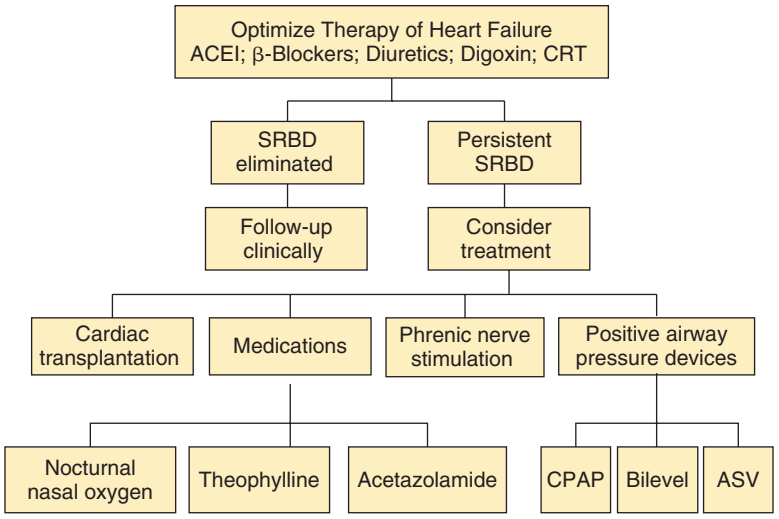

Figure 129-9 Treatment of central sleep apnea in patients with systolic heart failure. ACEI, Angiotensin-converting enzyme inhibitor; APSSV, adaptive pressure support servo-ventilation; CRT, cardiac resynchronization therapy; nCPAP, nasal continuous positive airway pressure; PAP, positive airway pressure; SRBD, sleep-related breathing disorder. (Modified from Javaheri S. Sleep-related breathing disorders in heart failure. In: Mann DL, editor. *Heart failure: a companion to Braunwald's heart disease*. Philadelphia: Saunders; 2004. p. 482.)

Optimization of Cardiopulmonary Function

Intensive therapy for heart failure with diuretics, angiotensin-converting enzyme inhibitors, beta blockers, and cardiac resynchronization therapy (CRT) can improve periodic breathing.[5] Because pulmonary congestion and edema are associated with narrowing of P_{CO_2} reserve,[51] reduction in wedge pressure should be associated with widening of P_{CO_2} reserve and improvement in CSA. Furthermore, with therapy, arterial circulation time decreases (as stroke volume increases and cardiopulmonary blood volume decreases), and functional residual capacity may increase (because of a decrease in cardiac size, pleural effusion, and intravascular and extravascular lung water). These changes contribute to the stabilization of breathing.

Beta blockers, by increasing stroke volume and decreasing pulmonary capillary pressure, should be particularly helpful in improving periodic breathing in systolic heart failure. An additional beneficial effect of beta blockers may relate to their counterbalancing of nocturnal cardiac sympathetic hyperactivity, resulting from repetitive arousals and desaturation. The reduction in cardiac sympathetic activity may have contributed to improved survival in trials of beta blockers in patients with heart failure. One particular side effect of beta blockers, however, is related to their effect on melatonin. Melatonin, a sleep-promoting chemical, is secreted via the cyclic adenosine monophosphate–mediated beta-adrenergic signal transduction system. Some beta blockers (exceptions include carvedilol), by inhibiting this process, decrease melatonin secretion[104,105] and could potentially contribute to worsening of sleep.

Regarding improvement in cardiac function and CSA, a few studies of CRT[106-110] showed some improvement in CSA, particularly noticeable in those with CRT-induced hemodynamic improvement. However, CRT devices are ineffective for OSA; although, in one study,[106] OSA improved, and improvement correlated with a decrease in circulation time.

If periodic breathing persists after cardiopulmonary function is optimized, several approaches are possible (see Figure 129-9).

Cardiac Transplantation

Preliminary studies, reviewed by Javaheri,[5] and a study of 45 patients with heart failure[111] have shown that, after cardiac transplantation, CSA is virtually eliminated. However, with time, a large number of cardiac transplant recipients develop OSA.[92] In this study, 36% had an AHI of 15 per hour or greater.[111] OSA developed in those who had gained the most weight after transplantation, and it was associated with habitual snoring, poor quality of life, and systemic hypertension. Cardiac transplantation was also associated with a high prevalence of restless legs syndrome and periodic limb movements (Figure 129-10).[111]

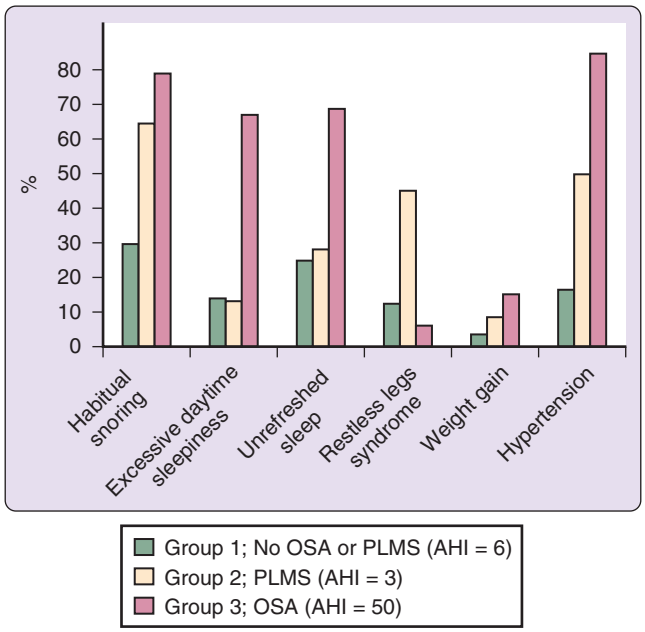

Figure 129-10 Phenotype of patients after heart transplantation. Group 1 did not have obstructive sleep apnea (OSA) or periodic limb movements during sleep (PLMS), Group 2 had PLMS, and Group 3 had OSA. AHI, Apnea–hypopnea index. Weight gain is in kilograms since the transplantation. (Modified from Javaheri S, Abraham W, Brown C, et al. Prevalence of obstructive sleep apnea and periodic limb movement in 45 subjects with heart transplantation. *Eur Heart J* 2004;25:260–6.)

Positive Airway Pressure Devices

Continuous Positive Airway Pressure

Several devices, including CPAP, bilevel pressure, and ASV, have been used to treat CSA in patients with heart failure.

In contrast to treatment of OSA, where application of nasal CPAP invariably results in virtual elimination of obstructive disordered-breathing events, treatment of CSA in patients with heart failure is difficult, and response to therapy is not uniform.[112] In our study,[102] first-night CPAP titration was effective in improving CSA in 43% of the patients (57% were considered CPAP nonresponsive). In the multicenter Canadian trial,[113] 47% of the patients were considered CPAP nonresponsive at 3 months. In this trial,[113] 132 patients were randomized to the control group and 128 to the CPAP arm. The baseline features were similar in the two randomized groups. The patients in the therapeutic arm were adapted to CPAP over 1 to 3 nights (without formal titration), and the maximum pressure was set at 10 cm H_2O or lower at whatever was tolerated.

A second polysomnography was performed at 3 months in both groups. There was no significant change in AHI in the control group. In the CPAP arm, the average AHI decreased by 50%, with considerable improvement in desaturation. Furthermore, the average plasma norepinephrine level decreased, and LVEF increased (all statistically significant). These measurements remained unchanged in the control group. However, after an interim analysis was performed, the safety-monitoring committee recommended termination of the study. This, in part, was related to worsened transplantation-free survival (primarily due to increased number of deaths from progressive heart failure and sudden death) of the CPAP-treated patients compared with the control group ($P = .02$). Although the survival curves diverged after about 3 years (favoring the CPAP arm), the difference was not statistically significant ($P = .06$).

We speculated that CPAP therapy could have resulted in excess early mortality for several reasons, including the following[114]: (1) Those who died were heart failure patients with CSA, whose periodic breathing was CPAP nonresponsive; and (2) those who died were heart failure patients whose ventricular function (according to the Frank-Starling curve) was preload dependent.

If right and LV function is preload-dependent, any reduction in venous return by the increased intrathoracic pressure, with application of CPAP, could decrease right ventricular stroke volume and return to the left ventricle, decreasing LV stroke volume and causing hypotension, diminished coronary blood flow, myocardial ischemia, and arrhythmias. Any such effect of CPAP on blood pressure is further augmented during sleep when blood pressure normally decreases.

The aforementioned assumptions that, in the Canadian trial, excess cardiovascular death due to CPAP occurred primarily in CPAP nonresponders were confirmed by a post-hoc analysis of mortality of patients with CSA (Figure 129-11).[80] In those whose CSA responded to CPAP, transplantation-free survival was significantly improved when compared with the untreated control group. In addition, the mortality of CPAP nonresponders appeared to be the worst, although the number of patients was small for statistical significance.

In the Canadian trial[113] at 3 months, 43% of heart failure patients with CSA were CPAP nonresponsive, compared with 57% in our study[102] of first-night use. Typically, CPAP-responsive patients had less severe CSA than CPAP-nonresponsive patients. In our study,[102] in CPAP-responsive patients, the average AHI decreased from 36 to 40 per hour, with elimination of desaturation. An important observation was that the number of premature ventricular contractions, couplets, and ventricular tachycardia decreased. This effect was presumed to result from decreased sympathetic activity, because arousals decreased and saturation improved. Heart failure patients with severe CSA (57% of the patients) did not respond to CPAP, and use of CPAP had no significant effect on ventricular irritability.

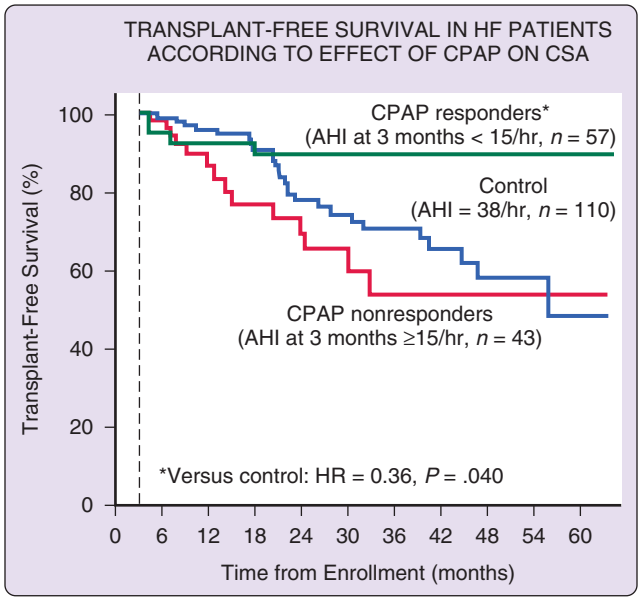

Figure 129-11 Probability of survival in patients with systolic heart failure (HF) comparing continuous positive airway pressure (CPAP) responders to a control group (patients with systolic heart failure and similar apnea–hypopnea index [AHI]) and to CPAP nonresponders. CPAP responders had a significantly increased probability of survival compared with the control group. CPAP nonresponders tended to have a poor survival when compared with the control group, although this was not significant. CSA, Central sleep apnea; HR, hazard ratio. (From Kryger MH. *Atlas of clinical sleep medicine.* Philadelphia: Elsevier; 2010; modified from Artz M, Floras JS, Logan AG, et al. Suppression of central sleep apnea by continuous positive airway pressure and transplant-free survival in heart failure. *Circulation* 2007;115:3173–80.)

The mechanisms of improvement in CSA in CPAP-responsive patients are multifactorial. One may relate to improvement in pulmonary congestion, which should widen Pco_2 reserve.[51] CPAP may improve stroke volume by decreasing LV afterload, which decreases arterial circulation time. CPAP should increase functional residual capacity, which decreases underdamping, and CPAP opens the upper airway, which is a benefit for those patients with CSA in whom upper airway closure occurs.

Adaptive Servoventilation

However, as noted earlier, 43% to 57% of heart failure patients with CSA are nonresponsive to CPAP. For these patients, and those who are intolerant to CPAP, until recently ASV devices were recommended (see end of this section).[72] These devices provide varying amounts of anticyclic inspiratory pressure support during different phases of periodic breathing, augmenting ventilation when the patient's minute ventilation decreases below a target and withdrawing support when the patient's ventilation is above the target.[112] In this way, periodic breathing is eliminated while on the device. In addition, the device initiates a breath on a timely basis, preventing development of a central apnea. Finally, the new generation of these devices is equipped with automatic end expiratory positive pressure algorithms[71,112,115] that operate to eliminate obstructive disordered breathing events. Having this virtue, these devices were expected to be advantageous for treatment of complex sleep-related breathing disorders when both CSA and OSA and hypopneas are present. Specifically in patients with heart failure, such complex breathing events are frequently observed during polysomnography. In addition, the phenotype of sleep apnea may vary during progression of heart failure and during acute decompensation when excess fluid from the lower extremities translocate to the neck area in supine position. Under such circumstances, upper airway obstruction could occur,[57,58] and a fixed end expiratory positive airway pressure with either a CPAP or bilevel device is inadequate to eliminate obstructive events.

ASV devices have been used to treat CSA in patients with congestive heart failure, generally with favorable results. In an acute (1-night) study[116] in 14 subjects with HFrEF and CSA, the ASV device decreased the AHI more than oxygen, CPAP, and bilevel devices. Indeed, in a meta-analysis of patients with congestive heart failure, in whom ASV therapy was compared to a control arm (the control arm could be medical therapy, oxygen, CPAP or bilevel), we concluded that ASV was much more effective in reducing AHI.[117] Specifically, in crossover studies, the mean AHI decreased from about 50/hour to 6/hour, compared to 20/hour. Multiple long-term studies with ASV have been reported, and these have been reviewed recently.[112,117] In general, most (but not all) of these studies show significant improvement in biomarkers of heart failure, LVEF, and reduction in primary end points, commonly a combination of mortality and readmission to the hospital, as noted previously.[83,88-91,118]

In a prospective parallel design, randomized controlled trial[119] from Norway, 51 patients with congestive heart failure and CSA, ages 57 to 81 years, were randomized to either an ASV or a control group; 30 patients completed the study (15 from each group). Three months treatment with ASV significantly improved LVEF from 32% to 36%, 6-minute walk, and a New York Heart Association classification. These

variables did not change significantly in the control group. These results were somewhat different from a similarly designed German study,[120] in which significant but equal increments in LVEF occurred after 3 months, both in the ASV arm and the control group. However, consistent with the results of the previous study,[119] reduction in N-terminal pro-brain natriuretic peptide was significantly greater in the ASV arm. However, in our meta-analysis[119] discussed previously, ASV therapy significantly improved LVEF when compared to the control. Furthermore, in a recent well-designed trial,[120] in which 23 patients with persistent CSA (in spite of using CPAP for 3 months) were randomized to either continued CPAP ($n = 11$) or ASV ($n = 12$), LVEF increased significantly (32% to 38%) in the ASV group. Furthermore, reductions in plasma B-type natriuretic peptide and urinary norepinephrine and an increase in 6-minute walk distance and quality of life as measured by short form 36 were significantly greater with ASV than CPAP.

Meanwhile, as noted previously, with automatic variable end expiratory positive pressure algorithms, ASV devices are effective in treating both CSA and OSA. In the three trials[122-124] that compared CPAP versus ASV in patients with heart failure and coexistent OSA and CSA, ASV was significantly more effective in improving LVEF than CPAP. Because both obstructive and central sleep disorders commonly occur together, and the phenotype may change with time (e.g., obstructive events becoming prominent during acute decompensation of the heart failure), ASV devices with automatic end expiratory positive pressure rhythm can be quite effective under such circumstances.

A large multi site international clinical trial (SERVE-HF)[124a] that evaluated the effect of treating central sleep apnea with an ASV device in patients with heart failure and reduced ejection fraction (HFrEF) has raised serious concerns about the safety of ASV in these patients. Not only was ASV ineffective, but post-hoc analysis found excess cardiovascular mortality in treated patients. The cause of the excess mortality is unknown; the authors hypothesized that CSA might be a compensatory mechanism with a protective effect in HFrEF.

However, there are several other (perhaps more) plausible explanations for the excess cardiovascular mortality in the trial. These include methodological issues, the use of the old generation ASV device, which is no longer manufactured by the sponsor of the trial, residual sleep-disordered breathing with significant oxygen desaturation, patient selection, data collection, and treatment adherence as well as group crossovers as potential confounding factors (Javaheri et al, unpublished). Below, only the device-related issues are briefly reviewed.

The data from the trial[124a] show that the device was ineffective in a number of patients (note the large range of AHI values downloaded from the ASV devices across the months of follow-up in Table S4 in the supplementary appendix of reference 124a). There could be multiple reasons for these residual events. Two important issues regarding the algorithm of the first generation ASV device used in SERVE-HF could have been contributory: First, it allows for only fixed expiratory positive airway pressure (EPAP), and second, there are flaws in the inspiratory pressure support algorithm that were addressed and improved considerably in the latest generation models.[122] Regarding fixed EPAP, it is known that the phenotype of sleep-disordered breathing may change over time from predominantly central to predominantly obstructive events, and data from Table 2 in the study[124a] are confirmatory. In that case, in the face of obstructive apneas and the fixed expiratory pressure of the device, the ASV device used was equipped with only one strategy for suppressing these events: progressively increasing inspiratory pressure support in an attempt to open the closed airway. Once the airway opened, the prevailing high pressures may have resulted in an excessive rise in intrathoracic pressure with consequent adverse hemodynamic effects. In addition, excess ventilation due to excessive inspiratory pressure support could result in hyperventilation and alkalemia which is arrythmogenic, and at the same time the baseline Pco_2 could be lowered excessively promoting recurrence of apneas. The current generation of ASV devices can be set to increase EPAP automatically in response to obstructive apneas and would not have been subject to this failure.

Independent of the reasons why the trial failed, manufacturers of ASV devices have declared that ASV devices are contraindicated for heart failure patients with central sleep apnea when LVEF is 45% or less. Since we no longer use ASV, our current approach to such patients is to first make sure that heart failure is maximally treated, both pharmacologically and device-wise, when indicated. Then gentle CPAP titration is performed with maximum pressure not to exceed 10 to 12 cm H_2O. If the AHI decreases below 15/hour of sleep, long term CPAP therapy is recommended. Otherwise nocturnal O_2 titration is recommended with the least amount of supplemental O_2 needed to eliminate hypoxia and maintain arterial oxyhemoglobin saturation above 92%, avoiding hyperoxia.

Meanwhile we are anxiously waiting for the results of the ADVENT trial[124b] and the remede trial.[124c] The latter uses a transvenous phrenic nerve pacemaker (see also Chapter 126).

Cardiac Pacing

In 15 subjects with predominantly mild to moderate CSA, some of whom had mild LV systolic dysfunction, atrial overdrive pacing improved periodic breathing.[125] These subjects had permanent atrial-synchronized ventricular pacemakers placed for symptomatic sinus bradycardia. Atrial overdrive (an average of 72 beats per minute versus spontaneous 57 beats per minute) moderately (but significantly) decreased the AHI from 28 to 11, improved arterial oxyhemoglobin desaturation, and decreased arousals. The mechanism remains unclear, but it could have been the improved cardiac output. However, if cardiac pacing improves CSA, biventricular pacing[126] should be more effective than atrial pacing overdrive,[106-110] as discussed earlier. In one study,[108] CRT decreased central AHI from 31/hour to 17/hour. There was no effect on obstructive disordered breathing events.

Transvenous Unilateral Phrenic Nerve Stimulation

Most recently, transvenous unilateral phrenic nerve stimulation has been used to stimulate phrenic nerve and treat CSA. In this acute study,[127] 16 patients underwent two successive nights of polysomnography—one night with and one night without phrenic nerve stimulation from either the right brachiocephalic vein or the left pericardiophrenic vein. Stimulation resulted in significant improvement in the AHI Central Apnea Index, arousal index, and oxygen desaturation index 4%. No significant changes occurred in the Obstructive Apnea

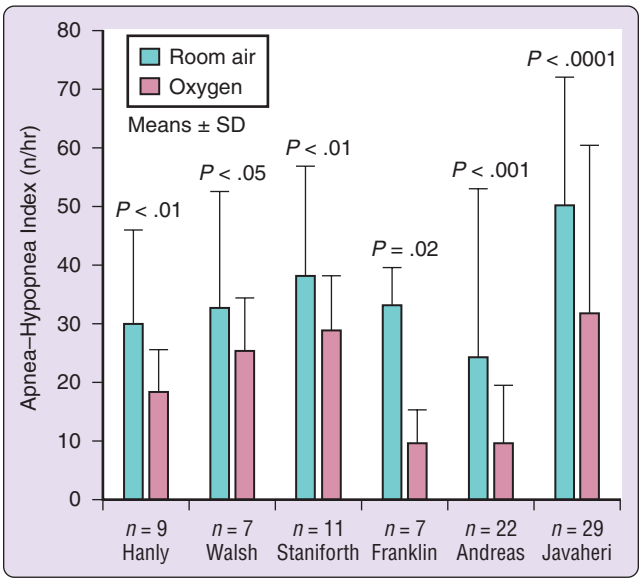

Figure 129-12 Effects of supplemental nasal oxygen on apnea–hypopnea index in patients with systolic heart failure.

Index or AHI. This approach may represent a novel therapy for CSA and warrants further study. Currently, a randomized clinical trial is in progress.

Medications

Nasal Nocturnal Oxygen. Systematic studies in patients with systolic heart failure[128-133] have shown that nocturnal therapy with supplemental nasal oxygen improves CSA (Figure 129-12). Oxygen therapy may also decrease arousals and improve the hypnogram by shifting sleep structure to deep sleep stages. In addition, randomized placebo-controlled double-blind studies have shown that short-term (1 to 4 weeks) administration of nocturnal supplemental nasal oxygen improves maximal exercise capacity[130] and decreases overnight urinary norepinephrine excretion.[131]

Three randomized clinical trials of nocturnal nasal oxygen therapy[133-136] for 9-, 12-, and 52-week periods, reported that, when compared with the control group, oxygen therapy improved CSA and desaturation and significantly increased LVEF and quality of life of patients with heart failure. In the oxygen-treated group, LVEF increased 5% (versus 1% in the control group) in the 12-week study,[136] and 5.5% (versus 1.3% in the control group) in the 52-week study.[135]

Supplemental administration of nasal oxygen may decrease periodic breathing by several mechanisms.[134] These include an increase in the difference between the prevailing P_{CO_2} and the P_{CO_2} at the apneic threshold; a reduction in the ventilatory response to CO_2 and perhaps to hypoxemia; and an increase in body stores (e.g., lung contents) of oxygen, which increases damping. Prospective placebo-controlled long-term studies, however, are necessary to determine whether nocturnal oxygen therapy has the potential to decrease mortality of patients with systolic heart failure.

Theophylline. Open[7,137] and blind studies[138] have shown the efficacy of theophylline in the treatment of CSA in heart failure. In a double-blind randomized placebo-controlled crossover study of 15 patients with treated, stable systolic heart failure, oral theophylline at therapeutic plasma concentration (11 μg/mL, range 7 to 15 μg/mL) decreased the AHI by about 50% and improved arterial oxyhemoglobin saturation.[137]

Mechanisms of action of theophylline in improving central apnea remain unclear.[123] At therapeutic serum concentrations, theophylline competes with adenosine at some of its receptor sites. In the central nervous system, adenosine is a respiratory depressant, and theophylline stimulates respiration by competing with adenosine. Conceivably, therefore, an increase in ventilation by theophylline decreasing the plant gain could decrease central apnea during sleep. Theophylline does not increase ventilatory response to CO_2.

Potential arrhythmogenic effects and phosphodiesterase inhibition are common concerns with long-term use of theophylline in patients with heart failure. Therefore, further controlled studies are necessary to ensure its safety. If theophylline is used to treat CSA, frequent and careful follow-ups are necessary.

Acetazolamide. In a double-blind placebo-controlled crossover study[139] of 12 patients with heart failure, acetazolamide, administered at about 3 mg/kg one-half hour before bedtime, decreased the central AHI significantly from about 57/hour (in the placebo arm) to 34/hour. Acetazolamide improved arterial oxyhemoglobin desaturation significantly. Furthermore, patients reported improved subjective perceptions of the following: overall sleep quality, feeling rested on awakening, falling asleep unintentionally during daytime, and fatigue. Acetazolamide, therefore, could have other advantageous effects when used in patients with heart failure and CSA, including acting as a mild diuretic and also normalizing the alkalemia (caused by loop diuretics) commonly present in patients with heart failure. In our patients, arterial blood pH decreased from 7.43 to 7.37.[139]

Acetazolamide improves CSA by decreasing the plant gain as shown in naturally sleeping canine experiments[140] and patients with heart failure with CSA.[141]

Benzodiazepines. Benzodiazepines, by decreasing arousals, may decrease CSA. However, a placebo-controlled double-blind study[142] showed a reduction in arousals but failed to show any improvement in CSA in patients with systolic heart failure. Although benzodiazepines do not increase the number of central apneas, their use may increase the likelihood of developing obstructive apneas in some heart failure patients.

Inhaled CO_2 and Addition of External Dead Space. Several studies have shown that low-level inhalation of CO_2 and addition of external dead space (by increasing P_{CO_2}) improve CSA.[145-147] However, studies[146,147] show that CO_2 inhalation increases spontaneous arousals, which are associated with increased sympathetic and decreased parasympathetic activity. One study[145] also showed that addition of dead space was associated with increased arousals. Knowing the adverse cardiovascular effects of increased sympathetic overactivity in heart failure, use of CO_2 and external dead space to treat CSA in heart failure should be avoided. However, dynamic CO_2 inhalation,[148-150] when it can be inhaled intermittently within a part of breathing cycle, could eventually prove useful.

CLINICAL PEARLS

- Because of the increased average life span and improved therapy of ischemic coronary artery disease and hypertension, the prevalence of heart failure remains high.
- Periodic breathing is common in heart failure and is characterized by apnea, hypopnea, and hyperpnea, which cause sleep disruption, arousals, hypoxemia/reoxygenation, hypercapnia/hypocapnia, and changes in intrathoracic pressure. Periodic breathing includes both obstructive and central sleep-related breathing disorders. All of these adversely affect sleep and cardiovascular function.
- Periodic breathing may contribute to the remodeling of LV dysfunction and to the progressively declining course of heart failure.
- Several studies have demonstrated that both CSA and OSA are associated with increased mortality of patients with heart failure and systolic dysfunction.
- There are only a few long-term studies on treatment of sleep apnea in systolic heart failure. These show that effective treatment of both CSA and OSA with CPAP improves mortality of patients with heart failure.
- At this time ASV is not recommended in CHF when LVEF is less than 45%.

SUMMARY

Heart failure is a common disorder that has a significant economic impact and is associated with excess morbidity and mortality. Because of increased average life spans and improved therapy for hypertension and ischemic coronary artery disease, the incidence and prevalence of heart failure remain high.

One factor that may contribute to the progressively declining course of heart failure, hospital readmission, quality of life, and premature mortality is the occurrence of periodic breathing, with repetitive episodes of apnea, hypopnea, and hyperpnea. Episodes of apnea, hypopnea, and the following hyperpnea collectively cause hypoxemia and reoxygenation, hypercapnia and hypocapnia, changes in intrathoracic pressure, and sleep disruption and arousals. These pathophysiological consequences of sleep-related breathing disorders have deleterious effects on the cardiovascular system, and they may be most pronounced in the setting of established heart failure and coronary artery disease.

Multiple studies have demonstrated increased readmission and premature mortality independently associated with obstructive and CSA comorbid with heart failure. In addition, multiple studies have also demonstrated that effective treatment of both obstructive and CSA decreases hospital readmission and improves survival, particularly in those patients who are most adherent to therapy.

ASV devices with automatic inspiratory pressure support and automatic end expiratory positive pressure algorithms, along with a backup rate, are quite effective in the treatment of hybrid sleep-related breathing disorders consisting of both central and OSA but are not recommended when LVEF is less than 45%. The best approach for patients with low LVEF is not clear, and future research will be needed to guide the management of these patients.[151]

Chapter
130

Sleep and Fatigue in Cancer Patients

Josée Savard; Marie-Hélène Savard; Sonia Ancoli-Israel

Chapter Highlights

- Insomnia and fatigue are common in cancer patients before treatment, while undergoing chemotherapy or radiation therapy, and after the completion of therapy. These symptoms appear to be part of the same cluster.
- Actigraphy data show disrupted rest-activity patterns in cancer patients, especially during chemotherapy.
- The relationship between sleep disruption and fatigue appears to be bidirectional. Fatigue is a common consequence of insomnia, but it can also increase the risk for insomnia, most likely through behavioral changes (e.g., napping) that disturb the sleep-wake cycle.
- Several cancer-specific factors may trigger the onset of sleep disturbances, including adjuvant treatments, nocturnal hot flashes, pain, opioids, and antiemetic medications. Fatigue may also be caused by a combination of factors including physical (e.g., cachexia, inflammation, hematologic and endocrine abnormalities), psychological (e.g., depression), and social factors.
- There is accumulating evidence supporting the efficacy of psychological interventions (cognitive-behavioral therapy in particular), activity-based interventions, and bright-light therapy to treat cancer-related sleep disturbances and fatigue.
- More longitudinal studies are needed to characterize the natural course of sleep complaints, circadian rhythms impairments, and fatigue during the cancer care trajectory and to better understand how these disturbances are interrelated.

This chapter is dedicated to the memory of Dr. J. Christian Gillin, dear friend and colleague, who died of cancer and was fatigued, but never let it get to him. He was an inspiration and role model to us all.

Supported by NCI CA112035, NCI CA158954, Moores UCSD Cancer Center, and the Canadian Institutes of Health Research.

Patients with cancer complain of fatigue before treatment, during chemotherapy or radiation therapy, and after the completion of therapy.[1] These patients also complain of sleep disruption.[2] Both fatigue and poor sleep likely contribute to decreased quality of life.[3,4] There is a growing body of literature on the relationship between fatigue and the quality or quantity of sleep. This chapter reviews the evidence on cancer-related sleep disruption and fatigue and their treatment as well as the interrelationships among poor sleep, desynchronized circadian rhythms, and cancer-related fatigue.

EPIDEMIOLOGY

Sleep Disruption

Early cross-sectional studies, mainly conducted in the post-treatment phase, revealed that between 30% and 50% of cancer patients report sleep difficulties and that nearly 20% meet the diagnostic criteria for an insomnia disorder (for a review of these studies, see[5-12]). However, these studies were limited by issues such as the use of small, convenience samples and of sleep measures composed of a single item or a small number of items. Moreover, sleep was often assessed several months and even years after the completion of treatment. Because of their cross-sectional nature, these studies did not provide information on the natural course of sleep impairments (incidence, remission, persistence) throughout the cancer care trajectory and beyond.

More recently, two large-scale longitudinal studies were conducted in nonmetastatic patients with heterogeneous cancer sites to assess the evolution of sleep impairments over time. Savard et al[13,14] observed 991 patients awaiting surgery for mixed cancer sites. Patients were assessed at baseline during the perioperative phase and 2, 6, 10, 14, and 18 months later. At baseline, 59% had insomnia symptoms, including 28% with an insomnia disorder, as assessed by a phone diagnostic interview and the algorithm developed by Morin and colleagues.[15] Accordingly, patients were considered to have an insomnia disorder when they met the following criteria: sleep-onset latency or wake after sleep onset of more than 30 minutes, at least 3 nights per week; sleep efficiency of less than 85%, for at least 1 month; impaired daytime functioning or marked distress; or using a hypnotic medication 3 nights/week or more for at least 1 month. Although these rates steadily decreased over time, 36% of the sample still suffered from insomnia symptoms, whereas 21% met the criteria for an insomnia disorder 18 months later, which remains much higher than in the general population. Moreover, the general persistence rate (i.e., insomnia present at two consecutive time points on 2- to 4-month intervals) was 51%, whereas 35% of patients had insomnia persisting for at least three consecutive time points. Insomnia disorder was a particularly enduring condition, with persistence rates varying from 69% to 80%.

In another large-scale prospective study, Palesh et al[16] assessed the presence of insomnia in 823 patients scheduled to receive at least four cycles of chemotherapy for various types of cancer of all stages. Sleep difficulties were assessed on day 7 of cycle 1 and cycle 2 of chemotherapy using the six sleep-related questions from the Hamilton Depression Inventory. The insomnia disorder was defined by the presence of difficulty in falling asleep, difficulty in staying asleep, and early morning awakenings (at least 30 minutes) for at least 3 nights per week for 2 weeks. This more liberal definition (not taking into account sleep efficiency and insomnia-related functioning impairments and distress), assessed with a questionnaire rather than a diagnostic interview, yielded greater prevalence rates. At cycle 1, 80% of patients exhibited insomnia symptoms, including the 43% meeting the criteria for an insomnia disorder, rates that decreased to 68% and 35%, respectively, at cycle 2. Among good sleepers at cycle 1, 35% developed insomnia symptoms at cycle 2, of whom 10% developed an insomnia disorder.

The prevalence of sleep disturbances varies as a function of cancer sites. Early studies indicated that sleep disturbances were more frequent in breast and ovarian cancer patients.[17,18] More recently, Palesh et al[16] found that the prevalence of insomnia symptoms or disorder was the highest in breast (85%) and gynecologic (83%) compared with hematologic, lung, and gastrointestinal cancers. The prevalence of the insomnia disorder alone was the highest in patients with lung cancer (51%) and the lowest in those with a gastrointestinal cancer (24%). Savard et al[13] also found the highest rates of insomnia symptoms among breast (42% to 69%) and gynecologic (33% to 68%) cancer patients, whereas the lowest rates were obtained in men with prostate cancer (25% to 39%) throughout the study. Subanalyses conducted in patients with urinary and gastrointestinal cancer, showing no difference between men and women, suggest that higher rates found in women with breast and gynecologic cancer are not solely attributable to gender.[14]

Sleep disturbances are also common in patients with advanced cancer. From about half to three quarters of outpatients attending cancer or palliative care clinics report some sleep disturbances.[19-21] In a study of patients with metastatic breast cancer, 63% reported sleep disturbances. Difficulty in falling asleep was associated with both depression and pain, whereas increased awakening during the night was associated with only depression.[22] Similarly, another study conducted among 101 patients with advanced cancer (any type) found that sleep difficulties were associated with increased pain, depressive, and anxiety symptoms and a poorer sense of well-being.[23] In a prospective study, 15% of terminally ill cancer patients had sleep disturbance (insomnia or hypersomnia) and 29% had subclinical disturbance at the moment of registration to a palliative care unit. These rates increased to 26% and 37%, respectively, at the time of admission. There was a change in sleep status in 67% of patients between the two time points; sleep deteriorated (46%) more frequently than it improved (21%).[24] Another study found that patients with advanced lung cancer reported poorer sleep and more daytime sleepiness than healthy controls and that their sleep disturbances were characterized by breathing difficulties, cough, nocturia, and frequent awakenings, all of which may be suggestive of sleep-disordered breathing.[25] Finally, a study suggested that poor sleep quality and use of sleep medications were, along with hopelessness and depression, the best predictors of desire for hastened death in 102 terminally ill patients attending a palliative care unit,[26] thus emphasizing the importance of offering appropriate sleep management to these patients.

A few studies used polysomnography (PSG) to assess sleep disturbances objectively in cancer patients. When the sleep of patients with breast or lung cancer, patients with insomnia, and volunteers with no sleep problems were

compared using PSG, insomnia patients had the shortest total sleep time, but lung cancer patients had the longest sleep-onset latency, lowest sleep efficiency, and greatest wake time during the night.[27] Savard et al[28] found an average sleep efficiency of 84% among a sample of 56 women treated with chemotherapy, radiotherapy, and hormone therapy for early-stage breast cancer. On average, wake after sleep onset was 54 minutes, whereas sleep-onset latency was 20 minutes. In that sample, sleep-onset latency, rapid eye movement (REM) sleep latency, wake after sleep onset, sleep efficiency, and distribution of sleep stages were similar to those found in healthy women of the same age. Conversely, in a sample of 114 advanced cancer patients, Parker et al[29] showed, compared with normative data, a reduced sleep quantity and quality, with a sleep efficiency of 77% on average and virtually no slow wave sleep. More research is needed to better quantify PSG alterations associated with different types of cancer and their progression.

The available literature, although limited, also suggests the presence of sleep disorders other than insomnia in cancer patients. Elevated prevalence rates of obstructive sleep apnea (OSA), ranging from 12% to 92%, were found in small-scale studies (17 to 33 patients) conducted among patients with head and neck cancer.[30,31] There is also some evidence suggesting that OSA may be associated with treatments such as surgery and radiotherapy among these patients,[32] but prospective studies are warranted to investigate to what extent OSA is caused or exacerbated by the cancer itself or by cancer treatment. Sleep disordered breathing in the form of obstructive and central apneas also appears to be frequent in patients with brain tumors, with tumor removal resulting in a significant decrease in the apnea-hypopnea index.[33] Rates of OSA have also been found to be high in women with breast cancer who had completed chemotherapy, with almost half of the patients (48%) having at least five respiratory events per hour of sleep.[34] In the same study, the prevalence of periodic limb movements was 36%. Both of these sleep disorders were substantially more frequent than in age-comparable women without cancer. These high prevalence rates of periodic limb movements and OSA may help explain some of the sleep disturbance found in this population. However, others reported no difference in the amount of sleep-disordered breathing between cancer patients and insomnia patients or healthy volunteers.[27]

Actigraphy, a noninvasive, continuous, ambulatory measure of circadian rest-activity rhythms, has also been used to objectively characterize the sleep and rhythms of patients with cancer.[35-37] Studies comparing cancer patients with healthy controls have consistently shown less contrast between daytime and nighttime activity in cancer patients, a pattern indicative of circadian disruption.[38-44] Among patients with advanced cancer, objective data from actigraphy have shown high sleep fragmentation despite normal sleep duration.[19]

Chemotherapy appears to be particularly disruptive of rest-activity circadian rhythms,[45,46,46a] although radiation therapy was also found to have a detrimental effect.[46a,47] In a study of 85 women with breast cancer, 72-hour actigraphy showed that the first administration of chemotherapy was associated with transient disruption of sleep-wake rhythm, whereas its repeated administration resulted in progressively worse and more enduring impairments.[46] A recent study, conducted among 49 patients with advanced cancer assessed with actigraphy from 3 days before to 10 days after the administration of a chemotherapy cycle, found 45% of patients showing a sustained deterioration of their rest-activity pattern after chemotherapy administration, with both increased nighttime activity level and decreased diurnal activity level. The other patients experienced some alterations but recovered at the end of the chemotherapy cycle (31%) or showed either no alteration (10%) or improvement of their rest-activity pattern throughout chemotherapy (14%).[48] Whereas there are some data suggestive of improvement of the rest-activity patterns back to precancer treatment levels once the active phase of cancer treatment is over, at least among patients with early-stage disease, the disturbance remains worse than in matched controls.[38]

Fatigue

Fatigue is one of the most frequent and disturbing complaints of patients with cancer,[1,49] with 70% to 100% of patients during active treatment and approximately 30% after the treatment phase reporting feeling weak and tired.[50] Cancer-related fatigue has been defined as a "persistent, subjective sense of tiredness related to cancer and cancer treatment that interferes with usual functioning."[51] It is believed to be distinct in nature from general fatigue, as it is unrelated to exertion level and is not relieved by rest or sleep. Fatigue may interfere with daily functioning and reduce quality of life[52] and is associated with elevated direct and indirect costs.[53] Cancer-related fatigue is one of the key reasons for discontinuation of treatment and participation in clinical trials.[54]

Overall, studies suggest that fatigue assessed subjectively with various questionnaires is highly prevalent before[55] as well as during[56] adjuvant treatments. In addition, several large-scale studies indicate that fatigue can continue for months and even years after the completion of therapy.[57-61] Fatigue is present before the start of chemotherapy,[35] and it increases significantly with the introduction of chemotherapy.[45,62-64] Different patterns have been observed for radiotherapy. Purcell et al[65] observed that fatigue increased at the end of radiotherapy, followed by a decrease 6 weeks later among 210 prostate and head and neck cancer patients. Another study, conducted in 87 oropharyngeal cancer patients, revealed that fatigue peaked about 1 to 2 weeks after the completion of radiotherapy, whereas this symptom persisted for up to 2 years after for half of the sample.[66] In the breast cancer context, some authors observed an increase in fatigue during radiotherapy, followed by a return toward baseline levels 6 to 8 weeks after treatment completion.[67,68] In contrast, others found persistent elevated levels of fatigue among women with breast cancer several weeks after radiotherapy completion.[69] In a longitudinal study conducted among 60 patients with mixed cancer sites, 22% of participants had severe persistent fatigue in the first year after cancer treatments, a rate that remained fairly stable throughout that period.[70] There are likely to be many reasons for these differences found across studies, including the differences in fatigue measurement, the types of treatments received (e.g., surgery, chemotherapy, hormone therapy), the number and duration of the treatments, and the level of preexisting fatigue.[70-72]

PATHOGENESIS

Insomnia and Sleep Disturbances

A younger age has consistently been found to be associated with an increased risk for cancer-related insomnia.[2,17,73] In addition, the cancer journey typically involves a combination of treatments that may include surgery, chemotherapy, radiation therapy, and hormone therapy, all of which have the potential to provoke or to intensify sleep disturbances because of their emotional impact, their direct physiologic effects, or their side effects.[74] Chemotherapy is thought to be particularly harmful.[3,75] Patients report more subjective sleep disturbance (lower sleep quality and duration, total sleep time) during the active phases of chemotherapy compared with rest periods.[76] Longitudinal studies using subjective measures have also shown gradual increases in sleep impairment with this treatment[77] as well as persistence of elevated insomnia rates across chemotherapy cycles.[16] Conversely, another study found no change in sleep with the introduction of chemotherapy for breast cancer as measured prospectively with a sleep diary, but most participants already had poor sleep before the initiation of this treatment.[78] Of note, studies that measured PSG data have not observed a significant deterioration of PSG sleep parameters with the introduction of chemotherapy.[79,80]

Many cancer-related somatic symptoms may affect sleep negatively. Dyspnea, urinary symptoms (e.g., due to radiation therapy in the urogenital area), gastrointestinal symptoms (e.g., chemotherapy-induced nausea), and pain (e.g., associated with use of aromatase inhibitors) in both men and women are all very likely to impair sleep.[46a,81] In addition, medications that are commonly administered with chemotherapy, such as opioids, antiemetic medications, and corticosteroids, are also known to disrupt sleep.[82-84] The occurrence or exacerbation of menopausal symptoms appears to be another important contributor to cancer-related sleep disturbances. Indeed, the estrogen deficiency induced by chemotherapy and hormone therapy, the abrupt cessation of hormone replacement therapy at cancer diagnosis, or an ovary removal may trigger or exacerbate preexisting hot flashes. Savard et al[85] showed that changes occurring in self-reported vasomotor symptoms between the end of initial adjuvant treatments and a 3-month follow-up were significantly associated with parallel changes in insomnia complaints. Two other studies from the same team using objective measures showed greater PSG sleep disturbances associated with nocturnal hot flashes detected with sternal skin conductance. In the earlier study[86] conducted among 24 breast cancer survivors, the 10-minute periods around hot flashes had more wake time and more stage changes to lighter sleep than other 10-minute periods during the night. In addition, compared with nights without, nights with hot flashes had a significantly higher percentage of wake time, a lower percentage of stage 2 sleep, and a longer REM latency. In the more recent study[28] conducted in 56 women treated for breast cancer, slower and longer hot flashes, but not increased hot flash frequency, were associated with several sleep impairments, including a greater total wake time, lower sleep efficiency, and increased number of awakenings.

The amount of insomnia in cancer patients can be as high as the amount of insomnia found in depressed patients; therefore, clinicians should not overlook the possibility that poor sleep in cancer patients may indicate some psychological distress. The study by Sharma et al[87] revealed that cancer patients with high levels of psychological distress were 4.5 times more likely to report sleep difficulties than those with low levels. In one sample of newly diagnosed breast cancer patients, insomnia was the most frequent symptom, reported by 88% of patients, and was correlated with high levels of psychological distress and anxiety.[88] However, contrary to the belief that disturbed sleep before treatment is attributable to the increased stress and anxiety resulting from a recent diagnosis of a potentially life-threatening illness, insomnia and fatigue were rated high even in those patients who rated themselves low on anxiety. Similarly, another study revealed that 46% of prostate cancer survivors with an insomnia disorder did not have clinical levels of anxiety or depressive symptoms.[89] Thus, there is evidence that although insomnia and psychological distress are interrelated, there are still a significant proportion of patients who have isolated insomnia.

Pain has often been thought to be the cause of sleep disruption, not only in patients with cancer but in patients with a multitude of other medical conditions.[90] In a sample of 2862 cancer outpatients, the risk of reporting insomnia symptoms was 2.7 times higher for those having pain,[87] which is consistent with other empiric evidence showing that cancer-related pain significantly predicts the incidence or exacerbation of sleep difficulties.[91,92] There are also data showing increased objectively assessed sleep disturbances and rest-activity rhythm impairments measured with actigraphy among men, but not women, with pain.[93]

One hypothesis explaining the association between pain and insomnia comorbid with cancer is that pain may be the initial cause of the frequent awakenings, but psychological distress prevents the patient from falling back to sleep.[94] A second hypothesis explains that whereas sleep leads to recovery and repair of tissue and may offer a temporary cessation of the psychological awareness of pain, poor sleep leads to difficulty in managing pain.[95] In this way, a cycle of pain and poor sleep may become self-perpetuating.

Fatigue

Fatigue is also likely to be caused by multiple factors including physical (e.g., cachexia; weight loss; biochemical, hematologic, and endocrine abnormalities), psychological (e.g., depression), and social factors (Figure 130-1). Anemia and other biochemical abnormalities are commonly found in cancer patients and cause fatigue,[68] although hemoglobin levels are only moderately related to fatigue and quality of life. One study examining the incremental effect of increasing hemoglobin on quality of life found that improving anemia improved quality of life only to a point, beyond which there was no further improvement.[96] Alternative possible physiologic mechanisms include inflammation, serotonin dysregulation, hypothalamus–pituitary–adrenal axis dysfunction, circadian rhythm disruption, altered muscle metabolism, and genetic dysregulation.[97,98] Among these potential mechanisms, inflammation is probably the one currently receiving the most attention and is believed to be a common pathway through which cancer and its treatment could lead to a variety of symptoms, including fatigue and sleep disturbances.[97,99]

Several studies have found significant relationships between reports of fatigue and depression,[100-102] but it is unclear to what extent these are etiologically related. A decrease in

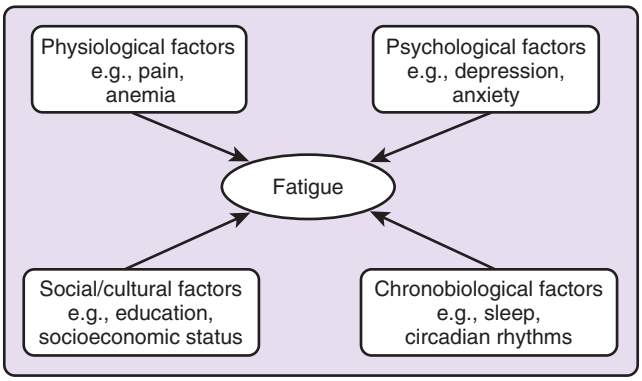

Figure 130-1 Diagrammatic representation of possible factors affecting fatigue. (From Ancoli-Israel S, Moore PJ, Jones V. The relationship between fatigue and sleep in cancer patients: a review. *Eur J Cancer Care [Engl]* 2011;10:245–55, with permission.)

activity level could constitute a common mechanism. This behavioral change, frequently observed among depressed individuals, may contribute in the long term to physical deconditioning, which may in turn exacerbate fatigue.[64] However, depression is far less common than fatigue in cancer patients, which suggests that fatigue often occurs independently. In fact, fatigue and depression show different patterns of evolution over the cancer care trajectory.[103,104] Moreover, it has been shown that an antidepressant treatment decreases depression without concurrently improving fatigue, thus suggesting differential mechanisms.[105,106] Depression has been found to significantly predict subsequent fatigue among breast cancer patients,[64] but negative results have also been found.[107-110] Overall, more research is needed to understand the pathogenesis of cancer-related fatigue.

Relationship Among Sleep Disturbances, Circadian Rhythms, and Fatigue

Studies on symptom clusters have revealed that sleep and fatigue are often part of a same cluster of three or more symptoms.[111-116] Moreover, most cross-sectional and prospective studies have found a strong correlation between sleep disturbances and fatigue,[109,111,117,118] with a similar trajectory over time.[38]

The relationship between sleep disruption and fatigue appears to be bidirectional. Patients typically report fatigue as the main consequence of their poor sleep.[119,120] Accordingly, there is evidence that sleep disturbance is a significant predictor of fatigue,[109,121-123] but the reverse may also hold true. A longitudinal study showed that fatigue significantly predicted a subsequent increase in insomnia symptoms during the cancer care trajectory, whereas insomnia was not found to predict subsequent fatigue.[110] The impact of fatigue on sleep could be due to behavioral changes occurring with fatigue. Indeed, fatigued individuals tend to nap more during the day and extend their sleep periods during the night, which may in the long run impair their circadian rhythm and make their nighttime sleep less consolidated and lighter.[124,125] This may be particularly the case during cancer treatments, when patients suffer from higher levels of fatigue and are very likely and often encouraged to rest to recuperate.[126,127]

Evidence on the relationship between circadian rhythms and subjective ratings of fatigue has been mixed, with most studies finding a significant relationship.[37,45,128] Daytime inactivity and nighttime restlessness were associated with higher subjective ratings of fatigue in one series of studies.[128] Women with breast cancer undergoing adjuvant chemotherapy reported more fatigue during treatment and less fatigue at chemotherapy cycle midpoints, in a "roller coaster" pattern. Activity levels were negatively correlated with reports of fatigue, that is, those with more fatigue showed less activity. Activity levels were reduced during the three treatment sessions compared with the cycle midpoints, thus showing the reverse "roller coaster" pattern, with inversely changing fatigue scores. Patients tended to have more nighttime restlessness at treatment times compared with cycle midpoints when higher activity during the day prevailed and there were fewer nighttime awakenings.[128,129] Others[37] found that self-reported fatigue was significantly associated with less stability of the rest-activity pattern across time but not with the proportion of time spent resting or sleeping during the day. Moreover, changes in fatigue from the second to the fourth on-study chemotherapy cycles were significantly associated with changes in the consistency of the sleep-wake pattern. Conversely, a study of breast cancer patients before chemotherapy[35] found no significant relationship between any of the rhythm variables or objective sleep variables assessed by a 72-hour actigraphy recording and subjective reports of fatigue. Another study conducted in breast cancer patients before chemotherapy found that most actigraph measures of sleep-wake, activity-rest, and circadian rhythms derived from a 48-hour recording were not significantly associated with fatigue.[130] Together, these studies suggest that fatigue becomes a significant correlate of circadian rhythms only after chemotherapy has been initiated in breast cancer patients. However, a more recent study comparing 148 women with stage I-III breast cancer scheduled to receive at least four cycles of adjuvant or neoadjuvant chemotherapy with 61 cancer-free healthy women found more severe cancer-related fatigue and disrupted circadian activity rhythms in the cancer patients both before chemotherapy and at the end of cycle 4.[43] More longitudinal studies are needed to verify to what extent the relationship between circadian rhythms and fatigue varies as a function of cancer treatments.

TREATMENT

The complaints of sleep disturbances and fatigue in cancer are often overlooked in clinical practice, and when a treatment is initiated, it is often a pharmacologic one (e.g., sedative-hypnotics for insomnia, psychostimulants for fatigue). Whereas pharmacologic therapy may be appropriate at times (e.g., short-term or occasional use), there is accumulating evidence supporting the efficacy of alternative treatments, including psychological treatments, activity-based interventions, and bright-light therapy.

Sleep

Pharmacotherapy

Hypnotic medications, particularly benzodiazepines, are by far the most commonly prescribed treatment for sleep disturbances in cancer patients. A study conducted among 1984 cancer survivors found that 41% had received a prescription for a sleeping medication since their cancer diagnosis and that 23% were currently using one.[131] The median duration of use

was 34 months, which considerably exceeds the recommendations from the 2005 National Institutes of Health state-of-the-science conference on insomnia of using hypnotic medications for no longer than 4 to 6 weeks.[132] At this conference, it was also concluded that the newer, shorter acting nonbenzodiazepines were safer and more effective than the older, longer acting benzodiazepines for the treatment of insomnia. More recently, other agents, such as a melatonin receptor agonist, have also been approved by the Food and Drug Administration for the treatment of insomnia. Although the efficacy of these medications is well established in primary insomnia, their usefulness has yet to be investigated in patients with comorbid cancer and insomnia.

Cognitive-Behavioral Therapy

The National Institutes of Health state-of-the-science conference on insomnia also concluded that cognitive-behavioral therapy (CBT) is the most effective treatment for primary insomnia.[132] There is now a large body of evidence supporting its efficacy for treating insomnia in cancer survivors.[133-141] Overall, these studies have been consistent in demonstrating that CBT (combining stimulus control, sleep restriction, cognitive restructuring, sleep hygiene, and sometimes relaxation) results in increased sleep efficiency and reduced total wake time, decreased psychological distress, and improved general quality of life. One study also showed changes in immune functioning[142] associated with CBT for insomnia, but the clinical relevance of these changes in terms of cancer prognosis or other health outcomes is unknown.

There is also some evidence showing that cancer-related fatigue may be improved after CBT for insomnia.[136,143] For instance, a study reported that 17.4% of individuals with cancer showed a remission in fatigue after CBT for insomnia compared with 2.6% of participants in the treatment-as-usual group.[113] However, nonsignificant results have also been found in other studies.[133,140] This may be due, in part, to the lack of sensitivity to change of some fatigue measures, but it still indicates that the relationship between sleep and fatigue is a complex one.

Mindfulness-Based Stress Reduction

Whereas early uncontrolled studies suggested that mindfulness-based stress reduction (MBSR) interventions could result in improved sleep quality in cancer patients,[144,145] recent studies have shown more modest results. One of them, which used a noninferiority research design, was conducted among 111 patients with various types of cancer and compared an eight-session CBT with a mindfulness-based cancer recovery intervention (MBCR, an adaptation of MBSR).[138] Short-term outcomes of MBCR on the Insomnia Severity Index were inferior to those of the CBT condition but became noninferior at the 3-month follow-up, suggesting that CBT is associated with faster improvements. Lengacher et al[146] randomly assigned 79 women who recently completed treatments for breast cancer to either a 6-week MBSR protocol or a control condition. Sleep was assessed with actigraphy, a sleep diary, and the Pittsburgh Sleep Quality Index. They found significant effects of MBSR at the 3-month follow-up on actigraphic parameters (sleep efficiency, percentage of sleep time, and number of waking bouts) but no significant effect on subjective sleep parameters. Another randomized controlled trial, conducted among 336 breast cancer patients,[147] compared an 8-week MBSR protocol with treatment as usual. Results indicated a significant and immediate benefit of the intervention on sleep as assessed with the Medical Outcomes Study Sleep Scale, but this effect was no longer significant at the 12-month follow-up.

Physical Activity

Among the cancer population, physical exercise has been found to be associated with numerous beneficial effects: improved quality of life; reduced fatigue, anxiety, pain, and depressed mood; and a possible decreased likelihood of cancer recurrence.[148,149] Only a few studies have specifically evaluated the effect of physical activity on sleep quality and quantity among cancer patients.[150-157] Although some benefits have been found, most of these trials did not select patients on the basis of minimal insomnia severity at baseline. Thus, it is not clear to what extent physical activity is potent enough to treat an insomnia disorder or chronic insomnia. In addition, questions regarding the optimal type, frequency, and dosage of exercise needed to improve sleep have yet to be answered. Comparisons with more established treatments, such as CBT, are also warranted.

Fatigue

Pharmacotherapy

There have been multiple trials of pharmacologic treatment of fatigue, reviewed by Bower.[158] Agents studied have included hematopoietic growth factors, progestational steroids, methylphenidate, and paroxetine. A meta-analysis of 27 of these randomized controlled trials concluded that treatment with hematopoietic agents led to improvements only in fatigue caused by chemotherapy-induced anemia; methylphenidate led to greater reductions in fatigue compared with placebo, whereas progestational steroids and paroxetine had no effect.[159] However, all these studies recruited patients who reported severe fatigue. Studies in cancer patients with milder levels of fatigue showed no response to pharmacotherapy.[158]

A more recent meta-analysis that included only studies of methylphenidate trials in patients with advanced-stage cancer concluded that this psychostimulant was more effective than placebo in improving cancer-related fatigue.[160] Despite this conclusion, however, only one of five studies included showed a statistically significant treatment effect. Other recent studies with larger samples of cancer patients showed no benefit for methylphenidate versus placebo for improving fatigue in general, although there was some positive effect for those with severe fatigue.[161,162]

Modafinil, a nonamphetamine-based stimulant, represents another potential treatment for cancer-related fatigue. One large multicenter trial of patients undergoing chemotherapy found beneficial effects of modafinil among patients who reported severe fatigue at baseline but not among those with mild or moderate fatigue.[163]

Overall, the results of these studies suggest that pharmacologic agents may not be the most effective first-line treatment for fatigue in cancer patients.

Nonpharmacologic Interventions

Several nonpharmacologic interventions for fatigue have been assessed in cancer patients. In 2007, a review of the literature identified a total of 41 publications, 24 assessing the efficacy of various psychological interventions, such as CBT, and 17

reporting on the efficacy of activity-based interventions.[164] Overall, the effect size obtained was of a small magnitude across all types of intervention and outcome measures (e.g., fatigue, vigor). When types of intervention were compared, a larger effect size was found for psychological interventions than for activity-based interventions. However, none of these studies selectively included severe fatigue, thus limiting the power to detect intervention effects. Moreover, no study has yet investigated the potential superior effect of an approach combining psychological and exercise-based interventions.

Possible Mechanisms of Nonpharmacologic Interventions

Not much is known about the possible mechanisms of nonpharmacologic interventions for cancer-related insomnia and fatigue. Biologic, environmental, behavioral, and cognitive factors are all potential candidates. There is some evidence showing that the effects of CBT in improving sleep would be mediated by both nonspecific (e.g., treatment expectancies) and specific (e.g., reduced maladaptive sleep habits and dysfunctional beliefs) factors.[165]

Although empiric findings are lacking, an exercise program may be beneficial for a variety of reasons, including the resynchronization of the rest-activity rhythms. A second benefit of outdoor exercises would be the increased exposure to bright light, which may promote greater daytime alertness and better sleep at night. Patients who report more fatigue tend to be exposed to less light.[166] Although the causality of sleep or fatigue and light exposure in cancer patients is not confirmed, there may be a negative feedback loop, such that less light exposure desynchronizes patients' circadian rhythms, which then causes or deteriorates fatigue and sleep impairments, and fatigue further leads to less light exposure.[166] Two small studies have shown that increased bright-light exposure, both during chemotherapy and in survivors after chemotherapy, improved or stabilized fatigue, sleep, circadian activity rhythms, and quality of life.[167-170] Larger studies are under way exploring the benefit of this easy-to-administer treatment.

DIFFERENTIAL DIAGNOSIS: IS IT SLEEPINESS, FATIGUE, OR SOMETHING ELSE?

The clinician needs to determine the cause of a patient's symptoms, recognizing that the words used by the patient to describe his or her symptoms may be vague. Is the symptom related to sleepiness (the patient may describe unintended episodes of falling asleep in the daytime or have an elevated Epworth Sleepiness Scale score) or to fatigue (complaints of muscle weakness, lack of energy, but without weakness)? Patients may also have symptoms attributable to specific effects of cancer or its treatment. When the patient has complaints related to one or more of these realms, they may become very difficult to manage.

When daytime sleepiness can be attributed to a specific sleep disorder, treatment should target that sleep disorder. If a patient has restless legs syndrome, the clinician should make sure that the patient does not have iron deficiency, which commonly occurs in gastrointestinal carcinomas. If the patient has developed movement disorders secondary to a chemotherapeutic agent, a trial of a dopaminergic agent should be initiated. If a patient has developed OSA, for example, secondary to enlarged lymph nodes in the pharynx, as might occur with lymphoma or with nasopharyngeal carcinoma, continuous positive airway pressure treatment as well as specific treatment directed at these areas should be initiated. If the patient has developed clinical depression along with insomnia, concurrent therapy for the mood disorder as well as for insomnia should be initiated. If the cancer is causing pain that is disturbing sleep, the pain needs to be treated concurrently with the insomnia. Hypoxemia caused by spread of cancer to the lung or the development of lung fibrosis in response to chemotherapy or radiation therapy may require treatment, as patients with hypoxemia are known to have disturbed sleep.

As described before, fatigue, weakness, and loss of energy are all hallmarks of cancer. Although the pathophysiology is still poorly understood, the clinician should try to determine if the fatigue is caused in part by a correctable factor, such as an electrolyte imbalance (as might occur in a patient receiving chemotherapy with severe nausea) or vomiting, an underlying infection, or an undiagnosed metabolic disorder (such as thyroid disease or diabetes mellitus). Diabetes mellitus may develop as a result of some types of therapy, such as large doses of corticosteroids. Fatigue might also be exacerbated by poor sleep, in which case treating sleep disturbances might result in improvements in fatigue.

PITFALLS AND CONTROVERSIES

Although the numbers of research studies in the last few years have increased, there is still much that remains unknown about the cause, consequences, and cures of sleeping difficulties and fatigue in patients with cancer. In particular, more longitudinal studies are needed to characterize the natural course of sleep complaints, circadian rhythms impairments, and fatigue during the cancer trajectory and to better understand how these disturbances are interrelated. Areas for future research also include a better characterization of those disorders across cancer sites. More research is also warranted on patients with advanced cancer, including clinical studies investigating the efficacy of nonpharmacologic interventions for sleep disturbances and fatigue, as it is unclear whether the same treatment modalities can be offered to these patients. Finally, mechanisms through which these interventions are effective also deserve investigation.

CLINICAL PEARL

Fatigue and sleep disturbances are among the most common and most distressing complaints of patients with cancer. When left untreated, these symptoms can significantly impair patients' quality of life. Clinicians should screen routinely for these disturbances and administer evidenced-based treatment strategies to help patients coping with them.

SUMMARY

Significant progress has been made in the last decades in the study of sleep and fatigue in cancer. Although causes and mechanisms of the sleep disruption or the fatigue experienced

by these patients remain to be fully elucidated, the available evidence suggests that both are common. Sleep disruption and fatigue are major complaints in patients with cancer, before treatment, while undergoing chemotherapy or radiation therapy, and after the completion of therapy. The relationship between fatigue and the quality or quantity of sleep or between fatigue and the sleep-wake circadian rhythm cycle is still unclear. Some of the cancer-related fatigue may be related to disturbed sleep or to disturbed sleep-wake rhythms. In cancer patients, as in other medically ill individuals, disturbed sleep may be important not only to the expression of fatigue but to the patients' quality of life, to their tolerance to treatment, and to the development of mood disorders, particularly clinical depression. Disruptions in circadian rhythms themselves affect sleep quality as well as many other physiologic mechanisms that pertain to fatigue. The degree of sleep disruption found in patients with cancer is not trivial. Objectively recorded sleep and biologic rhythms have not been well investigated in patients with cancer, but because it appears that a large proportion of them may in fact not be getting a good night's sleep, more research is needed to better characterize the sleep disruption and to establish the efficacy of various treatment approaches to improve sleep in this population.

Fibromyalgia and Chronic Fatigue Syndromes

Christine Won; Douglas Kirsch

Chapter Highlights

- Sleep-related complaints and sleep disturbances are principal features of fibromyalgia and chronic fatigue syndrome. (There is some debate about the relationship of nomenclature between myalgic encephalomyelitis and chronic fatigue syndrome; this chapter will refer to it solely as chronic fatigue syndrome.) Sleep quality affects patients' pain and fatigue symptoms as well as quality of life. The pathophysiologic role of sleep disturbances in fibromyalgia and chronic fatigue syndrome is currently unknown despite the recognition of this as a frequent symptom.
- Several polysomnographic findings have been described in patients with fibromyalgia and chronic fatigue syndrome. The relevance of sleep electroencephalogram findings to daytime symptoms of fibromyalgia and chronic fatigue syndrome are not well understood. Conventional methods for sleep stage scoring or quantifying electroencephalogram may not be sensitive enough to detect important sleep changes in patients with fibromyalgia or chronic fatigue syndrome.
- Comorbid sleep disorders may affect sleep quality of patients with fibromyalgia and chronic fatigue syndrome, and treating primary sleep disorders may augment therapy for these syndromes. Therapy includes pharmacologic and nonpharmacologic approaches that directly target sleep disorders or sleep complaints.
- This chapter illustrates the complexities of identifying, measuring, and treating sleep disturbances in syndromes defined by chronic pain and fatigue.

FIBROMYALGIA AND SLEEP

Fibromyalgia (FM) is characterized by generalized pain, chronic fatigue, and nonrestorative sleep. The 1990 American College of Rheumatology criteria defined FM as the presence of more than 11 of 18 tender points, which are bilateral, occur above and below the waist, involve axial sites, are distributed widely, and occur for at least 3 months.[1] An alternative criteria published in 2011 uses a patient-reported survey asking about locations of pain and the presence and severity of fatigue, sleep disturbances, memory deficits, headaches, irritable bowel, and mood problems. The new criteria do not require tender-point examination; however, they identify most of those individuals who would meet 1990 criteria, while including many others.[2] The global prevalence of FM is approximately 3% to 8%. Approximately 75% of patients with FM are women, and most patients are aged 30 to 50 years.[3]

Although current diagnostic criteria for FM do not include sleep-related abnormalities, sleep disturbances and complaints of poor sleep quality and daytime fatigue are common. In fact, sleep-related complaints are second only to pain.[4] Nonrestorative sleep correlates closely with somatic symptoms and pain severity. A specific etiology for FM is unknown, although it is speculated that disturbances in central nervous system (CNS) function likely contribute. The pathophysiologic role of sleep disturbances in FM is currently unknown despite the recognition of this as a frequent symptom.

Polysomnographic Features of Fibromyalgia

Patients with FM compared with healthy individuals demonstrate greater disturbances during sleep on polysomnography. Sleep-onset latency and stage N1 tend to be increased, whereas total sleep time and sleep efficiency are reduced. There are more frequent arousals and awakenings as well as longer awakening periods. Patients with FM have three times more arousals per hour than healthy subjects.[5] They have an increased number of sleep-stage shifts and a shorter duration of N2 sleep stage.[6] In addition, polysomnography data suggest that patients with FM have reduced total rapid eye movement (REM) and slow wave sleep time corrected for age, and these changes are associated with increased musculoskeletal and mood symptoms.

Several findings related to sleep electroencephalography (EEG) microstructure have been described using power spectral and frequency domain analysis. Beta frequency (14 to 38 Hz) is generally considered to reflect arousal; it is associated with lightened sleep perception and is linked with depression. When muscle and joint pain are experimentally provoked during sleep, beta power and alpha (8 to 13 Hz) frequency bands are increased on spectral analysis, while delta (0.5 to 4 Hz) and sigma (12 to 14 Hz) power is reduced.[7] Sigma frequency, likely reflecting sleep spindles, is generated from corticothalamic networks, appears to be responsible for lack of perceptual awareness and unresponsiveness during

sleep, and is associated with perception of greater sleep depth. Thus a reduction in sigma frequency suggests a higher level of alertness during sleep in patients with FM. Patients with FM also demonstrate fewer sleep spindles per minute of stage N2 sleep and reduced spindle frequency even when controlling for age, depression, and psychiatric diagnosis. Reduced spindle number and spindle frequency activity in stage N2 sleep may affect sensory processing in the thalamus and is associated with a lower pain threshold.[8]

Occipital alpha frequency (8 to 13 Hz), which is associated with relaxed wakefulness with eyes closed in healthy individuals, has been found to intrude on the sleep EEG in patients with FM.[9,10] Alpha intrusion has been identified in 70% of patients with FM compared with 16% of control subjects.[10] Two patterns of alpha activity during sleep have been described: (1) a phasic alpha pattern or alpha-delta sleep, which describes a pattern of alpha activity superimposed on delta waves of slow wave sleep (found in 71% of patients with FM with alpha intrusion); (2) a tonic alpha pattern, in which the alpha frequency occurs throughout NREM sleep (found in 29% of patients with FM with alpha intrusion). Alpha-delta sleep is associated with worse sleep efficiency, perception of lighter sleep, longer pain duration, and increased morning stiffness and pain. In patients with FM, but not in healthy controls, the alpha-delta ratio increases exponentially through the night.[11] Nonrestorative sleep has been described in 100% of patients with FM with the alpha-delta pattern, 25% with the tonic alpha pattern, and 58% of patients with FM without significant alpha intrusion. Alpha intrusion is also associated with symptoms of vigilance during sleep manifested as an increased tendency to wake to an external response and the perception of shallow or unrefreshing sleep.[12] There is no association between the occurrence of depressed mood or memory complaints in patients with FM and any of the alpha frequency patterns.[13]

Whether alpha intrusion is causative or results from chronic pain is unclear. When painful stimuli to muscles and joints are applied during slow wave sleep, an arousal effect with decreased delta waves and increased alpha activity is observed. Stimulation of superficial pain to the skin, on the other hand, does not elicit the same EEG response during sleep, suggesting that deep but not superficial pain alters sleep architecture.[7] Alternatively, alpha sleep may predispose the individual to increased arousability because of pain or other stimuli.

Not all investigators agree that the alpha EEG findings during sleep are particularly significant because they do not occur in all patients with FM. Additionally, this signal pattern also occurs in normal individuals and in patients with other pain syndromes such as rheumatoid arthritis.[14] The alpha intrusion pattern may be observed in 15% of normal subjects. Approximately 40% of subjects with alpha intrusion have pain syndromes, and most subjects exhibiting this pattern have a non-pain-related medical or psychiatric condition.[15] The occurrence of alpha intrusion in normal subjects is associated with subjective complaints of disturbed sleep.[16] Furthermore, alpha intrusion may be elicited by auditory or deep pain stimuli during slow wave sleep in normal individuals.

Therefore the alpha EEG findings, although not specific to FM, correlate with the subjective feeling of nonrestorative sleep and are observed in most patients with FM. The amount of this rhythm correlates with objective measurements of pain, and decreasing the amount of alpha intrusion with medications results in perceived improvement in sleep and pain. The biochemical and cellular processes that occur with this EEG finding are unknown and warrant further study.

Cyclic alternating pattern (CAP) describes a phenomenon whereby the EEG activity is periodic within NREM sleep. CAP is characterized by sequences of transient electrocortical events that are distinct from background EEG activity and recur at up to 1-minute intervals. This periodic activity, originally thought to be arousals, is now theorized to be the process of sleep maintenance and sleep fragmentation. CAP phase A1 pattern is considered to be an index of sleep stability, whereas CAP phases A2 and A3 are markers of sleep instability or poor sleep quality.[17] CAP A2 and A3 are increased in patients with FM compared with controls. Greater frequency of these subtypes are associated with increased number of tender points in patients with FM.[18] Furthermore, when A2 and A3 subtypes are decreased pharmacologically, patients with FM describe improvements in fatigue and in Hospital and Anxiety and Depression Scale (HADS) score.[19] Some scientists suspect that excessive phasic EEG activity may reflect enhanced or abnormal activity within the insula, anterior cingulate cortex, and ventromedial prefrontal cortex, which are in some way responsible for modulating abnormal nociceptive processing. However, it remains unclear whether CAP EEG findings reflect disturbed sleep processes and are pathogenic in FM, or whether they are consequences of pain and other syndromes found in patients with FM.

Pathophysiologic Correlates of Altered Sleep in Fibromyalgia

Neurologic mechanisms that regulate sleep and are in turn affected by sleep disturbances may play a role in the etiology and maintenance of FM. Several studies have shown that patients with FM have decreased levels of serotonin and the serotonin metabolite, 5-hydroxyindole-3-acetic acid, in the cerebrospinal fluid and blood serum.[20,21] Serotonin modulates pain transmission, and decreased serotonin synthesis induces a hyperalgesic state as well as insomnia. The precursor to serotonin, 5-hydroxytryptamine, is released at axonal nerve endings in the basal hypothalamus as a neurotransmitter during wakefulness and is important in the sleep state–dependent modulation of the nociceptive process of pain. A reduction in serotonin may be partially responsible for reducing delta sleep and predisposing to an alpha EEG rhythm. High levels of substance P are found in the cerebrospinal fluid of patients with FM and may contribute to serotoninergic deficiency.[22] Substance P appears to be a biologic marker for the presence of chronic pain.[23,24] Studies suggest that some individuals have a genetic predisposition for FM through the elevated frequency of polymorphisms in the serotonin transporter, dopamine D4 receptor, and catechol-*O*-methyltransferase genes.[25,26] Together, these findings suggest serotonin plays a role in promoting both analgesia and sleep.

Serotonin is transformed into melatonin in the pineal gland. The decrease in serotonin in patients with FM has been speculated to result in decrease melatonin synthesis, leading to abnormal sleep patterns. Some studies have described low nocturnal melatonin peak levels and a decrease in overall melatonin secretion in patients with FM.[27] In addition, melatonin has been used successfully to treat sleep-wake cycle

disturbances in some patients with FM and has resulted in improved pain.[28] However, other studies have found no difference in melatonin levels between patients with FM and healthy controls and have not found an association between melatonin levels of patients with FM and disease duration, sleep disturbances, fatigue, and pain scores.[29,30]

There is substantial evidence indicating that sensitization of the central nervous system pain pathway plays a crucial role in the pathophysiology of FM.[31] Neuroimaging studies show that patients with FM may exhibit abnormal perception of painful stimuli through central changes that result in increased pronociception or through decreased activity in descending pain inhibitory pathways such as the anterior cingulate cortex and thalamus.[32] There is altered regional cerebral blood flow to the thalamic areas where encoding and inhibiting pain transmission occurs and to areas where ablation has been shown to result in persistent insomnia in cats.[33,34] Altered thalamic regional cerebral blood flow may cause loss of growth hormone (GH) secretion during slow wave sleep and result in sleep alterations in patients with FM. Somatomedin C or insulin-like growth factor-1, which regulates GH production, is low in about one third of patients with FM,[35] and exogenous GH may improve sleep quality in patients with FM.[36]

Fibromyalgia may be considered a stress-related disorder. Stressors such as physical trauma, hormonal alterations, and emotional stress play an important role in triggering the development of FM and its somatic symptoms, including widespread chronic pain. Stress may directly affect the hypothalamic-pituitary-adrenal axis and the autonomic system, which induces central alterations that blunt cortisol, lead to abnormal regulation of GH, and cause heart rate variation and sensitivity to orthostatic changes on tilt-table tests.[37,38] Stress may directly affect sleep, causing sleep disruption especially during slow wave sleep, and further modulate the hypothalamic-pituitary-adrenal axis and exacerbate musculoskeletal pain and fatigue symptoms. Sleep disturbances are also related to disturbances in mood and cognition and may affect coping mechanisms to stress.

Common Sleep Complaints and Sleep Disorders in Fibromyalgia

One of the most prevalent and clinically challenging complaints in this patient population is unrefreshing or nonrestorative sleep, which is present in more than 75% of patients with FM.[39] Patients often report feeling unrested or worse after a night of sleep. In addition, patients with FM commonly report sleep fragmentation, early morning awakenings, and insomnia.[40] Despite reporting significant subjective sleepiness and fatigue, however, patients with FM demonstrate less objective daytime sleepiness on Multiple Sleep Latency Tests (MSLT) than healthy controls.[41]

Primary sleep disorders, such as sleep apnea, restless legs syndrome (RLS), and periodic limb movements of sleep, may be found in patients with FM. It has been reported that approximately 2% of women presenting to a rheumatology clinic with a new diagnosis of FM will have sleep apnea.[42] Women with FM may be more likely to have other sleep-related breathing disorders such as oxygen desaturation, inspiratory airflow limitation, and upper airway resistance syndrome, rather than frank sleep apnea. Treatment of sleep disordered breathing with positive airway pressure (PAP) therapy improves functional outcomes in female patients with FM.[43] In contrast, 44% of men presenting to a rheumatology clinic with a new diagnosis of FM have been purported to have sleep apnea,[44] although this finding has not been consistently supported. FM was found only in approximately 3% of patients presenting at a pulmonary-based sleep disorders clinic.[45] Thus sleep apnea and other types of sleep-disordered breathing may be found in select patients with FM, but current evidence is not convincing for a direct association between sleep apnea and FM.

RLS has been described to be more frequent in female patients with FM (20% to 64%) compared with women in the general population (2% to 15%).[46-48] Genetic studies suggest a common genetic background and coheritability of FM and RLS.[49,50] The occurrence of RLS in patients with FM leads to worse sleep quality and quality of life.[51] The reason for the high prevalence of RLS in this population is unknown but may result from common central processes such as dysfunction of the dopaminergic system. There are emerging data suggesting that the experience of pain among patients with FM may be in part due to dysfunction in the release of dopamine within the CNS. When subjected to deep muscle pain, normal subjects release dopamine in the basal ganglia, whereas fibromyalgia patients do not. In normal subjects, the amount of dopamine release correlates with the amount of perceived pain however there is no such correlation in fibromyalgia patients.[52]

Approach to the Management of Sleep Disturbances in Fibromyalgia

The general goal of FM treatment is to develop an individualized therapeutic program that involves various approaches. Fibromyalgia symptoms of pain and mood disturbances and sleep disturbances affect quality of life, including the patient's ability to work, to participate in everyday activities, and to maintain relationships. For these reasons, therapies directed at alleviating sleep symptoms are integral to the treatment plan of patients with FM.

Actigraphy may aid in identifying issues related to sleep-wake schedules and sleep maintenance issues. Sleep quality reported by patients with FM is directly related to total sleep time and sleep fragmentation, and fatigue in patients with FM is directly related to wake time after sleep onset and sleep efficiency measured by actigraphy.[53] Addressing sleep management issues, such as a regular sleep-wake and light-dark schedule, sufficient sleep time, a sleep-conducive bedroom environment, and avoidance of alcohol, caffeine, nicotine, and other substances that might interfere with sleep, is essential in the management of sleeping difficulties in patients with FM. Other lifestyle recommendations may include daily morning or early afternoon exercise, avoiding heavy meals before bedtime, and nighttime relaxation exercises. Finally, the patient's medications should be reviewed to determine whether medications are contributing to sleep fragmentation or daytime fatigue.

At present, only three drugs—pregabalin, duloxetine, and milnacipran–are approved by the U.S. Food and Drug Administration to reduce FM symptoms.[54] Pregabalin is an anticonvulsant that downregulates presynaptic excitatory neurotransmitter release through its action on an $\alpha_2\beta$ receptor that regulates flow of calcium channels.[55] It is found to be effective in reducing the severity of the two major FM symptom domains: pain and sleep disturbance.[56] Duloxetine

and milnacipran, serotonin-norepinephrine reuptake inhibitor antidepressants, increase the availability of serotonin and norepinephrine at CNS synaptic clefts. They have the potential to reduce pain by correcting the functional deficit of 5-hydroxytryptamine and norepinephrine neurotransmission in the descending inhibitory pain pathway.[57]

In addition, several pharmacologic agents have been tested specifically for their potential to improve sleep in patients with FM. These medications include chlorpromazine, amitriptyline, zopiclone, fluoxetine, mirtazapine, trazodone, and cyclobenzaprine. Chlorpromazine has been shown to decrease alpha-delta EEG frequencies, while reducing pain and trigger point tenderness.[58] Zopiclone has been shown to marginally increase delta sleep, improve subjective sleep quality, and decrease awakenings during the night.[59] Tricyclic antidepressant medications such as amitriptyline, which affects serotonin metabolism in the CNS, reduce alpha-delta sleep time and promote restorative sleep in patients with FM, although effects appear to decline after 6 months of therapy.[60,61] Fluoxetine has been shown to help sleep and depressed mood in women with FM.[62] Amitriptyline and fluoxetine combined have resulted in significant improvement among patients with FM in general sleep scores and appeared to be superior to either drug alone.[63] Mirtazapine has a pharmacologic profile that includes serotonergic and antihistaminic properties, which lead to antidepressive as well as sedative effects. Mirtazapine has been shown to reduce pain and fatigue and to improve sleep quality in most patients with FM.[64] Trazodone has been shown to markedly improve sleep duration, sleep efficiency, and sleep quality based on the Pittsburgh Sleep Quality Index in patients with FM. Improvements with the use of trazodone were also observed on the Fibromyalgia Impact Questionnaire, the Beck Depression Inventory, the HADS, and pain interference with daily activities.[65] Trazodone plus pregabalin administered over 12 weeks showed significant improvement in sleep quality, depression, pain, and global fibromyalgia severity.[66] Very low-dose cyclobenzaprine (1 to 4 mg) at bedtime resulted in improvement in CAP sleep EEG and improved FM symptoms. Responding patients showed lower frequency of CAP A2 and A3 and reported improved fatigue and HADS depression score. CAP changes appeared to be a useful biomarker that predicted treatment benefit.[19] These findings underscore the clinical benefit of treating sleep complaints and normalizing sleep architecture in FM.

Sodium oxybate has been evaluated in double-blind randomized placebo-controlled trials for treatment of FM. Sodium oxybate has been noted to reduce tender points and fatigue symptoms and to improve sleep quality in patients with FM. Six of seven pain and fatigue scores (overall pain, pain at rest, pain during movement, end-of-day fatigue, overall fatigue, and morning fatigue) were relieved for approximately one third of subjects treated with sodium oxybate compared with 6% to 10% in the placebo group.[67,68] Sodium oxybate also led to improved scores on the Epworth Sleepiness Scale, Jenkins scale for sleep, Functional Outcomes of Sleep Questionnaire, and Short Form-36 health questionnaire. Doses of both 4.5 and 6 g split into two doses (bedtime and 2.5 to 4 hours later) improved outcomes, although only the 6-g dose improved sleep efficiency, stage N2 sleep, and slow wave sleep.[69] This pharmacologic therapy also significantly decreased alpha intrusion, sleep latency, and REM sleep.

Nonpharmacologic therapies for improving sleep and FM symptoms have been explored. Spinal and extremity joint manipulation or mobilization, massage, and various soft tissue techniques improve pain intensity, FM symptom impact, depressive symptoms, and sleep quality. Sex differences are observed in response to these treatments, with women having a greater reduction in pain and FM symptoms than men, although sleep quality improve equally in men and women.[70]

Screening for primary sleep disorders, such as obstructive sleep apnea, restless legs syndrome, and circadian disorders, is important in patients with FM. Even mild inspiratory flow limitation is associated with sleep fragmentation, arousals, fatigue, and excessive daytime sleepiness, notably in women with FM. Nasal PAP therapy in patients with sleep-disordered breathing may improve fatigue, pain, sleep fragmentation, disability, and Rheumatology Distress Index scores.[43] When patients with FM and RLS are treated with pramipexole, a dopamine-3 receptor agonist, they experience significant improvement in measures of pain, fatigue, and functional and global status.[71]

In conclusion, screening for and treating primary sleep disorders, implementing good sleep hygiene recommendations, and pharmacologic management of FM may improve sleep quality and FM symptoms. Treatment strategies should be individualized to improve the patient's quality of life.

CHRONIC FATIGUE SYNDROME AND SLEEP

Chronic fatigue syndrome (CFS) is a disabling condition characterized by severe fatigue lasting for more than 6 months and the presence of at least four out of eight minor criteria. CFS may overlap with other chronic somatic syndromes, such as fibromyalgia syndrome and irritable bowel disorder. Diffuse muscular pain, fatigue, and sleep disturbances are part of the definitions of both CFS and FM. As a result, 20% to 70% of patients with FM meet criteria for CFS, and 35% to 70% of those with CFS have coexistent FM.[72,73] These conditions may constitute continuums of the same physiologic and psychosocial processes, with varying degrees of pain, fatigue, and disturbed sleep.

Complaints of unrefreshing or nonrestorative sleep are very common in patients with CFS. Disturbed sleep is a known cause of fatigue and may play a role in the pathogenesis of CFS. However, the nature of the sleep impairment in CFS remains unknown. Although complaints of unrefreshing sleep are pervasive, there are no apparent neurophysiologic correlates of dysfunctional sleep in CFS, and there are no polysomnographic findings that discriminate between subjects with CFS and normal controls. These observations suggest that psychosocial factors may affect the perception of poor sleep quality. Primary sleep disorders occur often in patients with CFS and may contribute to the presence of daytime dysfunction. However, there is currently little evidence to indicate that treating primary sleep disorders improves fatigue associated with CFS. Therefore primary sleep disorders are likely comorbid rather than an associated condition of CFS.

Polysomnographic Findings in Chronic Fatigue Syndrome

Despite the fact that sleep complaints are frequently reported in patients with CFS, there are no specific or consistent polysomnographic findings that characterize sleep in patients with

CFS. Polysomnographic EEG may show increased number and duration of awakenings.[74,75] Reduced total sleep time and sleep efficiency, both in single night in-laboratory PSG recording and in-home studies, have been described.[76,77] Sleep-onset latencies are often longer in patients with CFS compared with healthy control subjects.[78] It has been reported that patients with CFS may have altered parasympathetic activity at sleep onset, which may contribute to difficulty with sleep initiation.[79] This finding may also reflect poor sleep hygiene or daytime napping, which may decrease nocturnal sleep drive. Based on limited data, there appear to be very few differences or mixed findings in sleep architecture between CFS patients and healthy individuals. Shorter durations of NREM stage 2 have been shown in those with CFS and FM, but not in those with CFS alone. Although total slow wave sleep time has been shown to be unchanged in monozygotic twins discordant for CFS, when the twin with CFS is intentionally sleep delayed by 4 hours, there is decreased slow wave activity during the first NREM period, which suggests a potential deficiency in sleep homeostasis.[80] Some have reported reduced REM sleep in patients with CFS,[76] whereas others have observed a higher percentage of REM sleep in patients with CFS compared with controls.[81-83] Probabilities and rates of sleep-state transitions between wake, N1, and REM into N2 sleep, and transitions from N3 into wake or N1, may also be greater in those with CFS and comorbid FM. In those with CFS without FM, sleep-state transitions from REM to wake may be greater.[84] CAP EEG has not been explored extensively in CFS; existing limited data suggest possibly an increase in CAP during NREM sleep in patients with CFS compared with healthy controls.[77] Therefore a single-night polysomnography performed with traditional technology does not appear useful for discriminating individuals with CFS from healthy controls or from other chronic pain or fatigue conditions, nor do these subtle differences in sleep architecture and EEG findings provide a correlate for sleep complaints in patients with CFS.[85]

Power spectrum analysis of the EEG does not seem to provide strong evidence for abnormal alpha intrusion in NREM sleep in subjects with CFS. No significant differences in spectral power in any frequency band have been found between cotwins with and without CFS.[86] In fact, some studies showed a reduction in alpha power by spectrum analysis during NREM stages 2 and slow wave sleep and during REM sleep in CFS subjects.[77,87] Analysis of other spectral bands (theta, delta, beta) shows inconsistent results. For example, delta power has been reported to be increased, decreased, or no different in CFS groups compared with normal controls.[86-88] Therefore, conventional methods for sleep-stage scoring or quantifying EEG have failed to find specific findings or may not be sensitive enough to detect sleep changes in patients with CFS.

Biochemical Correlates of Altered Sleep in Chronic Fatigue Syndrome

The pathogenesis of CFS remains unknown. Abnormalities of the central and autonomic nervous systems, and in some cases infections, have been hypothesized.[89] Adolescent patients with CFS often have findings of postural orthostatic tachycardia syndrome, suggesting autonomic dysfunction and a potential neutrally mediated cause of chronic fatigue.[90] The cognitive behavior model for CFS suggests predisposing and perpetuating factors. The onset may be related to an infection or other CNS abnormalities, but the perpetuation of the condition may be determined by psychosocial factors such as maladaptive behavior or negative conditioning.[91] Maladaptive responses include reduced physical activity, leading to autonomic dysfunction, increased nervous system sensitivity, and increased CFS symptom burden.

Common Sleep Complaints and Sleep Disorders in Chronic Fatigue Syndrome

Unrefreshing or nonrestorative sleep even after a night of sufficient sleep duration is a frequent complaint occurring in 87% to 95% of CFS patients.[92,93] Nocturnal neurophysiologic disturbances that result in the nonrestorative sensation following sleep in CFS patients are not detected by traditional sleep monitoring, suggesting current measurements may not be sufficiently sensitive to detect subtle disturbances in sleep in this population.

Subjects with CFS with complaints of nonrestorative sleep have a very high co-occurrence of complaints of daytime dysfunction. Objective testing has shown cognitive impairments in attention, motor functioning, information processing, and executive functioning.[94] Pathologic sleepiness, however, is not objectively demonstrated on MSLT despite CFS patients reporting greater subjective sleepiness and poorer sleep quality than healthy controls.[95,96] One potential reason for this may be that patients with CFS may suffer sleep quality misperception. Poor self-rated health and depressive symptoms have been found to be associated with overreporting of sleep difficulties and underestimation of sleep efficiency.[97] Alternatively, current measures may not reliably differentiate between fatigue and sleepiness, resulting in discordances between subjective and objective sleep-related measurements.[98]

Actigraphy studies in children with CFS report a sleep pattern consisting of more than 10 hours of continuous sleep.[99] Impaired daily sleep-wake rhythms and disturbed sleep were observed only in some children with CFS. Most actigraphy studies to date have shown mixed findings relating to circadian rhythm disturbances.[100-102]

Polysomnography studies on population-based subjects have shown the presence of a primary sleep disorder in approximately 18% of patients with CFS compared with 7% of controls.[83] In the clinical setting, 46% to 81% of patients with CFS have comorbid primary sleep disorders such as primary insomnia, obstructive sleep apnea, periodic limb movement disorder, or narcolepsy.[74,103] Organic sleep disorders, such as sleep apnea and narcolepsy, were once considered exclusionary for the diagnosis of CFS. This concept is challenged; it has been found that there are no significant differences between patients with CFS in the presence or absence of OSA with regard to subjective sleep variables, CFS symptoms, indexes of anxiety and depression, and Short Form-36 quality-of-life measures.[104] Although there is evidence to indicate that treatment of sleep-related breathing disorders with PAP therapy may reduce fatigue and increase vigor in otherwise healthy subjects, it is not clear whether primary fatigue due to CFS is similarly responsive to treatment of comorbid sleep disorders.[105] However, because of their high frequency and their potential compounding of symptoms in patients with CFS, a thorough evaluation for underlying organic sleep disorders and aggressive treatment are warranted.

CLINICAL PEARLS

- Sleep-related complaints such as poor sleep quality and nonrestorative sleep are pervasive in fibromyalgia and chronic fatigue syndrome and may be associated with complaints of pain and fatigue.
- Patients with fibromyalgia demonstrate greater sleep disturbances on polysomnography such as reduced total sleep time, sleep efficiency, REM and slow wave sleep, and increased arousals and alpha intrusion.
- Decreased serotonin levels in the CNS may contribute to altered nociception and sleep disturbances in fibromyalgia.
- Therapies targeted at improving sleep, including treating comorbid sleep disorders, are important adjuncts to treatment of fibromyalgia and chronic fatigue syndrome.

SUMMARY

Sleep disturbances, sleep complaints, and comorbid sleep disorders are common in patients with fibromyalgia and chronic fatigue syndrome. Many characteristic daytime symptoms, such as chronic pain and fatigue, may be related to nonrestorative sleep patterns associated with the diseases. Pain and sleep disturbances interact reciprocally—pain affects sleep processes, and sleep disturbances affect pain threshold—to influence disease severity and chronicity. Sleep disturbances therefore may contribute to fatigue, psychological disturbances, and impaired quality of life. To the extent that nonrestorative sleep may exacerbate fibromyalgia or chronic fatigue symptoms, treatments that directly improve sleep quality may improve daytime symptoms of these disorders.

Endocrine Disorders

Adriana G. Ioachimescu; Octavian C. Ioachimescu

Chapter Highlights

- The hypothalamus plays a major role in integrating sleep and various metabolic functions.
- Most hypothalamic and pituitary hormones exert important effects on sleep-wake homeostasis.
- Sleep-disordered breathing is very common in acromegaly (both obstructive and central sleep apnea).
- The association between hypothyroidism and obstructive sleep apnea remains controversial.
- The hypothalamic-pituitary-adrenal axis plays a significant role in stress coping, with major influences on sleep homeostasis.
- Low testosterone levels and obesity play important roles in obstructive sleep apnea.

The endocrine system can be conceptualized as an array of hypothalamus-pituitary-target organ axes, with the target organs being represented by the "effector" endocrine glands (e.g., thyroid, adrenal, gonads, adipose tissue; Figure 132-1). These effects are important in the sleep neurobiology because some of these hormones are neuropeptides and may have significant effects. We discuss mainly the endocrine effects of these hormones, whereas the paracrine, autocrine, and local neuromodulating effects of these factors are beyond the scope of this chapter. We will not discuss here in great detail the endocrine physiology in relationship to sleep or sleep deprivation, which are reviewed in detail in Chapter 20.

HYPOTHALAMIC DISORDERS AND SLEEP

Fine coordination between metabolic processes and sleep-wake states involves at least one major player: the hypothalamus, which is considered the grand regulator of the master endocrine gland, that is, the hypophysis (or pituitary gland). The hypothalamus is involved in regulating several metabolic processes: thirst, hunger and satiety, thermoregulation, autonomic nervous system, response to stress, and modulation of emotional behaviors. The hypothalamus controls sleep and metabolism in two different ways: directly (using neural connections that control arousal and metabolic pathways) and indirectly (using appetite and behavioral controls, stress-coping mechanisms, and several reward systems).

The homeostatic role of the hypothalamus is exerted by integrating inputs from peripheral and central circadian oscillators, data on current sleep debt (or "homeostatic sleep pressure," process S; see Chapter 36), autonomic nervous system, caloric intake, and body temperature changes and by orchestrating the metabolic rate, arousal mechanisms, and water and food intake. Although sleep is generally coupled with energy saving and wakefulness with energy intake and consumption, it is not surprising that there is common integration and regulation of these processes at the hypothalamic level.

Two brain areas are of crucial importance in the neuroendocrine and metabolic effects in discussion: (1) the anterior hypothalamus–suprachiasmatic nucleus (SCN, which generates oscillations or rhythmicities by translating day-night information relayed from the retina into transcriptional and translational feedback loops of various clock genes; see Chapters 32 to 40) and (2) the lateral hypothalamus (e.g., the area secreting hypocretin). The SCN orchestrates global and peripheral circadian rhythms through both endocrine and neural pathways. Hormonal systems that are under overt circadian control include the pineal gland (secreting melatonin), the hypothalamic-pituitary-adrenal (HPA) axis (active hormone: cortisol) and the hypothalamic-pituitary-thyroid (HPT) axis (active hormones: thyroxine [T_4] and triiodothyronine [T_3]). In addition, hormones under SCN control (e.g., cortisol) may act to entrain other circadian oscillators, located in peripheral tissues, organs, and systems.

Since the initial description of encephalitis lethargica or von Economo's "sleepy sickness" due to lesions of the dorsal part of the hypothalamus and our understanding that lesions of certain anterior hypothalamic areas lead to severe insomnia, the role of the hypothalamus in sleep-wake regulation has become more evident. The hypothalamic regions could be damaged by locoregional tumors or their treatment and by inflammatory or infiltrative conditions. Given the plethora of functions of the hypothalamus, its damage may be associated with a wide variety of sleep symptoms, including sleepiness, fatigue, and disturbances in the sleep-wake regulatory system and circadian rhythms.

Many case reports or short series illustrate that pathology of the lateral hypothalamus can lead to hypersomnia or narcolepsy, whereas involvement by infiltrative, inflammatory, or neoplastic conditions of the anterior hypothalamus may disrupt the circadian clock of these patients or lead to severe insomnia. Inflammatory infiltrates were observed in the hypothalamus of two patients who died with Kleine-Levin syndrome.[1,2] Although the exact biochemical changes or hormonal

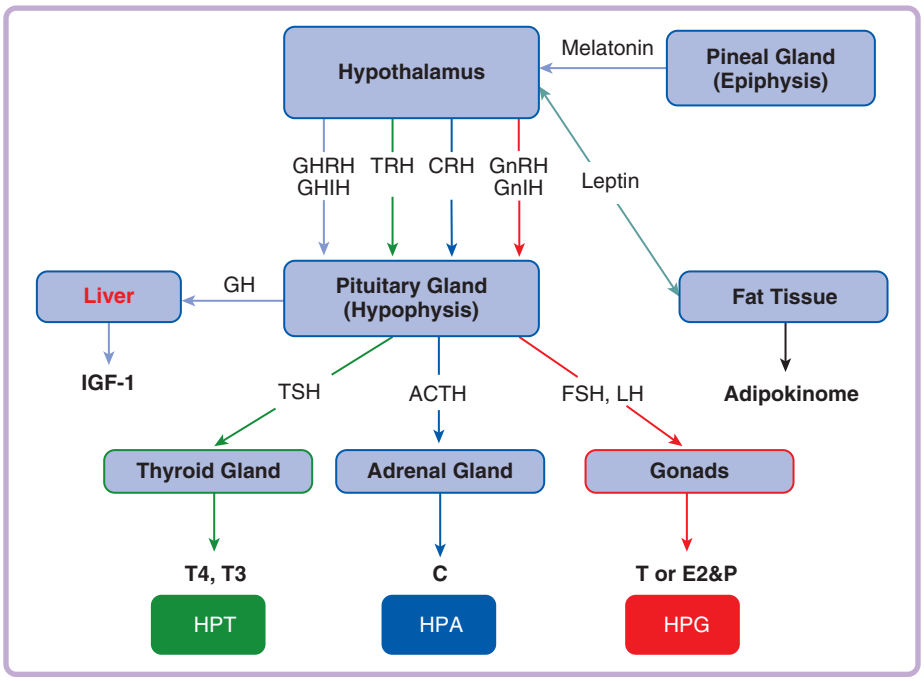

Figure 132-1 Diagram representing the main hypothalamic-pituitary–target gland axes: somatotropic axis (on the left, in *light blue*, via growth hormone [GH], growth hormone–releasing hormone [GHRH], growth hormone–inhibiting hormone [GHIH], and insulin-like growth factor-1 [IGF-1]), hypothalamic-pituitary-thyroid axis (HPT, in *green*, via thyrotropin-releasing hormone [TRH], thyroid-stimulating hormone [TSH], thyroxine [T_4], and triiodothyronine [T_3]), hypothalamic-pituitary-adrenal axis (HPA, in *dark blue*, via corticotropin-releasing hormone [CRH], adrenocorticotropic hormone [ACTH], and cortisol [C]), and hypothalamic-pituitary-gonadal axis (on the right, in *red*, via gonadotropin-releasing hormone [GnRH], gonadotropin-inhibiting hormone [GnIH]; follicle-stimulating hormone [FSH]; luteinizing hormone [LH], and testosterone [T] or estradiol [E2]/progesterone [P]). Additional interactions illustrated here are the interactions between the fat tissue, which secretes adipokines or so-called adipokinome, and the interaction between pineal gland and hypothalamus, via melatonin. Not illustrated here are the negative feedback loops exerted by the effector hormones (IGF-1, T_3, C, T, E2/P) on the hypothalamus and the pituitary gland; additionally, for purposes of simplicity, prolactin pathways were omitted.

changes occurring in this disorder are still unclear, it is conceivable that an autoimmune insult at the level of the thalamus or the hypothalamus is involved in the pathogenesis.

One special note needs to be made about hypothalamic obesity (see also Adipose Tissue). Most syndromes of morbid obesity result from single gene mutations expressed in the hypothalamus. Hypothalamic obesity is generally the result of impairments in the hypothalamic regulatory centers of body weight and energy expenditure and can be caused by anatomic destruction by tumors or other infiltrative processes, radiotherapy, Prader-Willi syndrome, and other disorders. Mutations in the *LEP*, *LEPR*, *POMC*, *MC4R*, or *CART* genes have been described in association with hypothalamic obesity.[4] Pathophysiologic mechanisms include loss of sensitivity to afferent peripheral humoral signals such as leptin, dysregulated insulin secretion, and impaired sympathetic nervous system activity. Dysregulation of 11β-hydroxysteroid dehydrogenase-1 activity and melatonin may also have a role in the development of hypothalamic obesity.

PITUITARY DISORDERS AND SLEEP

The anterior pituitary hormones are part of the following endocrine axes: HPA, HPT, and hypothalamic-pituitary-gonadal (HPG) as well as somatotropic (hypothalamic-pituitary–growth hormone) and lactotrophic (hypothalamus-pituitary-prolactin) systems. Vasopressin and oxytocin are synthesized and released from posterior hypophysis; they exert many autocrine, paracrine, or neuropeptidergic actions but have less known endocrine effects relevant to sleep or involvement in sleep disorders. Similarly, less is known about the physiologic roles of pituitary adenylate cyclase–activating polypeptide (PACAP), which may be involved in the homeostatic regulation of sleep.[5,6]

Growth Hormone–Secreting Tumors (Acromegaly and Gigantism) and Sleep Apnea

The neuroendocrine condition of growth hormone (GH) excess leads to acromegaly in adults and gigantism in children. The GH and insulin-like growth factor-1 (IGF-1) excess lead to acral enlargement, coarse facial features, and growth of the synovial tissues and articular cartilages (with acromegalic arthropathy in up to 75% of cases[7]). Sleep-disordered breathing (SDB) is very common in acromegaly. Studies have shown that up to 70% of patients diagnosed with acromegaly have sleep apnea, even after correction for obesity.[8-10] In a landmark study by Grunstein and colleagues performed on 53 consecutive referrals of patients with acromegaly, almost all patients with acromegaly had severe snoring.[11] Thirty-one patients (93%) referred because of suspected SDB had sleep apnea, compared with 12 patients (60%) referred without suspected sleep apnea. Central sleep apnea (CSA) was the predominant type of apnea in 33% of patients.

Excessive daytime sleepiness and fatigue have been reported as common symptoms in patients with acromegaly. The currently accepted explanations are represented by coexistent obstructive sleep apnea (OSA; most of the cases), direct effects of GH in promoting sleep (still unclear in humans), effect of prior cranial radiotherapy, coexistent hypogonadism or hypothyroidism, and hypothalamic GH-secreting tumors affecting somnogenic hypothalamic areas (rarely). Recognizing that SDB is underassessed in patients with acromegaly, current guidelines recommend that every patient diagnosed with this condition should be evaluated upfront for daytime symptoms or assessed by polysomnography (PSG) in collaboration with a sleep specialist.

The pathophysiologic mechanisms of SDB in acromegaly are still unclear. Several hypotheses have been proposed. OSA may result from macroglossia, hypertrophy of the submaxillary salivary glands, soft tissue thickening (especially of the soft palate and uvula), changes in the bone architecture of the upper airway (dorsocaudal rotation of the mandibular angle or reduced lingual "enclosure"), leading to smaller cross-sectional area and greater collapsibility of the hypopharynx. OSA may also result from altered neuromuscular control of the upper airway, dysfunction of the upper airway dilators such as sternohyoid myopathy, or obesity (if present). CSA in patients with acromegaly may be due to abnormalities in the control of breathing that result from left ventricular (systolic or diastolic) dysfunction, central pathways disinhibiting respiratory control, increased response to hypercapnic hypoxic drive, or direct or indirect effects exerted by GH on respiratory control centers.

The presence of OSA may confer additional cardiovascular risk for patients with acromegaly. GH and IGF-1 excess lead to left ventricular hypertrophy, systolic and diastolic myocardial dysfunction and cardiac dysrhythmias, and glucose intolerance and diabetes mellitus. Hypertension is highly prevalent in patients with acromegaly (up to 50% of cases), whereas cardiomyopathy is present in most patients. Hypertension is related to chronic hypervolemia (GH and IGF-1 increase sodium reabsorption by acting directly on the distal tubules epithelial cells' sodium channels[12]), endothelial dysfunction, insulin resistance, or coexistent sleep apnea that could further increase the blood pressure.[8] Most acromegaly patients die of cardiovascular disease.

OSA improves in many patients with acromegaly after GH tumor resection surgery. Nevertheless, prospective studies show that OSA persists in at least 40% of cases cured of acromegaly, requiring periodic reassessment.[8,13,14] Indeed, current guidelines state that, despite successful treatment of acromegaly, SDB does not consistently resolve, so posttherapeutic assessments with yearly evaluations (e.g., Epworth Sleepiness Scale, PSG, positive airway pressure use, and effectiveness data) are suggested.

Growth Hormone–Secreting Tumors and Restless Legs Syndrome

A group of investigators[15] looked recently into a possible association between acromegaly and restless legs syndrome (RLS), or Willis-Ekbom disease. Using both questionnaires and PSG, they found an increased prevalence of RLS in patients with active acromegaly.[15] Overall, approximately 21% of patients with acromegaly had RLS (36% in active disease group, 12% in controlled disease group, and 4% in healthy controls). Patients with active disease had worse acromegaly-related quality of life (QoL), higher severity of RLS symptoms by the International RLS Rating Scale, longer sleep latencies and wake after sleep onset, higher arousal and periodic limb movements during sleep indexes, and worse sleep efficiency.[15] Moreover, prevalence of RLS was not correlated with serum GH or IGF-1 levels, and the relationship stood even after exclusion of patients with OSA.[15] Interestingly, Taylor-Gjevre and colleagues[16] showed that the prevalence of RLS was almost as high (24.4%) in patients with osteoarthropathy, a condition frequently associated with acromegaly, so it would be interesting to parse out how many patients with acromegaly with and without osteoarthropathy have RLS.

Prolactin-Secreting Tumors (Prolactinoma)

Prolactinomas are prolactin (PRL)-secreting tumors and account for approximately 40% of pituitary adenomas. In patients with untreated prolactinoma, secondary hypogonadism is the most frequent endocrine abnormality. Patients with prolactinoma spend more time in slow wave sleep (SWS) than their healthy controls (on average, 79.4 vs. 36.6 minutes in controls), whereas rapid eye movement (REM) sleep does not seem to differ between the two groups. The current working hypothesis is that PRL stimulates both SWS and REM sleep, although the exact mechanism is still unclear. These findings are concordant with reports of good sleep quality in patients with prolactinoma, and discordant with the abnormal sleep of patients with other endocrinopathies.[17] An increased prevalence of obesity in male patients with prolactinoma has been described,[18,19] and because obesity is a risk factor for OSA, this morbid association should not be surprising. One study showed that elevated PRL levels may represent a modifiable and reversible cause of overweight state, especially in men.[20] Potential mechanisms explaining weight gain in patients with PRL-secreting pituitary adenomas are (1) associated hypogonadism; (2) increased hypothalamic pressure; (3) reduced dopaminergic tone; (4) leptin resistance; (5) adipokine imbalance such as hypoadiponectinemia; and (6) visceral fat deposition as a direct effect of PRL.

Adrenocorticotropic Hormone–Secreting Pituitary Tumors (Cushing Disease)

Excess adrenocorticotropic hormone (ACTH) secretion by pituitary tumors (Cushing disease, most frequently caused by pituitary microadenomas) or ectopically (by extrapituitary ACTH- or corticotropin-releasing hormone [CRH]-secreting tumors such as small cell lung cancer and atypical bronchial carcinoids) presents with manifestations due to the systemic effects of hypercortisolism.[21] When nocturnal cortisol secretory profile was analyzed in a group of patients with Cushing disease, adrenal activity was found to start predominantly during periods of non–rapid eye movement (NREM) sleep, similarly to matched healthy controls. Thus, even when the typical pituitary-adrenal axis nocturnal oscillation pattern is lost or blunted (such as in Cushing disease), the link between the endocrine activity and the ultradian rhythmicity of NREM and REM sleep seems to be preserved.[22]

Nonfunctioning and Gonadotropin-Secreting Pituitary Adenomas

Nonfunctioning macroadenomas (NFMAs) are pituitary tumors without systemic hormonal hypersecretion. Several

authors reported that patients with resected NFMAs have sleep complaints and circadian alterations as well as objective PSG or actigraphy changes.[23] In one study, patients with NFMAs had reduced sleep efficiency, less REM sleep, more N1 sleep, and more awakenings in the absence of associated apneas or periodic limb movements (compared with controls). Actigraphy revealed longer rest durations, more awakenings at night, and less activity during the day. Patients with treated NFMAs reported more fatigue and impaired QoL.[23] In another study, Joustra and colleagues[24] found melatonin secretion abnormalities in a significant percentage of patients with NFMAs and pituitary craniopharyngiomas, likely owing to either suprachiasmatic clock abnormalities induced by suprasellar extension or the treatment instituted for the pituitary tumor. Patients with NFMAs have also been found to have increased risk for developing metabolic syndrome (reduced high-density lipoprotein cholesterol and increased triglycerides)[25]; interestingly, identified factors were preoperative visual field defects and hypopituitarism. This association may be explained by hypothalamic dysfunction leading to the well-known hypothalamic obesity,[26] intrinsic imperfections of hormone replacement therapy,[25] direct effect of associated sleep disturbances,[27] or other, unidentified causes.

Craniopharyngioma

So far, little is known about the circadian and sleep-wake abnormalities of patients with craniopharyngiomas. Tumor growth and its treatment may lead to hypopituitarism, visual field defects, obesity, and sometimes increased daytime sleepiness.[28] Interestingly, the latter was associated with decreased nocturnal melatonin levels and higher body mass index (BMI); as such, further studies on the possible beneficial effects of melatonin substitution on daytime sleepiness and weight control in these patients are needed. Compared with healthy controls, patients successfully treated for craniopharyngiomas may report impaired QoL, excessive fatigue,[29] increased daytime sleepiness,[21,30,31] or severe sleepiness despite normal sleep patterns.[31,32] In one recent study,[33] craniopharyngioma patients presented with significantly decreased area-under-the curve melatonin concentrations compared with healthy controls and with a strong association between low midnight melatonin and reduced total sleep time, reduced time of night sleep, impaired sleep efficiency, and reduced physical activity.

Growth Hormone Deficiency

Adults with growth hormone deficiency (GHD) often complain of fatigue, fatigability, or impaired overall QoL.[34] Numerous animal[35,36] and human[37-39] studies have showed that growth hormone–releasing hormone (GHRH) has soporific effects, increasing total sleep time (TST) and SWS, even in the absence of GH.[35,40] As such, enhanced hypothalamic GHRH activity may lead to increased sleep pressure and excessive daytime fatigue, even in untreated GHD of primary pituitary origin because of the GH negative feedback loop (i.e., lack of GH leads to compensatory increase in GHRH). Furthermore, findings in rodents[36] and even in humans[41,42] indicate that GH itself may stimulate REM sleep. Thus there is enough evidence to go along with the hypothesis that patients with GHD may have sleep disturbances explaining daytime symptoms such as fatigue and impaired QoL. These sleep disturbances may differ according to the origin of GHD, that is, either pituitary (with overactive hypothalamic GHRH neurons) or hypothalamic (with reduced GHRH activity).

To date, few studies have objectively characterized sleep in GHD.[43-45] In one of the more recent studies,[46] authors evaluated sleep both subjectively and objectively in 30 adult patients with GHD (primary pituitary defects in 26 patients, hypothalamic causes in 4 patients, none on GH supplementation) and 30 matched healthy controls. The study found that GHD patients had worse scores on the QoL questionnaire, with tiredness being the most affected domain, irrespective of etiology. Patients with pituitary GHD spent more time in SWS and had a higher intensity of SWS than their controls. In contrast to pituitary GHD, patients with hypothalamic GHD had lower intensity of SWS than their controls. In the same study, older patients with pituitary GHD had more fragmented sleep and overall less REM sleep[46]; because insufficient REM sleep may be related to the emergence of memory disturbances,[47,48] it will be interesting to investigate to what extent GHD contributes to memory disturbances in elderly people.

OSA patients appear to have relative GH deficiency, which is likely related to hypoxia and abnormal sleep architecture from OSA and is reversible after continuous positive airway pressure (CPAP) therapy.[49,50] Contrary to earlier observations, more recent data suggest that GH therapy administered to patients with GHD does not induce or aggravate OSA. On the contrary, GH therapy seems to improve in these patients.[51] Twelve weeks, but not 6 weeks, of CPAP therapy for OSA increases IGF-1, with a further increase after 24 weeks. Total and pulsatile GH secretion, secretory burst mass, and pulse frequency are also increased by 12 weeks. CPAP therapy seems to improve specific elements of the GH–IGF-1 axis in a time-dependent manner.[52]

PINEAL DISORDERS AND SLEEP

The pineal gland is constituted by pinealocytes, which secrete melatonin (derived from serotonin), with important regulatory roles of the circadian and infradian rhythms. The pineal gland melatonin acts on numerous peripheral tissues, in concert with the melatonin secreted in the retina, bone marrow, platelets, and gastrointestinal tract. Although the complete surgical excision of the pineal gland leads to very few endocrine disturbances (which could point toward a vestigial aspect or a nonessential role), pineal pathology may occasionally have some consequences on sleep-wake homeostasis (Table 132-1). Pineal gland tumors are relatively rare but are the most frequent pineal pathology seen in clinical practice. These tumors may lead to signs and symptoms attributable to local mass effect, involvement of adjacent anatomic structures, and rarely endocrine effects. There are inconsistent data about the effects of hypermelatoninemia or hypomelatoninemia in certain types of tumors. Recent studies show that serum melatonin levels are generally very low or absent (rather than elevated) in both treated and untreated pineal tumors.[53] Nevertheless, two clinical presentations that have been reported deserve to be briefly mentioned here. First, rare cases of pineal tumors may present with clinical manifestations indistinguishable from narcolepsy ("secondary narcolepsy"), although they may also be due to concurrent hypothalamic involvements.[54,55] Second, cases of circadian-timed headaches, excessive daytime fatigue, and severe insomnia have been

Table 132-1 Main Neuropeptide Hormones in the Central Nervous System with Important Actions on Sleep-Wake Homeostasis

Source	Neuropeptide Hormone	Role in Sleep-Wake Homeostasis	Other Regulatory Roles
Hypothalamus	Hypocretin	Consolidates sleep Suppresses REM sleep	Feeding (+); mood; thermoregulation and energy expenditures; reward
	Melanin-concentrating hormone (MCH)	Promotes sleep	Feeding (+); memory
	Galanin	Promotes NREM sleep Promotes REM sleep	Anxiety; neuroregeneration; pain
	Growth hormone–releasing hormone (GHRH)	Promotes NREM sleep	Growth hormone (GH) release (+)
	Thyrotropin-releasing hormone (TRH)	Promotes wakefulness Inhibits NREM sleep	Feeding (–); energy homeostasis; locomotion
	Corticotropin-releasing hormone (CRH)	Promotes wakefulness Modulates REM sleep	Anxiety; depression; stress
	Cholecystokinin (CCK)	Promotes wakefulness Promotes NREM sleep	Anxiety; feeding (–); pain
	Somatostatin (SST)	Promotes wakefulness Promotes REM sleep Inhibits NREM sleep	GH release (–)
	Corticostatin (CST)	Promotes NREM sleep Inhibits REM sleep	GH release (–); learning; memory; pain (–)
	Brain-derived neurotrophic factor (BDNF)	Promotes NREM sleep (?) Inhibits wakefulness	Feeding (–); synaptic plasticity (+)
	Dynorphin	Promotes NREM sleep	Pain
	Melanocyte-stimulating hormone (MSH)	Promotes NREM sleep (?)	Stress regulation; feeding (–); motivation; pain; reward
	Neuropeptide Y	Modulates both NREM and wakefulness	Feeding (+); anxiety; addiction
	Vasoactive intestinal peptide (VIP)	Promotes REM sleep	Circadian regulation; feeding (–)
Anterior pituitary	GH	Promotes REM sleep Inhibits NREM sleep (?)	Cell growth (anabolic effects)
	Adrenocorticotropic hormone (ACTH)	Promotes wakefulness	Feeding (–); motivation; pain; reward
	Prolactin (PRL)	Promotes REM sleep	Lactation; stress modulation
	Pituitary adenylate cyclase–activating polypeptide (PACAP)	Promotes REM sleep	Circadian regulation; feeding (+); memory; stress; pain
Posterior pituitary	Vasopressin (AVP)	Circadian regulation (present also in the hypothalamus, including suprachiasmatic nucleus)	ACTH secretion (+); thirst and water excretion
	Oxytocin	Circadian regulation (?)	Lactation; anxiety; mood
Pineal gland	Melatonin	Promotes sleep	Circadian regulation; reproduction
Stomach (and hypothalamus)	Ghrelin	Promotes wakefulness	Feeding (+)
Adipose tissue (and hypothalamus)	Leptin	Promotes NREM sleep Promotes wakefulness (?)	Feeding (–); energy expenditure (+); thermogenesis (+)

reported and posited to be related to a pineal endocrine insufficiency because exogenous melatonin administration improved or resolved the presenting clinical symptoms.[56,57]

THYROID DISORDERS

Thyroid hormones influence many central nervous system (CNS) neurochemical pathways and networks involved in the sleep-wake homeostasis. Disturbances of the HPT axis such as altered thyroid function or abnormal thyroid-stimulating hormone (TSH) levels may affect the arousal-promoting system. Overall, the effects of thyroid hormones are more likely activating than soporific. So far, there have been only a few studies that shed light on the association between HPT axis and neural pathways involved in generating or maintaining alertness. Thyrotropin-releasing hormone (TRH) and its receptors are widely distributed in the CNS. Aside from its TSH-releasing effect, TRH exerts many other neuromodulatory actions, including stimulative, antidepressant, and neurotrophic effects.

A recent open-label study[58] examined the effects of a small dose of oral levothyroxine (25 mcg) on sleep and daytime somnolence of nine patients with idiopathic hypersomnia. The authors found that after 4 weeks of levothyroxine administration, TST and hypersomnolence improved significantly, effects that were maintained at 8 weeks. Unfortunately, posttreatment thyroid function testing was not available in most of the subjects. Mechanistically, it is possible that small doses of levothyroxine reduce TSH production or that patients with idiopathic hypersomnia may have intrinsic alteration of the HPT axis.

Hyperthyroidism and Restless Legs Syndrome

Reduced levels of dopamine (DA) in certain areas of the brain seem to play an important role in the pathophysiology of RLS, either as a primary biochemical disturbance or as a secondary condition such as in iron deficiency (because iron is a co-factor for tyrosine hydroxylase, a key enzyme in the synthesis of DA). DA agonists effectively alleviate RLS symptoms, and they are the first line of therapy. Currently, there is an accumulating body of evidence showing that DA may suppress the activity of the HPT axis.[59-61] First, the 24-hour profile of TSH resembles the typical circadian variation in clinical symptoms for RLS patients; levels of TSH increase in the evening, as does the severity of RLS symptoms (interestingly, dopaminergic tone seems also to increase in the evening[60]). Second, DA also modulates thyroid hormones by enhancing the biochemical functions of the cytochrome P-450 (CYP-450, heme and iron containing) liver enzymes that metabolize them and by inhibiting directly the pituitary TSH secretion. In addition, low iron levels diminish the available catalytic units of CYP-450 capable of degrading thyroid hormones.

One interesting recent theory[62] posits that the main cause of RLS is an imbalance between the dopaminergic system and HPT axis. This theory stems from several observations: (1) thyroid hormone levels seem to follow DA levels[59,60]; (2) TRH regulates TSH synthesis by stimulating transcription and translation of the TSH β-subunit gene, while DA inhibits this process[63]; (3) antidopaminergic agents (e.g., metoclopramide, neuroleptics) tend to worsen RLS complaints,[64] while DA agonists diminish RLS symptoms; (4) reduced levels of iron in the brain diminish the DA system activity, which in turn aggravates RLS; (5) the HPT axis increases its activity during sleep restriction,[65] which could also aggravate RLS; (6) some of the effects of elevated thyroxine levels, as seen in hyperthyroidism, resemble some symptoms of RLS; (7) opioids, the first class of drugs used to treat RLS, are also known to depress the HPT axis[66,67]; (8) several drugs known to alleviate RLS symptoms, such as carbamazepine, phenobarbital, and valproic acid, are inducers of CYP-450 system; and (9) conversely, tricyclic antidepressants, antihistaminic agents, selective serotonin reuptake inhibitors, and neuroleptics are CYP-450 inhibitors, and they all have the potential to worsen RLS symptoms.[62] Support of this theory comes from an earlier report of a patient with RLS and hypothyroidism on thyroid replacement therapy, who had a low serum ferritin level (iron deficiency). On successive challenge and withdrawal of L-thyroxine, there were significant changes in the International Restless Legs Syndrome Study Group (IRLSSG) severity score, periodic limb movement index, and sleep efficiency (all worse while taking thyroxine).[68] A study by Tan and colleagues[69] found a strong association between hyperthyroidism and RLS symptoms, despite the fact that the overall prevalence of RLS was very low (0.2%). The study examined 125 hyperthyroid patients, 21 hypothyroid individuals, and 434 normal healthy controls. None of the patients with thyroid disease had a diagnosis of RLS, as defined by the IRLSSG (i.e., none met all four IRLSSG criteria). In normal subjects, 4 out of 434 (0.9%) met the first three IRLSSG diagnostic criteria, as did 1 out of 21 hypothyroid individuals (4.8%) and 11 out of 125 hyperthyroid patients (8.8%). A recently published German study[70] analyzed the impact of comorbidities on prevalent and incident RLS in two distinct cohorts of patients (Dortmund Health Study [DHS], $n = 1312$, median follow-up of 2 years; and Study of Health in Pomerania [SHIP], $n = 4308$, median follow-up of 5 years). At baseline, 10.1% and 6.6% of patients had thyroid disease, and 7.3% and 10.1% had RLS in DHS and SHIP, respectively. Interestingly, odds ratios for incident RLS associated with thyroid disease (as defined by patient taking thyroid medications, either suppressive or replacement therapy) were statistically significant only in SHIP and found to be 1.63 (95% confidence interval, 1.04 to 2.58). Overall, the relationship of multimorbidity with RLS was stronger with incident than with prevalent RLS, suggesting that RLS developed subsequently to preexisting chronic conditions. This was an important observation because prior studies were mostly cross-sectional and thus unable to assess the temporal relationship between RLS and comorbidities.

Hypothyroidism and Obstructive Sleep Apnea

Hypothyroidism is one of the most common endocrine disorders; its prevalence tends to increase with age and is more common in women. It was estimated that approximately 2% of women between 70 and 80 years of age have overt hypothyroidism, whereas 5 to 10% of women older than 50 years of age have subclinical hypothyroidism.[71] Subclinical primary hypothyroidism generally refers to normal thyroid hormone levels with increased serum TSH in asymptomatic subjects.

In the general population, OSA is also a frequent condition.[72,73] Interestingly, OSA and hypothyroidism share a few similarities: (1) they are very prevalent disorders, (2) both have subclinical phenotypes that can go on undetected for years, (3) their exact prevalence in a particular population is often

unknown and inviting for wrongful extrapolations, (4) both are defined with somewhat fluid diagnostic criteria (e.g., hypopnea definition, apnea-hypopnea index [AHI] threshold, technology employed for diagnosis, TSH assays, threshold for subclinical hypothyroidism), and (5) they have common clinical manifestations and major comorbidities; for all these reasons, clinically they could be very easily confused with each other. For example, OSA is characterized by snoring, excessive daytime sleepiness, fatigue, apathy, frequent headaches, and memory impairments and is often associated with obesity or depression; these manifestations are quite nonspecific and also frequently seen in hypothyroidism. Furthermore, large goiters can also cause upper airway compression, ventilatory impairment, and possibly OSA.[74] Given these considerations, it is not surprising that a number of investigators found these conditions to coexist in 1.2% to 11% of the population studied.[75-77]

In a study on 50 consecutive patients with hypothyroidism, 30% were reported to have some degree of OSA.[78] In contrast, Bahammam and colleagues[79] failed to detect a significant difference in the prevalence of hypothyroidism in patients with or without a diagnosis of OSA. They found subclinical hypothyroidism in 11.1% of patients with OSA and in 4% of patients without OSA and concluded that subclinical hypothyroidism was more frequent in OSA.[79] In a cross-sectional study from Turkey,[80] from among 150 patients with OSA and 32 controls, thyroid ultrasonographic examination did not reveal any significant differences, and Hashimoto thyroiditis was found to have similar prevalence in OSA and control groups. In contrast, Bozkurt and colleagues[81] found that obese women with OSA had higher prevalence of Hashimoto thyroiditis, in parallel with OSA severity. Furthermore, Carratu and colleagues[82] found that subclinical hypothyroidism and thyroid replacement therapy did not change prevalence and severity of OSA. In another study, Mickelson and colleagues[77] evaluated the thyroid status of 834 patients with SDB and concluded that routine thyroid function testing was not necessary for these patients. Several authors found similar results and conclusions,[76,83,84] whereas others disagreed.[85,86]

Sleepiness, obtundation, and ultimately coma seen in advanced myxedema could be the result of either (1) a very reduced rate of basal metabolism, or (2) undiagnosed and untreated hypoxic (and possibly hypercapnic) OSA. Several mechanisms explaining the association between OSA and hypothyroidism have been posited: reduced cross-sectional area of the upper airway due to infiltration with mucopolysaccharides and water (e.g., macroglossia), myxedema-related upper airway myopathy, or reduced respiratory drive (as hypothyroidism blunts both hypoxic and hypercapnic ventilatory responses).[87,88] The downstream effects of the respiratory drive blunting on OSA likely vary by disease phenotype. As such, in patients with high loop gain or a tendency for ventilatory overshoot, blunted sensitivity may lead to relative stability of the airway and a decrease in OSA severity[89,90]; similarly, the impact of thyroid replacement therapy on SDB may also vary by phenotype.

The effect of thyroid hormone replacement therapy on OSA coexistent with hypothyroidism has been variable and based on rather small cohorts.[87] A more recent study of 50 patients suggested that OSA was a secondary phenomenon in many of the hypothyroid patients and that it may be reversible.[78] Thyroxine replacement therapy was associated with improvement in macroglossia, myxedema, and facial puffiness, suggesting that changes in upper airway anatomy seen in hypothyroidism may contribute to the development of OSA in these patients. Furthermore, several studies suggested the possibility of a stronger connection between OSA and cardiovascular complications in the initial phase of thyroid hormone replacement therapy because rapid restoration of the euthyroid state in these patients may confer additional cardiovascular risks.[87,91]

In summary, the association between OSA and hypothyroidism remains highly controversial and debatable, possibly because the hypothyroidism diagnosed nowadays is much milder than the severe myxedema seen in earlier investigations.

Hypothyroidism and Restless Legs Syndrome

Back in 1985, Schlienger[92] reported a case of RLS due to moderate hypothyroidism. Banno and colleagues[93] analyzed the comorbidities of RLS and found a trend toward a prior diagnosis of acquired hypothyroidism in female patients with RLS (within 5 years before PSG). Interestingly, women were twice as likely to be on thyroid replacement therapy at the time of evaluation. For some reason, patients with pulmonary hypertension were found to have a very high prevalence of RLS (43.6%), with moderate to severe symptoms. Among these patients, those with a history of hypothyroidism (67%) and those on opioids for relief of leg pain (69%) were more likely to have RLS.[94] Again, of interest is the fact that most of these patients were on thyroid replacement therapy.

Sleep Quality in Hypothyroidism

Excessive daytime sleepiness and fatigue are frequent symptoms in hypothyroidism. Although at times other sleep disorders (e.g., OSA, RLS) may be the cause of these symptoms, a primary CNS effect is also possible. Marked reductions in SWS have been described in patients with hypothyroidism, which are reversible with thyroid replacement therapy. Increased movements in sleep and reduced REM sleep have been described in patients with congenital hypothyroidism.

A recent study by Akatsu and colleagues[95] assessed the relationship between thyroid status and sleep quality in 5994 community-dwelling men older than 65 years; among the 682 men examined, 15 (2.2%) had subclinical hyperthyroidism (TSH <0.55 mIU/L) and 38 (4.9%) had subclinical hypothyroidism (TSH >4.78 mIU/L). Overall, there were no sleep qualitative differences between subclinical hypothyroidism and euthyroid status. Compared with euthyroid men, subjects with subclinical hyperthyroidism had lower mean TST (–27.4 minutes), lower mean sleep efficiency (–4.5%), and higher mean wake after sleep onset (+13.5 minutes), whereas 41% had increased risk for actigraphy-measured TST of less than 6 hours, and 83% had increased risk for sleep latency of 60 minutes or more (statistically nonsignificant). The study concluded that neither subclinical hypothyroidism nor hyperthyroidism was significantly associated with decreased sleep quality in elderly men.

ADRENAL DISORDERS AND SLEEP

The existing literature abounds in largely conflicting articles on the relationship between OSA and HPA activity in

humans. A recent study[96] looked at cortisol awakening response (CAR) in obese male subjects newly diagnosed with severe OSA compared with obese nonapneic matched controls and found the following: (1) a flattening of the CAR in OSA, (2) lower levels of cortisol at awakening in patients with OSA, (3) preserved circadian activity of the HPA axis, and (4) that 3 to 6 months of CPAP therapy led to significant restoration of the sleep architecture and the pattern of CAR (Figure 132-2)[96]; additionally, CPAP reduced the morning cortisol level differences between OSA patients and controls. In summary, the authors found a significant dysregulation of HPA axis activity in adult OSA patients, as shown by the flattening of the diurnal pattern of cortisol production, seen mostly in the first hour after awakening, which was restored after 3 or 6 months of CPAP therapy.[96]

Cushing Syndrome

Patients with Cushing syndrome typically have truncal or central obesity, diabetes mellitus, hypertension, acne, androgenic hirsutism, violaceus skin striae, psychiatric manifestations such as depression, and cognitive impairments. Most of these patients had sleep complaints and sometimes frank sleep disorders as comorbidities. In one study of 17 patients with pituitary ACTH–dependent Cushing disease and 5 patients with Cushing syndrome due to an adrenal tumor, 32% of patients had at least mild sleep apnea.[97] "Considerable" snoring and obesity were found in both apneic and nonapneic patients. Nonapneic patients with Cushing disease differed strikingly from healthy volunteers, having lighter and more fragmented sleep.[97] In another analysis by the same authors of patients with pituitary ACTH–dependent Cushing disease or ACTH-independent Cushing syndrome, patients with major depressive disorder, and normal healthy controls, there were substantial PSG similarities: All three patient groups demonstrated poorer sleep continuity, shorter REM latency, and increased first REM period density compared with normal subjects. Furthermore, ACTH-independent Cushing syndrome and major depressive disorder patients had elevated REM activity and density.[98] In another study, patients with Cushing disease *without* OSA exhibited poorer sleep continuity, shorter REM latency, and increased first-REM period density compared with normal subjects with reduced SWS.[99]

(From Ghiciuc CM, Dima Cozma LC, Bercea RM, et al. Restoring the salivary cortisol awakening response through nasal continuous positive airway pressure therapy in obstructive sleep apnea. *Chronobiol Int* 2013;30[8]:1024–31. Copyright Informa Healthcare USA, Inc.)

Adrenal Insufficiency

Adrenal insufficiency is caused by primary adrenal dysfunction (Addison disease, characterized by both mineralocorticoid and glucocorticoid secretion insufficiency and increased ACTH) or secondary adrenal dysfunction (i.e., a hypothalamic or pituitary dysfunction resulting in reduced cortisol levels but normal levels of mineralocorticoids). Very few systematic assessments of sleep have been done in patients with untreated Addison disease. One recent, single-center, cross-sectional study[100] found that fatigue was a frequent complaint in patients with adrenal insufficiency (between 41% and 50% of patients, depending on the etiology) and that fatigue is influenced by the cortisol levels; additionally, salivary cortisol levels were not correlated with instantaneous fatigue. Acute administration of exogenous cortisol can improve daytime fatigue significantly not only in patients with Addison disease but also in healthy women.[101]

SEX HORMONE DISORDERS AND SLEEP

Testosterone in Sleep Restriction

Impaired sleep quality, reduced TST, circadian rhythm disruptions, and SDB may be associated with reduced testosterone levels. (See Chapter 20 for discussion on the role of sex hormones on sleep in men). Although studies confirm the effect of total sleep deprivation[102,103] on lower testosterone, data on the effect of sleep restriction on the HPG axis remain somewhat contradictory. The effect of sleep deprivation on testosterone levels seems to be age dependent[104]; other factors explaining discrepancies in the literature may be confounding factors, such as time of the day spent asleep,[102,105] circadian shifts, changes in sex hormone–binding globulin (SHBG) levels, circadian rhythm disruptions, stress, depression, medications, and methodologies used (e.g., self-reported vs. objective TST). For example, although the physiology described previously suggests that it is the first 3 to 4 hours of sleep that are critical to determining the increase in testosterone, a recent study has shown that partial sleep restriction to 4.5 hours was associated with a lower morning testosterone level when sleep was permitted in the first half rather than the second half of the night.[102] This was not unexpected because testosterone levels have been shown to decrease with increasing time awake.[106] A recent study showed a marked reduction (10% to 15%) in circulating testosterone levels in young healthy men after 8 days of partial sleep restriction of 5 hours per day (00:30 to 05:30 hours)[107]; in this study, SHBG levels were not measured. In a subsequent study in which sleep was restricted during the first part of the night and permitted from 04:00 to 08:00 hours for 5 nights, there was no significant change in testosterone levels, whereas SHBG decreased.[108] Similarly, serum concentrations of testosterone, luteinizing hormone, and PRL were reduced after only 24 to 48 hours of total sleep deprivation.[109-111]

Sleep Apnea Effects on Testosterone

As discussed earlier, disturbed sleep quality, reduced TST, chronodisruption, and SDB may be associated with reduced testosterone levels, although the direct causality is sometimes challenged. This association may be in fact mediated by effects on SHBG or by comorbid conditions.

Low testosterone levels have been reported in men with OSA,[49] and this appeared to be independent of age, degree of obesity, and presence of awake hypoxemia or hypercapnia. Subsequently, in a study on 89 obese men (BMI ≥35 kg/m^2), the severity of OSA was inversely correlated with the free testosterone levels, even after correction for age and BMI.[112] In a case-control study of 15 men with OSA and 15 matched controls, both total and free testosterone levels were lower in OSA patients, and testosterone was inversely correlated with the OSA severity, as defined by the oxygen desaturation index (ODI), and independent of obesity.[113] Triglyceride and uric acid levels were also significantly higher in OSA patients. A negative correlation between testosterone and uric acid levels and a positive correlation between testosterone and high-density lipoprotein cholesterol levels were also found, independent of BMI and waist circumference. This study suggested that, in patients with obesity and OSA, the severity of hypoxia during sleep might be an additional contributing factor to reduced testosterone levels, regardless of BMI or central obesity. In addition to hypoxia, sleep fragmentation may contribute to reduced testosterone levels.[114]

Conversely, there is a body of literature that supports the idea that low testosterone in men with OSA is primarily related to obesity.[114-116] For example, in a cohort of 1312 men 65 years or older followed for 3.4 years, total testosterone levels were unrelated to age or TST but were inversely correlated with AHI and ODI. After adjusting for BMI and waist circumference, significant associations were either absent or markedly weakened.[117]

Although older data suggest that treatment of OSA by CPAP therapy or uvulopalatopharyngoplasty results in increases in morning plasma testosterone levels at 3 months,[49,118] most of the studies[50,119,120] showed that CPAP therapy used for a single night[121] up to an average of 10 months[122] is generally without effects on follicle-stimulating hormone, luteinizing hormone, or testosterone, even when good compliance is ensured. The only significant outliers are the older studies by Grunstein and colleagues[49] and Santamaria and colleagues.[118]

In contrast to the effect of CPAP therapy, there seems to be a linear relationship between the degree of weight loss and an increase in plasma total testosterone levels in obese men[123,124] (Figure 132-3). Given the increasing evidence that obesity is a major determinant of the age-related decline in testosterone, it is thus encouraging that this decline can be at least partially prevented, or reversed, by successful lifestyle modifications such as diet, exercise, or even surgery.

In conclusion, OSA may not have a direct effect on testosterone levels after adjusting for age and obesity, although sleep fragmentation and intermittent hypoxia may be significant contributors. Furthermore, CPAP therapy instituted for moderate or severe OSA does not consistently increase testosterone levels in all studies, whereas weight loss does so in a linear fashion.

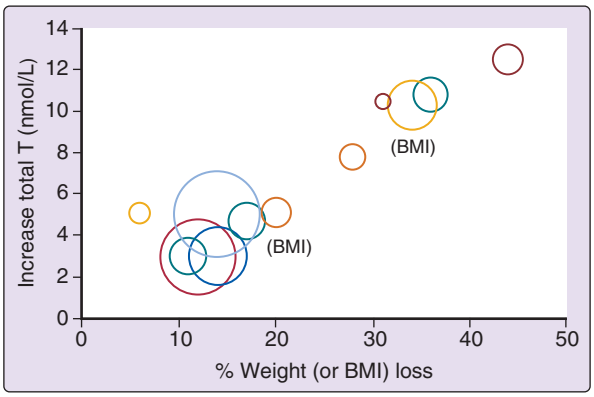

Figure 132-3 Effect of weight loss on testosterone (T) levels, as shown in different studies. Each *circle* represents a study, and its diameter is directly proportional to the study size. BMI, Body mass index. (From Fui MN, Dupuis P, Grossmann M. Lowered testosterone in male obesity: mechanisms, morbidity and management. *Asian J Androl* 2014;16[2]:223–31, which was modified after Grossmann M. Low testosterone in men with type 2 diabetes: significance and treatment. *J Clin Endocrinol Metab* 2011;96[8]:2341–53, Figure 1. Testosterone Effects on Sleep Apnea

A number of reports have described the development of OSA after testosterone therapy in both genders, although these reports or small studies used mainly supraphysiologic doses of intramuscular testosterone.[125-127] Although the evidence is still rather anecdotal, exogenous testosterone administration has been considered deleterious enough in OSA that the current guidelines contraindicate testosterone therapy in the presence of untreated OSA.[128,129] In a recent study of obese men with OSA, testosterone undecanoate versus placebo was administered intramuscularly at baseline, 6 weeks, and 12 weeks. The authors used the modified Duffin rebreathing method in isohyperoxic and isohypoxic conditions and assessed the changes in minute ventilation versus CO_2 concentrations or $Paco_2$.[130,131] Ventilatory recruitment threshold is defined as the breakpoint between the horizontal and the linear ascending part of the graph. The slope of the latter is represented by the central and mixed central-peripheral chemosensitivity to CO_2 in hyperoxic and hypoxic conditions, respectively. Testosterone administration was associated with a slightly worse ODI at 7 weeks, but not at 18 weeks. There were no correlations between ODI and testosterone levels,[132] but positive correlations were noted between changes in serum testosterone and hyperoxic ventilatory recruitment threshold and between changes in hyperoxic ventilatory recruitment threshold and hypoxic burden at 6 to 7 weeks, but not at 18 weeks.[133] The authors suggested that time-dependent alterations in ventilatory recruitment threshold may mediate the changes in respiration during sleep observed with testosterone.

In summary, according to the current evidence and apart from transient adverse effects, testosterone treatment at normal doses may not lead to SDB.

Testosterone and Sleep Quality

Both insufficient and excessive testosterone levels have been shown to affect sleep and sleep architecture. In a cohort study of men aged 65 years or older, those with lower testosterone levels had reduced sleep efficiency, increased nocturnal

awakenings, and less time in SWS.[117] In mice, the loss of testosterone following gonadectomy resulted in a very small reduction in the amount of SWS, which was reversed by testosterone replacement, even after 6 hours of sleep deprivation.[134] In humans, the administration of testosterone and the abuse of androgenic or anabolic steroids have been reported to be associated with reduced TST, insomnia, and increased awakenings.[125,135] Administered acutely, methyltestosterone increases arousal and diminishes sleep changes attributed to activation of the brain serotonergic system.[136] In a study of patients with drug-induced hypogonadism[137] with and without gonadal steroid replacement, hypogonadal males had reduced 24-hour PRL levels and a reduced percentage of deep sleep in the hypogonadal state compared with those receiving testosterone replacement. Melatonin secretion was found to be increased in male patients with GnRH deficiency and in low-testosterone hypergonadotropic hypogonadal patients.[138] The observation of reduced TST without worsening alertness on task with high-dose testosterone therapy was also intriguing in this context.[125] In summary, low testosterone levels may affect overall sleep quality, and this may be improved by replacement-range doses. It seems that higher doses of exogenous testosterone or anabolic steroids are associated with more significant abnormalities of sleep duration and architecture.

Sex Hormones and Sleep-Disordered Breathing in Women

Lower estradiol levels have been associated with poor sleep quality in 45- to 49-year-old women.[139] Sleep disruption during pregnancy and after birth is well recognized, and menopause is often associated with insomnia (see Chapter 159). The latter is likely related to several factors, including hot flashes, mood disorders, and development or worsening of SDB, in parallel with a higher propensity to have central or android obesity (vs. gynoid) type.[140]

Estrogens and progesterone seem to be protective factors against development of OSA in women, thus explaining the gender-based differences in disease prevalence and severity. The evidence comes from studies in which sleep was evaluated during different phases of the menstrual phase,[141,142] menopause,[143] hormone replacement therapy (postmenopausally),[143] or pregnancy.[144,145] Some authors found that upper airway resistance is lower during the luteal compared with follicular phase.[141] Progesterone is thought to promote its effects through direct stimulation of respiratory drive by increased ventilatory responses to hypercapnea and hypoxia[146,147] and by enhancing upper airway dilator muscle activity[148] (and consequently, reduced upper airway resistance).

Lower estradiol levels have been associated not only with abnormal sleep architecture but also with a higher severity of OSA across a broad age spectrum (24- to 72-year-old women).[142] Conversely, postmenopausal subjects who received estrogen replacement therapy seem to have less severe SDB compared with those taking placebo.[143,149] Currently it is still unclear whether hormonal therapy has an advantageous risk-to-benefit ratio for SDB in women.[150,151] Similarly, although progesterone levels fall after menopause, no consistent therapeutic effect of progesterone administration in OSA has been demonstrated[150] (Table 132-2).

Androgens may also explain the observed gender-based dimorphisms in sleep architecture and SDB severity. O'Connor and colleagues[152] performed a retrospective analysis of 830 patients with PSG-diagnosed OSA and found that the total AHI was significantly higher in men compared with women; the REM difference (REM AHI minus NREM AHI) was higher in women than men across all levels of SDB severity, even after adjustment for age, weight, or duration of apnea. The study showed that women with SDB tend to have more frequent respiratory events during REM sleep compared with men and to have a higher prevalence of OSA that occurs mostly in REM sleep. Koo and colleagues[153] also analyzed the sexual dimorphism of OSA by assessing REM-related SDB among 1540 patients with OSA. Among 221 subjects (14.4%) who met the criteria for REM-related SDB (i.e., AHI ≥5 events/hour, NREM AHI <15, and REM AHI/NREM AHI >2), female patients had higher prevalence than men (24.5% vs. 7.9%), whereas younger women had a significantly higher prevalence than older women (27.2% vs. 18.6%); similarly, younger men had a significantly higher prevalence than older men (9.9% vs. 4.5%). In conclusion, REM-related SDB was found to be more prevalent in women than men and more prevalent in younger individuals of both genders, suggesting that differences may depend also on age (or duration of OSA).

Several studies showed that testosterone influences both neural control of breathing[154] and upper airway mechanics.[126] For example, Zhou and colleagues[155] examined the effect of transdermal testosterone (5 mg/day, administered during the follicular phase of the menstrual cycle) on apneic threshold during sleep in eight healthy premenopausal women. The authors concluded that testosterone increases apneic threshold in premenopausal women, thus leading to breathing instability during sleep.

Sleep and Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) affects up to 10% of reproductive-age women of all ethnic groups, making it the most common endocrine disorder of women in this age range. PCOS is defined by four components: oligomenorrhea, clinical and biologic features of hyperandrogenism, polycystic ovaries by ultrasonography, and exclusion of other causes of androgen excess.

Several studies showed that PCOS is strongly associated with increased central adiposity and with OSA, in direct relationship with the degree of androgen excess.[156-160] Patients with PCOS are oligoovulatory or anovulatory (by definition); thus they have low circulating progesterone levels, which may contribute to the high prevalence of SDB in this condition. Furthermore, studies in adults with PCOS found various strengths of association between PSG measurements and serum androgens and parameters of glucose metabolism. For example, Fogel and colleagues[156] revealed that the AHI of obese PCOS patients correlated with total and free testosterone levels, whereas others[159] found a correlation between the risk for or severity of SDB and insulin levels or other measures of glucose tolerance. Vgontzas and colleagues[157] showed that the strongest risk factor for OSA in women with PCOS were fasting insulin levels and glucose-to-insulin ratio, a measure of insulin resistance.

ADIPOSE TISSUE

The adipose tissue represents one of the largest and most active endocrine organs, known to be secreting a plethora of

Table 132-2 Known Associations between Neuroendocrine Abnormalities and Major Sleep Conditions

Sleep Disorder/ Endocrine Abnormality Associated	Somatotropic Axis	HPT Axis	HPA Axis	HPG Axis	Other
OSA	Reduced GH and IGF-1 levels (correlated with severity of SDB)	Controversial (hypothyroidism is a risk factor for OSA)	Unclear (exaggerated response of corticotrophs to CRH, not explained by obesity alone)	Low testosterone (males), elevated androgens and reduced progesterone (females) are risk factors for OSA (obesity is a confounder)	Increased sympathetic activity, changes in adipokinome (increased leptin, leptin resistance, decreased adiponectin), decreased hypocretin, higher incidence of diabetes mellitus, hyperinsulinemia, and metabolic syndrome Activated RAAS
Insomnia	Unclear	Hyperthyroidism	Hypercortisolism	In perimenopausal women: reduced sleep quality, sleep maintenance insomnia ("hot flashes") Abnormal CAR?	Unclear
RLS	Acromegaly patients have higher rates of RLS	Hyperthyroidism and hormone replacement for hypothyroidism are associated with RLS	Unclear	Unclear	Unclear

CAR, Cortisol awakening response; CRH, corticotropin-releasing hormone; GH, growth hormone; HPA, hypothalamic-pituitary-adrenal; HPG, hypothalamic-pituitary-gonadal; HPT, hypothalamic-pituitary-thyroid; IGF-1, insulin-like growth factor-1; OSA, obstructive sleep apnea; RAAS, renin-angiotensin-aldosterone system; RLS, restless legs syndrome; SDB, sleep-disordered breathing.

hormones. White adipocytes are secretory cells, releasing lipid products such as fatty acids resulting from lipolysis, cholesterol, prostaglandins, endocannabinoids, fat-soluble vitamins such as α-tocopherol and active form of vitamin D_3, glucocorticoids (converting cortisone to cortisol), estrogens, and others. Several major protein hormones are synthesized and secreted by adipocytes, the most prominent of which are leptin and adiponectin, which are produced primarily (not exclusively) in the fat cells. The circulating level of leptin is generally directly related to the body mass or the amount of fat; by contrast, circulating adiponectin levels are reduced in obesity. Leptin is involved in regulation of appetite, angiogenesis, and insulin secretion, whereas adiponectin is mainly insulin sensitizing, antiinflammatory and proangiogenic.

Obesity and Sleep

In obesity, secretion of a number of adipokines is dysregulated and associated with adipose tissue inflammation and, possibly, with the development of obesity-associated complications (vs. pure surrogate, "innocent" biomarkers). There is a solid body of literature showing that, as obesity worsens and adipose tissue grows disproportionately to its vascular supply, local hypoxia develops, and other downstream biologic changes converge to develop more robust local and systemic inflammation (Figure 132-4).

The relationship between quantity of sleep (TST) and obesity has been extensively examined in the past decade.[161-168] Most of the studies found a significant association between obesity and short sleep in children and some even in adults (although the latter was weaker). For example, Magee and Hale[166] reviewed 20 longitudinal studies published before 2010 and found an inconsistent relationship between short sleep and obesity in adults and a positive relationship in children. Nielson and colleagues[167] analyzed another set of 23 original studies and found similar conclusions. Before this, a meta-analysis on this topic published in 2008,[164] which included 45 cross-sectional or prospective studies of adults or children, found that short sleep conferred an odds ratio (OR) for developing obesity of 1.6 (1.4 to 1.7) in adults and 1.9 (1.5 to 2.4) in children. Patel and Hu[165] also considered cross-sectional and prospective studies of children and adults separately. The results from both study designs were consistent in children, whereas studies of adults were less so.

As far the relationship between sleep quality and obesity goes, this was less studied and reported. One recent study[168] examined in a family medicine setting the relationship between obesity and three sleep characteristics (duration, quality, and stability). Among 225 consecutive patients seen over a period of 10 weeks who completed a battery of questionnaires, 78% reported poor quality sleep, 59% had high Berlin questionnaire–based apnea risk scores, 12% reported RLS symptoms, and 9% reported a prior diagnosis of sleep apnea; 62% were obese. The authors found significant associations between sleep quality, duration or bedtime stability, and

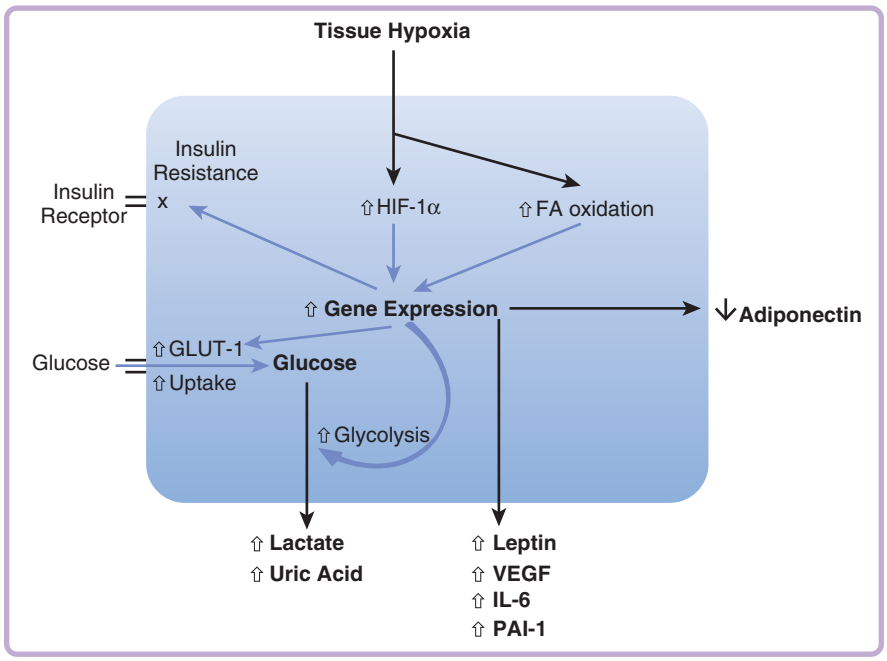

Figure 132-4 Diagram illustrates the effects of intermittent hypoxia at the level of a white adipocyte: activated transcription factor (hypoxia-induced factor-1α [HIF-1α]) leads to expression of more than 1000 genes; fatty acid (FA) oxidation in the mitochondria; increased glucose uptake through the cell membrane, mainly due to increased availability of glucose transporter-1 (GLUT-1); blocking of the insulin receptor, with subsequent insulin resistance; and activation of glycolysis, which leads to increased production of lactate, which will be released into the circulation. In terms of adipokines, low oxygen tension at the level of the adipose cell leads to reduced adiponectin and increased leptin, vascular endothelial growth factor (VEGF), and plasminogen activator inhibitor-1 (PAI-1).

obesity. The association between sleep quality and obesity was negative and linear, while the association between sleep duration and obesity was U shaped (as seen in multiple other publications and without a clear explanation to date). Less stable bedtimes during the week (OR = 2.3) or on the weekend (OR = 1.8) were also associated with obesity. The association between sleep quality and obesity was not explained by patient demographics or snoring.[168]

What is the pathogenic connection between obesity and poor or short sleep? First, short sleep, poor quality sleep, or unstable bedtimes may provide more opportunities to eat and could launch a metabolic cascade that increases appetite, reduces satiety, and worsens the fatigue, leading to adverse behavioral changes (e.g., curtailed levels of exercise, increased intake of hypercaloric, concentrated sweets) and more fat mass deposition. Conversely, obesity is an inflammatory condition that leads to release of biologically active cytokines, which could lead to activation of the HPA axis, with subsequent reduced TST or impaired sleep quality; in turn, this could perpetuate the vicious cycle.

Indeed, both TST reduction (with preserved SWS) and SWS suppression (with preserved TST) have been shown to be associated with insulin resistance (without compensatory hyperinsulinemia), resulting in impaired glucose tolerance and increased risk for type 2 diabetes mellitus. Furthermore, sleep restriction is also associated with decreased serum levels of leptin (an anorexigenic hormone) and increased levels of ghrelin (an orexigenic hormone), leading to hunger, exacerbated appetite, and craving for hypercaloric foods. Further evidence suggests that reduced TST may represent a permissive environment for the activation of multiple genes that may contribute to the development of obesity. Indeed, the heritability of BMI is higher in short sleepers. Therefore the chronic and progressive sleep curtailment seen nowadays in modern Western society conceivably may contribute to the current obesity, diabetes, and metabolic syndrome epidemics seen in both adults and children.

Besides the relationship between obesity and sleep, central, android-type obesity is also a powerful and consistent epidemiologic predictor of OSA.[169,170] Conversely, significant weight loss leads to improvement in SDB severity and associated metabolic abnormalities.[170] Because association does not mean causality, the reverse is also possible, that is, that OSA promotes the development of obesity. Although the data are limited for the latter directionality,[171] several mechanisms are conceivable. For example, chronic intermittent hypoxia and sleep fragmentation of SDB could alter the central control of energy regulation and general metabolism (e.g., trough-altered serotonergic activity in the hypothalamus[171] through leptin, insulin resistance, or hyperinsulinemia), and increase appetite and oral intake. As such, selective serotoninergic agonists and antagonists have been tried as treatments for central obesity[170] and for OSA but with limited effects.[172] The low circulating testosterone and GH levels noted in OSA also seem to occur in some patients with central obesity.[49,170] In obesity, recombinant GH administration appears to reduce central body fat, whereas CPAP therapy for OSA may restore the GH secretion during sleep.[171] If indeed OSA causes central obesity, it would be expected that treatments that reverse SDB would result in weight loss. Some studies of patients with OSA suggested that CPAP therapy reduces visceral fat mass, even without significant changes in BMI,[173,174] but large, controlled,

and randomized studies specifically addressing this issue are still lacking. As mentioned previously, central obesity is also associated with hyperinsulinemia and insulin resistance, but their exact links with OSA are still under investigation. Hyperinsulinemia has been found in some patients with OSA independent of weight, BMI, or central type of obesity.[175] Nevertheless, the questions of whether and to what extent CPAP improves insulin resistance or diabetes control remain controversial. Further discussion on the interrelationships among obesity, diabetes, and metabolic syndrome and SDB can be found in Chapter 118.

CLINICAL PEARLS

- Endocrine derangements may lead to or are associated with hypersomnia, OSA, RLS, insomnia, circadian disorders, and other sleep disorders.
- Endogenous or exogenous excess of growth hormone, cortisol, or androgens may predispose to development of OSA.
- Excess of catecholamines, cortisol, or thyroxine is associated with insomnia.
- OSA may be associated with low testosterone (direct effect or mediated by aging, obesity, fragmented sleep, and intermittent hypoxia).
- Adipose tissue is one of the largest and most active endocrine gland and secretes a very complex set of factors that constitute the "adipokinome."

SUMMARY

In a general conceptual framework, sleep is under both neural and hormonal control. Neural control is exerted through a complex network of nuclei or neuronal groups, highly interconnected and multifunctional, whereas hormones exert many autocrine, paracrine, or endocrine effects. There is a strong connection between sleep and metabolic processes. Disorders of the hypothalamus-pituitary-target organ axes frequently present with sleep symptoms and, occasionally, with frank comorbid sleep disorders. Accumulating evidence suggests an important role played by sleep curtailment or specific disorders in the pathogenesis of metabolic disturbances associated with obesity. Furthermore, sleep disorders such as OSA are very common in several endocrine disorders, such as acromegaly, obesity, and diabetes. Most patients with acromegaly have some degree of SDB, either OSA or CSA. OSA seems to be associated with low testosterone levels, whereas androgen administration appears to exacerbate OSA. Furthermore, there is some evidence of a protective effect of female sex steroids on upper airway patency during sleep. It is still controversial whether hypothyroidism is a distinct risk factor for SDB.

Chapter 133

Pain and Sleep

Anthony G. Doufas

Chapter Highlights

- Chronic pain and poor sleep hygiene are major public health challenges with great economic and societal impact. Pain disturbs sleep, and recent evidence from longitudinal cohorts indicates that impaired sleep may in turn promote or exacerbate chronic pain.
- Experimental and epidemiologic evidence supports a bidirectional influence between pain and common pain-related comorbidities, such as insomnia and mood disorders, in patients with chronic pain. This chapter presents current evidence regarding the theories and potential mechanisms mediating the development and maintenance of this interactive nexus of comorbidities in patients suffering from chronic pain.
- A diligent diagnostic approach is considered essential to comprehensively manage patients with chronic pain and comorbid insomnia. This chapter describes sleep assessment instruments that are in wide use in clinical and research practice in both pain and sleep medicine.
- Evidence from randomized controlled trials provides support for comprehensive, multimodal management of comorbidities associated with chronic pain, including insomnia and depression. This chapter examines recent randomized controlled trial evidence for the effectiveness of modern pharmacologic and behavioral interventions in the treatment of chronic pain patients.

Sleep and pain are both critical processes of life with great biologic and evolutionary value. In the normal state, pain and sleep operate together through a sensitive and well-orchestrated physiologic balance, which primarily serves to protect the sleep function. When pain is excessive or its function becomes deregulated, pain can alter sleep and diminish its capacity to provide the necessary physiologic and mental recovery for the individual. Although the physiologic link between sleep and pain remains elusive, clinical and experimental evidence supports a bidirectional, dynamic influence between the two. Steadily accumulating evidence from observational micro- and macro-longitudinal studies, as well as from randomized controlled interventions, suggests that inadequate or disrupted sleep may exacerbate an existing pain condition or mediate the development of a new pain condition, which in turn may augment sleep dysfunction.

EPIDEMIOLOGY OF PAIN AND COMORBID INSOMNIA

Because of their sheer prevalence and significant impact, chronic pain and impaired sleep qualify as two major, yet unmet, public health challenges that are associated with enormous economic and societal cost.[1-5] According to the National Center for Health Statistics, 43% of Americans are affected by a chronic pain condition, with low back pain being the most prevalent (25% in average) pain-related diagnosis, whereas 42 million people (National Sleep Foundation; 2000 Sleep in America poll) report frequent sleep disruptions (more than few nights a week) as a consequence of pain or physical discomfort.[6] Moreover, the 2006 Voices of Chronic Pain Survey indicates that, apart from sleep, other important aspects of quality of life, such as mood function and the ability to concentrate during normal daily activities, are most commonly and severely affected in patients with chronic pain.[6] International large population surveys have estimated similar prevalence rates for chronic pain conditions (1-year prevalence up to 40%) in both developed and developing countries, with joint-related (17.5%) and low back (18.5%) pain ranking at the top.[7] Large epidemiologic cross-sectional assessments in general and clinical populations suggest a dense connection between impaired sleep, physical pain, and mood disturbances, primarily expressed as anxiety and depression disorder.

Community-based studies estimate that more than 40% of people who suffer from chronic insomnia (the most common sleep disorder) do so in the context of a pain condition,[8] whereas moderate to severe sleep disturbances and comorbid depression occur in up to 80% of patients with chronic pain.[6,9-11] Although cross-sectional population assessments are important in characterizing the various morbidity phenotypes in patients suffering from chronic pain and disturbed sleep, they cannot provide evidence regarding the causal pathophysiologic mechanisms underlying the commonly observed associations. Instead, longitudinal observational cohorts are better fit to evaluate potential causal factors or modifiers of the relationship among sleep, pain, and mood dysfunction in patients suffering from chronic pain. Table 133-1 presents recent evidence from such longitudinal cohorts that evaluated the change in pain- and sleep-related outcomes in patients with primary insomnia or pain at the beginning of the assessment period.

Table 133-1 Prospective Longitudinal Studies Evaluating the Relationship between Impaired Sleep and Pain*

Baseline Condition	Study	Population	Follow-Up Period	Sleep Measures	Pain Type	Pain Measures	Outcome	Results
Impaired sleep	Cavinet et al., 2008[13]	Middle-aged healthy population (n = 3767)	1 yr	Insomnia questionnaire (4-item)	Musculoskeletal pain	Frequency of pain symptoms	Risk for developing pain	Increase in the odds for developing pain for both men (adjusted OR = 1.83; 95% CI, 1.16–2.87) and women (adjusted OR = 1.92; 95% CI, 1.34–2.75)
	Odegard et al., 2011[16]	Headache-free population (HUNT-2 and HUNT-3, n = 15,060)	11 yr	Sleep-onset and terminal insomnia (composite score)	Headache (all types)	ICHD-2 criteria	New-onset headache	Increase the risk for new-onset headache (adjusted RR = 1.4; 95% CI,1.2–1.7)
	Mork et al., 2012[136]	Unselected CWP-free women (n = 12,350)	11 yr	Sleep problems (ordinal variable)		CWP and musculoskeletal pain (yes/no)	New-onset CWP	Increase in the risk for new-onset CWS (adjusted RR = 3.4; 95% CI, 2.3–5.2)
	Jansson-Fojmark et al., 2012[14]	Unselected CWP-free women (n = 1551)	1 yr	Sleep problems by questionnaire (yes/no)	Musculoskeletal pain	Frequency of pain symptoms	Persistence of pain	Increase in the odds for persistence of pain (OR = 1.49; 95% CI, 1.15–1.97)
	Sanders et al., 2013[17]	Healthy TMD-free (OPPERA, n = 3263)	3 yr	PSQI (7-item, composite score)	TMD	Questionnaire and clinical examination	First-onset TMD	Increase in the risk for first-onset TMD (adjusted hazard ratio = 1.32; 95% CI, 1.18–1.47)
	McBeth et al., 2014[15]	Middle-aged free of CWP (n = 4326)	3 yr	Sleep problems (4-item ordinal scale)	CWP	CWP (ACR criteria)	Prevalence of CWP	Increase in the odds for CWP (adjusted OR = 1.8; 95% CI, 1.2–2.8)
Pain	Odegard et al., 2013[19]	Insomnia-free population (HUNT-2 and HUNT-3, n = 19,279)	11 yr	Sleep-onset and terminal insomnia (composite score)	Headache and chronic musculoskeletal pain	ICHD-2 criteria; Nordic questionnaire and ACR criteria	New-onset insomnia	Increase in the odds for headache (adjusted OR = 2.2; 95% CI, 1.9–2.6) and chronic musculoskeletal pain (adjusted OR = 1.8; 95% CI, 1.6–1.9)
	Tang et al., 2014[20]	Older adults (n = 6676)	3 yr	Jenkins sleep scale	Musculoskeletal pain	ACR criteria	New-onset insomnia	Increase in the risk for new-onset insomnia (adjusted† OR = 1.46; 95% CI, 1.21–1.75 for some pain, and 1.80; 95% CI, 1.47–2.22 for CWP)

*This list presents in chronologic order major prospective longitudinal cohorts that were published in the past 5 years.
†Statistical model adjustment included the presence of sleep disturbances at baseline.
ACR, American College of Rheumatology; CWP, chronic widespread pain (a newer term for fibromyalgia); HUNT, Nord-Trøndelag Health Study, Norway; ICHD, International Classification of Headache Disorders; OPPERA, Orofacial Pain: Prospective Evaluation and Risk Assessment Study; PACE, Paracetamol for Low-Back Pain Study; PSQI, Pittsburgh Sleep Quality Index; TMD, temporomandibular disorder.

Insomnia as a Risk Factor for Chronic Pain

Subjects who suffer from primary insomnia (i.e., insomnia with no obvious medical cause) have been found to be more sensitive to experimental pain than normal sleepers,[12] suggesting the presence of a reciprocal action between disturbed sleep and pain. This relationship is also supported by recent longitudinal studies showing the development of new pain or worsening of a pain condition in patients suffering from chronic sleep loss.

Evidence from large prospective longitudinal studies (see Table 133-1) with follow-up periods ranging from 1 to 11 years have demonstrated that disturbed sleep in pain-free subjects could significantly increase the risk (odds and relative risk ratios ranging from 1.3 to 3.4) for different chronic pain conditions, including musculoskeletal pain,[13,14] chronic widespread pain,[15] headaches,[16] and temporomandibular joint disorder.[17]

Pain as a Risk Factor for Insomnia

In the acute experimental setting, electroencephalography has shown that pain invades sleep and disturbs its structured continuity and architecture. Among other factors, the magnitude of these acute effects of pain on the sleep function depends on the severity of nociceptive stimuli as well as on the vulnerability of sleep to the disruptive influence of such stimuli.[18] Currently it remains unknown whether chronic infliction of pain can alter the sensitivity of sleep to painful or other stimuli, thus resulting in the development of an insomnia-like sleep disturbance.

Evidence from a large-scale prospective longitudinal Norwegian cohort (Nord-Trøndelag Health Study, n = 19,279) has shown that, compared with pain-free controls, insomnia-free subjects who were suffering from headache or chronic musculoskeletal pain at baseline were twice as likely to develop insomnia 11 years later (odds ratio [OR] = 1.8; 95% confidence interval [CI], 1.8 to 2.2),[19] Similarly, various types of chronic pain complaints among older adults were associated with an increased risk for insomnia of up to four times for the next 3 years.[20] Interestingly, the combination of physical limitations and reduced social participation explained more than 65% of the effect of pain on insomnia onset.

Depression as a Comorbid Link Between Chronic Pain and Impaired Sleep

Abnormal sleep is a primary symptom of affective diseases and has also been incriminated as a risk factor for the development of depression.[21] In addition, mood disorders are quite common among patients suffering from chronic pain.[22] Evidence from large international (World Mental Health Surveys, n = 42,249)[7,23,24] and national (National Comorbidity Survey, n = 5877)[25] cross-sectional surveys showed that chronic pain conditions increased the odds for developing depression and anxiety disorders by two to four times, with approximately 20% of pain patients reporting symptoms of depression and 35% of them reporting an anxiety disorder in the past year.[25] The close relationship between mood disorders and insomnia in the context of chronic pain has also been demonstrated in a large community-based sample of 18,980 European participants, where pain conditions like backache and joint or articular disease were as strongly associated with symptoms of insomnia as they were with depression and bipolar disorders (OR ≈ 5).[8] Interestingly, although pain-related insomnia shares several mood, cognitive, and behavioral characteristics with primary insomnia,[11,26,27] insomnia due to pain seems to last longer and is associated with more daytime dysfunction[28] compared with primary insomnia.[8] This points to a possible interactive effect of impaired sleep and pain on daily functioning, a hypothesis that has recently received support by evidence from two separate cohorts of Norwegian (n = 6892) and Finnish (n = 6060) employees, in which pain and insomnia at baseline synergistically predicted objective health outcomes and disability retirement in these populations.[29]

A recent longitudinal investigation found that anxiety and depression in pain patients increased the likelihood for persistence of insomnia over the course of a year,[14] and a possible bidirectional association between anxiety and chronic pain has recently been suggested by other longitudinal cohorts examining these outcomes in patients suffering from acute and chronic pain.[30,31] Among the 614 participants in the Netherlands Study of Depression and Anxiety who were free of depression and anxiety at baseline, those with multiple locations of joint-related pain were at higher risk for first-onset mood disorder during the 4-year-long follow-up period (adjusted hazard ratio of 2.9; 95% CI, 1.7 to 4.8).[31] Alternatively, feelings of anxiety experienced in the early phase after lower extremity trauma predicted the presence of pain up to 24 months later.[30]

It needs to be recognized that the morbid nexus between pain, abnormal sleep, and mood dysfunction is dense, and cause-and-effect relationships cannot be inferred without the application of well-designed targeted interventions.

BIOLOGIC AND BEHAVIORAL MECHANISMS FOR THE PAIN-SLEEP ASSOCIATION

In the past decades, several human studies involving both healthy and clinical populations have attempted to elucidate the nature of the association between abnormal sleep and pain processing. Investigations focusing on the experimental curtailing or disruption of sleep, and others that have examined pain processing in individuals suffering from primary sleep or chronic pain disorders, suggest that deterioration of sleep function might enhance pain responses, possibly through multiple biologic and behavioral mechanisms.[32-34] Although most of these investigations involve a small number of subjects and suboptimal control conditions, an informal meta-analytic review of this research appears to support the pain-enhancing effect of fragmented or heavily curtailed sleep.

Pain Disturbs Sleep

The central nervous system (CNS) is organized to protect the integrity and preserve the continuity of sleep. For this purpose, neural filters at the brainstem level and descending inhibitory pathways that are activated during sleep regulate the arousing effect of ascending sensory information.[35,36] Thus, although the application of nociceptive stimuli during sleep may alter sleep microstructure and cause sleep-stage shifts associated with arousal patterns in humans,[37] deeper stages of sleep seem to be more resistant to such effects compared with lighter ones.[38,39] The overall response of sleeping humans to nociceptive stimuli, which may even invade consciousness and be incorporated into dreams,[39] is determined by the magnitude and type of these stimuli.

This line of research is important because (1) interindividual variations in the vulnerability of patients to pain-related insomnia might partly be due to differences in the capacity of the CNS to regulate the input of sensory information during sleep, and (2) chronic engagement of CNS sensory filters by nociceptive information might ultimately alter their function (neuroplasticity), with potential implications in the natural course of both pain disease and insomnia.

Experimental Sleep Disturbance Enhances Sensitivity to Pain

Over the years, several human studies using various experimental pain paradigms induced by thermal or mechanical stimuli have focused on elucidating the effect of abnormally short sleep on pain processing.[33] Experimental conditions involving total sleep deprivation were associated with the development of hyperalgesia and spontaneous pain symptoms in healthy volunteers, whereas targeted elimination of specific sleep stages, like rapid eye movement (REM) or slow wave sleep (i.e., stage 3 non–rapid eye movement [NREM] sleep), has not demonstrated conclusive findings.

The "forced awakenings" method[40] has been developed as a means to disrupt sleep continuity without completely eliminating a particular stage of sleep. This has provided researchers with an experimental paradigm more relevant to chronic pain patients, whose sleep is commonly disrupted by pain. Thus, when sleep was experimentally curtailed by forced awakenings in healthy volunteers, central pain-inhibitory mechanisms (namely, conditioned pain modulation) were impaired and spontaneous pain was increased.[40] This finding is of potential clinical relevance because impaired conditioned pain modulation regulation has been demonstrated in several chronic pain conditions, including chronic widespread pain,[41] temporomandibular joint disorder,[42,43] and low back pain,[44] in which sleep disturbances are also highly prevalent. In an effort to further elucidate the association between pain and sleep, a recent experimental study showed that fragmented, but not shortened, sleep was observed in mice with musculoskeletal sensitization (a "chronic pain" analogy),[45] and this sleep disturbance phenotype resulted in further aggravation of both nociceptive and sleep-wake outcomes.[46]

General musculoskeletal sensitization with spontaneous pain symptoms has been described in healthy humans following experimentally generated total and partial sleep deprivation for one or more consequent nights. Compared with normal sleepers, these experimental interventions led to activation of major inflammatory pathways,[47] with increased concentrations of proinflammatory cytokines like tumor necrosis factor-α, interleukin-1β, and interleukin-6 in the peripheral blood.[48] Although these experimental interventions were extreme, they demonstrate that peripheral inflammatory response may be another potential mechanism for the hyperalgesic effect of sleep loss.[49]

Pain Responses in the Context of Chronic Sleep Loss and Primary Sleep Disorders

The experimental application of painful stimuli in volunteers indicated that physiologic sleepiness (as determined by the Maintenance of Wakefulness Test) due to chronic sleep loss was associated with increased sensitivity to experimental pain[50] and decreased codeine analgesia.[51] This increased sensitivity to painful stimuli was reduced when subjects recovering from chronic sleep loss were given the opportunity to sleep for an extended period.[52]

Hyperalgesic responses to experimental pain in patients with primary sleep disorders like insomnia[53] and restless legs syndrome[54] were associated with a significant weakening of central pain-inhibitory[53] mechanisms or an amplification of descending pain-facilitatory[54] signals. Moreover, treatment with continuous positive airway pressure (CPAP) reversed the observed hyperalgesia in subjects suffering from sleep-disordered breathing,[55] although it is not clear whether the effect of CPAP on hyperalgesia[55] was due to CPAP restoration of normal sleep architecture or correction of the associated nocturnal hypoxemia. A recent analysis of data from the Cleveland Family Study demonstrated a significant positive association between recurrent nocturnal hypoxemia and pain complaints in subjects with sleep-disordered breathing, independent of sleep fragmentation.[56] This, along with other findings from human[57,58] and in vitro[59] experiments, may incriminate intermittent hypoxia as another potential mechanism, in addition to sleep disruption, involved in altering pain processing in humans.[60]

Behavioral, Mood, and Neurochemical Alterations in Pain and Comorbid Insomnia

The observed cognitive and affective changes encountered in patients suffering from pain or insomnia could also act as potential confounders of the relationship between sleep and pain. For example, the ability of attention to modulate pain perception is one of the main mechanisms people employ to cope with pain.[61] Insomnia with objectively determined short sleep duration has recently been associated with deficits in the executive attention control function,[62] which is also found to be impaired in pain-free volunteers after one night of partial sleep restriction.[63] Similarly, application of painful stimuli in volunteers showed that attentional bias toward pain and pain-related information reduced distraction from the painful stimuli,[64] undermined sleep,[26] and strengthened the association between daily pain severity and disability in patients with chronic pain.[65]

Pain catastrophizing[66] has been shown to magnify pain, possibly because it has detrimental effects on sleep.[67] Presleep cognitive arousal in patients with chronic pain was found to be a more reliable predictor of subsequent sleep quality than was presleep pain.[68] These intriguing findings point to the hyperarousal hypothesis for insomnia[69] as a potential underlying mechanism linking insomnia to depression and pain. According to this concept, in individuals with a neurocognitive state of intense focus and rumination about sleep, an acute stressful event that could otherwise only transiently affect sleep may trigger and perpetuate a more permanent process of sleep disturbance associated with changes in mood. This interplay between a vulnerable hyperfocusing psychology and a biology characterized by the preponderance of arousal-promoting activity in the CNS might be responsible for a set of maladaptive responses, ultimately resulting in morbid sleep- and pain-related-outcomes. Similarly, the "dopamine hypothesis"[70] posits that dysregulation of central dopaminergic transmission (a major arousal-promoting pathway involved in sleep-wake regulation) that diminishes mesocorticolimbic dopaminergic activity may act as a common precursor for several of the ill phenotypes encountered in chronic pain patients, including hyperalgesia,

insomnia, and depression.[33,71,72] Although the dopamine hypothesis is intriguing in conception, it is yet unclear to what extent the emerging nociception phenotypes could be the result of a dopaminergic dysfunction alone or an interaction between dopaminergic and other neurotransmission or neurophysiologic processes.[73]

Numerous neurochemical pathways of sleep-wake regulation,[74] including cholinergic,[75] adenosinergic,[76,77] gamma-aminobutyric acid (GABA)–ergic,[78] serotonergic,[77] and orexinergic[79,80] transmission, have been found to intersect with pain-related functions, making them attractive candidates for establishing mechanistic foundations for the association between sleep, pain, and relevant changes in mood. Nevertheless, experimental evidence shows that the relationship between arousal-promoting actions in the CNS and sensitivity to nociceptive stimuli is not monotonic; that is, the derived nociception phenotypes strongly depend on various factors. These include the type (e.g., various subtypes of dopamine, orexin, or serotonin receptors) and location (i.e., central versus peripheral nervous system) of activated receptors, the employed experimental model (e.g., acute versus chronic neuropathy pain), and, most important, the complex interaction between several neurotransmission paths.[75,80,81] The success of multimodal therapy strategies for chronic pain also emphasizes the experimental evidence that multiple brain regions and neurochemicals (including genetic and epigenetic molecules) modulate the psychophysiology of human pain.

Although primary and pain-related insomnia share several behavioral and phenomenologic characteristics,[11,26,27] neuroanatomic and clinical evidence support that chronic pain comorbidities like insomnia and depression might arise through a unique, pain-evoked pathophysiology and should be treated differently.[82] For example, human functional imaging studies have demonstrated that pain perception engages limbic and cortical areas of the brain, which are important for the regulation of mood and cognition.[82,83] In addition, patients with chronic pain and comorbid depression have been shown to respond less favorably to antidepressants compared with those who were pain free.[84] This evidence may indicate the existence of a deeper, physiology-based dissimilarity between primary insomnia and insomnia or depression as comorbidities of chronic pain.

Epidemiologic studies of pain and theoretical models for chronic disease[82,85] suggest that the transition from an acute pain episode to a chronic state of persistent pain is characterized by molecular and anatomic alterations (neuroplasticity). These alterations may contribute both to the chronicity and irreversibility of pain disease[86,87] and to the development of comorbidities like insomnia and depression.[88] Interestingly, individuals who suffer from chronic insomnia demonstrate an increased potential for neuroplasticity changes in response to training or other triggering events.[89] In addition, an abnormally high plasticity background in these patients might be also relevant to the development of mood disorders[90] or persistent insomnia syndrome.[91]

ASSESSMENT OF SLEEP IN THE CONTEXT OF CHRONIC PAIN

To accurately characterize the relationship between disturbed sleep and pain and effectively manage chronic pain patients, it is essential to use reliable instruments to assess both sleep- and pain-related phenotypes. The 2008 Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) consensus on interpreting the clinical importance of treatment outcomes in chronic pain trials found that the interference of pain with sleep, as assessed by the Brief Pain Inventory Interference Scale,[92] is one of the main factors affecting quality of life in this patient population. Thus it is among the primary therapeutic outcomes of interest.[93,94] A deeper and better understanding of the physiologic interaction between impaired sleep and pain would directly depend on our ability to reliably translate sleep behavior phenotypes to easily obtainable clinical surrogates.

In contrast to pain, sleep can be evaluated both by objective and subjective measures. Overnight, attended polysomnography (i.e., the evaluation of quantitative and qualitative parameters of sleep with the use of electroencephalographic, respiratory, and electrocardiographic monitoring modalities) is considered a gold standard for the objective assessment of sleep. Actigraphy monitoring, another method for the objective evaluation of sleep, has also been used in clinical trials, although it has less specificity than polysomnography in detecting wakefulness after sleep onset.[95] However, the ability to apply objective tests in large clinical trials has been limited by the associated cost and cumbersome preparation logistics. Despite the fact that patients tend to misperceive their sleep and objective tests demonstrate superior performance or measure different sleep qualities[96] than do self-reported sleep assessment methods,[97] the latter demonstrate sufficient validity[98] to be used in large chronic pain cohorts with longitudinal trial designs. Table 133-2 presents a list of scoring instruments that have been employed to assess pain-related sleep disturbances.

These scoring instruments consist of either a simple, one-item assessment scale for sleep quality or more complex and extended questionnaires assessing several aspects of sleep behavior; that is, sleep initiation and maintenance, number of awakenings, and the restorative quality of sleep. Validation studies have demonstrated that these tests can discriminate between subjects with insomnia and those with normal sleep. Certain assessment instruments, such as the Medical Outcomes Study sleep scale,[99-101] the Chronic Pain Sleep Inventory,[102] and the Insomnia Severity Index,[103,104] were able to detect changes in sleep behavior associated with the use of analgesia in pain patients. It is still not clear, however, how such tests should be constructed in order for them to have clinically meaningful effects in the management of chronic pain patients. Are more elaborate scoring instruments and those containing pain-specific components (e.g., Brief Pain Inventory Interference Scale,[92] Chronic Pain Sleep Inventory,[102] and Daily Sleep Diary[105]) better equipped to characterize sleep disturbances in the context of pain compared with simple single-item scales? A recent validation study of the single-item Sleep Quality Scale (11-point; 0 for *best possible sleep* to 10 for *worst possible sleep*) showed that in patients treated for chronic widespread pain, the simple instrument correlated closely with the Medical Outcomes Study sleep scale and was also sensitive enough to detect improvement in the quality of sleep as a result of pain treatment.[106]

Sleep is lately receiving more attention inside the overall evaluation framework of the chronic pain patient.[3,94] An outcomes-based approach is certainly required to guide future research to determine the type of sleep assessment that could

Table 133-2 Scales and Questionnaires that Are Commonly Used to Evaluate Sleep in Patients Suffering from Chronic Pain

Measure/Scale	Content	Item Format	Scoring Format	Method of Administration	Score Output	Validation Populations
Brief Pain Inventory (BPI)[92]	Location, intensity, and pain interference with several functions, including sleep	15 items composed from 2 multiple-item scales	2 open-ended and 1 yes/no question and 12 Likert scales (0–10)	Self-report	Mean of items 3–6 for pain severity score and mean of the 7 components for pain interference score	Arthritis and low back pain[137]
Chronic Pain Sleep Inventory (CPSI)[102]	Sleep initiation, need for sleep medications, midsleep and morning awakenings because of pain, and overall sleep quality	5 items; assessment of various sleep behaviors in patients with chronic pain	Each of the 5 items is scored using a 100-mm visual analogue scale (0–100)	Self-report	Items are scored independently; a single index of sleep problems due to pain is scored from 3 out of the 5 items	Chronic pain due to osteoarthritis
Daily Sleep Diary (DSD)[105]	Sleep onset, sleep duration, nighttime and early-morning awakenings, nonrestorative sleep, and overall sleep quality	7 items; frequency and severity of distinct sleep behaviors	Free entry, categorical, and 5- and 6-point ordinal scales	Self-report	Independent scoring for each individual DSD item	Chronic pain patients
Functional Outcome of Sleep Questionnaire (FOSQ)[138]	Impact of sleep disturbance on daily function	30 items; rating all evaluated functional outcomes	4- and 5-point rating scales	Self-report	Summation of the scores from all items; total score: 0–120	Patients with sleep-disordered breathing
Insomnia Severity Index (ISI)[103]	Nature, severity, and impact of insomnia	7 items; severity of insomnia and impact on mental health and daily function	5-point ordinal and Likert scales (0–4)	Self-report	Summation of the responses to each of the items; total score: 0–28	Insomnia patients[104]
Jenkins Sleep Scale (JSS)[139]	Symptoms related to sleep onset, maintenance, and nonrestorative sleep	4 items; rating the severity of various insomnia symptoms	6-point ordinal scale (0–5)	Self-report	Summation of the responses to each of the items; total score: 0–20	Air traffic controllers
Medical Outcomes Study (MOS) sleep scale[99]	Sleep initiation, maintenance, and quantity; nonrestorative sleep	12 items; rating various aspects of sleep behavior	5- and 6-point ordinal scales and free entry for the quantity of sleep	Self-report	Scores aggregated in 7 subscale domains and the composite sleep problems index; possible score for each subscale: 0–100	Patients with neuropathic[99] and chronic widespread[101] pain
Pittsburgh Sleep Quality Index (PSQI)[140]	Sleep-wake patterns, sleep duration and latency, sleep disturbances, sleep medications, nonrestorative sleep, and overall sleep quality	19 items; severity and frequency of disturbances in sleep continuity, various insomnia symptoms, and global quality of sleep	Free entry and 4-point ordinal scales	Self-report	7 component scores each rated from 0–3; total sleep quality score: 0–21	Patients with sleep disorders and depression
Sleep-EVAL Expert System[8]	Difficulties in sleep onset and maintenance; nonrestorative sleep	4 items; rating the severity of various insomnia symptoms	Dichotomous (yes/no) response	Clinician interview	Independent scoring of each of the 4 items	Psychiatric populations and patients with sleep disorders

add clinical value to the management of patients with chronic pain (e.g., objective versus subjective tests, extended and more complex questionnaires versus shorter and simpler ones, combination of objective and subjective methods).

MANAGEMENT OF PATIENTS WITH CHRONIC PAIN AND COMORBID INSOMNIA

Because of the physiologic and phenotypic complexities associated with the interaction of pain, pain-related insomnia, and comorbid mental illness in chronic pain, the therapeutic management of this patient population is a challenging task. The significance of these comorbid relationships is further emphasized by the adoption of multimodal therapeutic interventions that combine analgesic, hypnotic, and antidepressant effects. Thus it is encouraging that sleep-related outcomes are being incorporated into randomized controlled clinical trials designed to evaluate treatments for chronic pain. The inclusion of sleep assessments in such trials might also provide indirect evidence for the physiologic basis of the association between pain and disturbed sleep. Table 133-3 presents a list of important recent randomized placebo-controlled trials evaluating treatments for various types of chronic pain conditions, in which both pain and sleep-related outcomes have been assessed.

Interventions Targeting Pain

Pharmacologic analgesic interventions in patients suffering from chronic pain of various etiologies include acetaminophen, nonsteroidal antiinflammatory drugs, and opioids.[107-109] In patients suffering from chronic widespread or neuropathic pain, tricyclic and nontricyclic antidepressants and anticonvulsant drugs, prescribed as adjuvant or even monotherapy therapy, have also shown relative success in improving pain-related outcomes.[110-112] With the exceptions of acetaminophen and newer antidepressants (e.g., trazodone, mirtazapine, and buproprion) and anticonvulsants (e.g., gabapentin, pregabalin), most analgesics seem to alter sleep in a manner quite similar to that of pain (i.e., by disrupting sleep continuity or suppressing both REM and slow wave sleep).[113] It is thus not surprising that effective analgesia with agents like opioids and nonsteroid antiinflammatory drugs may not be associated with a complete restoration of normal sleep architecture, despite improving subjective sleep assessment outcomes.[114-116] Because systematic objective and longitudinal assessment for the sleep-disrupting effects of analgesics is missing, it is currently unclear whether a sole disturbance of sleep architecture (i.e., not associated with subjective complaints) constitutes a physiologic insult with the potential of altering pain outcomes or changing the natural course of pain disease in the long-term. This issue directly relates to the yet unanswered question about the clinical meaning of the various sleep phenotypes evaluated by different assessment methods.

Interventions Targeting Insomnia

Several recent randomized placebo-controlled, double-blinded trials have demonstrated the efficacy of novel CNS depressants and nonbenzodiazepine hypnotics that specifically target sleep function in reducing pain and improving function in patients suffering from chronic widespread and low back pain.

Sodium oxybate is the sodium salt of gamma-hydroxybutyrate, an endogenous metabolite of GABA with CNS-depressant properties.[117] Administration of sodium oxybate in patients suffering from chronic widespread pain significantly improved subjective sleep, pain, and functional outcomes, whereas it also increased physiologic sleep stability and the amount of slow wave sleep in polysomnography recordings.[118,119] Similarly, the administration of eszopiclone, a nonbenzodiazepine hypnotic,[120] in patients suffering from chronic low back pain, was associated with a significant increase in total sleep time, a reduction in pain, and an improvement in the ratings of depression.[121]

Although rigorous consensus criteria[93] may question the clinical meaningfulness of the improvement in pain-related and other functional outcomes demonstrated by the small analgesic effects in some of these interventions,[118,121] these findings are the first important randomized controlled trial (RCT) evidence that interventions targeting sleep-related physiology may alter pain perception and improve associated functional outcomes in patients suffering from chronic pain.

Interventions Targeting Both Pain and Disturbed Sleep

Melatonin is pineal gland hormone with a circadian pattern of secretion and well-known sleep-wake regulation, antiinflammatory, and antihyperalgesic effects. Although melatonin has demonstrated efficacy both in treating pain and improving sleep quality when administered in patients with temporomandibular joint disorder[122] or endometriosis-associated chronic pelvic pain,[123] the small sample size of these trials does not allow for robust conclusions regarding possible interactions between the pain-relieving and sleep-restoring effects of the drug.

Pregabalin, a novel anticonvulsant agent with calcium channel α_2-δ ligand properties,[124] has been shown to be effective both in treating pain and restoring the quality of sleep in patients with neuropathic disease, and it is one of first-line therapies recommended[111,125] for neuropathic pain. Studies in volunteers[126] and patients suffering from chronic pain[98,127] have demonstrated the beneficial effects of pregabalin on sleep function. The fraction of slow wave sleep is increased, and there is an associated improvement in self-assessed sleep quality. Both the analgesic and sleep-enhancing effects of pregabalin are presumably mediated by the same molecular mechanism, that is, a reduction in the influx of calcium ions into oversensitized neurons, followed by a subsequent reduction in the synaptic activity of the latter.[124] A recent retrospective analysis has shown that patients with neuropathic pain and comorbid sleep problems tend to respond better to the pain-relieving effects of pregabalin, suggesting that the analgesic action of the latter might be mediated through its sleep-restoring effects.[128] However, the nonspecific character of pregabalin's mechanism of action makes it difficult to test of this hypothesis prospectively.

Cognitive behavior therapy for the treatment of sleep disturbances has been a successful psychological intervention in patients suffering from primary[129] or comorbid (e.g., pain-related) insomnia.[130] However, the pain-relieving effects of this treatment modality have been weak, at best.[129,131,132] A recent RCT evaluating both pain- and sleep-related behaviors in older patients with osteoarthritis demonstrated that 9 months of cognitive behavior therapy failed to significantly

Table 133-3 Randomized Controlled Trials Evaluating the Effects of Various Interventions on Pain- and Sleep-Related Outcomes in Patients with Comorbid Chronic Pain and Impaired Sleep*†

Disease	Study	Population	Blinding	Control	Follow-up	Intervention	Intervention Focus	Pain Measures	Sleep Measures	Improved Outcome		Sleep-Pain Agreement
										Pain	Sleep	
Chronic widespread pain	Arnold et al., 2010[110]	CWP ($n = 507$)	Double	Placebo	12 wk	Duloxetine (SNRI)	Pain	BPI, SF-36 bodily pain	BPI and 11-point Likert scale (0–10)	Yes	Yes	Yes
	Moldofsky et al., 2010[118]	CWP ($n = 151$)	Double	Placebo	8 wk	Sodium oxybate (γ-hydroxybutyric acid)	Sleep	VAS, FIQ pain, SF-36 bodily pain	PSG, ESS, JSS, FOSQ	Yes	Yes	Yes
	Russell et al., 2011[119]	CWP ($n = 334$)	Double	Placebo	14 wk	Sodium oxybate (γ-hydroxybutyric acid)	Sleep	VAS, FIQ pain, SF-36 bodily pain	JSS	Yes	Yes	Yes
	Roth et al., 2012[98]	CWP ($n = 206$)	Double	Placebo	4 wk	Pregabalin (anticonvulsant)	Pain and sleep	NRS (0–10)	PSG, self-reported sleep assessments	Yes	Yes	Yes
	Kashikar-Zuck et al., 2012[141]	Juvenile CWS, ($n = 112$)	Single	CWP education	6 mo	CBT	Pain	VAS (0–10)	VAS (0–10)	No	No	Yes
Low back pain	Steiner et al., 2011[142]	CLBP ($n = 539$)	Double	Placebo	84 days	Buprenorphine (partial agonist of the μ-opioid receptor)	Pain	NRS (0–10)	MOS sleep scale (0–100)	Yes	Yes	Yes
	Williams et al., 2014[143]	Acute low back pain ($n = 1596$)	Double	Placebo	3 mo	Paracetamol (mild analgesic)	Pain	Days until recovery from pain, NRS (0–10)	Sleep quality from PSQI (item No 6)	No	No	Yes
	Goforth et al., 2014[121]	CLBP ($n = 52$)	Double	Placebo	1 mo	Eszopiclone (nonbenzodiazepine hypnotic)	Sleep	VAS (0–100)	Total sleep time (sleep diary)	Yes	Yes	Yes
Neuropathic pain	Richter et al., 2005[144]	Painful diabetic neuropathy ($n = 219$)	Double	Placebo	6 wk	Pregabalin (anticonvulsant)	Pain	NRS (0–10, daily), SF-MPQ (weekly)	Sleep interference (NRS, 0–10, daily)	Yes	Yes	Yes

	Siddall et al., 2006[145]	Central neuropathic pain (n = 137)	Double	Placebo	12 wk	Pregabalin (anticonvulsant)	Pain	NRS (0–10, daily), SF-MPQ	Sleep interference (NRS, 0–10, daily), MOS sleep scale	Yes	Yes	Yes
	Kalliomäki et al., 2013[146]	Posttraumatic neuralgia (n = 133)	Double	Placebo	1 mo	Chemokine receptor 2 (CCR2) antagonist (antiinflammatory)	Pain	NRS (0–10, every 12h), NPSI	Sleep interference (NRS, 0–10)	No	No	Yes
	Serpell et al., 2014[147]	Peripheral neuropathic pain (n = 173)	Double	Placebo	15 wk	Tetrahydrocannabinol/ cannabidiol (THC/ CBD)	Pain	Peripheral neuropathic pain (NRS, 0–10, daily), BPI	Sleep quality (NRS, 0–10, daily)	Yes	Yes	Yes
Temporomandibular disorder	Vidor et al., 2013[122]	Myofacial TMD pain (n = 32)	Double	Placebo	4 wk	Melatonin	Pain and sleep	VAS (0–10, daily)	Sleep quality (VAS, 0–10, daily)	Yes	Yes	Yes
Osteoarthritis	Vitiello et al., 2013[130]	Elderly (>60 yr) patients with osteoarthritis (n = 367)	Double	Education only	9 mo	CBT for pain and insomnia	Pain and sleep	Chronic pain scale (6 items; 0–10)	Insomnia severity index, sleep efficiency (actigraphy)	No	Yes	No
Postherpeutic neuralgia	Dworkin et al., 2003[148]	Postherpeutic neuralgia (n = 173)	Double	Placebo	9 wk	Pregabalin (anticonvulsant)	Pain	NRS (0–10, daily), SF-MPQ	Sleep interference (NRS, 0–10, daily), MOS sleep scale	Yes	Yes	Yes
	Apalla et al., 2013[149]	Postherpetic neuralgia (n = 30)	Double	Placebo	24 wk	Botulinum toxin A	Pain	NRS (0–10)	Sleep quality scale (5 items)	Yes	Yes	Yes
Chronic pelvic pain	Schwertner et al., 2013[123]	Endometriosis (n = 36)	Double	Placebo	8 wk	Melatonin	Pain and sleep	VAS (0–10, daily)	Sleep quality (VAS, 0–10, daily)	Yes	Yes	Yes

*Emphasis is given to the agreement between the changes in the pain- and sleep-related outcomes as a result of interventions targeting sleep, pain, or both sleep and pain functions.

†This list presents in chronologic order main prospective trials that were published in the past decade. Investigations with no clear prospectively defined hypotheses regarding the examined outcomes, as well as studies with conclusions based on exploratory and/or subgroup unplanned analyses, were not included.

ACR, American College of Rheumatology; BPI, Brief Pain Inventory; CBT, cognitive behavior therapy; CLBP, chronic low back pain; CWP, chronic widespread pain (a newer term for fibromyalgia); ESS, Epworth Sleepiness Scale; FIQ, Fibromyalgia Impact Questionnaire; FOSQ, Functional Outcomes of Sleep Questionnaire; IBS, irritable bowel syndrome; JSS, Jenkins Scale for Sleep; MOS, Medical Outcomes Study; NPSI, Neuropathic Pain Symptom Inventory; NRS, Numeric Rating Scale; PSG, polysomnography; PSQI, Pittsburgh Sleep Quality Index; TMD, temporomandibular disorder; SF-36, The 36-Item Medical Outcomes Study Short-Form Health Survey; SF-MPQ, Short Form McGill Pain Questionnaire.

improve pain compared with only education-based management.[130] Nonetheless, a recent secondary analysis of this RCT evidence by the same investigators showed that, independent of the received treatment, patients who experienced sleep improvement in the first 2 months of the treatment were more likely to demonstrate sustained improvement in their pain severity scores during the remaining 16-month follow-up period.[133]

As shown in Table 133-3, recent randomized placebo-controlled blinded interventions for a variety of chronic pain conditions have demonstrated that agreement between treatment-induced changes in pain- and sleep-related outcomes is common, regardless of the effectiveness of the therapy under evaluation. This observation confirms previous findings from a systematic review of Cochrane meta-analyses, showing that changes in insomnia- and pain-related outcomes of various RCT interventions tend to be in the same direction.[134] Although these findings support a strong link between sleep and pain functions, it is evident that, when employed alone and independent of the targeted function (i.e., sleep or pain), no current pharmacologic or behavioral modality is both sufficiently safe and effective to improve chronic pain in the long term. A combination of treatments, treatment modalities, and treatment targets (i.e., pain, insomnia, depression) may result, through already determined therapeutic paths, in larger analgesic and safer effects. Moreover, more accurate characterization of the various patient morbidity phenotypes may reveal new markers for identifying those who are responsive to each particular treatment or combination of treatments.[133,135]

CLINICAL PEARL

Pain disturbs sleep, and impaired sleep might exacerbate responses to pain. Insomnia and depression are highly prevalent among patients with chronic pain, and primary sleep disorders such as insomnia and sleep apnea have also been associated with various types of pain complaints. The sleep medicine physician should be aware of the complex epidemiology of chronic pain disease and follow a diagnostic approach that includes a comprehensive evaluation of both pain- and sleep-related phenotypes as well as a thorough assessment of the patient's mental health. Different types of chronic pain benefit from different pharmacologic approaches (e.g., modern antidepressants, sodium oxybate, and anticonvulsants for chronic widespread pain, and anticonvulsants for neuropathic pain), but all interventions are uniformly associated with improvement in both sleep and pain functions independent of their therapeutic target. Cognitive behavior therapies, despite their effectiveness in treating insomnia, have yet to show an important benefit as a holistic therapy for the chronic pain patient with comorbid insomnia.

SUMMARY

Chronic pain and poor sleep hygiene are major public health challenges with great economic and societal impact. An interaction between the two is slowly being established based on micro- and macro-longitudinal studies in healthy humans and in patients with chronic pain. Both the activation of major inflammatory pathways and inhibition of central descending analgesic signals seem to be candidate mechanisms for the hyperalgesic effect of acute sleep impairment. In patients suffering from chronic pain, the mood disorders and cognitive changes associated with preoccupation with pain- or sleep-related information seem to potentiate the bidirectional influence between pain and comorbid insomnia. Self-administered sleep assessment instruments have demonstrated that they can reasonably discriminate between patients with insomnia and normal sleepers. In addition, when applied to pain patients, they can detect improvement in sleep quality associated with the use of analgesia. Pharmacologic approaches that target either pain- or sleep-related outcomes in patients with chronic pain have resulted in a significant improvement in both outcomes. Evidence suggests that the effect sizes of such interventions on sleep, or pain, may be further enhanced by combining pharmacologic and behavioral therapies for both sleep- and pain-related symptoms.

Chapter 134

Sleep and Chronic Kidney Disease

John G. Park; Kannan Ramar

Chapter Highlights

- Sleep disturbances such as insomnia, restless legs syndrome, periodic leg movements during sleep, and obstructive sleep apnea are common across the wide spectrum of chronic kidney disease (CKD) patients. CKD is linked to an increased risk for sleep disorders through various pathophysiologic mechanisms. The occurrence of CKD continues to rise, and as a result the prevalence of sleep disorders is likely to grow. Similarly, sleep disorders may increase risks associated with CKD and contribute to the rising prevalence of CKD.
- Comorbid sleep disorders add significant burden to the quality of life, health care costs, and morbidity and mortality of patients with CKD.
- This chapter provides an up-to-date review of the current available literature regarding sleep disturbances in patients with CKD and discusses the associated clinical implications as well as treatment options for the various sleep disorders common to this population.

Chronic kidney disease (CKD) is defined as abnormalities of kidney structure or function (defined by estimated glomerular filtration rate [eGFR] <60 mL/minute per 1.73 m^2) that is present for 3 or more months, with negative implications on health.[1] CKD is a common but serious condition associated with an increasing incidence and prevalence (16.8%) in the United States, particularly with the increasing prevalence of diabetes, metabolic syndrome, and hypertension, all being significant risk factors for CKD.[2,3] CKD is associated with increased mortality, decreased quality of life, and increased health care costs. CKD is also linked to an increased risk for sleep disorders. This chapter discusses these various sleep disorders across the spectrum of CKD and reviews the consequences and treatment options in this specific population.

EPIDEMIOLOGY

The prevalence of sleep disorders in patients with end-stage renal disease (ESRD) requiring dialysis is well established. Poor sleep, as defined as sleep-wake complaints, sleep-disordered breathing, and excessive daytime sleepiness, occurs in 45% to 80% of dialysis patients. This prevalence is much higher than that of the general population or CKD patients not requiring dialysis.[4-6] In contrast, the prevalence of sleep disorders in non–dialysis-dependent CKD patients varies widely between 14% and 85%. The reasons for this wide variation are multifactorial and may be related to the use of subjective versus objective data to assess sleep, the type of sleep disorder that is being evaluated, and the stage of CKD.

Some studies have not shown significant differences in the Pittsburg Sleep Quality Index (PSQI) between CKD patients and general medical outpatients,[7] whereas others have found progressive worsening of sleep quality with progression of renal disease based on CKD stages.[8] Poor sleep quality on the PSQI has been noted in 84.6% of CKD patients compared with 59.5% of patients with hepatitis C.[9] Inadequate sleep (defined as ≤6 hours/night) has shown to differ by CKD stages, with 37.4%, 43.0%, and 30.9% reported for no CKD, CKD stages 1 and 2 (eGFR ≥60 mL/minute per 1.73 m^2 with albuminuria), and CKD stages 3 and 4 (eGFR 15 to 59 mL/minute per 1.73 m^2), respectively.[10] Leg symptoms and sleeping pill use were more frequent in CKD stages 3 and 4 compared with stages 1 and 2 or no CKD.[10] Poor sleep quality, when measured by the Kidney Disease Quality of Life (KDQOL) survey, has been reported in approximately 57% of patients with CKD and was more common in CKD stages 3 to 5 (mean eGFR 24.9 ± 10.6 mL/minute per 1.73 m^2).[11]

Reduced sleep efficiency and greater sleep fragmentation as measured by wrist actigraphy have been noted in CKD compared with non-CKD patients.[12] Similarly, patients with CKD stages 4 and 5 had short and fragmented sleep resulting in total sleep time and sleep efficiency being worse than patients on hemodialysis (HD).[13] Patients with non-HD CKD had a higher prevalence (54.3%) of sleep-disordered breathing and periodic limb movement disorder (30%) compared with the general population.[14]

Although further studies are needed to clarify the heterogeneity of the results, the overall evidence points toward higher prevalence of sleep disorders in CKD patients compared with the general population. This association may also be bidirectional. CKD may promote sleep disturbances with anemia, resulting in restless legs syndrome (RLS) and periodic limb movements during sleep (PLMS), or in fluid gain that is noted in CKD, resulting in sleep-disordered breathing. Similarly, sleep-disordered breathing may result in hypertension, which may then worsen CKD.

INSOMNIA

Insomnia is defined as a persistent difficulty with sleep initiation, duration, consolidation, or quality that occurs despite adequate opportunity and circumstances for sleep, and results in some form of daytime impairment (*International Classification of Sleep Disorders*, third edition [ICSD3]). (See Chapter 80 for comprehensive discussion of insomnia.) Sleep complaints most typically include difficulty initiating or maintaining sleep.

Insomnia symptoms are more common in patients with CKD compared with the general population. About 60% of subjects on HD have insomnia, ranging from difficulty falling asleep in nearly one half of patients to difficulty maintaining sleep or having early morning awakening in one fourth of patients.[15] In another multicenter trial involving more than 11,000 patients on maintenance HD, one half of them reported poor sleep quality.[16] Not surprisingly, the prevalence of routine use of sleep hypnotics was 25.8%,[15] which not only might interact with the patients' other medications but also may adversely affect some physiologic functions such as daytime sleepiness. Although the mechanism is not entirely understood, poor sleep quality appears to increase the mortality risk among patients with CKD.[16]

It is likely that psychological and physiologic factors are responsible for the high prevalence of insomnia complaints in patients with CKD. Higher prevalence of anxiety, stress, and depression is reported in patients with CKD, and these are well known risk factors for insomnia.[17] Rapid fluid, electrolyte, and acid-base changes that occur are often associated with central nervous system symptoms such as changes in arousal and fatigue during or immediately after treatment. A fall in cerebral spinal fluid pH during dialysis and slow movement of bicarbonate across the blood–brain barrier may also be contributing factors to daytime somnolence and subsequent decreased nocturnal sleep quality and ventilatory instability. In addition, several studies have reported an increase in cytokine production secondary to blood interactions with the bioincompatible equipment used in the HD procedure.[18] These substances have both somnogenic and pyrogenic properties and have been linked to a number of postdialysis symptoms, including daytime sleepiness and sleep disturbances.[19] In particular, the somnogenic effects of cytokines are most pronounced during the day when binding of these substances to brain receptor sites is typically much lower than during the night. Dialysis-associated changes in melatonin levels and pattern of secretion may play a role in disrupting the circadian cycle.[20] Timing of HD session may also affect circadian systems by altering exposure to zeitgebers such as wake-up and bed times, activity patterns, meal times, light exposure, and social activity (Figure 134-1). In addition, HD induces a heat load, and patients often respond with an increase in body temperature of approximately 0.5° to 1.0° C; this increase in body temperature may persist for several hours after treatment.[21] These changes may disrupt the circadian regulation of sleep and explain the increased sleep onset and rapid eye movement (REM) latencies and decreased percentage of REM sleep, measures that are specifically linked to body temperature rhythms, in subjects on HD.

There is very little evidence to guide treatment of insomnia among CKD patients. The main goal of treatment is to improve sleep quality to reduce daytime impairment such as daytime fatigue and sleepiness. This can be accomplished by either pharmacologic, nonpharmacologic, or a combination of both of these approaches. The evidence, efficacy, and safety profile of both of these approaches for insomnia are well outlined in Chapters 80 to 88. However, studies using these approaches specifically in insomnia patients with CKD are very limited.

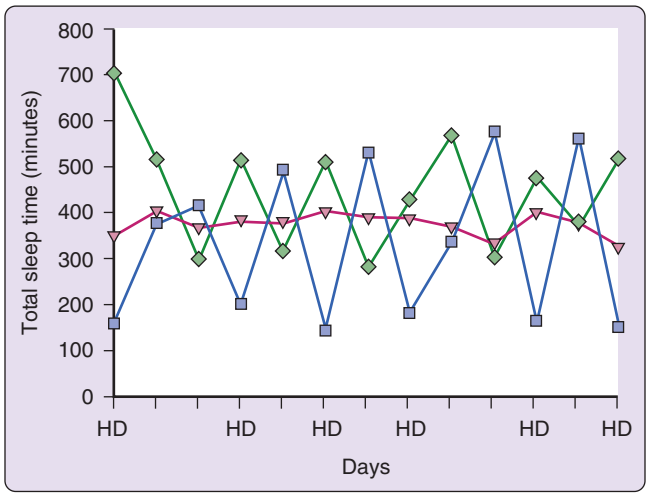

Figure 134-1 Total sleep time (TST) on hemodialysis (HD) treatment and non-HD nights. *Diamonds* represent subjects with longer TST on post-HD nights. *Squares* represent subjects with shorter TST on post-HD nights. *Triangles* represent subjects with a stable sleep pattern on pre- and post-HD nights.

Although nonpharmacologic approaches such as sleep hygiene, stimulus control, and cognitive behavior therapy (CBT) have been well studied in insomnia patients in the general population, there are limited data for CKD patients with insomnia. In a study of patients on peritoneal dialysis, CBT has shown to improve fatigue as measured by the Global Fatigue Severity Scale (GFSC) and decrease inflammatory cytokines.[22] In patients on HD, CBT results in improved PSQI, Global Fatigue Severity Scale, and Beck Depression and Anxiety Inventory scores along with reduced inflammatory markers and oxidative stress.[23] When the benefit of exercise during dialysis was evaluated, it was noted that aerobic activity with moderate intensity during the first 2 hours of a dialysis session could improve sleep quality as measured by the PSQI.[24] The effect of acupressure to improve sleep quality and fatigue in renal patients on HD was evaluated in a randomized controlled trial of 1 month. Patients who received acupressure had significantly lower levels of fatigue, better sleep quality, and less depression compared with controls. Despite the overall limited data of nonpharmacologic approaches to treat insomnia in CKD patients, it is reasonable to consider these approaches because their side effects and complications are relatively very few.

Caution needs to be exercised when considering a pharmacologic approach in CKD patients because of the requirement of dose changes, drug interactions (particularly in the setting of polypharmacy in this patient population), and side effects. In a small randomized study comparing zaleplon with placebo using the PSQI to assess for sleep quality, zaleplon reduced sleep latency and improved sleep efficiency and sleep quality without significant side effects in HD patients.[25] In another randomized crossover study comparing the effects of

clonazepam with zolpidem, both drugs improved PSQI in HD patients; clonazepam was more effective in decreasing PSQI scores than zolpidem, whereas the latter was better tolerated.[26] HD causes physiologic changes that affect the ability to dissipate heat after HD, which may result in insomnia on the nights following treatment. The use of cool diasylate during HD has been shown to improve nocturnal sleep (i.e., shorter sleep latency, longer sleep duration, and longer REM latencies) by decreasing sympathetic activation.[27]

In summary, nonpharmacologic methods such as behavioral techniques and cognitive therapy as well as pharmacologic approaches and combinations of these methods may be used for the treatment of insomnia in patients with CKD, noting the previous caveats. There remains a need for studies assessing the effect of long-term therapies for chronic insomnia in CKD patients.

RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENTS DURING SLEEP

Although the pathogenesis is not well understood, CKD is one of the secondary causes of RLS and PLMS (see Chapter 95 for comprehensive discussion of RLS and PLMD). Prevalence of RLS in CKD patients not yet on dialysis is reported to be 11% to 26% based on structured interview studies rather than questionnaires alone.[28,29] In nondialyzed CKD patients, it has been reported that approximately 11% fulfilled the RLS criteria of the International Restless Legs Syndrome Study Group[30] compared with 3% in healthy controls.[28] Looking at RLS across different stages of renal dysfunction, the prevalence among CKD patients may be as high as 26%[29] compared with what has been described in the general population (3% to 15%).[31-33] An increased prevalence of RLS has also been described in Japanese patients with CKD; 3.5% of Japanese patients with CKD had RLS compared with 1.5% of healthy controls.[34] The occurrence of RLS is also greater in children with CKD (15.3%) compared with healthy controls (5.9%) and appears to be underdiagnosed.[35,36] In children, there is no association between RLS and CKD stage, etiology, duration, dialysis, or transplant status. Children with RLS are more likely to rate their sleep quality as poor and report using sleep medications.

Among patients with ESRD requiring HD, RLS is present in 14% to 58%.[37-39] Some of the earlier studies suggested even higher prevalence rates, but they may have been limited by inconsistent criteria used for RLS or use of surveys without a structured clinical interview to validate symptoms.[40] The wide range of prevalence may also be due to small sample size in some studies and the location of patient recruitment (dialysis centers vs. sleep centers). Most of the studies suggest prevalence rates of 20% to 30% among ESRD patients requiring HD.

PLMS is reported in 42% of CKD patients on the transplant waitlist compared with 27% of patients after kidney transplantation.[41] A study using 48-hour seven-channel ambulatory polysomnogram (PSG) that included electromyogram signals from bilateral anterior tibialis muscles, found PLMS (defined by periodic limb movement index [PLMI] ≥5/hour of sleep) to be present in 85.4% of HD subjects.[39] Defining "clinically relevant" as PLMI ≥25/hour, 71% met that criterion. They also noted that those who also had RLS had much higher PLMI (median PLMI of 87/hour in those with coexisting RLS versus 16/hour in those without RLS).[39]

These data suggest that the overall rate of RLS is much more frequent in patients with CKD and ESRD than the general population. Similar to patients without CKD, PLMS are much more frequent in those with coexisting RLS. The exact mechanism of how CKD results in increased RLS remains elusive, but some proposed theories associate the sleep-related movement disorder to uremia[42] and low intact parathyroid hormone,[43] whereas the association with reduced ferritin has been much less robust compared with subjects without CKD. There also appears to be a strong genetic influence in single-nucleotide polymorphisms that may still influence the development of RLS even among CKD patients.[44]

Clinical Characteristics

Similar to in the general population, RLS appears to be more prevalent among females with CKD, but the mean ages between those with and without RLS do not differ.[28,29,37] Furthermore, the prevalence of RLS appears to increase with worsening eGFR.[34,45] Molnar and colleagues looked at a group of 176 CKD patients on a waitlist for renal transplantation and found the prevalences of RLS to be 1.8%, 5.1%, 6.5%, and 23.5% in patients with eGFRs greater than 60, 30 to 59, 15 to 29, and less than 15 mL/minute per 1.73 m^2, respectively[45] (Figure 134-2). In HD patients, there are inconsistent findings regarding RLS association with sex, age, iron, hemoglobin, and ferritin.[37,38,46] One study concluded the only difference in laboratory values between HD patients with or without RLS was the level of C-reactive protein.[47] Compared with idiopathic RLS subjects, those with RLS and ESRD had much higher PLMI (103.6 ± 74.4 vs. 22.0 ± 18.9; P <.001) and much longer suggested immobilization test index (PLMS per hour of immobility tested during awake) (127.9 ± 82.3 vs. 13.8 ± 29.0; P <.001).[48] These findings suggest some physiologic differences between uremic RLS and idiopathic RLS.

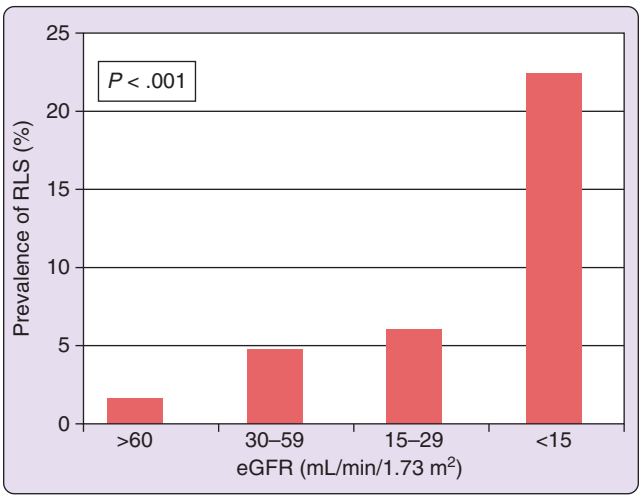

Figure 134-2 Association between presence of restless legs syndrome (RLS) and severity of chronic kidney disease based on estimated glomerular filtration rate (eGFR). (From Molnar MZ, et al. Restless legs syndrome in patients after renal transplantation. *Am J Kidney Dis* 2005;45[2]:388–96, used with permission.)

Morbidity and Mortality

Not unexpectedly, RLS is independently associated with a multitude of sleep-related complaints, worse quality of life, and increased mortality. In patients with CKD and ESRD, RLS is independently associated with greater fatigue.[49] Part of the reason for this increased fatigue may be the increased risk for sleep apnea (see Sleep-Related Breathing Disorder) and insomnia in CKD patients with RLS.[39,50,51] RLS is also independently associated with depression in patients on HD and after renal transplantation, even after adjusting for the presence of insomnia or use of antidepressants (because antidepressants may cause RLS symptoms).[52,53] These findings likely explain the worse quality of life reported by patients with CKD and RLS compared with those with idiopathic RLS.[54] RLS is independently associated with lower quality-of-life assessments even after adjusting for insomnia, age, gender, and comorbid conditions.[51,55,56]

Although the data on RLS and PLMS contributing to cardiovascular morbidity in the general population are inconclusive, there are some data suggesting that RLS in ESRD patients may increase cardiac morbidity. The incidence of new cardiovascular events (myocardial infarction, cerebral stroke, or peripheral artery occlusion) in patients with CKD and RLS is 64.5% compared with 39.1% in patients without RLS and likely contribute to a higher 18-month mortality in this group[57] (Figure 134-3). In a follow-up study of nearly 30 months, ESRD patients with RLS have increased adjusted hazard ratio (HR) of mortality (adjusted for age, sex, comorbid conditions, functional status, and clinic location) of 1.39 (HR = 1.08 to 1.79) compared with ESRD patients without RLS.[55] Increased PLMS seem to predict mortality. Survival rate at 20 months among ESRD patients with PLMI of more than 20/hour is 50% compared with 90% in ESRD patients with PLMI of less than 20/hour.[58]

Treatment

Based on a limited number of studies addressing the needs of CKD patients, the overall treatment approach to RLS does not appear to be different from that of non-CKD patients.[59]

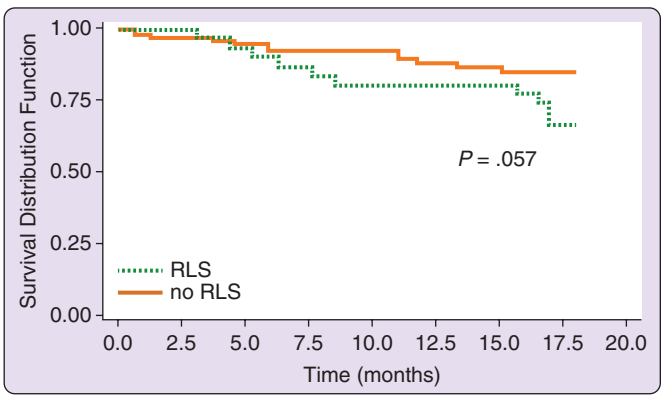

Figure 134-3 Kaplan-Meier estimates of all-cause mortality at 18 months in patients with and without restless legs syndrome (RLS). (From La Manna G, et al. Restless legs syndrome enhances cardiovascular risk and mortality in patients with end-stage kidney disease undergoing long-term haemodialysis treatment. *Nephrol Dial Transplant* 2011;26[6]:1976–83, used with permission.)

Few small trials have shown the benefit of exercise in reducing RLS symptoms, including exercise during dialysis.[60,61] In CKD patients, the treating clinician must keep in mind that most of the medications currently used to treat RLS are renally excreted. Therefore it would be advisable to start at the lowest dose possible and uptitrate the dose at a slower rate than for those with normal renal function. In patients who are on dialysis, it would be advisable to give a dose after dialysis. There are few comparative studies of different agents, and those studies are significantly limited by small sample size, such that one class of medication cannot be recommended over another as the initial agent. Medications such as iron supplementation, gabapentin, dopamine agonists, benzodiazepines, and narcotics could be considered based on severity of symptoms.[59,62]

Kidney transplantation is reported to have some benefit in improving RLS symptoms. Resolution of RLS symptoms is reported to occur between 1 and 38 days after undergoing renal transplantation, and symptoms may recur in 10 to 60 days in those whose transplantation fails.[63,64] In a follow-up period of up to 3 years, patients whose transplanted kidneys are still functioning have continued resolution of RLS.[64] These findings suggest that normalizing renal function can improve RLS symptoms, but the specifics of this mechanism remain elusive.

SLEEP-RELATED BREATHING DISORDER

There appears to be a strong association between CKD and sleep apnea, of which the most common form is obstructive sleep apnea (OSA) (see Section 14 for a comprehensive discussion of sleep breathing disorders). Its prevalence in CKD and HD patients ranges from 30% to 73%.[14,65-68] This wide range of reported prevalence is due to the variable cutoff value of the apnea-hypopnea index (AHI) or respiratory disturbance index (RDI) that was used to define OSA as well as the varying degree of renal dysfunction. For example, in a study of 1624 subjects who were diagnosed with OSA (based on AHI ≥5 events/hour), 30.5% had CKD.[65] This prevalence of CKD was threefold higher in the OSA group than the control group (prevalence of 9.1%).[65] In a much smaller study of 63 subjects on HD, 51% had OSA, defined as RDI of 15 or more.[69] It is however worthwhile to note that a cross-sectional study of patients enrolled in the Kaiser Permanente health care system found that among 85,376 patients with CKD, only 3.3% had sleep apnea (based solely on diagnostic codes or positive airway pressure device prescriptions).[70] This low prevalence rate seems inconsistent with most of the other literature, and in fact the 3.3% prevalence rate is even lower than the rate among the non-CKD population.[71,72]

Despite the variability in the prevalence studies mentioned previously, a more consistent finding is the increasing prevalence of OSA with worsening renal function.[73-75] Using an RDI of 15 or greater, 38% of subjects with CKD were shown to have OSA, whereas 51% of subjects with ESRD had OSA.[69] It has been demonstrated that for each 10 mL/minute per 1.73 m^2 decrease in eGFR, the odds ratio for OSA is 1.42, even after adjustment for age, body mass index (BMI), and presence of diabetes.[76] Similarly, it has been shown that patients on HD have an odds ratio of 4.14 for having an AHI of more than 15, compared with 2.19 in CKD patients (eGFR ≤40 mL/minute per 1.73 m^2).[75]

A few studies specifically address central sleep apnea (CSA) in CKD. The number of CSA events may be six times higher, with greater resultant desaturations, in those with CKD than those with normal renal function.[66] Compared with those with eGFR of 90 mL/minute per 1.73 m^2 or greater, the percentage of total RDI that is due to CSA events is three times greater in those with eGFR of 60 mL/minute per 1.73 m^2 or less (14.9% of total RDI compared with 4.9%).[13] Patients on HD with sleep apnea have CSA-predominant sleep apnea (defined by CSA index >5).[77] In these CSA-predominant subjects, there is a greater incidence of atrial fibrillation. Interestingly, the central apnea index is lower on the night of HD, suggesting that volume overload may contribute to the development of CSA in susceptible patients.[77]

Identifying CKD patients with OSA requires a high index of suspicion because these patients seem to present with less severe or atypical sleep-related complaints.[78-80] A history of snoring and witnessed apneas are reported less often in ESRD subjects than in controls.[80] Similarly, complaints of unrefreshing sleep and morning headaches are less frequent in ESRD subjects.[80] The mean maximal snoring intensity during the PSG is less in ESRD subjects compared with controls.[80] Furthermore, subjects with ESRD have lower BMI and neck circumference compared with controls with comparable AHI.[80] When compared with CKD subjects without OSA, CKD patients with OSA do not report worse sleepiness as measured by the Epworth Sleepiness Scale.[79]

Pathophysiology

CKD may potentiate the likelihood of sleep apnea through mechanisms of volume overload, fluid redistribution, and altered chemoresponsiveness. Internal jugular vein volume and upper airway mucosal water content, and not upper airway cross-sectional area, correlate with AHI in subjects undergoing HD.[81] This correlation remains significant even after adjusting for age, sex, height, BMI, and percent reduction of urea. This is consistent with the finding that even a 0.5-L rostral fluid shift during recumbency can lead to significant increase in neck circumference and upper airway resistance.[82,83] The findings that nocturnal HD can reduce AHI and that AHI may increase back to baseline when off of nocturnal HD support the fluid-shift theory because nocturnal HD can mitigate nocturnal fluid shifts by extracellular fluid removal at night and by improved ultrafiltration owing to longer dialysis periods.[4]

Another contributing mechanism may be altered chemosensitivity. Unstable chemosensitivity leads to destabilization of respiratory control and may contribute to the severity of OSA.[84] Subjects with ESRD and coexisting OSA have higher ventilatory sensitivity to arterial partial pressure of carbon dioxide than those without OSA.[68] This relationship is independent of age, sex, or BMI. By switching from conventional HD to nocturnal HD, chemoresponsiveness to hypercapnia may be reduced and lead to a decrease in AHI.[85]

Although chronic uremia has also been proposed to result in upper airway muscle dysfunction, there have not been convincing data to confirm this theory. Rather, it is more likely that multiple factors are ultimately responsible for the increased likelihood of OSA in CKD. For any given individual, one factor may have a greater influence over another, leading to the variable expression of OSA in these patients.

Influence of Sleep Apnea on Outcomes

Patients with OSA have pathophysiologically shared comorbidities, including hypertension, diabetes mellitus, and obesity, with CKD patients, and therefore it is difficult to attribute worsening kidney function to OSA alone. However, there is some evidence to suggest that the coexistence of OSA in patients with CKD may worsen microalbuminuria and eGFR and be associated with increased levels of cystatin C (a sensitive biomarker that reflects impaired renal function and is associated with latent CKD).[86,87] Furthermore, being at high risk for OSA (as defined by scoring positively in two of three main domains in the Berlin Sleep Apnea Questionnaire) may be an independent risk factor for kidney graft loss, particularly in female transplant recipients.[52] Potential mechanisms by which OSA contributes to worsening renal function may include intermittent hypoxemia, sympathetic surges associated with arousals, and systemic inflammation, which may lead to endothelial dysfunction and tubulointerstitial injury.[88,89]

OSA also contributes to worse quality of life, as it does in those without CKD. Those with OSA and CKD score worse in vitality, social functioning, and mental health measures on the Short Form (36) Health Survey.[90] Patients with CKD and moderate or severe OSA (AHI >15) have greater complaints of excessive daytime sleepiness and impairment in verbal memory, working memory, attention, and psychomotor speed compared with those without OSA.[91]

Treatment

With OSA and CKD independently increasing cardiovascular morbidity and mortality, it is crucial to treat OSA to mitigate these consequences. Unfortunately, although there is an exhaustive literature confirming the benefit of continuous positive airway pressure (CPAP) therapy in treatment of OSA, there is a limited literature regarding CPAP therapy specifically in CKD patients.[92] Some studies have shown the efficacy of CPAP in improving glomerular hyperfiltration and eGFR in subjects with OSA but with normal baseline renal function.[53,93] Adaptive servoventilation therapy in CKD patients with moderate to severe obstructive and central sleep apnea, and heart failure (mean ejection fraction of around 45%), may result in improvement in eGFR, New York Heart Association functional class, and serum levels of brain natriuretic peptide, creatinine, cystatin C, C-reactive protein, and noradrenaline.[94,95]

Beyond positive airway pressure devices, changing the type of dialysis in renal failure patients has been shown to improve sleep apnea. As mentioned earlier, nocturnal HD compared with conventional HD may improve AHI severity[4] (Figure 134-4). Nocturnal HD may also lead to a decrease in sleep percent time spent at oxygen saturation less than 90%, a decrease in heart rate, and an increase in vagal tone.[96] Nocturnal HD may also result in a decrease in chemoreflex response and improve AHI.[85]

Nocturnal peritoneal dialysis (NPD) may also result in improvement in OSA compared with continuous ambulatory peritoneal dialysis (CAPD). When subjects matched for demographics, BMI, comorbidities, adequacy of dialysis, and peritoneal transport properties are converted from NPD to CAPD, AHI worsens markedly.[97] It appears that NPD is more effective in treating OSA because of its greater efficacy in fluid removal based on greater reduction in total body water,

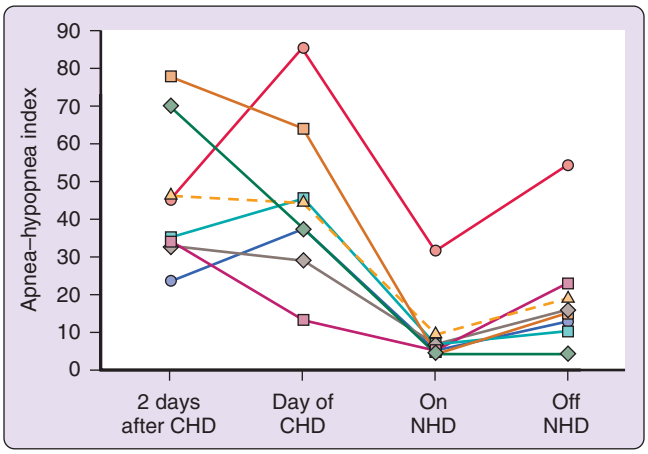

Figure 134-4 Apnea-hypopnea index (AHI) in seven patients with a baseline AHI >15 events/hour. Mean values are represented by the *broken line*. CHD, Conventional hemodialysis; ND, nocturnal hemodialysis.

as measured by multifrequency bioelectrical impedance analysis, and in percent reduction in hydration fraction, despite similar targeted dialysis regimen adjusted to achieve euvolemia and a weekly Kt/V_{urea} (measure of dialysis adequacy) of 1.8 to 2.1 in both groups.[97] Magnetic resonance imaging assessment of the upper airways confirms significant reductions in nasopharyngeal and oropharyngeal volumes, minimal pharyngeal cross-sectional area, and tongue volume enlargement after converting to NPD from CAPD.[98]

Several studies report improvements in OSA after renal transplantation. Since earlier reports of significant improvement in AHI after transplantation,[99] there have been conflicting results reported by others. Several reports suggest that not all patients undergoing transplantation had resolution of their OSA, with some suggesting that less than half of their study patients had resolution.[100-102] The small sample sizes of these reports and varying durations between the pretransplantation and posttransplantation PSG (which may result in BMI increase due to immunosuppressives) may account for the conflicting results. However, taken together, these reports suggest that some patients with OSA may significantly improve after transplantation.

CPAP should still be considered the initial therapy of choice for patients with OSA and CKD because of its proven efficacy. For CKD patients, there appears to be other means by which OSA can be controlled. These additional considerations include converting from conventional to nocturnal HD or from continuous ambulatory peritoneal dialysis to nocturnal peritoneal dialysis. Furthermore, transplantation may potentially improve OSA, but this effect may be counterbalanced by the potential weight gain associated with medications required as part of the antirejection regimen.

CLINICAL PEARL

Concurrent sleep disorders are common in patients with CKD, and the prevalence of various sleep disorders seems to increase with worsening kidney function. Because of coexisting comorbidities, their presenting symptoms may be atypical or initially attributed to other conditions. Thus it is important for the clinician to specifically inquire about coexisting sleep disorders such as insomnia, RLS, or sleep apnea. When employing pharmacologic therapies, clinicians must carefully consider renal metabolism of some medications and appropriately adjust the dose or timing of the medication. Treating these coexisting disorders can substantially improve patients' quality of life and, particularly in the case of sleep apnea, may also mitigate worsening morbidities.

SUMMARY

Sleep disturbances such as insomnia, RLS, PLMS, and OSA are common across the spectrum of CKD. The pathophysiologic mechanisms that drive these sleep disorders in CKD patients are complex and incompletely understood. What is appreciated is that sleep disorders have significant effects on morbidity, quality of life, functional status, and possibly mortality in this population. Therefore an assessment of sleep-related complaints and sleep disorders should be pursued in all CKD patients. Treatment of sleep disorders may be complex and unique to this population because of the nature of their underlying medical disease.

Chapter 135

Sleep in the Critically Ill Patient

Siavash Farshidpanah; Margaret A. Pisani; E. Wesley Ely; Paula L. Watson

Chapter Highlights

- Sleep disruption was for many years regarded as an unfortunate, unavoidable, and relatively unimportant consequence in the course of critical illness management. Improved understanding of the potential importance of sleep in recovery has made sleep in the intensive care unit a new area of research and clinical focus.
- Poor sleep quality is common in critically ill patients, and efforts to understand the causes and promote improved sleep may result in a positive impact on patient outcomes such as delirium, time on mechanical ventilation, and post-illness mood disorders.
- Efforts to study sleep in critically ill patients are currently labor-intensive, expensive, and limited by electroencephalographic abnormalities caused by neuropathology and frequently used psychoactive medications. However, clinicians and researchers should be excited about more cost-effective technology and new proposed staging criteria based on the most recent data.
- Improving the sleep of critically ill patients should begin with optimizing environmental factors and minimizing use of medications known to disrupt sleep. If necessary, pharmacologic sleep aids can be used.

INTRODUCTION

More than four million adults are cared for in U.S. intensive care units (ICUs) each year.[1,2] With advancements in care, more patients are surviving their critical care illness, and significant efforts are now being directed toward optimizing modifiable risk factors that can further improve ICU outcomes. Nearly 60% of patients report sleep disruptions as a major cause of distress during their ICU stay. Poor sleep quality during critical care illness has been described for the past four decades[3-6] and was previously perceived as an unavoidable effect of ICU management. In addition to emotional distress, sleep deprivation in this group of patients has been hypothesized to contribute to impaired immune function, prolongation of mechanical ventilation, delirium, and cognitive dysfunction. In this chapter, we will review the methods available to measure sleep, the characteristics of sleep in ICU patients, clinical outcomes that might be adversely affected by poor sleep quality, and, last, methods to improve sleep in critically ill patients.

MEASUREMENT OF SLEEP IN THE INTENSIVE CARE UNIT

Sleep can be evaluated in three domains: quantity, quality, and pattern of distribution. Nursing logs and systematic observation by health care staff would be an obvious, cost-effective tool to evaluate sleep. Despite a few early efforts that found good correlation between nursing observation and polysomnographic (PSG) measures of sleep,[7,8] other studies show a typical overestimation on the part of health care staff and an underestimation by patients.[4,5,9,10] PSG is the gold standard method for measuring sleep in ICU patients, although other modalities have been studied, and alternative approaches are being explored.

Polysomnography

PSG is regarded as the most reliable method for measuring sleep in critically ill patients. However, several important factors hinder its widespread use to evaluate sleep in this population. Trained personnel are required to conduct the initial setup and maintain electrode signal quality throughout the study. The use of electroencephalographic (EEG) electrodes and leads may interfere with routine patient care needs, and the quality of PSG recording may be compromised by electrical interference from the many patient care devices found in the typical ICU room.[11] The measurement of sleep is also complicated by the atypical sleep patterns frequently present in ICU patients. Critically ill patients frequently experience as much sleep time during the day as during the night[12] (Figure 135-1). Therefore, if a full assessment of a patient's sleep is to be obtained, 24-hour recordings are necessary.

Although PSG is the gold standard for sleep measurement, there is now a widespread acceptance by researchers in the field that the standard Rechtschaffen and Kales (R&K) and even the newer American Academy of Sleep Medicine (AASM) guidelines for scoring are not reliable in critically ill patients.[13,14] The interpretation of EEG data in this population is complicated by the effects of both the underlying illness and the multiple psychotropic medications that these patients receive during their ICU stay.[15-17] Cooper and colleagues[12] were the first to note the difficulty in applying

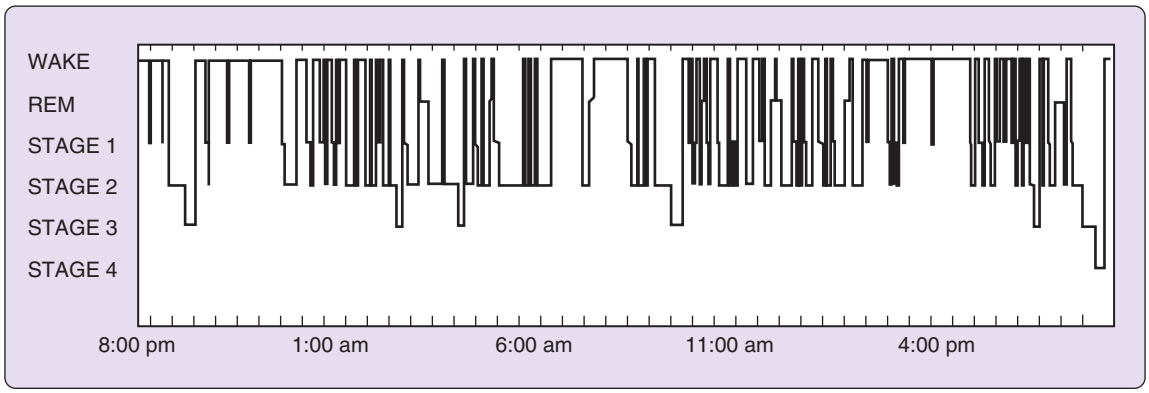

Figure 135-1 A 24-hr hypnogram of an ICU patient. Sleep during critical care illness is severely fragmented and distributed evenly across 24 hours. Oftentimes, a clear circadian rhythm is not seen in these patients. REM, Rapid-eye movement sleep. (From Cooper AB, Thornley KS, Young GB, et al. Sleep in critically ill patients requiring mechanical ventilation. *Chest* 2000;117:809–18, with permission.)

standard scoring criteria to this population, finding that electrophysiologic sleep was not identifiable in 12 of 20 ICU patients in their study. These 12 patients either lacked the normal transitions of sleep stages or had slowing of EEG activity—sometimes without evidence of EEG activation to painful stimuli and, thus, more consistent with coma than sleep. These patients were noted to have received higher doses of sedative medications than patients with EEG-identifiable sleep.

Further evidence of the limitations of R&K criteria was noted by Ambrogio and colleagues[18] who compared manual sleep assessment to spectral analysis. They found that the interobserver reliability of R&K methodology was poor ($\kappa = 0.19$). Two other research groups have also evaluated the limitations of R&K criteria in critically ill patients and have proposed new scoring criteria. Drouot and colleagues,[19] in a study of 57 ICU patients who had been free of sedative and other psychotropic medications for at least 48 hours, found that R&K sleep scoring was not feasible in 16 (28%) patients. They recommend adding two new states: atypical sleep and pathologic wakefulness (Figure 135-2). Watson and colleagues[20] encountered similar limitations of the standard scoring criteria in their study of 37 mechanically ventilated patients. As previously described by Cooper and colleagues and by Drouot and colleagues, patients in this study also had atypical sleep characterized by a lack of K-complexes and sleep spindles as well as pathologic wakefulness. As opposed to the study by Drouot, patients receiving psychotropic medications were included in this investigation. Watson and colleagues proposed a comprehensive scoring criteria that incorporated both stages of encephalopathy (based on previous neurology literature[21]) and typical sleep (Figure 135-3, *A* and *B*). This approach allowed the co-evaluation of sleep state and consciousness in critically ill patients throughout the course of their illness even while pathologic brain activity was present. While there is controversy on whether this approach should be called a *sleep* staging method,[22,23] there is evidence that tracking the pathologic brain waves can lead to discoveries regarding prognosis and outcomes (Figure 135-4).[24,25] At this time, there are no scoring criteria that have been adequately validated for measurement of sleep in critically ill patients, and more research is needed in this area.

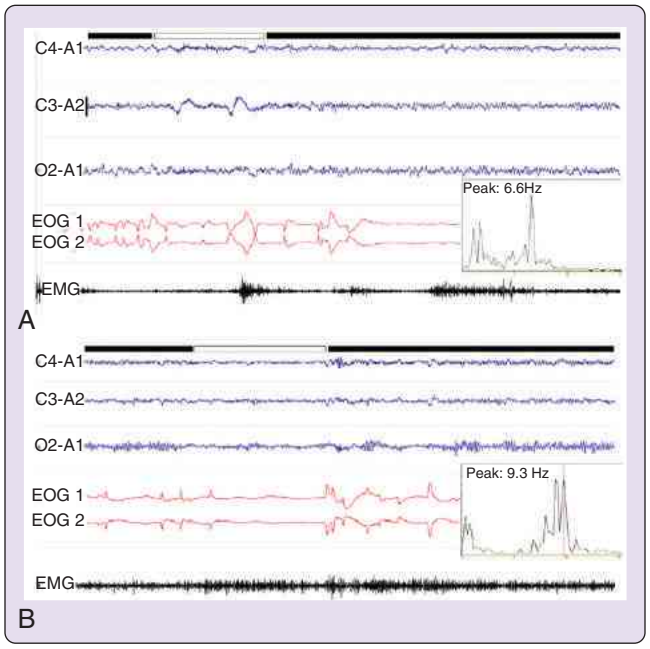

Figure 135-2 Polysomnographic features of critically ill patients showing pathologic wakefulness. **A,** EEG shows slow background frequency with numerous rapid eye movements typical of wakefulness and high submental EMG activity. These findings were obtained while the patients were fully awake. *Inset* shows spectral power with peak EEG frequency. **B,** Alpha waves in a normal wake EEG occurring only during periods with closed eyes. *Inset* shows spectral power with peak EEG frequency. The *white horizontal bars* indicate periods with open eyes, and the *black bars* indicate periods with closed eyes. EEG, Electroencephalogram; EMG, electromyogram. Processed Electroencephalographic Monitors

Given the difficulty and expense of performing PSG, there has been interest in the use of processed EEG devices to monitor sleep in the ICU. Processed EEG monitoring tools, such as the bispectral index (BIS) monitor, were introduced into clinical care in the 1990s to monitor levels of sedation in patients undergoing anesthesia. These devices record brain

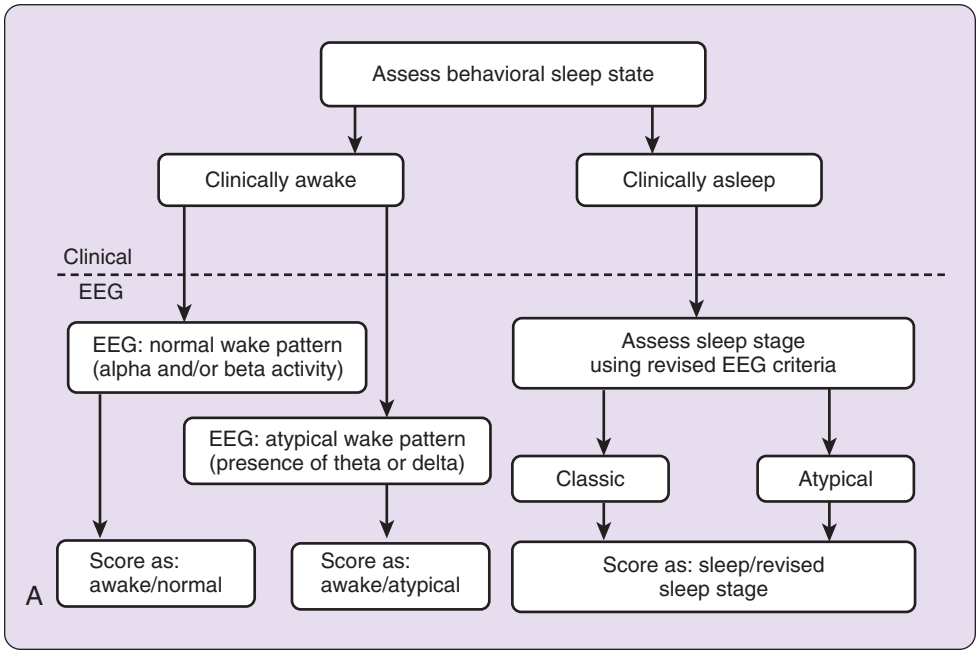

Figure 135-3 **A,** Proposed approach to scoring sleep in critically ill patients. Due to the presence of pathologic wakefulness, a clinical assessment of the behavioral sleep state is first necessary. It should then be determined whether the EEG pattern is normal. If normal, classic sleep stages can be used. If the EEG pattern is abnormal, atypical stages as demonstrated in **B** should be used. **B,** Six proposed atypical sleep stages noted on EEG obtained during 24-hr illness. **A_t1** (atypical stage 1), characterized by having at least 10% alpha and/or theta activity (indicated by the *arrow*) but may also include delta activity (indicated by the *circle*). **A_t2** (atypical stage 2), characterized by the presence of polymorphic delta but with the presence of background beta, alpha, or theta activity (indicated by the *arrow*). **A_t3** (atypical stage 3), characterized by a polymorphic delta activity without the presence of background beta, alpha, or theta activity. **A_t4** (atypical stage 4), defined by a burst-suppression pattern, intermittent EEG activity alternating with periods of isoelectric EEG activity is classified as atypical stage 4. **A_t5** (atypical stage 5), defined by a suppression pattern EEG, a very low-voltage EEG activity (<20 μV amplitude) is classified as atypical stage 5. **A_t6** (atypical stage 6), characterized by a complete lack of EEG/cortical activity as shown. EEG, Electroencephalogram. (From Watson PL, Pandharipande P, Gehlbach BK, et al. Atypical sleep in ventilated patients: empirical electroencephalography findings and the path toward revised ICU sleep scoring criteria. *Crit Care Med* 2013;41:1958–67, with permission.)

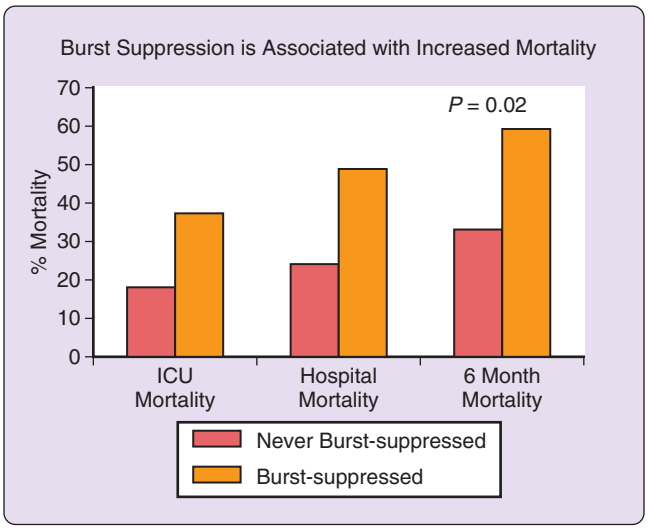

Figure 135-4 Presence of burst suppression is associated with increased mortality. (From Watson PL, Shintani AK, Tyson R, et al. Presence of electroencephalogram burst suppression in sedated, critically ill patients is associated with increased mortality. *Crit Care Med* 2008;36:3171–7, with permission.)

activity via two to four leads placed on the forehead and report a numerical value calculated from analysis of the EEG waveforms that correlates with clinical depth of anesthesia in healthy volunteers.[26] Reference values of 90 to 100 infer an awake or conscious clinical state, whereas a value of zero reflects isoelectric EEG activity.[27,28] Effort has been made to evaluate the utility of BIS in assessing the level of sedation outside of the operating room, including various ICU settings.[29-36]

At the time of this printing, two studies have aimed to use BIS in the evaluation of sleep rather than sedation or consciousness levels in critically ill patients. Nicholson and colleagues[37] observed sleep in 27 medical ICU patients during the recovery phase of critical illness and used BIS values to classify patients as awake (if more than 85), light sleep (if 60 to 85), slow wave sleep (SWS) (if less than 60), or as rapid eye movement (REM) sleep (if BIS>60 with reduced electromyogram [EMG]). Bourne and colleagues[38] used BIS monitors in a study aimed at evaluating the effects of exogenous melatonin on sleep (which they defined as a BIS level below 80) in the ICU. However, both studies relied on previously published BIS values for sleep identification that had been established in healthy volunteers,[39,40] and neither study used PSG as a reference to stage sleep. No study to date has validated BIS measurement of sleep in ICU patients by comparing BIS to PSG as a standard.

The EEG in critical illness is frequently altered, showing a slowing in EEG frequency even in the wake state, which will skew the BIS value to lower than expected for a patient's level of consciousness. Conversely, the BIS signal is subject to electrical interference, which can lead to spuriously high BIS values and, thus, overestimating a patient's level of consciousness. Additionally, the overlap of the BIS values for a given stage of sleep likely prevents its use as a depth of sleep monitor.[41] These issues currently decrease the reliability of processed EEG monitors when used alone for measurement of ICU sleep.

Actigraphy

Actigraphy has been widely used in research for nearly three decades as a surrogate measure for sleep in clinical practice.[42] Although not officially recommended for monitoring of sleep in the ICU setting, many groups have attempted to validate its use in this population with varying degrees of success.[43] Actigraphy in critically ill patients does not correlate well with PSG[44] and lacks specificity for identifying sleep transitions.[45,46] This is not surprising, given that the basis of actigraphic "sleep" is lack of limb movement, which may occur for various other reasons (neuromuscular blockade, physical restraint, acute neurologic deficit, ICU myopathy, etc.) in critically ill patients. Nonetheless, the relative unobtrusive nature and cost-effectiveness of this tool make it appealing for use in long-term follow-up studies on the effects of sleep-promoting interventions.

Devices Based on Physiologic Changes during Sleep

As discussed elsewhere in this volume, there are well-documented autonomic changes that occur during the different stages of sleep. Investigators have tried to capitalize on these physiologic variations to develop automatic scoring algorithms that can identify sleep and its divided stages. These devices are unlikely to be useful in ICU patients. By virtue of their critical illness, patients' physiology is unlikely to be at baseline, and their autonomic response is often artificially manipulated via medications to acutely stabilize the patient in the ICU. Therefore, despite their validation in healthy subjects,[47,48] it is extremely doubtful that such devices can be reliably used for monitoring sleep in critically ill patients.

It is out of the scope of this chapter to provide a comprehensive list of devices or techniques and review the evidence. Currently, the gold standard to assess sleep in the ICU remains to be PSG. As a whole, the atypical EEG of ICU patients coupled with changes in guidelines from R&K to AASM have created a heterogeneous landscape of reported data over the past 40 years. However, despite these limitations, noticeably persistent patterns are observed when evaluating sleep in the ICU. In the next section, we will review findings from currently reported studies to review characteristics of sleep in the critically ill.

CHARACTERISTICS OF SLEEP IN THE INTENSIVE CARE UNIT

The characteristics of sleep can be broadly divided into those reported subjectively by patients themselves and those measured objectively by a range of assessment tools used by health care staff or clinical researchers.

Subjectively Reported Quality of Sleep

The overall results from studies to date reveal a consistent perception of poor sleep quality.[5,10,49,50] Patients specifically complain about trouble initiating sleep, experiencing lighter sleep, and noticing frequent awakenings with significant difficulty returning to sleep.

Subjective sleep quality reports are based on survey tools that patients complete at variable time points during their ICU stay. A few traditional sleep surveys, such as the Pittsburgh Sleep Quality Index (PSQI), have been applied in ICU

populations. Other tools, such as the Sleep in Intensive Care Questionnaire and the Richards Campbell Sleep Questionnaire (RCSQ), have been specifically developed for and validated in critically ill patients.[5,51] These tools are cost-effective, readily available, and easily applied by novice personnel without significant need for training. Although they have been compared even to PSG findings in ICU patients,[7,8,51,52] the chief limitation of self-report instruments for ICU patients is that sufficient cognitive function and memory recall function is required to render the survey reliable. For example, a study by Bourne and colleagues[46] reported that 20% of patients were unable to complete the RCSQ mainly due to delirium. A study led by Frisk[53] found an even higher failure rate, estimating that 50% of ICU patients were neither conscious nor orientated enough to complete the RCSQ. Although patient self-reports are helpful in providing an intimate look into the psyche and perception of critically ill patients,[54] a quantitative analysis of sleep may be more reliable.

Objectively Reported Sleep

The inherent limitations of objectively assessing sleep in the ICU were discussed earlier in this chapter. Despite these known difficulties, investigators have remained persistent in their efforts, and the existing sleep characteristics data will be reviewed next.

Critically ill patients appear to spend a prolonged time in non–rapid eye movement sleep stages N1 and N2.[7,44,55,56] Mild variations are reported among different ICU cohorts, but this difference is unlikely to be clinically significant. For example, in surgical ICU patients, N1 and N2 sleep comprised 96% to 99% of total sleep time (TST).[4,57,58] Meanwhile, medical and trauma ICU patients had 76%, 83%, and 80% to 100% of TST in N1 or N2 sleep, in three separate studies.[10,12,59]

The majority of data in critically ill patients show a decrease in SWS ranging from less than 1% [58] to 9 ± 18% of TST.[60] However, a study by Broughton and Baron[61] reported prolonged SWS up to 25% in patients immediately after myocardial infarction. More recently, Cabello[62] found SWS to be near the upper limits of normal (19% TST) in long-term ventilated medical ICU patients.

In the critically ill population, REM sleep is reduced across all ICU settings. Studies have shown a moderate decrease (10% to 15% of TST),[10,61,62] dramatic reduction (0.02% to 0.36% of TST),[20,58,63,64] including absence of REM sleep[60] in critically ill patients. Although no formal hypothesis exists, several explanations for the diminution of REM are worth considering. Some of the most commonly used medications in ICU (e.g., benzodiazepines, opioids) are known to suppress REM sleep.[65] Unconventional transitions through sleep stages in ICU patients have been reported,[12,55,58] which may mean that the normative data in the healthy cohort do not directly apply to the ICU. Another explanation may involve the discontinuous nature of sleep in the ICU precluding the natural progression toward REM throughout the night.

Reports on TST vary between studies that monitored only overnight sleep or an entire 24-hour cycle. If only overnight sleep is recorded, there is a trend toward decreased sleep ranging from 1 to 6 hours.[3,4,10,66] However, TST is surprisingly within the normal range of 6 to 8 hours when all sleep during a 24-hour cycle is captured.[12,57,58,60] Also, as might be expected, in patients receiving sedative mediations, the total "sleep" time is prolonged (10.9 to 18.9 hours).[67] The caveat is that sleep is scattered over 24 hours and markedly fragmented (Figure 135-1).

Arousal indices are difficult to assess in this population as inter-rater variability and scarcity of concurrent nursing documentation of extrinsic disruptions [68] complicate the reproducibility of these data. Nonetheless, indices of fragmentation are generally high during the sleep of ICU patients.[69] Cabello and colleagues[62] reported a median of 29 arousals per hour (interquartile range: 19–41), whereas Edell-Gustafsson and colleagues[57] noted even higher median hourly arousals of 56.6 ± 32.6 per hour. Viewed in more practical terms, other investigators reported the mean sleep duration before an arousal occurred ranging from 3 minutes[52] to 15 ± 9 minutes.[60]

In summary, ICU cohorts report subjectively poor quality sleep in the setting of normal TST measured over 24 hours. The proportions of individual stages are deranged with an increase in amounts of N1 and N2 possibly due to frequent arousals and awakenings. A corresponding decrease in SWS as well as stage REM is also noted. Sleep appears to be severely fragmented and evenly split between night and day. This means that roughly 50% of sleep is occurring during daytime even though external disrupting factors may be at a maximal at that time.

FACTORS CONTRIBUTING TO POOR SLEEP

The disrupting factors in the ICU are likely multifactorial and interrelated; however, for the purpose of discussion, these factors can be divided into two broad categories. *Extrinsic factors* include ambient conditions in which the patient is immersed (noise level, light intensity, etc.) as well as therapeutic applications (mechanical ventilation, medications, care events, etc.). *Intrinsic factors,* such as pre-illness natural sleep tendencies, emotional state, pain, and physiologic disruptions due to critical illness itself, also play a significant role in determining sleep quality.

Extrinsic Factors

Noise in the Intensive Care Unit

The majority of studies published in this realm have implicated noise as a bothersome environmental factor. Noise can produce physiologic changes similar to a generalized stress reaction, and these effects may prevent patients from initiating or maintaining sleep.[70] Whereas some authors have implicated noise from equipment and hardware in the room,[71,72] patients have identified hearing people (i.e., health care staff) talking as the most "annoying" impedance to their sleep.[73]

The World Health Organization Guidelines for Community Noise includes specific recommendations on noise levels in hospitals.[74] Based on a review of scientific studies, they concluded that hospitalized patients are more susceptible to excess stress levels generated by intrusive environmental noise. They recommend that sound level in hospitals should not exceed 35 decibels (dB) in patient care areas. Similar guidelines are also proposed by the U.S. Environmental Protection Agency; however, in critical care areas, noise levels often exceed these recommendations.[75] To add perspective, a recording of a vacuum cleaner yields 55 to 65 dB. Although individual tolerances vary, stress reaction and quantifiable effects from sleep disturbance are seen at time-averaged sound levels as low as 30 dB and peak sound levels above 70 dB.[76,77]

Increased sound levels account for approximately one-third of arousals and awakenings in ICU studies.[10,52] In particular, increased *peak* sound levels demonstrate unfavorable effects on sleep in ICU patients.[10,76,78] Elliot and colleagues[52] showed that, despite a slight decrease in noise level at night, the ICU remained above recommended levels both during the day (53.95 dB) and at night (50.20 dB). Two studies did not find that noise was a major factor,[5,49] but both of these studies relied on subjective retrospective recall, which could have been affected if patients did not reach conscious arousal long enough to form a memory of the disturbance. Freedman and colleagues[60] subsequently evaluated sleep disruption objectively using PSG. Although they noted noise was responsible for 11.5% of arousals and 17% of awakenings, they concluded that noise is not the main disturbing factor compared to other spontaneous (non-noise) arousals.[60] In a recent study, Tegnestedt and colleagues[79] noted that 64% of disruptive sounds were caused by monitor alarms and "[staff] conversations not related to patient care," which are avoidable. Overall, noise is persistently reported as a sleep-disruptive factor in the ICU environment.

Light in the Intensive Care Unit

Patients do not identify light intensity as a major disrupting force for their sleep.[5,49] Once again, caution should be taken with data obtained retrospectively from patients, because recall bias and the intensity of other disrupting factors may overshadow the impact that they felt from lighting differences. Furthermore, patients may not readily identify the potential effect on circadian rhythm changes. Light is the most potent "zeitgeber" for regulating our circadian rhythm,[80] and the study of endogenous melatonin secretion in healthy participants indicates that luminance levels of <100 lux (present in the ICU setting) may not be sufficiently bright to suppress melatonin secretion in some individuals.[81] In a study of 57 ICU patients, Elliot and colleagues[52] noted appropriately low light levels at night (median <2 lux), but the observed daytime luminance levels were only 74 lux and, therefore, too low to entrain a 24-hour circadian rhythm. Despite the lack of recognition by the patients, a non-circadian light exposure may contribute to sleep disturbance in ICU patients.

Mechanical Ventilation

The usual accessories required for mechanical ventilation include an endotracheal tube, suctioning apparatus, bite blocks, and usually a nasogastric tube, in addition to restraints. Although this setup alone can be a source of discomfort and makes sleep more difficult, during the past decade, much attention has been paid to how various modes of mechanical ventilation affect sleep in critically ill patients. Unfortunately, most studies are limited by small numbers of subjects, confounding factors (e.g., medications, severity of illness), and varying proprietary ventilator algorithms.

Early studies showed better sleep quality with assist-control ventilation (ACV) compared to pressure-support ventilation (PSV),[56,82] whereas later investigations indicated that proportional-assist ventilation resulted in better sleep than PSV.[83] Parthasarathy and colleagues[56] noted increased fragmentation of sleep during PSV compared to ACV because of the development of central apneas; this effect was more prominent in patients with heart failure. Cabello and colleagues[62] found no difference in sleep quality between three modes of ventilation (ACV, clinically adjusted PSV, or automatically adjusted PSV), noting equally abnormal sleep in the entire study population of conscious mechanically ventilated patients regardless of the assigned mode.

More recent studies continue to show conflicting results. Andrejak[84] found better sleep quantity and quality in patients receiving pressure-control ventilation compared to those on low-PSV. Roche-Campo and colleagues[85] did not find a difference in sleep quality on PSG recordings of nonsedated tracheostomized patients when comparing low PSV to spontaneous breathing in a cross-over study design. Although the number of arousals and awakenings were similar, they noted longer TST when patients were on mechanical ventilation.[85] The same group also compared a traditional ICU ventilator to a standalone noninvasive positive pressure ventilator (NIPPV); both devices were used with an oronasal mask in hypercapnic patients in the ICU. They found that patients experienced better sleep while on noninvasive mode of ventilation (regardless of the type of device used) compared to the spontaneous breathing periods.[86]

In summary, the true effect of mechanical ventilation or individual modes of ventilation on sleep is not yet fully clear. One hypothesis is that ventilator settings that reduce the likelihood of hypocapnia lead to fewer arousals from central apneas and thus improve sleep.[56,87] Intuitively, any mode that brings about better patient-ventilator synchrony will be less likely to disrupt sleep. A confounding factor is that most patients who are mechanically ventilated in the ICU are likely to receive some degree of sedation and analgesia.

Medications

Both the use and the withdrawal of common ICU medications are often implicated in sleep disruption because they act on shared receptor pathways used to regulate sleep. Benzodiazepines and opioids are among the most commonly administered medications in the ICU. Even in healthy patients and when administered at standard doses, these medications have well-described deleterious effects on sleep architecture.[88,89] Several authors have previously reviewed the effect of medications commonly administered (Table 135-1) in the ICU on sleep architecture.[90-92]

Although sedatives and opioids are sometimes used in an attempt to improve sleep in ICU patients, these medications are unlikely to provide the same restorative benefits as natural sleep. Benzodiazepines and opioids have been shown to decrease SWS, in favor of increasing N1 and N2 sleep, whereas propofol increases SWS and decreases REM sleep.[93] Additionally, benzodiazepines decrease sleep latency and REM sleep while increasing N2 sleep and possibly extending total sleep time.[89,94] Other classes of medications often used in the ICU, such as beta-antagonists and vasoactive agents, have also been shown to negatively affect sleep in healthy volunteers. Beta-antagonists prolong sleep latency and decrease the amount of REM sleep.[95] Norepinephrine and epinephrine are believed to reduce SWS and REM due to their stimulation of alpha-1 receptors as well as increase arousals by stimulating the reticular activating system.[96]

Sleep induced by sedatives is believed to differ in important aspects from normal sleep.[90] For example, a loss of transition through the sleep cycles and changes in sleep patterns are generally present regardless of the sedative administered. Dexmedetomidine sedation has been theorized to offer a

Table 135-1 Common Medications Used for Patients in the Intensive Care Unit

Drug Class	Examples of Drugs	Effect on Sleep Architecture	Potential Mechanism
CNS			
AED	Phenobarbital, carbamazepine, phenytoin	Very sedating. AEDs tend to ↑ TST, ↓ sleep latency. May ↑ SWS	Action on neuronal sodium influx in glutamate channels or GABA type A
TCA	Amitriptyline, imipramine, nortriptyline, desipramine, doxepin, clomipramine	Very sedating; suppresses REM sleep, ↑ TST, ↑ stage 2 sleep	Antimuscarinic activity, α1-receptior stimulation
Anxiolytic BzRA	Alprazolam, lorazepam, diazepam, oxazepam, propofol	Very sedating, ↑ TST, ↓ sleep latency ↓ SWS duration, ↑ stage 2 sleep same	GABA type A receptor stimulation; may also effect endocannabinoid
SSRI	Sedating: paroxetine, fluvoxamine; "activating": fluoxetine, sertraline, citalopram	In general, SSRIs tend to ↑ TST; less sedating than TCAs and MAOIs; ↓ REM, ↓ SWS ↑ TST, ↓ SE	↑5HT activity
SNRI	Venlafaxine	TST	↑5HT activity and NE activity
Mood stabilizer	Lithium	↑ TST, ↑ SWS, ↑ stage 2 sleep, ↓ REM,	Neuronal sodium channels
Antiparkinson	Bromocriptine, levodopa	Sedating; nightmares, ↓ SWS	Dopamine
cardiovascular stimulant	Norepinephrine, epinephrine dopamine		α1-, α2-, β-receptor stimulation; D2 α1-receptor stimulation
Lipophilic β-blocker	Propranolol, pindolol, metoprolol, timolol	Activating; ↑ awakenings, ↑TWT, ↓ REM, nightmares	CNS β-blockade
α^2-receptor agonist	Clonidine, DEX	↑ Stage 1, ↓ REM, nightmares ↑ TST	α2-receptor stimulation
α1-receptor blocker	Doxazosin, prazosin, terazosin	↑ TST	α1-receptor inhibition
Analgesic	Codeine, morphine,	Sedating; ↓ SWS, ↓ REM	μ-receptor stimulation
Opioid	hydrocodone	↓TST, ↓ SE	Prostaglandin synthesis
NSAID	Ibuprofen, indomethacin, celecoxib	Activating; ↓ TST, ↓ SE, ↑ stage 1, ↓ REM	inhibition
Other			Inhibits adenosine
Methylxanthine	Theophylline	Sedating	
Antihistamine	Diphenhydramine, promethazine	Sedating	Histamine 1 receptor blockade and can have Ach effect
Corticosteroid	Dexamethasone, prednisone	Activating; ↓ REM, ↓ SWS, nightmares	↓ Melatonin secretion

Although individual reactions may vary, some of the known effects on sleep architecture should be taken into account whenever possible to decrease the incidence of sleep disturbance during critical care illness.
Ach, Acetylcholine; AED, antiepileptic drug; BzRA, benzodiazepine; CNS, central nervous system; D or DOPA, dopamine; DEX, dexmedetomidine; GABA, gamma-aminobutyric acid; MAOI, monoamine oxidase inhibitor; NE, norepinephrine; NSAID, non-steroidal antiinflammatory drug; REM, rapid eye movement sleep; SE, sleep efficiency; SNRI, serotonin norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; SWS, slow wave sleep; TCA, tricyclic and tetracyclic antidepressant; TWT, total wake time; 5HT, serotonin, serotonergic.
From Hardin KA. Sleep in the ICU: potential mechanisms and clinical implications. *Chest* 2009;136:284–94.

more restorative—perhaps natural sleep-like—state than gamma aminobutyric acid (GABA)-ergic sedatives because alpha-2 agonists act on the sleep pathway at the brainstem level, whereas GABAergic agents act at the level of the hypothalamus.[97] Patients are more arousable when sedated with alpha-2 agonists compared to GABAergic agents such as benzodiazepines and propofol. This property is desired to facilitate weaning from mechanical ventilation, but it may not be conducive to the maintenance of sleep in a noisy ICU.

Acute medication withdrawal in ICU patients, the incidence of which is likely underestimated, may be an important issue affecting the sleep physiology of patients.[90] For example, in cases when REM-suppressing medications (such as benzodiazepines and opiates) are abruptly discontinued, the recovery sleep may have a disproportionately high percentage of REM sleep.[98] In the critically ill, this may play a more important role because cardiac and respiratory instability are greatest during REM sleep. Therefore, a gradual withdrawal of these agents whenever possible may reduce disruption of sleep neurophysiology.

Patient Care Events

Hands-on assessment at frequent intervals is a characteristic and necessary part of ICUs. In the reported literature, the number of direct patient contact occurrences ranges from 40 to 60 per night.[99,100] Although efforts should be made to coordinate care in such a way that allows for consolidated sleep times, only about 10% of arousals and awakenings have been shown to be attributable to patient-care activities.[10]

Intrinsic Factors

Sleep disruptions are not always clearly attributable to external causes and may be due to intrinsic factors that directly interfere with sleep. Some studies have implicated age because older patients may have a lower arousal threshold.[101] However, findings have been inconsistent with some showing older patients slept better in the ICU,[49] whereas others found age not to be a factor in determining quality of sleep in the ICU.[5] Pre-illness factors, such as psychological disorders (e.g., anxiety, posttraumatic stress disorder, panic attacks) as well as poor sleep habits and inconsistent bedtime routines, have been associated with disturbed sleep quality during acute hospitalization.[49,102] Additionally, circadian dysregulation and factors inherent to critical illness itself have been suggested as possible sleep-disruptive forces.

Disrupted Circadian Rhythm

The role of melatonin in the sleep of critically ill patients is the subject of renewed and increased attention. Although clinically not very useful, serum melatonin and urine 6-sulfatoxymelatonin (6-SMT, a melatonin metabolite) levels are accepted biologic markers for circadian rhythm.[103] In ICU cohorts, several studies show that melatonin secretion is decreased and does not follow a typical circadian pattern.[6,63,104-107] In a recent study of sedated and mechanically ventilated ICU patients, the authors noted a pronounced temporal disorganization of circadian rhythm. They report that most subjects exhibited preserved, but phase delayed, excretion of 6-SMT, implying a free-running circadian pacemaker.[63] Variations in the body core temperature acrophase in critically ill patients also suggest that the circadian rhythm is abnormal.[108] However, in contrast to these studies, Mundigler and colleagues[109] demonstrated an opposite effect in septic patients, showing persistently elevated levels of melatonin, which they hypothesized play a role in immune modulation and possibly contribute to the increased sleep noted during sepsis.

Importantly, some commonly used continuous infusions in the ICU (e.g., catecholamines and opioids) also affect melatonin secretion.[110] As reviewed earlier, sleep distribution and efficiency are abnormal in ICU patients; however, the role of decreased, non-circadian melatonin secretion as a contributing factor is still unclear. The use of exogenous melatonin to treat sleep disruption in the ICU is discussed later in the chapter.

Critical Illness

Acute illness can exacerbate sleep disruption and increase the need for sleep.[91] Data suggest that critically ill patients with higher severity of illness scores have greater sleep disturbance, as well as abnormal electrophysiologic sleep patterns showing absent sleep stages and increased low amplitude slow waves.[12,67] Freedman and colleagues[60] noted low-voltage mixed frequency or slow waves in nonsedated critically ill patients that had sepsis or positive blood cultures. These EEG changes were recorded both while the patient's eyes were open and closed, which was thought to reflect a dissociative state of consciousness reflecting neither normal sleep nor wakefulness.[60,111] This is similar to the pathologic wakefulness described by Drouot and colleagues[19] and Watson and colleagues.[64] One theory is that chemokines, such as interleukin-1 (IL-1) and tumor necrosis factor, are released during sepsis and induce a centrally mediated somnogenic effect[112,113] (Figure 135-5). Extending the hypothesis, Hardin[91] cites a possible protective effect because REM sleep, a vulnerable period associated with more cardiovascular instability, is significantly decreased in critical care illness (and sepsis, specifically).

All in all, multiple factors disturb sleep in critically ill patients. Some elements of extrinsic and intrinsic disrupting forces may be unavoidable in the setting of acute treatment. More research is necessary to determine which disrupting factors are associated with undesirable sleep-related ICU outcomes.

SLEEP-RELATED INTENSIVE CARE UNIT OUTCOMES

As a research field, sleep during critical care illness is still in its infancy, and, therefore, robust long-term ICU outcomes are not yet available. There is, however, growing evidence that disrupted sleep during the ICU negatively affects outcomes both during and following critical illness. Data from non-ICU subjects and animal studies indicate that sleep deprivation is adversely associated with immune and respiratory dysfunction. Specific data in ICU survivors associate poor sleep with worse psychological, neurocognitive, and quality of life (QoL) measures. Even after discharge, ICU patients report long-term sleep disruption. Overall, outcomes research in critically ill cohorts is challenging due to the many confounding factors, the presence of recall bias, and the absence of a true control group for comparison. Therefore, in this section, we will also consider hypotheses based on animal data, healthy volunteers, and non-ICU subjects.

Immune System and Healing

The effects of sleep deprivation on the immune system have not yet been directly studied in ICU populations. Given the vital role of host defense during critical illness, this is an important area for future research. See Figure 135-5 for proposed immune pathways involved in critically ill patients. In addition to cellular and humoral immunity, altered cytokine production is also implicated in wound healing.[114,115] Protein synthesis and metabolism have well described diurnal patterns and likely play a role in recovery from acute illness.[116-118] Patients in the ICU suffer from circadian dysregulation that may alter this diurnal pattern and further complicate their recovery. It is unclear whether the negative effects on immune function are associated with chronic versus acute sleep loss or sleep fragmentation. In a small study of healthy young males, oxygen consumption and carbon dioxide (CO_2) production increased during experimentally fragmented sleep but returned back to baseline during the recovery sleep period.[119] Furthermore, abnormalities in cellular metabolism, nitrogen balance, and hormonal secretions have been described in both sleep-deprived and critically ill patients; see Figure 135-6 for the suggested overlapping features.[69,120]

Respiratory Dysfunction

Sleep disruption in critically ill patients may increase the risk for respiratory muscle weakness, upper airway dysfunction, and sleep-related breathing disorder. In a classic article involving 30 healthy male volunteers, Chen and Tang[121] reported a decrease in respiratory muscle endurance after 30 hours of

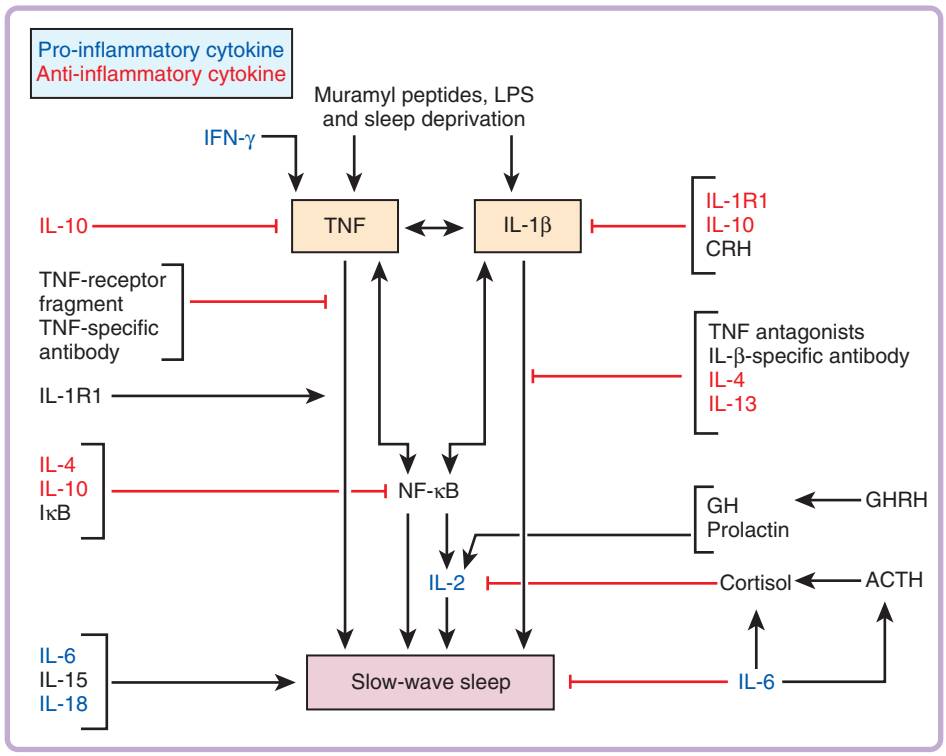

Figure 135-5 An overview of proposed immune mechanisms involved in sleep. This is not intended to be comprehensive but rather to illustrate some of the reciprocal effects of sleep and cytokines. In general, pro-inflammatory cytokines induce sleep, whereas anti-inflammatory cytokines inhibit sleep. ACTH, Adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; GH, growth hormone; GHRH, growth-hormone-releasing hormone; IκB, inhibitor of NF-κB; IL, interleukin; IL-1R1, type 1 interleukin-1 receptor; LPS, lipopolysaccharide; NF-κB, nuclear factor-κB; TNF, tumor necrosis factor. (From Bryant PA, Trinder J, Curtis N. Sick and tired: does sleep have a vital role in the immune system? *Nat Rev Immunol* 2004;4:457–67.)

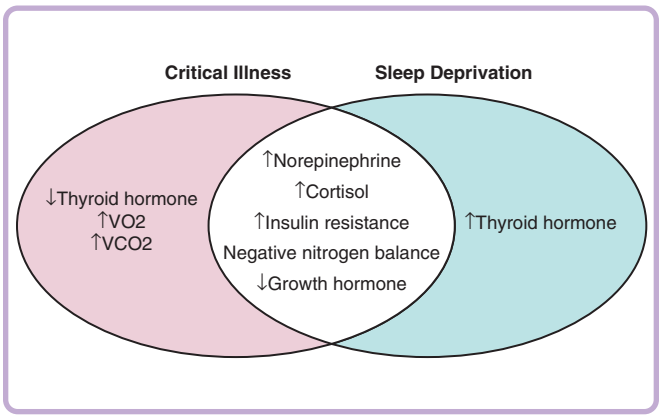

Figure 135-6 The overlapping metabolic and hormonal changes seen in sleep deprivation and critical illness. Although definitive studies in ICU patients are still lacking, several investigators have alluded to the similarities between these two states.

sleep deprivation. Leiter and colleagues[122] observed blunting of genioglossus EMG response to CO_2 as a result of sleep deprivation (which was worse with advanced age). In non-ICU patients with chronic obstructive pulmonary disease, Phillips and colleagues[123] noted a decrease in pulmonary function after only one night of sleep loss. In a small study of healthy subjects, Series and colleagues[124] demonstrated that increased upper airway collapsibility occurred primarily with sleep fragmentation rather than sleep deprivation per se. Taken together, these factors are hypothesized to either precipitate or exacerbate obstructive sleep apnea (OSA) in susceptible ICU patients. Therefore, some authors have argued in favor of early evaluation for sleep-related breathing disorder in suspected patients.[125,126] This may be particularly important for at-risk spontaneously breathing ICU patients for whom initiating NIPPV should perhaps be considered.

The data in animal models and non-ICU patients support the need for further investigation in order to optimize respiratory outcomes and prevent unnecessarily prolonged mechanical ventilation.

Neurocognitive Effects

The modifiable risk factors that can lead to neurocognitive dysfunction and delirium in the ICU have been extensively explored in the past decade and now include sleep. In other populations such as those with OSA, sleep fragmentation has been shown to result in a broad range of neurocognitive deficits that improve with treatment. Chronic partial sleep deprivation also causes neurocognitive deficits.[127] Because both sleep fragmentation and partial sleep deprivation are common in ICU patients, it is likely that poor sleep quality plays a role in the neurocognitive dysfunction frequently seen in these patients.

Delirium, a form of acute brain dysfunction commonly seen in ICU patients, has been implicated as both a cause and a consequence of sleep disruption. However, until the exact

mechanism is identified, it is impossible to differentiate whether sleep disruption leads to brain dysfunction or vice versa.[128,129] Delirium occurs in 20% to 50% of ICU patients with low severity of illness and 80% of those receiving mechanical ventilation.[130] Roche-Campo and colleagues[129] were the first to report evidence of a possible association between sleep disturbance noted on PSG and incidence of delirium in ICU. Subsequently, Trompeo and colleagues[94] found a 73.3% incidence of delirium in surgical ICU patients and noted that delirium was independently associated with sleep disturbance. More research is needed to investigate the specific role and possible dose–response relations between delirium and sleep in ICU patients. However, there may be a benefit in an integrated approach to address both sleep disruption and delirium because each has been independently associated with worse long-term outcomes.[131]

Psychological Effects and Quality of Life

Loss of sleep in a critical care setting is associated with decreased subjective QoL.[132,133] The negative effect on QoL lasts for variable periods of time following ICU discharge.[5,134-137] Survivors of ICU often develop depression, anxiety, and posttraumatic stress disorder, any of which can lead to sleep disruption and decreased quality of life.[138-140] It is unclear whether depression, anxiety, and delirium lead to poor sleep or vice versa. Most studies to date were performed by interviewing subjects retrospectively and, therefore, may be biased by the patients' poor recall.

Sleep During Post–Intensive Care Unit

Many patients continue to report sleep disruption long after their ICU stay. Sleep patterns may take days to months to normalize.[61,137,141-143] For example, survivors of the acute respiratory distress syndrome who reported sleep disturbance during their ICU admission noted persistent changes in their sleep quality 6 months or more after hospital discharge.[144] A study of cardiothoracic and neurosurgical ICUs enrolled 222 patients and used surveys (RCSQ) to retrospectively inquire regarding their sleep pre-ICU, while they were in the ICU and on the hospital ward.[137] Eighteen percent of participants reported insomnia prior to ICU admission, 73% reported poor sleep in the ICU, and 68% reported poor sleep on the hospital ward. Using the PSQI, 62% of participants noted poor sleep at 2 months, and 57% had poor sleep at 6 months. Examination of sleep quality over time showed that 7% of participants had poor sleep quality at all five time points, 10% had poor sleep that began in the ICU and continued out to 6 months, and 16% reported poor sleep after hospital discharge only. Choi et al[145] examined self-reported physical symptoms in 28 adult medical ICU survivors at 2 weeks, 2 months, and 4 months post-ICU discharge. Across all time points, sleep disturbance was one of the top complaints reported.[145] In a randomized controlled trial evaluating health status and QoL in 195 survivors of critical illness the authors assessed sleep at one, eight and 26 weeks after hospital discharge. Fifty percent of patients reported moderate to severe sleep disturbance at one week and one-third of patients were still reporting sleep disturbance at 26 weeks.[136] In addition, there were associations with poor sleep and worse scores on all measures of psychological outcomes at all three time points.

Patients' perceptions of the ICU vary, and it is recognized that, while some patients have clear memories of their ICU stay, others often have no memory of false memories. Further study is needed to clarify the impact of sleep quality during the ICU and hospital course on post-ICU sleep and to determine the best ways to prevent and treat post-ICU sleep disturbances.

MANAGEMENT OF SLEEP

In order to promote better sleep in the ICU, a multifaceted approach is necessary. The first step should include optimizing the environment in which the critically ill patient is expected to sleep. When possible, psychological and physical comfort should be addressed prior to initiating pharmacologic therapy for sleep.

Among the modifiable environmental factors, noise and light have been the most frequently studied. Applying earplugs, eye masks, and "white noise" sound machines improved sleep quality in various cohorts of critically ill patients[9,146-149] as well as in healthy volunteers exposed to recorded ICU sounds.[150-152] Other common-sense approaches to controlling these disrupting factors include opening blinds during the day and decreasing light intensity at night as well as reducing noise from avoidable sources (e.g., television, bedside phone, staff conversations). If possible, staff pagers should be set to vibrate, and bedside monitor alarm thresholds should be set more liberally when possible. Investigators have demonstrated improved sleep in critically ill patients by implementing two "quiet time" periods from 2:00 to 4:00 PM and 2:00 to 4:00 AM, when the physiologic propensity to sleep is highest.[153,154] After implementing a multifaceted paradigm shift to promote sleep in the ICU, Kamdar and colleagues[155] noted significant improvements in nighttime noise (as perceived by patients), a decrease in the incidence of delirium/coma, and an improvement in daily delirium/coma-free status. Coordinating routines and implementing non-disturbance periods are feasible,[57,156,157] and ICU nurses report an overall interest in sleep-promoting interventions.[158]

Other alterations to routine ICU care can also be considered. Non-critical care events should be minimized as a part of an integrated strategy for sleep promotion in the ICU. For example, routine medication delivery, laboratory blood draws, bathing, and bedding changes should be clustered outside of designated sleeping periods (especially at night). Individualizing settings to improve patient-ventilator synchrony will likely decrease patient effort and arousals. The patient's baseline apnea threshold, arterial partial pressure of CO_2 during sleep, and known sleep-related breathing disorders (i.e., OSA) might possibly influence ventilator settings. A list of the patient's home medications and chemical dependencies should be reviewed for mechanisms of action and withdrawal effects that may negatively impact sleep. Patients may experience nightmares, hallucinations, and parasomnias while in the ICU. It is helpful to place calendars, clocks (that designate AM and PM), and staff names within view of the patient to facilitate frequent reorientation. Last, some holistic techniques, such as guided-imagery relaxation,[159,160] back massage,[55] and even acupressure,[161] have resulted in improved sleep in randomized controlled trials in the ICU setting.

Despite optimization of modifiable disrupting factors, carefully selected pharmacotherapy to help treat pain, anxiety, and promote sleep may be necessary. Opioids should be used to target pain control rather than sedation or "sleep." If

Table 135-2 Clinical Trials Evaluating the Effects of Exogenous Melatonin Replacement in Critically Ill Patients

Author (Year)	Study Design	Reported Results	Comments
Shilo (2000)[171] *n* = 8	• Double-blind placebo controlled • 3 mg controlled-release melatonin or placebo given at 22:00	• Treatment dramatically improved both the duration and quality of sleep • Melatonin in ICU patients may help sleep induction and resynchronization of the "biologic clock"	• Wrist actigraphy was used to measure "sleep" and disruptions • Half of the ICU patients were on a ventilator • Control group included general medicine ward patients
Ibrahim (2006)[172] *n* = 32	• Double-blind, randomized, placebo-controlled • 3 mg oral melatonin or placebo given at 20:00	• Melatonin was well absorbed, and a standard dose increased blood levels approximately 1000-fold • Failed to increase observed nocturnal sleep	• Sleep was assessed by bedside nurse observation only • Use of "extra sedation" and haloperidol was nonsignificantly higher in control group
Bourne (2008)[38] *n* = 24	• Double-blind, randomized, placebo-controlled • 10 mg oral melatonin or placebo at 21:00 for four nights	• Nocturnal sleep quantity was severely compromised in both groups at the start of the study • Melatonin use was associated with increased nocturnal sleep efficiency	• "Sleep" monitoring was done by bispectral index (BIS) as well as actigraphy, nurse and patient survey • Proposed that 10-mg dose is too high and may lead to carryover of effects; suggested 1–2 mg immediate-release dose

All patients in these studies had undergone tracheostomy placement and were not receiving continuous sedation at the time of the study.

benzodiazepines are needed to treat anxiety, short-acting or medium-acting agents are preferred over formulations with longer half-lives. Although no specific efficacy data exist for using sedating antidepressants as hypnotics agents in the ICU, trazodone is frequently used in the inpatient setting due to its desirable pharmacokinetic properties (i.e., quick onset of action with an elimination half-life of 7 to 8 hours).[162] Sedating antihistamines (e.g., promethazine and diphenhydramine) should be avoided due to possible antimuscarinic effects associated with ICU delirium and daytime "hangover" effect.[163] Haloperidol and the new "atypical" antipsychotics (e.g., quetiapine, risperidone, and olanzapine) are often used as hypnotic agents due to their sedating properties. However, when administered in the absence of documented mental disorder, antipsychotics were associated with higher ICU and hospital length of stay as well as hospital mortality.[164] For intubated patients, continuous infusions of sedatives and analgesics should be titrated for comfort rather than to induce sleep. Dexmedetomidine has been suggested as a suitable agent to help with sleep as well as sedation, given its inhibition of norepinephrine release from the locus ceruleus, although further investigation is needed.[165] Gabapentin deserves consideration in critically ill patients because it has a large therapeutic window, a favorable side-effect profile, and it has been shown to increase SWS in healthy subjects.[166] Nonbenzodiazepine, nonopioid sleeping aids, such as zolpidem and eszopiclone have not been studied in critically ill patients. The recent concerns of parasomnias and increased falls during hospital admission in patients taking zolpidem[167] render these medications less desirable for routine management of sleep disruption in the ICU.

Melatonin and ramelteon are receiving renewed interest for use in the ICU population. In addition to possible effects on sleep, studies suggest that low endogenous melatonin levels during critical illness may be associated with delirium.[168] Three investigators have evaluated the efficacy of exogenous melatonin as a sleep aid in critically ill patients with conflicting results; the findings are summarized in Table 135-2. Ramelteon is an agonist of the MT1 and MT2 melatonin receptors and is used to treat insomnia. However, despite recently reported decreased delirium incidence in the ICU, the clinical impact of ramelteon on sleep has been noted to be small in critically ill patients.[169,170]

CONCLUSION

Sleep plays an integral role in our overall health and is vital to our ability to recover from illness. More research is needed to identify the exact bidirectional relationship between sleep and outcomes from critical care illness. The duration, quality, and distribution of sleep should be considered as a routine part of patient assessment—especially in critically ill patients who are more susceptible to sleep dysregulation.

CLINICAL PEARL

Sleep in critically ill patients is extremely fragmented and distributed across a 24-hour period without an apparent circadian pattern. Patients experience a significant decrease in the restorative sleep stages—SWS and REM. Multiple factors can disrupt sleep in the ICU; they include anxiety, noise, mechanical ventilation, medication effect, and critical illness itself. The loss of circadian melatonin secretion may also play a role in ICU sleep disruption. Sleep deprivation during critical care illness is an independent risk factor for worse clinical outcomes. A team-based and interdisciplinary approach toward implementation of nonpharmacologic measures to improve sleep should be considered whenever possible. Currently, no pharmacologic agent has been approved specifically for treating sleep disturbances in critically ill patients. However, small clinical trials have reported success with melatonin.

SUMMARY

Millions of patients are treated in ICUs each year and are known to suffer poor sleep during their critical care illness. Recently, increased focus on the intersection of sleep and critical care medicine has elucidated better understanding of the importance of sleep quality in this population. Sleep is best evaluated with PSG, although some alternative techniques have been used. During critical illness, patients experience increased N1 and N2 sleep and decreased SWS and REM sleep. In the ICU, sleep is likely to be fragmented and distributed in brief interrupted periods over 24 hours, not following a circadian pattern. Common sleep-disrupting factors in the ICU are noise, deleterious medication effects, and critical illness itself. The management of ICU patients should include a team-based and interdisciplinary approach to minimize disruptive factors that prevent patients from achieving consolidated sleep. Efforts should be made to address their anxiety and to reduce avoidable noise while trying to cluster the delivery of care outside of dedicated sleep periods. Currently, no pharmacologic agent is approved for use as a sleep aid in the ICU.

Psychiatric Disorders

Chapter 136

Anxiety Disorders and Posttraumatic Stress Disorder

Andrew D. Krystal; Murray B. Stein; Steven T. Szabo

Chapter Highlights

- Anxiety and trauma-related disorders are associated with complaints of disturbed sleep. This chapter provides a review of the diagnostic criteria, sleep features, and treatment of sleep-related problems in patients with panic disorder, generalized anxiety disorder, social anxiety disorder (social phobia), and posttraumatic stress disorder.
- Abrupt nocturnal awakenings are often encountered in anxiety and trauma-related disorders such as panic disorder and posttraumatic stress disorder, in which non–rapid eye movement and rapid eye movement sleep abnormalities have been implicated, respectively.
- Treatments that target sleep can improve outcomes in patients with anxiety and trauma-related disorders and will be discussed where possible.

Anxiety and trauma-related disorders are the most common group of mental disorders, affecting more than 18% of the general population in a 1-year period.[1] The National Comorbidity Survey Replication, a large, cross-national epidemiologic survey conducted in 2001 to 2003, found that 28.8% of adults 18 years and older had a diagnosis of an anxiety disorder at some point in their lifetime.[2] Up to one third of the population experiences insomnia at any given time,[3-5] and insomnia is often comorbid with mental disorders.[3,6] Although insomnia is often a preexisting condition in individuals who experience both insomnia and an anxiety disorder and some evidence suggests that disturbed sleep is likely a risk factor for the development of anxiety disorders, the most typical pattern is for insomnia to begin concurrent with or following the onset of an anxiety disorder.[3,7-10] Thus onset of an anxiety disorder often heralds the onset of a sleep problem. which suggests that a sizable portion of the burden of insomnia in the general population is associated with—and perhaps even etiologically attributable to—anxiety disorders.

Anxiety disorders are commonly seen in primary care settings where patient complaints of sleep problems are often prominent.[11] Sleep disturbances are included among the diagnostic features of generalized anxiety disorder (GAD), separation anxiety disorder, and posttraumatic stress disorder (PTSD). Treatments targeted to sleep problems and worry, tension, and other manifestations of anxiety are often similar (e.g., cognitive or behavioral techniques, benzodiazepine medications, relaxation). The antihypertensive prazosin, which is effective for treating nightmares and sleep disturbance in patients with PTSD, is a relatively recent addition to this set of therapies.[12] Thus it is important to consider the diagnosis and treatment of anxiety disorders when caring for a patient with prominent sleep complaints. The converse is equally true: Attention to sleep problems is integral to the management of patients with anxiety disorders. Whereas sleep dysregulation has been extensively studied in depressive disorders, the polysomnographic (PSG) study of anxiety disorders is less well developed, but given the comorbidity of anxiety disorders and

depression there are likely to be some common features. PSG studies of anxiety disorders indicate that there are abnormalities in initiating and maintaining sleep and in sleep stage distribution. Such studies are one of the primary foci of the material reviewed in this chapter.

There has been relatively little work on the origin of these dysregulations of sleep. However, there are well-documented neurobiologic links between anxiety and sleep dysfunction. This includes circadian gene abnormalities in individuals with anxiety disorders.[13] There is also elevated cortical and peripheral arousal in both anxiety and insomnia patients. In both groups there appears to activation of arousal systems.[14,15] In anxiety, limbic structures such as the amygdala and hippocampus are activated in response to emotion-provoking stimuli. These structures in turn stimulate systems mediating arousal, including lateral hypothalamic hypocretin-orexin neurons, noradrenergic neurons in the locus coeruleus, and serotoninergic neurons in the raphe nuclei, which promote wakefulness.

As sleep disturbances related to specific phobias have been seldom investigated and obsessive-compulsive disorders are now a distinct category apart from anxiety disorders in DSM-5, they are not included here. In the cases of PTSD (which has also been moved to a separate chapter in the *Diagnostic and Statistical Manual of Mental* Disorders, fifth edition [DSM-5] but will nonetheless be considered here) and panic disorder, an additional focus relates to the core paroxysmal events that can manifest in relation to sleep (e.g., nightmares, panic attacks). This chapter also reviews current pathophysiologic concepts for sleep disturbances in anxiety and related disorders, and it reviews the types of treatments (and their outcomes) that target or indirectly influence sleep in these conditions.

PANIC DISORDER

Epidemiology and Clinical Features

Panic disorder has a 12-month general population prevalence of 2% to 3%, is more common in women than men, and has a typical age of onset in late teens or early 20s (although it can start earlier in life).[1,2] Onset is rare in older adulthood.[2] The characteristic feature of panic disorder is recurrent unexpected panic attacks (Box 136-1), which are acute episodes of severe anxiety associated with a wide array of somatic symptoms, such as chest pain, tachycardia, shortness of breath, psychosensory disturbances (i.e., changes in sound or light intensity, alterations in the perception of time, derealization), and lightheadedness. Classic panic attacks reach peak severity quickly and last only seconds to minutes in most cases. Panic attacks are well documented to be able to occur during sleep; in this chapter, the terms *nocturnal panic* and *sleep panic* are synonymous and refer to the same phenomenon.

Panic disorder is diagnosed when a person experiences recurrent unexpected panic attacks (Box 136-2). Some persons experience infrequent panic attacks for years without conspicuous changes in their health. More often, however, panic attacks are complicated by anticipatory anxiety (i.e., apprehension about future attacks) or worry about possible underlying medical disorders (e.g., heart disease). Such concerns, if lasting for 1 month or longer after the panic attack or attacks, satisfy criteria for the diagnosis of panic disorder. Alternatively, behavioral change (e.g., frequent visits to the emergency department; avoidance of places where attacks have occurred in the past) subsequent to the attacks also justifies this diagnosis. Patients also may become frightened of places or situations in which unexpected panic attacks have occurred.

Marked distress in—or the actual avoidance of—places (e.g., bridges, tunnels, airplanes) or situations (e.g., driving, shopping, traveling) in which unexpected panic attacks or panic-like symptoms have occurred in the past is referred to as *agoraphobia*. Although agoraphobia is frequently a consequence of panic disorder, it can also occur independently of

Box 136-1 DSM-5 CRITERIA FOR PANIC DISORDER

Diagnostic Criteria: 300.01 (F41.0)

Recurrent unexpected panic attacks. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak within minutes, and during which time four (or more) of the following symptoms occur:

Note: The abrupt surge can occur from a calm state or an anxious state.

- Palpitations, pounding heart, or accelerated heart rate
- Sweating
- Trembling or shaking
- Sensations of shortness of breath or smothering
- Feelings of choking
- Chest pain or discomfort
- Nausea or abdominal distress
- Feeling dizzy, unsteady, lightheaded, or faint
- Chills or heat sensations
- Paresthesias (numbness or tingling sensations)
- Derealization (feelings of unreality) or depersonalization (being detached from oneself)
- Fear of losing control or "going crazy"
- Fear of dying

Note: Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen. Such symptoms should not count as one of the four required symptoms.

- At least one of the attacks has been followed by 1 month (or more) of one or both of the following:
  1. Persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, "going crazy")
  2. A significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar situations)
- The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism, cardiopulmonary disorders).
- The disturbance is not better explained by another mental disorder (e.g., the panic attacks do not occur only in response to feared social situations, as in social anxiety disorder; in response to circumscribed phobic objects or situations, as in specific phobia; in response to obsessions, as in obsessive-compulsive disorder; in response to reminders of traumatic events, as in posttraumatic stress disorder; or in response to separation from attachment figures, as in separation anxiety disorder).

Box 136-2 PANIC ATTACK SPECIFIER

Note: Symptoms are presented for the purpose of identifying a panic attack; however, panic attack is not a mental disorder and cannot be coded. Panic attacks can occur in the context of any anxiety disorder as well as other mental disorders (e.g., depressive disorders, posttraumatic stress disorder, substance use disorders) and some medical conditions (e.g., cardiac, respiratory, vestibular, gastrointestinal). When the presence of a panic attack is identified, it should be noted as a specifier (e.g., "posttraumatic stress disorder with panic attacks"). For panic disorder, the presence of panic attack is contained within the criteria for the disorder, and panic attack is not used as a specifier.

An abrupt surge of intense fear or intense discomfort that reaches a peak within minutes and during which time four (or more) of the following symptoms occur:

Note: The abrupt surge can occur from a calm state or an anxious state.

- Palpitations, pounding heart, or accelerated heart rate
- Sweating
- Trembling or shaking
- Sensations of shortness of breath or smothering
- Feelings of choking
- Chest pain or discomfort
- Nausea or abdominal distress
- Feeling dizzy, unsteady, lightheaded, or faint
- Chills or heat sensations
- Paresthesias (numbness or tingling sensations)
- Derealization (feelings of unreality) or depersonalization (being detached from oneself)
- Fear of losing control or "going crazy"
- Fear of dying

Note: Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen. Such symptoms should not count as one of the four required symptoms.

DSM-5, *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition. Copyright 2013 American Psychiatric Association.

panic disorder and is separately diagnosable in DSM-5. When not tied to panic disorder, agoraphobia (i.e., fear and avoidance of particular situations owing to fear of incapacitation or embarrassment) may be a complication of illness (and the repercussions thereof) such as vertigo or other forms of physical incapacity.

Sleep Features

At least two thirds of patients with panic disorder report moderate to severe sleep difficulties, including difficulty initiating and maintaining sleep, nonrestorative sleep, and nocturnal panic attacks.[16-18] Sleep difficulties and sleep deprivation can lead to worsening of anxiety symptoms, including panic attacks, in patients with panic disorder.[19] Most PSG studies have found decreased sleep efficiency and sleep duration in panic disorder patients,[20-24] although some studies have not found such disturbances.[21] Because panic disorder and major depression are often comorbid, it is possible that comorbid depression may be partially responsible for sleep disturbances in panic disorder; however, some of these studies have excluded subjects with comorbid depression.[22,24,25] Of those excluding comorbid depression, some still found evidence for sleep disturbance in persons with panic disorder.[22,24]

One type of sleep disturbance reported to occur in panic disorder is isolated sleep paralysis, a transient gross motor paralysis that can occur at sleep onset or offset. Although common in those with narcolepsy, it can also occasionally occur in those without this condition. It appears to arise when the involuntary immobility characteristic of rapid eye movement (REM) sleep intrudes into the waking state. This may relate to brainstem norepinephrine neurons in the locus coeruleus being quiescent in REM sleep and failing to revert to spontaneous pacemaker-like firing activity on waking, which is thought to lead to cortical arousal.[26,27] In addition to being unable to move during isolated sleep paralysis, some patients report anxiety, chest pressure, and other somatic sensations. Isolated sleep paralysis has not only been reported in association with panic disorder, it can also occur in other anxiety and trauma-related disorders such as PTSD.[28-32] One study investigating the prevalence of isolated sleep paralysis found that the prevalence of isolated sleep paralysis in subjects with a primary diagnosis of panic disorder (20.8%) did not seem differentially higher than that in PTSD (22.2%) or GAD (15.8%).[33]

Several surveys and studies of populations with panic disorder have documented the occurrence of panic attacks emerging from sleep as a not uncommon feature of the disorder. These episodes are often described as being awakened abruptly from sleep, usually with physical symptoms such as shortness of breath that also characterize the person's panic attacks in awake states. Sleep panic attack episodes appear to be non–rapid eye movement (NREM) sleep phenomena that occur at the transition between sleep stages N2 and N3 (NREM sleep stages 2 and 3) and thus they are not associated with dream mentation.[20,34,35] Approximately one half of patients with panic disorder report experiencing sleep panic attacks at some point during the course of their illness.[16,36] Some studies estimate that up to one third of patients experience recurrent nocturnal panic.[16,17,36,37] Although it has been suggested that nocturnal panic may itself be a marker of more severe panic disorder,[36,38] this has not consistently been found across studies.[37,39,40] Nocturnal panic appears to be associated with states of diminished arousal such as sleep and relaxation.[16,40-42] Although greater motor activity during sleep as evidenced by increased epochs of movement time has been reported with panic disorder, patients might actually move *less* on the nights when they experience sleep panic attacks,[43] leading the authors to suggest that movement during sleep may serve as a temporary protective mechanism against the episodes.

Several authors have suggested that the occurrence of panic attacks during NREM sleep implicates a more endogenous, physiologic (rather than cognitive or attributional) explanatory mechanism. Specific mechanisms that have been proposed include sensitivity to subtle increases in blood carbon dioxide levels,[44] irregular breathing during slow wave sleep,[45] and abnormalities in autonomic activity.[20,21,42] Additionally, these symptoms may also be mediated through activation of locus coeruleus activity.[35] Further, sodium lactate administered during sleep was found to be associated with increased cardiac and respiratory reactivity in panic disorder patients relative to controls,[46] and pentagastrin administered during sleep resulted in abrupt awakenings accompanied by panic symptoms in

patients with panic disorder.[48] These findings have been cited as evidence for a physiologic explanation for nocturnal panic because during sleep the influence of cognitive factors is purportedly less.

However, several studies suggest that cognitive factors also play a role. In an investigation employing caffeine administration during sleep, more fully elaborated panic attacks were preceded by a period of lighter sleep before awakening, providing support for a mixture of physiologic and cognitive influences on sleep panic.[49] In another study, participants with recurrent nocturnal panic attacks who were primed to expect intense physiologic changes during sleep (as indicated by an auditory signal) were less likely to awaken with panic symptoms than those for whom such a signal was unexpected, highlighting a role for presleep attributions.[50] Physiologic differences in those with nocturnal panic have also been found to normalize with cognitive behavior therapy (CBT).[51] Based on this evidence, it has been argued that although physiologic differences exist for those with nocturnal panic, they should be seen as a function of panic disorder psychopathology rather than as an explanatory mechanism.[42]

Treatment

The aim of drug treatment is to block panic attacks (waking and nocturnal panic attacks) and to eliminate secondary fears and avoidance activities (e.g., sleep phobias). The removal of exogenous stimulants (e.g., caffeine, amphetamine, catecholamine enhancers) and the correction of maladaptive behavior (e.g., sleep deprivation) that often exacerbate panic disorder should also be an integral part of the drug treatment program. If a thorough medical assessment has not recently been performed, this should be conducted (including, routinely, thyroid-stimulating hormone measurement to rule out most thyroid problems) before proceeding with specific antianxiety treatments.

Tricyclic antidepressants (e.g., imipramine) and monoamine oxidase inhibitors (e.g., phenelzine) were considered mainstays in the treatment of panic disorder as well as associated depressive symptoms that are commonly encountered. For reasons of tolerability and safety, these have been largely supplanted in the past two decades by the selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, sertraline, paroxetine, and controlled-release paroxetine, which are approved by the U.S. Food and Drug Administration (FDA) for this purpose. High-potency benzodiazepines (alprazolam, extended-release alprazolam, and clonazepam are approved by the FDA for this purpose) have also been widely used to treat panic disorder. Some medications (e.g., propranolol, buspirone, hydroxyzine) used often in the management of other forms of anxiety have been shown to be ineffective in the treatment of panic disorder.[52,53] Although there has been little pharmacologic research on the treatment of sleep disturbances associated with panic disorder, preliminary observations suggest that sleep-panic attacks are responsive to antidepressant-antipanic medications.[54,55]

Research has shown CBT to be at least as beneficial as first-line drug treatments.[56] CBT involves challenging irrational thoughts about panic symptoms and their consequences, the elimination of avoidance behavior, and gradual exposure to feared interoceptive sensations and agoraphobic situations. CBT also has the benefit of yielding long-lasting effects.[56] It is unclear whether standard CBT for panic disorder is beneficial in improving sleep, although one study suggests that combined pharmacologic treatment and CBT was insufficient in eliminating objective and self-reported sleep disturbances.[24] One CBT study included modifications targeted to nocturnal panic, such as psychoeducation about normal physiologic changes during sleep, challenging of catastrophic thoughts about nocturnal panic, interoceptive exposure to relaxation conditions, and sleep hygiene.[51] Compared with waitlist controls, participants who received this intervention fared better on measures of physiologic and self-reported anxiety and sleep quality, including nocturnal panic specifically. There is otherwise little information to guide the specific treatment of patients with panic disorder who have nocturnal panic attacks.[57]

In the absence of empiric data in this regard, it is recommended that patients with significant sleep disturbance including nocturnal panic attacks be treated with an antipanic agent or with CBT and that they undergo cognitive behavioral therapy for insomnia or sleep-targeted pharmacotherapy. Human subjects experiencing panic anxiety have been found to have elevated levels of the peptide hypocretin-orexin in their cerebrospinal fluid compared with subjects not experiencing it.[58] Based on the large body of evidence indicating that hypocretin-orexin activity promotes wakefulness, there is reason to believe that panic anxiety-related sleep disturbance might be mediated by this system.[59] As such, agents that block hypocretin-orexin receptors, which have recently become available in the United States (e.g., suvorexant) may be particularly useful in disorders of sleep associated with a panic anxiety component. Future research is needed to test this hypothesis.

GENERALIZED ANXIETY DISORDER

Epidemiology and Clinical Features

GAD is typified by chronic anxiety and excessive, pervasive worry (Box 136-3). In community surveys, the 12-month prevalence of GAD is approximately 3%,[1] with lifetime rates being higher (approximately 6%).[2] As is the case for all of the anxiety disorders the prevalence is higher in women than in men, with GAD showing an approximate 2:1 female-to-male ratio. The natural course of GAD can be characterized as chronic, with few complete remissions, a waxing and waning course of symptoms, and the substantial depressive comorbidity.

GAD, it might be argued, has been poorly named. This has led to a tendency to consider it a generic form of anxiety and to make the diagnosis inappropriately and pervasively. Many anxiety (and depressive) disorders are characterized by chronic anxiety and tension; these features alone are therefore insufficient to make this diagnosis. It is the presence of excessive and uncontrollable worry about multiple factors—such as work, health, and the well-being and safety of family members—that defines GAD. Patients with GAD often present to their primary care practitioner, where somatic complaints (e.g., headache, back or shoulder pain due to chronic muscle tension, chronic gastrointestinal distress) might predominate.

Sleep Features

Insomnia and GAD are highly overlapping, frequently comorbid disorders. Sleep disturbance, defined as difficulty

Box 136-3 DSM-5 CRITERIA FOR GENERALIZED ANXIETY DISORDER

Diagnostic Criteria: 300.02 (F41.1)

1. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance)
2. The individual finds it difficult to control the worry.
3. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):
   Note: Only one item is required in children.
   - Restlessness or feeling keyed up or on edge
   - Being easily fatigued
   - Difficulty concentrating or mind going blank
   - Irritability
   - Muscle tension
   - Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep)
4. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
5. The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).
6. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder [social phobia], contamination or other obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

DSM-5, *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition. Copyright 2013 American Psychiatric Association.

initiating or maintaining sleep, or sleep that is restless and unsatisfying, is one of the six features (a minimum of three of which are needed to establish the diagnosis) associated with chronic worry in the DSM-5 criteria for GAD. Three of the other five features—fatigue, irritability, and difficulty concentrating—are also possible consequences of sleep loss. The core cognitive feature of GAD, excessive worry ("apprehensive expectation"), is commonly implicated in the genesis and maintenance of insomnia problems, in that patients often report their worry as most uncontrollable and bothersome at bedtime, interfering with their ability to fall asleep. In a study of comorbid psychiatric disorders in an insomnia sample, GAD was the most commonly diagnosed anxiety disorder.[60] Conversely, difficulty sleeping has been reported in 56% to 75% of persons with GAD,[61,62] although empiric data are largely lacking on the prevalence of sleep disturbance in GAD samples. One difference between GAD and primary insomnia may be the foci of worry at night; in primary insomnia the focus of worry is typically the insomnia itself, whereas in GAD, the worry is focused on areas that are also preoccupations during the day (e.g., career, finances, relationships).

The PSG sleep of insomniac patients with GAD has been compared with that of healthy control subjects in a handful of studies.[63] Patients with GAD have increased sleep latency, increased wake time after sleep onset, lower sleep efficiency, and reduced total sleep time relative to controls. The sleep architecture findings in GAD are unremarkable, and the conclusion is that GAD is characterized by a nonspecific sleep-onset and sleep-maintenance insomnia that compromises sleep quality. Notably, these studies provide evidence that GAD can be differentiated from major depression: The classic reduction in REM sleep latency seen in endogenous major depression is usually not seen in nondepressed patients with GAD.[64-66] However, given that most patients with GAD, particularly those encountered in general medical settings, also suffer from major depression, it should be expected that more classic depression-related sleep problems (e.g., early morning awakening) also will be seen. It is doubtful that differentiation of GAD from other anxiety or depressive disorders can be made on the basis of differences in sleep symptoms or PSG findings.

Treatment

Treatment for this chronic condition is, not surprisingly, often prolonged (i.e., several years). Benzodiazepines (e.g., alprazolam, clonazepam) are used extensively in the management of GAD. The available evidence suggests that the anti-anxiety effects of these compounds persist indefinitely in most cases and are not associated with dosage escalation in the long term.[67] In addition, strong evidence from double-blind, placebo-controlled studies indicates that certain classes of antidepressants, such as the SSRIs[68] and the dual reuptake inhibitors (also known as norepinephrine and serotonin reuptake inhibitors [NSRIs]; e.g., venlafaxine extended-release)[69] are efficacious.[70] A substantial advantage of antidepressants over benzodiazepines is the fact that the former treat comorbid depression, whereas the latter do not. Tricyclic antidepressants are also effective, although their use has largely been supplanted by the SSRIs and NSRIs. Recently, effects of extended-release quetiapine fumarate (50 to 300 mg/daily) on long-term functioning and sleep quality in patients with GAD using a randomized-withdrawal, placebo-controlled maintenance study in 432 participants showed that quetiapine XR monotherapy was effective at maintaining improvements in functioning and sleep quality.[71] However, at this writing, neither quetiapine XR or any of the other "atypical antipsychotic" medications is FDA approved for the treatment of GAD (or any other anxiety disorder).

There is evidence to suggest that antihistamines may also be helpful for treating core GAD symptoms,[72,73] although few studies have been conducted to date. Clinical experience suggests that improvement in insomnia parallels the overall benefits associated with pharmacologic treatment of GAD; however, studies often do not report sleep findings in GAD. One placebo-controlled study found that adding the hypnotic eszopiclone to the SSRI escitalopram was beneficial for both insomnia symptoms and daytime anxiety associated with GAD.[74] However, when this study was repeated with zolpidem CR, improvement with sleep but not anxiety symptoms

was observed, suggesting that eszopiclone may have direct anxiolytic effects.[75] Pregabalin has been demonstrated to have efficacy for GAD in several placebo controlled trials and has been reported to alleviate sleep disturbances associated with GAD; however, it is not FDA approved for the treatment of GAD or insomnia.[76-78]

CBT is highly effective in treating GAD,[79] and such treatments have also been shown to be effective for insomnia complaints.[80] In older adults, in whom benzodiazepines may be relatively contraindicated because of concerns about adverse effects (e.g., falls leading to fractures), psychosocial treatments may be particularly appealing.[81] The potential efficiency of integrated psychotherapeutic interventions that target both excessive generalized worries and worries about sleep warrants further exploration[82]; however, empiric investigation of such treatment approaches is not yet available.

SOCIAL ANXIETY DISORDER (SOCIAL PHOBIA)

Epidemiology and Clinical Features

The term *social anxiety disorder* is synonymous with *social phobia,* and the two terms may be used interchangeably. Social anxiety disorder can be described as excessive fear of being judged negatively, embarrassed, or humiliated in one or more social situations (Box 136-4). Anxiety in social situations can take the form of a panic attack, marked by extreme discomfort and physical symptoms such as heart racing, shaking, sweating, blushing, and other symptoms. In other cases, the symptoms are less acute but last longer, especially in anticipation of or before an upcoming social situation (e.g., worrying for days or weeks ahead of time about having to attend a dinner party).

Overt signs of discomfort (blushing, tremor in voice, sweating, motor tics) that might be apparent to another person are extremely distressing to the social phobic patient. One of these symptoms ("I sweat too much"; "I have the shakes") might be the chief and exclusive complaint of the social phobic patient when seeking treatment from his or her family physician. Public speaking may also be endorsed as a prominent source of anxiety, although further inquiry often reveals social fears and avoidance in many more socially routine situations such as speaking to small groups, interacting with authority figures, and relating to peers. DSM-5 encourages the use of the specifier "performance-only type" for the subset of individuals whose social fears and anxiety truly are limited to public speaking or other performance situations.

Social anxiety disorder and the associated avoidance can significantly interfere with daily functioning and reduce quality of life.[81] Many patients report that they always have been "shy"; onset of the disorder is in early childhood (i.e., it has "always been there") in approximately half of cases, whereas in the other half it appears to develop de novo in adolescence among those without a background of pathologic shyness. Social anxiety disorder affects slightly more women than men, although men more commonly present to mental health treatment settings for its treatment.

Box 136-4 DSM-5 CRITERIA FOR SOCIAL ANXIETY DISORDER (SOCIAL PHOBIA)

Diagnostic Criteria: 300.23 (F40.10)

1. Marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others. Examples include social interactions (e.g., having a conversation, meeting unfamiliar people), being observed (e.g., eating or drinking), and performing in front of others (e.g., giving a speech).

Note: In children, the anxiety must occur in peer settings and not just during interactions with adults.

2. The individual fears that he or she will act in a way or show anxiety symptoms that will be negatively evaluated (i.e., will be humiliating or embarrassing; will lead to rejection or offend others).
3. The social situations almost always provoke fear or anxiety.

Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations.

4. The social situations are avoided or endured with intense fear or anxiety.
5. The fear or anxiety is out of proportion to the actual threat posed by the social situation and to the sociocultural context.
6. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
7. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
8. The fear, anxiety, or avoidance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
9. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder, such as panic disorder, body dysmorphic disorder, or autism spectrum disorder.
10. If another medical condition (e.g., Parkinson disease, obesity, disfigurement from burns or injury) is present, the fear, anxiety, or avoidance is clearly unrelated or is excessive.

Specify if:

- **Performance only:** If the fear is restricted to speaking or performing in public.

Specifiers

Individuals with the performance-only type of social anxiety disorder have performance fears that are typically most impairing in their professional lives (e.g., musicians, dancers, performers, athletes) or in roles that require regular public speaking. Performance fears may also manifest in work, school, or academic settings in which regular public presentations are required. Individuals with performance only social anxiety disorder do not fear or avoid nonperformance social situations.

Copyright 2013 American Psychiatric Association.

Sleep Features

Complaints of insomnia are not uncommon in patients with social anxiety disorder if the clinician specifically elicits them, although it is rare for a patient with social anxiety disorder to present with sleep disturbances as his or her chief complaint. Anecdotally, persons with social anxiety disorder are somewhat more likely to experience sleep difficulties, particularly increased sleep latency, when experiencing anticipatory anxiety in advance of a highly feared social event (e.g., job interview, oral presentation).

In one of only two published studies that specifically focus on subjective sleep in patients with social phobia, 60% of participants could be categorized as poor sleepers compared with only 7% of healthy controls.[83] A more recent investigation found that 18% of participants with social phobia had moderate to severe insomnia versus only 5% of controls, and an additional 40% had subthreshold insomnia symptoms.[84] Furthermore, this study found that the relationship between social phobia and insomnia was partially mediated by depressive symptoms.

The results of PSG are largely normal in social anxiety disorder, with sleep latency and sleep efficiency being similar in patients and healthy control subjects. REM sleep latency, REM sleep distribution, and REM sleep density are also normal in social anxiety disorder.[85]

Treatment

There is a solid evidence base for managing social anxiety disorder with either pharmacotherapy or CBT. Five classes of medications are effective in the treatment of social phobia: high-potency benzodiazepines (alprazolam, clonazepam), monoamine oxidase inhibitor antidepressants (i.e., phenelzine, tranylcypromine), SSRIs (paroxetine and sertraline have FDA approval for the treatment of social phobia), SNRIs (venlafaxine extended-release has FDA approval for the treatment of social phobia), and, in limited circumstances, beta blockers (e.g., atenolol, propranolol).[86] Clinical experience suggests that some patients with the performance-only specifier of social anxiety disorder (e.g., public speaking or anxiety limited to other performance situations such as playing a musical instrument in public) may respond to beta blockers on an as-needed basis, whereas individuals with more generalized, pervasive social anxiety symptoms require regular dosing—to *prevent* the occurrence of symptoms in situations that occur so commonly that as-needed medication cannot be used—with either a benzodiazepine or one of the aforementioned antidepressants.

Individual and group CBT are also effective, and their duration of effects is longer than that for medication treatments.[87-89] A combination of psychosocial and drug therapies may be considered to achieve an optimal response; often, rather than starting CBT and medications together, a stepped approach can be employed, starting with one modality and adding the other if needed.[90] Whereas there had been initial excitement about the possibility of speeding or otherwise facilitating the effects of CBT with D-cycloserine for social anxiety disorder,[91] a recent study failed to show benefits of such an approach over CBT alone..

Interestingly, poorer pre-CBT sleep quality has been noted as a predictor of poorer response to subsequent CBT, with the concomitant suggestion that sleep problems should be addressed before starting CBT. The impact of successful social anxiety disorder treatment on sleep symptoms has not been ascertained. For transient insomnia symptoms, a short course of hypnotics may be beneficial.

POSTTRAUMATIC STRESS DISORDER

Epidemiology and Clinical Features

PTSD, previously included within the anxiety disorders, in now included in a separate trauma-related disorders chapter in DSM-5. PTSD is characterized by the recurrent, unwanted mental and emotional reexperiencing of a previous traumatic event. The trauma is one that would be experienced by almost anyone as profoundly disturbing, usually falling into the category of an event that was life-threatening (e.g., violent attack with physical injury, sexual assault, serious motor vehicle collision) or profoundly and abruptly life-altering (e.g., sudden death of a loved one from accidental or unanticipated medical causes). Traumatic experiences that yield PTSD, such as military combat or domestic violence (i.e., intimate partner abuse), often occur as repeated episodes and not single events.

After exposure to severe traumatic experiences, it is the norm to experience brief (lasting several days) periods of anxiety, recurrent thinking about the event, and insomnia. In cases in which these symptoms persist more than a few days and cause functional impairment, accompanied by prominent feelings of unreality or memory problems (i.e., dissociative symptoms), a diagnosis of acute stress disorder may be appropriate. In most such cases, the symptoms wane over the ensuing weeks, but when they do not (which is the pattern in 10% to 30% of cases, depending on the nature and severity of the traumatic event) and the symptoms interfere with functioning or cause great distress, a diagnosis of PTSD may be applied. To qualify for a PTSD diagnosis, characteristic symptoms must be noted in four domains: reexperiencing symptoms (e.g., nightmares or daytime intrusive thoughts or images, including flashbacks), negative cognitions and mood, avoidance and numbing symptoms (e.g., avoidance of reminders of the trauma), and hyperarousal symptoms (e.g., insomnia or increased startle response) (Box 136-5).

Lifetime prevalence of PTSD is reported to be as high as 7% to 8%, with a 12-month prevalence in the range of 2% to 3%. PTSD is approximately twice as prevalent in women as men in the general population. Common sources of PTSD in men (although increasingly in women) are military combat and physical assault; in women, intimate partner violence and violent injury (often associated with sexual assault) are common sources. Like many other anxiety and related disorders, PTSD is often encountered comorbid with major depression, both in general population samples and in clinical settings.

Sleep complaints are virtually ubiquitous in patients with PTSD.[92] Patients sometimes report not having slept well for decades, with these reports corroborated by their bed partners. Extreme hypervigilance (sometimes bordering on paranoia, but evidently linked to habits learned during combat experiences) may take the form of a combat veteran with PTSD spending several hours each evening "patrolling" the perimeter of his home to ensure that it is protected from intruders. Nightmares, often accompanied by vivid recall on wakening, are commonplace, as is extreme motor activity, according to companions' reports. It is not uncommon to encounter patients who have tried numerous over-the-counter and prescription medications to help with their sleep, to no avail. Many patients also have alcohol abuse problems, which can complicate the clinical picture and make determining the nature of the sleep disorder even more difficult. In some cases, other risk factors for disturbed sleep—such as obstructive sleep apnea—are present, making an informed evaluation by a sleep expert (with a particular focus on possible sleep-disordered breathing) of considerable value.

Individuals suffering with PTSD are afflicted with hyperactivity of the norepinephrine system during waking and

Box 136-5 DSM-5 CRITERIA FOR POSTTRAUMATIC STRESS DISORDER

In posttraumatic stress disorder, the person has been exposed to a traumatic event in which both of the following were present:

- The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury or a threat to the physical integrity of self or others.
- The person's response involved intense fear, helplessness, or horror. In children, this may be expressed instead by disorganized or agitated behavior.
- The traumatic event is persistently reexperienced in one (or more) of the following ways:
  - Recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions. In young children, repetitive play can occur in which themes or aspects of the trauma are expressed.
  - Recurrent distressing dreams of the event. Children can have frightening dreams without recognizable content.
  - Acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur on awakening or when intoxicated).
  - Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.
  - Physiologic reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.

The person persistently avoids stimuli associated with the trauma and has numbing of general responsiveness (not present before the trauma), as indicated by three (or more) of the following:

- Efforts to avoid thoughts, feelings, or conversations associated with the trauma
- Efforts to avoid activities, places, or people that arouse recollections of the trauma
- Inability to recall an important aspect of the trauma
- Markedly diminished interest or participation in significant activities
- Feeling of detachment or estrangement from others
- Restricted range of affect (e.g., unable to have loving feelings)
- Sense of foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span)

The person has persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:

- Difficulty falling or staying asleep
- Irritability or outbursts of anger
- Difficulty concentrating
- Hypervigilance
- Exaggerated startle response

Duration of the symptoms is longer than 1 month.

The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if the symptoms are acute (duration less than 3 months) or chronic (duration 3 months or longer).

Specify if the symptoms have delayed onset (onset at least 6 months after the stressor).

DSM-5, *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition. Modified with permission from the American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*. 5th ed. Washington, DC: American Psychiatric Press; 2013. Copyright 2013 American Psychiatric Association.

sleep.[93,94] Preclinical work has implicated changes in the amygdala, which leads to activation of the locus coeruleus through corticotropin-releasing hormone receptors as a key mechanism mediating hyperarousal, hypervigilance, and sleep disturbances in PTSD.[95] These considerations support the use of agents that enhance serotonin tone, such as most of the antidepressants because this inhibits locus coeruleus norepinephrine neurons and is also thought to inhibit amygdala activity.[96-98] They also support the use of α-adrenergic antagonists such as prazosin, which block locus coeruleus outputs that have hyperarousing effects (see later).

Sleep Features

Subjective sleep complaints in PTSD often include the two sleep symptoms listed in the diagnostic criteria: nightmares (which are viewed as reexperiencing phenomena) and insomnia (i.e., impairment in initiating and maintaining sleep). A survey of male Vietnam War veterans with PTSD confirms that insomnia complaints are very common symptoms of PTSD, although nightmares are more specific to the disorder.[99] In a community survey, PTSD was often (in approximately 70% of cases) associated with sleep complaints including insomnia as well as other types of sleep disturbance such as violent or injurious activities during sleep, sleeptalking, or hypnagogic and hypnopompic hallucinations.[100] These rates seem very high and need to be replicated, but they do point to the usefulness of a thorough sleep assessment in conjunction with diagnostic assessment of PTSD and other trauma-related disorders. Heightened arousal during sleep has also been reported by patients with PTSD, including excessive motor activity and awakenings with somatic anxiety symptoms.[101] Isolated sleep paralysis is also associated with PTSD, and with trauma exposure even in the absence of PTSD, although its specificity to PTSD relative to other anxiety disorders is unclear (see also Panic Disorder, earlier).[99,102,103] It has been reported that the severity of sleep complaints mediates the relationship between PTSD and functional disability.[104]

Findings on objective sleep disturbances in PTSD are inconsistent. Subjective reports of sleep disturbance are often discrepant with the findings of PSG. In early PSG studies of PTSD, mostly featuring male combat veterans during a chronic phase of the disorder, findings are mixed with respect to the presence of impaired sleep initiation and maintenance. Several studies report reduced sleep time or efficiency or increased awakenings in the patients with PTSD,[105] whereas in other studies measures of sleep maintenance did not differ from that of control subjects.[106-108] In the largest PSG study of PTSD conducted to date, investigators conducted sleep studies for two consecutive nights with 292 trauma-exposed young adults from the community, 71 of whom had lifetime PTSD.[109] On standard measures of sleep disturbance, no differences were detected between subjects with PTSD and controls, irrespective of trauma history or major depression in the control subjects. The investigators concluded that they found no objective evidence for clinically relevant sleep disturbances in PTSD. This study raises the possibility that the presence of sleep disturbance in PTSD may be a prevailing factor in determining treatment seeking and disability, so that patient samples are enriched for sleep disturbance.

However, the authors of a meta-analysis of 20 PSG studies found that overall, PTSD patients had increased

stage 1 sleep, decreased slow wave sleep, and increased frequency of eye movements during REM sleep periods (REM sleep density).[110] Moreover, they found that several moderating variables—age, sex, and comorbid depression and substance use—affected the relationship between PTSD and sleep disturbances. Another factor that can contribute to the lack of significant findings in individual studies, as raised in a review,[111] is that some persons with PTSD (and other psychiatric conditions, such as primary insomnia) might sleep better in the laboratory environment because of the perception that it is a "safe" setting, thus making evidence of objective sleep disturbance less discernible. Numerous studies have contributed data which indicate that individuals with PTSD have greater apnea-hypopnea index, more transitions from REM sleep to waking, and greater REM density,[112-114] but more work is needed to determine whether these features play a role in pathophysiology. Other sleep disturbances in PTSD include movement abnormalities and sleep-disordered breathing. Self-reports of excessive motor activity have been corroborated by studies documenting frequent periodic limb or gross body movement during sleep,[115-118] although one report found reduced movement time during sleep in patients with PTSD compared with controls.[119] The latter study also found reduced sleep movement time to be associated with self-report of trauma-related nightmares in the past month.[120]

The prominence of nightmares in PTSD (which most typically arise from REM sleep) has focused interest on REM sleep variables. Abnormalities in the timing or amount of REM sleep in PTSD have not been consistently found, but other subtle differences in REM sleep in PTSD are emerging. First, increases in REM sleep density have been reported.[120,121] Second, there is evidence for greater REM sleep fragmentation in PTSD. For example, increased frequency of REM sleep to wakefulness[103] and REM sleep to stage 1 transitions[121] has been reported. Third, abnormalities in REM sleep activity after trauma exposure might predict subsequent development of PTSD.[108]

In a study of physically injured subjects who were admitted to hospital and who had at least one night of PSG recording within a month of injury, development of PTSD symptoms was associated with a shorter average duration of REM sleep before a stage change and with more periods of REM sleep.[122] More recently, in a subsequent report from a subset of this sample, sympathetic activation indexes were higher during the REM sleep of the 9 subjects who were positive for PTSD symptoms, compared with the 10 subjects who were PTSD negative.[123] Furthermore, the development of PTSD symptoms after traumatic injury is associated with a more fragmented pattern of REM sleep and increased sympathetic activation during REM sleep. Taken together, these studies suggest that sleep in PTSD is characterized by REM sleep abnormalities, suggesting that increased noradrenergic activity during REM sleep may contribute to the development of PTSD. These hypotheses deserve to be explored further because they might suggest avenues for pharmacologic intervention to prevent the development of PTSD in persons exposed to traumatic events.

Treatment

As noted previously, thorough assessment of sleep complaints is integral to the overall management of PTSD. Although the absolute rates of sleep disturbances such as obstructive sleep apnea or parasomnias in patients with PTSD remain to be determined, clinical experience suggests that these are commonly encountered in this clinical population and should be seriously considered in most cases. In cases in which the suspicion is high, patients should be referred to a sleep physician for assessment. Patients with PTSD are also likely to have comorbid mental disorders such as major depression and other anxiety disorders such as panic disorder. Treatment therefore needs to encompass these clinical entities, as well as comorbid alcohol or other substance abuse or dependence, which are also often encountered in patients with PTSD.

There is a strong and growing evidence base for particular pharmacologic and psychological treatments for PTSD. Pharmacologic treatments with support for efficacy in the treatment of PTSD include the SSRIs (sertraline and paroxetine are approved by the FDA for this indication) and, to a lesser extent in terms of strength of evidence, tricyclic antidepressants and monoamine oxidase inhibitors.[124] The dual-reuptake inhibitor venlafaxine has also been recommended as a first-line treatment for PTSD. However, none of these agents has been demonstrated to have therapeutic effects on sleep in PTSD patients. An agent that has been found to have a particular beneficial effect on sleep in PTSD patients is the α_1-adrenergic receptor antagonist prazosin.[125-128] There is also some support for the adjunctive (or monotherapeutic) use of atypical antipsychotics (e.g., olanzapine, risperidone, or quetiapine), although not all trials have shown benefits.[129] Early results for the anticonvulsant tiagabine showed promise,[130] although findings from a large double-blind study found no differences in PTSD treatment efficacy from placebo.[131] A recent study indicating that changes in sleep occurring on the first night of tiagabine administration can predict subsequent PTSD response suggests the possibility that sleep changes may be mediators or early markers of subsequent therapeutic PTSD effects.[132] The use of prazosin in PTSD has become mainstream in many settings for the treatment of patients with PTSD. The benefits of prazosin for PTSD are likely a property of α_1-receptor antagonists as a class and not a prazosin-specific effect because terazosin has shown benefit in a case report.[133,134]

More than in any of the other anxiety and related disorders, the use of evidence-based psychotherapy is critical either as primary or adjunctive treatment for PTSD.[135-137] There is accumulating evidence that psychosocial treatments that focus on sleep aspects of PTSD such as nightmares can have strong therapeutic effects across the full spectrum of PTSD symptoms.[138,139] Practice guidelines based on evidence are available (Box 136-6).[140] Few studies have used psychotherapeutic interventions to treat PTSD and examined their effects on sleep quality. In one small study 5-week treatment using eye movement desensitization reprocessing therapy improved sleep consolidation and reduced wake time after sleep onset.[141] Another study reported the safe and effective use of CBT for insomnia in patients with comorbid insomnia and PTSD and improved sleep was reported to facilitate entry into exposure therapy for PTSD.[142] Additional studies that incorporate psychotherapeutic techniques with medication strategies are needed to formally evaluate their benefits.[143]

Box 136-6 TREATMENT RECOMMENDATIONS OF PTSD-ASSOCIATED NIGHTMARES

Level A: Supported by a substantial amount of high-grade evidence and/or based on a consensus of clinical judgment	Prazosin
Level B: Supported by a sparse amount of high-grade evidence or a substantial amount of low-grade data and/or clinical consensus by task force	Clonidine Venlafaxine is *not* suggested.
Level C: Supported by low-grade data without volume to recommend more highly and likely subject to revision with further studies	*Medications:* trazodone, atypical antipsychotic medications, topiramate, low-dose cortisol, fluvoxamine, triazolam and nitrazepam, phenelzine, gabapentin, cyproheptadine, and tricyclic antidepressants. Nefazodone is not recommended as first-line therapy for nightmare disorder because of the increased risk for hepatotoxicity. *Behavioral therapies:* Exposure, Relaxation, and Rescripting Therapy (ERRT); Sleep Dynamic Therapy; Hypnosis; Eye-Movement Desensitization and Reprocessing (EMDR); and the Testimony Method.

Modified from Aurora RN, Zak RS, Auerbach SH, et al. AASM Standards of Practice Committee. Best practice guidelines for the treatment of nightmare disorders in adults. *J Clin Sleep Med* 2010;6:389–401.

CLINICAL PEARLS

- Effective treatment of anxiety and trauma-related disorders includes assessing and managing sleep symptoms.
- Clinical experience suggests that education and encouragement about behavioral factors that disturb sleep can be helpful as an adjunct to treatment in nearly all cases.
- If sleep disturbances persist after the successful treatment of the primary anxiety disorder, the patient should be reevaluated for other possible medical or sleep disorders.
- In the case of PTSD, where there is reason to suspect that comorbid medical, psychiatric, and sleep disorders (e.g., alcohol or substance abuse, obstructive sleep apnea) are especially common, a high index of suspicion should be maintained and a thorough medical and sleep evaluation may be considered early in the course of assessment and treatment.

SUMMARY

Anxiety and trauma-related disorders are extremely common and often associated with disturbances of sleep. These disturbances vary across the anxiety disorders and related conditions and consist of difficulty falling asleep, difficulty staying asleep, early morning awakening, and nightmares. Patients with GAD can have increased sleep latency and significant reductions in total sleep time and sleep efficiency. Clinical experience suggests these disturbances are tightly linked to pathologic worry, and improvement in insomnia closely parallels the successful amelioration of core anxiety symptoms. PTSD and, to a lesser extent, panic disorder are often characterized by recurrent frightening arousals from sleep. Sleep complaints are so prevalent in PTSD that it could be argued that every assessment of sleep disturbance should include taking a thorough history of traumatic events. Conversely, every assessment of a patient with PTSD should include a through assessment of sleep symptoms and additional investigation and follow-up as warranted. Available evidence suggests that the predominant sleep pathologic process in PTSD relates to REM sleep, whereas that in nocturnal panic relates to NREM sleep. However, reports of high rates of obstructive sleep apnea and parasomnias in PTSD suggest that a more complex etiology for sleep disturbance might exist in some individual patients with this disorder. Although these sleep disturbances were long believed to be symptoms of the anxiety disorders, the available evidence increasingly suggests that the relationship of sleep problems and anxiety disorders may be more complex and in some cases bidirectional. This evidence strongly speaks for the need to target treatment specifically to the sleep problems in patients with anxiety-related conditions. Some, but clearly not all, evidence-based pharmacologic and psychosocial treatments for anxiety disorders seem to improve sleep as part of their spectrum of therapeutic effects. However, sleep outcomes are not often reported in clinical trials, leaving some uncertainty as to a given treatment's efficacy for sleep disturbances. In some instances, preferred medications with good evidence of efficacy for anxiety disorders (e.g., SSRIs) can actually worsen sleep while they ameliorate daytime and phobic anxiety. As a result, a specific sleep-targeted therapy is needed in many patients with anxiety difficulties. There is a growing set of evidence-based pharmacologic and behavioral interventions available for treating the sleep problems of anxiety patients. Addressing the sleep problems of patients with anxiety and trauma-related disorders using these interventions promises to improve outcomes.

Chapter
137

Unipolar Major Depression

Jared D. Minkel; Andrew D. Krystal; Ruth M. Benca

Chapter Highlights

- Major depression is extremely common and is among the leading causes of disability worldwide.
- Self-reports of insomnia and hypersomnia are nearly universal among patients with major depression.
- Polysomnographic indices document objective alterations in sleep continuity, slow wave activity, and rapid eye movement sleep in patients with major depression and control subjects. Their sensitivity and specificity, however, are not such that they can be used as a stand-alone test for major depression.
- Although sleep disturbances have long been thought of as symptoms of major depression, the available evidence indicates a more complex, bidirectional relationship.
- The nature of the relationship of disturbances in sleep and major depression remains to be fully elucidated. It is clear, however, that optimal clinical management of patients with major depression must include the identification and treatment of the sleep problems present.

Mood disorders are the second most common category of psychiatric disorders after anxiety disorders,[1] and major depression alone affects at least 350 million persons worldwide. Moreover, the associated disability of mood disorders is among the highest reported for any disease: In 2000, depression was the leading cause of disability and the fourth leading contributor to the global burden of disease. The World Health Organization has reported that depression is now the leading cause of disability worldwide.[2] The impact of mood disorders includes eventual suicide in 15% of those affected, as well as increased morbidity and mortality from other illnesses.

Subjective sleep complaints are some of the most consistent symptoms associated with major depression. Disruption of typical sleep patterns (insomnia or hypersomnia) is a diagnostic criterion for depressive episodes in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM5)[3] (Box 137-1). Sleep has been studied more extensively in patients with depression than in those with any other psychiatric disorder, and in addition to the subjective reports, objective, robust, and relatively specific changes in sleep architecture have been identified as correlates with the underlying neurobiology of depression. Sleep disturbance is now thought to play an important causal role in the onset and maintenance of many cases of major depression, and efforts are under way to identify novel targets for intervention based on these discoveries.

CLASSIFICATION AND DIAGNOSIS

Mood disorders are subclassified into depressive and bipolar disorders, based on the pattern of depressive and manic episodes.[3] Diagnostic criteria for major depressive episodes are listed in Box 137-1 and include the characteristic finding(s) of depressed mood or anhedonia lasting at least 2 weeks. *Recurrent major depression* includes multiple, distinct major depressive episodes separated by at least 2 months of remission. By contrast, *dysthymic disorder* includes persistent but less severe symptoms lasting for at least 2 years. *Manic episodes* are characterized by elevated or irritable mood lasting at least a week or requiring hospitalization. *Hypomania* is associated with similar but less severe symptoms and may be less persistent. Patients who experience one or more manic or hypomanic episodes are diagnosed with a *bipolar disorder*. This chapter focuses only on *unipolar depression*; see Chapter 138 for discussion of bipolar disorder.

Major depressive episodes may be further categorized with one of several specifiers, including melancholic, atypical, and seasonal, each of which is at least partly related to sleep patterns. Melancholic depression includes a loss of pleasure in all, or almost all, activities; a lack of improvement in mood in response to normally pleasurable stimuli; and early-morning awakening and diurnal variation in mood, with depression worse in the morning. Of interest, patients with melancholic depression are more likely to experience symptomatic improvement with total sleep deprivation. Depression with atypical features includes significant mood reactivity to positive events and weight gain and hypersomnia during periods of depression. Depressive episodes can have a seasonal pattern, with a typical onset in the fall or winter and remission in the spring or summer, suggesting a correlation with diurnal patterns of light exposure (Box 137-2).

EPIDEMIOLOGY AND RISK FACTORS

Major depression is a common disorder and is reported to have a lifetime prevalence of 29.9% and a prevalence

Box 137-1 *DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS* (DSM5) CRITERIA FOR MAJOR DEPRESSIVE EPISODE

At least five of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either depressed mood or loss of interest or pleasure. Symptoms that are clearly the result of a general medical condition or that are mood-incongruent delusions or hallucinations should not be included.

- Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful); in children and adolescents, can be irritable mood
- Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day as indicated by either subjective account or observation made by others
- Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month) or decrease or increase in appetite nearly every day; in children, consider failure to make expected weight gains
- Insomnia or hypersomnia nearly every day
- Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
- Fatigue or loss of energy nearly every day
- Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
- Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
- Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

The symptoms are not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).

The symptoms are not better explained by a psychotic or delusional disorder such as schizophrenia or schizoaffective disorder.

Responses to a significant loss (e.g., bereavement, financial ruin) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered.

There has never been a manic episode or a hypomanic episode (unless the manic-like or hypomanic-like episodes are substance-induced or are attributable to the physiologic effects of another medical condition).

Modified from American Psychiatric Association: *Diagnostic and statistical manual of mental disorders, 5th edition: DSM-5.* Washington, DC: American Psychiatric Publishing; 2013.

Box 137-2 *DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS* (DSM5) CRITERIA FOR SEASONAL PATTERN SPECIFIER

This specifier applies to recurrent major depressive disorder if the following four criteria are met.

1. There has been a regular temporal relationship between the onset of major depressive episodes in bipolar I or bipolar II disorder or recurrent major depressive disorder and a particular time of the year (e.g., regular appearance of the major depressive episode in the fall or winter). Do not include cases in which there is an obvious effect of seasonal factor–related psychosocial stressors (e.g., regularly being unemployed every winter).
2. Full remissions (or a change from depression to mania or hypomania) also occur at a characteristic time of the year (e.g., depression disappears in the spring).
3. In the past 2 years, two major depressive episodes have occurred that demonstrate the temporal seasonal relationships defined in the first two criteria, and no nonseasonal major depressive episodes have occurred during that same period.
4. Seasonal major depressive episodes (as described above) substantially outnumber the nonseasonal major depressive episodes that might have occurred over the person's lifetime.

Modified from American Psychiatric Association: *Diagnostic and statistical manual of mental disorders, 5th edition: DSM-5.* Washington, DC: American Psychiatric Publishing; 2013.

of 8.6% for the past 12 months in U.S. adults,[4] with an increased risk (odds ratio [OR], 1.7) in women.[5] The reason for increased rates of major depressive episodes in women is unclear, but hormonal factors as well as differences in psychosocial stressors may be important contributors, and it is likely that the increased rates of both insomnia and depression in women are related. Lifetime and 12-month prevalence rates for insomnia have not typically been reported in large-scale studies, but a 2009 study of 464 good sleepers in Quebec, Canada, followed over 12 months reported insomnia prevalence of 7.4%, with no difference in risk based on gender.[6] Major depression has its onset in early adulthood at a median age of 32 years; a pattern of recurrent episodes with recovery between episodes is typical. However, increased number and severity of episodes and poorer interepisode recovery can lead to an overall worse prognosis, suggesting that chronic treatment may be beneficial for patients with recurrent illness.

PATHOGENESIS

Despite the devastating impact of mood disorders, relatively little is known about their etiology or pathophysiology. It has long been hypothesized that deficiencies in central nervous system monoaminergic systems, including noradrenergic, serotoninergic, and dopaminergic neurotransmission, are responsible for depression, and most effective antidepressant treatments, including medications and

electroconvulsive therapy, increase intrasynaptic concentrations of monoamines.[7,8]

Neural plasticity—modulated by amino acid neurotransmitters, such as glutamate, and brain-derived neurotrophic factor (BDNF), discussed further on—has been shown to play a role in depression.[7,8] In addition to recognizing the role of neurotransmitter systems in mood pathophysiology, researchers have begun to elucidate the neuroanatomic, endocrine, and genetic factors involved.[7,8] Studies of normal sleep and disrupted sleep also demonstrate clearly that most of the systems involved in mood regulation also appear to be involved in the regulation of sleep and wakefulness, suggesting that dysfunction in particular brain systems could lead to both mood and sleep abnormalities.

Emerging evidence also suggests that stress may play an important role in the pathogenesis of depression, especially for people with marked stress sensitivity. Both human and animal studies have demonstrated that stress interferes with normal reward function, which may be one of the primary mechanisms explaining the high rates of depression after stressful experiences.[9] Stress also interferes with sleep, suggesting that it may be a common neurobiologic factor linking poor sleep and depression. The neurogenetics of stress sensitivity currently is being investigated by a number of researchers, and some candidate genes have been identified related to corticotropin-releasing hormone (CRH) and other polymorphisms at different nodes within the hypothalamic-pituitary-adrenal (HPA) axis.[9] Future studies may clarify how stress, sleep, and depression are related, but at present, these relationships are not well understood.

CLINICAL FEATURES

Subjective Sleep Complaints

Problems with sleep are some of the earliest and most commonly reported symptoms of depression. Specific sleep complaints include difficulty falling asleep, frequent nocturnal awakenings, early-morning awakening, nonrestorative sleep, decreased or increased total sleep, and disturbing dreams. Insomnia, hypersomnia, or both are reported by approximately 75% of adults, children, and adolescents with major depression.[10,11]

Association of Sleep Disturbance and Unipolar Major Depression

Sleep problems are extremely common in the general population and often are associated with psychiatric comorbidity. More than 35% of adults report some sleep problem.[12] In the general adult population, 14% to 20% of persons with significant complaints of insomnia and approximately 10% of those with hypersomnia showed evidence of major depression, whereas rates of depression were less than 1% in those without sleep complaints.[12,13] Additionally, the degree and duration of insomnia were positively correlated with more severe or recurrent major depression, or both. An assessment of the lifetime prevalence of sleep disturbance and psychiatric disorders in young adults also found greatly increased rates of major depression in persons with insomnia (OR, 3.8) in comparison with those with no sleep complaints (2.7%).[14]

The association between insomnia and depression may be even greater in clinical samples. More than one half of patients with insomnia and medical or psychiatric patients evaluated by clinical interview in sleep disorders centers had a sleep disorder associated with mood disorder according to the *International Classification of Sleep Disorders* (ICSD) diagnosis.[15] In children seen in general pediatrics clinics, insomnia and daytime fatigue were strongly correlated with elevated scores on the Child Behavior Checklist, and insomnia was particularly associated with symptoms of depression, anxiety, and attentional problems.[16] In one series of 265 consecutive children seen in a hospital-based sleep clinic, 19.6% were diagnosed with behavioral insomnia of childhood, second in frequency only to sleep apnea (67.9%). Of all children seen, 5.3% were diagnosed with unipolar depression.[17]

Predictive Value of Sleep Complaints

It has historically been assumed that major depression causes changes in sleep patterns. Sleep disturbances, however, also can affect major depression, and epidemiologic data support this latter association. Insomnia often precedes the onset of a first episode of major depression.[14,15] Self-reported insomnia symptoms as well as objective abnormalities in sleep latency, continuity, and duration (assessed by polysomnography) have been shown to predict depression longitudinally.[18] By contrast, insomnia was more likely to occur subsequent to the onset of anxiety disorders,[14] although persistent insomnia in childhood has been shown to predict anxiety in early adulthood.[19] Adolescents have been found to show a similar temporal relationship between onset of insomnia relative to depression or anxiety.[14]

In prospective two-wave longitudinal studies, subjects who reported sleep disturbance at both the initial and 1- to 3-year follow-up interviews were much more likely to have experience new-onset major depression.[20,21] The presence of insomnia or difficulty sleeping at an initial assessment also is associated with a long-term (beyond 30 years) increased relative risk for development of major depression.[22,23]

In a meta-analysis of prospective studies on risk factors for depression among community-dwelling elderly persons, 57% of the risk for depression was attributable to insomnia, and insomnia was second only to recent bereavement in predicting depression.[24] Women with more disrupted sleep also had more depression both before and after giving birth, and the presence of initial insomnia seemed to be the most relevant screening question for identifying women at risk for postpartum depression.[25] Children who reported decreased amounts of sleep[26] or insomnia[14] were more likely to acquire symptoms of depression and reduced self-esteem.

In patients who have had a previous episode of depression or mania, sleep changes remain a robust predictor of recurrent mood episodes, and their persistence is associated with a more severe clinical course. Insomnia and fatigue were the most commonly reported symptoms preceding a recurrent major depression.[27]

Interepisodic Persistence of Subjective Sleep Disruption

Although insomnia can resolve with remission from major depression, it also often persists. In fact, insomnia is the most commonly reported residual symptom during remission of major depression.[28] Persistence of sleep disturbances has been shown to predict increased severity and recurrence of major

depression.[28] A three-year prospective study of 267 depressed primary care patients found that sleep problems were present for 85% to 94% of the time during a depressive episode but also persisted for 39% to 44% of the time when depression was in remission.[29] This observation is consistent with findings from the STAR*D trial that insomnia persisted in 55% of those whose depression remitted with citalopram.[30] In a population-based study of more than 24,000 participants, persistent insomnia was associated with a 6.2-fold increased risk of developing major depression.[31] Persistent major depression also increased the likelihood of developing insomnia (6.7-fold increased risk), indicating bidirectional influences of sleep disturbance and depression. These findings demonstrate the importance of addressing sleep disturbance in both clinical practice and scientific investigations of depression.

Polysomnographic Findings

Major depression has been studied polysomnographically more than any other psychiatric disorder, and a majority of patients have been found to have objective sleep disturbances.[32] Since at least the late 1960s, polysomnographic indices have been extensively evaluated for their potential as biologic markers of major depression. Objective sleep abnormalities in depression have been grouped into three general categories: disturbance of sleep continuity, alterations of non–rapid eye movement (NREM) sleep (slow wave activity [SWA] and amount and distribution of stage N3 sleep), and abnormalities of rapid eye movement (REM) sleep.[33] Although these biomarkers have been reliably identified, sensitivity and specificity levels that would allow polysomnography to be used as a stand-alone test for major depression have not yet been established.[34]

Depressed patients showed prolonged sleep latency, increased wakefulness after sleep onset, and early-morning awakening, which results in sleep fragmentation and decreased sleep efficiency. Patients with depression have decreased amount and percentage of N3 sleep. Slow wave sleep loss is most significant during the first NREM period, but depressed patients appear to have reduced delta (1 to 4.5 Hz) power on the sleep electroencephalogram (EEG) and decreased slow wave counts throughout the night.[35] The distribution of N3 during the night is abnormal, with a decreased ratio of SWA in the first relative to that in the second NREM period.[36] The most robust finding in depression is a decreased REM sleep latency (time from onset of sleep to onset of REM sleep).[32] Other REM sleep abnormalities include a prolonged first REM sleep period and increased REM density. Increased percentage of REM sleep also has been observed. Common sleep complaints and polysomnographic abnormalities are listed in Box 137-3. Results from the few studies investigating dysthymia have been variable, but they suggest that some of the characteristic sleep findings of major depression are present but not to the same extent.[37,38]

Sleep disturbances in patients with depression are not limited to periods of acute depressive episodes: Several studies have reported abnormal sleep parameters in patients during remission and during acute illness. Some sleep abnormalities may be more severe in acute than in remission phases, including increased REM density and reduced sleep efficiency.[39] However, reduced REM sleep latency and decreased slow wave sleep can persist for prolonged periods in otherwise asymptomatic persons. Thus sleep disturbances—particularly reduced REM sleep latency and slow wave sleep abnormalities—may be trait markers for some patients with major depression, rather than simply indications of an acute state of illness. The persistence of sleep abnormalities suggests that sleep disturbance could indicate a biologic susceptibility to depression and predate the illness, or that sleep changes may be caused by depression and persist much longer than other affective symptoms.[33] Additionally, first-degree relatives of subjects with major depression also show reduced REM sleep latency and slow wave sleep deficits, whether or not they have a personal history of a mood disorder,[40] suggesting that sleep changes in depression include a hereditary component.

Box 137-3 SLEEP ABNORMALITIES IN DEPRESSION

Subjective Complaints

Insomnia
- Difficulty falling asleep
- Increased awakening at night/restless sleep
- Early morning awakening
- Decreased amounts of sleep

Sleep described as less deep or less refreshing
Disturbing dreams

Polygraphic Findings

Sleep continuity disturbances
- Prolonged sleep latency
- Increased wake time during sleep
- Increased early morning wake time
- Decreased total sleep time

Stage N3 sleep deficits
- Decreased N3 amount
- Decreased N3 percentage of total sleep

REM sleep abnormalities
- Reduced REM sleep latency
- Prolongation of the first REM sleep period
- Increased REM activity (total number of eye movements during the night)
- Increased REM density (REM activity/total REM sleep time)
- Increased REM sleep percentage of total sleep

REM, Rapid eye movement; SWS, slow wave sleep.

Advanced Sleep Electroencephalographic Analysis

Traditional polysomnography studies are recorded from only a few electrodes and have relied primarily on sleep architecture—an indirect assessment of brain activity during sleep—as the primary analysis variable. However, technologic improvements in EEG systems and computerized analysis have provided new tools to more directly assess normal and disrupted brain function in major depression by analyzing the fundamental oscillations of the sleep EEG. Techniques include quantitative analysis of EEG activity across a broad range of frequencies (power spectral analysis), the automated detection and investigation of specific EEG waveforms such as slow waves, spindles, and REMs, as well as measures of the similarity of EEG oscillations across brain regions over time (synchrony and coherence). One advantage of these approaches is the ability to more completely assess specific EEG frequencies or waveforms, independent of sleep stage

(e.g., slow waves can be evaluated in all NREM sleep, not just N3).

Power Spectral Analysis

Sleep EEG power spectra for individual subjects are highly consistent between nights.[41] Power spectral analysis has been used to characterize SWA (1 to 4.5 Hz EEG power) in control and depressed subjects, which confirmed that N3 reductions in major depression were correlated with decrements in SWA, validating the use of EEG power spectra to quantify sleep slow waves.[42] Increases in SWA and N3 on the first night of antidepressant medication treatment have been found to predict subsequent treatment response to antidepressant medications[42]; however this has not yet been replicated. Although these findings might point to SWA as a state marker of depression, the bulk of the evidence indicates that decreased SWA in depressed patients compared with control subjects persists after remission, suggesting that it is more likely to be a trait marker of major depression.[42]

High-Density Electroencephalogram

Traditional polysomnography uses a relatively small number of electrodes (eight or fewer) to collect information about brain activity during sleep. Newer technology allows for a much greater amount of data to be collected, thus providing a more complete view of EEG brain activity. High-density EEG refers to a technique whereby much of the scalp is covered by electrodes (256 electrodes total). This technique offers a versatile, yet less expensive approach to studying more changes in activity in specific brain regions in patients with depression when compared with other brain imaging techniques, such as functional magnetic resonance imaging or positron emission tomography. A series of studies investigating sleep and depression using this technique have identified abnormalities in sleep spindles and SWA that would not have been possible to characterize using traditional EEG.[43,44]

Automated Analysis of Slow Waves

Manual identification of slow waves is complemented by using automated or semiautomated algorithms, which provides a quantitative index with improved sensitivity.[42] The *delta sleep ratio* has been defined as the ratio of the average slow (delta) wave counts per minute in the first NREM sleep period to the average counts per minute in the second NREM sleep period.[42] In control subjects, this ratio (typically greater than 1.6) reflects the higher density of slow waves in the first NREM sleep period. Depressed subjects tend to have a lower ratio (1.10 or less), reflecting this abnormal distribution.[42] The delta sleep ratio has been thought to reflect an abnormal sleep homeostatic process in depression (deficient process S^{38}). In major depression, REM sleep onset is earlier, and SWA is less during the first NREM sleep period, which is the opposite of the normal homeostatic pattern.

The delta sleep ratio has been shown to predict treatment response and likelihood of recurrence: Patients with higher delta sleep ratios were more likely to respond to treatments, and those with lower ratios were more likely to experience recurrent depression.[45,46] Although reduced SWA in the first NREM sleep period also has been found in subjects with schizophrenia, only subjects with depression showed a reduced delta sleep ratio, suggesting that this measure may be more specific for major depression.[47]

Coherence of Sleep Electroencephalogram Rhythms

Coherence is a measure of the similarity of EEG rhythms at different cortical locations. EEG coherence is thought to reflect the functional relationships among different cortical regions. Decreased coherence may indicate impaired brain connectivity associated with psychiatric disorders including major depression.[48] Both intra- and interhemispheric coherence in the delta (0.5 to 4 Hz) and beta (16 to 32 Hz) frequency ranges have been shown to be lower in adolescents and adults with major depression than in control subjects, even in the absence of differences in sleep stage amounts.[48,49] Reduced coherence also appears to be a factor in offspring at risk for developing major depression,[50] and it correlates with risk of recurrence in children and adolescents with major depression,[49] suggesting that it may be a biologic marker of depression.

Mechanisms Associated with Sleep and Unipolar Major Depression

The high coincidence and overlapping symptoms of major depression and insomnia point to a common neurobiology. Attempts have been made to explain the mechanisms for sleep changes in depressive disorders as well as to correlate them with other biologic abnormalities in depression. A number of hypotheses have been advanced and include neurotransmitter imbalance, abnormalities in brain activation, dysregulation of the HPA axis, inflammation, and genetic polymorphisms.

Neurotransmitter Imbalance

The monoamine hypothesis suggests that decreased levels of serotonin, norepinephrine, and dopamine result in the symptoms of depression. This model fits with the proposed action of most antidepressant medications and with the characteristic findings of increased REM and decreased slow wave sleep during depression. Considerable evidence suggests that REM sleep is promoted by cholinergic activation within the medial pontine reticular formation and is inhibited by aminergic (serotoninergic and noradrenergic) activation (see Chapter 8).[51] Thus short REM sleep latency and elevated REM density in depression could be related to enhanced cholinergic neurotransmission or diminished aminergic neurotransmission, or both. Each of these systems is under strong genetic control and could define an endophenotype of depression.[52]

Antidepressant medications produce immediate increases in monoamine levels yet have a therapeutic lag of weeks.[8] This delay is likely to be related to secondary neuroplastic changes that mediate the longer-term effect of antidepressants. The glutamate system is a key neuromodulator related to plasticity, and it also is intimately tied to both sleep and mood regulation.[53] Glutamate interacts with cholinergic neurons to increase activity of the reticular system associated with REM sleep onset. During NREM sleep, excitatory glutamate neurotransmission has a prominent role in the thalamocortical generation of sleep EEG oscillations.[51] Additionally, sleep increasingly has been shown to be necessary for plastic processes such as learning and memory, and it affects the expression of plasticity-related genes.[54] The intertwined processes of mood, sleep, and plasticity, and their modulation through factors such as glutamate and BDNF, make them appealing targets for future therapies for major depression.[53]

Abnormalities in Brain Activation

Neuroimaging has been an invaluable tool for identifying specific brain structures with altered activity or function in major depression.[55] The same modalities can be applied in healthy and depressed subjects during waking and sleep states to identify brain regions involved in regulating sleep and how their activity is altered in depressed patients with sleep disturbances. During normal NREM sleep, metabolic activity is broadly decreased over waking levels in the frontal, temporal, and parietal cortices. Subjects with current major depression exhibited a smaller decrease in these cortical regions from waking to sleep, and they showed a relative hypoactivity during wakefulness.[56] Other brain areas involved in emotional regulation (anterior cingulate cortex, amygdala, parahippocampal cortex, thalamus) also displayed a smaller difference in metabolic rates between waking and NREM sleep and elevated metabolic rates during sleep in depressed subjects relative to control subjects.[55] Altered function in these regions could relate to a failure of arousal mechanisms to decline from waking to sleep, as well as changes in cognition, attention, and emotional regulation in depression.[57] Similarly, increased metabolic activity in diffuse cortical and subcortical structures during REM sleep was seen in depressed subjects, over that in control subjects.[57] These alterations also could reflect the imbalance of monoaminergic and cholinergic systems in altered mood states, and they could explain the increased REM sleep, decreased REM sleep latency, and decreased slow wave sleep in depression.

Other imaging studies have focused on changes in brain activity after total or partial sleep deprivation of depressed patients. Approximately 50% of patients with major depression show rapid symptomatic improvement after sleep deprivation, as discussed later on (reviewed by Berg and associates[58]), further supporting the hypothesis that sleep and mood regulation are controlled by overlapping brain regions. Patients who responded to sleep deprivation initially exhibited increased metabolic activity in the amygdala, orbital prefrontal cortex, inferior temporal lobe, and anterior cingulate that normalized after sleep deprivation.[59,60] Predeprivation perfusion levels correlating with the reduction of depressive symptoms and with single photon emission computed tomography studies suggest that sleep deprivation responders may have a particular deficit in dopaminergic and serotoninergic systems involved with attention, arousal, and mood.[59]

Dysregulation of the Hypothalamic- Pituitary-Adrenal Axis

Some sleep abnormalities observed in patients with major depression may be related to dysregulation of the HPA axis. Supporting this hypothesis, depressed patients demonstrate excessive CRH and cortisol secretion and also show a lack of cortisol suppression in response to challenge with dexamethasone.[61] Chronic stress also increases secretion of cortisol, linking life events to mood episodes. CRH is known to increase arousal, disrupt sleep, and possibly contribute to reduced REM sleep latency.[62,63] Growth hormone–releasing hormone (GHRH) has a reciprocal relationship with CRH and promotes sleep. GHRH and growth hormone also may be decreased in some patients with depression, further contributing to slow wave sleep decrements.[63] Administration of a CRH receptor antagonist was reported to improve sleep EEG patterns in depressed patients.[64]

Additional evidence suggests that poor sleep may contribute to HPA axis dysregulation independently from major depression. Elevated cortisol under stress has been associated with increased awakenings and more time spent in stage 1 and stage 2 sleep.[65] In children, poor sleepers have been shown to have increased morning cortisol over that in good sleepers. Experimental studies have shown that sleep deprivation elevates cortisol release and blood pressure in response to psychosocial stressors.[66,67] Taken together, these findings suggest bidirectional influences of stress and poor sleep mediated by HPA axis dysregulation, which speak for addressing sleep problems in patients with major depression.

Inflammation

Ample evidence shows that depression is associated with a chronic, low-grade inflammatory and immune response.[68] Both chronic and acute sleep deprivation are associated with altered cellular and immune functioning. Although findings have not been consistently reported, some evidence suggests that insufficient sleep may impair immune system function by increasing proinflammatory cytokines (as reviewed by Berk and colleagues[68]). Experimental studies in rats[69] and nonhuman primates[70] suggest that proinflammatory cytokines may cause symptoms of depression. Correlational findings in human studies also are consistent with this hypothesis.[71] It is therefore possible that insufficient sleep contributes to unipolar depression, at least in part, by increasing inflammation.

Genetic Polymorphisms

At least 33% of the risk for major depression can result from genetic factors, and numerous candidate genes have been implicated.[72] Additionally, a growing number of genes have a role in major depression and in sleep regulation. Both the gene for monoamine oxidase A (MAO-A) and the serotonin transporter gene promoter (linked polymorphic region [5-HTTLPR]) have been implicated in depression and can correlate with insomnia scores (MAO-A) or treatment response to sleep deprivation (5-HTTLPR).[73] Similarly, some early work pointed to associations of clock genes, which regulate circadian rhythms, and disrupted sleep in major depression. Multiple reports have now linked a *CLOCK* gene polymorphism (3111 T/C) to the presence of insomnia or decreased sleep time in depressed patients.[74] Of note, however, a recent large study using summary data from the Psychiatric Genomics Consortia found no evidence that genes related to sleep and circadian rhythms increased risk for major depression.[75]

Primary Sleep Disorders and Unipolar Major Depression

An increased association between primary sleep disorders and major depression also has been postulated. Persons with sleep apnea have a 1.8-fold increased risk of developing major depressive disorder, and those with depression, a 1.6-fold increased risk for obstructive sleep apnea (OSA).[76] Similarly, in a longitudinal study, persons with sleep-related breathing disorders showed a severity-related risk of developing depression, with ORs ranging from 1.6 (minimal) to 2.6 (moderate or more severe sleep-related breathing).[76] Depression also may be a modifier of clinical course: In patients with OSA and depression, depression is directly associated with severity of daytime fatigue independent of severity of OSA.[77] Other

studies have shown that treating OSA results in sustained symptomatic improvement in patients with depression, and the degree of improvement in OSA with continuous positive airway pressure also correlated with the amelioration of depression.[78]

The relationship between major depression and restless legs syndrome is less well defined. Several studies have shown an inconsistent correlation between the two disorders, even with implementation of appropriate controls for the potential exacerbation of restless legs syndrome by serotoninergic antidepressants.[79]

TREATMENT

Patients with major depression often present to primary care physicians or sleep clinics with complaints of insomnia or fatigue, or both. However, because of the strong association between major depression and insomnia, any patient presenting with sleep complaints must be screened for depression. Recognition of major depression is important for determining appropriate treatment, and screening also must include a careful assessment of possible suicide risk. In the evaluation for depression, it is important for the clinician to establish rapport and create a permissive and supportive atmosphere for the patient to discuss any psychological symptoms. It is often necessary to ask about depressed mood and anhedonia in several ways (Box 137-4 gives examples) before the patient recognizes or admits to these symptoms. Several self-report measures have been validated for measuring the severity of patients' depression and also may be helpful in the initial detection of these symptoms. These assessment tools include the Patient Reported Outcomes Measurement Information System (PROMIS) depression measures developed by the National Institutes of Health[80] (available free of charge through www.nihpromis.org), the Center for Epidemiological Studies Depression Scale (CES-D),[81] and the Beck Depression Inventory (BDI-II).[82]

Treatment of Sleep Disturbance in Patients with Unipolar Depression

Major depression and the accompanying sleep disturbances may be treated with medication, psychotherapy, or both. Patients with moderate to severe depression usually are treated with medication, either alone or in combination with psychotherapy (Table 137-1).[83]

Box 137-4 EXAMPLES OF QUESTIONS TO ELICIT PRIMARY SYMPTOMS OF DEPRESSION

Depressed Mood

How has your mood been recently?
Have you been feeling down, depressed, sad, or blue lately?
Has your sleep problem affected your mood?

Loss of Interest or Pleasure

Has your ability to enjoy things changed?
Has your interest in things decreased?
Are you less motivated to do things that are normally enjoyable for you?

Treatment with Medication

Depression. Selective serotonin reuptake inhibitors (SSRIs) currently are the most widely prescribed class of drugs for depression in the United States. Along with the serotonin-norepinephrine reuptake inhibitors (SNRIs) (i.e., desvenlafaxine, duloxetine, and venlafaxine) and newer atypical antidepressants (e.g., bupropion, mirtazapine), they have become first-line agents because of their safety and improved side effect profiles in comparison with the tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs). However, SSRIs, SNRIs, and bupropion can cause significant sleep disruption and worsen insomnia in some patients.[83] By contrast, trazodone, nefazodone, and mirtazapine are sedating and can improve sleep initiation and maintenance.[83] It is therefore important for patients to understand the effects of their antidepressant medications on sleep-wake systems, to promote adherence to the appropriate regimen including timing of doses.

Although use of TCAs and MAOIs has diminished because of the associated side effects and greater potential toxicity, these drugs may be effective in patients who fail to improve with the newer antidepressants. Most TCAs are quite sedating and may therefore be helpful to depressed patients with insomnia; they continue to be used for treatment of migraine headaches and other chronic pain conditions. Low doses of TCAs have commonly been prescribed for insomnia, and a few studies have shown good efficacy and tolerability of low-dose TCAs as hypnotics in the absence of significant depression.[84] MAOIs are sometimes used, albeit rarely, in patients who fail to improve with other antidepressants, particularly patients with atypical features (hypersomnia, increased appetite) or significant comorbid anxiety. The most serious potential side effect of MAOIs is the danger of hypertensive crisis if they are used in combination with sympathomimetic drugs or with foods containing tyramine.

For severely depressed patients, including those with psychotic features or strong suicidal intent or whose depression is resistant to antidepressants alone, additional treatment modalities, including electroconvulsive therapy and antipsychotic medications, should be considered. Second-generation antipsychotics (SGAs) (e.g., risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole) are used to enhance the antidepressant response to SSRIs or as mood stabilizers in patients with bipolar disorders (see Chapters 42, 138, and 139 for further discussion of antipsychotic medications). Patients with severe fatigue or hypersomnia also might benefit from adjunctive use of stimulant medications, although the evidence for direct effects on mood or treatment course is limited.[85] Recent large reviews of the effects of antidepressant medications have shown that the magnitude of the effect of medication increases as severity of depression increases.[86,87] For mild depression, medication has not been shown to have advantages over placebo. Therefore medications that include side effects generally should be avoided in this population.

Use of the *N*-methyl-D-aspartate (NMDA) antagonist ketamine is a recent innovation in the treatment of major depression that has provided the first intervention, other than electroconvulsive therapy and sleep deprivation (see further on), that produces a more rapid improvement in depression and does so in treatment-resistant patients. Some work has been completed indicating that changes in sleep may occur in

Table 137-1 Treatment of Major Depression*

Medication	Usual Dosage Range	Pharmacologic Mechanism	Side Effects	Effects on Sleep
Tricyclic Antidepressants (TCAs)				
Amitriptyline (Elavil) Imipramine (Tofranil) Doxepin (Sinequan) Nortriptyline (Pamelor) Clomipramine (Anafranil) Desipramine (Norpramin) Protriptyline (Vivactil)	50–150 mg 50–200 mg 75–300 mg 50–150 mg 150–250 mg 75–200 mg 20–60 mg	Inhibit serotonin and norepinephrine reuptake Anticholinergic Antihistaminergic	*Anticholinergic effects*: blurred vision, dry mouth, urinary retention, orthostatic hypotension, flushing, tachycardia, confusion, others (drugs are listed in decreasing order of severity of these effects) *Other side effects*: liver toxicity, lowering of seizure threshold, sweating, weight gain	Sedation (drugs listed in decreasing order: clomipramine, desipramine, and protriptyline may be nonsedating or activating) REM sleep suppression Increased stage 2 sleep
Monoamine Oxidase Inhibitors (MAOIs)				
Phenelzine (Nardil) Isocarboxazid (Marplan) Tranylcypromine (Parnate) Selegiline transdermal (Emsam)	15–60 mg 40–60 mg 10–30 mg 6–12 mg/24–hr patch	Inhibit monoamine oxidase Increase norepinephrine, serotonin, and dopamine	Hypertensive crisis in combination with tyramine-containing foods or sympathomimetics Anticholinergic effects Dizziness, agitation Liver toxicity Weight gain	Insomnia Potent REM sleep suppression
Selective Serotonin Reuptake Inhibitors (SSRIs)				
Fluoxetine (Prozac) Paroxetine (Paxil) Sertraline (Zoloft) Citalopram (Celexa) Escitalopram (Lexapro) Vortioxetine (Brintellix)	20–60 mg 20–60 mg 50–200 mg 20–40 mg 10–20 mg 5–20 mg	Inhibits reuptake of serotonin	Gastrointestinal disturbances Sexual dysfunction Anxiety, agitation Possible increased risk for suicide	Insomnia REM sleep suppression Increased eye movements in NREM sleep
Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)				
Venlafaxine (Effexor) Desvenlafaxine (Pristiq) Duloxetine (Cymbalta) Levomilnacipram (Fetzima)	150–375 mg 50 mg 30–120 mg 40–120 mg	Inhibit reuptake of serotonin and norepinephrine	Anxiety Anorexia Hypertension Possible increased risk for suicide	Insomnia
Other Antidepressants				
Trazodone (Desyrel)	150–600 mg	Inhibits serotonin reuptake 5-HT_2 receptor antagonist	Few anticholinergic effects Priapism Nausea, dizziness, dry mouth	Decreased REM sleep Increased SWS Sedation
Nefazodone (Serzone)	200–600 mg	Inhibits serotonin reuptake 5-HT_2 receptor antagonist	Few anticholinergic effects Priapism Nausea, dizziness, dry mouth	No change or increased REM sleep Increased SWS Sedation
Bupropion (Wellbutrin)	150–450 mg	Inhibits norepinephrine and dopamine reuptake	Gastrointestinal upset Lowering of seizure threshold Anxiety	Insomnia Increased REM sleep
Mirtazapine (Remeron)	15–45 mg	Alpha$_2$ adrenergic receptor antagonist 5-HT_{1a} agonist 5-HT_2 and 5-HT_3 receptor antagonist	Increased appetite, weight gain Dizziness	Sedation
Vilazodone (Vibryd)	10-40 mg	Inhibits serotonin reuptake Partial agonist of 5HT_{1A} receptors	Gastrointestinal disturbances Sexual dysfunction Anxiety, agitation Possible increased risk for suicide	Insomnia REM sleep suppression Increased eye movements in NREM sleep

*In October 2004, the U.S. Food and Drug Administration (FDA) directed manufacturers to add a black box warning to the health professional labeling of all antidepressant medications, to include warnings about increased risks of suicidal thinking and behavior, known as suicidality, in young adults ages 18 to 24 years during initial treatment (generally the first 1 to 2 months), and to emphasize the need for close monitoring of patients starting on these medications.

5-HT, 5-Hydroxytryptamine; NREM, non–rapid eye movement; REM, rapid eye movement; SWS, slow wave sleep.

conjunction with the antidepressant effects of ketamine. A recent study comprising 30 patients found that a positive response to ketamine was associated with increased SWA during early sleep and elevated BDNF levels.[88] *Delta sleep ratio,* defined as the ratio of SWA between the first two NREM sleep episodes, also has been found to be lower in depressed patients than in healthy control subjects. A positive correlation was found between baseline delta sleep ratio and improvement in depression severity after ketamine administration.[89]

Concurrent Treatment of Depression and Insomnia

Some depression treatment studies have investigated the efficacy of coadministering antidepressants (SSRIs or TCAs) with hypnotic agents such as eszopiclone,[90] zolpidem,[91] or lorazepam.[92] The results from the limited number of studies suggest that addition of a hypnotic generally was well tolerated, improved insomnia associated with depression, and, in one study also was associated with abatement of core symptoms of depression.[90] Hypnotics alone, however, constitute insufficient treatment for depression and are not a substitute for approved antidepressant treatments. The mechanism whereby eszopiclone was found to relieve core depression symptoms and the lack of efficacy for other medications such as zolpidem are unclear. One possibility is that eszopiclone has some direct antidepressant effects owing to its pharmacology, which differs from that of zolpidem. Further studies are needed to resolve this issue.

Insomnia that persists despite treatment with other antidepressants or mood stabilizers may require additional pharmacotherapy or behavioral therapy. Trazodone has been shown to have hypnotic effects in patients with insomnia and depression[93] and often is combined with other antidepressants to improve sleep.[94]

Preliminary evidence from a small randomized, controlled pilot study found that among patients suffering from both insomnia and depression who received cognitive-behavioral therapy (CBT) for insomnia, in addition to antidepressant treatment with citalopram, higher rates of remission from both depression and insomnia were typical.[95] These findings have not yet been supported by a larger study, but the initial data suggest that treatment approaches integrating behavioral and pharmacologic interventions may improve treatment outcome.

Sleep Effects of Psychiatric Medications. Antidepressants have a variety of effects on sleep: more sedating or anticholinergic agents (e.g., trazodone, nefazodone, mirtazapine, TCAs) can cause hangover effects; conversely, activating antidepressants (e.g., bupropion, SSRIs, MAOIs) can cause or exacerbate insomnia, especially if taken near bedtime.[96] SSRIs have been associated with frequent eye movements in NREM sleep, which can persist for prolonged periods after cessation of treatment; the clinical significance of this effect is unknown.[97] TCAs and SSRIs have been implicated in precipitating or exacerbating restless legs syndrome and periodic leg movements, and they can exacerbate symptoms of insomnia or daytime fatigue by this mechanism in some patients.[98] REM sleep behavior disorder also has been reported after administration of various REM sleep–suppressing antidepressants.[97] Despite their increasingly common use, few studies have been conducted to investigate objective sleep changes related to the use of SGAs.[83] In general, SGAs appear to decrease sleep onset latency and to improve sleep continuity and efficiency, but they also commonly cause weight gain, which can increase the risk of OSA.

Nonpharmacologic Treatments

Empirically validated psychotherapies (e.g., CBT and interpersonal therapy) are approximately as efficacious as medications, except in very severe depression. These treatments may be particularly useful for patients who experience strong side effects of medication or who have specific contraindications such as pregnancy. Patients with significant insomnia should be instructed in the basic behavioral interventions for sleep, such as avoiding excessive time in bed and keeping a regular sleep-wake schedule. Behavioral techniques such as stimulus control and relaxation may be useful for some patients as well. For more severe or chronic symptoms, CBT for insomnia is effective in improving sleep disturbances associated with major depression but is not yet widely available.[99] Cognitive therapy also has been shown to be an effective treatment for insomnia that focuses on reducing worry and unhelpful self-monitoring and avoidance behaviors[100,101] and can be easily integrated with psychological treatments for depression. Psychological and behavioral interventions are reviewed in detail in Chapters 85 and 86.

For patients with seasonal depression and hypersomnia, bright light therapy has been shown to be effective, either alone or in combination with antidepressant medication. Light therapy and its use in treating depression are reviewed in detail in Chapter 39.

Treatment of Unipolar Major Depression with Sleep Deprivation

A variety of sleep manipulations, including total and partial sleep deprivation or selective deprivation of REM or slow wave sleep, have been shown to have rapid antidepressant effects, although they have not come into widespread clinical use.[102-104] A single night of total sleep deprivation has been documented to have antidepressant effects (50% reduction of Hamilton Depression Rating Scale scores); response rates are 30% to 60%, with peak antidepressant effects by the afternoon following a night of total sleep loss.[102,103] Patients with a more pronounced diurnal pattern of illness exhibit better responses to sleep deprivation. The major drawback to total sleep deprivation as a therapy for depression, however, has been the immediate reversibility of the antidepressant effects by recovery sleep, including short naps, in at least 50% to 80% of responders, in addition to the problems associated with sleep deprivation itself (e.g., increased sleepiness, limited ability to sustain treatment).

Sleep deprivation has been combined with other treatment modalities—including medications (lithium, antidepressants), sleep phase advance, light therapy, and transcranial magnetic stimulation—with mixed results. The aim is to obtain a rapid response in concert with sustained improvements from other modalities.[103]

Like total sleep deprivation, partial deprivation can be immediately effective and has yielded comparable response rates in some studies.[102,103] The timing of partial sleep deprivation (e.g., sleep restricted to the first or second half of the night) does not appear to be as critical as the degree of

deprivation.[103] Chronic REM sleep deprivation also improved depressive symptomatology,[102,103] although the response was not as robust, and it was not clear that NREM sleep was not affected. Unlike with total sleep deprivation, however, the antidepressant effects of chronic REM sleep deprivation took several weeks to appear and were not immediately reversed after recovery sleep. Selective deprivation of slow wave sleep also has been shown to relieve depression symptoms,[104] with the magnitude of the response correlating with the magnitude of the reduction in SWA relative to baseline.

Although the mechanisms underlying the antidepressant effects of sleep deprivation are not entirely known, some promising correlates have been reported. Functional neuroimaging studies suggest an association with effects on limbic structures. Increased rates of glucose metabolism[59] or blood flow[60] in the amygdala and cingulate before sleep deprivation have been reported in depressed subjects who respond to sleep deprivation. Normalization of activity after sleep deprivation in these limbic structures was associated with a decrease in depression.[59,60] Antidepressant responses to partial sleep deprivation have been shown to be related to BDNF, a protein involved in the pathophysiology of depression.[105] Responders showed significant diurnal BDNF serum variation both before and after partial sleep deprivation that was not present in non-responders, suggesting that BDNF may be involved in positive responses, but is not the primary mechanism. Preliminary data from a sample of 12 healthy young male subjects suggest that sleep deprivation may elevate tryptophan, serotonin, and taurine, possibly contributing to the antidepressant effects of sleep deprivation.[106] The antidepressant response to sleep deprivation also has been correlated with other biologic markers in sleep EEG[46,104] and genetic[73] studies. Abnormalities in slow wave sleep are one of the most consistent biologic markers of depression. Additionally, response to sleep deprivation can serve as a biologic marker of a major depression subtype, as well as the basis for designing novel antidepressants.

These findings should not lead clinicians to conclude that insufficient sleep is generally helpful for patients with depression. On the contrary, patients who obtain suboptimal levels of sleep have been shown to have poorer outcomes. In addition, experimental studies have shown that sleep deprivation tends to have deleterious effects on positive emotion in healthy adults.[107,108] Unless sleep restriction is done therapeutically, it should be avoided in patients with depression.

Clinical Application of Sleep Studies

Sleep studies have potential utility in psychiatry for diagnosis and for evaluating treatment. Although a specific psychiatric diagnosis cannot be made solely on the basis of standard polysomnographic data, sleep studies can sometimes answer specific questions. Sleep complaints in most patients with major depression usually are related to the underlying psychiatric illness; however, diagnostic polysomnography can sometimes be helpful given the risk for primary sleep disorders in psychiatric patients, and vice versa. Furthermore, in patients with major depression and significant sleep complaints that do not respond to therapy, it is important to consider the possibility of a concomitant primary sleep disorder, such as OSA, particularly in view of the overlap of common symptoms. For example, sleep apnea and periodic limb movements can disrupt nocturnal sleep and lead to insomnia, fatigue, and poor concentration, which also are symptoms of depression. It is also important to consider side effects of psychiatric medications that may be responsible for precipitating or exacerbating sleep disorders.

The potential prognostic utility of sleep studies in major depression has not yet been fully realized. It is possible that specific sleep abnormalities, such as REM and slow wave sleep changes, may be diagnostic or predictive of treatment response. However, these findings have not shown consistency that is adequate to justify widespread implementation.[32,42] Alternatively, medication-induced changes in sleep patterns may be correlated with treatment response to antidepressants. The amount of REM sleep suppression during the first night of treatment with TCAs was correlated with eventual antidepressant response in several studies,[109,110] although prolongation of REM sleep latency alone was less consistent in predicting treatment response. Sleep variables also may be helpful in identifying persons susceptible to developing affective illnesses or relapses. For instance, a decreased delta sleep ratio has been shown to correlate with an increased risk of relapse and predict treatment outcome.[39,45]

In interpreting sleep studies in clinical settings, it is important to bear in mind that reduced REM sleep latency can be present in a variety of conditions other than mood disorders. Short REM sleep latency and decreased slow wave sleep have been reported in other conditions, including schizophrenia, borderline personality disorder, eating disorders, and alcoholism.[32] Early appearance of REM sleep also is characteristic of narcolepsy. Short REM sleep latency and REM sleep rebound commonly occur in patients who recently have undergone withdrawal from antidepressant medications, benzodiazepines, or alcohol and in patients with OSA during initial continuous positive airway pressure titration.

CLINICAL COURSE AND PREVENTION

Major depression tends to be a remitting and relapsing disorder with a long course, although some patients experience only a single episode. Increasingly, it is recognized that repeated episodes of depression contribute to a poor prognosis, which underscores the importance of early and effective treatment. Patients with multiple episodes of depression probably require chronic treatment to prevent or minimize recurrence.

After treatment with pharmacotherapy or psychotherapy (or both), approximately one third of depressed patients recover fully, one third experience partial remission, and one third do not respond significantly to treatment. Treatment of depressive episodes reduces episode duration, but it should be continued for at least 6 months to 1 year after remission because of the higher risk of relapse during this period. All patients, including those considered to be in remission, can continue to experience residual symptoms of depression. Sleep disturbance is one of the more common residual symptoms and has been estimated to occur in up to 44% of patients in remission from major depression.[111] In addition, insomnia is one of the most predictive symptoms heralding the onset of an episode of depression,[14,112] as discussed earlier. Thus it is not surprising that patients with major depression often suffer from chronic sleep problems.

PITFALLS AND CONTROVERSIES

Considerable evidence indicates that sleep is biologically linked to major depression, although the mechanisms underlying this link are incompletely understood. Perhaps the most basic question is whether a causal link exists between sleep and depression, regardless of the specific mechanism involved. For example, although sleep abnormalities are extremely common in patients with depression, it is unclear if this association indicates that these abnormalities are caused by major depression or whether they occur independently and predispose affected persons to major depression. Indirect evidence suggests that changes in sleep herald the onset of mood episodes. On the other hand, some changes in sleep that occur in patients with depression, such as short REM latency, are unlikely to be causal. For example, although narcoleptic patients have extremely short REM sleep latencies, they are not invariably depressed, and inducing "depressive" sleep patterns in normal persons with cholinergic agents does not cause depression. Although some studies have begun to address the causal relationship of sleep changes and major depression and have evaluated the impact of insomnia treatment on depression outcomes, the effect of concurrent treatment for sleep problems on the clinical course of major depression is not yet fully elucidated.

Continued study of sleep in major depression and in psychiatric disorders in general can be expected to elucidate neurobiologic and genetic mechanisms involved in sleep regulation and psychiatric illnesses and to provide novel directions for future neuropharmacologic treatments.[113,114] Longitudinal studies may be particularly helpful in clarifying the relationship between depression and sleep.[115]

CLINICAL PEARL

Because of the strong association between sleep disturbance and major depression, all patients with sleep complaints should be screened for mood disorders, and vice versa. Sleep may not normalize with resolution of major depression, and recurrence or worsening of sleep can predict the relapse of depressive symptoms. Concurrent and aggressive treatment of sleep problems, in addition to the treatment for mood, is important for decreasing morbidity and improving the patient's quality of life.

SUMMARY

Major depression is commonly associated with sleep disturbance, and sleep problems are part of the diagnostic criteria for this disorder. Although subjective complaints of insomnia are most common, hypersomnia and fatigue are also sometimes reported during periods of depression. Insomnia and hypersomnia are associated with an increased risk for the development or recurrence of depression and increased severity of symptoms. Polysomnographic studies of depressed patients have consistently revealed abnormalities in sleep architecture in comparison to controls, including decreased time in slow wave sleep, reduced latency to REM sleep onset, and disrupted sleep continuity. These associations provide insight into the neurobiologic relationships between mood and sleep. Both subjective and objective sleep abnormalities commonly persist even during periods of clinical remission, making sleep disturbance a chronic problem for many patients with a history of a mood disorder. Accordingly, assessment for depression is essential for any patient with a sleep complaint, and sleep problems often require specific and potentially ongoing treatment in persons with major depression.

Chapter 138

Bipolar Disorder

Allison G. Harvey; Adriane M. Soehner; Daniel J. Buysse

Chapter Highlights

- Different types of sleep and circadian disturbances characterize *mood episodes* (depression, mania, mixed) and *interepisode periods* of bipolar disorder. Sleep disturbances may include insomnia, hypersomnia, reduced sleep need, delayed sleep phase, and irregular sleep patterns. The heterogeneity of these problems in bipolar disorder raises significant challenges for clinical management and research.
- There are several reasons that sleep disturbance may be one important (albeit understudied) mechanism contributing to the mood disorders. Specifically, sleep disturbance is a risk factor for episodes, can contribute to relapse, has an adverse impact on mood regulation, is critical for cognitive functioning, compromises health, and may contribute to substance use comorbidity and suicidality.
- Sleep and circadian rhythms may become perturbed in bipolar disorder because of inadequate, irregular, or inappropriate timing of exposure to light and dark, irregularities in social rhythms, and specific variants in clock gene function.
- Medication treatments for bipolar disorder can produce sedation, and some can also cause insomnia. They also have effects on circadian function.
- Preliminary data suggest that benzodiazepines are associated with worse overall outcome in bipolar disorder. Sedating tricyclic antidepressant drugs should be avoided in the treatment of bipolar depression because of an increased risk of mania.
- Promising psychosocial treatments for sleep and circadian disturbance in bipolar disorder include a combination of cognitive-behavioral therapy for insomnia, interpersonal and social rhythm therapy, chronotherapy, and motivational interviewing.

Bipolar disorder is a common, severe, and chronic psychiatric condition.[1] The lifetime prevalence of the spectrum of bipolar disorders is 2.6% to 6.5%.[2,3] Bipolar I disorder is diagnosed when a patient has experienced at least one manic episode lasting at least 1 week and involving a distinct and abnormal elevated or irritable mood, whereas bipolar II disorder is diagnosed when a patient has experienced at least one episode of major depression and at least one hypomanic episode.[1] The impact of episodes of mania, hypomania, and depression is enormous. People who have been hospitalized as a result of a bipolar episode typically spend 20% of their life in episodes[4] and 50% of their time unwell.[5] Notwithstanding important advances in pharmacologic and nonpharmacologic treatments for bipolar disorder, many patients are seriously symptomatic in the interepisode period despite good adherence and adjunctive interventions, and the risk of relapse is high.

SUBJECTIVE SLEEP COMPLAINTS AND POLYSOMNOGRAPHIC FINDINGS

Clinical Features of Sleep

A range of sleep and circadian disturbances are prominent features of bipolar disorder. Within the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, several types of sleep disturbance are listed as diagnostic criteria for mania, depression, and mixed episodes.[1] Sleep disturbance persists during the interepisode period; up to 70% of adults with bipolar disorder report clinically significant sleep disturbance between episodes.[6] There is also evidence that sleep disturbance can precede the onset of the disorder by several years.[7] Sleep disturbances during mood episodes and interepisode periods of bipolar disorder may include insomnia, hypersomnia, reduced sleep need, delayed sleep phase, and irregular sleep patterns. More specifically, insomnia is highly prevalent in bipolar disorder. As many as 100% of people with bipolar disorder report experiencing insomnia while depressed,[8] and 55% report having insomnia during the interepisode period.[6] Episodes of depression can also be characterized by hypersomnia, or prolonged time in bed with associated excessive sleepiness, although one study carrying out multiple sleep latency testing in this context did not find evidence for sleepiness,[8] and 25% of people endorse symptoms of hypersomnia during the interepisode period.[9,10] Reduced need for sleep is often exhibited during mania and mixed episodes and is characterized by a decrease in total sleep time.[11] Furthermore, people with bipolar disorder are more likely to report circadian dysfunction, such as a delayed sleep phase preference, compared with healthy individuals.[12] Irregular sleep patterns also

characterize bipolar disorder; the mean variability in total sleep time across a week averaged 2.78 hours in a large sample of individuals with bipolar disorder.[13] In interepisode bipolar disorder, lower and more variable sleep efficiency and variability in falling asleep time were related to worse illness course and outcome.[14] Notably, these different types of sleep disturbance can coexist, particularly insomnia and hypersomnia.[9,10] Moreover, in one study, individuals diagnosed with bipolar disorder and individuals at high risk for bipolar disorder both exhibited recurring insomnia, hypersomnia, sensitivity to circadian shifts, and difficulties in waking up relative to a nonpatient group.[15] The heterogeneity of sleep and circadian disturbances in bipolar disorder raises significant clinical management and research challenges.

Polysomnographic Findings

Polysomnographic findings in bipolar depression generally resemble those in unipolar depression but are not consistently observed; the lack of consistent findings is likely related to small sample sizes and considerable heterogeneity among patients. Akin to unipolar depression, patients with bipolar depression tend to experience shortened rapid eye movement (REM) latency relative to healthy adults,[16,17] although this is not a consistent finding.[18] REM density in a bipolar depressed sample was elevated compared with healthy adults and not significantly different from a unipolar depressed group.[17] Reduced non-REM (NREM) stage 3 (N3) has been observed in small samples of bipolar depressed patients relative to healthy adults[19] and at a level equivalent to that of unipolar depressed patients.[20] However, one study found no differences in N3 relative to healthy adults.[18] Finally, in bipolar depressed patients, one investigation reported reduced stage N1 sleep,[18] but most reports have not.[17,19] Within bipolar subtypes, one study observed that depressed bipolar I patients exhibited a trend toward greater fragmentation of REM sleep relative to depressed bipolar II patients.[20] Another study observed no differences between bipolar I and bipolar II patients in NREM and REM sleep parameters, although bipolar II patients demonstrated longer REM latency relative to patients with unipolar depression.[21] Few studies have examined quantitative sleep electroencephalography in bipolar disorder. These studies have reported a trend toward greater sleep spindles in bipolar depressed patients relative to unipolar depressed patients[22] and no difference in delta power among individuals with bipolar depression compared with matched controls ($n = 8$ per group).[23]

Sleep architecture findings during mania are also mixed. Two small studies have shown that adults with mania tend to exhibit shortened REM sleep latency and increased REM density[24,25] relative to healthy nonpatients, although these differences were not observed in another report.[26] One study observed that N1 and N3 percentage was increased in manic patients compared with healthy adults,[27] but another did not report altered NREM sleep in mania.[26]

During the interepisode phase, two studies have found evidence for increased REM density in both unmedicated[28] and medicated bipolar samples.[29] Increased REM density was also observed in a sample of interepisode bipolar disorder patients relative to controls and particularly following a sad mood induction conducted just before bedtime.[30] The latter study also reported a trend toward a shorter first REM episode following the sad mood induction compared with a baseline night in the bipolar disorder group, whereas a trend in the opposite direction was observed for the control group. Talbot et al[30] suggested that these results raise the possibility that the bipolar group may have exhibited an adaptive increase in REM density following a sad mood (as did the control group) but that this attempt to regulate mood during sleep was offset by the shorter length of REM period in the bipolar group relative to the control group. However, one study found no differences in sleep architecture between healthy adults and interepisode bipolar participants.[31] In all three studies, there were no observed differences in NREM sleep in the bipolar samples relative to healthy adults.[28,29,31]

In summary, polysomnographic studies in bipolar disorder are difficult to conduct because of the heterogeneity of clinical features and difficult to interpret because of small sample sizes and medication effects. Most studies indicate that bipolar disorder, like unipolar depression, is characterized by reduced sleep continuity, short REM latency, and increased REM density, with inconsistent findings regarding quantitative electroencephalography.

SLEEP DISTURBANCES AND CORE DOMAINS OF DYSFUNCTION

Figure 138-1 graphically summarizes three pathways, which are discussed in this section, by which sleep disturbance in bipolar disorder may contribute to significant impairment among people with bipolar disorder.

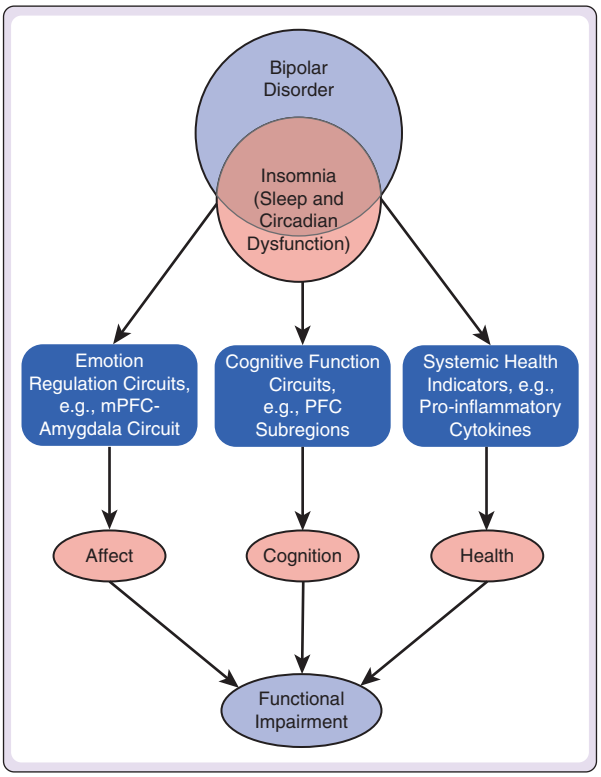

Figure 138-1 Conceptual model depicting sleep disturbance in bipolar disorder as a pathway contributing to poor outcomes (*ovals*) through specific neural and systemic mechanisms (*rectangles*). PFC, Prefrontal cortex; mPFC, medial prefrontal cortex.

Affect

Affective dysregulation in the form of alterations in the processes and neural circuits underlying mood is a hallmark feature of bipolar disorder. Mounting evidence suggests that sleep disturbance contributes to affective dysregulation. Sleep disturbance is a common prodrome, or precursor, of relapse.[32] Experimentally induced sleep deprivation is associated with the onset of hypomania or mania in a subset of patients.[33–35] Patients with short sleep exhibit greater mood symptom severity, poorer daytime functioning, and lower life satisfaction compared with those with longer sleep times.[13] Moreover, shorter total sleep time is associated with increased mania and depression severity during 12 months.[36] In a 7-day diary study, greater total wake time was associated with next-day morning negative mood in individuals with bipolar disorder, and evening negative mood was associated with subsequent total wake time in both bipolar disorder and insomnia.[37]

Few investigations have examined the relationship between sleep architecture and mood in bipolar disorder. In one study of interepisode bipolar disorder, sleep architecture was not correlated with concurrent mood symptoms.[29] However, greater REM density was correlated with more severe depressive symptoms and greater functional impairment at 3 months, whereas prolonged duration of the first REM period and a greater amount of slow wave sleep were positively correlated with manic symptoms and impairment at 3 months. In addition, the amount of N2 sleep was negatively correlated with manic symptoms and impairment at 3 months. In manic patients, Hudson et al[25] found that time spent asleep and REM percentage inversely correlated with mania severity.

The observed associations between sleep and affect in bipolar disorder are not surprising given that in studies of healthy adults without psychiatric illness, sleep has a critical mood-regulatory function. Neuroimaging investigations indicate that sleep loss impairs top-down inhibitory control exerted by medial prefrontal cortex on amygdala and reward circuitry.[38,39] Circuits involved in emotion regulation and sleep regulation also interact in bidirectional ways.[40] Moreover, abnormalities in REM sleep across phases of bipolar illness may be another pathway by which sleep contributes to mood and emotion regulation difficulty in bipolar disorder.[41] Indeed, there is evidence that REM sleep is important for the encoding, regulation, and consolidation of emotional memories.[42]

Health

Medical morbidity and premature mortality are characteristic of bipolar disorder.[43] Indeed, bipolar disorder confers a 1.5- to 2.5-fold increase in risk for mortality from cardiovascular disease (CVD), making CVD the leading cause of death of individuals with bipolar disorder.[44] CVD risk factors, such as hypertension, obesity, and diabetes mellitus, occur with greater frequency in bipolar disorder relative to the general population.[45,46] The accumulation of CVD risk in bipolar disorder might be attributed to long-term psychopharmacologic treatment or unhealthy lifestyles (inadequate exercise, poor diet). However, insomnia may also contribute to poor health[47,48] both indirectly and directly through increased mechanisms, such as increased proinflammatory cytokine activity.[49,50]

Cognition

Cognitive dysfunction in the form of alterations in the processes and neural circuits underlying a broad range of cognitive processes, such as attention, memory, and problem solving, is characteristic of bipolar disorder[51] during acute and interepisode periods and is associated with poorer functional and psychosocial outcome.[52] Given that there are dramatic adverse effects of sleep deprivation in healthy adults on a range of cognitive tasks[53,54] associated with various subregions of the prefrontal cortex[55,56] and that insomnia is also characterized by subtle cognitive deficits,[57] it seems likely that sleep disturbance contributes to cognitive dysfunction in bipolar disorder, although this hypothesis remains to be formally tested.

Additional Domains

Sleep disturbances are risk factors for substance use problems[58] and suicide[59] among individuals *without* bipolar disorder. Because substance use and suicide are particularly prevalent among individuals with bipolar disorder,[60,61] a hypothesis to test in future research is that sleep disturbance contributes to these problems specifically among individuals with bipolar disorder. However, given the relatively low prevalence of bipolar disorder and the actual rate of suicide, it may be most useful to examine sleep-suicide relationships through intermediate mechanisms, such as alterations in executive and reward function.[62,63]

PATHOPHYSIOLOGY OF SLEEP DISTURBANCE IN BIPOLAR DISORDER

Inadequate, Irregular, or Inappropriate Timing of Exposure to Light and Dark

The mood and activity symptoms of bipolar disorder are often cyclic, suggesting that even at the symptom level, a relationship with endogenous rhythmic processes, including circadian rhythms, is core to the disorder. Behaviors that influence the amount of exposure to light and dark are also likely to be important to both sleep and circadian functioning as well as to mood. Circadian processes, including circadian sleep-wake propensity (process C), are controlled by the suprachiasmatic nuclei (SCN) in the hypothalamus. The SCN receive environmental light and dark information. The amount and timing of light influence the increased release or suppression of melatonin. This is because one of the important downstream projections of the SCN is the pineal gland, which secretes melatonin. Secretion of melatonin peaks at night, is suppressed by light, and is practically nonexistent during the day. As melatonin release contributes to sleepiness, exposure to light during this period may suppress melatonin onset. Accordingly, inadequate, irregular, or inappropriate timing of exposure to light and dark, related to the selection and timing of activities, may have an adverse impact on sleep (including the light from computer screens and televisions). There is accruing evidence for the impact of and possible sensitivity to light and dark in patients with mood disorders.[64] This is perhaps not surprising given that the behavioral changes that can be associated with mood disorders may alter exposure to light and dark (inadequate dark during mania, inadequate light during depression).

The endogenous period generated in the SCN is close to but generally not equal to 24 hours. The process by which the

circadian clock is kept in appropriate phase with seasonally shifting astronomical day length is called *entrainment*. In other words, an important feature of the circadian system is its fundamentally open nature. Entrainment occurs through *zeitgebers*, which are environmental events that can affect the phase and period of the clock. The primary zeitgeber in most species is the daily alteration of light and dark. Hence, the selection and timing of daily activities will have an impact on exposure to light and dark, which in turn will influence sleep and circadian rhythms. Indeed, the selection and timing of engagement with activities may be important contributors to mood disorders, a topic to which we return later in the discussion of interpersonal and social rhythm therapy (IPSRT).

Unstable Social Rhythms

Other powerful *nonphotic* cues that influence the SCN include social cues, such as the timing of social interactions and meals,[65] which can be described as social rhythms. For example, higher daily regularity in social rhythms (e.g., social interactions or mealtimes occurring at about the same time each day) is associated with a stronger endogenous temperature rhythm, suggesting stronger overall circadian functioning.[66] Moreover, more regular social rhythms are associated with better subjective sleep quality.[66] Given that depression is associated with lower social support[67] and more social strain,[68] it is possible that disruption to social rhythms is a risk factor for mood disorders. Again, this issue is expanded on later.

Circadian Genes

The molecular mechanisms of the circadian clock in mammals are well understood. Specifically, cells in the SCN generate self-sustained rhythmicity through an autoregulatory transcription-translation feedback loop regulating expression of the *CLOCK*, *Period* (*Per1, Per2, Per3*), *cryptochrome* (*Cry1, Cry2*), *TIM*, *BMal1*, *NPAS*, *DEC1*, and *DEC2* genes.[69] Several studies have reported links between the circadian genes and the mood disorders. For example, bipolar disorder and treatment response have been associated with mutations or polymorphisms in *TIM*, *Clock* (311 T to C) and *BMal1*,[70] and *CLOCK* (homozygous for the C allele). Clock genes have also been implicated in other mood disorders: *Per2*, *NPAS2*, and *Bmal1* are associated with seasonal affective disorder,[71] and *Per1*, *CLOCK*, and *Baml1* mRNA levels are associated with major depressive disorder.[72]

Although this line of research is in its infancy and is often limited by small samples, the findings are consistent with the growing overall picture of sleep and circadian vulnerability as a feature of the mood disorders. Importantly, and consistent with the proposal that psychiatric disorders are likely to be associated with multiple genes of small effect,[73] most of the associations reported are modest, and failures to replicate are common.[74]

TREATMENT OF SLEEP DISTURBANCE IN BIPOLAR DISORDER

Sleep disturbances in bipolar disorder can be treated with pharmacologic, behavioral, and somatic (e.g., bright light) interventions. Pharmacologic treatments can be divided into those aimed at treating the core features of bipolar disorder and those aimed at treating sleep disturbances associated with bipolar disorder. However, this distinction is imperfect because medications that target mood cycling can also have important effects on sleep and circadian function, and medications that target sleep and circadian disturbances can affect mood.

Current treatment guidelines (summarized in[75]) recommend the following medications for first-line treatment of *depression* in bipolar I disorder: quetiapine, olanzapine, olanzapine-fluoxetine combination, lamotrigine, lithium, and valproate. Selective serotonin reuptake inhibitor (SSRI) antidepressants or bupropion may also be used in combination with an antimanic agent (e.g., lithium, valproate). Second-line treatments include combinations of these various agents as well as consideration of treatments such as antidepressants, electroconvulsive therapy, and psychotherapy. Notably, each of the first-line treatments can produce sedation, and some of them (e.g., lamotrigine) can also cause insomnia. Thus, the time of administration may be an important treatment consideration. For instance, medications such as quetiapine and olanzapine may be given at bedtime to help treat insomnia, and lithium may be given in divided doses but with the largest dose at night. In clinical trials, atypical antipsychotic drugs such as quetiapine have been associated with not only relief of bipolar depression but also improved sleep.[76]

The sedative and sleep-promoting effects of medications used for bipolar depression result from a variety of effects on neurotransmitter and receptor function. Antipsychotic drugs antagonize dopamine DA_2 and DA_3 receptors and histamine receptors. Atypical antipsychotic drugs also have significant serotonin receptor *antagonist* effects, particularly at $5\text{-}HT_{2A/2C}$ and $5\text{-}HT_7$ receptors, and serotonin $5\text{-}HT_{1A}$ *agonist* effects.[77] Lithium, valproate, and lamotrigine reduce dopaminergic and glutamatergic neurotransmission and increase GABAergic neurotransmission, likely through second messenger pathways including adenylate cyclase and phosphoinositide pathways.[78] Lamotrigine and valproate also block voltage-gated sodium channels and calcium channels.[79]

Current guidelines (summarized in[80]) recommend the following medications for first-line treatment of mania in bipolar disorder: lithium, valproate, atypical antipsychotic drugs, haloperidol, carbamazepine, and combinations of lithium or valproate with antipsychotic drugs. Second-line treatments involve various combinations of these drugs, electroconvulsive therapy, and other antipsychotic and anticonvulsant drugs. As is the case with treatment of bipolar depression, the timing of sedating medications may be used to help manage the sleep disturbance associated with acute mania.

In addition to their effects on sleep and wakefulness, medications used to treat bipolar disorder also have effects on circadian function (see[81–83] for reviews). For instance, lithium delays circadian rhythm phase and lengthens circadian rhythm period in animals and humans and can increase PER2 rhythm amplitude. This effect may relate to lithium's inhibition of glycogen synthase kinase 3β, which interacts with multiple proteins involved in the transcription-translation feedback loop of the molecular clock. Likewise, valproate has been observed to increase the amplitude of clock gene protein expression, to shift circadian phase, and to lengthen circadian period. SSRI antidepressants, on the other hand, can advance circadian phase, shorten circadian period, and alter phase shifts in response to light or other stimuli. These effects may be modulated by innervation of the SCN by serotonergic neurons from the raphe nuclei. Some of the circadian effects described for SSRIs and mood

stabilizers, like lithium, appear to be in opposite directions. This may have a clinical correlate in the ability of SSRIs to precipitate mania among patients with bipolar disorder. Finally, the antidepressant agomelatine, a combined melatonin MT_1 and MT_2 receptor agonist and serotonin $5\text{-}HT_{2C}$ receptor antagonist, has sleep and circadian effects. These include increased slow wave sleep, synchronization of free-running circadian rhythms, and phase-shifting effects similar to those observed with melatonin.

Medications used to treat insomnia outside of bipolar disorder, such as benzodiazepine receptor agonists and sedating antidepressants, may have mood effects among patients with bipolar disorder. Zolpidem was the most commonly prescribed medication for insomnia in bipolar disorder in one chart review,[84] but case reports on benzodiazepines for insomnia in bipolar disorder have not been encouraging.[85,86] Indeed, drawing from the large sample who participated in the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD), Perlis et al[87] reported that benzodiazepines were associated with worse overall outcome. Likewise, systematic reviews of the treatment of nonbipolar depression suggest that concomitant treatment with benzodiazepine receptor agonists and antidepressants may improve initial treatment adherence and response but not longer term treatment response.[88] Sedating tricyclic antidepressant drugs, often used as second-line agents for the treatment of primary insomnia, should be avoided in the treatment of bipolar depression because of an increased risk of mania.[89] A case report on gabapentin[90] and open trials of medications targeting circadian rhythms[91,92] are more promising but preliminary.

There may be some advantages to treating sleep disturbance in bipolar disorder nonpharmacologically because there are fewer side effects and interactions with concurrent mood-stabilizing treatments and some insomnia medications pose a risk of abuse, a concern given the prevalence of comorbid substance use in bipolar disorder.[93] Existing evidence-based nonpharmacologic interventions for bipolar disorder include psychoeducation,[94] prodrome monitoring,[95] IPSRT,[96] family therapy,[97] and cognitive-behavioral therapy (CBT) administered individually[95] or in groups[98] as well as combination approaches.[99] These treatments, several of which include some attention to sleep disturbances, reduce relapse among adults with bipolar disorder. However, most of the trials of these treatments have not included sleep as a primary emphasis nor have they included sleep outcome measures or incorporated specific insomnia treatment techniques.

In light of the ongoing need for novel, effective, well-tolerated treatments for bipolar disorder, we recently developed and tested a bipolar disorder–specific modification of CBT for insomnia (CBTI-BP). We present the details of this novel treatment to illustrate how sleep and circadian principles can be incorporated into the treatment of bipolar disorder. The modifications were focused on improving safety and targeting the unique features of sleep in bipolar disorder by integrating elements from IPSRT, chronotherapy, and motivational interviewing. CBT for insomnia (CBT-I) was selected as the basis for the treatment because (1) substantial evidence demonstrates the efficacy of CBT-I,[100] even for insomnia comorbid with depression,[101] post-traumatic stress disorder,[102] and schizophrenia[103]; (2) when insomnia is comorbid with another psychiatric disorder, the symptoms associated with the other psychiatric disorder can also improve after CBT-I[101,103]; (3) previous treatments for bipolar disorder have not been informed by the principles underlying CBT-I[14]; and (4) CBT-I improves sleep efficiency, reduces night-to-night variability, and improves sleep-onset latency, all of which are problematic for patients with bipolar disorder.[14] Elements were added from IPSRT[96] to regularize daily social rhythms (i.e., mealtimes, social contact, exercise) and to build on regular bed and wake-up times traditionally emphasized in CBT-I. Promising data on chronotherapy, such as dark therapy and light therapy,[64] were integrated by adding a 30- to 60-minute wind-down period in dim light and exposure to light on waking within an individualized wake-up routine. However, the optimal duration and intensity of morning light have not been identified empirically. Motivational interviewing[104] was incorporated in every session, given the challenges inherent to behavior change and recognizing the rewarding nature of many sleep-incompatible behaviors. The targets of CBTI-BP along with the treatment elements are summarized in Table 138-1.

The unique features of bipolar disorder necessitated modifications to CBT-I. Specifically, the sleep restriction component of CBT-I was limited to mitigate the risk of sleep loss triggering mania,[33–35] and the nighttime awakening procedures of stimulus control were limited to reduce potential engagement in goal or reward pursuit[105] during prolonged awakenings. The highly variable sleep-wake schedules, tendency toward delayed bedtimes, sensitivity to light,[106–108] sleep inertia, and daytime sleepiness present in many bipolar patients were also areas of emphasis in treatment. Trials of CBT-I in primary insomnia have shown improvements in subclinical mood symptoms[100] but have not determined whether CBT-I can stabilize mood in bipolar disorder. The bipolar disorder treatments have not examined efficacy *on sleep–specific symptoms*.

In a pilot investigation of this approach alongside routine psychiatric care, interepisode bipolar disorder I participants with insomnia were randomly allocated to CBTI-BP ($n = 30$) or to psychoeducation (PE; $n = 28$) as a comparison condition.[109] Outcomes were assessed at baseline, at the end of eight sessions of treatment, and 6 months later. The results indicated that during the 6-month follow-up, the CBTI-BP group had fewer days in a bipolar episode relative to the PE group (3.3 days vs. 25.5 days). The CBTI-BP group also experienced a significantly lower hypomania or mania relapse rate (4.6% vs. 31.6%) and exhibited a trend toward lower overall mood episode relapse rate (13.6% vs. 42.1%) compared with the PE group. Relative to PE, CBTI-BP also reduced insomnia severity and led to higher rates of insomnia remission after treatment and at 6 months. Notably, this approach appears to be safe and tolerable.[110] These results underscore the value of treatments that aim to improve sleep and to reduce circadian disturbances in bipolar disorder and support the proposal that disturbed sleep constitutes a mechanism that substantively contributes to bipolar disorder.

CONCLUSIONS

Thus far, research evidence consistently supports a link among sleep, mood, impairment, and quality of life in bipolar disorder. However, several important gaps in knowledge remain. At a foundational level, more research is needed to

Table 138-1 Summary of a Bipolar Disorder–Specific Modification of Cognitive-Behavioral Therapy for Insomnia (CBTI-BP)

Targets of CBTI-BP	CBTI-BP Treatment Approaches
Building motivation to change and/or not valuing sleep	Sleep and circadian education and motivational interviewing
Irregular bed and wake-up times	Regularize night-to-night bed and wake times
Irregular daytime rhythms	Interpersonal and social rhythms therapy to regularize times for meals, socializing, exercise, and other daytime rhythms
Difficulty getting to sleep, wakings in the night, or waking too early in the morning	Stimulus control, including establishing a wind-down routine, and sleep restriction Dim light exposure at bedtime and during awakenings
Difficulty waking up	Devise a wake-up routine and daytime activity scheduling to establish activities to get up for Bright light exposure on waking
Daytime impairment	Education and behavioral experiments to test contributors to daytime impairment, including the identification of "energy-sapping" and "energy-generating" activities
Unhelpful beliefs about sleep	Education, cognitive therapy, and behavioral experiments to test unhelpful beliefs
Poor sleep efficiency	Stimulus control and sleep restriction
Too much time in bed	Sleep restriction
Delayed phase	Advancing bedtimes by 30–60 min/wk
Sleep-related worry	Cognitive therapy to teach methods to manage thoughts that interfere with sleep
Maintenance of behavior change	Relapse prevention

understand the prevalence of sleep disturbances (insomnia, hypersomnia, delayed sleep phase, reduced sleep need) across the life course of bipolar disorder, in the bipolar disorder subtypes, and during mixed mood episodes (i.e., when diagnostic criteria are met for *both* a manic episode and an episode of depression). In addition, the nature and role of sleep architecture in the course of bipolar disorder remain understudied, with the majority of polysomnographic investigations in bipolar disorder having been conducted approximately two to three decades ago. It will also be crucial to identify causal and potentially bidirectional pathways between sleep disturbance and mood in bipolar disorder. There is robust behavioral and neuroimaging evidence among healthy nonpatient samples that sleep deprivation undermines emotion regulation the following day. Further neuroimaging studies of bipolar patients may elucidate the mechanisms by which sleep and circadian symptoms and treatments influence mood, cognition, and activity in bipolar patients.

Given the high rates of sleep disturbance in bipolar disorder, it is surprising that few controlled trials of medication or psychological interventions for sleep have been conducted in this population. There is exciting preliminary evidence that treating sleep disturbance with adaptations of CBT-I can reduce relapse rates, supporting the notion that treating sleep can improve the course of illness. However, certain treatment complexities in bipolar disorder need to be better understood. For example, phase of bipolar illness may affect selection of treatment approaches. During manic or mixed episodes, a pharmacologic approach for sleep may be most appropriate to aid in fully stabilizing a patient. Yet, during bipolar depression or the interepisode period, psychological approaches may be preferable because of the reduced risk of negative side effects. Larger controlled trials testing psychological and pharmacologic therapies in bipolar disorder hold promise not only for improving sleep but also for increasing mood stability and enhancing quality of life.

CLINICAL PEARLS

- Disturbed sleep and circadian rhythms constitute a mechanism that substantively contributes to symptoms and functional impairments in bipolar disorder.
- Treatments that aim to improve sleep and circadian disturbances in bipolar disorder should be provided as part of front-line treatment.
- Behavioral approaches emphasizing the stabilization of bed and wake times, along with dim light conditions at night and bright light conditions on waking, appear to be helpful for reducing impairment and vulnerability to relapse.

SUMMARY

Sleep and circadian dysfunctions are important mechanisms contributing to the onset and maintenance of symptoms and dysfunction in bipolar disorder. Sleep disturbance is a risk factor for episodes, can contribute to relapse, has an adverse impact on emotion regulation, compromises health, is critical for cognitive functioning, and may contribute to substance use comorbidity and suicidality. Factors driving sleep and

circadian disturbance in bipolar disorder may include inadequate, irregular, or inappropriate timing of exposure to light and dark, irregularities in social rhythms, and specific variants in clock gene function. The accumulated evidence has informed a range of novel, powerful, simple, and inexpensive treatments with potential for significant improvements in quality of life, decreasing length and severity of episodes and reducing the risk of subsequent episodes.

Chapter
139

Schizophrenia

Kathleen L. Benson; Irwin Feinberg

Chapter Highlights

- Schizophrenia, perhaps the most devastating neuropsychiatric illness, is associated with immense human suffering and economic cost. Currently schizophrenia can neither be prevented nor cured. No specific or diagnostic laboratory abnormality has yet been identified; consequently, schizophrenia remains a clinical diagnosis. This chapter discusses the complex etiology and pathology associated with schizophrenia. Included in the range of pathologic findings are abnormal sleep patterns.
- Subjective complaints of poor sleep quality have been validated by objective polysomnographic (PSG) assessments. This chapter reviews these PSG assessments. These studies include overnight measures of sleep maintenance and sleep staging using conventional measures of sleep scoring as well as overnight measures of sleep-related brain wave activity. Circadian rhythm abnormalities are also reviewed.
- Most patients with schizophrenia require long-term treatment with antipsychotic medications. These agents are classified as first-generation or second-generation antipsychotics. They differ in their receptor binding profiles, clinical efficacy, and range of side effects. This chapter addresses the effects of antipsychotic agents on measures of sleep maintenance and sleep stages.
- Schizophrenic patients also suffer from a range of dyssomnias including poor sleep hygiene, irregular sleep-wake patterns, parasomnias, obstructive sleep apnea, restless legs syndrome, and periodic limb movements during sleep. This chapter describes how antipsychotics agents may induce or exacerbate dyssomnias.

In many ways, the normal dream experience is similar to psychosis. Hallucinations, perceptual distortions, bizarre thinking, and temporary delusions can intermingle with more normal thought and perceptual processes. Consequently, the discovery of rapid eye movement (REM) sleep and its associated dream reports[1] not only ushered in the modern era of sleep research but also stimulated many of the seminal studies of the sleep of schizophrenics. These studies[2-5] explored the hypothesis that the pathogenesis of schizophrenia might rest with REM sleep abnormalities or, more directly, with the intrusion of the dream state into waking. These early polysomnographic (PSG) studies of sleep in schizophrenic patients found no gross abnormalities of REM sleep or any evidence of an intrusion of REM sleep into wakefulness. However, in subsequent years, a large body of research revealed other abnormalities more frequently present in the sleep patterns in schizophrenia.

Schizophrenia is associated with immense human suffering and economic cost and is often accompanied by disturbances of sleep. This chapter provides an overview of the clinical features of schizophrenia and associated risk factors and neuropathology. It also describes the sleep abnormalities frequently encountered in schizophrenia and their neurobiologic correlates. Finally, we address the issues surrounding antipsychotic medications and their side effects, particularly those associated with the development of comorbid dyssomnias.

EPIDEMIOLOGY AND RISK FACTORS

Epidemiologic studies of schizophrenia suggest a median lifetime prevalence of 0.7% with a male-to-female incidence ratio of 1.4:1 worldwide.[6] The age of onset is usually in the second decade of life and the disorder seems to begin earlier in men than in women.

Although the etiology of schizophrenia is enigmatic and its elucidation a continuing challenge, several factors have been associated with an increased likelihood for disease development. First, a genetic predisposition greatly elevates the risk for developing schizophrenia. Meta-analysis of twin studies indicates that the heritability of schizophrenia is high, roughly 81%.[7] Broadly speaking, the prevailing genetic models encompass two scenarios: first, an additive polygenic model consisting of multiple combinations of common mutations that cumulatively increase the risk for schizophrenia; and second, a heterogeneity model postulating highly penetrant, individually rare mutations that are associated with high risk for disease development.[8] A recent genome-wide association study identified 108 schizophrenia-associated loci.[9] The additive polygenic model would suggest that multiple forms or phenotypes of schizophrenia might exist. The twin study meta-analysis[7] also demonstrated significant shared or common environmental effects influencing liability to schizophrenia. The environments of twins tend to increasingly

diverge during childhood, adolescence, and adulthood but are similar or shared in utero and in the postnatal period. Several environmental factors (from the prenatal period through adolescence) may increase the liability to schizophrenia. Epigenetic mechanisms, largely through modulation of gene expression, could be the vehicle that mediates these gene-environment interactions.[10] In conclusion, multiple genetic variants in combination with a range of environmental factors suggest that schizophrenia is best viewed less as a unitary disorder but more as a family of disorders.[11]

DIAGNOSIS

The term *schizophrenia* derives from Bleuler's description of the splitting or disintegration of normal thought processes.[12] His belief that cognitive impairment or thought disorder is the defining symptom of schizophrenia shaped the course of diagnostic criteria developed during the 20th century. Current criteria for the diagnosis of schizophrenia are defined in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5; Box 139-1).[13] Black and Andreasen[14] describe schizophrenia as a clinical diagnosis that has no specific laboratory abnormalities that are diagnostic. Schizophrenia is also, in large part, a diagnosis of exclusion, which requires eliminating psychotic disturbances that might be produced by a wide range of medical, psychiatric, and substance-abuse disorders. The number and diversity of symptoms that can arise in individual patients can challenge the clinical diagnosis.

The characteristic symptoms of schizophrenia[13] (see Box 139-1) are organized into two main categories: positive and negative symptoms. According to DSM-5, "positive symptoms appear to reflect an excess or distortion of normal functions, whereas the negative symptoms appear to reflect a diminution or loss of normal functions." Positive symptoms can be further subdivided into a psychotic dimension that includes hallucinations and delusions and a disorganization dimension that includes disorganized speech and behavior. Negative symptoms include flattening of affect, avolition, and poverty of speech. The second diagnostic criterion[13] (see Box 139-1) reflects a marked deterioration in occupational and social functioning.

The sleep abnormalities found in schizophrenia lack diagnostic specificity. Consequently, they do not reliably differentiate schizophrenia from other psychiatric disorders. It is unlikely, therefore, that a sleep clinic would be asked to diagnose schizophrenia. However, the sleep clinic could help differentiate schizophrenia from narcolepsy, which can manifest with a strong hallucinatory component.[15] Given the high frequency with which sleep problems occur in patients with schizophrenia, sleep clinicians may also be faced with managing sleep problems in these patients.

Box 139-1 DSM-5 DIAGNOSTIC CRITERIA FOR SCHIZOPHRENIA

Diagnostic Criteria

A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be (1), (2), or (3):
   1. Delusions
   2. Hallucinations
   3. Disorganized speech (e.g., frequent derailment or incoherence)
   4. Grossly disorganized or catatonic behavior
   5. Negative symptoms (i.e., diminished emotional expression or avolition)

B. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved before the onset (or when the onset is in childhood or adolescence, there is failure to achieve expected level of interpersonal, academic, or occupational functioning).

C. Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or by two or more symptoms listed in criterion A presented in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

D. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms, or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

E. The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

F. If there is a history of autistic disorder or another pervasive developmental disorder, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations are also present for at least 1 month (or less if successfully treated).

PATHOLOGY

Although the etiology of schizophrenia is poorly understood, accumulating evidence reveals a wide range of brain abnormalities.[14] Brain structural abnormalities have been found in postmortem studies and in living subjects by computed tomography and magnetic resonance imaging.[13,14] Regarding the latter, structural dysmorphologies have included enlarged lateral and third ventricles; loss of total gray matter, frontal, and temporal lobe volume; and a reduction in total brain size. These findings seem to be present at the onset of illness and do not seem to be the result of progressive degeneration; however, most findings are nonspecific and are observed in other psychiatric disorders. Functional imaging studies using positron emission tomography or regional cerebral blood flow have reported decreased metabolism in the frontal cortex (hypofrontality) and left hemisphere dysfunction.

Abnormalities of neurotransmitter systems have also been extensively investigated. For many years, the prevailing theory of schizophrenia has centered on the dopamine (DA) system. The DA hypothesis of schizophrenia derived from two

observations. First, the potency of standard antipsychotic medication correlates with the amount of D_2 receptor blockade. Second, drugs such as amphetamines, which enhance DA activity, can cause a psychosis that mimics paranoid schizophrenia and can exacerbate schizophrenic symptoms. The hypothesis holds that psychotic symptoms such as hallucinations and delusions are associated with hyperactivity of the mesolimbic DA system. Coupled with or independent of DA dysfunction, an abnormality of the excitatory neurotransmitter glutamate may also play a role in the pathophysiology of schizophrenia.[16,17] Agonists of metabotropic glutamate receptors are currently being investigated as treatments for schizophrenia.[18] Metabotropic glutamate receptor agonists actually decrease brain excitability. They also have profound effects on the sleep electroencephalogram (EEG), diminishing REM sleep and non–rapid eye movement (NREM) fast frequencies in the rat.[19] Serotonin (5-hydroxytrypamine [5-HT]) and norepinephrine have also been associated with the pathophysiology of schizophrenia because the potency of second-generation antipsychotics has been linked to 5-HT and α-adrenergic receptor blockade. Finally, cortical and subcortical abnormalities of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) may have a potential role in the pathophysiology of schizophrenia.[20,21]

Additionally, immune system abnormalities with associated neuroinflammation may play a role not only in elevating the risk for schizophrenia but also in schizophrenia-related brain dysfunction after the onset of the disease. Most research has focused on early life exposure to infection, the development and effects of proinflammatory cytokines, and immune-related genes.[22,23] Some investigators believe that schizophrenia is an autoimmune disease triggered by maternal antibodies to viral infection.[24]

Because no discrete pathologic abnormality has emerged as an etiologic factor, it has been proposed that schizophrenia might be an abnormality of neuronal connectivity[25] or of integrative neuronal circuits.[26-29] Failures of communication within and between neuronal substrates are consistent with the current prevailing view that schizophrenia is a neurodevelopmental disorder.[30,31] Although abnormal events can occur early in development (prenatal or perinatal), maturational abnormalities can appear during the second decade of life[32] or even into middle age.[33]

CLINICAL COURSE AND PREVENTION

In the prevailing pathophysiologic model, schizophrenia is viewed as a neurodevelopmental disorder with onset typically (but not always) in late adolescence. The onset may be abrupt or insidious—that is, beginning with a prodromal phase characterized by subtle changes in behavior, mild thought disorder, and social withdrawal. The prodromal phase is followed by an active phase marked by positive psychotic symptoms such as hallucinations and delusions. This phase can wax and wane, but some degree of psychoticism usually persists during the waning or residual phase. Positive symptoms (relapse or acute exacerbation) can recur episodically. Over the course of the illness, positive psychotic symptoms can gradually decline; in contrast, negative symptoms such as affective flattening and avolition tend to increase with the progression of the disease.

For about 50% of patients, the onset of the illness is both progressive and insidious; for the remainder, the onset is acute, with little or no prodromal syndrome. Also, for about 50% of patients, the course of the illness is continuous; for others the course is marked by episodic flare-ups. The likelihood of relapse has been associated with stressful life events, a critical and hostile family environment, and drug abuse.

If a positive outcome is defined as the absence of psychotic symptoms and normal levels of social functioning, long-term follow-up studies suggest that 20% to 30% of patients have a full recovery. Another 20% to 30% of patients recover to levels where they can function occupationally and socially, but they have residual symptoms. Approximately 50% continue to show moderate to severe dysfunction requiring numerous outpatient interventions or rehospitalization with each relapse. Approximately one fifth require long-term institutionalization. Although antipsychotics can lower the number of hospitalizations, antipsychotic treatment does not fundamentally alter these outcomes. Better outcomes are associated with acute onset, episodic course, female sex, and lack of family history of schizophrenia.

The course of illness in schizophrenia can include dysphoria or depressive episodes, particularly early in the course. Relative to other major psychiatric disorders, schizophrenic patients tend to marry less, are more likely found in an institutional setting, and have poorer occupational functioning. Schizophrenic patients also have a twofold to threefold increased risk for dying; this higher mortality rate encompasses both suicide as well as physical illness.[6] One intriguing question, still unresolved, is why the incidence of schizophrenia has not declined over the past century despite both greater mortality and decreased fecundity in this illness. One possible explanation is that the illness occurs as a stochastic error in the genetic development of the enormously complex human nervous system.[34]

Schizophrenia is certainly among the most devastating psychiatric illness in its human and economic costs. At present, we can neither cure this disorder nor prevent its occurrence. Most schizophrenic patients, after an early onset, will endure lifelong mental disability as well as social and economic marginalization.

SLEEP-RELATED FEATURES

Subjective Sleep Complaints

With the onset of psychotic symptoms, and with each subsequent relapse, sleep is usually markedly impaired. The sleep of schizophrenic patients who are in a state of psychotic agitation usually, but not invariably, is manifested by prolonged periods of sleeplessness. In times of less severe psychotic agitation, sleep is often characterized by pronounced insomnia—long sleep-onset latencies, reduced total sleep time, and sleep fragmented by bouts of waking. Recurrence or exacerbation of symptoms is often heralded by increasing insomnia. Even among clinically stable, medicated patients with schizophrenia, ongoing subjective sleep disturbance is common, particularly early and middle insomnia.[35,36] There may also be a reversal of sleep and wake so that the patient sleeps during the day and remains awake at night. Subjective complaints of poor sleep quality are correlated with sleep-wake reversals.[37]

Schizophrenic patients also complain of poor sleep quality, including restlessness and agitation, disturbing hypnagogic hallucinations, and nightmares. Subjectively assessed poor sleep quality is predictive of self-assessed poor quality of life

and impaired coping skills.[38,39] Although there are no systematic studies, anecdotal clinical reports suggest that alcohol and substance abuse can disturb sleep and cause the patient to relapse. Alternatively, use of these drugs may be an attempt to self-medicate and attenuate the psychic misery of this illness.

Polysomnographic Features

PSG studies have provided a comprehensive and objective description of the range of dyssomnias found in schizophrenia, and they have been broadly consistent with subjective complaints. However, these PSG studies have, on occasion, produced discrepant findings, owing perhaps to differences in protocol design, composition of control groups, sample size, inclusion criteria (e.g., age, medication status and history, clinical features, and clinical history), and algorithms used to quantify sleep parameters. In this section, we rely on meta-analyses[40,41] and a review[42] to summarize the diversity of these findings.

The reader should note that sleep stages reported in this chapter are based on the sleep scoring rules and terminology that prevailed before 2007 and that are broadly consistent with those developed by Rechtschaffen and Kales.[43] They are designated "classic terminology" in Table 139-1. Table 139-1 provides a simplified translation of classic terminology to terminology as revised in 2007 by the American Academy of Sleep Medicine.[44]

Total Sleep, Sleep Maintenance, and Sleep Continuity

Overnight PSG studies have shown that the sleep of schizophrenic patients is characterized by poor sleep efficiency. Often this takes the form of a reduction in total sleep time as well as early, middle, and late insomnia. The most consistently reported abnormality is early insomnia or difficulty reaching a state of persistent sleep. Even a daytime measure of sleep propensity reported that mean sleep latency in the Multiple Sleep Latency Test was 36% longer in unmedicated patients with schizophrenia than in nonpsychiatric controls.[45] Furthermore, many of the overnight PSG studies that have evaluated schizophrenic patients treated with antipsychotics have observed a reduced sleep propensity suggesting that some degree of residual insomnia is not an uncommon outcome of standard antipsychotic treatment. Note also that severe insomnia is one of the prodromal signs of impending psychotic decompensation or relapse subsequent to discontinuing antipsychotic medication.[46-48]

Table 139-1 Comparison of Sleep Stage Designations

Classic Terminology	Revised Terminology
Wakefulness	Stage W
Stage 1 sleep	Stage N1 (NREM 1 sleep)
Stage 2 sleep	Stage N2 (NREM 2 sleep)
Stage 3 sleep	Stage N3 (NREM 3 sleep)
Stage 4 sleep	Stage N3
Slow wave sleep (S3 + S4)	Stage N3
Stage REM sleep	Stage R (REM sleep)

Abnormalities of REM Time and REM Eye Movements

Despite early speculation regarding potential REM sleep abnormalities in schizophrenia, studies comparing schizophrenic patients with healthy control subjects have consistently shown that REM sleep time is not systematically augmented or reduced.[40,41] Eye movements during REM sleep have also been studied. Visual scoring of REM sleep eye movements report no difference in density of eye movements between schizophrenic patients and control subjects.[49,50] An automated eye movement detection system[51] yielded the same conclusion but extended the observation in finding no differences in eye movement density in schizophrenic patients, nonpsychiatric control subjects, and patients with major depressive disorder.

REM Sleep Latency

Many PSG studies have quantified the latency to the onset of the first REM sleep period.[40-42] Several have compared the REM latency of unmedicated schizophrenic patients with that of nonpsychiatric control subjects. Approximately half have reported significant between-groups differences, with the schizophrenic patients demonstrating abnormally short REM latency. Even in studies finding no between-groups differences, a bimodal distribution of REM latency values in schizophrenic patients has been observed, suggesting that there are subgroups of schizophrenic patients with sleep-onset REM periods.[49,52] Short REM latency might represent an active or primary alteration of REM sleep mechanisms. Alternatively, as suggested by Feinberg and colleagues,[53] a slow wave sleep (SWS) deficit in the first NREM period might permit the passive advance or early onset of the first REM period.

Abnormalities of NREM Sleep

SWS deficits are often, but not consistently, observed in PSG recordings of schizophrenic patients. In visually scored PSG, SWS is reported as the summation of sleep stages 3 and 4, with stage 4 sleep having the greater incidence of underlying slow wave activity. Documentation of SWS or stage 4 deficits has been reported in many studies of schizophrenic patients.[38-40] The possibility that SWS deficits might serve as a trait marker in patients with schizophrenia was suggested by a study reporting no SWS differences between schizophrenics and first-degree relatives.[54] Although some research has suggested that prior exposure to, or withdrawal from, antipsychotics might explain these inconsistencies,[50] SWS deficits have been observed in antipsychotic-naive patients in their first episode of schizophrenia.[55] In addition to clinical heterogeneity, another factor might contribute to the inconsistency, notably the insensitivity of visual scoring to variations in the incidence and amplitude of the slow or delta wave (0 to 3 Hz) EEG oscillations that make up SWS.

Sleep-Related Brain Wave Activity

Studies[56-59] using computer quantification of the frequency content of the sleep EEG (e.g., Fourier analysis, period and amplitude analysis) have confirmed the degradation of sleep-related delta activity in schizophrenic patients relative to age-matched nonpsychiatric control subjects. Significant decrements in delta amplitude between schizophrenic patients and nonpsychiatric controls have been observed despite

comparable amounts of visually scored SWS.[60] Laterality of frontal cortex delta counts is reduced in schizophrenic patients relative to healthy controls, suggesting right frontal pathophysiology among the schizophrenic patients.[59]

In contrast to degradation of delta (0 to 3 Hz) activity, power in the high-frequency beta (20 to 35 Hz) and gamma (35 to 45 Hz) ranges of the sleep EEG may be greater in unmedicated schizophrenic patients relative to healthy controls.[61] Also, the number, duration, and amplitude of NREM sleep spindles (12 to 16 Hz) may be reduced in medicated schizophrenic patients, a finding that suggests some abnormality in thalamic-reticular and thalamocortical function in schizophrenia.[62] In addition, reductions in the number and density of sleep spindles in schizophrenic patients may be associated with impaired memory consolidation.[63]

Slow Wave Sleep Homeostasis

Deficits of SWS, whether scored visually or quantified by computer algorithm, raise concern about the integrity of homeostatic regulatory mechanisms in schizophrenia. In 1974, Feinberg advanced the homeostatic model of SWS; according to this model, the homeostatic drive builds up during waking and dissipates in SWS across successive NREM cycles.[64] In healthy subjects, SWS increases in proportion to the amount and intensity of prior waking, suggesting that the homeostatic or dynamic response might serve a restorative role in the central nervous system. This homeostatic drive is demonstrated by a rebound in SWS or EEG delta activity following the naturalistic probe of total sleep deprivation.

Two studies have looked at potential homeostatic dysregulation in schizophrenia. In the first, no homeostatic recovery of visually scored SWS was found after 85 hours of total sleep deprivation.[65] More recently, SWS visual scoring and computer analysis of delta activity were examined after 1 night of total sleep deprivation.[66] Stage 4 sleep was absent on both baseline and recovery nights, but period and amplitude analysis of EEG delta activity revealed a significant (although modest) recovery night increase in delta incidence and amplitude relative to baseline. Therefore it would appear that the homeostatic drive in schizophrenia is operative but diminished. In support of this conclusion, it has been shown that on an intranight basis, the time course of delta activity dissipation over all NREM sleep cycles is normal in schizophrenic patients.[60]

Circadian Rhythm Abnormalities

Although circadian rhythm disturbances have also been reported in patients with schizophrenia, the findings are largely inconsistent.[67-69] Studies of the circadian organization of sleep-wake and rest-activity cycles have reported both phase-delayed and phase-advanced sleep patterns, irregular sleep-wake patterns, and free-running rest-activity patterns.[70-73] A phase-delayed pattern would be congruent with the well-documented difficulty of sleep initiation as well as the observation that schizophrenics tend to favor "eveningness" on the morningness-eveningness scale.[74]

Because disturbed patterns of melatonin secretion have been associated with insomnia, patterns of melatonin secretion have been examined in schizophrenic patients. Both phase-advanced[75] and phase-delayed[76] melatonin secretion has been reported. There are also reports of blunted nocturnal secretion of melatonin, including a report that normalization of melatonin levels may not occur following clinical improvement with antipsychotic treatment.[77,78]

The inconsistencies associated with studies of circadian rhythm abnormalities in patients with schizophrenia may, in part, be attributed to a wide range of methodologic shortcomings inherent in these circadian rhythm studies,[69] to a diminished exposure to sunlight, activity, and other effective zeitgebers, or to lifestyle choices often involving preferences for staying awake at night and sleeping during the day. Circadian rhythm abnormalities are not diagnostic of schizophrenia but occur with sufficient frequency to merit further research.

Correlation with Clinical and Neurobiologic Measures

Many of the sleep abnormalities associated with schizophrenia have been studied in relationship to global symptom severity, the severity of positive and negative symptoms, clinical prognosis, and neurocognitive impairment.[42]

Brain dysmorphologies have also been studied in relationship to sleep abnormalities in patients with schizophrenia. On a theoretical level, SWS deficits have been associated with microstructure brain abnormalities. Feinberg[32] has proposed that schizophrenia is a neurodevelopmental disorder arising from a malfunction in the normal maturational process of synaptic elimination during the second decade of life; excess synaptic pruning would result in less capability for synchronous EEG slow wave activity and a deficit of SWS. Empirically, SWS deficits or a reduction in its stage 4 component have been associated with enlarged ventricular system volume.[79,80] A related study using antipsychotic-naive schizophrenic patients did not concur.[50] PSG studies have also noted a relationship between brain dysmorphologies in schizophrenia and sleep maintenance abnormalities.[50,79,81]

These reports of brain dysmorphologies and their relationship to sleep abnormalities in patients with schizophrenia must be viewed with some interpretive restraint. Terms such as "enlargement" and "atrophy" need longitudinal assessment, but all the reported studies employed a cross-sectional design. Volumetric status of the reported brain structures before the point of cross-sectional assessment is only speculative. We must also view with some restraint any contention that sleep abnormalities with a neuroanatomic correlate must have a stable or traitlike presentation over time. First, many of the dyssomnias of schizophrenia do change over time in response to antipsychotic treatment. Second, consistent with the observation of adult neurogenesis[82] in the human brain are demonstrations of longitudinal changes in the brain structure of schizophrenic patients undergoing antipsychotic treatment.[83-85]

Our understanding of how neurochemical mechanisms might correlate with, or possibly mediate, the sleep abnormalities of schizophrenia is limited to a small number of studies whose findings may be confounded by long-term exposure to antipsychotics. Furthermore, although dopamine and glutamate dysfunction might occupy prominent roles in the pathophysiology of schizophrenia, the relationship of sleep abnormalities in schizophrenia to either of these neurochemical systems has not been directly demonstrated.

Limited reports involving four other neurotransmitter systems have been published. Cholinergic supersensitivity has been associated with short REM latencies in patients with

schizophrenia.[86] Among unmedicated schizophrenic patients, SWS deficits have been linked to a 5-HT dysfunction; this study reported a positive correlation between SWS time and cerebrospinal fluid (CSF) levels of the 5-HT metabolite 5-hydroxyindole acetic acid.[87] A separate study reported that increased CSF levels of norepinephrine and its principal metabolite, 3-methoxy-4-hydroxyphenylglycol, accompanied psychotic decompensation and relapse-related insomnia.[46] CSF hypocretin, a wake-promoting neurotransmitter that excites midbrain dopamine neurons, has been correlated with sleep latency, suggesting a relationship between hypocretin and hyperarousal in schizophrenia.[88]

TREATMENT

Treating Schizophrenia with Antipsychotic Agents

Consistent with standards of practice, most patients with schizophrenia are treated with one or more of the antipsychotic agents listed in Table 139-2. Antipsychotics differ in their chemical design and have differential effects on DA, 5-HT, α-adrenergic, cholinergic, and histaminic receptors and their various subtypes.[89,90] The receptor binding profiles of these agents are associated with different side effects and clinical outcome.

Types of Antipsychotic Agents

First-Generation Antipsychotics

The therapeutic efficacy of the first generation of antipsychotics is attributed to their ability to block the dopamine D_2 postsynaptic receptor, particularly the D_2 receptors in the striatum, but the clinical benefits associated with these first-generation antipsychotics have occurred with some cost. Because of their signature-binding profile, these antipsychotics often result in extrapyramidal side effects (EPS) such as akathisia, dystonia, and parkinsonism. A more damaging side effect associated with D_2 receptor blockade is tardive dyskinesia. The traditional antipsychotics are also associated to varying degrees with antihistaminergic and anticholinergic side effects, including sedation, changes in blood pressure and myocardial conduction, sexual dysfunction, and weight gain. A rare but potentially fatal side effect associated with hyperthermia is the neuroleptic malignant syndrome.

Table 139-2 Commonly Used Antipsychotic Medications

Antipsychotic Medication	Usual Adult Daily Maintenance Dose (mg)
First-Generation Antipsychotics	
Chlorpromazine (Thorazine)	50–400
Fluphenazine (Prolixin)	1–15
Haloperidol (Haldol)	1–15
Perphenazine (Trilafon)	8–24
Thioridazine (Mellaril)	50–400
Thiothixene (Narvane)	6–30
Trifluoperazine (Stelazine)	4–30
Second-Generation Antipsychotics	
Aripiprazole (Abilify)	10–30
Clozapine (Clozaril)	200–600
Olanzapine (Zyprexa)	5–20
Quetiapine (Seroquel)	150–750
Paliperidone (Invega)	6–12
Risperidone (Risperdal)	2–8
Ziprasidone (Geodon)	80–160

Second-Generation Antipsychotics

Several factors played a role in motivating the development of the second-generation antipsychotics. First, up to 30% of patients with chronic schizophrenia have a poor or inadequate response to first-generation antipsychotics. Second, although traditional antipsychotics have demonstrated success in ameliorating positive symptoms, they have been less successful in treating negative symptoms. Third, the side effects associated with traditional antipsychotics, particularly EPS and tardive dyskinesia, were a source of noncompliance and raised difficult management issues. Clozapine was the first of the second-generation antipsychotics to demonstrate good clinical efficacy with little or no EPS. The atypical antipsychotics now include six other agents, listed in Table 139-2. Although they demonstrate unique receptor binding profiles, as a group they are characterized by weaker affinity for the D_2 receptor (relative to traditional antipsychotics) and strong affinity for serotonin receptors.[90] Second-generation antipsychotics are now considered first-line treatment for schizophrenia. Relative to the traditional antipsychotics, they may offer better compliance.

However, second-generation antipsychotics are not the panacea once envisioned.[91] Only clozapine has clearly demonstrated superior effectiveness in treatment-refractory schizophrenia and in childhood schizophrenia. None of the atypical antipsychotics has been strongly effective against negative symptoms. Like the traditional antipsychotics, the atypical antipsychotics can have serious side effects. Although the incidence of EPS and tardive dyskinesia remains low with atypical antipsychotics, both EPS and tardive dyskinesia can occur with atypical antipsychotics, particularly at higher doses. Clozapine is associated with increased risk for agranulocytosis and seizures at higher doses. The atypical antipsychotics are associated with increased morbidity owing to weight gain, dyslipidemia, and impaired glucose regulation including type 2 diabetes mellitus. Actigraphic monitoring of schizophrenic patients treated with olanzapine or risperidone documented reduced 24-hour activity (owing to a longer time in bed) and, notably, reduced 10-hour daytime activity; low amounts of physical activity may also contribute to the metabolic side effects of these antipsychotic agents.[92] Finally, antipsychotic-related weight gain may be particularly striking and puts the patient at increased risk for developing sleep-related breathing disorders and other obesity-related morbidities.

The National Institute of Mental Health–sponsored Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study[93] compared a single first-generation antipsychotic to several second-generation antipsychotics in terms of effectiveness and side effects. This study found no significant difference in efficacy between perphenazine and three atypical antipsychotics (risperidone, quetiapine, and ziprasidone). Olanzapine, which was found to be more effective than the other drugs in terms of discontinuation rate, was also

associated with greater weight gain and metabolic morbidities. The CATIE study underscores the need for a more systematic comparison of first- and second-generation antipsychotics with respect to their efficacy, side effects, and expense, all of which have a major impact on treatment compliance. Discontinuation rates of antipsychotics are alarmingly high for a chronic illness. Within 1 year of initiating treatment with atypicals (aripiprazole, olanzapine, risperidone, ziprasidone, or quetiapine), approximately 90% of schizophrenic patients had discontinued their antipsychotic medication.[94]

Sleep-Promoting Effects of Antipsychotics

Broadly speaking, first-generation antipsychotics alter sleep architecture by improving sleep maintenance with augmentations of total sleep time and sleep efficiency and reductions in sleep latency and waking.[95-99] With less consistency, the traditional antipsychotics have been associated with increases in REM latency,[95-98] REM sleep time,[96,97] and REM eye movement density.[95,97,99] In one study, chlorpromazine was associated with increased SWS time.[95]

With regard to the effect of second-generation antipsychotics on sleep patterns in schizophrenic patients, clozapine has been the most widely studied. Clozapine has been shown to have strong consolidating effects on sleep, including increased total sleep time, sleep efficiency, and stage 2 sleep and decreased sleep latency and wake time after sleep onset.[99-101] Relative to a medication-free baseline, a significant decline in SWS and stage 4 was observed in schizophrenic patients treated with clozapine.[100] Olanzapine has also been shown to be a sleep-promoting agent with increases in both sleep efficiency and SWS[102,103]; a reduction in sleep spindle density has also been reported.[104] Likewise, a significant enhancement of SWS has been noted in schizophrenic patients treated with risperidone.[105] Paliperidone's effects on sleep patterns in patients with schizophrenia revealed increased sleep efficiency, total sleep time, and stage 2 and stage REM minutes as well as decreased sleep latency, waking, and stage 1 minutes.[106] PSG evaluations of schizophrenic patients treated with quetiapine, ziprasidone, and aripiprazole have not been undertaken; however, effects of quetiapine and ziprasidone on the sleep of healthy controls include improvements in sleep induction and consolidation.[107,108]

Treating Comorbid Psychiatric Illness

Although monotherapy with second-generation antipsychotics is standard practice, augmentation with additional antipsychotics is not uncommon and can optimize therapeutic response. In addition to antipsychotics, schizophrenic patients may be prescribed other psychoactive agents to treat comorbid psychiatric illness. For example, schizophrenic patients with problems of impulse control and patients with schizoaffective disorder may be prescribed adjunctive mood stabilizers such as valproate. It is not uncommon for comorbid depression to be diagnosed in schizophrenic patients, and adjunct antidepressants may be prescribed. Mood stabilizers often demonstrate beneficial effects on sleep, whereas antidepressants may either ameliorate or exacerbate sleep problems, depending on the agent and individual. Schizophrenic patients may be enrolled in dual-diagnosis programs to treat comorbid problems of alcohol and substance abuse; by themselves, alcohol and substance abuse can contribute to significant sleep disruption.

Treating Sleep Disorders in Patients with Schizophrenia

After the symptoms of schizophrenia and other comorbid medical and psychiatric illnesses have been optimally treated, clinicians might need to address a range of residual sleep disorders. These residual sleep disorders can encompass insomnia, hypersomnia, and parasomnias.

Insomnia

The CATIE study[93] reported that rates of residual insomnia in antipsychotic-treated schizophrenic patients ranged from 16% to 30%. It is not uncommon for insomnia to be attributed to poor sleep hygiene, sleep-related movement disorders, and untreated hyperarousal associated with the schizophrenia illness.

Inadequate Sleep Hygiene. Many schizophrenic patients lack daytime structure and prefer to avoid social interactions. Consequently, they can develop bad habits in relation to sleep initiation and sleep maintenance, including sleep reversals and polyphasic sleep patterns with extended periods of daytime napping. Daytime naps affect nocturnal sleep more when the naps are taken later in the day. This situation may be further complicated by excess caffeine intake and the self-prescribed alcohol or psychoactive drugs such as cocaine. Patients with schizophrenia are always good candidates for sleep hygiene counseling.

Sleep-Related Movement Disorders. Because prevalence studies of sleep disorders in antipsychotic-naive schizophrenic patients are lacking, baseline rates for comorbid sleep disorders in this population have not been established. Although in some cases insomnia may be associated with lifestyle habits, in others sleep disturbance may be a side effect of treatment with antipsychotic medication.

Because restless legs syndrome (RLS) and periodic limb movements of sleep (PLMS) respond to DA agonists, DA deficiency is thought to be central to their pathophysiology.[109] Consequently, the D_2 receptor blockade of antipsychotic agents might induce RLS and PLMS in antipsychotic-treated schizophrenic patients. Consistent with this hypothesis, the prevalence of RLS in antipsychotic-treated schizophrenic patients has been reported to be more than twice that of healthy controls.[110] Although the diagnosis of RLS is made by clinical interview, the diagnosis of PLMS requires overnight PSG; consequently, the prevalence of PLMS in patients with schizophrenia has been less systematically examined. PLMS prevalence rates for schizophrenic patients with a history of treatment with first-generation antipsychotics have been reported to be in the 13% to 14% range.[111,112] Certain atypical antipsychotics, such as olanzapine[113-114] and risperidone,[115] have been associated with the development of RLS and PLMS. Although DA agonists such as ropinirole and pramipexole are first-line treatments for RLS and PLMS, treatment options for schizophrenic patients with RLS or PLMS should be carefully considered. One might first consider a reduction in antipsychotic dose or a change to a different antipsychotic agent rather than introduce another agent with an opposing mechanism of action. Patients might also be evaluated for possible iron deficiency, a known risk factor for the development of RLS, or use of substances, such

as caffeine, that might worsen sleep-related movements. Although agents such as ropinirole and pramipexole are not first-line choices for patients with schizophrenia, such agents might be necessary when their benefits outweigh the risk. Chapter 95 addresses evaluation and treatment options for patients with RLS or PLMS.

Clinicians should note that akathisia, which is characterized by intense motor restlessness and pacing, is a common side effect of antipsychotic treatment. By itself, akathisia can cause significant sleep disruption. Although RLS might be confused or overlap with the restlessness of akathisia, the clinical presentation of RLS is more likely to be associated with a circadian worsening of symptoms in the evening or at night and symptomatic relief by movement.

Schizophrenia-Related Hyperarousal. Antipsychotic-treated schizophrenic patients may also experience a residual and persistent insomnia directly associated with hyperarousal or an inadequately treated component of their clinical illness. A range of options for treating residual insomnia in patients with schizophrenia has been recently reviewed.[116,117] Given sufficient severity, the clinician may opt to treat residual insomnia by changing to a different, more sedating antipsychotic agent, changing the dose of the prescribed antipsychotic agent, or adding an adjunctive, more sedating antipsychotic medication. Alternatively, supplemental use of anxiolytics or sedative-hypnotics might be considered[118]; however, these agents should be prescribed cautiously, particularly for patients with a sleep-related breathing disorder or a history of alcohol or drug abuse. Because disturbed patterns of melatonin secretion have been associated with insomnia, the use of melatonin as an alternative adjunctive treatment for residual insomnia in schizophrenia has been the subject of investigational study. Two studies examined the effect of exogenous melatonin on residual insomnia in antipsychotic-treated schizophrenic patients. Melatonin replacement was associated with improved sleep maintenance measured by actigraphy[119] and by self-report.[120]

Hypersomnia

The CATIE study[93] also reported rates of antipsychotic-related somnolence. Rates of somnolence in antipsychotic-treated schizophrenic patients ranged from 24% to 31%. Medication compliance is associated with patients' attitudes toward antipsychotic treatment and related side effects, and it is important to note that sedation has a significant negative effect on these attitudes.[121] Somnolence in antipsychotic-treated schizophrenic patients may be a side effect of antipsychotic treatment, or it may be symptomatic of a sleep disorder such as a sleep-related breathing disorder enhanced by, or induced by, antipsychotic treatment.

Somnolence as a Side Effect of Antipsychotic Medication. Among first-generation antipsychotics, sedation is a side effect associated with high-milligram, low-potency agents such as chlorpromazine. In contrast, the low-milligram, high-potency agents such as haloperidol have lower sedation rates. Among second-generation antipsychotics, clozapine and olanzapine are the most sedating. The remaining atypical agents have lower rates of sedation. Sedation rates also reflect the half-life of the agent as well as dosing levels. Clinicians typically address excessive antipsychotic-related sedation by changing antipsychotic agents or reducing dosage.

As an alternative to changing antipsychotic agents or reducing their dosage, several studies have examined the effect of modafinil as an adjunct to antipsychotic treatment. Modafinil is a wake-promoting agent whose mechanism of action remains unclear. Its primary U.S. Food and Drug Administration–approved target is the excessive daytime sleepiness associated with narcolepsy. However, it has been suggested that modafinil may improve excessive daytime sleepiness in a variety of off-label conditions such as antipsychotic-induced daytime somnolence. Case studies[122] and an open-label pilot study[123] have shown that modafinil can increase wake time, reduce total sleep time, and ameliorate fatigue in antipsychotic-treated schizophrenic patients. However, several randomized, double-blind, placebo-controlled trials of modafinil as an adjunct to antipsychotic treatment reported that modafinil, relative to placebo, did *not* significantly improve antipsychotic-associated sedation or fatigue.[124-127] Taken together, these studies suggest that the use of modafinil to counter somnolence in antipsychotic-treated schizophrenic patients is not justified at this time. Off-label use of modafinil as an adjunct to antipsychotic treatment in schizophrenia needs further study with larger patient samples and with particular scrutiny given to the possibility of exacerbating psychosis in patients with schizophrenia.[128]

Somnolence Associated with Sleep-Disordered Breathing. The prevalence of sleep-disordered breathing (SDB), such as obstructive sleep apnea (OSA), in antipsychotic-naive schizophrenic patients has not been established. Antipsychotic-treated schizophrenic patients who have volunteered for research protocols have demonstrated a high prevalence rate for SDB, with reported estimates of 17%,[111] 19%,[129] 25%,[130] and 48%.[112] These studies varied in terms of sample size, age, sex, type of antipsychotic, and measurement instrument (PSG, oximetry, sleep questionnaire, and ambulatory apnea monitor, respectively).

In contrast, among schizophrenic patients referred to a sleep clinic for a suspected sleep disorder, more than 46% had a respiratory disturbance index greater than 10 events per hour; the mean respiratory disturbance index was 64.8 events per hour.[131] In this study, the most powerful predictor of OSA syndrome was obesity. Weight gain has long been a reported side effect of antipsychotic treatment, and as discussed previously, weight gain secondary to the use of the atypical antipsychotics has been associated with morbid obesity, diabetes, and the development of moderate to severe SDB.[132]

Daytime somnolence is a relatively common side effect of antipsychotic treatment, but clinicians must consider the possibility of comorbid SDB for schizophrenic patients who have a history of obesity or who have gained weight secondary to antipsychotic treatment. Schizophrenic patients with comorbid SDB can be treated effectively with nasal continuous positive airway pressure and can demonstrate relatively good compliance and significant clinical improvement.[133-135]

Parasomnias

First-generation antipsychotics, particularly in combination with lithium,[136,137] can induce somnambulism. Sleepwalking also has been documented in patients treated with second-generation agents such as olanzapine.[138,139] Because

sleepwalking is associated with impaired arousal from SWS, patients treated with lithium and olanzapine may develop somnambulism because these agents have been credited with SWS enhancement. It has been reported that clonazepam may be a treatment option for antipsychotic-induced somnambulism[140] but with the same caveats as those noted for hypnotic use. Another parasomnia, sleep-related eating disorder, may be induced by antipsychotics such as haloperidol,[141] olanzapine,[142] and risperidone.[143] Treatment options for sleep-related eating disorders might include topiramate, a selective serotonin reuptake inhibitor, or a sedative agent, although this latter class has itself been associated with parasomnias.

FUTURE DIRECTIONS

One of the ongoing controversies is the diagnostic specificity of sleep abnormalities. Although a range of abnormalities is observed in schizophrenia, they lack diagnostic specificity. Long sleep-onset latencies and other sleep maintenance abnormalities found in schizophrenia are observed with insomnia occurring in many settings, including in patients with other psychiatric conditions such as major depression. Sleep-onset REM periods and SWS deficits are also observed in depressive illness.

A goal less ambitious than establishing diagnostic specificity is to find a brain abnormality that would reliably characterize a subgroup of patients in a meaningful way. SWS deficits (measured as sleep stages 3 and 4 with visual scoring or as delta power or integrated amplitude with computer analysis) could furnish a biologic basis for separating subgroups of schizophrenic patients. Although low SWS is not specific to schizophrenia, it is a highly reliable, enduring trait that is consistently found in 40% to 50% of samples and might provide a meaningful phenotype. Despite its reliability, SWS deficits have received attention from only a few schizophrenia researchers and remain a neglected research area in a critically important psychiatric illness that has few consistently documented brain abnormalities. Given the paucity of clues to brain dysfunction in schizophrenia, SWS investigations could prove a fruitful field for further research. Such studies might explore dynamic features of SWS, such as its trends across NREM periods[144] and the more recently discovered inverse oscillation of sigma and delta frequencies.[145]

The synaptic pruning model of schizophrenia noted that it was possible that too few, too many, or the wrong synapses might be pruned during adolescence.[32] One testable hypothesis might be that patients characterized by an enduring decrease in SWS would show different trajectories or greater amounts of cortical thinning detectable by structural magnetic resonance imaging.[146] There are, of course, many other hypotheses that could be advanced. Given the paucity of biologic abnormalities in schizophrenia, it is puzzling that so robust and consistent a brain abnormality as low SWS should have been so neglected.

Further empirical research might also address the role of SWS deficits in both clinical presentation and outcome. The homeostatic property of SWS suggests that SWS serves some central nervous system restorative function whose loss would have negative neuropsychiatric consequences; if so, are SWS deficits in schizophrenia associated with greater cognitive impairment and thought disorder, and do schizophrenic patients with less SWS impairment face a better clinical outcome? As a corollary, do antipsychotics that augment SWS produce a greater likelihood of positive clinical outcome?

Although insomnia is a defining characteristic of schizophrenia, we do not understand the role that sleep disruption might play in the illness. Is insomnia only a byproduct of schizophrenia, or does ongoing sleep disturbance also affect the course of the illness? Because ongoing sleep disturbance might have a negative effect on clinical outcome, treatment plans for schizophrenic patients should explicitly incorporate strategies to deal aggressively with complaints of poor sleep quality. The restorative effect of antipsychotics on sleep maintenance and structure may enhance their clinical efficacy and increase tolerance. A positive clinical outcome may require the restoration of sleep's recuperative powers.

Comorbid sleep disorders in schizophrenics should be treated. Untreated sleep disorders can augment the fragility of underlying sleep processes in schizophrenia, with potentially adverse effects on clinical outcome. Research into sleep and circadian mechanisms in these patients may yield novel treatments.[147]

CLINICAL PEARL

Schizophrenia is often associated with severe insomnia that can be a harbinger of relapse. Caregivers should routinely query schizophrenic patients about changes in their sleep patterns and should modify treatment in the face of severely increasing insomnia. Caretakers should also be instructed in the specific sleep disorder syndromes that tend to occur in this population and should use this knowledge to routinely evaluate the possibility of emergent sleep disorders stimulated by antipsychotic treatment.

SUMMARY

Subjective and objective assessments of sleep in schizophrenia reveal a wide range of sleep abnormalities with insomnia, principally sleep-onset insomnia, being the most common presentation. Among schizophrenics, worsening insomnia may be a harbinger of impending relapse and psychotic decompensation. Other sleep abnormalities, such as SWS deficits, can be found with sleep staging or measures of sleep EEG frequency content. Broadly speaking, most antipsychotic agents have a positive effect on the insomnia of schizophrenia. However, some schizophrenic patients medicated with antipsychotics experience undertreated or residual insomnia, whereas others may experience significant somnolence. Heightened sedation is an unwanted side effect of some second-generation antipsychotics. Antipsychotic agents may also induce or exacerbate comorbid dyssomnias such as RLS and SDB. All dyssomnias in schizophrenia should be vigorously addressed because a positive clinical outcome may be associated with the normalization of sleep and its restorative processes.

Chapter
140

Medication and Substance Abuse

Timothy Roehrs; Thomas Roth

Chapter Highlights

- Most psychoactive drugs with abuse liability have effects on sleep and wakefulness.
- The mechanisms underlying substance abuse are known, but the role of the drug's sleep-wake state–altering effects in substance abuse is not fully known, although it is likely to be important.
- Some of the drugs of abuse are legal and widely used socially and may be the cause of patients' sleep or alertness complaints.
- Other drugs with abuse liability are drugs indicated in the treatment of sleep disorders.
- This chapter provides guidelines for sleep disorders clinicians to differentiate drug-seeking behavior from therapy-seeking behavior.

Various legal medications and all illegal central nervous system (CNS)–acting drugs have a high abuse liability, that is, the likelihood for development of physiologic or behavioral dependence on these substances is heightened. The various terms often used in discussing substance abuse are confusing, are controversial, and need clarification. Physiologic dependence is a state induced by repeated drug use that results in a withdrawal syndrome when the drug is discontinued or an antagonist is administered. Many legal medications and illegal drugs can produce physiologic dependence, although the syndrome intensity, relation to dose, and necessary duration of use vary among different drugs. The fact that a drug produces physiologic dependence, meaning that a withdrawal syndrome appears when the drug is discontinued, does not necessarily imply substance abuse.

In the sleep field, a phenomenon suggestive of the presence of physiologic dependence on a drug is rapid eye movement (REM) sleep rebound. When drugs that suppress REM sleep are discontinued, a REM rebound (i.e., increased REM pressure) is seen, which is manifested by reduced REM sleep latency, by increased REM sleep time and REM density, and subjectively with reports of nightmares. Most of the antidepressant medications at therapeutic doses suppress REM sleep, and a REM sleep rebound occurs when the drug is discontinued. However, a REM sleep rebound after antidepressant use does not lead to resumption of antidepressant use. On the other hand, a reduced REM latency (e.g., one sign of REM pressure and an underlying REM sleep disturbance) in abstinent alcoholics is predictive of alcoholic relapse.

Physiologic dependence may be a component of but is neither a necessary nor a sufficient condition for behavioral dependence. Behavioral dependence is a pattern of behavior characterized by repetitive and compulsive drug seeking and consumption, despite considerable substance-related problems. The formal diagnostic criteria according to the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) are discussed later. Whereas the sleep disorders clinician will not make formal diagnoses, awareness of the criteria is important for referral decisions. Substance abuse and dependence are common, as 18% of the U.S. population will experience a substance abuse disorder during their lifetime, and about 20% of patients in general medical practice and 35% of psychiatric patients present with substance abuse disorders.

Virtually all drugs with a high abuse liability have profound effects on sleep and wake. For this reason, sleep disorders clinicians should assess *all* the drug-taking behavior of their patients, including prescribed and over-the-counter drugs, recreational drugs, tobacco and caffeine, health foods, steroids, botanicals, and natural substances. This chapter reviews the sleep-wake alterations produced by administration and discontinuation of various drug classes associated with abuse. Also discussed is the way that the state-altering characteristics (i.e., their disruptive effects on sleep or daytime alertness) of these drugs contribute to their dependence liability. Finally, what is known about the neurobiologic and behavioral mechanisms that underlie these drugs' abuse liability and their state-altering effects is discussed.

Some drugs of abuse have no legal therapeutic indications (i.e., various inhalants, LSD); others have narrowly defined therapeutic indications (i.e., amphetamine, methylphenidate), and some have broader therapeutic indications (i.e., benzodiazepine receptor agonists). Other drugs of abuse have wide use as social drugs (i.e., alcohol and caffeine). Marijuana occupies a unique position as it remains illegal federally but as of 2014 is legal in 20-plus states for specific therapeutic indications and in a few states for recreational and social use. For these various reasons, guidelines are provided for sleep disorders clinicians that will help them differentiate drug-seeking behavior from therapy-seeking behavior. In drug-seeking behavior, the drug and its effects are the focus of the drug use, whereas in therapy-seeking behavior, the medications' ability to reverse the signs and symptoms of the disease is the focus of the drug use. This distinction is important because many of the drugs used by sleep disorders clinicians are used chronically, and hence it is important to differentiate long-term use

from abuse. Many of these medications also have scientifically documented efficacy and are hence indicated for specific sleep disorders; some of these drugs also are abused and, importantly, may be the cause of a sleep disorder.

DIAGNOSIS OF SUBSTANCE-RELATED DISORDERS

The generally accepted diagnostic classification system for substance-related disorders is DSM-5. DSM-5 reflects a major departure from DSM-IV and DSM-IV-TR. Substance-related disorders are divided into two major classes: (1) substance use and (2) substance-induced disorders. Substance use disorders, formerly termed substance abuse and substance dependence (DSM-IV-TR), are characterized by behaviors and consequences (a total of 11 criteria are listed) in groupings that show *impaired control, social impairment, risky use, and pharmacologic consequences* (i.e., tolerance, withdrawal) associated with use of 10 classes of substances. Rather than distinguishing abuse and dependence as in DSM-IV-TR, DSM-5 rates the severity of the disorder by the number of symptoms present: mild, two or three; moderate, four or five; and severe, six or more. Substance-induced disorders are characterized by symptoms reflecting the presence of intoxication, withdrawal, or a mental disorder. As this category name implies, the disorder has to be associated with current or very recent use of the substance.

Whereas most of the drugs of abuse are disruptive of sleep or daytime alertness, such disturbances are not major criteria for substance abuse in DSM-5. They are mentioned as possible symptoms in a withdrawal syndrome, which is one of the 11 criteria for a substance use disorder. DSM-5 emphasizes that symptoms of tolerance development and withdrawal, *only* occurring in the context of medical treatment with prescribed medications, should not receive a diagnosis of substance-related disorder (distinguishing drug seeking from therapy seeking in clinical practice is discussed later). Also as discussed in this chapter later, the role of disruptions of sleep and daytime alertness in substance use disorders is not elaborated in DSM-5.

The attempt to understand substance abuse scientifically has proceeded at two levels of analyses, behavioral and neurobiologic. Interestingly, the scientific evidence at these two levels of analysis has converged. For sleep scientists and clinicians, an obvious question is, "How does a drug's effect on sleep and daytime alertness relate to the behavioral and neurobiologic changes that occur in a person abusing the substance?"

Behavioral Mechanisms

Substance use, whether in a therapeutic and socially accepted recreational form or in an excessive, socially unacceptable, and physically hazardous form, is a behavior that can be analyzed to determine factors important to the initiation and maintenance of substance abuse. Drugs are viewed as reinforcers when they promote and maintain drug seeking and drug self-administration as a function of the effects the drug produces. Those effects may include the drug's pharmacologic effects as well as various nonpharmacologic consequences. Two mechanisms of drug reinforcement are hypothesized. First, the drug produces an inferred "mood-elevating" or "euphorigenic" effect and thus acts as a positive reinforcer. In the second, the drug acts as a negative reinforcer by reversing an inferred "aversive" state, such as a withdrawal syndrome, insomnia, or excessive sleepiness-fatigue. The two processes, positive and negative drug reinforcement, are not necessarily mutually exclusive and may operate concurrently or at the different stages in a drug abuse cycle (i.e., its initiation, maintenance, or relapse). These two reinforcement processes lead to the initiation and maintenance of excessive and hazardous drug use. How the sleep-wake state–altering consequences of the drugs addressed in this chapter may function as positive or negative reinforcers can be illustrated.

The alerting effects of stimulants are reinforcing for individuals who are sleepy, fatigued, and having difficulty in functioning to their desired level. Healthy normals will self-administer a stimulant when they are sleepy but not when alert.[1] That self-administration does not necessarily imply abuse. In substance abuse, however, the sleepiness may be present as part of a withdrawal syndrome due to abstinence following chronic nonmedical use of a stimulant. It has been hypothesized that continued substance use, difficulty in reducing use, or relapse may reflect "self-medication" to reverse the excessive sleepiness of the abstinence. For example, in chronic caffeine or nicotine dependence, the 8-hour sleep period is functionally an enforced abstinence, and given the pharmacokinetics of these drugs, the 8-hour abstinence during the sleep period is followed by enhanced sleepiness in the morning and, in extreme cases, smoking during the night. Caffeine or nicotine taken immediately on arising reverses the sleepy state. "When do you have your first morning cigarette?" is a question clinicians can use to gauge the severity of nicotine addiction. In amphetamine or cocaine abuse, excessive sleepiness during the initial drug abstinence has been consistently reported. Again, use of these stimulants will reverse the sleepiness.

During a period of chronic drug use, daytime sleepiness may also result from a drug-induced disturbance of nocturnal sleep. All the stimulants as reviewed later disrupt nocturnal sleep to some degree, depending on dose and proximity of their use to the sleep period. Disrupted and fragmented sleep produces daytime sleepiness. One could hypothesize that a drug-induced sleep disturbance at night leads to daytime sleepiness, which then enhances the likelihood of the self-administration of a stimulant. This is the common vicious circle seen in heavy coffee drinkers.

The state of sleepiness may not necessarily be drug induced. It may also be due to chronic insufficient sleep in healthy normals or to disturbed sleep efficiency and circadian dysrhythmia seen in altered work schedules. We have already noted that healthy normals will self-administer a stimulant when experiencing sleepiness. Night workers and rotating shift workers have shortened and disturbed sleep when sleeping during the day as well as increased sleepiness when awake at night. Rotating shift workers and night workers report a disproportionate use of sedating drugs, especially alcohol, to improve sleep and stimulants, especially caffeine, to improve alertness.[2,3] This substance use may increase risks of substance abuse.

The sedative-hypnotics, tetrahydrocannabinol (THC), and alcohol may become reinforcers and lead to substance dependence or abuse through their capacity to induce sleep in persons with insomnia or to reverse a waking "hyperaroused" state. People with insomnia and no history of alcoholism or drug abuse, given an opportunity to choose between previously experienced color-coded ethanol and placebo beverages

at night before sleep, chose ethanol, whereas healthy normals with a similar level of self-reported social drinking chose placebo.[4] Interestingly, people with insomnia not only showed nighttime self-administration of benzodiazepine receptor agonists but also self-administered them during the daytime. However, only those who showed evidence of daytime physiologic hyperarousal self-administered during the day.[5] Whether these drug self-administration patterns reflect drug seeking or therapy seeking needs to be considered, and the issue is further discussed later.

Neurobiologic Mechanisms

The positive-reinforcement neurobiology of drug self-administration is generally accepted to involve mesocorticolimbic projections originating in the ventral tegmental area of the rostral reticular activation system and terminating in the nucleus accumbens. It is a dopaminergic system.[6] Most drugs of abuse interact in some way with this system. This reinforcement system is part of a broader dopaminergic system that projects into several forebrain regions and as a whole is considered to have executive and integrative functions.[6] The dopaminergic neurons of the ventral tegmental area are modulated by a number of other neurotransmitter systems. It is through this modulation that sleep-wake state and level of sleepiness-alertness during wake could have an impact on a drug's reinforcing properties.

In chronic use, it is hypothesized by Koob that the neurobiologic systems involved in acute positive reinforcement adapt by establishing "opponent" processes.[6] These opponent processes neutralize the acute reinforcing effects of the drug and during abstinence are left unopposed. Consequently, they produce the abstinence syndrome, an inverse state to the drug state, which becomes a basis of negative reinforcement (i.e., reversal of abstinence symptoms). For example, stimulant abstinence produces sleepiness, which in turn leads to self-administration of stimulant drugs. Koob hypothesized that the opponent processes do not necessarily develop through the same neurobiologic system that produces positive reinforcement. Other neurobiologic systems and, for the purposes of this chapter, possibly sleep-wake systems could be one basis of the opponent processes. Two important sleep-wake findings are consistent with this model. They are the REM suppression and REM rebound associated with administration and discontinuation of most all of the drugs with an abuse liability. Second, the persisting disturbance of sleep that is found after weeks and months of abstinence suggests that some type of neurobiologic adaptation within sleep-wake systems to the chronic drug exposure has occurred.

SLEEP-WAKE ALTERATIONS AND SPECIFIC SUBSTANCES

Alcohol and Alcoholism

Epidemiology and Risk Factors

The U.S. prevalence of alcohol dependence by age, sex, and race-ethnicity is available at www.niaaa.nih.gov. For 2012, the past-month prevalence of alcohol dependence among those 21 years and older was estimated to be 6.9%, with the rate being 10.8% for men and 3.4% for women. The rates for those aged 12 to 20 years were 4.3% for heavy drinking and 15% for binge drinking. These rates can be much higher in general medical or psychiatric clinics, with 20% to 50% of men and 6% to 10% of women suffering from alcoholism.

Alcohol in Healthy Adults

Alcohol in large doses is mildly stimulating on the rising phase of the plasma concentration curve and sedating on the declining side of the curve.[7] In lower doses, it has little stimulatory effects on the rising phase and is mildly sedating on the declining phase. Studies of alcohol effects on sleep typically administer alcohol 30 to 60 minutes before sleep, which results in peak concentrations occurring before or at bedtime. The studies have used doses ranging from 0.16 to 1.0 g/kg, the rough equivalent of one to six standard drinks, producing breath ethanol concentration (BrEC) up to 0.105% at bedtime.[8] Sleep latency is reduced over this dose range, and one study reported increased sleep time at a low 0.16 g/kg dose but not at the higher 0.32 and 0.64 g/kg doses of that study. Improved sleep *only* at low doses is likely due to a second half of the night sleep disruptive rebound wakefulness that occurs with the higher doses. The typical BrEC at lights out for higher dose studies is between 0.05% and 0.09%, and given that ethanol is metabolized at a rate of 0.01% to 0.02% BrEC per hour, within the first 4 to 5 hours of the sleep period, ethanol has been completely metabolized. This leads to rebound wakefulness during the last hours of the sleep period.[9] Thus, for the whole night, sleep time is not increased at high doses and often is actually decreased.

In addition to these effects on sleep induction and maintenance, ethanol affects the normal progression of sleep stages.[10] A dose-dependent suppression of REM sleep, at the least in the first half of the night (i.e., when ethanol blood levels are present), and in *some* studies increased slow wave sleep in the first half of the night are reported. Slow wave sleep enhancement occurs in subjects with less than age-corrected amounts of slow wave sleep at baseline. When first-half REM sleep suppression is observed, a second-half REM sleep rebound is reported as well. As with rebound wakefulness, the second-half REM sleep rebound likely relates to the timing of complete ethanol elimination from the body. Repeated nightly administration of ethanol leads to tolerance development to both the sleep induction and sleep stage effects but interestingly not to the rebound effects. Finally, discontinuation of ethanol is followed by a REM sleep rebound, although the appearance of a REM sleep rebound is likely related to dose, duration of use, basal level of REM sleep, and extent of prior REM sleep suppression and tolerance development.

The aftereffects of heavy alcohol consumption, commonly referred to as hangover, are typically experienced after peak BrECs of 0.100% and greater.[11] Some laboratory studies of heavy drinking, hangover, and next-day cognitive and psychomotor performance have demonstrated impairment in the morning with BrEC zero 14 hours after ethanol ingestion the previous night and approximately 4 hours before going to bed.[12] Some studies have related the next-day impairment to the degree of ethanol-related sleep loss and fragmentation during the previous night.[13] Even with low alcohol doses and in the absence of hangover symptoms, the sleep-disruptive and performance-impairing effects may continue after alcohol is completely metabolized and BrEC is zero. Late afternoon drinking with BrEC zero at bedtime disrupted sleep in the second half of the night, and morning or midday drinking

continues to impair performance for 2 to 3 hours after BrEC is zero.[14,15]

Several clinical implications of these alcohol effects in healthy people might be discussed. Regular heavy drinking and chronic insomnia complaints, particularly sleep maintenance insomnia, are easily identified; but occasional insomnia can be related to a patient's occasional heavy drinking. Sleep diaries that query about social drug use as well as the sleep complaints can help identify for the clinician and patient this relation of the alcohol use and sleep problems. Inquiry as to the quantity and timing of the patient's alcohol consumption and attempt to sleep may reveal the sleep-disruptive potential of the alcohol. Just as important are the potential next-day impairing effects of evening alcohol consumption as discussed earlier. Recognition that sleep-disruptive alcohol consumption combined with sleepiness due to other causes can have additive daytime impairing effects is also important.

Alcohol Effects in Primary Sleep Disorders

Approximately 30% of individuals with insomnia in the general population use alcohol to help them sleep, and 67% of those people have reported that the alcohol was effective in inducing sleep.[16] The laboratory studies of healthy normals showing sleep-disruptive ethanol effects used higher doses (e.g., BrEC >0.05% at bedtime, about five or six drinks) than the doses (e.g., one or two drinks) reportedly used by insomniacs. In laboratory studies of people with primary insomnia, ethanol administered 30 minutes before sleep, which raised BrEC to only 0.04% at bedtime, improved sleep without producing a second-half wakefulness rebound.[17] Compared with age-matched people without insomnia and with a similar social drinking history, those with insomnia chose to self-administer alcohol before sleep more frequently. The risk associated with using alcohol as a sleep aid is that tolerance to its initial beneficial effect develops within three to five nights, and people with insomnia increase their self-administered dose to compensate.[18] Later in the chapter, guidelines are offered for determining when what could be initially considered therapy seeking (e.g., use of alcohol as a sleep aid) has shifted to drug seeking.

Alcohol is a mild respiratory depressant in the wake state, and during sleep it exacerbates obstructive sleep apnea syndrome and may precipitate sleep disordered breathing in at-risk persons. In one study, patients with moderate obstructive sleep apnea, defined as an average respiratory disturbance index (RDI; number of apneas and hypopneas per hour of sleep) of 22, received 300 mL of bourbon 2 hours before bedtime.[19] That dose of ethanol increased the RDI to 28. In another study, patients with a range of sleep-related breathing disorders were studied.[20] An unspecified dose and BrEC increased the RDIs of every patient with baseline RDI between 14 and 54. The effects of ethanol are also found in other sleep-related respiratory disorders. For example, in several patients with chronic obstructive pulmonary disease, ethanol worsened the degree of hypoxemia, and in several patients with only a snoring history, it induced apnea.[20] That an asymptomatic snorer with no apnea will develop apnea after ethanol was convincingly shown in a later study.[21] In one study, ethanol (BrEC = 0.08%) in snoring men increased their RDIs to a pathologic level (i.e., RDI >10).[22] On the other hand, the findings in asymptomatic individuals without risk factors have been inconsistent.

The risk of periodic limb movements (PLMs) during sleep was increased in association with self-reported alcohol consumption in a sample of sleep disorders clinic patients.[23] However, in a sample of patients abstinent of alcohol, the rate of PLMs was not different from the rate of a general sleep disorders clinic sample.[24] Alcoholism is associated with deficiencies in iron, ferritin, magnesium, and vitamin B_{12} and polyneuropathy, all of which are also associated with PLMs and restless legs syndrome (RLS). To the extent that the patient with alcoholism has any of these deficiencies, RLS and PLMs may be precipitated or exacerbated.

Sleep and Alcohol Effects in Alcoholism

Patients with alcoholism commonly complain of sleep problems, daytime sleepiness, and parasomnias. During drinking binges, people with alcoholism report polyphasic sleep patterns, with short sleep periods followed by short wake periods that are distributed across the 24-hour day. This type of sleep pattern is seen in organisms without a circadian pacemaker (i.e., lesioned suprachiasmatic nuclei). It is possible that during these binges, the sleep-wake cycles of people with alcoholism are so chaotic that they are arrhythmic. It would be of interest to see the circadian pattern of temperature, dim light melatonin onset, and other phase markers in this population. Laboratory studies of patients with alcoholism show that sleep latency and total sleep time are disturbed on both drinking and discontinuation nights.[25] The prolonged sleep latency in alcoholism when drinking contrasts with the reduced sleep latency that alcohol produces in people without alcoholism and suggests tolerance development and possible neurobiologic changes as discussed before. In addition, as in insomnia and some healthy normals with basally low amounts of slow wave sleep, drinking in people with alcoholism is associated with increased slow wave sleep and REM sleep suppression, with rapid tolerance development to these effects.[25]

The acute alcohol abstinence phase lasts 1 to 2 weeks, although some of the withdrawal symptoms, such as mood instability, disturbed sleep, and craving, remain beyond this period. During the acute abstinence phase, slow wave sleep is reduced, sometimes to minimal levels, and REM sleep continuity is disrupted.[26] There are frequent REM episodes and shortened non-REM (NREM)–REM cycles during the acute abstinence.

Recovery and Long-term Abstinence

Some of these abnormal sleep patterns can persist for up to 3 years in some patients with alcoholism. Sleep remains shortened and REM sleep pressure elevated, as evident in elevated levels with shortened latencies to REM sleep.[27] Figure 140-1 illustrates the abnormally short sleep and elevated REM sleep percentage in abstinent primary alcoholism. Whereas it is tempting to attribute these sleep abnormalities to the excessive alcohol drinking of the patients, the sleep problems could have preceded the development of the alcoholism or they could be secondary to the development of other medical and psychiatric disorders during the alcoholic drinking of the patient.

Regardless of the cause of the sleep disturbance evident in alcoholism, both objective and subjective measures of sleep taken after the immediate acute abstinence predict the likelihood of relapse during the long-term abstinence. Early laboratory studies suggested that low levels of slow wave sleep are

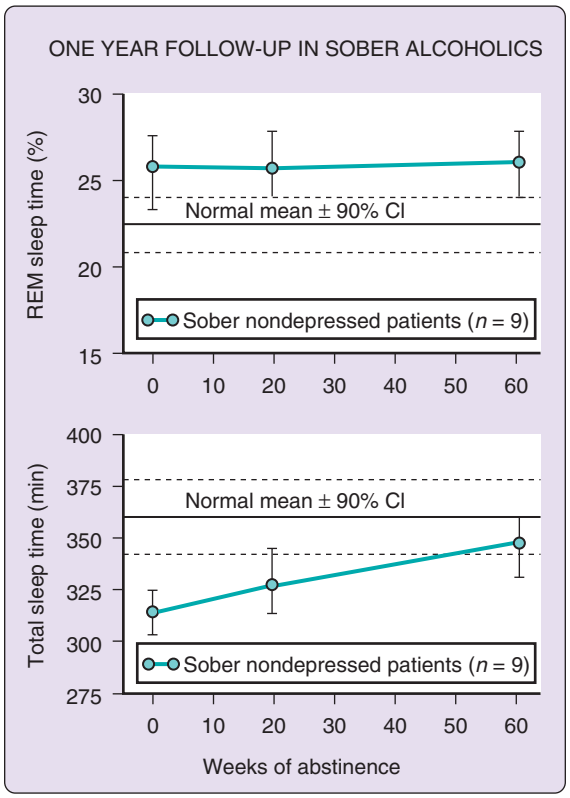

Figure 140-1 Polygraphic sleep recordings for rapid eye movement (REM) sleep percentage and total sleep time in nine male, sober, recovering, primary nondepressed, alcoholic patients for more than 1 year. Note that both measures differ from those of age-matched healthy control subjects for most of the recovery period. Values for the patients are mean ± standard error of the mean; values for healthy control subjects are mean + 90% confidence interval (CI). (Modified from Drummond SP, Gillin JC, Smith TL, Demodena A. The sleep of abstinent pure primary alcoholic patients: natural course and relationship to relapse. *Alcohol Clin Exp Res* 1998;22:1796–802.)

predictive of alcoholism relapse.[28] More recent studies have identified REM sleep disturbances, either elevated REM sleep percentage or shortened REM sleep latency, as predictive of relapse.[29] Interestingly, that risk was greater than that associated with other variables, such as age, marital status, employment, duration and severity of alcoholism, hepatic enzymes, and depression ratings.

Treatment of the Sleep Disturbance of Alcoholism

Treatment of sleep disturbance in patients with alcoholism is challenging as there are few placebo-controlled studies to guide the clinician. The benzodiazepine receptor agonists are the drug class of choice for insomnia treatment in patients without alcoholism. However, whereas these drugs have a relatively low abuse liability in those without alcoholism, their risk in outpatients with alcoholism after acute inpatient withdrawal is unknown.[30] These drugs are effective for the immediate inpatient withdrawal syndrome because they share the same mechanism of action as that of alcohol itself, promotion of γ-aminobutyric acid inhibition. A further caution to their outpatient use is that they have a high potential for toxicity and overdose when combined with alcohol, thereby being dangerous for the people with alcoholism who relapse.

Sedating antidepressant medications, such as trazodone and doxepin, are often used in the United States to treat primary insomnia and insomnia comorbid with depression. Trazodone has been used to treat sleep disturbance in alcoholism patients in open-label, noncontrolled studies.[30] In doses of 50 to 300 mg, it improved self-reported measures of insomnia. Currently, the three Food and Drug Administration–approved alcoholism treatments are disulfiram, naltrexone, and acamprosate. Unfortunately, sleep problems have not been major outcome measures in those studies testing the efficacy of these agents used as alcoholism treatments. One exception is a recently completed large trial of the anticonvulsant gabapentin, in which both sleep and drinking outcomes were improved.[31]

Cognitive-behavioral therapy for insomnia (CBT-I) is an alternative to medications, and several trials in alcoholism with sleep disturbance have been conducted. A randomized controlled trial of brief CBT-I associated with alcoholism was done in 60 patients without comorbid depression.[32] The CBT-I treatment, compared with wait-list controls, improved sleep diary measures of sleep quality, sleep efficiency, awakenings, and time to fall asleep. However, CBT-I had no impact on drinking relapse rates during the 6-month follow-up period. An open trial of CBT-I in patients with alcoholism similarly found improved sleep but not improved drinking outcomes.[33]

It is tempting to assume that the excessive alcohol intake is the sole or primary cause of insomnia in alcoholism. Earlier it was noted that other primary sleep disorders and possibly circadian disorders are present in patients with alcoholism at a higher rate than in those without alcoholism. Furthermore, depression is often present in alcoholism, and the sleep disturbances of depression have been well documented. Appropriate treatment of the comorbid sleep or psychiatric disorder should be pursued. Insomnia treatment in patients with alcoholism must begin with referral to addiction treatment specialists. Treating the insomnia alone will not initiate abstinence. Patients with alcoholism often deny their drinking problems and may focus on their sleep problems to avoid confronting their drinking problems.

Epidemiology and Risk Factors for Drugs of Abuse

Prevalence data on abuse of specific drugs other than alcohol are highly variable across years and regions of the country. U.S. prevalence estimates on use and dependence are collected annually by the U.S. government Office of Applied Studies in the Substance Abuse and Mental Health Services Administration. Prevalence tables by drug, age, sex, and region of the country for lifetime, past year, and past month use and for dependence or abuse are available at www.oas.samhsa.gov. In the 2013 National Survey on Drug Use and Health, 9.4% of Americans 12 years and older were current illicit drug users, which includes marijuana, cocaine, heroin, hallucinogens, inhalants, and the nonmedical use of prescription medications.

Stimulants

Caffeine

Caffeine often is not considered a drug of abuse by society, and even within the medical community, its potential for abuse is not fully appreciated. Laboratory data indicate there are conditions under which caffeine is persistently

self-administered and that it does have abuse liability, albeit a relatively low liability compared with other recognized drugs of abuse.[34] As might be expected, caffeine in doses of 150 to 400 mg administered immediately before sleep prolongs the onset of sleep and reduces total sleep time in healthy normals.[34-39] To compare the disruptive effects of caffeine with the psychomotor stimulants, in one study 300 mg of caffeine reduced sleep efficiency from 89% to 74%, whereas 40 mg of pemoline reduced it to 80%, and 20 mg of methylphenidate reduced it to 61%.[36] As to sleep stage effects, some studies report reductions of stage 3–4 sleep,[35,36] but unlike with the psychomotor stimulants, stage REM sleep is not affected.

Discontinuation of the chronic use of caffeine is associated with mood and performance disturbance. A withdrawal syndrome was observed after a double-blind, placebo-controlled cessation of chronic but moderate (235 mg daily on average) caffeine consumption.[37] Putting the dose in context, an 8-ounce cup of coffee contains 100 mg of caffeine. On the second day of caffeine cessation (20 hours after caffeine use), in addition to the ubiquitous headache, reduced vigor and increases in sleepiness, fatigue, and drowsiness were experienced. For moderate to heavy caffeine users, the morning cup of coffee immediately after arising probably restores caffeine levels and alertness as the 8-hour sleep period is essentially a caffeine discontinuation.

Nicotine

That nicotine is a drug of abuse is undisputed, and some have argued that it rivals the abuse liability of cocaine. The study of nicotine's effects on sleep has been facilitated with the development of nicotine delivery systems (i.e., nicotine gum and patches) for use in clinical smoking cessation programs. In healthy normals, transdermal nicotine (7 to 14 mg) produced a dose-dependent increase in wakefulness and a reduction in percentage REM sleep relative to a placebo patch.[40] A second study of nonsmoking normals also found that 17.5 mg transdermal nicotine increased wake time and decreased REM sleep percentage.[41] In obese, nonsmoking patients with sleep disordered breathing, 15 mg transdermal nicotine reduced both total sleep time and percentage REM sleep; it did not improve the sleep disordered breathing of these patients, which was the study's primary purpose.[42]

The discontinuation of nicotine in nicotine-dependent individuals is associated with a disturbance of sleep and alertness. In an uncontrolled study that compared the sleep of smokers during the week before and after cessation of chronic smoking, the number of arousals, awakenings, and sleep stage changes were all increased during the cessation week.[43] In a double-blind study using a placebo versus nicotine patch during the discontinuation of the average daily use of 30 cigarettes, the number of arousals was increased relative to the smoking baseline in the placebo group, whereas in the nicotine (22 mg) patch group, arousals were reduced and stage 3–4 sleep was increased relative to the smoking baseline.[44] However, given the pharmacokinetics of nicotine, any smoking baseline is a partial discontinuation during the usual 8-hour sleep period of nonsmoking. Because the nicotine patch was worn continuously, it is probable that sleep was improved relative to a partial discontinuation (i.e., a smoking baseline). Such is consistent with the several questionnaire studies that find smokers are more likely than nonsmokers to report problems falling asleep and staying asleep.[45]

Psychomotor Stimulants

Cocaine. Cocaine is the CNS stimulant with the greatest abuse liability. Some laboratory studies have examined the effects of cocaine and its discontinuation on sleep and daytime alertness. Clinical assessments have described continued and prolonged wakefulness during "cocaine runs," days of protracted cocaine use. The cocaine runs are then followed by "crashes," which are characterized by excessive sleep and sleepiness.[46] Several polysomnography (PSG) studies of cocaine discontinuation in cocaine-dependent persons have reported elevated sleep time and a REM sleep rebound during the initial abstinence. That disturbance was then followed by a persisting insomnia and REM sleep disturbance for the 3-week study duration.[47] A laboratory study of cocaine administration and discontinuation found that 600 mg/day intranasal cocaine (insufflated from 1900 to 2100 hours) severely disrupted sleep, delaying its onset at the 2300 hours bedtime for up to 3 to 4 hours and suppressing REM sleep.[48] During the first two discontinuation days, average daily sleep latency on the Multiple Sleep Latency Test (MSLT) was less than 5 minutes (i.e., a pathologic level of sleepiness), most probably because of the severe sleep disturbance of the prior 5 days of cocaine self-administration. The MSLT also showed multiple sleep-onset REM periods, probably due to the prior REM sleep suppression during the cocaine administration nights. Then, even after 14 days of abstinence, a nocturnal sleep and REM sleep disturbance remained, although the MSLTs were free of sleep-onset REM periods and the sleep latencies returned to normal levels. Later, we discuss how these state-altering effects may serve to maintain cocaine dependence. Some PSG studies have now shown that slow wave sleep and REM sleep disturbances are predictive of relapse during short-term abstinence.[49]

Amphetamine. Amphetamine is also a drug of abuse. During the 1950s, before its manufacture and distribution became tightly controlled, an epidemic of amphetamine abuse occurred in the United States. Although it is not the drug of choice, it has therapeutic indications for the treatment of narcolepsy and attention deficit/hyperactivity disorder (ADHD). Few PSG studies of amphetamine administration and discontinuation have been done. In one of the earliest PSG drug studies, 10 or 15 mg of *d*-amphetamine doubled sleep latency and suppressed REM sleep in healthy young adults.[50] Another study of healthy adults and patients with narcolepsy reported that a 7 to 8 AM administration of methamphetamine (10 mg) reduced sleep efficiency that night (11 PM bedtime) in control subjects and at 40- to 60-mg doses in the narcoleptics.[51] No REM sleep effects were observed in the normals. However, the patients received higher doses, and their REM sleep latency was increased and REM sleep time was reduced. A study of amphetamine-dependent subjects assessed sleep during the drug's discontinuation.[52] On the second night after the last amphetamine dose, REM sleep time rebounded and remained elevated for three to five nights. This REM sleep rebound was delayed relative to that associated with cocaine discontinuation, which may be due to the pharmacokinetic differences between the drugs (i.e., the longer half-life of amphetamine). The rebound also was longer lasting, which may be due to differences in the duration or amount of prior use or in the level of REM sleep suppression caused by the

drug. Total sleep times were elevated during the same 3- to 5-day period, probably reflecting recovery sleep due to the prior drug-induced sleep loss, but subsequently sleep times became shorter than normal, suggesting continuing insomnia. As in abstinence from cocaine dependence, the continued insomnia in amphetamine abstinence raises questions about a stimulant-induced persisting alteration of CNS sleep-wake mechanisms.

No studies of the effects of amphetamine discontinuation on daytime levels of sleepiness-alertness have been done in amphetamine-dependent persons. One would predict that amphetamine discontinuation is associated with increased daytime sleepiness and multiple sleep-onset REM periods on the MSLT similar to what is reported for the discontinuation of cocaine.

Methylphenidate. Methylphenidate is generally considered a safer drug as regards its abuse liability, although case reports of its abuse have appeared over the years. Its indications are for ADHD and narcolepsy. It is the drug of choice for ADHD and a second-choice drug for narcolepsy. In healthy normals, 20 mg reduced total sleep time, increased the latency to REM sleep, and reduced the minutes of REM sleep, whereas 10 mg increased only REM sleep latency.[53] In an earlier study, 5 mg was reported to increase the latency to REM sleep and to reduce the percentage of REM sleep without affecting other sleep measures.[54] In children with ADHD, studies of the effects of methylphenidate taken during the day on subsequent sleep are inconclusive. Sleep time was shortened in one study[55] and increased in another,[56] and in one study REM sleep was fragmented.[56] However, these studies can be questioned for a variety of methodologic and control issues.

We are unaware of studies that have documented the discontinuation effects of methylphenidate in dependent individuals. Increased daytime sleepiness with multiple sleep-onset REM periods would be predicted. The role that the excessive sleepiness following discontinuation of any of these stimulant drugs may have in their continued use and abuse is illustrated by self-administration studies done in healthy normals. When given an opportunity to self-administer methylphenidate (20 mg), healthy normals, with no current or previous substance abuse history, choose active drug on only 20% of the opportunities after 8 hours of time in bed the previous night but on 80% of the opportunities (i.e., 20% placebo choice) after 4 hours of time in bed.[1] These data are consistent with and extend the cocaine data, showing that stimulants have performance-enhancing effects in sleep-deprived healthy normals and profoundly reinforcing effects for sleepy individuals or normal individuals experiencing sleep loss.

Opioids

The opioids are drugs with a high abuse liability. They have disruptive effects on sleep continuity and sleep staging. Heroin (3, 6, and 12 mg/70 kg) administered intramuscularly in a double-blind placebo-controlled design to abstinent opioid-dependent people produced dose-related decreases in total sleep time, stage 3–4 sleep, and REM sleep.[57] Heroin is metabolized to morphine, and as would be expected, morphine (7.5, 15, and 30 mg/70 kg) also produced a dose-related decrease in sleep time, stage 3–4 sleep, and REM sleep in the abstinent opioid-dependent people.[58] Finally, methadone (7.5, 15, and 30 mg/70 kg) also decreased total sleep time, stage 3–4 sleep, and REM sleep in abstinent opioid-dependent people.[59] All these drugs also produced increased brief arousals and frequent sleep stage changes (i.e., sleep fragmentation). Several studies have indicated that tolerance to the sleep-disruptive effects develops within weeks.[60] With tolerance development, the sleep fragmentation is lessened, and the REM sleep–suppressive effects tend to diminish.

The discontinuation of chronic opioid use is associated with sleep disturbance. Heroin-dependent people being maintained on methadone in an outpatient research treatment program were discontinued from their treatment and sleep was recorded in the laboratory.[61] Sleep latency and latency to REM sleep were prolonged and percentage stage 3–4 sleep was reduced compared with normals. Interestingly, after a week of buprenorphine 4 mg, a partial μ opioid agonist, the sleep patterns normalized.

Opioids also have an impact on other sleep disorders. Although not the first line of treatment, opioids improve RLS and are often used in patients who do not respond to dopamine agonists. In contrast, given negative effects on respiratory drive, they are contraindicated in sleep apnea.

Sedative-Hypnotics

Within society and the medical community, sedative-hypnotics are considered to have a relatively high abuse liability. The scientific evidence from epidemiologic and laboratory studies indicates that the abuse liability of modern sedative-hypnotics is relatively low. The distinction "modern" is critical in that the early sedative-hypnotics, barbiturates and ethanol-based drugs (i.e., ethchlorvynol, choral hydrate), clearly produce both physical and behavioral dependence, but the modern benzodiazepine receptor agonists are not as likely to do so.

In the 1980s, daytime self-administration studies were done in normals, persons with substance abuse histories, and patients with anxiety disorders; the results showed a generally low behavioral dependence liability. The benzodiazepine receptor agonists were self-administered by people with a substance abuse history at low and declining rates over time[62] and were not differentially self-administered relative to placebo by the normals or patients with anxiety disorders.[63,64] Research has found that some patients with anxiety disorders self-administered alprazolam relative to placebo.[65] Our short-term studies of pre-sleep zolpidem or placebo self-administration in patients with insomnia have found that triazolam and placebo are self-administered at similar rates (67% to 88%) in a single-choice paradigm (i.e., choice of taking the available capsule or not).[66-68] However, when subjects were forced to choose on a given night between triazolam and placebo, triazolam was preferred 80% of the time.[68] Most important, when subjects were given an opportunity, in a single-choice paradigm, to self-administer multiple capsules on the same night, a 0.27-mg average nightly triazolam dose was self-administered (i.e., one capsule), whereas the placebo dose was escalated to the three-capsule maximum. Long-term studies of nightly use of zolpidem or placebo for 1 year showed that (1) zolpidem was preferred to placebo by people with insomnia, but its overall rate of self-administration did not increase during 12 months of nightly use (i.e., a stable average nightly dose of 9.5 mg was self-administered), whereas placebo self-administration did increase during the 12 months, again to the three maximum capsules[69]; (2) 12 months of

nightly zolpidem use did not produce rebound insomnia or withdrawal signs and symptoms after chronic use[70]; and (3) relative to placebo, zolpidem increased total sleep time, and this hypnotic efficacy did not diminish during 8 months of nightly use.[71]

Hallucinogens

THC

THC is one of the principal active ingredients in marijuana. In the United States, marijuana still remains the most frequently abused illicit drug, although its popularity appears to cycle, trending up and down over decades. THC is classified as a mild sedative at low doses and a hallucinogen at high doses.

Study of THC's effects on sleep and wakefulness occurred predominantly during the 1970s. Low doses of THC (4 to 20 mg), in either experienced marijuana users or nonusers, had mildly REM sleep–suppressive effects.[72-74] In several of the studies, total sleep time or stage 3–4 sleep was increased,[72,74] which then decreased after a week of repeated nightly use.[74] At high doses (50 to 210 mg) in naive or experienced marijuana users, THC again suppressed REM sleep, but effects on total sleep time were not observed,[75] and stage 3–4 sleep was reduced in one report.[76] Some of the studies reported a REM sleep rebound on the THC discontinuation nights,[72,75] and some reported a reduction in sleep time or an increase in sleep latency.[73,75] All of these studies have involved pre-sleep laboratory administration of THC. Several studies in situ or in semicontrolled laboratory situations with moderate and heavy marijuana users smoking their usual marijuana cigarettes during the day or early evening have also been done. Self-reported or rater-observed sleep time was increased in two such studies.[77,78] In a PSG study, little or no effects on sleep measures were observed.[79] These mild sedative effects have also been observed during daytime studies using performance assessments. In situ assessment of daily activity levels also showed reduced activity during moderate or heavy marijuana use.[78]

MDMA

An amphetamine derivative that has become increasingly popular as a recreational drug and drug of abuse is (±)3,4-met hylenedioxymethamphetamine (MDMA) or "ecstasy." This drug has hallucinogenic properties and acts indirectly by stimulating the release of brain monoamines.[80] Exposure to MDMA decreases total sleep time with a decrease in NREM sleep but no significant effects on REM sleep. Among NREM sleep stages, individuals who use MDMA have less stage 2 sleep, but there are no apparent differences in stage 1 or slow wave sleep (stages 3 and 4).[81] In a placebo-controlled study, acute MDMA shortened sleep primarily by increasing sleep latency and reducing stage 3–4 sleep and suppressing REM sleep.[82] The MDMA-reduced sleep time was not associated with increased daytime sleepiness the following day as seen in a 4-hour sleep restriction condition (Figure 140-2). Average daily sleep latency on the MSLT the day after nighttime placebo was increased in MDMA users compared with age-matched controls, and MDMA users had an elevated number of sleep-onset REM periods compared with controls.

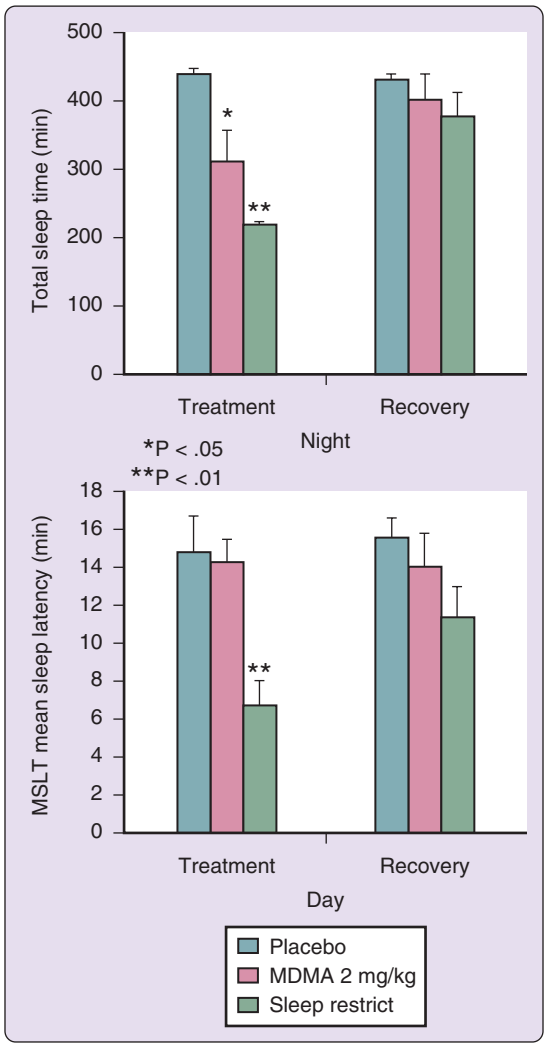

Figure 140-2 Polygraphic sleep recordings for total sleep time and mean sleep latency on the Multiple Sleep Latency Test (MSLT) were less than 5 minutes (i.e., a pathologic level of sleepiness), most probably because of the severe sleep disturbance the following day in moderate MDMA users (n = 7) after placebo, MDMA 2 mg/kg, or a 4-hour restricted bedtime. Drug or placebo was administered at 1800 hours, and bedtime was 2300 to 0700 hours on drug or placebo nights and 0300 to 0700 hours on sleep-restricted nights. Note the unusually high MSLT times after placebo and again after MDMA despite the MDMA-shortened sleep time the previous night. After sleep restriction, the MSLT time did decline. (Modified from Randall S, Johanson CE, Tancer M, Roehrs T. Effects of acute 3,4-met hylenedioxymethamphetamine on sleep and daytime sleepiness in MDMA users: a preliminary study. *Sleep* 2009;32:1513–9.)

Treatment of the Sleep Disturbance in Drug Abuse

The literature on treating sleep disturbance in drug abuse is even more limited than that for alcoholism, but the few studies are provocative. A trial of CBT-I and daytime sleepiness in adolescents improved the sleep of those completing more than four sessions.[83] The improved sleep showed a trend toward reducing substance abuse problems at the 1-year follow-up. A treatment trial of nicotine-dependent adults compared a 16-hour versus 24-hour nicotine patch during smoking abstinence.[84] The patches reduced smoking urges, with the 24-hour patch having a greater effect than the 16-hour patch. The 24-hour patch improved sleep, specifically the amount of slow wave sleep. This result in nicotine-dependent adults is in contrast to the sleep-disruptive effects of a nicotine patch on the sleep of nonsmokers. In the drug abuse treatment literature, sleep is rarely included as an outcome measure. The need for

Table 140-1 Characteristics of Drug-Seeking versus Therapy-Seeking Behavior

Drug-Seeking Behavior

- Drug chosen over other commodities or activities
- Drug taken in excessive, nontherapeutic amounts
- Drug taken on chronic basis, leading to tolerance and physical dependence
- Drug taken in nontherapeutic context

Therapy-Seeking Behavior

- Drug has demonstrated efficacy
- Duration and dose of self-administration are limited to therapeutic effects
- Patient has signs and symptoms for which drug is indicated
- Drug is believed to be and is experienced as being efficacious

clinical trials that focus on treatment of sleep complaints in substance abuse is clearly evident.

CONTROVERSIES AND PITFALLS

Drug Seeking versus Therapy Seeking

It is often difficult to differentiate drug seeking from therapy seeking in clinical practice. In drug seeking, the drug and its effects, typically its euphorigenic effect, are the focus of the drug use, whereas in therapy seeking, the alleviation of disease-related symptoms is the focus of the drug use. However, in the clinic, drug seeking and therapy seeking can become closely intertwined, and what was once therapy seeking can shift to drug seeking. The clinical challenge to sleep disorders clinicians is to differentiate the two phenomena in making diagnoses and appropriately treating patients. Some of the potentially differentiating and defining characteristics of drug seeking versus therapy seeking are presented in Table 140-1. The defining characteristic of drug seeking is evidence that the drug is taken in excessive amounts and in nontherapeutic contexts and is preferred to other commodities (e.g., money) and various social and occupational activities. The degree to which the drug is chosen over other commodities or social activities is evidence for the extent of its risk for abuse. Supportive of its reinforcing capacity is evidence in the scientific literature that the drug is readily discriminated from placebo by behavioral and subjective assessment. These assessments typically rate the drug for it euphorigenic and drug-liking effects, that is, the drug's subjective effects are the focus of its use. Then, to the degree that the dose is escalated over time, one has evidence of the development of tolerance and possible physical dependence.

In contrast, therapy seeking is evident if the drug has demonstrated efficacy for the disorder or condition being treated. As well, the patient has the signs and symptoms and the appropriate diagnosis for the indicated use of the drug. The pattern of drug taking, its dose and duration of use, is consistent with its therapeutic effects. Finally, the patient believes that the drug is effective and readily experiences its therapeutic effects. However, the distinction between drug seeking and therapy seeking becomes difficult in situations in which therapy-seeking behavior shifts to drug-seeking behavior. For example, one is concerned about the use of ethanol as a hypnotic by an insomniac. Whereas pre-sleep ethanol use may initially be effective in improving sleep, rapid tolerance development is likely, which may lead to dose escalation. Further, other reinforcing effects of ethanol (i.e., its euphorigenic effects) may be discovered by the person, especially as dose is escalated, and its use may then extend beyond the therapeutic context (i.e., before sleep as a hypnotic). A similar shifting pattern can be described for stimulant or opiate use. On the other hand, drug seeking may be maintained because the drug, in addition to its mood-altering and euphorigenic effects, also has therapeutic effects (i.e., the stimulant effects of cocaine or amphetamine do reverse the excessive sleepiness that is experienced during drug discontinuation). Thus, the dependence is maintained by both its mood-altering effects and its therapeutic effects, what others have termed self-medication (i.e., both positive and negative reinforcing effects).

Sleep-Wake Disturbance in Alcoholism and Drug Abuse

The role of sleep-wake disturbance in alcoholism and substance abuse is not well understood. It is known that insomnia is a risk factor for substance abuse. Yet, earlier in discussing diagnoses, the point was made that sleep-wake disturbances are not major criteria in making DSM-5 abuse diagnoses. The extent to which insomnia or daytime sleepiness leads to new cases of alcoholism or drug abuse is not known. Furthermore, the degree to which treatment of insomnia or daytime sleepiness in abstinent alcoholism and drug abuse reduces risk of relapse is not known. To date, the few alcoholism treatment trials have failed to clearly demonstrate that improved sleep reduces relapse, and the only drug abuse treatment trial, although encouraging, is not conclusive. There is the inherent assumption in this discussion that sleep disturbance is causally related to alcoholism or drug abuse, as either the precipitant or consequent, but it may be comorbid and independent or related to a third common factor.

CLINICAL PEARL

The sleep clinician, in assessing patients with sleep complaints, must query about substance use, including prescribed and over-the-counter drugs, legal recreational drugs, and illegal recreational drugs. Attention to the quantity and pattern of use is important. When substance abuse is suspected, referral to a substance abuse specialist is desirable. When drugs with a known abuse liability are prescribed, patients should be observed closely to monitor their appropriate therapeutic use. Use of alcohol as a sleep aid should be discouraged as tolerance develops rapidly to its low-dose beneficial effects.

SUMMARY

Almost all of the psychoactive drugs with a known abuse liability have profound effects on sleep and wakefulness. Substance abuse is characterized by physiologic (e.g., withdrawal syndrome on drug discontinuation) and behavioral (e.g., repetitive, compulsive drug seeking and consumption and

relapse) dependence, in which the relative contribution of each can vary according to the drug and its duration of use. The neurobiologic mechanisms underlying both physiologic and behavioral dependence are known, but the role of the abused drug's sleep-wake state–altering effects in substance abuse is not fully known, although it is likely to be important. Some of the drugs of abuse are legal and widely used socially and may be the cause of patients' sleep or alertness complaints. Other drugs with abuse liability are drugs indicated in the treatment of sleep disorders. For that reason, guidelines have been provided for sleep disorders clinicians to help in differentiating drug-seeking behavior from therapy-seeking behavior.

Chapter
141

Sleep Disturbances in Attention-Deficit/Hyperactivity Disorder

Samuele Cortese; Michel Lecendreux

Chapter Highlights

- Although sleep disturbance is not mentioned in the criteria for attention-deficit/hyperactivity disorder (ADHD) in the most recent version of the *Diagnostic and Statistical Manual of Mental Disorders* (fifth edition), in the past decade there has been an increasing interest in the relationship between ADHD and sleep.
- In this chapter, we first review brain correlates possibly underpinning both ADHD and conditions characterized by sleep disruption. These include both cortical (e.g., dorsolateral prefrontal) and subcortical (e.g., locus coeruleus) structures.
- The second part of the chapter focuses on the empiric evidence supporting the management of sleep disorders in individuals with ADHD. Because, with the possible exception of melatonin for sleep-onset delay, the number of randomized controlled trials is still limited, most of the recommendations are based on a recent expert consensus workshop.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Attention-deficit/hyperactivity disorder (ADHD) is the most common neurodevelopmental disorder in children. According to the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5),[1] ADHD is defined by a persistent and impairing pattern of inattention or hyperactivity/impulsivity. The disorder is often comorbid with other neuropsychiatric conditions, such as oppositional defiant disorder/conduct disorder and mood and anxiety disorders. Besides the core symptoms of ADHD, deficits in executive functions (a set of cognitive skills that are necessary to plan, monitor, and execute a sequence of goal-directed complex actions) are commonly although not consistently associated with ADHD.[2]

ADHD is a major public health issue. Its estimated worldwide pooled prevalence is around 5% in school-age children, as found in a 2007 meta-analysis[3] and confirmed by its recent update.[4] Impairing symptoms of ADHD have been shown to persist in adulthood in up to 65% of individuals,[5] with an estimated pooled prevalence of ADHD in adulthood of approximately 2.5%.[6] In adults, ADHD may be comorbid with personality disorders, such as borderline personality disorder.[7] The core symptoms of ADHD and its comorbid conditions impose an enormous burden in terms of psychological dysfunction, adverse vocational outcomes, stress on families, and societal financial costs. Average annual incremental costs of ADHD have been estimated at $143 to $266 billion in the United States.[8] In Europe, annual national costs range between €1041 and €1529 million.[9]

Available therapeutic strategies for ADHD include pharmacologic and nonpharmacologic strategies. Pharmacologic treatments, which are generally well tolerated,[10] are an important element of therapeutic strategies for ADHD and are recommended as the first-choice option in some countries[11]; in other countries, they are recommended only for severe cases and those who fail to respond to nonpharmacologic interventions.[12,13] ADHD medications include psychostimulant (e.g., methylphenidate or amphetamine derivatives) and nonpsychostimulant (e.g., atomoxetine or guanfacine) drugs. Strong evidence from randomized controlled trials (RCTs) shows that different classes of psychostimulants (e.g., methylphenidate[14-17] or mixed amphetamine salts[18] and other amphetamines[19]) and some nonpsychostimulant treatments, such as atomoxetine,[20-23] are significantly more efficacious than placebo in considering short-term improvement in ADHD core symptoms. The efficacy of nonpharmacologic strategies, such as behavioral therapies, cognitive training, neurofeedback, and dietary treatment, for ADHD core symptoms is still unclear,[24] although these interventions may be effective for ADHD-related conditions and consequences of ADHD (e.g., oppositional behaviors in the case of behavioral therapies and executive impairment in relation to cognitive training) and may be preferred to medication by some patients and families.

ADHD and Sleep Disturbances: Historical Perspective

Whereas the comorbidity between ADHD and psychiatric disorders has been extensively addressed in previous research, the association with sleep disorder/disturbances has received less attention until recently. Indeed, sleep problems were mentioned in early descriptions of the disorder. For instance, in 1957, Laufer and Denhoff[25] wrote, "Generally the parents of hyperkinetic children are so desperate over the night problems that the daytime ones pale in significance." Later

on, Douglas[26] mentioned alterations in the "regulation of arousal and alertness to meet task demands" associated with ADHD.

Alterations in sleep, and more precisely "moves about excessively during sleep," were one of the possible diagnostic criteria for ADHD in the DSM-III.[27] On the grounds of the lack of specificity for ADHD, sleep disturbance was removed as a criterion for the disorder in the following editions of the DSM, likely contributing to a decrease in the attention paid to the relationship between ADHD and sleep in both research and clinical settings. However, in the past decade, there has been a renewed interest in the relationship between ADHD and sleep, as shown by the results of a simple PubMed search with the search terms "(ADHD OR Hyperkinetic Disorder OR Attention Deficit) AND sleep" (Figure 141-1). Although the DSM-5[1] ADHD criteria do not mention the word "sleep" (neither in the diagnostic criteria nor in the differential diagnosis), several recent guidelines and clinical recommendations on ADHD do refer to sleep disturbances as possible comorbidities or as disorders to consider in the differential diagnosis. For instance, the clinical practice guideline for the diagnosis, evaluation, and treatment of ADHD by the American Academy of Pediatrics[28] indicated that sleep disorders are among the conditions that can coexist with ADHD and recommended that primary care clinicians include sleep apnea as one of the conditions that are likely to be comorbid with ADHD. In addition, the European consensus statement on diagnosis and treatment of adult ADHD[29] pointed out that ADHD patients are at increased risk of having a sleep phase delay as a result of having chronic sleep-onset difficulty and recommended that a sleep assessment be included in the diagnostic process of ADHD.

ADHD AND SLEEP: GENERALITIES

Up to 70% of children with ADHD have been reported to have mild to severe "sleep problems."[30] In terms of adult ADHD, there are no epidemiologic studies that investigate subjective sleep complaints, nor are there large polysomnographic investigations in this population, but sleep disturbances are also considered to be common in adults with ADHD.[31]

Prevalence rates of sleep disturbances/disorders differ as a function of ADHD subtypes, with highest prevalence in the combined subtype,[32] although sleepiness may be more frequent in the inattentive subtype.[33]

The most recent meta-analysis on sleep disturbances in ADHD, which focused on children and adolescents,[34] found significantly more sleep problems in children with ADHD than in healthy controls without ADHD based on subjectively rated sleep items, including bedtime resistance, sleep-onset difficulties, night awakenings, difficulties with morning awakenings, sleep-disordered breathing, and daytime sleepiness. The meta-analysis[34] also found that compared with controls, children with ADHD had (1) significantly greater sleep-onset latency and less total sleep time based on actigraphy, (2) significantly greater number of stage shifts/hour of sleep and apnea-hypopnea index (AHI) and significantly lower sleep efficiency based on polysomnography, and (3) shorter average sleep-onset latency on the Multiple Sleep Latency Test (indicating that children with ADHD have higher levels of daytime sleepiness than controls do). Of note, studies assessing children treated with medications or with comorbid anxiety/mood disorders were excluded from the meta-analysis; therefore, the authors concluded that the significant differences in sleep parameters (both subjective and objective) are not accounted for exclusively by ADHD drugs or psychiatric comorbidities. However, other conditions occurring with ADHD were not addressed in this meta-analysis and could be responsible for the observed sleep disturbance. Indeed, it is likely that several mutually exacerbating factors ranging from behavioral/environmental conditions to primarily physiologic alterations may underlie sleep complaints in ADHD.[35] For a list of such factors that might contribute to sleep-onset difficulties, see Table 141-1. Although a previous meta-analysis[36] limited to polysomnographic studies showed only significantly higher values of the periodic limb movement index in ADHD compared with controls, the lack of significant findings on the other objective parameters may be accounted for by the smaller number of studies included in this older meta-analysis.

The association between ADHD and alterations of sleep processes has prompted investigation on possible

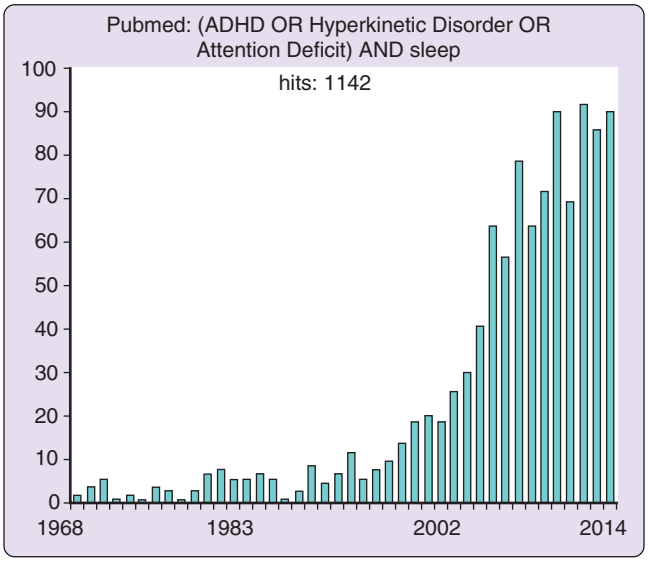

Figure 141-1 Scientific publications on ADHD and sleep, per a PubMed search (May 5, 2014).

Table 141-1 Conditions Underlying Sleep Disturbances (in particular, sleep-onset delay) in Individuals with ADHD

- Sleep disorders such as circadian rhythm sleep disorder or restless legs syndrome
- Poor sleep hygiene (e.g., use of electronics before bedtime)
- Psychiatric comorbidities (e.g., mood/anxiety disorders)
- Associated medical conditions and their treatments (e.g., obesity)
- Medication used to treat ADHD or comorbid conditions
- ADHD per se (individuals with ADHD may find it difficult to slow down their thoughts to settle for sleep, with consequent sleep-onset delay[33])

neurobiologic overlap at the brain level. In the following section, we provide an overview of the possible common brain mechanisms underlying both ADHD and sleep disorders. We then present the current evidence and, in the absence of empiric studies, provide recommendations for the management of sleep disturbances in individuals with ADHD based on recent expert consensus.[37] Because most of the studies have been conducted in pediatric samples, we focus on children, but we also present evidence from adult studies where it is available. The vast literature on the impact of sleep deprivation/disorders on neurocognitive functions, in particular, executive functions, that may be abnormal in individuals with ADHD goes beyond the scope of this chapter; the interested reader is referred to specific reviews of the literature on this topic.[38]

NEUROBIOLOGIC OVERLAP OF ADHD AND SLEEP DISORDERS

In a consensus conference paper on future perspectives of research on ADHD and sleep, Owens et al[39] pointed out that the cortical and brainstem regions involved in the regulation of sleep-wake function are also key areas implicated in the pathophysiologic mechanism of ADHD.[40] These include the frontal, dorsolateral prefrontal, ventrolateral prefrontal, and dorsal anterior cingulate cortices as well as the striatum (caudate and putamen) and lateral temporal and parietal regions. In addition, altered connectivity in key circuits pertaining to sleep-dependent learning, including disruption of limbic prefrontal circuits and alterations in connectivity between prefrontal regions (especially the ventral medial prefrontal cortex) and the hippocampus and amygdala, have been demonstrated in ADHD.[41]

Kirov and Brand[42] have noted that dopaminergic, noradrenergic, and serotoninergic abnormalities may underlie both ADHD and alterations in the pattern of sleep stage distribution across the night (changes in sleep architecture). They proposed a neurochemical model predicting possible changes in sleep architecture and other sleep problems in ADHD (Figure 141-2). More specifically, these authors suggested that (1) a nigrostriatal deficit may underlie periodic limb movements in sleep and restless legs syndrome (RLS) in ADHD, (2) a serotoninergic deficit may lead to deficient melatonin synthesis that in turn would contribute to delayed sleep phase syndrome, and (3) a mesolimbic (ventral tegmental area/nucleus accumbens) dopamine deficit may result in an altered monoamine-acetylcholine ratio, which would contribute to rapid eye movement (REM) sleep overdrive.

Another brain structure that may be functionally abnormal in both ADHD and sleep/circadian rhythm disorders is the locus coeruleus. Imeraj et al[43] postulated that a dysfunction of this structure could underlie both a disruption in circadian rhythm and disturbances in arousal-related processes that are considered to be abnormal in ADHD according to the cognitive energetic model originally developed by Sergeant (Figure 141-3).

Finally, evidence from genetic studies points to the involvement of the catecholaminergic system in both ADHD and sleep regulation. Specific genetic alterations, such as those of *CLOCK* genes, have been suggested to be common to both ADHD and circadian rhythm disorders.[39]

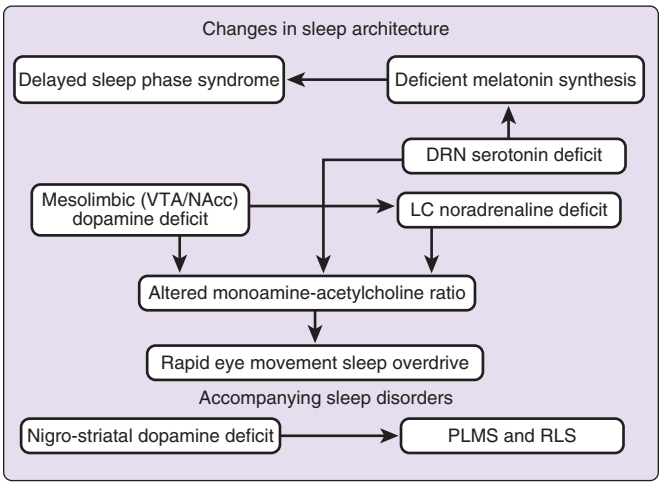

Figure 141-2 Neurochemical model of sleep disturbances in ADHD proposed by Kirov and Brand. DRN, Dorsal raphe nucleus; LC, locus coeruleus; NAcc, nucleus accumbens; PLMS, periodic limb movements in sleep; RLS, restless legs syndrome; VTA, ventral tegmental area. (From Kirov R, Brand S. Sleep problems and their effect in ADHD. *Expert Rev Neurother* 2014;14:287–99, with permission.)

SPECIFIC SLEEP DISORDERS IN ADHD

This section focuses on the management of sleep disturbances in ADHD. The levels of evidence are graded on the basis of the Scottish Intercollegiate Guidelines Network (SIGN) grading system (http://www.sign.ac.uk/) (Table 141-2). As previously mentioned, the etiology of sleep disturbances in ADHD is likely multifactorial; therefore, we present the management of the most common conditions (Table 141-1) underlying sleep complaints in ADHD. In particular, we focus on the most common sleep disorders and on the effects of ADHD medication on sleep; we refer the reader to other chapters of this book for information on the management of comorbid psychiatric disorders and somatic conditions associated with ADHD. When no empiric evidence is available, suggestions on the clinical management of specific disorders are based on the recommendations of the participants in a recent consensus conference.[37]

Behavioral Insomnia of Childhood

Precise estimates regarding the prevalence of behavioral insomnia of childhood as defined in the *International Classification of Sleep Disorders* (third edition) in children with ADHD are not available. However, clinical experience and expert consensus[37] suggest that this disorder is fairly common in children with ADHD referred to ADHD clinics.

Whereas the efficacy of behavioral treatments for behavioral insomnia in children in general is supported by empiric evidence,[44] at the time of this writing there is very little research evaluating behavioral sleep interventions specifically for children with ADHD. One case series found that a structured five-session therapy provided to three children with ADHD was successful at improving symptoms of insomnia.[45] This structured five-session therapy, which consisted of psychoeducation about sleep in children (e.g., basic sleep structure and function, sleep problems, and impact on daytime

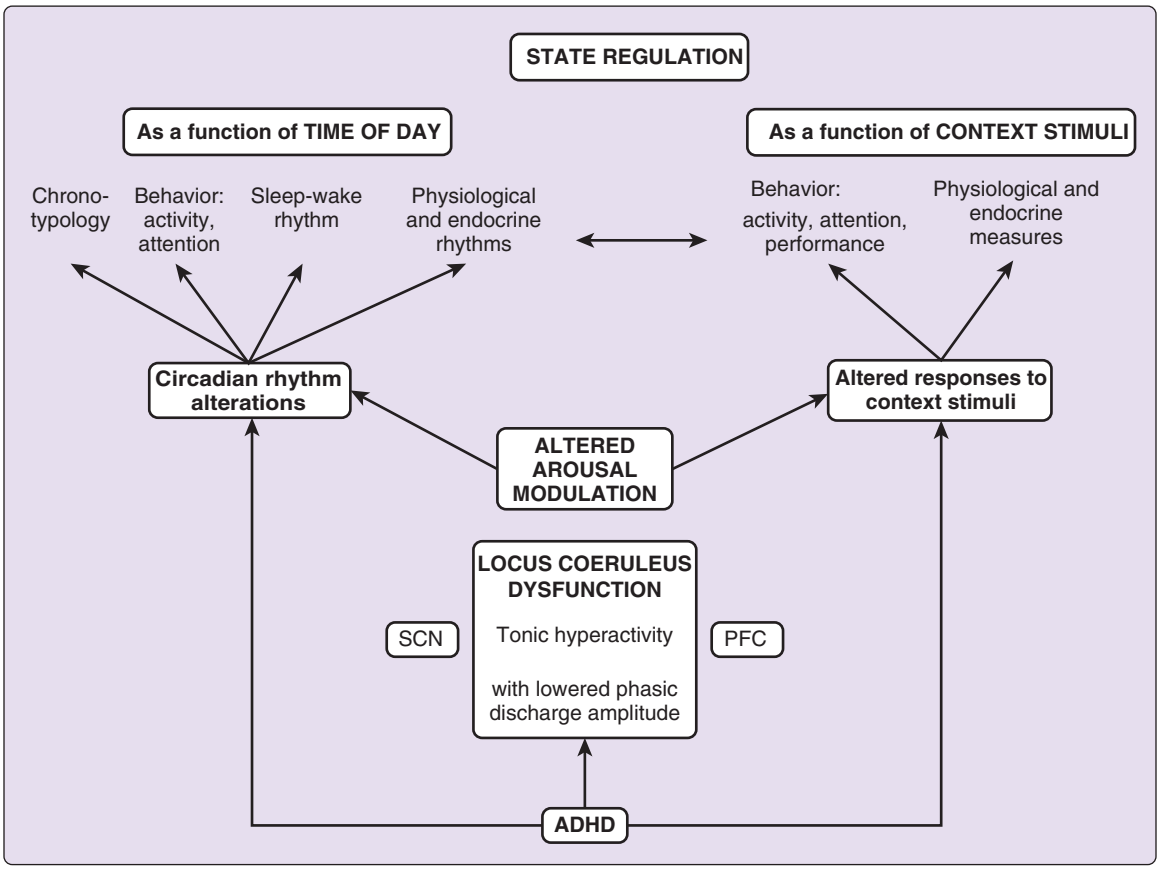

Figure 141-3 Model proposed by Imeraj et al on the involvement of the locus coeruleus in arousal dysfunctions and circadian rhythm disorders in ADHD. Altered circadian profiles in attention-deficit/hyperactivity disorder: an integrative review and theoretical framework for future studies. *Neurosci Biobehav Rev* 2012;36:1897–919, with permission.)

Table 141-2 Scottish Intercollegiate Guidelines Network (SIGN) Grading System

Levels of Evidence

1++ High-quality meta-analyses, systematic reviews of RCTs, or RCTs with a very low risk of bias
1+ Well-conducted meta-analyses, systematic reviews of RCTs, or RCTs with a very low risk of bias
1– Meta-analyses, systematic reviews of RCTs, or RCTs with a high risk of bias
2++ High-quality systematic reviews of case-control or cohort studies
High-quality case-control or cohort studies with a very low risk of confounding, bias, or chance and a high probability that the relationship is causal
2+ Well conducted case-control or cohort studies with a low risk of confounding, bias, or chance and a moderate probability that the relationship is causal
2– Case-control or cohort studies with a high risk of confounding, bias, or chance and a significant probability that the relationship is not causal
3 Nonanalytic studies (e.g., case reports, case series)
4 Expert opinion

Grades of Recommendation

A At least one meta-analysis, systematic review, or RCT rated as 1++ and directly applicable to the target population; *or*
A systematic review of RCTs or a body of evidence consisting principally of studies rated as 1+, directly applicable to the target population, and demonstrating overall consistency of results
B A body of evidence including studies rated as 2++, directly applicable to the target population, and demonstrating overall consistency of results; *or*
Extrapolated evidence from studies rated as 1++ or 1+
C A body of evidence including studies rated as 2+, directly applicable to the target population, and demonstrating overall consistency of results; *or*
Extrapolated evidence from studies rated as 2++
D Evidence level 3 or 4; *or*
Extrapolated evidence from studies rated as 2–

RCTs, Randomized controlled trials.
For critical appraisal of studies, see http://www.sign.ac.uk/guidelines/fulltext/50/annexoldb.html.

functioning), sleep hygiene, bedtime routines, and a faded bedtime with response cost procedure, was also included in an RCT of children aged 6 to 12 years (two thirds of the sample were healthy controls without ADHD and one third of the sample had ADHD). Unpublished results of this RCT indicate that children with ADHD responded as favorably as the control subjects did.[46] There is also another ongoing RCT[47] studying treatment of sleep problems in children with ADHD using two face-to-face consultations and one follow-up phone call. Preliminary results of this study[48] indicate that intervention was feasible and resulted in improved sleep, at least as rated by parents.

Because of the lack of research in this area, it is necessary to rely on expert consensus recommendations regarding treatment,[37] which include using behavioral therapies demonstrated to be effective in children without ADHD,[49] and to modify these for children with ADHD. For example, in promoting positive bedtime routines, children with ADHD may require more warnings before being called to bed so that they know that bedtime is coming. In addition, the routine should be structured to allow sufficient time to complete each activity (e.g., getting ready with school bag, brushing teeth) but not so much time that the child has opportunities to become distracted. It is critical that the instructions are given by parents one step at a time. Further, the bedtime routine should be posted where it can be easily seen by the child.[33]

Recommendation by the expert consensus group[37]

Behavioral interventions, adapted for ADHD children, should be the first line of treatment.

Level of evidence: Pending the full publication of two ongoing RCTs.[46,48]

Circadian Rhythm Sleep-Wake Disorder

Although estimates of prevalence of this disorder in individuals with ADHD based on formal criteria are lacking, evidence from studies on melatonin patterns, both in children[50] and in adults,[51] suggests that individuals with ADHD may present with delayed sleep phase. (For a detailed discussion of delayed sleep phase syndrome, see Chapter 40.)

One case report in a child[52] and one open-label trial[53] in adults with ADHD showed the effectiveness of phototherapy. Melatonin represents an alternative treatment approach. The expert consensus[37] recommended administration of melatonin (3 to 5 mg) 2 hours before the estimated dim light melatonin onset or 4 hours before the average sleep-onset time. Two RCTs,[54,55] a follow-up study of one of them,[54] and an open-label study[56] have shown that evening melatonin is an effective treatment of sleep-onset insomnia, possibly related to delayed sleep phase syndrome, among children with ADHD.

Recommendation by the expert consensus group[37]

Options for sleep-onset insomnia within the framework of delayed sleep phase syndrome include bright light therapy, chronotherapy, and melatonin.

Level of evidence for bright light therapy and chronotherapy: E (evidence level: E, case reports[52,57]); *for melatonin:* B (extrapolated evidence from two RCTs rated as 1++ or 1+[54,55]).

Restless Legs Syndrome/Periodic Limb Movement Disorder

According to a review conducted in 2005,[58] about 44% of subjects with ADHD have been found to have RLS or RLS symptoms, and up to 26% of subjects with RLS have been reported to have ADHD or ADHD symptoms. However, these figures need to be considered with caution because of methodologic issues in the included studies, such as the lack of ADHD diagnosis or possible recruitment bias of subjects in specialized clinics for sleep. More recent and likely less biased studies suggest that the prevalence of RLS in individuals with ADHD is approximately 10% to 20%.[59,60]

As detailed in Chapter 95, the management of RLS/periodic limb movement disorder (PLMD) includes nonpharmacologic as well as pharmacologic strategies for moderate to severe cases. Nonpharmacologic strategies include establishing healthy sleep habits, physical exercise, and avoiding exacerbating factors, such as irregular sleep schedule, low body iron stores, pain, caffeine, nicotine, alcohol, and certain medications (e.g., selective serotonin reuptake inhibitors).[61] A case series and a case report support the effectiveness of dopaminergic agents (L-dopa, pergolide, or ropinirole) for RLS in children with ADHD.[62,63] Finally, another recent case series suggests that levetiracetam may be an option for ADHD children with RLS and interictal epileptic discharges. No data on the long-term effectiveness and tolerability of these agent in children are available.

Although there is no formal consensus on the treatment of iron deficiency, thought to be involved in the pathophysiologic mechanism of RLS, some experts have recommended oral iron supplementation with low iron stores, 50 to 65 mg of elemental iron once or twice a day, and suggested rechecking of serum ferritin levels in 2 to 3 months.[61]

Recommendation by the expert consensus group[37]

Establish healthy sleep habits, avoid factors exacerbating RLS (e.g., pain, caffeine, nicotine, alcohol); oral iron supplementation if iron deficiency is found. For severe cases: consider use of L-dopa or other dopaminergic agents (off label on children).

Level of recommendation for the treatment of RLS/PLMD in children with ADHD (for dopaminergic agents): C/D (one RCT with risk of bias, plus case reports).

Sleep-Related Breathing Disorders

Some studies suggest that the prevalence of sleep-related breathing disorders (SRBDs) in children with a diagnosis of ADHD is at least 18% to 32%[64,65] and may be as high as 50% to 65%.[66-69] However, some authors do not agree with these high figures.[70-72] This discrepancy is mainly related to definitions of SRBD in children (for a detailed discussion, see[73]). The majority of children with ADHD appear to have mild rather than severe forms of SRBD (i.e., AHI >1 and <5).[73] Thus, it has been suggested that severe SRBD and its associated daytime manifestation, such as sleepiness, may mask the hyperactivity.[73] In addition, symptoms of SRBD, such as snoring, are also common in children with ADHD or ADHD-like behaviors. Between 20% and 66% of children with a diagnosis of ADHD or symptoms of ADHD have been reported to habitually snore,[59,74,75] with the

ADHD-hyperactive/impulsive being the most common presentation.[76]

We located three studies that investigated SRBD treatment in a group of children diagnosed with ADHD according to formal criteria (DSM-IV).[69,77,78] Weber et al[78] assessed children with a clinical history of obstructive ventilator disorders (because many children did not complete polysomnography); they found that after adenotonsillectomy, there were reductions in reported attention deficit (87.5% to 33.3%), hyperactivity (75% to 50%), and impulsivity (50% to 33%) for 8- to 10-year-olds. However, because of small sample sizes, these reductions were not statistically significant. In a prospective controlled trial that aimed to assess hyperactivity and inattention before and 1 year after adenotonsillectomy,[77] 28% of children had ADHD at baseline, but half of the children no longer met criteria for an ADHD diagnosis at 1 year after surgery. In another prospective, nonrandomized, open trial,[69] in children with ADHD (DSM-IV criteria) and mild SRBD (i.e., AHI >1 and <5), treatment groups included (1) methylphenidate, (2) adenotonsillectomy, and (3) no treatment. At 6-month follow-up, ADHD symptoms had improved in both intervention groups compared with the no-treatment controls. In addition, the adenotonsillectomy group demonstrated significantly greater improvement than the medication group in the hyperactivity and inattention scales as well as in the total score of the ADHD rating scale. In summary, data from these studies suggest that treatment of SRBD improves ADHD symptoms.

Recommendation by the expert consensus group[37]

All children undergoing evaluation for ADHD should be screened for symptoms of SRBD, particularly snoring; if findings are positive, polysomnography should be performed. An AHI > 1 on polysomnography and the presence of large tonsils/small airway on examination should alert the practitioner to consider adenotonsillectomy as a treatment intervention.

Level of evidence for the treatment of sleep disordered breathing according to the SIGN system: B/C (one RCT rated as 2++[77] and open-label study rated as 2+[69]).

EFFECTS OF ADHD MEDICATIONS ON SLEEP

Subjective and objective studies of the effect of stimulants on sleep have produced mixed results.[79] Whereas polysomnographically determined lengthened total sleep time, increased sleep stage shifts, increased number of REM periods, elevated indexes of REM activity and REM period fragmentation, and parent-reported longer latencies to sleep onset or higher rates of insomnia in ADHD children treated with stimulants versus controls have been reported in some studies, others did not confirm these findings. It is challenging to combine the results of these studies because of different stimulant formulations, dose, and dose scheduling. Moreover, some of the studies compared children with ADHD receiving medication with nonmedicated healthy controls. Therefore, it is unclear whether the sleep disturbances resulted from the children's having ADHD or from their being treated with methylphenidate. However, clinical experience suggests that stimulants may negatively affect sleep. The vulnerability to these negative effects is likely to be related to individual factors. As correctly pointed out by Brown and McMullen,[80] whereas some patients with ADHD are able to get to sleep easily within just a few hours of taking a dose of stimulant, others need an interval of 6 to 8 hours.

As for atomoxetine, in a randomized, double-blind, crossover study comparing the effect of methylphenidate (given thrice daily) and atomoxetine (given twice daily) on the sleep of children with ADHD, Sangal et al[79] found that methylphenidate increased both polysomnographic and actigraphic sleep-onset latency significantly more than did atomoxetine. Moreover, both child diaries and parent reports indicated a better quality of sleep with atomoxetine compared with methylphenidate. Both medications decreased nighttime awakenings, but the decrease was greater for methylphenidate.

Implementation of healthy sleep habits is recommended as a first option even if the sleep complaints are thought to be medication related; in one RCT,[55] sleep hygiene was effective in a subsample of children with ADHD treated with stimulants. If, after several weeks (during which the negative effect of medication may also spontaneously decrease), sleep hygiene is not effective, possible further options are reducing the total dose, changing the dose regimen or formulation so that less medication is administered later in the day, changing to a different stimulant (e.g., switching to methylphenidate from amphetamine or vice versa), changing to a nonstimulant (e.g., atomoxetine), adding an alpha$_2$-agonist, and adding another medication (e.g., melatonin or sedative-hypnotics as "last resort" option). An RCT[81] showed that adding melatonin (3 to 6 mg) can significantly decrease sleep-onset delay in ADHD children treated with methylphenidate (1 mg/kg).

Recommendation by the expert consensus group[37]

- Promoting healthy sleep habits
- If sleep difficulties persist: try alternative dosages, formulations, or ADHD medications or add a sleep-promoting medication (e.g., melatonin).

Level of evidence for melatonin: B (one RCT rated as1+[81]); *for other approaches:* D (expert consensus).

CLINICAL PEARLS

- The key to the management of sleep problems in ADHD is an appropriate differential diagnosis. Healthy sleep practices are the foundation of management strategies.
- Behavioral interventions should be the first-line treatment of insomnia. If behavioral strategies are not effective, melatonin should be considered for sleep-onset difficulties. Bright light therapy, chronotherapy, and melatonin are options for circadian rhythm disorders.
- Adenotonsillectomy should be considered if the AHI is > 1 and there is evidence of enlarged tonsils/small airway on examination.
- Off-label dopaminergic agents should be considered only for severe cases of RLS/PLMD.
- Options for sleep disturbances induced by ADHD medications include alternative dosages, dose regimen, formulations, or ADHD medications and adding a sleep-promoting medication (e.g., melatonin).

SUMMARY

Although long overlooked, sleep disturbances are highly relevant in the clinical management of individuals with ADHD.

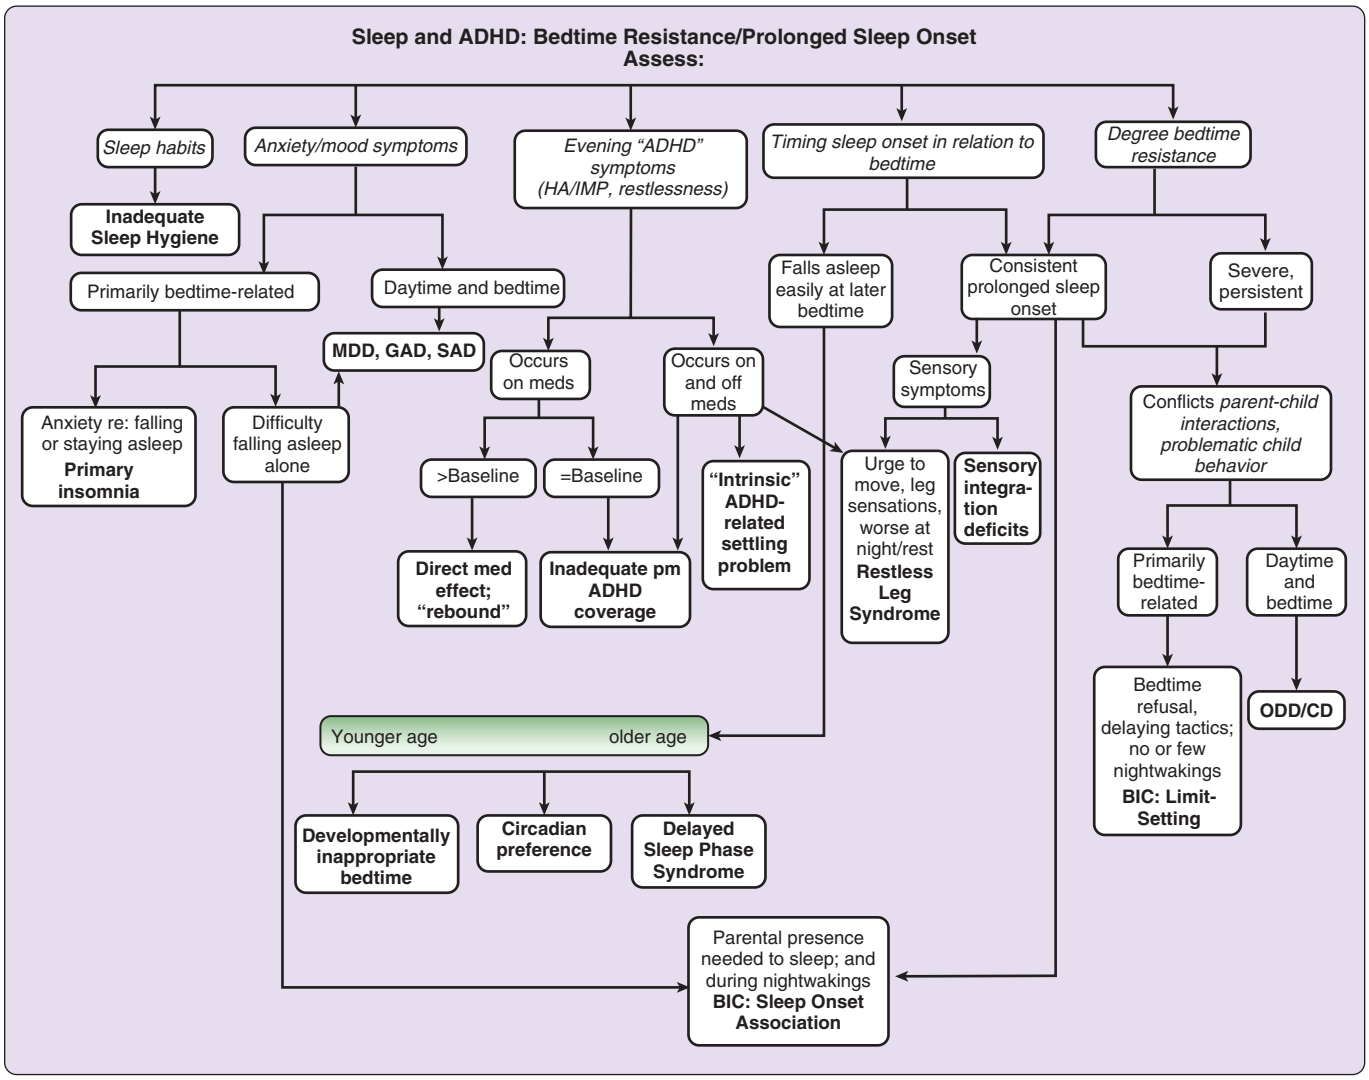

Figure 141-4 Diagnostic algorithm for the management of sleep-onset difficulties/bedtime resistance in children with ADHD. HA/IMP, Hyperactivity/impulsivity; MDD, major depressive disorder; GAD, generalized anxiety disorder; SAD, social anxiety disorder; ODD/CD, oppositional defiant disorder/conduct disorder; BIC, behavioral insomnia of childhood. (Reproduced with permission from Owens JA. A clinical overview of sleep and attention-deficit/hyperactivity disorder in children and adolescents. *J Can Acad Child Adolesc Psychiatry* 2009;18:92–102.)

The relationship between ADHD and altered sleep/arousal mechanisms is also relevant from a research standpoint because it might lead to further insights into the pathophysiologic process of both sleep and attentional processes. Brain regions possibly involved in mediating both conditions include cortical (e.g., dorsolateral prefrontal) and subcortical (e.g., locus coeruleus) structures. The most common conditions affecting sleep quality or quantity in ADHD include behavior insomnia, circadian rhythm sleep-wake disorder, delayed sleep phase type, sleep-related disordered breathing, RLS/PLMD, and sleep disturbances due to ADHD medications. Sleep hygiene therapy is recommended as the first step in management. Behavioral therapies should be considered as first-line treatment of behavioral insomnia, although further evidence from RCTs is needed to prove their efficacy in individuals with ADHD. Among pharmacologic options, RCTs support the use of melatonin to reduce sleep-onset delay, whereas there is more limited evidence for other medications. Figure 141-4 summarizes the algorithm for the management of bedtime resistance/prolonged sleep onset in children with ADHD.

18 Dentistry and Otolaryngology in Sleep Medicine

Chapter
142 Role of Dentistry and Otolaryngology in Sleep Medicine

Gilles Lavigne; Michael Simmons; Nelly Huynh; Fernanda R. Almeida; Olivier M. Vanderveken

Chapter Highlights

- This new section of this volume links medicine and dentistry experts' knowledge on dealing with sleep disorders.
- Reviewed in separate chapters of this section are methods to improve upper airway function during sleep by addressing underlying skeletal imbalances by orthodontic treatment in children, by surgery in adults, and by oral appliance therapy with the treatment goal of reducing upper airway collapsibility.
- Additional chapters address tooth grinding/sleep bruxism, alone or in presence of orofacial pain, with indications for and limitations of oral appliances and surgical interventions in managing sleep-disordered breathing.
- Finally, this section addresses reducing poor outcomes related to use of medications for oral or intravenous sedation or general anesthesia in patients undiagnosed but at potential risk for sleep-disordered breathing.
- Interdisciplinary collaboration is an important goal in the efforts to improve sleep behavior, with an overall impact on patient health and well-being. Correction of facial growth disturbances may be an adjunctive treatment option that may be used depending on the unique presentation of each patient.
- A better understanding of patient phenotypes requires a collaboration of multiple disciplines to improved treatment outcomes in the future.

The addition of a section on ear-nose-throat (ENT) and oral-dental aspects of sleep medicine—a major component of the evolving field of "integrated sleep medicine"—to *Principles and Practice of Sleep Medicine* has been a long-time goal of one of the editors, Dr. Meir Kryger, which is realized in this sixth edition of the book. Dr. Kryger has been a strong advocate of interdisciplinary collaborations in managing patients with sleep disorders and their associated comorbidities.

In the past several decades, sleep medicine has been dominated by the presence of respiratory medicine, neurology, and psychology. With recognition of the high prevalence of sleep disorders and the technological innovations currently available for the management of sleep-disordered breathing (SDB), however, rapid and strong growth of sleep medicine as a subspecialty of both medicine and dental science is under way.

SLEEP SOCIETIES: HISTORICAL PERSPECTIVE ON INTEGRATED SLEEP MEDICINE

All over the world, sleep medicine has become organized and integrated into several health disciplines, merging knowledge and nurturing exchanges between basic science, medicine, dentistry, pharmacology, nutrition, psychology, nursing, social health, health economics, and others.

International Societies

For more than 25 years, the World Sleep Federation (WSF) and later the World Association of Sleep Medicine (WASM) have been dedicated to improving dialogue within the sleep community, promoting innovation in research and technologies, elevating the standard of care, and optimizing access to evidence-based diagnostic and management paradigms. Interdisciplinary meetings are held by these associations and their allied societies. The WSF and the WASM have organized more than six world meetings since they were founded (in 1988 and 2003, respectively).

Continental and National Societies

In North America, the American Academy of Sleep Medicine was created in 1975 (already 40 years ago!), in its precursor state as the Association of Sleep Disorders Centers. The American Academy of Sleep Medicine is the main body for the following journals: *Sleep, Journal of Clinical Sleep Medicine,* and the most recent addition from the American Academy of Dental Sleep Medicine, *Journal of Dental Sleep Medicine.* By 2013 the American Academy of Sleep Medicine had approximately 10,000 members, of whom approximately 5% were dentists. Many special-interest groups developed along the way in neurology, ENT, and respiratory medicine and in dental sleep medicine. Reflecting the importance of sleep medicine, many physicians also hold subspecialty certification in sleep medicine from the American Board of Otolaryngology and the American Board of Psychiatry and Neurology. Creation of the WASM was driven mainly by neurologists and neuroscientists, but this body is now enlarging its scope, facing the needs of integrated expertise in sleep medicine; this is reflected in the content of its journal, *Sleep Medicine.*

The American Academy of Dental Sleep Medicine evolved from the Sleep Disorders Dental Society, originating in 1991 with its first meeting of 25 members in 1992, expanding to more than 3000 members in 2013. This body provides a bridge for sleep clinicians and researchers in the fields of dentistry, otolaryngology, surgery, and respiratory and behavioral sleep medicine. In Canada, the Canadian Sleep Society has a dental medicine chapter, with members also attending the Sleep Disorders Dental Society meetings.

The European Sleep Research Society (ESRS) was created from a symposium held in Würzburg, 1971, on "Die Natur des Schlafes"("The Nature of Sleep"). In 2015, the ESRS held a joint meeting with the European Respiratory Society in Barcelona, Spain, and the ESRS and the WSF will co-host the Seventh World Congress of the World Sleep Federation in Istanbul, Turkey. The ESRS is the main body editing the *Journal of Sleep Medicine*. The European Academy of Dental Sleep Medicine (EADSM), formerly known as the European Dental Sleep Medicine Academy and officially founded in 2006, aims at being a European platform for dental sleep medicine. In 2015, the EADSM organized its sixth conference in Antwerp, Belgium. In addition, many European countries such as Germany, United Kingdom, France, The Netherlands, Belgium, Spain, Portugal, Italy, and Sweden, among others, have their own national dental sleep medicine societies.

The Federal Latin American Sleep Societies, founded in 1984, also has grown, and delegates from Argentina, Bolivia, Brazil, Chile, Colombia, Ecuador, Mexico, Peru, and Uruguay have been actively involved to organize and disseminate sleep medicine in their countries. In Brazil, the Brazilian Sleep Association, founded in 1985, has held biannual meetings since 1993, and today has approximately 1000 members. It recently has helped with and endorsed the creation of the Brazilian Dental Sleep Association, which sponsored approximately 40 certified dentists in dental sleep medicine.

Other sleep societies such as the Asian Sleep Society and the Australian Sleep Society include regular activities in dental sleep medicine in their annual programs. The position of dentistry in sleep medicine is well illustrated by the fact the journal *Sleep and Breathing,* an interdisciplinary sleep journal (as most are these days), is the official journal of the Australasian Academy of Dental Sleep Medicine (AustADSM), the British Society of Dental Sleep Medicine (BSDSM), the European Academy of Dental Sleep Medicine (EADSM), the Japanese Academy of Dental Sleep Medicine (JADSM), and the Korean Academy of Dental Sleep Medicine (KADSM).

Recently, the Indian Association of Surgeons for Sleep Apnoea was created to bring together specialists from various fields such as ENT surgeons, pulmonologists, oral-maxillofacial surgeons, anesthesiologists, and radiologists. Such trends seem now irreversible and illustrate the need of integrated sleep medicine in the world.

INTEGRATION OF HEALTH DISCIPLINES IN SLEEP MEDICINE AND RESEARCH

Nowadays, it is not surprising to observe that more and more otorhinolaryngologists (also called ENT specialists), anesthesiologists and surgeons, and dentists and orthodontists are collaborating with pulmonologists, neurologists, and psychologists to manage various sleep disorders and concomitant health conditions. Improvement in oropharyngeal airway patency during sleep in children and adults can be achieved by orthodontic and surgical jaw corrections (see Chapters 143 and 149)[1]. Use of general anesthesia done in patients presenting with several concomitant medical conditions is a

challenge, and risks need to be assessed if obesity and sleep apnea are present (see Chapter 148). In addition, with recognition of breathing dysfunction in children with a small lower jaw or mandible (retrognathic cases), deep palate, or large tonsils or adenoids, careful evaluation is warranted, with use ofspecific precautions for anesthesia.

Sleep bruxism, characterized by tooth grinding and repetitive jaw muscle activity, and comorbid temporomandibular dysfunction have been in the domain of dentistry for many years but became integrated into dental sleep medicine in the past two to three decades (see Chapters 144 and 145). The putative interrelationship and/or the role of risk factors of "wake-time" breathing disorders, neurologic conditions, insomnia, and pain cannot be overlooked. A single health care discipline cannot manage complex complaints or persistent sleep disorders in the presence of these comorbid conditions. Sleep bruxism can be concomitant with sleep apnea (association possible in a subgroup of patients/phenotypes to be identified; low evidence for cause-and-effect link), headache, and temporomandibular dysfunction, REM behavior disorder, epilepsy, and other disorders.

It is obvious that the informed physician and dentist have to collaborate in increasing numbers for several reasons: (1) to identify causal and contributory disorders more efficiently in a wider range of the population of patients with undiagnosed problems, (2) to understand the role of comorbid conditions that can contribute to the development of chronicity of poor sleep, (3) predict and explain why a given subject is likely to be a poor responder to specific therapeutic interventions, and (4) to select the most suitable management approaches in accordance with individual patient characteristics including economic status. Furthermore, recent advances in complementary and alternative medicine have to be integrated into sleep medicine because patients are frequent users, as illustrated in Chapter 150.

ENTs, oral-maxillofacial surgeons, and orthodontists are key specialists in achieving functional upper airway maximal patency to achieve the best results in patients with pathologic conditions or atypical growth of the nose, oropharyngeal, and jaw bone structures. It also is obvious that dental specialists in sleep medicine and orofacial pain are key health practitioners in managing simple and idiopathic sleep bruxism, alone or with comorbid temporomandibular dysfunction and/or headaches. Dentistry's role is important in the detection of concomitant sleep disorders and referral for diagnosis when insomnia, SDB, or concomitant neurologic conditions are suspected. Dentists, orthodontists, and oral-maxillofacial surgeons with sufficient training and experience in the subspecialty of sleep disorders are key players in SDB management with oral appliances, orthodontic correction, or telegnathic maxillofacial surgery.

FUTURE DIRECTIONS: EDUCATION AND COLLABORATION

The interface between sleep medicine and dentistry is currently promoted by the international Oral Appliance Network on Global Effectiveness research group, created to evaluate the long-term effectiveness of oral appliance therapy in patients with obstructive sleep apnea and to assess long-term health outcomes of oral appliance therapy related to cardiovascular disease.[2] This is a truly multidisciplinary team, with respiratory and sleep medicine physicians working alongside dentists and researchers.

To achieve more efficient early detection of SDB or sleep-wake disorders, training of the current and next generations of family physicians, family dentists, nurses, psychologists, physical therapists, health educators, and school teachers is critical.[3] The health and well-being of the patient population can be markedly improved by increasing awareness at an earlier age, early prevention, and overall public education in the importance of sleep. In fact, teachers spend more time with children during their wake periods than their parents; dentists are the health care providers who see more than 70% of persons of all ages at least once a year; and primary care providers often have the family history on file to address issues such as childhood obesity, lack of exercise, and other factors potentially affecting patient health in adulthood. To meet the major public health challenge of "better sleep = better health," the role of first-line health professionals and educators should be encouraged in early detection of sleep disorders and access to simple prevention measures (e.g., diet recommendations, sleep hygiene, oropharyngeal exercise) at an early age to prevent growth and development abnormalities triggering sleep disorders later in life.

Oropharyngeal Growth and Skeletal Malformations

Chapter 143

Stacey Dagmar Quo; Benjamin T. Pliska; Nelly Huynh

Chapter Highlights

- Sleep-disordered breathing (SDB) is marked by varying degrees of collapsibility of the pharyngeal airway. The hard tissue boundaries of the airway dictate the size and therefore the responsiveness of the muscles that form this part of the upper airway. Thus, the airway is shaped not only by the performance of the pharyngeal muscles to stimulation but also by the surrounding skeletal framework.
- The upper and lower jaws are key components of the craniofacial skeleton and the determinants of the anterior wall of the upper airway. The morphology of the jaws can be negatively altered by dysfunction of the upper airway during growth and development. In turn, the altered morphology of the jaws can be positively influenced by orthodontic treatment.
- The association between altered dentofacial morphology and SDB has been well documented in children, adults, and patients with craniofacial syndromes. Whether this disease of childhood has the same origins as adult obstructive sleep apnea but more subtle manifestations has not been determined. The length and volume of the airway increase until the age of 20 years, at which time there is a variable period of stability, followed by a slow decrease in airway size after the fifth decade of life. The possibility of addressing the early forms of this disease with the notions of intervention and prevention can change the landscape of care.
- Correction of specific skeletal anatomic deficiencies can improve or eliminate SDB symptoms in both children and adults. It is possible that the clinician may adapt or modify the growth expression, although the extent of this impact is uncertain. These strategies seek to alter an abnormal facial growth pattern wherein SDB worsens over time. Future research should focus on determining in which individuals dentofacial morphology makes a significant contribution to the pathogenesis of SDB. This may bring clinicians one step closer to targeting specific treatments that more effectively treat the disorder.

This chapter is directed to provide an integrated vision to both the scientist and clinician dealing with growth and development of the oropharyngeal structures. It is divided into three sections. The first reviews the fundamentals of growth of the craniofacial complex and the development of the upper airway. The second section outlines those characteristics based on current definitions of the sleep-disordered breathing (SDB) syndrome, that is, there is a broad range of anthropomorphic characteristics and OSA severity that needs to be better delineated. The last section reviews management and treatment strategies based on what is known about craniofacial development and anatomy. This chapter is a primer to other chapters in this section and to the ones in Section 14.

CRANIOFACIAL GROWTH AND DEVELOPMENT

Early theories of craniofacial development were based on the belief that growth of the face and jaws was essentially immutable because of intrinsic regulation by inherited genetic traits. Research centered on finding the location or sites where these traits were expressed that drove normal form and function of the other surrounding structures. During the early twentieth century, it was believed that differential deposition and resorption on the surface of bones were largely responsible for growth of the craniofacial skeleton. This remodeling theory then gave way to one heralding the role of the sutures, which held that similar to the epiphyses of the long bones, it was the connective tissue and cartilaginous joints of the craniofacial skeleton that produced expansive proliferative growth forcing the bones and soft tissues away from each other.[1] Exemplifying this theory was the concept that the mandible was much like a horseshoe-shaped long bone, with the condylar cartilage acting like open-ended epiphyseal plates, pushing the mandible down and away from the rest of the head.

Several inconsistencies in the hypothesis that sutures alone could be the determinants of craniofacial growth surfaced. Sutural growth was more similar to periosteal apposition of bone than previously understood, and sutures acted as reactive sites of bone growth rather than growth centers. Scott, in 1953, proposed the nasal septum theory of growth, which held as its main tenet that the anterior and inferior growth of the nasal septal cartilage was the determining, driving force of facial growth.[2] Whereas Scott's theory contributed to the understanding that growth at the sutures and surface

remodeling were essentially reactive sites of bone growth, it was still founded in the paradigm that craniofacial development and morphogenesis were genetically predetermined and unalterable.[1] In modern perspective, the nasal septal cartilage is considered an important growth center; however, the mechanism behind this growth has been appropriately updated as described here.

A fundamental shift in the field of craniofacial biology emerged with Moss' introduction of the functional matrix hypothesis in 1960.[3] Whereas all previous theories deemed craniofacial growth to be predetermined by genetic traits, the functional paradigm introduced the idea of plasticity of development and growth of the craniofacial skeleton.[1] According to this theory, the role of our genes was to initiate the process by setting the initial context under which development could occur; beyond that, it was the extrinsic environmental and functional demands of the various craniofacial components that determined all future aspects of growth. This theory revolutionized the field by introducing two important concepts. First, it brought the possibility of growth modification as a treatment option for malocclusions or facial malformations by changing the direction of facial development to a more desired outcome. Second and perhaps more important, the plasticity of development opened a new area of research, focusing on the critical time and specific factors that lead to the maladaptive plasticity of the form and function of the craniofacial complex.[4]

With the emergence of developmental molecular biology, the genetic and external or epigenetic regulation of craniofacial growth is now better understood, and the modern synthesis is that both genomic and epigenetic factors are necessary contributors to craniofacial development.[5,6] Several genes and gene products regulate the morphogenesis and intrauterine development of the craniofacial complex. There is an extremely complex interaction between these genetic factors and epigenetic influences. The plasticity of early development depends not only on the effects of certain environmental conditions on the underlying genetic code but also on previous environmental conditions that may have directly upregulated or downregulated specific genetic regulatory factors and indirectly further influenced the response.

Prenatal Craniofacial Growth

The earliest form of the face appears in the fourth week of life with the enlargement and movement of the frontonasal prominence as well as the paired maxillary and mandibular prominences stemming from the first branchial arch. These five prominences emerge to encircle the stomodeum, or primitive mouth. A critical aspect of this process is the migration of cranial neural crest cells into the developing facial prominences. Unlike in the rest of the body, these neural crest cells develop into the majority of the craniofacial hard tissues, including the bone, cartilage, and teeth of the craniofacial complex.[7] The specific end tissue into which these cranial neural crest cells develop is determined largely by the family of Homeobox or HOX genes. The variable expression of HOX transcription factors causes the groups of cranial neural crest cells in the distinct prominences to respond differently to the same growth factors.[8]

After rapid growth of the two mandibular prominences, there is midline fusion in the fifth week of development.[9] Initial mandibular development is dependent on tightly controlled molecular signaling between the oral ectoderm and the underlying core of cranial neural crest.[7] Further development is contingent on the formation and growth of Meckel cartilage, the first skeletal element of the mandible. The subsequent elongation of this rod of cartilage leads to promotion of outgrowth of the mandible, and the primary ossification of the mandible occurs as intramembranous bone formation along this cartilaginous core.[10] As the bony mandible further develops, Meckel cartilage largely disappears, eventually to persist only as small portions of the incus and malleus of the middle ear. In addition to the mandible, the mandibular processes also form the lower lip and the lower areas of the cheeks.

The lateral and medial nasal processes originate as ectodermal thickenings on the surface of the frontonasal process early in the fifth week of embryonic life. Subsequent broadening of the head and medial growth of the maxillary processes result in medial displacement of the early nasal processes. As the two medial nasal processes merge at the midline, the philtrum and columella of the nose are formed. Deeper aspects of the medial nasal processes will differentiate to form the nasal septum, which is a key growth center of the midface postnatally. Fusion of the medial nasal process with the maxillary process leads to formation of the majority of the upper lip, the zygomas, and the maxilla bilaterally. The lateral nasal processes go on to form the sides and alae of the nose as the subsequent 2 weeks sees the formation of the future nostrils and nasal cavity with the development of the primary and secondary palates.[11] Secondary palate formation relies on the coordinated growth and movement of the primordia of the tongue and both lower and upper jaws. During the sixth week of development, paired lateral palatal shelves arise as medial projections from each maxillary process. Critically, at this time, there is rapid anterior growth of the early mandible by proliferation of Meckel cartilage, which displaces the tongue forward, lowering it relative to the palatal shelves.[12] Once the tongue has descended, during the seventh week, the palatal shelves rotate from a vertical to a horizontal position directed toward the midline. Further growth of the shelves sees them fuse at the midline as well as with the primary palate anteriorly and the nasal septum superiorly.[13]

By the ninth week of fetal development, the initial cartilaginous facial skeleton is well established, composed of the chondrocranium forming the skull base, the nasal capsule in the upper face, and the Meckel cartilage in the lower face. Within the twelfth week of fetal growth, areas of ossification begin to appear and bone begins to rapidly replace this cartilaginous template to form the early cranial base. At this same time, the bones of the cranial vault as well as the mandible and maxilla develop through intramembranous ossification.

Postnatal Craniofacial Growth

The general pattern of postnatal development is the cephalocaudal gradient of growth, in which there is an axis of increased growth that extends away from the head. Structures away from the brain tend to grow more and later than those structures closer to the brain. Mandibular growth begins later and continues longer than does the growth of the midface.[14] This pattern of growth continues until maturity and is exemplified in the proportionality of head size to total body length. At birth, the head makes up almost a quarter of the total body length, which decreases to around

12% in the adult. Facial growth can be summarized as being driven forward initially by growth of the cranial base, then the maxilla and mandible both grow back and up to fill in the space created as they are being pulled down and forward away from the cranial base by the soft tissues in which they are embedded.

During infancy and early childhood, the cranial base increases in length through endochondral ossification that occurs at important growth sites called synchondroses. The synchondroses push the growth of the face forward until around the age of 7 years, when they begin to become less active and later ossify and fuse. Much of the forward movement of the maxilla is due to the growth of the cranial base pushing it downward and forward from behind. Further forward displacement of the maxilla results from bone apposition at the sutures located posteriorly and superiorly that connect it to the cranial base. Unlike the forward displacement generated by the synchondroses, the bone formation at these sutures is instead responsive in nature to the downward and forward pull of the maxilla from the growth of the associated soft tissues and nasal septum. Much of the increase in size of both the nasal and oral cavities occurs from surface remodeling of the maxilla and not from sutural growth. As the maxilla is translated downward and forward, the periosteum acts to remove bone at the floor of the nose, while at the same time bone is formed on the roof of the mouth. Over time, this results in a hollowing out and widening of the nasal cavity.[15] In addition, the palatal vault deepens with age despite the bone apposition on its surface because of the increased growth of the alveolar process that accompanies tooth eruption. Transverse growth in maxillary width results from growth at the midpalatal suture and appositional remodeling along the lateral aspects of the posterior region of the maxilla and the maxillary tuberosity.[16] This bone deposition at the tuberosity allows sagittal lengthening of the maxilla. The midpalatal suture begins to fuse in early adolescence but stays amenable to orthopedic force required for maxillary expansion treatment until around the age of 14 years in most individuals.

Lacking open sutures necessary for suture apposition of bone, the mandible instead grows by endochondral ossification at the condyle as well as by a combination of extensive surface bone remodeling. Unlike an epiphyseal plate or synchondroses, the growth of the condyle is responsive to translation of the mandible rather than driving it.[17] Transverse increases in the body of the mandible occur through surface apposition and remodeling of bone. The dentoalveolar structures develop with the eruption of the teeth, which continue to erupt throughout life to maintain occlusal contact, matching the vertical growth of the ramus.

First described nearly a century ago,[18] the hard and soft tissues undergo different rates of growth throughout childhood development. This is evident in the upper airway of children and has important implications for obstructive sleep disorders. Because of the significance of suckling to the newborn infant, the epiglottis is located close to the soft palate, which facilitates separation of the pathways for respiration and deglutition.[19] Neonates are born as obligate or preferential nasal breathers, but this changes as the upper airway matures. Between the ages of 1 and 2 years, vertical growth allows the larynx to descend to the level of the fifth cervical vertebra, and the epiglottis descends, which accommodates the newly acquired function of speech for the child.[20] The hyoid bone descends to a lower position in the neck, and the posterior third of the tongue descends to form the anterior wall of the oropharynx. Due mainly to hypertrophy of the adenoids and tonsils that frequently can exceed the growth of surrounding skeletal structures, adenoid and tonsillar tissue is found to be largest relative to the surrounding anatomy between the ages of 4 and 6 years.[21-23] This not coincidentally is the same age range at which OSA is most frequently seen in children. The upper airway volume then increases in adolescence because of both the concurrent increase in vertical skeletal growth and involution of the lymphoid tissue, which decreases in size after 12 years of age.[22,24] During the adolescent years, the upper airway also becomes larger in the transverse dimension and more elliptical.[24] The length and volume of the airway increase until the age of 20 years, at which time there is a variable period of stability, followed by a slow decrease in airway size after the fifth decade of life.[25]

DENTOFACIAL MORPHOLOGY ASSOCIATED WITH SLEEP DISORDERED BREATHING

Dentofacial morphology in children and in adults has been assessed by lateral and anterior-posterior cephalography, dental casts of the upper and lower teeth, digital photography, and three-dimensional magnetic resonance imaging (Table 143-1).[26] Cephalography is limited by landmark identification, measurement variability, and two-dimensional assessment of a three-dimensional anatomy. In children, only a few studies assess three-dimensional dentofacial measures.[27,28] However, all these imaging methods are performed while the patient is either awake or sedated, which does not reflect upper airway volume and soft tissue sleep-related changes. Whereas dentofacial morphology is an important component to the multidisciplinary assessment and management of SDB, there is no single cephalometric measurement that can effectively predict OSA severity,[29] as outlined in Table 143-1.

Children

In children, although adenotonsillar hypertrophy and obesity often contribute to SDB, dentofacial morphology can further contribute to the narrowing of the upper airway. Behavioral or functional oral breathing in SDB is associated with altered craniofacial growth,[30] altered muscle recruitment in the nasal and oral cavities,[31] and change in posture.[32] These ideas will be further explored in this chapter, in the section on treatment strategies. For children between 6 and 8 years, dentofacial morphology is a stronger risk factor for SDB than obesity is.[33] Cephalometric studies suggest that a long and narrow face, transverse deficiency, and retrognathia are craniofacial morphologic factors associated with a narrow upper airway and SDB in children,[34-37] which are also particular to oral breathing.[38]

Studies measuring differences in position between the maxilla and mandible (ANB: A point, nasion, B point) show an increased ANB angle in children with OSA or with primary snoring compared with controls.[36,39-43] In the primary snorers, this was associated with a decreased SNB angle (sella, nasion, B point),[36,42,43] which is a measure of retrognathia. In children with OSA, a decreased SNB angle and lower hyoid bone position and mandibular volume[28] were observed with three-dimensional imaging.

Table 143-1 Craniofacial Morphology Associated with Obstructive Sleep Apnea

	Adults	Children
Long and narrow face		Marino 2009,[34] Pirila-Parkkinen 2009,[35] Pirila-Parkkinen 2010,[36] Tsuda 2011[37]

Retrusive maxilla	Paoli 2001,[59] Guilleminault 1984,[60] Lowe 1995,[61] Lowe 1986,[62] Lyberg 1989,[64] Miles 1996,[65] Johal 2007,[69] Ishiguro 2009,[70] Chi 2011,[26] Iked 2001,[66] Sforza 2000,[67] Tangugsorn 2000,[68] Banhiran 2013,[71] Gungor 2013[72]	
Palatal morphology, increased length and thickness of soft palate	Lyberg 1989,[64] Johal 2007,[69] Kurt 2011[77]	

An increased mandibular plane angle and increased lower anterior facial height are associated with OSA.* However, a meta-analysis showed significant heterogeneity across selected studies,† suggesting insufficient evidence of a strong association. Retrognathia creates a posterior displacement of the tongue base, which further narrows the upper airway and is associated with a high-arched (ogival) palate due to tongue position.[41,49] Although a narrow maxilla is associated with OSA and snoring, only a few studies have reported this from dental impressions of hard and soft tissues[35,40,43,44] as this cannot be measured from lateral cephalograms. Moreover, orthodontic correction of a narrow maxilla (rapid maxillary expansion) has been reported to reduce respiratory indexes.[50-52] These earlier studies suggesting an association between morphology and sleep apnea do not fully explain causality of dentofacial morphology in the pathophysiologic process of SDB.

In children with OSA, it was suggested that 50% also have sleep bruxism, a concomitant sleep movement disorder[53] that can affect their dentofacial health, although no causal relationship has been established. Parents report tooth grinding twice more often in children who are habitual snorers than in non-snorers[54] and more often in younger children than in older ones.[54] Up to 60% of children with sleep bruxism but without sleep apnea have a retrusive mandible; 28% have short faces (brachyfacial type).[55] Adenotonsillectomy reduced sleep bruxism muscle activity in 75% of OSA children as reported by questionnaires.[56] A temporary maxillary occlusal splint of 3 mm in thickness was worn 3 months by children (aged 6 to 8 years) with a history of sleep bruxism, oral breathing, and snoring.[57] As reported by questionnaires, tooth-grinding noises were decreased in 89% of patients, whereas snoring was reduced in 55.5% of patients.[57] This could be explained by potentially restoring nasal breathing during sleep as all

*References 27, 30, 35, 36, 39-41, 44-48.
†References 27, 35, 36, 39-41, 43-45.

participants adapted from oral breathing to nasal breathing after treatment.[57] The associations between SDB and sleep bruxism in children need further investigation and objective data. A full description of sleep bruxism is found in Chapters 147 and 150.

Adults

In adults, obesity is the main anatomic risk factor for SDB. Like children, dentofacial morphology can also contribute to a compromised upper airway, and this is more often observed in nonobese patients with OSA.[58,59]

Overall, studies have reported a retrusive mandible, macroglossia, lowered hyoid bone position, and retrusive maxilla to be associated with OSA[26,59-72] and snoring.[73] A lower hyoid bone position is suggested to be a proxy of tongue shape, posture, and tone, which could increase upper airway collapsibility.[26,74] Magnetic resonance imaging studies in Asian and white populations observed a shorter and smaller mandible in patients with sleep apnea than in controls.[26,69,75] This was significant in men with sleep apnea[26,75] and not reported in women.[26] Mandibular morphology seems to be a stronger risk factor than maxillary morphology for OSA in adults.[26] Taking into account the genetic influence on dentofacial morphology, comparison of a cohort of siblings with and without sleep apnea found a short mandible and a lower hyoid bone position to be the most important risk factors for sleep apnea.[76]

Palatal morphology and increased length and thickness of the soft palate are also risk factors for OSA[63,64,69,77] and for snoring.[77] In addition, patients with sleep apnea are reported to have longer soft palates than snorers.[73] In comparing lateral cephalograms and dental casts of OSA adults with those of controls, an increased palatal depth was seen as measured at the first and second premolars and molars,[78] although this was not a consistent finding.[79] By anteroposterior cephalometric measurements, patients with OSA had narrower maxillas.[80]

Craniofacial Syndromes

Multiple craniofacial syndromes can have a higher incidence of SDB because of modified craniofacial morphology or hypertrophy of soft tissues. Outlined in Table 143-2, among the mandibular hypoplasia syndromes are Pierre Robin, Prader-Willi, Treacher Collins, and Marfan. Moreover, some syndromes can be associated with neuromuscular disorders, which can further negatively affect breathing during sleep. In children with craniofacial syndromes and SDB, the causes of obstruction or restriction of the upper airway can be at multiple levels, requiring multidisciplinary management and multiple treatments.[81-85]

SDB is often associated in children with midface hypoplasia; 50% of nonsyndromic and syndromic craniosynostosis children,[86] such as children with Apert, Crouzon, and Pfeiffer syndromes, develop SDB.[82,87,88] SDB improves during the first 3 years of life in the absence of midface hypoplasia.[89] However, this is not observed in children with syndromic craniosynostosis and midface hypoplasia (Apert or Crouzon/Pfeiffer).[89] Midface advancement surgery was successful in the short term with improved respiratory outcomes in 55% but was ineffective in 45% of children.[82] In this latter group, endoscopy and volume measurements showed obstruction of the hypopharynx.[82] After adenotonsillectomy, 60% of children with syndromic craniosynostosis had less desaturation events (Sao_2 4%).[81] Achondroplasia, an autosomal dominant congenital disorder, is also characterized by midface hypoplasia, leading to increased risks for development of SDB. Approximately 35% of patients with achondroplasia have SDB,[90] associated with increased lower facial height and retrognathia.[91]

Table 143-2 Syndromic and Craniofacial Morphology Associated with Obstructive Sleep Apnea

- **Maxillary hypoplasia or midface hypoplasia**
  such as syndromic craniosynostosis (Apert, Crouzon, Pfeiffer), achondroplasia, trisomy 21, and cleft palate
- **Mandibular hypoplasia**
  such as Pierre Robin, Prader-Willi, Treacher Collins, and Marfan
- **Mandibular hypoplasia or micrognathia**
  such as Pierre-Robin, Smith-Lemli-Opitz syndrome, and trisomy 21
- **Orofacial hypotonia**
  such as Smith-Lemli-Opitz syndrome and trisomy 21
- **Cleft lip and palate**
  such as Pierre Robin
- **Maxillary and mandibular hypoplasia**
  such as Turner syndrome
- **Neuromuscular disorders**
  such as Duchenne muscular dystrophy, myopathies, Guillain-Barré syndrome, and myasthenia gravis

In addition to midface hypoplasia, patients with trisomy 21 also have micrognathia and orofacial hypotonia, which predisposes them to SDB[92] in 50% of pediatric and adult cases.[83,93-95] Although suggested as the first-line treatment, adenotonsillectomy resolves SDB in only 27% to 34% of cases.[96,97] Other alternative treatments are positive airway pressure therapy, mandibular distraction osteogenesis, midface advancement, and oral appliances. Oral appliances with tongue-stimulating knobs have been shown to improve orofacial muscle function.[83,84,98-103]

Cleft lip and palate children showing midface hypoplasia have a significantly higher incidence of SDB (22% to 37.5%)[85,104] than do healthy children (5%).[105] Furthermore, 34% of syndromic children with cleft lip and palate reported symptoms, whereas 17% of nonsyndromic children with cleft lip and palate did.[85] Following various surgical interventions (e.g., adenotonsillectomy, flap takedown, tonsillectomy, and partial adenoidectomy), only 38.5% of patients had improved SDB.[85]

Syndromes characterized by micrognathia and orofacial hypotonia, such as Smith-Lemli-Opitz syndrome, or by smaller maxilla and mandible, such as Turner syndrome, can also have increased incidence of SDB.[106,107]

Pierre Robin sequence is characterized by a triad of craniofacial anomalies consisting of micrognathia, cleft palate, and glossoptosis leading to respiratory and feeding issues. Most infants with Pierre Robin sequence (85%) also have sleep breathing disorders.[108] Nonsurgical management of Pierre Robin sequence in infants includes positional therapy, placement of nasopharyngeal airway, and oral appliances with velar extension. Positional therapy is successful in 49% to 52% of cases.[109,110] Oral appliances with velar extension were reported in one study to effectively reduce OSA at hospital

discharge and 3 months later, in the absence of any adverse events.[111] Surgical management includes tongue-lip adhesion or glossopexy, subperiosteal release of the floor of the mouth, mandibular distraction osteogenesis, and tracheotomy. Mandibular distraction osteogenesis is reported to have better outcome measures than tongue-lip adhesion in regard to oxygen saturation, apnea-hypopnea index (AHI), and number of postprocedure tracheostomies.[112] However, both surgeries had comparable complications.[112]

TREATMENT STRATEGIES

Management and treatment acknowledge that SDB has a cumulative positive feedback loop in which repetitive respiratory-related arousals cause changes to the properties of the upper airway, and this causes end-stage sequelae that exacerbate the initial stimulus.[113] This section focuses on the treatment strategies for the pediatric patient. For more information on adult SDB treatment, refer to Section 14 of this volume.

The indication for treatment underlies what is pathologic and what is normal. What constitutes disease that necessitates treatment? Recent evidence shows that simple snoring carries consequences of cognitive impairments, suggesting that benign primary snoring should be treated as a disease. The incidence of snoring is much higher than the incidence of OSA,[114] and snoring is now recognized as an abnormality in children.[115] If snoring is the start of the cascade of abnormal breathing, early treatment may be correlated to improved outcomes. Even with early intervention, the recurrence of SDB has been documented in studies of pediatric patients observed through adolescence.[116,117] So, whereas the timing of treatment is relevant, early detection and treatment of SDB children are only part of the solution because there can be a familial inheritance of both symptoms and anatomic risk factors.[118-120] Consequently, asymptomatic children with at-risk morphologic characteristics and a familial history of SDB should be monitored for further evaluation.

There is not a linear relationship of symptoms to severity of the disease, and similarly, if there is a disproportion in anatomic structures, it may not necessarily correlate with the symptoms or the severity of the disease.[121] A study that observed SDB children 4 years after treatment showed that despite the improvement in respiratory parameters, complaints of daytime sleepiness persisted in the treated and untreated SDB group compared with asymptomatic, non-SDB controls. For the health care practitioner treating children, there are screening measures to decide if a child needs further care. Again, see Section 14 of this volume for more information on SDB and OSA diagnosis and management. These factors can be distilled down to the presence of daytime or nighttime symptoms, the orofacial anatomy, and the familial history of SDB (Box 143-1). The treatments for pediatric SDB are multiple and listed in Box 143-2.[122,123] The intent of early treatment is to halt the continued cycle of worsening OSA and also to prevent early systemic complications. The consequences of neurocognitive deficits and cardiovascular changes are evident in children,[124,125] similar to the systemic changes seen in adults. It is possible that OSA in an adult could have begun in childhood or adolescence.[126] However, there are no long-term outcome studies that demonstrate the progression of these changes from childhood into adulthood, nor is there any evidence that these effects seen in children are severity dependent or evolve into the adult presentation with end-organ morbidity.

Increase in airway size (nasopharynx, oropharynx, hypopharynx)
Improvement in muscle response
Craniofacial growth modification

There are three general treatment strategies for SDB. The problem of collapsibility affecting airflow exchange in SDB can be primarily related to inadequate airway size creating airflow resistance, and the first line of treatment is directed at enlarging the airway. Magnetic resonance imaging studies of OSA children show a smaller upper airway cross-sectional area.[127] However, children with normal oropharyngeal anatomy may suffer from OSA,[128] and the AHI has not been shown to directly correlate with airway volume.[121] First-line treatment approaches to increasing space in the nasopharynx, oropharynx, and hypopharynx are reviewed. SDB may also encompass a component of muscle alteration that may be a primary (etiologic) or secondary effect.[113] The second component of therapy addresses the muscle remodeling and myopathy that may be associated with SDB. The third strategy incorporates the challenge to complete care, and that raises the question of whether a cure or complete resolution of the disease is possible by changing the underlying facial growth pattern and modified anatomy to eliminate this as an etiologic factor in the disease. This paradigm for care is summarized in Box 143-3.

Strategy 1: Increase in Airway Size

Location–Nasopharynx

Although the area of greatest collapsibility is the soft tissue of the oropharynx, the properties along the entire upper airway will affect this collapsibility. Each part of the pharynx (i.e., nasopharynx, oropharynx, hypopharynx) serves different

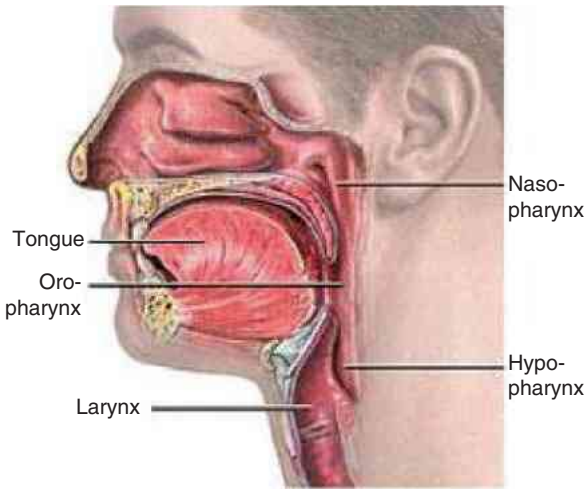

Figure 143-1 The pharynx, where airway collapsibility occurs, is divided into three sections: nasopharynx, oropharynx, and hypopharynx.

functional roles, and so treatments to increase airway size are reviewed according to site in the pharynx (Figure 143-1).

The entrance to the airway at the initial site of airflow is the nasopharynx. The treatments to increase the size of the nasopharynx (Box 143-4) address either removal of obstructions inside the nose or enlargement of the space itself. The nasal influences on snoring and SDB are widely known because nasal obstruction can cause sleep disturbances that affect daytime performance.[129] The degree of nasal obstruction does not correlate with the severity of OSA,[130] probably because the extent of nasal resistance does not correlate with the amount of nasal airflow.[131] This is evident in patients with choanal atresia who have nasal obstruction as a clinical feature. In this population, it was reported that 65% are diagnosed with OSA[132] versus the entire patient group. Systematic review of the relationship between nasal obstruction and OSA shows that nasal obstruction plays a modulating role in OSA but is not a direct causative factor.[133] Whereas the relationship between nasal obstruction and SDB is not linear, it is thought either to be linked to an increase in nasal resistance initiating unstable oral breathing or to result from impaired nasal reflexes that hinder continued ventilation.[134] Increased nasal resistance depresses the critical closing pressure of the pharyngeal muscle walls, rendering the airway more collapsible. The critical closing pressure is correlated with the severity of SDB.[121] Pharyngeal compliance is impaired in a cycle in which SDB can both result from and be worsened by nasal obstruction.[135]

Reduction of Inflammation and Medication Management. SDB is more prevalent in patients with allergic diseases.[136] Allergic rhinitis hinders nasal respiration by increasing nasal resistance and is considered a risk factor for SDB.[137] Allergic rhinitis is one of the major causes of impaired nasal function, and it affects up to 40% of the general population in developed countries, with an increasing prevalence. Although the evidence generally supports a connection between SDB and allergic rhinitis, this connection is not definitive, and the mechanism linking these two diseases and the mechanism of how nasal inflammation causes SDB are unclear.[138] However, nasal resistance measured by anterior rhinometry is increased in children with OSA compared with control subjects.[139] Larger population studies[140] and several smaller studies demonstrated an improvement in SDB by treatment of allergic rhinitis through medication management.[141] Nasal corticosteroids in children with moderate sleep OSA was effective in improving symptoms but not in eliminating the disorder,[140] thus suggesting the role of inflammation in the disease.[142] The cause and effect link is not yet fully understood or explained between allergic rhinitis and SDB. This topic is explored in more detail in Chapter 119.

Orthodontic Expansion. As early as the 1860s, the midpalatal suture was separated within 2 weeks,[145] using an orthodontic screw-type expander device to widen the transverse dimension of the upper jaw either to correct a transverse deficiency or to create space for the permanent teeth. Early studies of maxillary expansion show that both dentoalveolar and craniofacial structural changes were created.[146,147] The amount, location, and rate of force application to the facial skeleton from expansion appliances create localized changes in the bony housing surrounding the teeth, with a potential effect at the sutural level of the maxilla.[148,149] Rapid maxillary expansion (RME) which refers to a rate of expansion of at least 0.25 mm/day, was described in the medical literature dating back to 1975[150] as a therapy for medical ailments and referenced in the dental literature for medical problems since 1974.[151] This early work described maxillary expansion to treat problems such as enuresis, nasal congestion, and asthma. These symptoms also describe the OSA syndrome, although the syndrome was not coined until 1976.[152]

In 1980, surgical widening of the maxilla to increase the lateral dimension of the nasopharynx was first described as a treatment for adult OSA. Nonsurgical rapid palatal expansion was first suggested as a therapy for OSA in 1998.[143] Pirelli et al[144] published seminal work in 2004 using rapid maxillary expansion (RME) to successfully treat OSA syndrome in children with narrow maxillas. Several other groups have corroborated this work, and now other published studies also describe the effectiveness of maxillary expansion in treating children with or without narrow palates, with or without retrognathic mandibles. These studies are outlined in Table 143-3, and the general appliance design is depicted in Figure 143-2. In the maxilla, the applied force from the expansion appliance creates midpalatal (also called median palatal or palatal) suture separation. This results in distraction osteogenesis across the palate, resulting in an increase in width of the maxilla (Figure 143-3).[147] Both oral and nasal volume is increased as the triangular nasal fossa is enlarged by widening of the nasal floor and outward movement of the lateral nasal walls.[153] The volumetric increase evident in the nasal fossa but not posteriorly in the nasopharynx[154] has an effect on nasal airflow, but this is not a proportional relation.

Several studies show that maxillary expansion reduces nasal resistance.[153,155-157] In a systematic review of all expansion studies across several different databases, there were

eight controlled studies with 6-month follow-up after therapy that measured changes in airway dimensions and functions after RME. These studies support a moderate level of evidence that RME therapy in a growing child causes increases in nasal cavity width and in the posterior nasal airway, associated with reduced nasal resistance and increased total nasal flow.[158,159] The stability of the results can be expected for at least 11 months after the orthopedic therapy.[160] In one study, nasal airflow measured by rhinomanometry improved in the supine position in 65% of the patients.[161] Changes in nasal geometry of increases in intranasal width[153,162,163] and increases in both nasal cross-sectional area and nasal volume[153,164] were noted. Airway properties were examined, showing decreases in nasal resistance measured by rhinomanometry[153] and acoustic rhinometry,[164] along with changes in head position and decreases in the craniocervical angle.[161,165,166] RME therapy through sutural opening creates an increase in the nasal cavity width, area, and volume in children, which allows a reduction in nasal resistance.

The studies in Table 143-3 support maxillary expansion as a treatment modality for pediatric OSA syndrome. The majority of children responded to expansion therapy, and OSA was eliminated in a few children.[144,167] Most of the expansion studies looked at children with narrow upper jaws (selection criteria for treatment) and malocclusions, including crossbites, dental crowding, and mandibular retrusion. Expansion as a first-line therapy was initiated in a few of the studies. Mandibular retrusion was not specifically a factor in selection of patients, although it was noted in more than half of the patients studied. Two of the studies used bimaxillary expansion.[117,167] Bimaxillary expansion was employed because of the dental compensation in both the maxilla and mandible from a narrowed maxilla. The dentition is tipped inward toward the tongue, which creates a narrowed intraoral space. Dental expansion of the lower dentition aids in achieving maximum skeletal expansion of the upper jaw. The effectiveness of bimaxillary expansion as a treatment option for pediatric SDB was first described a decade ago.[168] The overall expansion data of all studies are varied, but mostly with a general improvement in both sleep parameters and subjective symptoms of SDB.

The therapeutic effects of maxillary expansion include increasing space for dental crowding,[169] increasing airway dimensions, and decreasing nasal resistance[153,155,156] in addition to treating SDB (Table 143-3). These studies also demonstrate a greater gain when RME treatment is rendered before the pubertal growth spurt peak, demonstrating an age-related phenomenon to long-term success. In the studies outlined in Table 143-3, expansion was started as early as age 3 years up to age 15 years. Whereas nonsurgical expansion of the palate is still possible beyond the age of 15 years, because of increased interdigitation of the suture in an older child, the widening that occurs is more often dental tipping that increases the intraoral volume and not true skeletal expansion

that increases the intranasal space. Greater changes in nasal width were evidenced when expansion was done early in maturation versus late in maturation.[162] By the age of 4 years, the craniofacial skeleton has reached 60% of its adult size; by the age of 7 years, 75% total craniofacial growth is complete, and by the age of 12 years, 90% total craniofacial growth is reached.[170] This suggests that RME therapy should be considered as an early-stage treatment in pediatric SDB, as the intervention timing seems critical for predicting RME orthopedics outcomes.

Maxillary expansion is a common noninvasive orthodontic treatment that is well tolerated by children. Advantages as therapy for SDB include little or no risk of morbidity or discomfort, with treatment performed in an outpatient setting during a 4- to 6-month period. There is a high level of acceptance for initiating this type of therapy, especially because many children with SDB also have concomitant dental crowding. However, some type of holding or retaining appliance is needed to maintain the expanded arch form, and so there is long-term ongoing care. If early expansion is advocated, a holding appliance may be in place for many years, and the timing is dependent on the eruption status of the dentition and the ability to sustain nasal respiration.

The reported risks of RME therapy include bite opening, relapse, microtrauma of the temporomandibular joint and the midpalatal suture, gingival recession, and root resorption.[158,160] Whereas these effects are not usually encountered, the incidence is also age dependent, seen more with maturation. There are no current guidelines for selection of patients, other than the studies that treated children with narrow palates and dental crossbites, in which teeth of the upper arch do not horizontally overlap teeth of the lower arch. Future work will help identity which types of patients will benefit most, how much expansion can be gained, and at what age to start expansion.[171] An example of the shape changes and the amount of space that can be gained is shown in Figure 143-4.

Whereas the expansion results for SDB are promising, these studies were not controlled or randomized and were limited to only a few groups that reported data. Few new therapies of pediatric SDB have been validated with randomized controlled trials.[251] Current pediatric guidelines recommend referring children with maxillary transverse narrowing for orthodontic therapy and possible RME treatment for persistent OSA syndrome after adenotonsillectomy.[122] Orthodontic expansion therapy has three potential effects for the SDB child. It can widen the intranasal volume to reduce nasal resistance, which improves airway collapsibility and SDB; it can facilitate other SDB treatment, such as positive pressure therapy, by allowing improved nasal airflow; and it can facilitate the transition from oral to nasal respiration, which can have a secondary effect on oropharyngeal growth. Because maxillary expansion is so well tolerated by children, it is expected that in the coming years, larger scale trials will examine the efficacy of jaw expansion as one component of improving the properties of the developing airway in a child with SDB. The effect of RME on orofacial growth and facilitating nasal respiration is discussed in the next part of this chapter.

Figure 143-4 Example of the amount of expansion that can be created. Preexpansion model shows a width of 42 mm, measured from the central groove of the upper primary second molar, compared with postexpansion width of 52 mm.

Surgical Expansion: Removal of Soft Tissue. An alternative mode of increasing airway size is through the surgical removal of structures or obstructions. This is further described in Chapter 149, and for children, these procedures may include reduction of the inferior nasal turbinates, sinus surgery, or adenoidectomy. There is a nonlinear relationship between the level of nasal resistance and the severity of SDB. This may explain why the reported cure rate of adenotonsillectomy for OSA in meta-analyses of children with a mean age of 6.5 years was only 59.8%, showing that adenotonsillectomy as the first-line and most common therapy for pediatric OSA may be insufficient.[172]

Location–Oropharynx

The retropalatal area is represented here, which is often the site of greatest airway narrowing in children. SDB children have more fluctuation in airway size, with narrowing during inspiration that is more prominent in higher oropharyngeal levels.[127] Surgical adenotonsillectomy can enlarge this space, as shown in Box 143-5. Whereas maxillary expansion increases the intraoral space, imaging studies using cone beam computed tomography and lateral cephalography do not depict any changes at the oropharyngeal level with RME. OSA children have narrowed space at this level compared with controls, but after RME therapy, there was no evidence of increased oropharyngeal airway volume.[173,174] However, it has been postulated that the increased oral volume resulting from maxillary expansion induces a postural change in the tongue position.[175]

Surgical Expansion: Removal of Soft Tissue. Hypertrophy of the tonsils (pharyngeal and palatine) is the second major cause of respiratory obstruction in childhood, followed by allergic rhinitis, and is found to be associated with allergic rhinitis in many children, exacerbating the respiratory symptoms.[176] As described earlier in this chapter, tonsils generally initiate hypertrophy within the first 3 years of life, the period of highest immunologic activity during childhood. Because tonsil growth outpaces craniofacial growth from 3 to 7 years

of age, most symptoms are observed during this period, coinciding with the peak incidence of childhood OSA syndrome.[177] Tonsil atrophy starts after 10 years of age and is completed in adulthood.[178] The first-line therapy for pediatric SDB is adenotonsillectomy, which has been associated with a decline in the critical closing pressure of the muscles along the pharynx, rendering the upper airway less collapsible.[121] Surgical therapies are further described in Chapter 149.

Location–Hypopharynx

Hypopharyngeal airway obstruction can be caused by the prominence or relaxation of the base of the tongue, the lateral pharyngeal wall, and, occasionally, the aryepiglottic folds of the epiglottis. The treatments to increase the size of the hypopharynx are outlined in Box 143-6.

Oral Appliances. Several case report studies show the effectiveness of oral appliances that hold the lower jaw forward in treating SDB and OSA in children. The use of oral appliances in the treatment of adults is well established, and the specific mechanics of how these appliances work is further discussed in Chapter 147. Oral appliances that advance the jaw forward are similar to the functional appliances used in orthodontics that address problems of mandibular deficiency. In children, these appliances create changes in the dentition and the growth of the maxillomandibular complex, and these alterations are thoroughly described in the orthodontic literature. A 2007 Cochrane review[179] examined studies in children aged 15 years and younger using mandibular advancement appliances. It concluded that there was not sufficient evidence to support treatment of pediatric OSA syndrome using oral appliances. In the more than 200 studies, only one study was recognized for inclusion,[180] which examined children aged 4 to 10 years against a control group of no treatment, showing a reduction in respiratory parameters in the majority of the treatment group. It must be highlighted that oral appliances can affect the forward growth of the upper and lower jaw, which likely makes their use inappropriate unless the child presents with retrognathia. The long-term side effects of this growth on the pediatric developing airway warrant further examination.

Surgical Expansion: Skeletal Surgery. Orthognathic advancement surgery is not considered a treatment option for the pediatric patient until after jaw growth cessation. Because of the late-stage timing, other therapies would be enacted before orthognathic surgery is planned. Mandibular advancement surgery enlarges the hypopharyngeal space, whereas maxillary advancement surgery enlarges the oropharyngeal cavity. Bimaxillary or maxillomandibular advancement surgery creates expansion across the entire pharynx, primarily at the oropharynx and hypopharynx, with a secondary impact on the nasopharynx. Expansion/advancement surgery is described in Chapter 149.

Continuous Positive Airway Pressure. Nasal continuous positive airway pressure (CPAP) stents the pharyngeal airway open and prevents the muscular walls from collapsing. It is not a curative strategy as it does not increase the airway size or change the neuromotor properties of the surrounding musculature. Studies in children[181] demonstrate the efficacy of CPAP therapy in reducing or eliminating symptoms and improving respiration but also acknowledge the challenges of compliance with and adherence to routine use. Consequently, CPAP is used as a secondary measure when adenotonsillectomy, bimaxillary expansion, or pharmacologic management has not improved SDB or as a primary option for obese children or children with craniofacial syndromes. This form of therapy is further outlined in Chapter 115.

Strategy 2: Improvement in Muscle Response

If OSA is modeled as a disease of progressive muscle degeneration, one strategy for treatment would counter these resultant muscular changes that stem from pharyngeal muscle damage. The collapsible pharynx is a tube composed of paired muscles with no bony perimeter, mediating airflow from the nose in the upper airway to the lungs of the lower airway. With repetitive collapse in OSA, the sustained pressure in the collapsible pharynx can result in repetitive microtrauma to the pharyngeal muscles.[182,183] Over time, these insults can lessen muscular neural control of the upper airway muscles that regulate airway opening and collapse, the interplay of the airway dilating opening muscles against the airway contracting or closing muscles. The pharyngeal muscle activation can become altered such that the response to neurochemical (hypoxemia or hypercapnia), neuromechanical (respiratory effort), or sensory (afferent input) stimuli becomes diminished or absent.

The tongue muscle is one of the largest structures defining the oropharyngeal airway and bounds its anterior aspect with motor innervation by the hypoglossal nerve and sensory innervations by the lingual nerve and glossopharyngeal nerve. As the largest and most studied pharyngeal dilator muscle, it almost directly controls airway patency by its forward movement, enlarging the airway. It is composed of extrinsic muscles (genioglossus, hyoglossus, and styloglossus) that alter its position and intrinsic muscles that alter its shape, both of which can affect airway size and shape.

Although SDB is often an anatomic problem of small size, the tongue volume in children with OSA syndrome does not differ from that of controls.[184] Similarly, the other muscles that border the pharyngeal airway, such as the pterygoid muscles, pharyngeal constrictor muscles, and parapharyngeal fat pads, were similar in size in both normal and OSA syndrome–affected children. In children with OSA syndrome, there was no muscle thickening of the lateral pharyngeal wall as reported in adults, suggesting that the surrounding craniofacial structures create the deficient anatomic volume differences and not the muscular soft tissues. In contrast to OSA children, OSA adults show evidence of muscle remodeling in phenotype of muscle size or fiber type,[185] which affect the sensory properties and strength performance of the muscle system. So, whereas the size of the muscle tissue mass is not enlarged in children with OSA syndrome, it implies that repetitive activations to the muscle can create muscle enlargement and changes in muscle properties (i.e.,

length, force) and innervations (i.e., spindle, motoneuron) that then can become problematic in adults.[186] It is not known if the upper airway neural abnormality is related to muscle activation or muscle recruitment; much more work is need to understand such complex interactions and impact on breathing.

At sleep onset, pharyngeal muscle activity is reduced, and it becomes slightly atonic during rapid eye movement sleep (see Chapters 21 to 23 for more information on muscle physiology and breathing). During adolescence, the dilating upper airway reflexes show a gradual reduction of responsiveness, and so the collapsibility of the upper airway increases.[187] Some amount of airway reflex attenuation or blunting occurs with age. Normal children and adolescents show neuromuscular compensations of increasing genioglossus electromyographic (EMG) activity in response to increased resistive loading, indicating that these children and adolescents have active upper airway neuromuscular reflexes during sleep. OSA syndrome children and adults show higher EMG activity during wake than normal controls and lower EMG activity during sleep.[188,189] These daytime increases in EMG activation impart a resistance to collapse,[190] and these mechanisms have been described in obese non-OSA children[191] as a neural compensation. Snoring may or may not be present in children, but over time it creates vibratory stress as mediated in the upper airway and is hypothesized to induce change or injury to the affected pharyngeal muscles.

Because of this eventual blunted airway muscle reflex to motor and sensory stimuli, efforts have been targeted toward muscle rehabilitation, specifically to address deficiencies in muscle activation. It is thought that these changes in the upper airway muscles are reversible. Electrical neurostimulation as a form of muscle training activation on animals and human subjects was experimented to maintain pharyngeal airway patency during sleep. Stimulation was applied directly on the hypoglossal nerve[192] or the dilator muscles.[192-195] These studies show mixed results, but current investigations are ongoing.

Myofunctional Therapy

More recent work in muscle rehabilitation explores pharyngeal muscle exercise therapy to change muscle strength, posture, and responsiveness. These oropharyngeal exercises of myofunctional therapy (MFT, also called orofacial myofunctional therapy and orofacial myology) are intended to improve the neuromechanical performance of the pharyngeal dilators. History dates MFT to the field of speech pathology, with references to the orthodontic literature in 1906, recognizing the role of the facial musculature in the development of malocclusions. The term myofunctional therapy was coined in 1935.[196] MFT by definition is a tongue and lip muscle exercise therapy to treat malocclusions and other dental and speech disorders, usually as a result of an anterior tongue displacement pattern.[197] It has also been implemented as a cotherapy for orthodontic management of craniofacial growth along with the treatment of crossbites and anterior open bite malocclusions.[198,199] With a high level of evidence, a form of oral MFT has been used to treat dysphagia resulting from neuromuscular movement disorders or stroke patients.[200] The potential mechanisms implicated in the growth deceleration of OSA include dysphagia resulting from adenotonsillar hypertrophy.[201]

The tenets of MFT address muscle hypotonia and weakness by strengthening the nasal mode of respiration using resistance and range of motion exercises. Performance of these exercises during the day supposes that airway collapsibility during sleep will be reduced. As the pharyngeal muscles are involved in creating speech, swallowing and deglutition, and breathing, therapy will treat dysfunctions in abnormal drinking, chewing, and swallowing while correcting the resting posture of the lips, tongue, and jaw by repatterning of facial muscles.[202] This is thought to restore the altered sensory input and proprioception to the affected musculature. Swallowing as an upper airway reflex is impaired in OSA patients,[203] suggesting that targeted therapy for swallowing could improve upper airway motor tone, although the degree of swallowing impairment does not correlate with OSA severity.[204] Preliminary studies of muscle rehabilitation exercises combined with oral shields were effective in reducing reports of snoring in normal and overweight (but not obese) middle-aged individuals as measured on an analog scale in non-OSA adults.[205] OSA young adults in a small-scale trial using MFT for 2 months showed overall improvement in AHI, oxygen saturation, and strength of the perioral musculature. The small sample size of six patients warrants further investigation to strengthen these findings.[206]

Randomized and controlled studies using MFT in adults reinforce the efficacy of muscle exercises on decreasing airway collapsibility in the middle-aged population with moderate OSA. One study with almost daily didgeridoo instrument playing for 4 months' duration in combination with breathing training yielded improved results of AHI and SDB symptoms as measured by various scales.[207] Another investigation using a highly specified regimen of oropharyngeal exercises examined an overweight, middle-aged, and predominantly male cohort that underwent 3 months of upper airway muscle rehabilitation. Compared with controls, the treatment group showed improvements in all outcome variables of improved AHI severity, lowest oxygen saturation, and symptoms and thus laid the foundation for further exploration.[208]

The muscle remodeling phenomenon seen in adults has not been evidenced in children, but the tenets of muscle strengthening can be applied to pediatric SDB. A retrospective study of adolescent youth showed resolution of the breathing abnormalities seen during sleep, but only after MFT was supplemented to the treatment regimen. Prior adenotonsillectomy and orthodontic expansion were other treatments used to increase nasopharyngeal and oropharyngeal space; however, flow limitations and daytime symptoms of mild OSA persisted after these therapies.[123] A prospective study of MFT and twice-daily nasal lavage was instituted for a 2-month period for children older than 4 years with residual moderate to severe OSA after adenotonsillectomy. This randomized and controlled work showed considerable improvement in AHI severity in all 14 children using MFT.[209]

These studies provide evidence to identify MFT as a potential adjunctive treatment for SDB in adults and children. MFT yielded improvements in both respiratory parameters and symptoms of SDB. The aspect of inadequate muscle activation or recruitment is not completely managed with mechanical (CPAP), surgical, orthodontic, or medication therapy. MFT may address these problems of diminished pharyngeal muscle motor tone from neural motor and

sensory deficiencies in all parts of the pharynx, extending from the nasopharynx to the hypopharynx. Future work in this area will likely outline screening and treatment parameters and identify the most effective muscle rehabilitation techniques for managing SDB. Most patients who undergo MFT do not have imaging to demonstrate an abnormal swallow reflex or have EMG tests to show abnormal muscle activation, and so identification of selection criteria is ambiguous. Longer term studies can address questions of treatment timing, age, and severity appropriateness and lend more definition to the initiation, end point, and duration of MFT. (See also Chapter 150 for other approaches to improving SDB.)

Strategy 3: Craniofacial Growth Modification

Changing the Pattern of Respiration

Does oral breathing cause abnormal orofacial development, and if so, does this cascade of altered growth exacerbate SDB or predispose a growing child to SDB? A simple cause and effect relationship between upper airway respiratory function and dentofacial and skeletal morphology has not yet been determined, despite the myriad studies in the clinical specialties of otolaryngology, oral surgery, and orthodontics—all areas that are specific to treating the upper airway, the jaws, or the teeth. However, there are associations between OSA syndrome, craniofacial anatomy, facial growth, jaw size and shape, and malocclusions as outlined earlier in this chapter. The genesis of these relationships stems from the hypothesis that oral breathing from impaired nasorespiratory function can affect craniofacial growth. Although controversial, the relationship between nasal obstruction and facial growth has been demonstrated in animal experimental and human clinical trials.[210]

Because the nasal respiratory pattern is critical in the development of a normal upper airway, initial SDB treatment strategies in children are targeted to promote and to sustain nasal respiration. Removal of nasal obstructions can promote nasal respiration, during the day and night, but the relevance of establishing daytime nasal respiration in affecting nighttime upper airway properties is not known. If nasal obstruction is sufficiently severe, a transition to oral breathing may occur. Nasal breathing is the primary route of airflow, responsible for most inhaled ventilation during wake and sleep states. The transition from nasal to oronasal breathing at night increases with age.[211] Transitioning to primarily oral airflow can be detrimental because it can change the upper airway properties. Open mouth breathing during sleep can create lengthening of the pharynx and lowering of the hyoid bone,[212] which increases the upper airway resistance from increased collapsibility of the pharyngeal lumen and posterior retraction of the tongue. Upper airway resistance during sleep is significantly lower during nasal breathing than during oral breathing,[213-215] which may further compromise the airway and increase the effort of breathing if oral breathing is sustained during sleep.[135]

Oral breathing in children can also have a potentially dysmorphic effect on the developing orofacial complex. Based on the earlier described functional matrix theory of Moss, it is thought that nasal respiration provides continuous airflow through the nasal passage during breathing to induce a constant stimulus for the lateral growth of the maxilla and for lowering of the palatal vault. The position and shape of the bone are the result of air pressures through the nasal and oral cavities.[216] The second effect of oral breathing on the facial skeleton is mediated by changes in muscle recruitment patterns, which result in an altered soft tissue and skeletal morphology and posture.[217] Increased nasal resistance can yield a more collapsible airway, and it potentiates mouth breathing that can create the postural and thus muscular changes that lead to unfavorable jaw growth. So the oral breathing cycle is perpetuated once it is initiated. This suggests that one of the tenets of SDB therapy would be to change the respiratory pattern from oral breathing to a predominantly nasal breathing mode.

Before strategies to create oral breathing can be created, it is challenging to understand what oral breathing means. There is not a standard well-accepted test to define an oral breather. The controversy stems from the inability to quantify nasal versus oral respiration or if spontaneous transitions from oral to nasal breathing occur and the lack of long-term data with growth maturation. Reliable tests to assess continuous airflow through the nose and mouth are lacking, and often the assessments are made on clinical presentation and subjective perceptions of the patient. Tests that measure airflow and nasal resistance, such as anterior rhinometry, acoustic rhinometry, nasal peak flow, rhinomanometry, and pneumotachography, are not routinely used because the testing results do not consistently correlate with the patients' subjective complaints.[218,219] Oral breathing is thought of as an oral habit or as an adaptive response to a perturbation. Despite the associations to maxillomandibular growth, few studies explore how to cure oral breathing. The most common respiratory mode is a combination of simultaneous oral and nasal airflow.[220] During sleep, normal subjects without nasal disease or SDB are nasal breathers, with only 4% of total ventilation time spent breathing orally.[221] Neonates are born as obligate or preferential nasal breathers, but as outlined earlier in this chapter, this changes as the upper airway matures. Even patients with severe nasal obstruction from either allergies or soft tissue enlargement display some measure of nasal respiration.[222]

Given the multifactorial nature of the nasorespiratory pattern and function on the expression of SDB and facial growth, relief of nasal obstruction to create nasal respiration is only part of the solution. There are likely other multilevel variables that should also be addressed, such as the development of nasal breathing at the habitual level. Some children with adequate upper airways breathe through the mouth because of habit.[222] Nasal obstruction can be the stimulus for oral breathing, but removal of nasal obstruction to create nasal patency does not always induce a spontaneous change in the respiratory pattern.[223] Although RME therapy can enlarge the intranasal space and reduce nasal resistance, the oral respiratory mode does not automatically revert,[155] suggesting that a patterned mode of breathing develops.[224] Increased nasal airflow is not enough to achieve nasal breathing because other factors, such as nasal concha hyperplasia, nasal polyps, adenoidal hypertrophy, and septal deviation, are responsible for oral breathing.[225] Even after surgical removal of enlarged tonsils in children, changes in airway muscle tone were variable after surgery,[226] demonstrating a spontaneous but partial motor tone and posture improvement.

Oral breathing is associated with tonic changes in the orofacial musculature but also in head posture, where the head is extended and forward of the spine.[227] In this position, the

cervical musculature shows higher muscle activity, measured by electromyography, in at-rest oral breathers compared with nasal breathers, showing that there is cervical musculature recruitment.[228]

This modification of the muscle recruitment pattern when the mode of respiration changes from nasal to oral breathing was demonstrated in experimental animals.[217] Therapy exercises aimed at these cervical muscles can create reduced EMG activity as seen in nasal breathers.[228] So the postural mode can influence the respiratory mode as in habitual oral breathers,[229] and this affects muscle balance. This suggests that muscle exercise therapy treatment be incorporated to reinforce a habitual mouth-closed mode of breathing. MFT could target the orofacial and cervical musculature either to reverse the adapted muscle recruitment patterns or to strengthen tonicity to change the upper airway caliber. Use of MFT as adjunctive therapy to firmly establish the nasal mode of respiration is an area to be explored.

Passive Force Application

Shape Changes in the Upper Jaw. As described earlier in this chapter, the muscle pattern exerts a passive tension on the developing airway through the force mediated on the maxilla. Numerous studies have shown a relationship between nasal airway obstruction and aberrant facial growth. In monkeys, the nasally obstructed animals had longer faces and unusual dental malocclusions. In children, these same morphologic effects of impaired nasal respiration are evident, including narrowing of the maxilla, reduced development of the mandible, increased vertical growth of the lower face, dental crowding and malocclusion,[30,230] and altered head posture. A new posture compensates for the decrease in nasal airflow to allow respiration. However, these are not consistent phenomena in children with oral breathing tendencies.[231]

These changes are typified in Figure 143-5 and occur passively because there is no directly applied force or load. In response to chronic oral breathing, three distinct

Figure 143-5 A–F, Natural growth of the maxillomandibular complex in response to adenotonsillar hypertrophy and oral breathing. **A** and **B,** Taken at age 4.5 years. **C** and **D,** Taken at age 6 years. **E** and **F,** Taken at age 9 years. Note the gradual constriction of the upper jaw from the age of 4.5 to 9 years, while the lower jaw remains an intact shape.

developmental changes may be manifested. The upper jaw narrows, suggesting that the volume of the nasal cavity becomes smaller as the upper jaw continues to narrow. As nasal volume decreases, the nasal resistance increases, which can exacerbate upper airway collapsibility, causing a cycle of progressively worsening SDB. This induced distortion in morphogenesis could partly explain the pathogenesis of SDB. The second developmental change is seen in the dentition, as the teeth add a second layer of insult to this distortion by compensatory inward tipping in both the upper and lower jaws. This restricts the intraoral volume even more, which potentiates a postural and neuromuscular adaptation of the genioglossus muscle. It can be argued that aggressive efforts are needed to combat the inherent tendency for upper jaw narrowing in oral breathers, even after the obstacles to nasal airflow are removed, because of the muscle alterations. The subsequent effect on the mandible is the third level of passive distortion that intensifies the pharyngeal collapsibility as the hypopharynx narrows with the backward rotation of the mandible. This narrowing is specifically evident at the retroglossal area.

Shape Changes in the Lower Jaw. In a growing child, abnormal nasal resistance may affect the maxilla and the mandible.[232] During puberty, these deleterious changes can be magnified because of the growth velocity seen during teenage years. Deleterious effects of mouth breathing are the sensory stimulus that propagates abnormal tongue position and altered orofacial musculature tone. The muscle recruitment pattern is modified when nasal respiration changes to oral breathing.[217] Some of these growth responses can be exaggerated because of the concurrent effect of molar tooth eruption occurring at the same time.

In oral breathers, it has been reported that mandibular growth is redirected posteriorly. Oral breathing that develops from nasal obstruction has an effect on the largest pharyngeal dilator muscle that keeps the airway open, the genioglossus. In an open mouth posture, the genioglossus adopts a low-lying position in the floor of the mouth. The relationship of breathing to airway problems shows a lowered position of the hyoid bone in OSA syndrome patients. In this dorsocaudal position, EMG activation of the tongue on experimental animals shows a weaker protrusive force,[210,217,233,234] which suggests a possible mechanism for increased collapsibility as decreased genioglossus tension led to an increased muscle length in experimental animals.[233] The increased size of the genioglossus would narrow the pharyngeal airway, and this increases collapsibility. Genioglossal activity is increased with nasal compared with oral breathing, with supine versus sitting body position, and during inspiratory resistive loading,[235] probably because of an altered respiratory drive and reflex activation. This effect coupled with the potential edema from the negative airway pressure generated during sleep[236] exacerbates the disorder, exemplifying the necessity to treat the sequelae of the root cause. A cyclic pattern of distortion develops in which the lower jaw rotates backward because of mode of breathing. This changed positvion narrows the retroglossal airway, which could potentiate increased repetitive activation stimuli to keep the airway open, leading to an increase in pharyngeal muscle mass. Further muscle injury can result from snoring, vibration, or increased airway resistance.

The term adenoid facies has historically been used to describe the long, narrow, flat face of the individual with oral hypotonia and protruding teeth and lips that are widely separated at rest, often accompanied by an open bite malocclusion.[30] The original work on experimental animals by Harvold et al[210] demonstrated that there is a variable response to this insult of forced oral respiration. Oral breathing was not linked to a specific skeletal structure. Similarly, there is not a defined facial type or malocclusion that accompanies adenotonsillar hypertrophy in an oral breather. Several studies corroborate this conclusion because there is not a consistent relationship between nasal resistance and dentofacial morphology, as described earlier in this chapter. These differences are illustrated in Figure 143-6, which shows varied facial phenotypes with OSA. Medical intervention has not been shown to influence the pattern of facial growth in children with allergies. Surgical therapy to relieve nasal airway obstruction in children (whether adenoidectomy or turbinectomy) has not been shown to predictably affect ultimate facial form.[237]

The three cases illustrated in Figures 143-7 to 143-12 demonstrate the variable response of mandibular growth to impaired nasal respiration. All three patients had therapy for their malocclusion, but the problem of allergies and oral respiration persisted. The records shown were taken during a period of adolescent growth, illustrating a lack of forward upper jaw development. Whereas there is an inherited growth pattern that accounts for the familial tendency or inheritance in OSA, there can be different epigenetic expressions of craniofacial malformation overlaid on the inherent preexisting growth presentation.

Comparison of the general superimposition tracings, from three subjects, shows a general descent and slight rotation of the maxilla but variable responses of the mandible (Figures 143-8, 143-10, and 143-12). All three subjects had nasal obstruction that persisted after expansion treatment, and the disproportionate jaw growth was expressed during adolescence. The mandible showed posterior rotation (Figure 143-8) and straight vertical descent with no forward growth (Figure 143-12) or forward growth rotation, versus forward anterior mandibular growth rotation (Figure 143-10). The dentoalveolar development from tooth eruption can affect the forward (Figure 143-10) or backward rotation (Figures 143-8 and 143-12) of the mandible, and this important effect cannot be discounted. These are three different expressions of mandibular growth, from the same stimulus of increased airway resistance from nasal obstruction causing differences in muscle recruitment patterns that changed muscle tone and function. This created variable adaptations of soft tissue, which influence the skeletal morphology. Thus, the oral breather may present with a normal appearance to severe skeletal and dental irregularities. "Nasal obstruction presents the trigger factor, but it is the deviant muscle recruitment which causes maldevelopment."[210]

These cases illustrate the answer to the question about disease propagation if craniofacial malformation is not only a cause of SDB but a consequence of SDB. It is a variable response, depending on how the effect of impaired nasal respiration affects the muscle recruitment and activation. For some patients, this paradigm of propagation would hold true. The challenge is to identify those patients who are more at

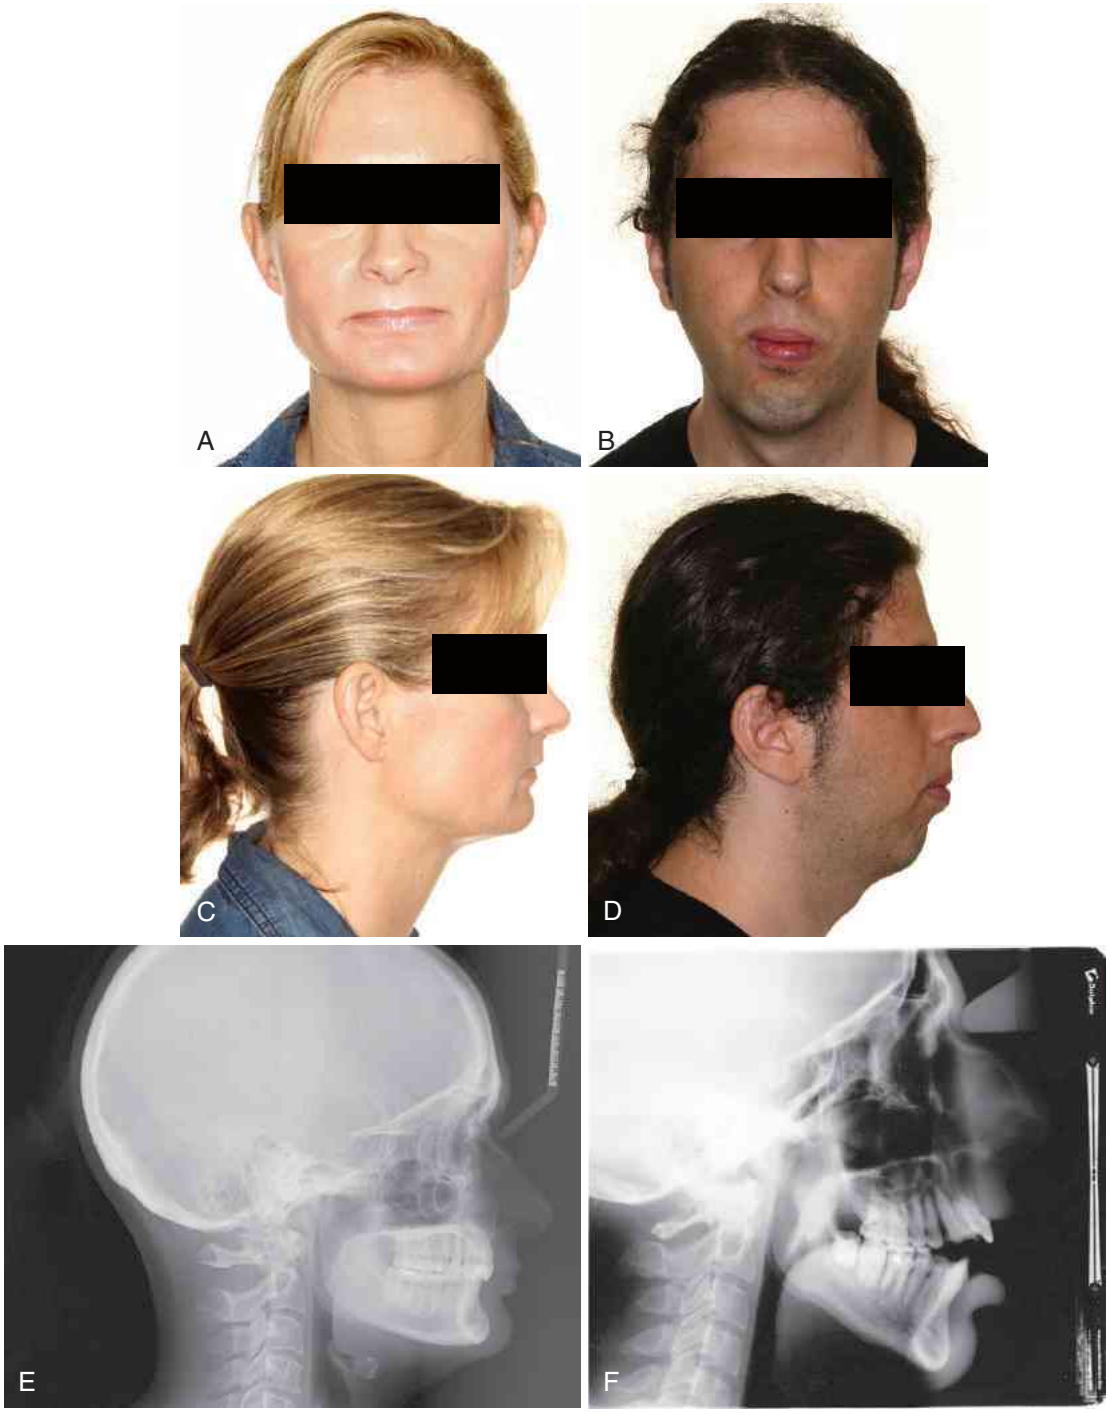

Figure 143-6 Contrasting facial morphologies associated with OSA. **A, C,** and **E** Decreased lower facial height of an individual with a closed gonial angle and bimaxillary retrusion. **B, D,** and **F** Increased lower facial height of an individual with bimaxillary dental protrusion and an open gonial angle.

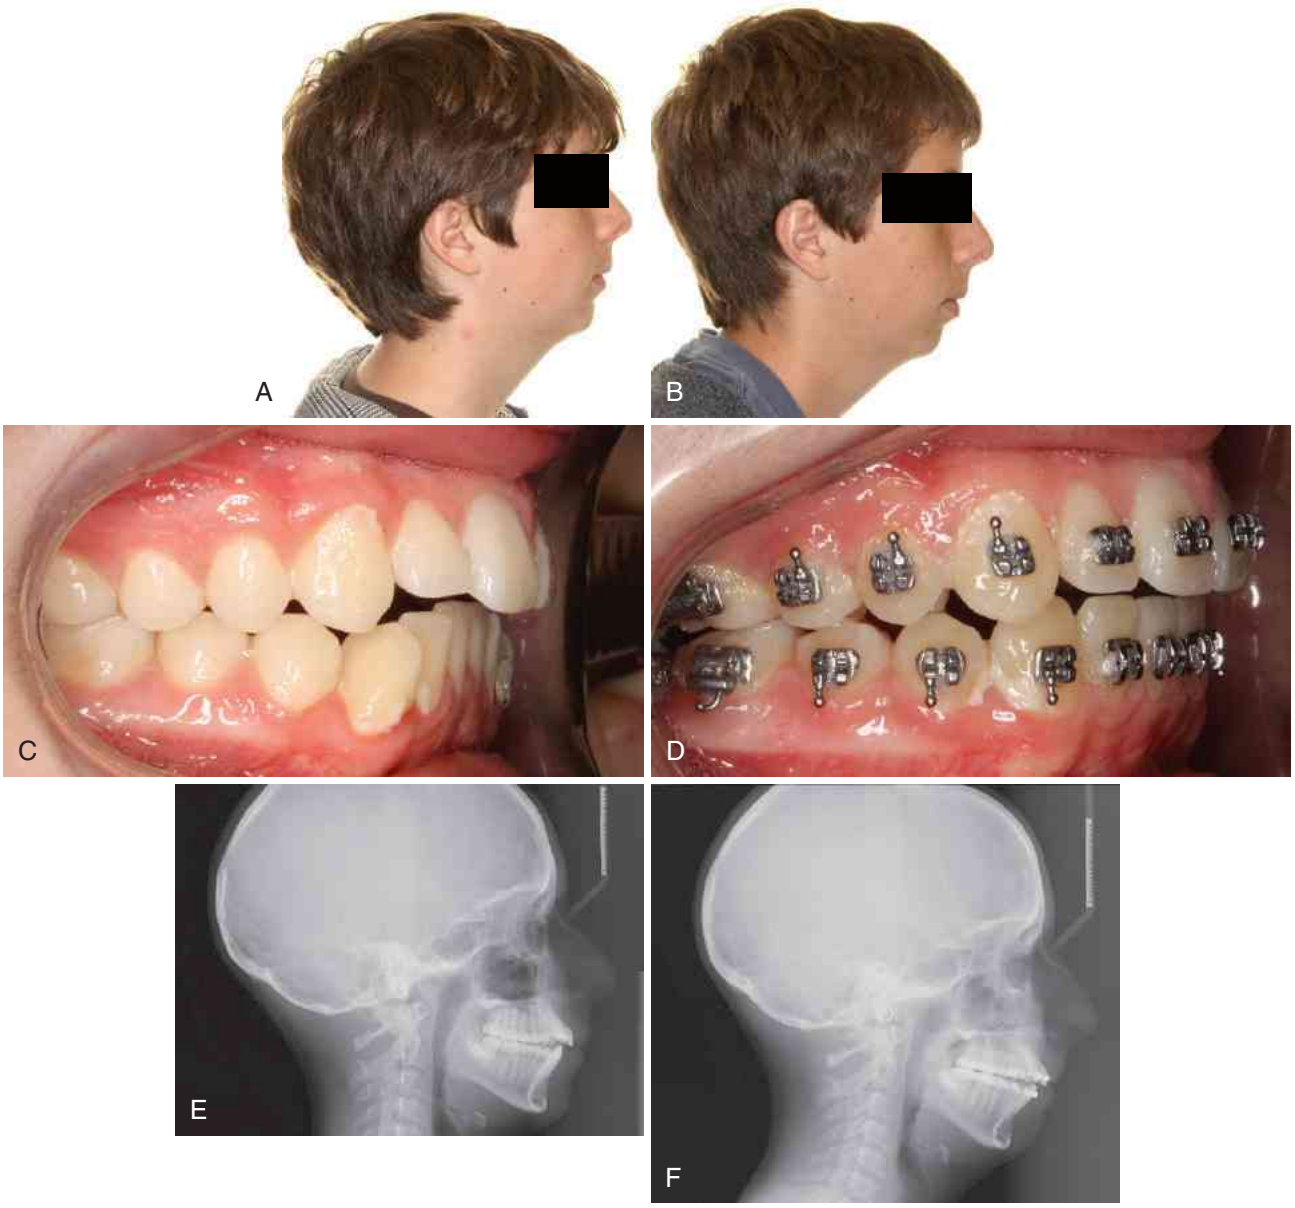

Figure 143-7 Growth changes during adolescence. **A, C,** and **E** Presentation at the age of 14 years before the initiation of orthodontic therapy for malocclusion correction. **B, D,** and **F** Growth and dental changes 12 months later.

risk for aberrant muscle alterations, and for these patients muscle rehabilitation may be beneficial.

Active Force Application

Induced Bone Remodeling. If bone remodeling is the result of passive force application, active force application as an epigenetic effect to direct bone development could be a strategy to increase airway size or to redirect unfavorable growth patterns, beyond the inherent genetic expression. Not all patients develop a dysmorphic growth pattern as a result of impaired nasal respiration, so interventional therapy to modify existing growth patterns may not be justified when an aberrant growth pattern cannot be predicted. However, if these therapies help improve the critical closing pressure, the pharyngeal collapsibility would ultimately be improved or even normalized.

The consideration for this direction of care lies in the shortcomings of current therapies. The "gold standard" for treatment of OSA in adults is nasal CPAP. Whereas adenotonsillectomy is the first-line therapy for children, nasal CPAP is considered after other therapies have not completely improved respiration. Nasal CPAP is burdened with problems of compliance due to mask fit, comfort, or initiation of CPAP use. As an extraoral appliance, it will exert a molding force on the facial skeleton and the dentoalveolar bone. This force can cause remodeling and redirection of maxillomandibular jaw growth in the pediatric patient.[238-241] This retrusive remodeling force from the positive pressure from the mask or machine can create a skeletal jaw imbalance and negate all earlier efforts to enlarge the airway size, as seen in Figure 143-13, *A* and *B*. As increased nasal resistance is both a cause and consequence of SDB, an often prescribed option for treatment not only treats the problem but can perpetuate the problem too. However, induced bone remodeling through active force application can rectify these iatrogenic craniofacial alterations (Figure 143-13, *C*). There remains the question as to how long this imbalance is to be sustained.

Placing applied pressure (or force or loading) on the craniofacial bone causes shape and size changes. Future directions in care will test these boundaries. RME appliances use the dentition for force delivery, but there can be unwanted tooth movement side effects that accompany the skeletal change. Removable appliances that attach to the teeth to change the muscle tension on the underlying bone have been used with a small degree of success. One future avenue for force delivery uses temporary attachment devices, called TADs, anchored directly into the bone, that bypass the dentition.[242,243] The advantage of this type of direct force application to the bone is the direct and possible increased effect of loading on bone modeling while minimizing the side effects to the adjacent teeth and periodontium.

Through the combination of therapies, it may be possible to modify the inherent growth pattern. Efforts to target therapy at the site of greatest airway narrowing or obstruction may not be adequate because airway narrowing and collapse are thought to occur at multiple sites.[244] There are currently no studies that detail the effectiveness of a comprehensive and combined approach of treatments and growth modification to the nasopharynx, oropharynx, and hypopharynx while also implementing muscle rehabilitation to address the concomitant neuromuscular adaptations of an impaired airway. Although there are studies that document the efficacy of adenotonsillectomy and jaw expansion together as a treatment modality[167] and studies that describe adenotonsillectomy and MFT,[245] there remains to be examined the full complement of creating the largest patency of the airway using the modalities described in Box 143-3. These types of studies would be difficult to design, and longitudinal data across several different populations would be needed. The 11 known collections of longitudinal craniofacial growth records of untreated children in the United States and Canada could serve as the comparison of treated to untreated populations. This monumental effort would necessitate the collaboration of the multiple specialists involved in the treatment of upper airway disorders.

Prophylactically treating the entire pharynx, instead of targeting the site of greatest obstruction or narrowest opening, may seem aggressive and extreme. However, children with SDB have blunted responses to hypercapnia,[246] demonstrating early neural deficits that are thought to be reversed with treatment, but it is not known if there is complete recovery. Reports of a high recurrence of SDB in later teenage years[117] suggest that some neural dysregulation persisted and perhaps worsened after previous treatment. Treatment is usually initiated from daytime or nighttime symptoms. The onset of symptoms may underlie a larger problem, as it is not known how long the primary cause needs to be present before symptoms develop. The most viable treatment may be consistent early screening to identify patterns before the onset of symptoms. By the time treatment is rendered, even if it is done at any early age, there may already be alterations in muscle recruitment and tone that initiate the development of a craniofacial malformation. A recent population-based longitudinal study observing children from 6 months to 7 years of age found that early symptoms of snoring, mouth breathing, and witnessed apneas had statistically significant effects on behavior in later

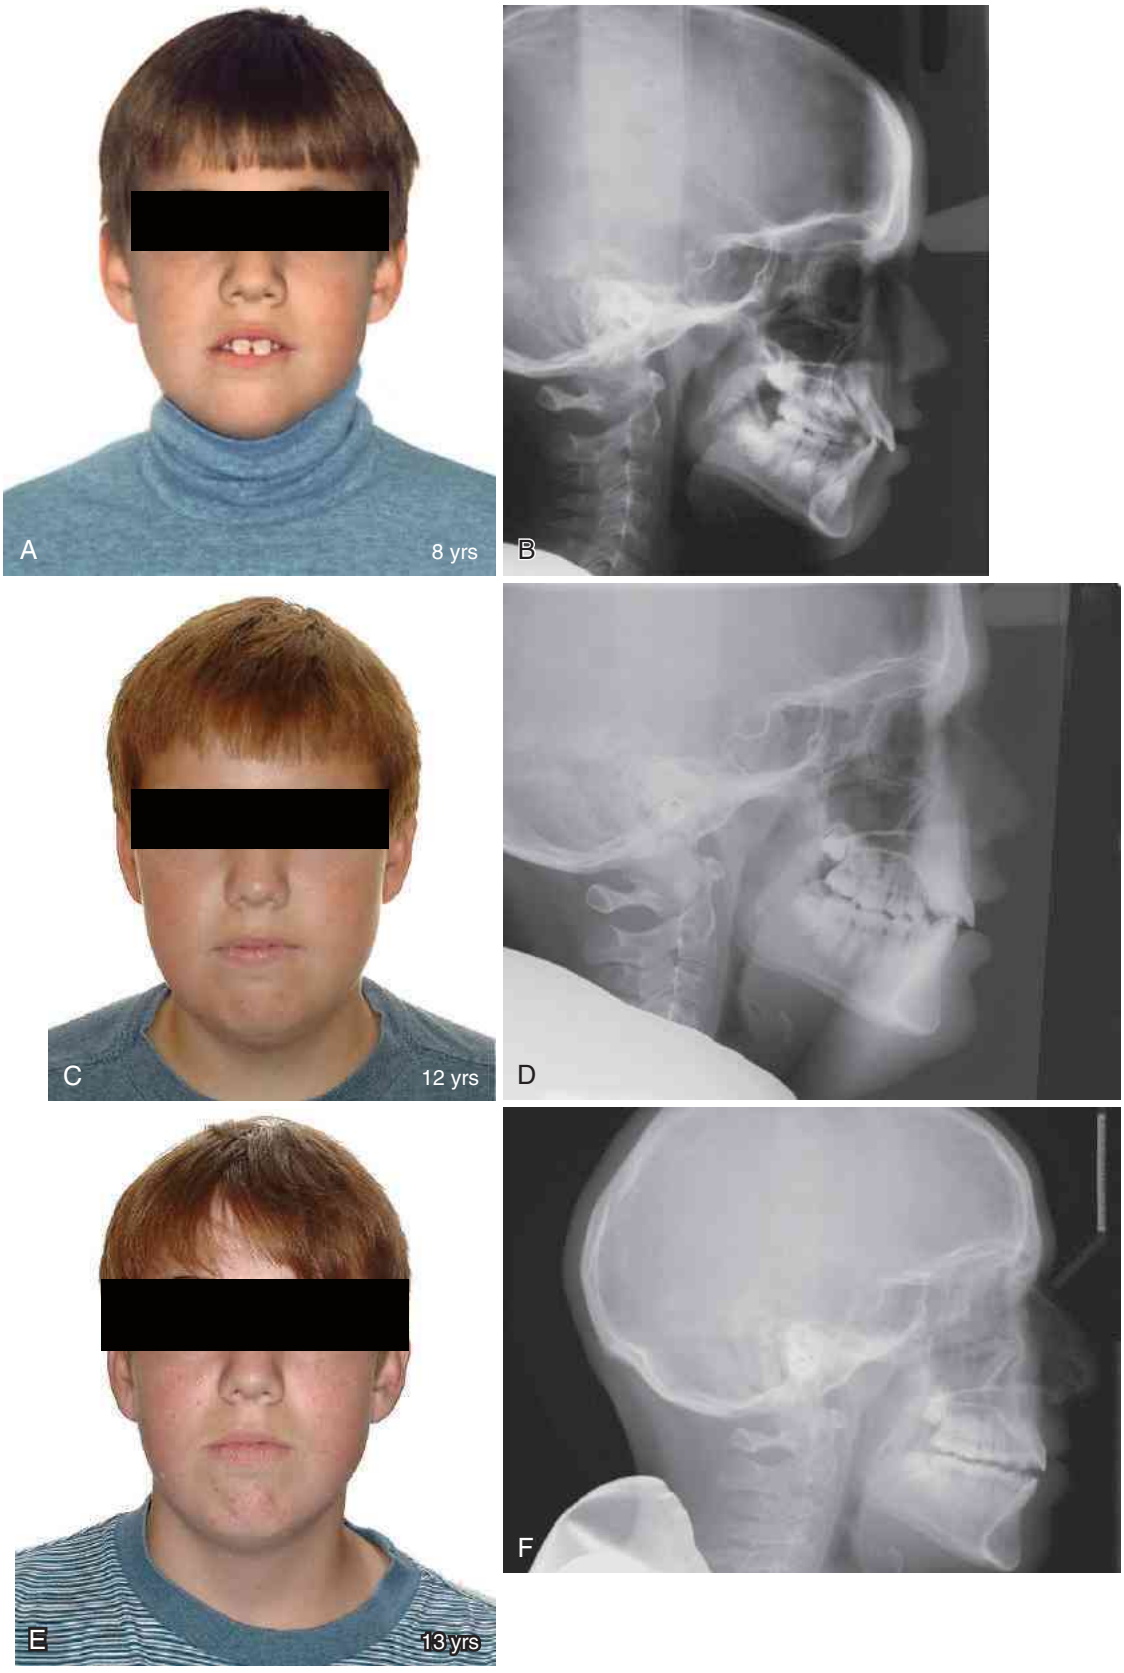

Figure 143-9 This patient had orthodontic intervention of maxillary expansion for the malocclusion. **A** and **B,** Facial proportions and jaw relationship at the age of 8 years, initial presentation. **C** and **D,** Vertical lowering of the mandible after 4 years. **E** and **F,** Narrowed posterior airway space, continued vertical lowering of mandible, and forward jaw rotation after 5 years. No treatment interventions were rendered between 12 and 13 years of age. Note the dramatic change in growth velocity of the lower jaw from the age of 12 to 13 years.

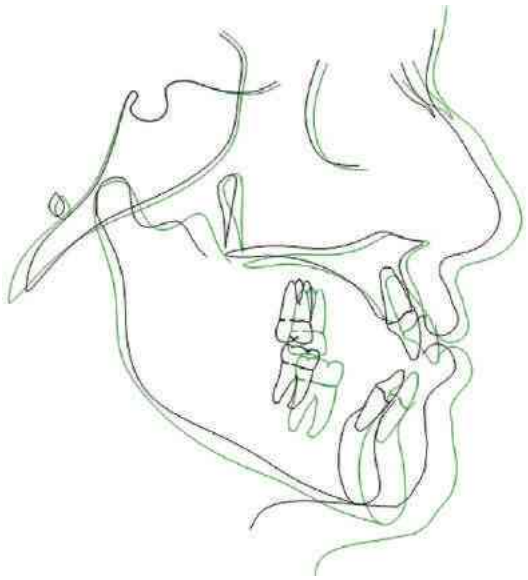

Figure 143-10 General superimposition from 12 to 13 years of age of the patient in Figure 143-9. Method of Bjork, superimposed on cranial base. Forward growth rotation of the maxilla and mandible are evident.

childhood, suggesting that early symptoms warrant examination as early as the first year of life.[247] Herein lies the challenge of defining reliable screening patterns that are predictive of the disease.

A stepwise evidence-based approach for the diagnosis and multitherapeutic management of childhood SDB has been recently presented.[248] This approach, starting with weight control followed in succession with nasal corticosteroids, adenotonsillectomy, dentofacial orthopedics such as mandibular advancement or maxillary expansion, CPAP, and maxillofacial surgery, is illustrated in Figure 143-14. This case demonstrates that despite early best efforts at recognition, diagnosis, and intervention of multiple therapies, including adenotonsillectomy, allergy management, multiple rounds of bimaxillary expansion, and nasal CPAP, the upper airway problems may still persist. For this particular case, problems of CPAP adherence rendered it ineffective as long-term treatment. Ultimately, on growth cessation, maxillomandibular advancement was the final treatment rendered, which normalized respiratory parameters and symptoms. Anatomic insufficiencies were improved to maximize the enlargement of the pharyngeal space.

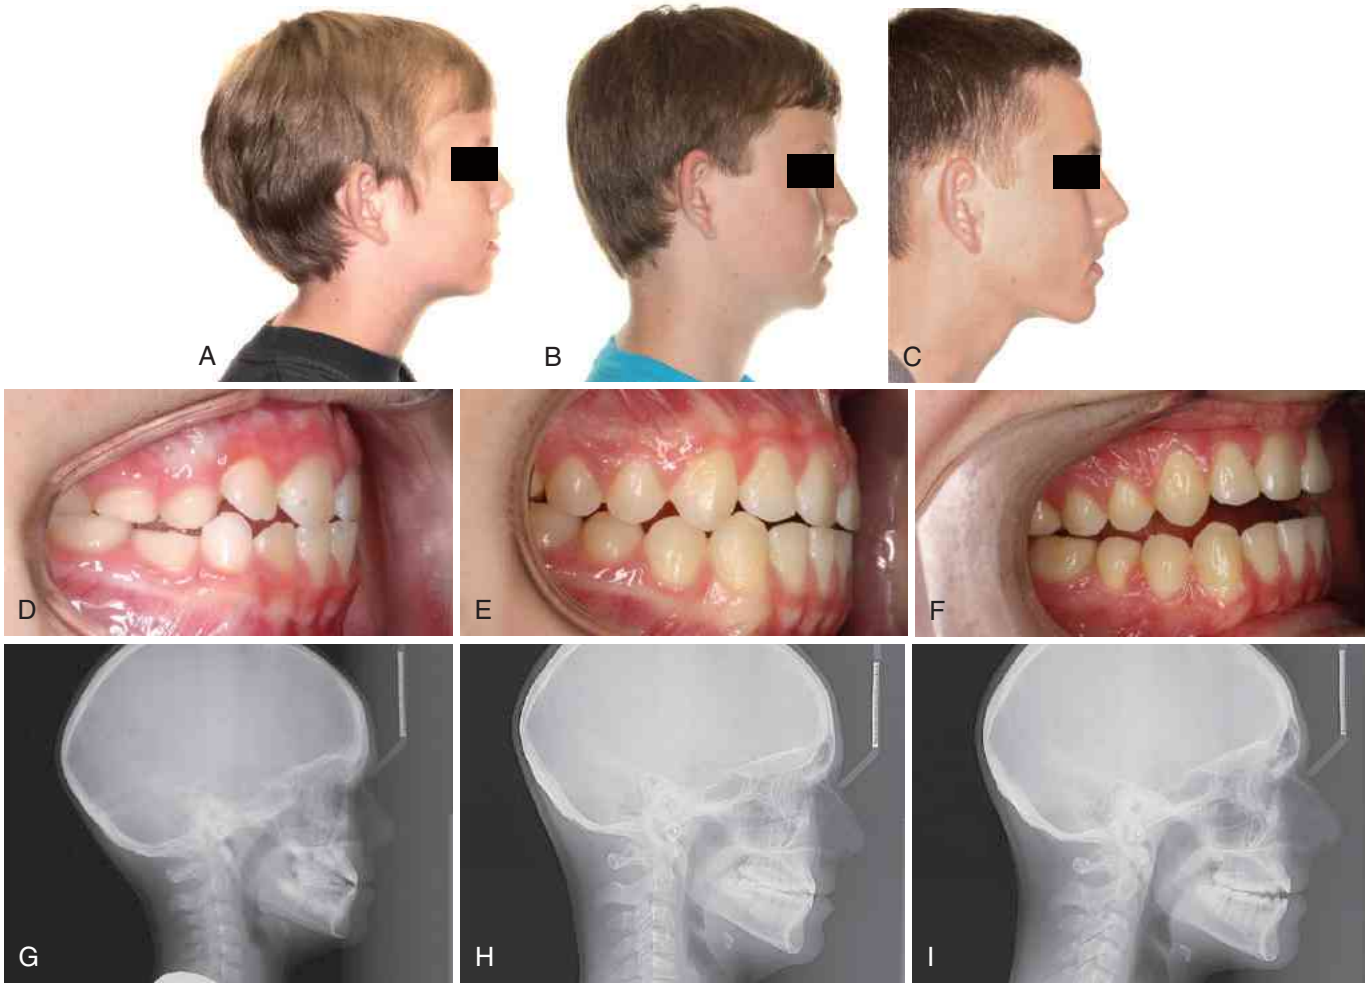

Figure 143-11 **A–C,** Growth changes during adolescence. Initial presentation at the age of 8 years, when upper jaw expansion was done. **D–F,** Growth presentation 5 years later. **G** and **H,** Growth presentation with no treatment interventions between the ages of 13 and 15 years.

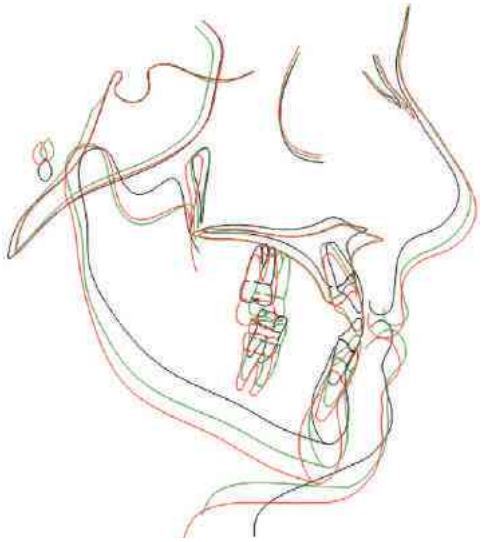

Figure 143-12 General superimposition, method of Bjork, superimposed on cranial base of the patient in Figure 143-11. The lowering of the mandible for oral respiration was followed by a downward displacement of the maxilla with an increased extrusion of the teeth.

Figure 143-13 Effect of CPAP on facial growth. **A,** Lateral cephalogram of an adolescent boy before initiation of nasal CPAP. **B,** Lateral cephalogram showing retrusion of the upper jaw in response to nasal CPAP (mask type: nasal mask) for 12 months. **C,** Lateral cephalogram showing protraction of upper jaw from orthodontic orthopedic forward traction of 8 months to the maxilla, while still using CPAP (mask type changed to nasal pillows).

CLINICAL PEARLS

- The altered craniofacial morphology associated with SDB has been well classified and trends to growth of longer and narrower facial structures. The exact mechanism by which this maladaptive plasticity of growth occurs is not well understood but is most likely related to impaired function that is both caused and perpetuated by genetic and epigenetic factors.
- Nasal CPAP as an extraoral appliance will exert a molding force on the facial skeleton and the dentoalveolar bone, causing remodeling and redirection of maxillomandibular jaw growth in the pediatric patient. This retrusive remodeling force from the positive pressure from the mask or machine can create a skeletal jaw imbalance and negate all earlier efforts to enlarge the airway. Pediatric mask selection should minimize face contact to reduce the retrusive molding pressure to the maxilla.
- When children with SDB present with the specific abnormality of narrowed palate or posterior dental crossbite, treatment with rapid palatal expansion is an effective, noninvasive therapy to improve disease symptoms. Another common means to orthodontically increase airway volume, using a mandibular advancement device in children, has limited but promising evidence in retrognathic SDB patients.
- Improvement of both subjective and objective measures of SDB by MFT has been demonstrated in children and adolescents through the mechanisms of muscle strengthening and reinforcing nasal respiration. Despite impressive results, the overall number of patients is small, and future research should develop the full extent to which this form of treatment can be effectively applied.

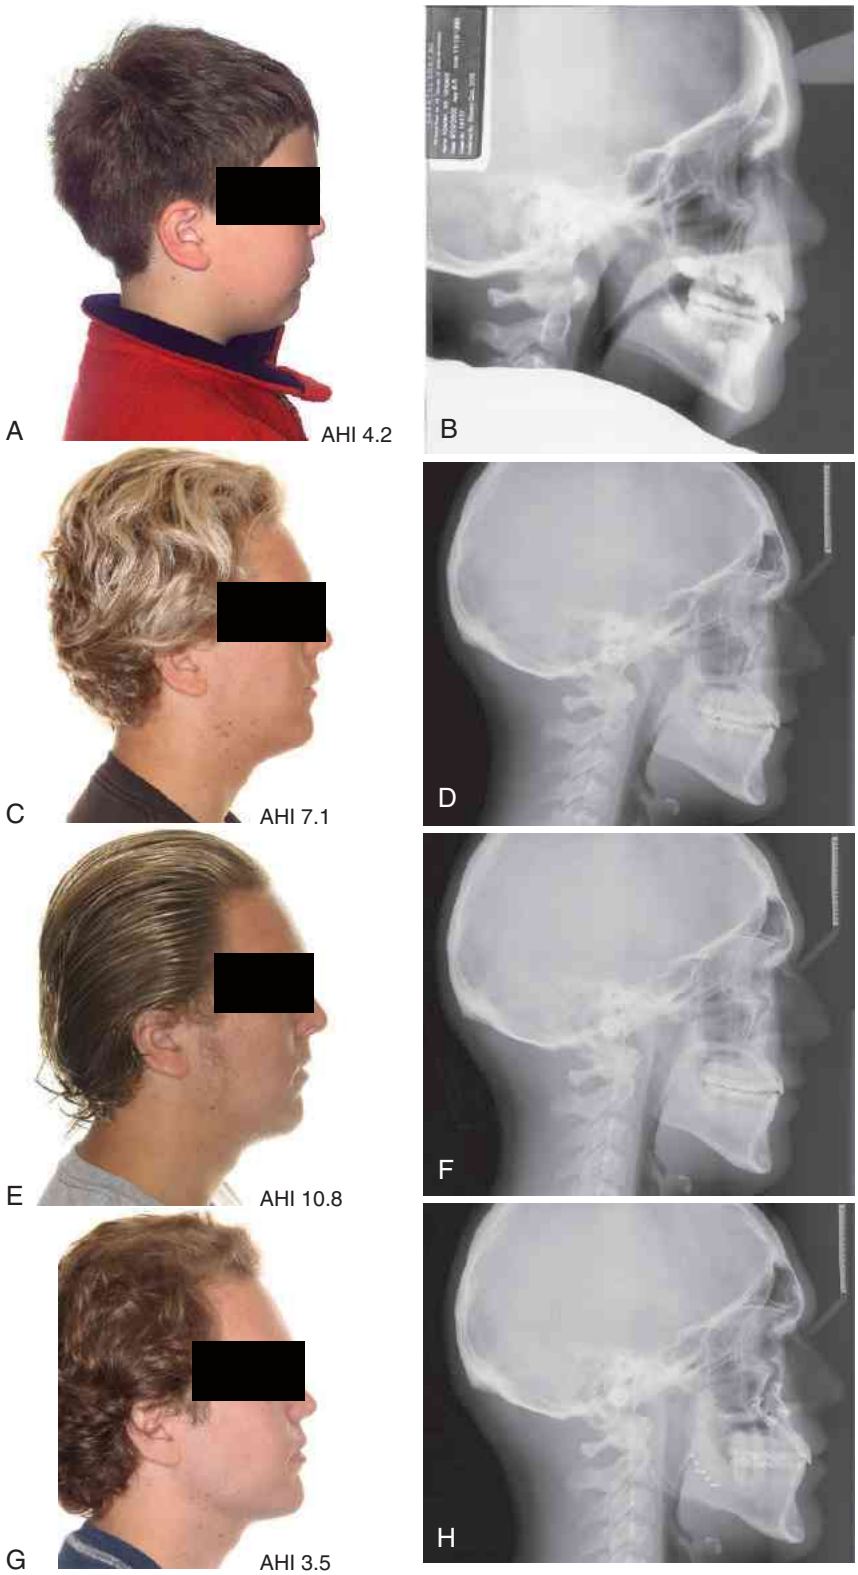

Figure 143-14 Craniofacial development from the ages of 8 to 19 years. **A** and **B,** Records at age 8 years show airway and facial proportions after adenotonsillectomy, indicating residual SDB/OSA (AHI 4.2, residual symptoms). Bimaxillary orthodontic expansion initiated. Initial diagnosis of OSA at age 5 years (AHI 2.9 with daytime symptoms). **C** and **D,** Age 15 years, after bimaxillary expansion was completed at age 8 years and again at age 10 years. AHI increased to 7.1. **E** and **F,** Age 17 years, in preparation for maxillomandibular advancement. AHI increased to 10.8 with disproportionate increase in symptoms. **G** and **H,** Age 19 years after maxillomandibular advancement, with normalization of AHI and resolution of symptoms. Note the pharyngeal airway enlargement and accompanying facial soft tissue profile changes.

SUMMARY

Many of the factors leading to pediatric SDB create secondary morphologic changes that exacerbate and perpetuate the syndrome. The approach to establish normal daytime and nighttime respiration is a multidisciplinary endeavor, involving the treatment of all three components of the pharynx and the attendant surrounding musculature. As multiple treatments may act synergistically, a greater degree of collaboration between specialists in sleep medicine, otolaryngology, allergy, and orthodontics is warranted to establish the contribution made by each discipline to the outcome of pediatric OSA. To achieve successful treatment of upper airway disorders, future efforts aimed at modifying the anatomy can hold the promise of prevention of problems of constricted size and impaired muscle function because oropharyngeal malformation may be not only a cause but also a consequence of SDB.

Chapter 144

Sleep Bruxism: Definition, Prevalence, Classification, Etiology, and Consequences

Peter Svensson; Taro Arima; Gilles Lavigne; Eduardo Castrillon

Chapter Highlights

- Sleep bruxism (SB) is a sleep-related movement disorder characterized by teeth grinding or clenching frequently but not exclusively associated with sleep arousal. SB has traditionally been considered an oral parafunction with involuntary rhythmic or spasmodic nonfunctional gnashing, grinding, or chewing movements of the mandible, triggered by occlusal discrepancies, which then could lead to occlusal trauma and dysfunction of the stomatognathic system. Current lines of research, however, have downplayed the importance of occlusal and anatomical factors for SB and, rather, emphasized central nervous system factors and regulation of the autonomic nervous system. Knowledge on definitions, pathophysiology, and mechanisms of SB has distinct implications for management of SB in the clinic.

DEFINITIONS

Gnashing and clenching of the teeth have been reported since early times in human history. Statements on this particular oral activity can be found even in the old testament of the Holy Bible.[1] *Bruxism* has been the preferred term to characterize these oral behaviors and is originated from the Greek word *brygmos* (βρυγμός) that means gnashing of the teeth. Bruxism has been the focus for many health professions and, more specifically, in dentistry for many years and was described for the first time in the scientific literature by Marie and Pietwiekwicz.[2]

A variety of definitions of bruxism has been proposed and used, but most of them have been criticized for not providing specific or operationalized criteria.[3] A recent publication from an international expert group addressed this issue, discussing all of the different definitions available. They proposed the following new consensus-based definition:

> Bruxism is a repetitive jaw-muscle activity characterized by clenching or grinding of the teeth and/or by bracing or thrusting of the mandible. Bruxism has two distinct circadian manifestations: it can occur during sleep (indicated as SB) or during wakefulness (indicated as awake bruxism: AB)[3]

This chapter will focus on sleep bruxism (SB).

PREVALENCE

The prevalence of SB varies, depending on the specific criteria to define bruxism and the methods used to establish the diagnosis. Most of the literature available on the epidemiology of SB are based on self-reports, that is, simple questions such as: Are you aware of clenching or grinding your teeth during sleep?—or questionnaires (e.g., oral behavior check list).[4] Using this methodology, SB is reported between 8% and 31% of the general population.[5] SB has been reported in the literature as occurring as "frequent as three times a week" with a prevalence of 9.3%, as "frequent" bruxism in 14%, and as "often" bruxism in 15.3%.[5] For comparison, awake bruxism (AB) is reported as "often" in 22.1% and "any AB during the last 6 months" in 31% of the population. Overall, these prevalence figures suggest that SB is, indeed, a very common phenomenon in the population.

There are nevertheless obvious limitations with prevalence data based on self-reports of SB, for example, if the patients sleep alone, they may not be aware of their SB behavior or, if their sleep partner sleeps very deeply, they may not be told. Furthermore, information from health care providers can cause bias. A classical example is that the majority of patients who may report SB have received the information from their dentist.[6]

The gold standard for a more definite SB diagnosis is based on the use of polysomnographic (PSG) analyses, including audio and video recordings as described chapter 145.[7] (Figure 144-1). Due to its practical complications, heavy load in data analysis, and relatively high costs, there is not much epidemiologic information on SB using PSG criteria. One recent large-scale PSG study reported a prevalence of 7.4% SB in adults using exclusively PSG methodology.[8] Unfortunately, this report lacked video and audio recordings that are needed to fulfill the gold standard requirements and remove false-positive events, for example, derived from body movements or scratching the skin/electrodes.[7,9] It has also been suggested that an overestimation of the SB prevalence is possible when only self-reports are used.[8,10] Interestingly, SB prevalence appears not to differ between genders but to decrease with age.[5,11] The reason for the age-dependency, so far, is not well understood but must await confirmation from PSG-based SB

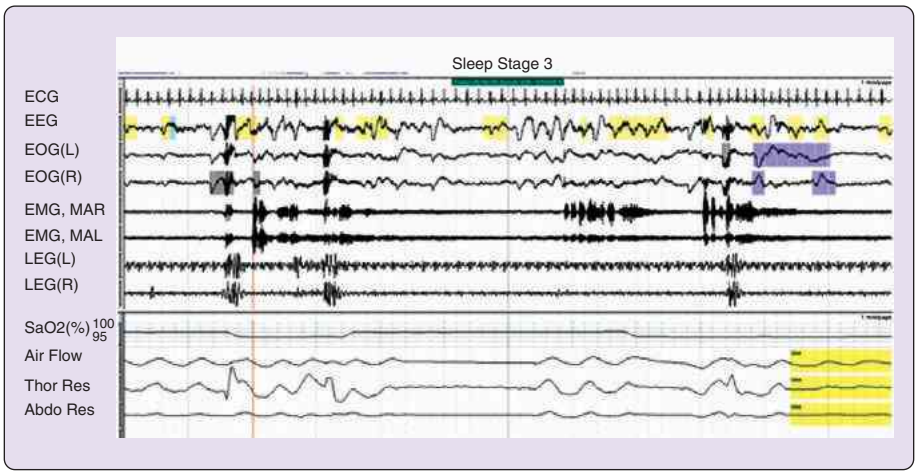

Figure 144-1 A typical polysomnographic (PSG) recording for the assessment of rhythmic masticatory muscle activity (RMMA). This recording includes electrocardiogram (ECG), electroencephalogram (EEG), electrooculogram (EOG), electromyogram (EMG) of the right masseter (MAR) muscle, EMG of the left masseter (MAL) muscle, movement recording of the right leg (LEG[R]), movement recording of the left leg (LEG[L]), oxygen saturation (SaO_2[%]), airflow, thorax expansion resistance (ThorRes), and abdomen expansion resistance (AbdoRes). Gold standard criteria for sleep bruxism demand that PSG recordings for RMMA also include synchronized audio and video recordings (not included in this figure). (Courtesy Faramarz Jadidi, PhD.)

studies. Despite the small amount of scientific information about genetics in SB, a recent review suggested that SB may, at least in part, be genetically determined and environmentally expressed (see the later section on etiology and pathophysiology for more information).[12-15] However, it will be a complex task to identify specific candidate genes for SB, and more research in this field will be needed.

CLASSIFICATION

One of the most logical ways to classify bruxism is to use the circadian rhythm to divide this oral activity into AB and SB, recognizing it may overlap in some subjects[16] because the physiology/pathophysiology may differ.[5,17] There are, however, many additional possibilities to subclassify SB given the definition of "repetitive jaw-muscle activity," for example, depending on the specifics of the electromyographic (EMG) activity (type, duration, frequency, amplitude, total amount, etc.). One could speculate that concentric, short-lasting, infrequent, and low-intensity jaw muscle contractions would have different clinical consequences (e.g., tooth wear, orofacial pain, and headache) than eccentric, longer-lasting, frequent, and high-intensity jaw muscle contractions; further studies are obviously needed to test such hypotheses. Lavigne and colleagues[7] used operationalized research criteria, derived from the literature, to define phasic, tonic, and mixed EMG bursts and episodes and established cutoff values for SB and non-SB. These three types of EMG burst are scored as an episode, called *rhythmic masticatory muscle activity* (RMMA). These research criteria have subsequently been refined in a follow-up study.[18] Before these criteria are extrapolated for clinic use, further validation is needed with various recording systems, full PSG or limited number, or EMG channels.[19,20] Furthermore, the specifics of such EMG criteria need to be elaborated, for example, to take into account the amplitude, total amount of jaw muscle activity (area under the EMG curve), and so forth.

The International Classification of Sleep Disorders—Second Edition (ICSD-2) has placed SB under the group of sleep-related movement disorders and emphasized the link to arousal responses; it is again included into the same sleep disorder category for the third edition (2014) (www.aasmnet.org/store/product.aspx?pid=849). Sleep-related movement disorders are characterized by simple and stereotypic movements that disturb sleep, while the patients may or may not be aware of such movements. A recent study showed that SB events and periodic limb movement are time-linked, suggesting that, at least some of the underlying mechanisms may be in common. (See Chapter 95 for more information on Restless Legs Syndrome and Periodic Limb Movements during Sleep.)[21] The more mechanism-based ICSD classification of SB is entirely compatible with the consensus-based descriptive definition of SB by Lobbezoo and colleagues.[3]

It should be recognized that the clinical diagnosis of SB is associated with considerable diagnostic uncertainty like most other medical diagnoses and, for example, neuropathic pain.[22] Another approach that has been suggested to classify bruxism is the use of grading system criteria proposed by the group of experts in the consensus report.[3] This diagnostic grading system takes into account the methods and their validity to determine the presence of SB. Three levels were proposed: possible, probable, and definitive. Possible AB or SB is based on self-reports using the history or questionnaires. Probable AB or SB will be the same as for possible AB or SB plus the outcome from the clinical examination, for example, tooth wear or hypertrophic jaw muscles. Definitive will be the same as probable plus evidence from a PSG study following the gold standards for SB,[7] whereas for AB it was proposed to use the criteria for probable plus ecological momentary assessment of EMG.[3] It is suggested to apply this grading system to better characterize and classify SB, which should allow better insights into both risk factors and pathophysiology of SB, but also to better understand the potential pathophysiological consequences of SB.

ETIOLOGY AND PATHOPHYSIOLOGY

Basically, the etiology of SB is still controversial, and it may be more appropriate to talk about risk factors instead of etiological factors. Historically, SB has been associated with three major domains: anatomical, psychological, and central nervous system (CNS) factors. A short review of these topics is provided in the following.

In the dental community, the anatomical factor has for a long time been considered a main factor for SB because the prevalence of SB was much higher in population groups with malocclusion than in comparable groups with normal occlusion.[23] This tendency was also seen in patients with so-called occlusal discrepancies.[24] A classical mechanistic hypothesis was that SB would be caused by dental factors, for example, occlusal disharmony/supracontacts, which would "irritate" the CNS and trigger excessive jaw-muscle activity, that is, bruxism.[25] Logically, the adjustment or correction of occlusal disharmony, therefore, would result in the immediate disappearance of the habitual grinding of the teeth because the disharmony/supracontacts would be "equilibrated" by selective grinding or advanced dental restorative procedures.[24,26] Further support to this hypothesis was derived from the observation that SB is most prevalent in 8- to 15-year-old children, that is, with mixed dentitions and more instable occlusions.[27] However, these views are now downplayed because of a lack of good evidence to support any close relationships or causality between occlusal factors or craniofacial morphology and SB in well-designed studies with operationalized criteria.[17,28-30] Further, experimental studies with insertions of artificial and reversible supracontacts have shown a decrease, rather than an increase, in jaw-muscle activity during sleep, contradicting the occlusal-based hypothesis of SB.[31] In other studies, it was shown that the elimination of interferences in occlusion and articulation did not influence jaw-muscle activity during sleep.[32,33] Today, therefore, SB is considered to be mainly regulated and influenced by the CNS autonomic nervous system (CNS-ANS) with psychological-hyperarousal factors with little, if any, contribution from anatomical factors (occlusion, craniofacial morphology)[29,34-36] (see also Chapter 23).

Psychological factors such as anxiety,[37-43] neuroticism,[44] competitiveness,[45] emotional tension,[46] aggressiveness,[47] stress, and maladaptive/less positive coping strategies[48] have frequently been associated with SB, although some controversy remains on their specific contribution; some phenotype may be present in some individuals and not in others.[49] In particular, questionnaires and self-report data have linked SB to stress,[37,39,41,43,50-56] and some studies have also used excretion of urinary catecholamine or salivary chromogranin A as biomarkers of stress and found significant relationships.[50,57] It appears that a variety of psychological vulnerability factors, indeed, may predispose, maintain, or exacerbate SB.

Finally, the role of comorbidity and CNS should be considered in our search of understanding the pathophysiology of rapid eye movement (REM) sleep motor anomaly SB. Restless legs syndrome (RLS)[7,58] and another sleep-related movement disorder, such as REM-sleep behavior disorder (RBD), are considered to be concomitant to SB and seems to be a significant risk factor for SB in some individuals (see Chapter 145).[58,59] It remains to be demonstrated whether this co-occurrence is due simply to age (intersecting epidemiology, that is, prevalence of SB and RLS or RBD merge with a higher probability of comorbidity across ages: SB in younger ages and RLS or RBD in older ages) or whether there are some common pathophysiological bases (see also Chapter 23). Sleep apnea is considered, in some individuals, as another significant risk factor of SB. The clinical interest in the putative link between SB and sleep breathing disorders is growing; however, the strength of such an association is still debated, and causality is not yet fully proven.[60-65] Use of several types of medications or neuroactive substances, such as selective serotonin reuptake inhibitors,[66,67] dopamine antagonists,[68] or recreational drugs (amphetamine, alcohol, nicotin, caffeine),[11,69] is also considered as risk factors for some vulnerable SB patients; however, the level of evidence is often modest. Genetic susceptibility, as mentioned previously, has been relatively little examined, but there is some evidence of a hereditary predisposition based on twin studies, but accounting only for 20% to 50% of the variance.[14,15,70,71] The lessons learned, for example, from pain genetics would predict that it is highly unlikely to identify a single gene responsible for SB,[12] but rather that several genes and their haplotypes will interact in a complex manner with environmental, psychological, and endogenous factors.[72,73]

In general, SB patients are not bad sleepers; it is their sleep partners who have most sleep disturbed by the grinding sounds. Comparisons between young and healthy patients with SB and control subjects have shown normal sleep organization and macrostructure.[59,74] Several critical parameters of sleep, such as sleep latency, total sleep time, percentage of time spent in the various sleep stages, and number of awakenings, are within normal limits in sleep bruxers.[18,74,75,76] They also report a normal amount of time spent awake during the sleep period, and they demonstrate sleep efficiency that falls within the usual range of good sleepers (greater than 90%). Moreover, sleep bruxers without pain or insomnia rarely complain about poor sleep quality. Several studies have analyzed the sleep in details in sleep bruxers, and there is emerging evidence of a sequence of biological events, which culminate with excessive jaw-muscle activity, that is, teeth grinding or clenching. First, SB may occur in all sleep stages, but it has been established that SB episodes are most frequently (>80% of the time) encountered in sleep stages 1 and 2 (N 1 and 2), in the minutes before REM stage and not as previously suggested during REM sleep.[7,77-84] Furthermore, studies have now linked SB to a cyclic alternating pattern (CAP).[76,85] The CAP consists of a cyclic pattern of electroencephalographic (EEG), electrocardiographic (ECG), and EMG activation every 20 to 60 seconds,[86] and about 80% of SB episodes are observed in association with the CAP.[76] This may serve as a resetting mechanism for physiologic functions in relation to sleep environment or endogenous factors that act as a permissive window to allow the occurrence of otherwise inhibited motor activity such as SB or other body or limb movements.[76,87] The association between SB and CAP is further supported by findings showing that more than 50% of SB episodes occur in clusters (within 100 seconds), and that approximately 15% to 20% occur in the transition from deep sleep (Stage 3/4) to REM sleep.[85] These findings are also consistent with the observation that SB is preceded by alpha EEG activity and is associated with a tachycardia.[88-91] Lavigne and colleagues have made a series of important contributions to the understanding of the SB in the sequence of biological events during sleep.[7,18] The sequence seems to be initiated by a change in the

autonomic-cardiac sympathetic and parasympathetic balance, which subsequently is followed by a rise in EEG activity with more delta activity. This arousal response is followed by tachycardia and increased jaw-opener muscle activity with an increase in respiratory amplitude (1 to 2 breaths), and, finally, EMG activity in the jaw-closing muscles is often described as rhythmic jaw movements or as RMMA, as described previously.[36,92] Also, the blood pressure surge is linked to RMMA episodes, and combined findings support the concept that SB is secondary to exaggerated transient motor and ANS activation in relation to micro-arousals.[93-95] The presence of RMMA and SB-tooth grinding is frequent in young and healthy SB patients, but it is not always the case in the general population; older subjects may have concomitant sleep breathing disorders or insomnia, as described previously, who could also contribute to more or less vulnerability of RMMA-SB.[8,64] The sleep arousal axis allows a better understanding of the integration between the ANS and the CNS; the sympathetic/parasympathetic balance during sleep may influence SB and also explain why cardiovascular/respiratory factors may interact with SB.[59,94,96] Micro-arousals seem to be important, although not the only factor contributing to the genesis of RMMA-SB, and, indeed, experimental studies with application of vibrotactile stimuli during sleep indicate that such stimuli may cause micro-arousal without awakenings but with activation of SB and RMMA.[93]

In summary, anatomical factors like dental occlusion appear to have little, if any, influence on the genesis of SB. There appears to be no single etiological factor that explains SB but rather a set of factors, which may interact and exacerbate normal sleep-related bruxism. To avoid confusion, the term *etiological factors* should be used cautiously and better substituted by *risk factors*. So far, the most evidence supports the hypothesis that SB is centrally mediated and under the influence of the autonomic system function and brain arousal responses.

It is important to note that knowledge on pathophysiology and mechanism of SB is not only an academic exercise because there are important clinical consequences of the phenomenon. First, it should be recognized that the consequences of SB can form a continuum from no effects to significant and deleterious impact on oral structures and quality of life (e.g., severe tooth attrition, jaw muscle soreness and pain, and headache). This means that SB should not be treated in each and every patient but rather should be based on a careful examination and analysis of the problems and needs in the individual patient. Second, oral appliances may reduce tooth wear and grinding sounds, but SB cannot be cured by occlusal rehabilitation procedures; the occurrence of sleep-related RMMA will persist. The use of psychological methods (relaxation and cognitive behavioral therapy) may help, although evidences are yet scarce; in some cases, medication may be justified to alleviate the ANS and CNS arousal permissive influences on SB genesis. Subsequent chapters will address in more details the management of SB (see chapters 147 and 150).

CLINICAL PEARLS

- SB is a frequent condition and based on self-reports affecting between 8% and 15% of the population.
- SB has a counterpart during awake states, but the pathophysiology as well as clinical consequences may differ.
- A diagnostic grading system is suggested to distinguish between possible, probable, and definitive types of SB.
- SB cannot be explained by only dental factors such as occlusion or craniofacial morphology but is influenced by a range of psychological factors and CNS function in combination with ANS.
- Micro-arousal responses seem essential for a sequence of biological events and may contribute to have a permissive effect leading to SB.

SUMMARY

SB is considered a common condition associated with activation of the jaw-closing muscles leading to teeth grinding or jaw clenching. The potential consequences of SB form a continuum from no deleterious effects to severe tooth wear and tooth destruction to headache upon awakening and craniofacial pain complaints. In addition, sleep partners can be disturbed by the noise from tooth gnashing, and SB can have a negative impact on the quality of life. It is a consistent finding that children (15%) more often report SB than adults (8%). There is a general consensus that there is no single cause of SB but that CNS and psychological factors, including stress, may contribute; in severe cases, excessive sleep arousal responses are influenced by autonomic factors. Diagnosis and clinical examination of the orofacial region are essential to be performed. A definite diagnosis of SB, however, can be made with only PSG recordings of jaw muscle activity, together with audio-video signals. Due to the multifactorial etiology and complex pathophysiology of sleep bruxism, management is always symptomatic.

Sleep Bruxism: Diagnostic Considerations

Frank Lobbezoo; Kiyoshi Koyano; Daniel A. Paesani; Daniele Manfredini

Chapter 145

Chapter Highlights

- The main challenge in relation to sleep bruxism concerns its diagnosis. So long as consensus on how to diagnose sleep bruxism is lacking, studies on the condition will lack comparability and global acceptance. The recent suggestion for a diagnostic grading system of "possible," "probable," and "definite" sleep bruxism is an important step toward consensus.
- For a "possible" or " probable" diagnosis of sleep bruxism, self-report and clinical approaches are indicated, whereas for a "definite" diagnosis, instrumental assessments such as polysomnography, preferably in combination with audio-video recordings, are required.
- As yet, insufficient evidence has been accumulated to support the use of ambulatory electromyographic devices as stand-alone tools for the diagnosis of sleep bruxism, as tested against full polysomnographic recordings.
- In the absence of full consensus on the diagnosis of sleep bruxism, an accurate differential diagnosis that considers oral-motor disorders, such as orofacial dyskinesia and oromandibular dystonia, will be difficult. Likewise, purported associations of sleep bruxism, such as those suggested for rapid eye movement behavior disorder, obstructive sleep apnea, and gastroesophageal reflux disease, will be hard to interpret unequivocally in terms of cause-and-effect implications.
- It will be a stimulating challenge for the near future to operationalize the foregoing suggestions for diagnostic grading, taking into consideration the important work that has already assessed this topic.

DEFINITION OF BRUXISM

Recently, an international group of experts has defined bruxism as a repetitive jaw muscle activity characterized by clenching or grinding of the teeth and/or by bracing or thrusting of the mandible. The condition has two distinct circadian manifestations: sleep bruxism (SB) and awake bruxism.[1] The new consensus definition, which is suggested for clinical and research purposes in all relevant dental and medical domains, has already been included in leading documents such as the orofacial pain guidelines of the American Academy of Orofacial Pain[2] and the third edition of the *International Classification of Sleep Disorders* (ICSD3),[3] showing its emerging international acceptance.

This chapter reviews recent insights into the methodologic aspects and the differential diagnosis for bruxism restricted to sleep. More details on the definition, epidemiology, consequences, and management of SB can be found in Chapters 144, 146, 147, and 150.

DIAGNOSIS OF SLEEP BRUXISM

For the assessment of SB, multiple diagnostic tools are available. Whether any of them, alone or in combination, is uncontestably valid, however, remains unknown and thus a matter of debate. As briefly described in Chapter 144, in a consensus effort of experts, Lobbezoo and colleagues[1] have suggested a grading system for SB: For a "possible" diagnosis, self-report of the condition or a proxy (such as a bed partner or a parent) report is sufficient. For a diagnosis of "probable" SB, clinical features suggestive of SB should be present as well, whereas for a "definite" diagnosis, positive findings on polysomnography, preferably in combination with positive findings on audio-video recordings and with bruxism outcome measures above a predefined threshold, are required in addition to the patient's self-report and consistent clinical features on physical examination.

Presented next are various diagnostic approaches to SB, elaborated in some detail.

Self-Report

For a "possible" diagnosis of SB, a self-report of the condition can be obtained by questionnaires and/or by oral history taking. Questionnaires can be used to obtain information about the condition itself, and on its possible causes and consequences, as well as possible comorbid conditions and differential diagnostic considerations (see Differential Diagnosis, further on). An example of a questionnaire for the assessment of sleep bruxism that can be used in the research setting as well as in the clinic is the so-called BRUX scale, developed and tested for its psychometric properties by van der Meulen and associates.[4] The BRUX scale consists of four questions

that can be answered on a 5-item verbal scale (ranging from never to always), two of which deal with SB (Box 145-1). The BRUX scale is part of a more extensive tool: the Oral Parafunctions Questionnaire (OPQ).[4] Apart from four bruxism questions (the BRUX scale), the OPQ inquires about chewing on pens or pencils, nail biting, and chewing gum (the BITE scale) as well as about vacuum sucking with the tongue, playing or pushing with the tongue, lip biting, sucking on lips/cheeks, and playing with a denture (the SOFT scale). In addition, the OPQ assesses behaviors that may strain the jaw, such as sleeping on the belly. Not only the latter behavior but also some of the other behaviors ("parafunctions") can occur during sleep, and their effects should thus be distinguished from SB.

Another comprehensive tool for the assessment of SB and other (possibly comorbid) oral behaviors is the Oral Behaviors Checklist (OBC).[5,6] This 21-item tool was composed based on expert opinions and on patient contributions. Like the OPQ, the OBC uses a 5-point scale for its responses (for sleep-related behaviors: none of the time, <1 night/month, 1 to 3 nights/month, 1 to 3 nights/week, 4 to 7 nights/week).

Box 145-1 BRUX SCALE OF THE ORAL PARAFUNCTIONS QUESTIONNAIRE (OPQ)* FOR THE ASSESSMENT OF SELF-REPORTED BRUXISM

Questions

1. How often do you clench your teeth during sleep?
2. How often do you grind your teeth during sleep?
3. How often do you clench your teeth while awake?
4. How often do you grind your teeth while awake?

Response Options

Never (0)
Sometimes (1)
Regularly (2)
Often (3)
Always (4)

*Developed by van der Meulen MJ and colleagues; reported in van der Meulen MJ, Lobbezoo F, Aartman IH, Naeije M. Self-reported oral parafunctions and pain intensity in temporomandibular disorder patients. *J Orofac Pain* 2006;20:31-5.

While the daytime behaviors were tested for reliability by means of electromyographic recordings, the sleep-related behaviors were not subjected to reliability assessments so far. Of importance, whereas the OPQ asks about the presence or absence of single parafunctions, the OBC contains several questions that ask about the presence or absence of multiple behaviors in one and the same question—for example: "Based on the last month, how often do you clench or grind teeth when asleep, based on any information you may have?" Because clenching and grinding are commonly considered distinct conditions, this mode of inquiring yields less information than when single behaviors are being assessed.[7] Nevertheless, the OBC was well received by the international community (see further on; see also Table 145-1).

Multiple self-report tools are available for the assessment of the possible causes and consequences of SB. For one of the most commonly suggested consequences, specifically, temporomandibular disorders (TMD), and for several possible causes of SB (see Chapter 144), the recently published *Diagnostic Criteria for TMD* (DC/TMD)[8] suggests a comprehensive protocol for the assessment of several physical and psychological domains by means of (in most cases) validated questionnaires. The domains and their respective assessment tools are shown in Table 145-1. Although the DC/TMD is a leading and largely evidence-based system, clinicians are free to select their own questionnaires for the assessment of SB as well as of its possible causes and consequences.

When a questionnaire is completed and analyzed before the clinical consultation, the clinician knows better what to expect. In addition, patients usually have gained an improved awareness of their oral behavior, which helps improve the reliability of the oral history—the second way of obtaining self-reported data on SB. An important advantage of an oral history over the use of questionnaires is the way in which the questions are formulated: They can be adapted to the individual patient's knowledge and cognitive abilities. For research purposes, on the other hand, an oral history lacks standardization. Also, oral history taking may be influenced by the clinician's preconceived ideas about SB. A disadvantage of the use of questionnaires for the diagnosis of SB is that approximately 80% of bruxism episodes are free of grinding sounds.[9] Consequently, owing to lack of awareness for many such events, self-reports of the condition may be characterized by

Table 145-1 Questionnaires for Assessment of Physical and Psychological Domains in Temporomandibular Disorders and Sleep Bruxism as Recommended by the Diagnostic Criteria for TMD (DC/TMD)

Domain	Questionnaire	Abbreviation
Pain intensity, physical function	Graded Chronic Pain Scale	GCPS

Physical symptoms (somatization)	Patient Health Questionnaire-15	PHQ-15
Parafunction	Oral Behaviors Checklist	OBC

Data from Schiffman E, Ohrbach R, Truelove E, et al: Diagnostic Criteria for Temporomandibular Disorders (DC/TMD) for Clinical and Research Applications: recommendations of the International RDC/TMD Consortium Network and Orofacial Pain Special Interest Group. *J Oral Facial Pain Headache* 2014;28:6-27, Table 7.

underscoring, with respect to the standard reference for a definite SB diagnosis (see further on under Instrumental Assessment). At present, the only investigation reporting both polysomnographic and self-reported SB diagnosis in a large sample showed polysomnographic confirmation of SB in less than one half of the patients self-reporting this behavior.[10] Furthermore, the occurrence and severity of SB fluctuate over time,[11] which further hampers the accuracy of self-reports of SB. Hence, questionnaires should be interpreted with caution, and preferably, they should be used in combination with other diagnostic tools.[12]

As a final remark, it must be pointed out that, despite the aforementioned disadvantages, self-reported approaches to SB diagnosis have been used to collect data for several research purposes. The generalization of findings on most SB issues is thus limited.[13,14]

Clinical Examination

A clinical examination that assesses "probable" SB (as described previously) focuses on the extraoral assessment of masticatory muscle hypertrophy (see earlier) as well as on the intraoral assessment of hyperkeratosis (i.e., tooth-induced impressions in cheeks ["linea alba"], tongue ["indentations"], and/or lips),[15,16] tooth wear (Figure 145-1, *A, B*),[17] fracture or failure of restorations and implants,[15,18,19] and signs such as tooth mobility, pulp necrosis, and traumatic ulcers.[16] Of importance, all of those clinical features lack specificity in the assessment of SB. Masseter muscle hypertrophy, for example, should be distinguished from parotid salivary gland pathology, although it also can be associated with awake bruxism activities or other poor oral habits.

Figure 145-1 Example of sleep-related grinding damage. **A,** Frontal view. **B,** Occlusal view on the lower jaw.

Tooth wear can have multiple causes.[20] Whereas attrition is caused by tooth-tooth contacts as in sleep grinding, abrasion is due to tooth contact with objects (e.g., toothbrushes, pens, or fingernails), and erosion is a chemically caused type of tooth wear (as with reflux of stomach contents or an acidic diet). The interpretation of tooth wear in SB recognition is not simple, because no single cause is present and the wear could have happened years before the examination. As a consequence, this complicates the interpretation of a worn dentition in terms of tooth-grinding activities as well. This is illustrated by the study of Abe and coworkers,[17] who concluded that although the presence of attrition is indeed associated with the presence of SB, the degree of attrition did not show a dose-response relationship with the severity (specifically, the frequency of jaw muscle contractions per hour of sleep) of SB.

From a dental point of view, the direction of tooth grinding is an important factor to consider in restorative dentistry: a restoration should be loaded toward the central axis of the tooth, and not away from the center as to prevent fractures of the fillings. So long as the tooth wear is confined to the enamel, the direction of grinding can be established with the so-called "scratch test," whereby a small scratch is placed on the wear facet by means of a scalpel. At baseline and after a brief time interval of a few nights, dental precision impressions are made of the scratches and subsequently studied under scanning electron microscopy. Such scratches will show most microwear on their leading edge—that is, on the edge opposite to the grinding direction.[21] When extensive dental restorations are planned, this information can be taken into account.

Several reviews have been published on the effects of SB on dental implants[18,19,22] as well as on implant-supported prostheses.[23] In short, SB seems to be unrelated to biologic complications (e.g., failing osseointegration of the implants), although some evidence suggests that bruxism causes mechanical complications (e.g., fractures of implants or suprastructures/prostheses).

Apart from the aforementioned aspects, the clinical examination may include a functional examination of the masticatory system, based on the paradigm that bruxism and TMD pain are potentially causally related. To that end, the clinician may use the highly sensitive muscle and joint palpation tests, a negative outcome of which confirms the absence of TMD pain, and/or the highly specific dynamic/static pain tests, a positive outcome of which confirms the presence of TMD pain.[24] Whether or not SB and TMD are actually causally related, however, is highly debated in the literature. According to Lobbezoo and Lavigne,[25] the nature of this relationship is still unclear. A more recent, systematic review by Manfredini and Lobbezoo[14] yields a slightly different, although not opposing, insight into the purported causal association between SB and TMD: Investigations based on self-report or clinical examination, or both, suggested a positive association between the two conditions, although these studies are characterized by some potential bias and confounders at the diagnostic level. By contrast, studies based on use of more quantitative and specific methods to diagnose SB (e.g., polysomnography; see

later) showed much weaker associations with TMD symptoms. Apparently, the more precisely SB is defined, the less clear is its purported association with TMD. Consequently, the value of a TMD pain diagnosis is limited in the context of the assessment of SB.

A recent study assessed the correlation between questionnaire-based SB and a diagnosis of SB based on an oral history in combination with a clinical examination.[26] Proxy-reported sleep-related grinding showed a high correlation between both diagnostic approaches ($\Phi = 0.93$), whereas a lower (albeit still acceptable) correlation value was found for sleep-related clenching behavior ($\Phi = 0.64$). Interestingly, the non-proxy self-report yielded a lower correlation value ($\Phi = 0.63$) than the proxy-based one, which underlines the importance of including proxy (notably partner) reports in dedicated questionnaires and oral history taking.

Of note, at present, data are lacking on the correlation between clinically diagnosed SB and the definite diagnosis of this condition obtained by instrumental techniques (as described next). Thus further research on this topic is strongly encouraged.

Instrumental Assessment

A "definite" diagnosis of SB can be based on a positive polysomnographic recording, preferably in combination with audio-video recordings and with bruxism outcome measures above a predefined threshold, in concert with self-report of such episodes and expected clinical features on the physical examination. Because, as elaborated further on, polysomnography is a rather complicated, inaccessible, and expensive tool, several alternative instrumental techniques have been developed over the years with the aim of objectifying the presence of SB in individual patients. Following is an overview of the most commonly applied tools for the instrumental assessment of SB.

Intraoral Appliances

A commonly used tool to assess the presence and progression of sleep-related grinding is the hard occlusal stabilization appliance (Figure 145-2, *A, B*). This appliance (or "splint"), that is indicated for TMD pain as well as for SB, is worn over the upper or lower dental arch. A systematic review of the available randomized clinical trials demonstrated that the available evidence is insufficient for a recommendation for or against the use of stabilization splint therapy for the treatment of TMD.[27] Likewise, for the treatment of SB, a systematic review concluded the following:

> There is not sufficient evidence to state that the occlusal splint is effective for treating sleep bruxism. Indication of its use is questionable with regard to sleep outcomes, but it may be that there is some benefit with regard to tooth wear.[28]

In other words, it is likely that in at least some patients with SB, the grinding behavior persists—thereby wearing down the stabilization splint. Hence, the splint may function as a tool for the assessment of the presence and progression of SB. However, quantifying splint wear is fraught with difficulties, both of a technical nature and in terms of interpretation.[16]

Another frequently used intraoral appliance for the assessment of SB is the Bruxcore plate (BBMD; Bruxcore, Boston, Mass.)—a thin (0.51-mm) polyvinyl chloride sheet with four layers of two alternating colors that is fitted to the dental arch. When worn during the night, sleep-related grinding activities will lead to wear of the colored layer(s), thus yielding a measure for the amount of SB (Figure 145-3). Unfortunately, as outlined in detail by Koyano and associates,[12] several drawbacks are attached to this method, the most important one being the finding that the Bruxcore plate scores do not correlate with jaw muscle activities detected on the electromyogram (EMG) during sleep.[29] In all likelihood, this is due to the fact that bruxism is characterized not only by tooth grinding but also by clenching activities—the latter leading to less material wear than from grinding. Clearly, other methods are needed for the establishment of a definite SB diagnosis.

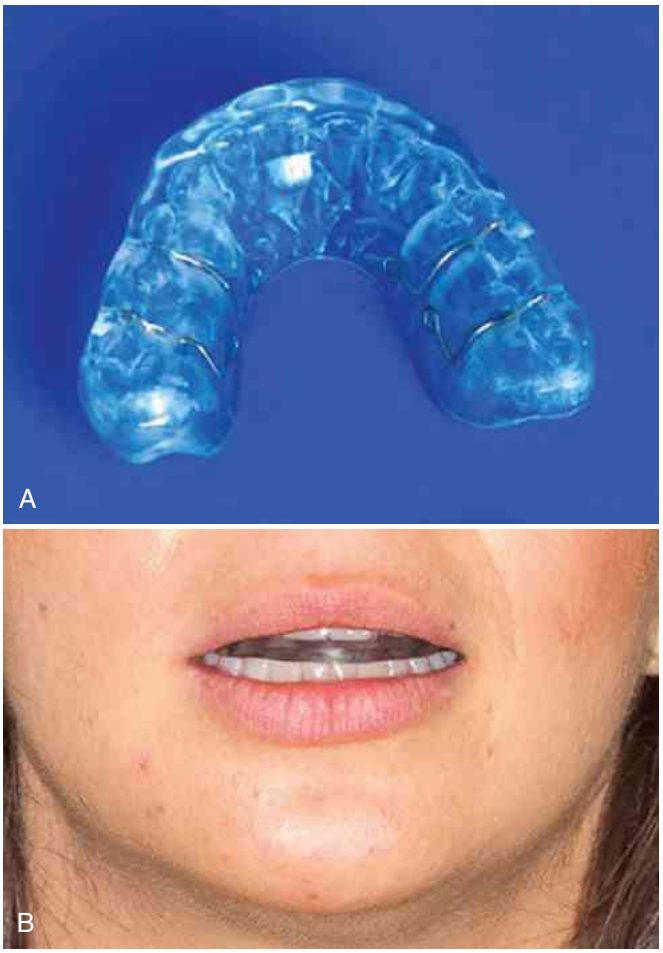

Figure 145-2 A, Example of a hard occlusal stabilization appliance, indicated for the management of sleep bruxism and commonly used to assess the presence and progression of the condition based on wear patterns on the occlusal surface. **B,** In situ on the upper jaw.

Electromyography

From the preceding discussion, it can be gathered that an objective assessment of jaw muscle activities is an essential step in the diagnosis of SB. To that end, electromyography is commonly used. A vast number of electromyographic devices are available, some of which have been developed specifically for the assessment of SB. Although they have various differences in technical and practical characteristics, they all are easy

to use, relatively cheap, and portable—thus allowing recording at home ("ambulatory recording"). A major drawback of ambulatory EMG recorders is that they do not provide the clinician with information about the sleep-wake state, nor do they allow the discrimination between SB activities on the one hand and other sleep-related/nocturnal orofacial activities on the other—thus potentially leading to overscoring of the number of "bruxism" events during the recording time. With that in mind, recent developments that combine EMG recordings with one or more additional leads (e.g., heart rate[30] or multiple leads including pulse wave intervals, actigraphy, and audio-video recordings[31]) may yield the optimal combination between electromyography alone and full polysomnographic recordings for the assessment of SB.

Figure 145-3 Example of a Bruxcore plate (BBMD; Bruxcore, Boston, Mass.), worn on the upper dental arch during the night. Sleep-related grinding activities are shown as wear of the halftone dot screen topmost surface, thus yielding a measure of the amount of sleep bruxism.

Polysomnography

According to the ICSD3,[3] polysomnography is needed for an accurate diagnosis of SB. Pioneer work on this topic has been performed by the research group of Lavigne and collaborators, on whose work most of the following information is based.[32-35] The repetitive jaw muscle activities that are recorded with polysomnography are indicated as rhythmic masticatory muscle activity (RMMA). Traditionally, the characteristics of the RMMA recording are used to define SB events (i.e., bursts and episodes); see Box 145-2. Of note, although separate criteria were previously proposed for ambulatory recordings using one or only a few leads,[36] current equipment usually allows for sufficiently high sample rates to enable application of the criteria as described in Box 145-2 for ambulatory recordings as well.

Full polysomnographic recordings can be obtained with ambulatory equipment in the home environment, but the recordings can also be performed in a highly controlled (but rather unnatural) sleep laboratory environment. Specifically

Box 145-2 SLEEP BRUXISM EVENTS (BURSTS AND EPISODES), DEFINED BY THEIR CONSTITUENT RHYTHMIC MASTICATORY MUSCLE ACTIVITY (RMMA) CHARACTERISTICS

Phasic (Rhythmic) Episodes

At least three suprathreshold EMG bursts* in the masseter and/or temporalis muscles, lasting ≥0.25 second† and <2 seconds and separated by two interburst intervals of <2 seconds‡

Tonic (Sustained) Episodes

One EMG burst of ≥2 seconds

Mixed Episodes

Both phasic and tonic characteristics

Nonclassified Bursts

Either one EMG burst lasting ≥0.25 second and <2 seconds, or two EMG bursts, lasting ≥0.25 second and <2 seconds and separated by one interburst interval of <2 seconds

*EMG threshold can established in different ways: >20% of the maximum voluntary contraction (MVC) level[33]; >10% of the MVC level[34]; or a multiplication (e.g., 3 times) of the background (noise) level of the EMG signal.
†EMG events <0.25 sec are considered twitches or myoclonic activities.
‡When the time interval between two bursts is ≥2 sec, a new event (burst, episode) starts.
EMG, Electromyogram.

Box 145-3 OUTCOME MEASURES AND DIAGNOSTIC CUT-OFF CRITERIA FOR SLEEP BRUXISM, BASED ON ANALYSES OF RHYTHMIC MASTICATORY MUSCLE ACTIVITIES (RMMA) DURING SLEEP

Sleep Bruxism Outcome Measures

Classical outcome measures[33]
- Number of sleep bruxism episodes/night
- Number of sleep bruxism episodes/hour (of sleep)
- Number of sleep bruxism bursts/hour (of sleep)
- Number of sleep bruxism bursts/episode

Additional outcome measure[66]
- Total bruxism time by total sleep time: bruxism time index (bti)

Sleep Bruxism Diagnostic Cut-off Criteria

Classical criteria[33]
- >4 episodes/hour, AND
- 6 bursts/episode and/or >25 bursts/hour, AND
- At least 1 episode/night with grinding sounds

Adapted criteria[35,67]
- Low intensity: >1 and ≤2 episodes/hour
- Moderate intensity: >2 and ≤4 episodes/hour
- High intensity: >4 episodes/hour

Data from Lavigne GJ, Rompré PH, Montplaisir JY. for the assessment of SB, polysomnography includes surface EMG recordings, obtained from at least one jaw-closing muscle (right and/or left masseter and/or temporalis muscle). The use of audio-video recordings is more feasible in the sleep laboratory environment than in the home milieu and contributes to the accuracy of a definite SB diagnosis.[37] These studies help in ruling out other orofacial activities that can be confused for SB events, such as swallowing, yawning, and sleeptalking.

Based on the works of Lavigne and collaborators (as noted previously and described in Chapter 144), research diagnostic criteria have been developed and also have evolved over the years. The classical and current recommendations are given in Box 145-3. An important limitation of the application of those criteria is the fact that the frequency and severity of SB are known to fluctuate considerably over time.[38] Van der Zaag and associates[11] quantified the diagnostic consequences of the time-variant nature of SB by suggesting the use of 95% probability cut-off bands around the previously suggested cut-off points that are included in Box 145-3. For example, with use of a cut-off point of 4 episodes occurring in each hour of sleep to distinguish sleep "bruxers" from "nonbruxers," the 95% probability cut-off band suggests that only patients with at least 7 episodes/hour are likely to be sleep bruxers, whereas persons with one or fewer episodes/hour are likely to be nonbruxers.[11] Of importance, the study authors indicated that because they worked with a mixture of previous data[33] and data that they collected themselves, the suggested cut-off bands should be considered an illustration of principle.

A recent systematic review assessed the diagnostic accuracy of portable instrumental devices for the measurement of SB against polysomnography assumed as the gold standard.[39] Using several databases and a quality assessment tool (i.e., Quality Assessment of Diagnostic Accuracy, version 2), the reviewers identified only four studies evaluating three different devices—Bitestrip, EMG-telemetry recorder, and Bruxoff—that could be included. In a disappointing turn, the validity of the included instrumental diagnostic approaches with respect to polysomnographic recordings was not only scarce but also not solid enough to support use of those techniques as stand-alone tools for disgnosis of SB. The most promising device was the Bruxoff,[30] which assesses not only the increased EMG masticatory muscle events that are characteristic for SB but also electrocardiographic changes that have been shown to occur in association with SB events,[40] thereby improving the diagnostic accuracy of the device over that of the other portable instruments. The outcome of the systematic review by Manfredini and colleagues,[39] however, implies that polysomnography is still the gold standard for diagnosis of SB. On the other hand, the validity of the polysomnographic criteria themselves to detect the pathologic consequences of SB, thus discriminating the "physiologic" phenomenon from the treatment-needing condition, has to be further explored.

DIFFERENTIAL DIAGNOSIS

SB can be confused with certain movement disorders and also may occur as a comorbid condition with other neurologic conditions. In this section, SB is considered in the context of oral movement disorders, rapid eye movement (REM) behavior disorder (RBD), sleep-disordered breathing, and gastroesophageal reflux disease (GERD).

Movement Disorders

Oral movement disorders are common conditions.[41] In some cases, the abnormal oral movement can be considered a focal manifestation of a generalized movement disorder such as Gilles de la Tourette syndrome, Huntington disease, idiopathic torsion dystonia, and Parkinson disease. The disorder also can be a side effect of medication taken for the generalized disorder.[42] In other cases, the oral movement disorder, notably orofacial dyskinesia or oromandibular dystonia, is the sole disorder present.

Orofacial dyskinesia is characterized by involuntary, mainly choreatic (dance-like) movements of the jaw, as well as other structures such as the face, lips, and tongue. The same structures can be affected by oromandibular dystonias, which consist of excessive, involuntary, and sustained muscle contractions. Both disorders have been reviewed extensively.[41,42] As possible causes, loss of inhibitory control of the basal ganglia, certain psychiatric diseases, excessive usage of dopaminergic medications, and the chronic use of antipsychotic drugs (neuroleptics) have been mentioned in the literature. When the disorder is caused by neuroleptics, it is indicated as a "tardive" condition. In addition, some anecdotal evidence from case studies suggests that certain dental conditions such as, for example, edentulism and dentoalveolar trauma, also may play a causal role in the etiology of orofacial movement disorders. Peck and coworkers[43] have formulated a set of diagnostic criteria for this condition; see Box 145-4.

When orofacial movement disorders persist in sleep, they can easily be confused with SB. Notably, orofacial dyskinesias and oromandibular dystonias can be misdiagnosed as grinding

Box 145-4 DIAGNOSTIC CRITERIA FOR OROFACIAL DYSKINESIA AND OROMANDIBULAR DYSTONIA

Orofacial Dyskinesia

History should be positive for the following:
- Neurologic diagnosis of dyskinesia in the orofacial region

Examination by neurologist should be positive for the following:
- Sensory and/or motor nerve conduction deficit, AND
- Central and/or peripheral myopathic disease, AND
- Muscular hyperactivity confirmed by intramuscular EMG

Oromandibular Dystonia

History should be positive for the following:
- Neurologic diagnosis of oromandibular dystonia

Examination by neurologist should be positive for the following:
- Sensory and/or motor nerve conduction deficit, AND
- Central and/or peripheral myopathic disease, AND
- Dystonia confirmed by intramuscular EMG

EMG, electromyogram.
Data from Peck CC, Goulet JP, Lobbezoo F, et al. Expanding the taxonomy of the diagnostic criteria for temporomandibular disorders. *J Oral Rehabil* 2014;41:2-23; and Balasubramaniam R, Ram S. Orofacial movement disorders. *Oral Maxillofac Surg Clin North Am* 2008;20:273-285, vii.[68]

(phasic) or clenching (tonic) behavior, respectively, especially when the disorder is confined to the jaw. SB also needs to be differentiated from faciomandibular myoclonus, parasomnias such as abnormal swallowing, night terrors, and confusional arousals, and—rarely—from sleep-related epilepsy.[3] This underlines the need for proper diagnostic procedures, including an extensive medical and dental history, the more so because the treatment of orofacial movement disorders differs from that of SB, with a primary role for medical specialists instead of dentists.

REM Behavior Disorder

REM behavior disorder is a neurologic disorder that occurs during the REM phases of sleep and features abnormal, powerful body movements mimicking motor behavior, in contrast with the muscle paralysis (atonia) that usually is observed during REM sleep. The disorder may lead to aggressive or complex behaviors, which may be accompanied by loud vocalizations related to the emotions experienced while dreaming. It essentially affects older men and may go undiagnosed for years before medical attention is sought. Diagnosis is confirmed with polysomnography, which typically shows absence of normal REM sleep atonia and sometimes abnormal behaviors. Treatment may be attempted with clonazepam. Because of its frequent association with the alpha-synucleinopathies, such as Parkinson disease, RBD is considered to be an important risk factor for later onset of neurodegenerative disorders, including dementia.[44,45] Pilot case studies reported that patients with RBD also may show tooth grinding.[46,47] In particular, a recent case-control paper comparing data from 28 patients with idiopathic or Parkinson disease–related RBD with those from 9 age- and sex-matched control subjects suggested that in the presence of high-frequency RMMA during sleep, RBD should be suspected.[47] Of interest, on the one hand, these findings support the hypothesis that different sleep disorders may co-occur in the same person as part of complex spectra of alterations of the normal sleep structure; on the other hand, they are in apparent contrast with currently available knowledge on idiopathic SB, which occurs mainly in NREM sleep stages 1 and 2, as described in other chapters.

Sleep-Disordered Breathing

Sleep-related breathing disorders are a group of conditions related with alterations of the normal airflow and respiration during sleep. As described elsewhere in this book, they commonly are divided into five categories: (1) obstructive sleep apnea (OSA) syndromes; (2) central sleep apnea syndromes; (3) sleep-related hypoventilation syndromes; (4) sleep-related hypoventilation resulting from a medical condition; and (5) other sleep-related breathing disorders.[3] In this discussion, the focus is on OSA, which has been called into cause for its possible relationship with SB.[48]

OSA is a breathing disorder that is characterized by the occurrence of apneic-hypoapneic episodes during sleep. It is considered to be a primary sleep disorder, characterized by the collapse of the pharynx over the upper airways, which may cause their total (i.e., apnea) or partial (i.e., hypopnea) obstruction and may lead to oxygen desaturation and arousal—that is, awakening from sleep.[3] Among others, obesity, male sex, menopausal state in women, and individual variability in lung volume and ventilation control have been identified as risk factors for OSA. Nevertheless, as in the case of SB, the pathophysiology of OSA is not yet fully understood, because it is plausible that a combination of neuromuscular and anatomic factors may play a role in the pathogenesis of obstruction.[49]

In the adult population, apneic episodes have been reported in more than 30% of patients with possible bruxism.[50] Because SB is correlated with arousal episodes,[51] and a high number of short arousal episodes also have been observed in patients with OSA, a possible relationship between the two phenomena (i.e., airway obstruction and SB episodes) has been hypothesized.[48] In some polysomnographic studies, an increase in the EMG activity of jaw muscles was observed in 40% to 60% of patients with OSA[52]; in some cases, a tonic or phasic activity of the masseter at the end of the apneic event has been described.[53–57] Findings regarding the temporal relationship between the two phenomena are inconclusive, however, and do not allow determination of important clinical questions: Does bruxism-like jaw muscle activity actually follow or precede the apnea? Do they coincide, or are the events temporally unrelated?

A recent paper suggested that four hypothetical scenarios may be identified: (1) the two phenomena are unrelated with respect to temporal sequence; (2) the onset of the OSA event precedes the onset of the SB event within a limited time span; (3) the onset of the SB event precedes the onset of the OSA event within a limited time span; or (4) the onset of both phenomena occurs at the same moment.[58]

The most plausible hypothesis is that all four of these temporal relationships between an SB event and an OSA event are actually possible, and that the relative predominance of one specific sequence of events may vary from patient to patient. For instance, the role of SB events may range from a protective activity against the apnea, in an attempt to protrude the relaxed mandible and restore airway patency,[48] to an OSA-inducing activity, as a consequence of the airways' mucosal swelling resulting from an SB-induced trigeminal cardiac reflex.[59] Interindividual differences, especially in the anatomic location of the airway obstruction, also may play a role in determining the nature of the SB-OSA relationship.

Gastroesophageal Reflux Disease

Gastroesophageal reflux is the physiologic regurgitation of stomach contents into the esophagus and the mouth, which normally may occur after eating and is asymptomatic. When the frequency and duration of such reflux episodes increase, signs and symptoms may emerge, reflecting the development of pathophysiologic changes leading to GERD. The predominant symptom is known as "heartburn," because of the classic painful chest sensation, and can affect 7 to 10% of people in the general population during waking hours. GERD is more common during sleep owing to the facilitation of reflux in the supine position, but very little is known about its sleep-time prevalence.[60]

With respect to SB, GERD assumes importance because of the need for taking this condition into account during the differential diagnosis when tooth wear (see Figure 145-1) and erosion are detected. Also, despite the absence of sound literature data on the issue, the possible coexistence of the two conditions may increase the risk for severe tooth damage. In particular, an interesting recent hypothesis suggested that SB-like RMMAs can be induced in healthy persons by

experimental esophageal acidification.[61] This suggestion found support in early observations of an increase in the number of SB episodes with lowering of the pH of saliva and esophageal contents,[62] as well as in a recent investigation describing a 73% prevalence of SB in patients with GERD.[63]

FINAL CONSIDERATIONS AND FUTURE DIRECTIONS

SB has been studied with increasing frequency over the past several decades. Notwithstanding the enormous effort, the condition is still not fully understood. An important development has been the formulation of a new definition by an international group of bruxism experts.[1] Because this definition has been widely adopted by leading professional and scientific organizations, at least future studies can be expected to be comparable regarding the description of SB. The main challenge in relation to SB, however, is still its diagnosis. So long as consensus on how to diagnose SB is lacking, studies on this condition will lack comparability and global acceptance. The suggestion from the consensus run by Lobbezoo and colleagues[1] for a diagnostic grading system ("possible," "probable," and "definite" SB, as defined earlier) is only a small first step towards a solution. It should be noted that the diagnostic approach followed depends on the study aim. For example, for a large-scale epidemiologic assessment, a "possible" diagnosis may be sufficient, in that large numbers of participants will compensate for the lower diagnostic accuracy. On the other hand, when associations of sleep-related events with SB phenomena are the aim of a study, a "definite" diagnosis with high accuracy will be necessary, with all of the possible drawbacks of limited availability and high costs attached to it. Of importance, in the absence of full consensus on the diagnosis of SB, a proper differential diagnosis that includes, for example, orofacial dyskinesia and oromandibular dystonia, will be difficult as well. Likewise, purported associations of SB, such as those suggested for RBD, OSA, and GERD, will be hard to interpret unequivocally in terms of their causal implications. It will be a challenge for the nearby future to operationalize the suggestions for diagnostic grading as formulated recently,[1] taking into consideration the important work that has already assessed this topic.[32,33,35,64,65,66,67]

CLINICAL PEARLS

- For a "possible" or "probable" SB diagnosis, self-report and clinical approaches are sufficient, whereas for a "definite" diagnosis, polysomnography, preferably with audio-video recordings, is required.
- SB should be differentiated from several other sleep-related conditions, among which are orofacial movement disorders with manifestations that persist in sleep.
- RBD, OSA, and GERD are important comorbid conditions in patients with SB with possible causal associations.

SUMMARY

SB is a repetitive jaw muscle activity characterized by clenching or grinding of the teeth and/or by bracing or thrusting of the mandible during sleep. For a diagnosis of "possible" or "probable" SB, self-report and clinical approaches constitute adequate confirmation; for a "definite" diagnosis, polysomnography, preferably with audio-video recordings, is required. As yet, the evidence is insufficient to support the use of ambulatory electromyographic devices as stand-alone tools for the diagnosis of SB, as tested against full polysomnographic recordings. This is even more critical in differentiation of SB from several other sleep-related conditions including orofacial movement disorders with manifestations that persist in sleep. RBD, obstructive sleep apnea, and GERD are important comorbid conditions in patients with SB with possible causal associations.

Chapter 146

Orofacial Pain and Temporomandibular Disorders in Relation to Sleep-Disordered Breathing and Sleep Bruxism

Gregory K. Essick; Karen G. Raphael; Anne E. Sanders; Gilles Lavigne

Chapter Highlights

- Among chronic orofacial pain conditions, temporomandibular disorders (TMDs) are the most common. The etiology of TMD is multifactorial. The role of sleep-disordered breathing (SDB) and sleep bruxism (SB) in the initiation and persistence of TMD pain is poorly understood but of considerable interest to dental clinicians who treat these patients.
- Evidence for SDB as a causal risk factor for TMD is limited at present to a few cross-sectional studies reporting higher prevalence of SDB or suspected SDB in patients with TMDs, and higher prevalence of TMDs among patients with SDB. One population-based prospective cohort study found that signs and symptoms of SDB predict incident TMD. Moreover, laboratory-based measures of sleep respiration indicate that respiratory effort–related arousals are more frequent in women with TMD than in control subjects. Prevalence of SDB also is greater in patients with fibromyalgia syndrome, a chronic pain condition commonly comorbid with TMD.
- The premise that SDB leads to SB, and in turn to TMD, is not supported by the available scientific evidence. Moreover, the strongest evidence refutes a relationship between SB and TMD. That patients with signs and symptoms of TMD often report grinding their teeth during sleep has been misinterpreted by clinicians as evidence of an association.
- This chapter describes a much more complex set of interrelationships that may explain an association between SDB and TMD. Proposed mechanisms include elevated background levels of activity in the masticatory muscles during sleep and wakefulness, intermittent hypoxia during sleep, altered autonomic nervous system function, oxidative stress, and inflammation.

Temporomandibular disorders (TMDs) are a heterogeneous family of musculoskeletal disorders that represents the most common chronic orofacial pain condition.[1-3] TMD is characterized by persistent pain in the temporomandibular joint, the periauricular region, and the muscles of the head and neck, and by painful chewing and impaired oral function. The *Diagnostic Criteria for Temporomandibular Disorders* (RDC/TMD) protocol, published by the International RDC/TMD Consortium, recently was updated; these critera are used to guide diagnosis of TMD for research purposes.[4,5] Although criteria for TMD have changed over the years, prevalence of TMDs has been estimated historically at between 5% and 12%, with higher rates among women (of reproductive age) than among men.[1,6-9] Estimates suggest that TMD results in almost 18,000,000 lost work days annually for every 100,000,000 working adults in America.[3] In view of the considerable cost to work productivity and to the health care system, much interest is directed at identifying risk factors associated with the onset and maintenance of TMD.[10]

One plausible risk factor for TMD to gain attention in recent years is sleep-disordered breathing (SDB). Some orofacial pain practices report that as many as 75% of patients diagnosed with TMD have clinical characteristics suggestive of SDB.[11] This coexistence of disorders has prompted many dental providers to believe that SDB contributes to sleep bruxism (SB), a disorder characterized by rhythmic grinding of the teeth during sleep. Furthermore, SB has been assumed to cause TMD in susceptible persons through microtrauma to the temporomandibular joint or masticatory muscles from hyperactivity during sleep.[12-15] Against this background, efforts to diagnose and treat SDB, as well as SB, in patients with TMD are assumed to reduce pain and correct dysfunction. However, no clinical trials have been conducted to determine whether treatment of SDB alters the natural course of TMD. For more information on sensory mechanisms, pain, and sleep interaction including also SB and SDB, readers are referred to Chapter 23; for SB etiology and mechanisms and SB diagnosis, they are referred to Chapters 144 and 145, respectively.

This chapter reviews the evidence supporting an association between SDB and TMDs, and between SDB and fibromyalgia syndrome (FMS), a related pain condition. Although

the literature supports a correlation with these pain conditions, efforts to establish causality have been minimal to date. Also addressed in separate sections are the association between SDB and SB and that between SB and TMD. As explained in these sections, however, SB is an unlikely causal risk factor for TMD, and more recent work calls into question the current understanding of the relationship between SDB and TMD. Presented in support of this argument is a summary of recent evidence showing that a sustained increase in background masticatory muscle activity during sleep, rather than SB, may more accurately explain the association between SDB and TMD, although this explanation remains speculative. Finally, alternative, hypothetical biologic mechanisms by which SDB and TMD may be associated are reviewed. Although of scientific interest, supporting evidence for these mechanisms also remains rudimentary at this time.

SLEEP-DISORDERED BREATHING AS A CAUSATIVE CANDIDATE FOR TEMPOROMANDIBULAR DISORDER

Remarkably few studies offer evidence for an association between SDB and TMD. In an early Brazilian study,[16] 87 patients (46 men) with a diagnosis of mild or moderate obstructive sleep apnea (OSA), as indicated by an apnea-hypopnea index (AHI) greater than 5 and less than 30 were evaluated for signs and symptoms of TMD according to the *Research Diagnostic Criteria for Temporomandibular Disorders* (RDC/TMD). Patients with mild OSA (AHI between 5 and 15) were additionally required to have symptoms consistent with OSA. An initial examination revealed that 45 (52%) patients presented with signs or symptoms of TMD for which the investigators gave a tentative diagnosis of TMD. Of the 32 (71%) who returned for the clinical assessment using the RDC, 75% presented with chronic pain associated with TMD, providing an estimated prevalence of TMD of 39% in patients with mild to moderate OSA—which was substantially greater than estimates published for the general adult population. Myofascial pain was the most common diagnosis. The study was limited by the lack of a control group, the relatively small sample size, and selection bias. For example, only patients who were candidates for oral appliance therapy for treatment of sleep apnea were enrolled, and a large number of subjects (29%) did not return to complete the physical RDC assessment for TMD.

Another observational study with an even smaller sample size and no control group was published the same year. Unlike in the earlier study, however, all 53 subjects met RDC/TMD criteria and were evaluated for experimental pain sensitivity and for sleep disorders with polysomnography (PSG).[17] Each subject completed a battery of commonly used pain and sleep questionnaires. Twenty-eight percent (50% of men and 23% of women in the study) met criteria for OSA, and 43% for insomnia signs and symptoms—greatly exceeding prevalence estimates for the general adult population. Most of the subjects with OSA (73%) were classified as having mild disease. For 13 subjects with OSA, the respiratory disturbance index averaged 13.7 events/hour.

Building on these two small studies, a large population-based epidemiologic family of TMD studies named OPPERA (Orofacial Pain: Prospective Evaluation and Risk Assessment) compared the strength of association between signs and symptoms of OSA and chronic TMD in a case-control study (n = 182 cases; n = 1534 control subjects). In a separate OPPERA study—this time a prospective cohort study—these same OSA signs and symptoms were measured at baseline in a TMD-free cohort of subjects (n = 2604) who were followed for a median 2.8 years to investigate the development of incident TMD.[18] Examiners in both OPPERA studies used RDC/TMD diagnostic criteria that required (1) self-report of pain in masticatory structures on 5 days or more per month and (2) examiner-confirmed arthralgia during jaw maneuver or digital palpation of the temporomandibular joint; and/or myalgia during jaw maneuver or digital palpation in at least three of eight muscle groups based on bilateral assessment of temporalis, masseter, lateral pterygoid, and submandibular muscles. For classification as having chronic TMD, subjects had to meet the foregoing RDC/TMD criteria and be symptomatic for at least 6 months. Subjects with at least two of four OSA signs and symptoms were classified as being at high risk for OSA. These four OSA signs and symptoms were taken from a screening questionnaire for OSA that is used to screen patients requiring anesthesia for surgery for risk factors.[19] The four OSA signs and symptoms were snoring, daytime fatigue/sleepiness, observed apnea during sleep, and hypertension. In addition, any OPPERA subject with a physician diagnosis of OSA was classified as being at high risk for OSA.

In OPPERA's chronic TMD case-control study, odds of TMD were elevated more than threefold (odds ratio, 3.6; 95% confidence interval, 2.0 to 6.5) in those at high risk for OSA, independently of demographic, autonomic, and behavioral characteristics. In the prospective cohort, OPPERA subjects at risk for OSA had 1.7 times the incidence of TMD over the median 2.8-year follow-up period, independently of demographic, autonomic, and behavioral characteristics. The association remained statistically significant with further adjustment for subjective sleep quality.

Both OPPERA studies were limited by the absence of PSG data. It is possible that the comparatively young age of OPPERA subjects (80% were younger than 35 years of age) underestimated the strength of the associations in the general population. Furthermore, a majority of OPPERA subjects were female (60%) and nonobese (80%)—the opposite of the characteristics in most SDB studies.[20] It also is possible that many participants classified by questionnaire as having OSA signs or symptoms in fact had milder forms of SDB such as upper airway resistance syndrome (UAR)[21] or respiratory effort–related arousal (RERA).[22]

That TMD may be associated with milder forms of SDB was shown in a recent PSG study of female patients with TMD (n = 124) and demographically matched control subjects (n = 46).[23] As in the foregoing studies, the patients met RDC/TMD criteria. Each participant underwent two PSG studies. Only data from the second night were used, to avoid the so-called first night effect associated with sleeping in a laboratory, a novel environment. Multiple pain ratings were collected for the day before and the day after the PSG studies. The patients with TMD had lighter and more disrupted sleep, a higher percentage of stage N1 sleep, and more sleep instability as seen by a greater number of awakenings and stage shifts toward N1. Furthermore, arousals associated with all respiratory events (apneas, hypopneas, and RERAs) were almost twice as frequent in the patients as in control subjects;

nevertheless, the mean AHI was similar for both groups at less than 4 (events/hour). Accordingly, the respiratory disturbance index showed a trend ($P = .06$) toward being higher in the TMD group (8.1/hour) than in the control group (5/hour) owing to a higher RERA frequency in the former. The increased frequency of RERAs was independent of the measures of usual sleep fragmentation outcome variables such as total number of arousals and percentage of N1 sleep but was directly related to the participant's subjective ratings of myofascial pain during the PSG night. The study may have underestimated the severity of the SDB in patients with TMD because owing to other study aims, approximately 10% of potential TMD group subjects screened were excluded from participation by the presence of severe insomnia or severe OSA or by having reported use of CPAP.

Not all studies investigating the relationship between SDB and TMD find a significant association. For example, an OSA population evaluated for oral appliance therapy had a prevalence of self-reported TMJ symptoms similar to that in historical control subjects.[24] Another study found no association between TMD and SDB as determined by questionnaire.[25] Two studies failed to find differences in respiratory measures from PSG data in RDC/TMD case and control participants.[14,26] Although validated methods for assessing TMD and SDB were employed, as in several studies just described, the sample sizes of 20 and 30 cases were small. Most recently, a study that sought to identify clinical comorbid conditions in TMD failed to detect a significant difference in the proportion reporting sleep apnea in a cohort of persons claiming to be affected by TMDs and musculoskeletal disorders and in a control group.[27] In general, these studies were limited by one or more factors, including the lack of use of recognized RDC assessments in identifying TMD, the use of self-report to identify TMD and/or OSA in the absence of PSG, and rather small samples of participants, with a large variability in methodology and variance in findings.

All considered, strength of the evidence for an association between SDB and TMD is moderate. Studies to date suggest a real or possibly elevated prevalence of SDB associated with TMD and an increased prevalence of TMD associated with SDB. One large prospective cohort study found that signs and symptoms of SDB preceded the onset of TMD in initially TMD-free subjects. Moreover, laboratory-based measures of sleep respiration indicate that RERAs are more frequent in women with TMD than in carefully demographically matched control subjects (Table 146-1). As yet, the

Table 146-1 Observations Supporting an Association between Sleep-Disordered Beathing (SDB) and Temporomandibular Disorders (TMDs) or Fibromyalgia Syndrome (FMS)

Observation	Supporting Study(ies)	Comments	Nonsupporting Study(ies)	Comments
Increased prevalence of TMD in patients diagnosed with OSA	Cunali et al., 2009[16]	Observational study; no control group; small sample size; subject selection bias	Petit et al., 2002[24]	Studies limited by one or more of the following: use of self-report to identify TMD and/or OSA, small samples of participants; large variability in methodology and variance in findings
Increased prevalence of OSA in patients diagnosed with TMD	Smith et al., 2009[17]	Observational study; no control group; small sample size	Collesano et al., 2004[25] Hoffmann et al., 2011[27]	
Increased odds of signs and symptoms of OSA in patients with chronic TMD	Sanders et al., 2013[18]	Large multicenter case-control study; no objective sleep data		
Initially TMD-free subjects with signs and symptoms of OSA more likely to develop first-onset TMD	Sanders et al., 2013[18]	Large multicenter prospective cohort study; no objective sleep data		
Increased frequency of RERAs in patients with TMD compared with control subjects	Dubrovsky et al., 2014[23]	Large sample case-control study	Camparis and Siqueira, 2006[14] Rossetti et al., 2008[26]	
Increased prevalence or severity of SDB in patients diagnosed with FMS	Gold et al., 2004[30]; May, 1993; Shah et al., 2006[33]; Prados et al., 2013[34]	Use of historical or no control subjects; patients selected from specialty clinics or community-based practice	Chervin et al., 2009[35]	Small case-control study; academic setting
Treatment of SDB in patients diagnosed with FMS helps relieve pain and dysfunction	Gold et al., 2004[30]; Sepici et al., 2007[31]; May et al., 1993[32]	No control group, anecdotal observations		

OSA, Obstructive sleep apnea; RERAs, respiratory effort–related arousals.

causal mechanisms underlying this relationship have not been elucidated.

SLEEP-DISORDERED BREATHING AS A CAUSATIVE CANDIDATE FOR FIBROMYALGIA SYNDROME

Further support for an association between SDB and TMD is provided by studies reporting an association between SDB and FMS, a persistent pain condition that is highly comorbid with TMD, exhibits similar characteristics, and is postulated to have similar causes.[28] People with FMS, as with TMD, exhibit increased pain sensitivity, but with FMS the clinical pain is widespread. It is estimated that 24% to 78% of patients with FMS meet criteria for TMD and that 9% to 18% of those with TMD meet criteria for FMS.[28,29]

A number of these studies report an increased prevalence of SDB in patients with FMS. For example, a study evaluated 28 women diagnosed with FMS and 11 women matched for age and obesity diagnosed with UAR.[30] Twenty-seven women in the FMS group exhibited SDB as determined during full-night PSG or during quantitative monitoring of inspiratory airflow and effort upon application of pressures between atmospheric and therapeutic CPAP. Moreover, anthropometric, PSG, and airflow-dynamics data, which included the pharyngeal critical closing pressure, did not differ between the two groups of women, suggesting similarity in the severity of the SDB. After CPAP treatment in 14 of the women with FMS, significant improvements were observed with respect to self-reported fatigue, pain, sleep problems, gastrointestinal symptoms, disability, and rheumatology distress. Although no controlled clinical trials have been conducted to date, anecdotal observations regarding symptomatic improvement in FMS on treatment of SDB with CPAP have been reported in other studies.[31,32] Also, other observational studies have reported a high prevalence of OSA: 83%[33] and 31.8%[34] in females and 44%[32] and 61%[34] in males with fibromyalgia. In a more recent study, however, a comparison of carefully selected female FMS case and control subjects failed to identify differences in standard polysomnographic measures or in measures of daytime sleepiness that would suggest a higher prevalence or severity of SDB in FMS.[35] See also Chapter 131 on FMS for more information on sleep interaction.

SLEEP-DISORDERED BREATHING AS A CAUSATIVE CANDIDATE FOR SLEEP BRUXISM

Bruxism refers to either clenching or grinding of the teeth. It can occur during wakefulness and/or during sleep (more information is available in Chapters 144 and 145). Here we debate the role of SDB in SB; in a later section of the chapter, we address the role of SB in TMD. It is believed and/or proposed by some clinicians that SDB plays a role in SB. Such thinking is well established, particularly for the pediatric population: An association between parent-reported SB (sleep tooth grinding) and SDB has been reported in multiple studies of children. For example, a cross-sectional telephone questionnaire survey of the parents of 3047 children in China revealed a 20.5% prevalence of sleep tooth grinding that was closely associated with habitual snoring.[36] Children with reported sleep tooth grinding were 56% more likely to exhibit habitual snoring than those without grinding. Another survey of parents of 1164 children in Turkey arrived at similar conclusions.[37] Sleep tooth grinding was reported by the parents of 21.6% of children, and habitual snorers were two times more likely than nonsnorers to grind the teeth. In a smaller study of children evaluated by PSG, parent-reported SB occurred in 31.1% of children diagnosed with obstructive sleep disorder, and all children with severe OSA exhibited SB based on parent report.[38] A survey of 69 children, collecting data before and 3 months after adenotonsillectomy for SDB, found a reduction in parental report of the child's bruxism or tooth grinding (from 45.6% to 11.8%) and a complete elimination of SDB symptoms.[39]

An association between self-reports of bruxism/tooth grinding and SDB has been cited for adults as well. A cross-sectional telephone survey of 13,057 respondents in Europe aged 15 years or older found that reported OSA was the highest risk factor (odds ratio, 1.8) for tooth grinding among all sleep symptoms and disorders queried by the investigators.[40] Another cross-sectional questionnaire study done on 1930 residents in Japan found that respondents who reported snoring were 2.6 times more likely to report that they grind their teeth during sleep than those who did not report snoring.[41] These findings, as well as those from studies described in the preceding paragraph, however, have to be interpreted with caution, because they are based solely on the reports of patients' sleep partners or parents.

SLEEP RECORDINGS OF SLEEP BRUXISM IN SLEEP-DISORDERED BREATHING

In contrast with studies that have used surveys and questionnaires to assess the SDB-SB relationship, most studies using overnight sleep studies have found no increase in prevalence of SB among persons with SDB. For example, a study of 12 adults with SDB and 12 age- and gender-matched control subjects found no difference in the frequency of "bruxing" episodes between the two groups, although the frequency of arousals was greater in the SDB group.[42] Bruxing episodes, defined as bursts of masseter EMG activity measured as greater than 40% of maximum during awake clenching, were mostly associated with respiratory events in the SDB group. By contrast, in the control group, bruxing episodes were associated with arousals from limb movements and isolated events. Ten years later, a study of 21 adults reported that 54% of adults with mild and 40% with moderate OSA met empiric criteria for SB based on the presence of two or more of the following: more than 2.5 rhythmic jaw-movement episodes per hour as determined by EMG during polysomnography, clinical observation (attrition, masticatory muscle fatigue, or temporomandibular joint discomfort) or subjective report of tooth grinding or clenching on one or more nights per week.[43] Because the number of rhythmic jaw movement episodes per hour was greater in patients with mild than in those with moderate OSA and the episodes were rarely associated with respiratory arousals, the study authors attributed their presence to the disturbed sleep characteristic of OSA rather than difficulty in breathing.

Similar to the lack of an increased prevalence of SB in adults with SDB, an increased prevalence of SDB has not been observed in adults with SB, as, for example, reported for a small general population sample.[44,45] A recent

comparison of PSG parameters for larger groups of 56 adults with and 569 adults without SB, based on PSG criteria and self-report, also failed to find any group differences in the AHI or nocturnal oxygen saturation.[46] In contrast with adults, a PSG study in children ages 2 to 16 years of age revealed a greater apnea index, AHI, and rapid eye movement (REM) sleep AHI in 70 subjects who met PSG criteria for SB, compared with 49 who did not.[47] An SB episode was defined as occurrence of three or more rhythmic contractions of the temporalis muscle lasting more than 3 but less than 15 seconds.

Collectively, the overwhelming majority of the self-report– or parent-report–based studies support that SB is elevated among both adults and children when SDB coexists as determined by the presence of symptoms suggestive of SDB or by PSG evidence of SDB. However, an increase in prevalence or in severity of SB in persons with SBD, at least in adults, has not been confirmed by PSG data. This lack of evidence brings into question the basis for self-report of SB, as discussed in Chapters 144 and 145.

SLEEP RECORDINGS OF INCREASED MASTICATORY MUSCLE ACTIVITY IN SLEEP-DISORDERED BREATHING

Bearing on a possible solution to this discrepancy between patient reports and objective laboratory findings, some groups of investigators have observed increased masticatory muscle activity in patients with SDB during sleep that is thought to result in forward posturing and stabilization, or in elevation of the mandible to help maintain airway patency. It might be that these muscle activities, even in the absence of tooth contact, are interpreted by adults (or parents of children) with SDB as tooth grinding or clenching during sleep. The earliest studies, conducted some 25 years ago, identified increased EMG activity of the masseter muscles during the inspiratory phase of sleep respiration in patients with OSA, but not in individuals with normal sleep respiration.[48,49] The activity in the masseter was accompanied by similarly timed phasic activity in the submental (genioglossus, geniohyoid, mylohyoid, and digastric) muscles, leading to periodic variations in the jaw gape from end inspiration to end expiration and variations between obstructed and nonobstructive breaths. However, the jaw was more open in patients with OSA than in persons with normal sleep respiration. The study authors surmised that activity in the masseter muscle stabilized the jaw, enabling the submental muscles to more effectively elevate and forwardly posture the hyoid bone, thereby improving airway patency overall in patients with OSA but promoting mouth breathing at the termination of apnea events.

The suggestion that increased activity in the masseter muscles can improve airway patency in patients with SDB received remarkably little attention until recent years.[11,50] In studies reported by one group of investigators, esophageal pressure and multiple channels of EMG data from the masticatory muscles were recorded in addition to the standard PSG channels in patients with mild OSA and UARS. The clinician investigators demonstrated that patients with UARS exhibit frequent periods of tonic contraction of the jaw-closing muscles (including the masseter), upon which esophageal pressure drops appreciably, indicating reductions in the respiratory effort needed to breathe. However, no objective monitoring of jaw position or of tooth contact was performed. Nor was it determined whether the patients met diagnostic criteria for bruxism based on a combination of self-report, clinical, and PSG criteria.

Other investigators have noted that contraction of the masseter and temporalis muscles occurs as part of the arousal response on a third or more of respiratory events in patients with SDB.[51,52] The contractions are dependent on the duration and intensity of the arousals and occur in patients who have no other clinical signs of SB or PSG evidence of SB—that is, of the typical rhythmic masticatory muscle activity (RMMA). It is suggested that these elevations in masticatory muscle activity represent a nonspecific, general motor manifestation of the arousal during sleep and also may contribute to the restoration of a patent upper airway.[51]

SLEEP BRUXISM AS A CAUSATIVE CANDIDATE FOR TEMPOROMANDIBULAR DISORDER

The beliefs that bruxism, sleep and/or awake, plays a role in the onset or maintenance of TMD is well-established clinical dogma (see also Chapter 145). Surveys confirm that dentists with expertise in management of TMD in both the United States and abroad believe that "oral parafunctional habits" are important in the onset of TMD.[53-57] The term "oral parafunction" typically is defined as any oral nonpurposeful activity or behavior involving the masticatory system. The oral parafunction most often linked with TMD is bruxism.[58] Many discussions, reviews, and research studies fail to clearly differentiate whether the bruxism activities are believed to occur during sleep or when awake. Nevertheless, bruxism during sleep is mainly characterized by tooth grinding, and bruxism during wake periods may be characterized mainly by clenching.

The link between SB and TMD has evolved from a long historical tradition, dating back more than half a century. In shifting from earlier mechanistic theories of TMD etiology,[59] the psychophysiologic model of masticatory muscle pain etiology was first proposed by Laszlo Schwartz in the 1950s[12,60] and expanded later by Daniel Laskin.[15] It focused on the muscle rather than the joint as a primary source of pain and integrated psychosocial factors as a cause. The foundation of the psychophysiologic model of TMD is that psychosocial stress initiates a distress response or "tension" in the affected person, causing dysfunctional oral habits such as tooth grinding and clenching. These oral habits are presumed to promote muscle contraction and hyperactivity and subsequent facial pain.

SELF-REPORTS OF SLEEP BRUXISM IN PATIENTS WITH TEMPOROMANDIBULAR DISORDERS

Turning toward research-based evidence, the approach taken in a recent review (described in Chapter 145)[61] is useful in that it separates conclusions about the bruxism-TMD relationship according to method of assessment. Twenty-one studies were identified over a 10-year period, which relied on participant self-report or questionnaire to identify bruxers, sometimes using only a single item. This issue is problematic because, as noted earlier, sleep and awake behaviors may have different consequences for development or maintenance of TMD. An overwhelming majority of the self-report–based

studies reviewed support the common belief that the frequency of some form of bruxism is elevated among patients with TMD.

Of note, in one study, two thirds of subjects with pain reported that it was their dentist who told them about their SB.[62] As identified years earlier, a central problem with the reliance on self-report is that it is tautologic.[63] If the patient's clinician "believes" that bruxism causes TMD pain and therefore tells the patient that he or she is presenting with or suffering from bruxism, studies relying on a patient's self-report will support the prevailing bruxism theory. Updating the self-report or questionnaire literature of SB since 2008, one study found that "dentist-verified" grinding (presumably during sleep) occurred at elevated rates among patients with unexplained facial pain, including those with TMD, compared with those with pain of dental origin.[64] A multisite study, however, reported inconsistent findings between the study sites in the relation between self-reported SB and specific subtypes of TMD or no TMD, concluding that patients may be unable to differentiate between sleep and awake bruxism and that the reliability of self-reported bruxism is questionable in general.[65] The variability in conclusions from even more recent studies undoubtedly reflects the problematic, low-validity assessment of SB based on questionnaire, even when a questionnaire attempts to differentiate between bruxism subtypes.

SLEEP RECORDINGS OF SLEEP BRUXISM IN PATIENTS WITH TEMPOROMANDIBULAR DISORDER

In contrast with the large number of studies examining the SB-TMD relationship using less-than-optimal methods, PSG-based studies are rare. The 10-year review cited only four studies, two of which appear to represent partial overlap in sampling.[61] One study compared groups diagnosed with SB with and without pain,[66] thus begging the question of whether SB is elevated in patients with TMD. Another study reported that subjects without TMD with relatively low levels of SB were more likely to report transient morning masticatory muscle pain than those with no or high levels of SB,[67] as has been reported also more recently.[68] The results, however, did not address the clinical syndrome of TMD or the myofascial pain of TMD, which tends to be worse in the late afternoon or evening.[69]

Two reports of a third study (one being a pilot report for the larger study) were distinguished by standardized definitions of SB events and inclusion of a control group without TMD pain.[26,70] The report with the larger sample[26] but not the smaller sample[70] found significantly higher rates of individuals meeting validated research criteria for SB[71] among participants meeting RDC criteria for TMD than among healthy control subjects. Concern about the study's recruitment methods must be raised, however, because one third of control subjects met research criteria for SB, as did nearly two thirds of subjects with TMD. By contrast, a large population study from Brazil estimated the prevalence of SB as 5.5% using a combination of questionnaires and PSG, or as 7.4% on the basis of PSG alone.[46] Other experts estimate self-reported tooth grinding prevalence as high as 8%.[72] This suggests that the reported[26] finding of unusually high rates of SB in both groups may stem from either use of nonstandard scoring methods for RMMA episodes or oversampling of persons engaging in SB in both case and control samples.

In a study that explicitly sampled patients with TMD and control subjects on the basis of presence or absence of meeting RDC criteria for myofascial TMD, rather than presence or absence of beliefs about engaging in SB, laboratory PSG evaluations found similarly low proportions in both groups of participants meeting PSG-based research criteria for SB (i.e., 10% and 11%, respectively).[73] Of note, as described earlier, the rate of self-reported SB was markedly higher among patients with TMD than among control subjects in this same sample.

Thus, as summarized in Lobbezoo and collaborators in Chapter 145 and in the review by Manfredini and Lobbezoo,[61] the highest level of association between SB and TMD is based on the lowest quality of evidence; on moving to studies with more specific and accurate methods of assessing SB, the association between SB and TMD begins to evaporate. The most parsimonious explanation at present is that no relationship exists between SB and TMD, at least in established TMD cases. The question of whether SB is involved in the initial onset of symptoms cannot be answered by the existing literature, nor is it likely that future research will provide an answer, in view of the low rates of SB in the general population.[46]

Despite this negative conclusion, it may seem paradoxic that a subset of patients with TMD note marked pain on waking. Both clinicians and patients may assume that this is indicative of SB activity during the night. In fact, owing to the lack of valid evidence, the second edition of the *International Classification of Sleep Disorders* (ICSD2) diagnostic and coding manual considered a patient report of "jaw muscle discomfort, fatigue and pain or jaw lock on waking" as one of the two criteria, along with "the presence of regular or frequent tooth grinding sounds occurring during sleep," that must be present to make a diagnosis of SB.[74] In the ICSD3, this was revised; again, such guidelines are intended to help sleep medicine professionals recognize and distinguish SB from other sleep disorders. Overnight attended PSG is recommended to investigate suspected SDB or sleep-related movement disorders.

Indeed, self-reported SB has been significantly associated with pain or jaw tension on waking in the morning in at least one report,[75] but PSG-confirmed RMMA episode frequency is not found to relate to morning muscle symptoms.[76] Also troubling is a finding from the large OPPERA prospective cohort study that a 21-item oral behaviors checklist that included several items on self-reported sleep and awake bruxism ranked fifth in importance, among more than 200 variables examined, for predicting incident TMD.[77] Thus factors related to self-reported oral behaviors seem to prospectively predict TMD onset or persistence, even if PSG-confirmed behaviors do not. Does a patient's being told by a dentist or hearing from the general public that bruxism "causes" TMD explain such reports? Although the basis for the contradiction between self-reports and PSG-confirmed SB is unclear, one must be circumspect about conclusions of future studies that rely on anything but PSG-confirmed SB.

A possible resolution to the contradiction between self-reports versus PSG-confirmed SB may lie in nighttime

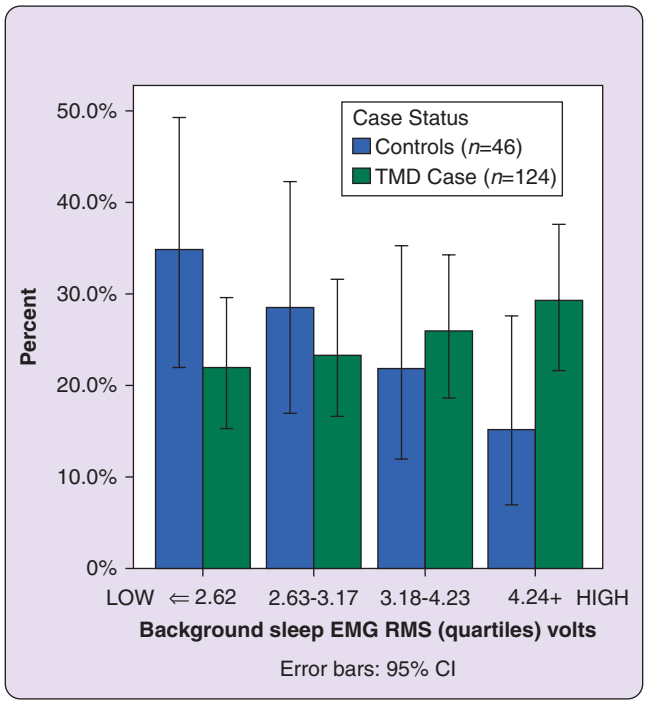

Figure 146-1 Distribution of quartiled background sleep EMG activity (RMS volts) among patients with temporomandibular disorders (TMDs) (n = 124) and control subjects (n = 46). Recent studies are dispelling the widely held view that sleep bruxism (SB) is an important risk factor for TMD development or persistence. It is now shown that background masticatory muscle activity during sleep is elevated in patients with TMDs. The underlying mediators of this relationship are not yet understood. RMS, Root mean square. (Data from Raphael KG, Janal MN, Sirois DA, et al. Masticatory muscle sleep background electromyographic activity is elevated in myofascial temporomandibular disorder patients. *J Oral Rehabil* 2013;40:883–91.)

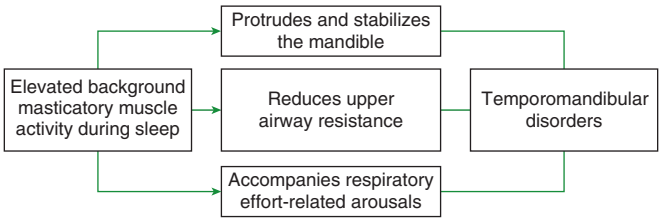

Figure 146-2 Hypothetical contributions of elevated masticatory muscle activity on the electromyogram (EMG) associated with sleep-disordered breathing (SDB) to temporomandibular disorders (TMDs). Some studies have reported increased EMG activity in the masticatory muscles of patients with SDB, and this increased activity could contribute to the elevation observed in patients with TMDs. Studies have suggested that the increased EMG activity in the masticatory muscles of patients with SDB is associated with mechanisms that maintain or restore airway patency or reflect a nonspecific increase associated with respiratory related arousals. However, further research is required to confirm a role for SDB in the increased EMG activity observed in TMD.

activity that is associated with jaw pain on waking, that is, masticatory muscle hypertonicity or elevated background sleep EMG activity occurring during nonbruxism periods. Recent findings indicate that patients with TMD have elevated levels of background sleep EMG activity compared with non-TMD control subjects[78] (Figure 146-1). Moreover, among the patients with TMD, background sleep EMG was positively associated with pain intensity ratings (on a 0 to 10 numerical scale) on morning waking, whereas the frequency of SB event–related EMG was negatively associated with the ratings, as has been observed in other investigations.[67,79] Nevertheless, the elevation in background sleep EMG activity found in patients with TMD persisted after institution of controls for numerous sleep parameters on which the groups did differ (e.g., RERAs, stage N1 shifts).

These observations indicate that patients who have elevated pain in the early morning may falsely attribute their pain to nighttime jaw muscle activity involving SB. This explanation, however, is only partially correct: Although jaw muscle activity may aggravate pain, low-level elevations of activity occurring outside of SB periods are more likely to be responsible for the morning pain aggravation. Of additional note, the increase in root mean square (RMS) EMG activity in the TMD group versus the control group occurring during background sleep EMG (outside of the period with RMMA) was approximately equal to the increase potentially attributable to regular tooth-to-tooth contact (within RMMA). This type of nonfunctional tooth contact during the awake state has been found to occur more often in individuals with TMD than in control subjects.[80-83] It is consistent with a body of experimental studies showing that low-intensity clenching (approximately 10% of maximum bite force) can cause pain and fatigue in the masticatory muscles.[84] Obviously, the clinical significance of and mechanism underlying this finding require further analysis.

Thus, on reviewing the evidence on the relation between SB and TMD pain, the best-quality studies do not support a convincing relationship. Rather, background masticatory muscle activity during sleep, outside of RMMA-SB periods, which is similar to low-intensity clenching or tooth-to-tooth contact during the day, is likely to be of greater pathogenic significance in the persistence of TMD pain. Furthermore, the understanding of any relationship between SDB and TMD cannot be simplified to a simple and single association with SB that is too often determined in clinical milieu. Given that masticatory muscle EMG activity may be elevated during sleep in persons with SDB even in the absence of clinical or EMG evidence of SB,[11,48-52] as described earlier in this chapter, we entertain the possibility that this elevated activity is of pathogenic significance in the persistence of TMD pain (Figure 146-2). This hypothesis is consistent with the stress-hyperactivity model of Ohrbach and McCall[85]:

> It is not the magnitude per se of the muscle activity in pain patients that is responsible for the nociception that leads to pain complaints. Rather, it is a persistent pattern of muscle reactivity, in the form of holding muscles in a particular shortened position, such as a 'braced jaw. ... (page 61).[85]

However, the prevalence of increased background masticatory muscle EMG activity during sleep in patients with SDB is unknown as well as whether patients with increased background EMG activity are more likely to develop or maintain TMD pain than patients who exhibit no increase.

OTHER MECHANISMS LINKING SLEEP-DISORDERED BREATHING TO TEMPOROMANDIBULAR DISORDERS

In addition to increased background masticatory muscle activity, other aspects of SDB may contribute to TMD. One

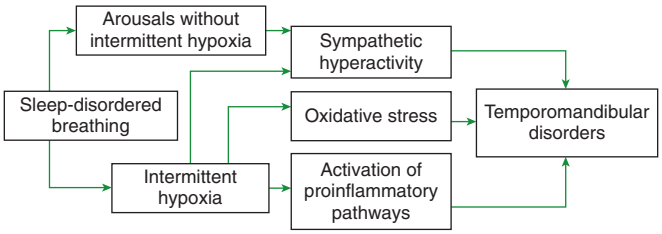

Figure 146-3 Hypothesized biologic pathways leading from sleep-disordered breathing to temporomandibular disorders. One pathway is mediated by arousal and sympathetic hyperactivity in the absence of intermittent hypoxia. A second pathway depicts an effect of intermittent hypoxia stimulating sympathetic hyperactivity, oxidative stress, and activation of proinflammatory pathways. At present, the evidence remains rudimentary and incomplete. Further studies are required to confirm these mechanisms.

innovative suggestion is that chronic intermittent hypoxia mediates the relationship between SDB and TMD. Intermittent hypoxia refers to the brief cyclic bursts of deoxygenation, arousal, and reoxygenation that uniquely characterize OSA or other forms of SDB. Discussed next is how three consequences of intermittent hypoxia—(1) sympathetic hyperactivity, (2) oxidative stress, and (3) activation of proinflammatory pathways—may promote TMD. For simplicity, Figure 146-3 depicts these relationships as unidirectional, whereas in reality some are bidirectional. As yet, these pathways are largely unexplored, and the supporting evidence remains incomplete. For complementary information on sleep related to the cardiac autonomic nervous system, breathing and hypoxia, host defense and immunity, and the endocrine stress response, the reader is referred to Chapters 14 to 17, 19 and 20, respectively, plus Chapter 133 for pain and sleep.

Intermittent Hypoxia, Sympathetic Hyperactivity, and Pain

Intermittent hypoxia increases sympathetic nervous system (SNS) activity,[86] and this response is measurable indirectly by heart rate variability (HRV). Decreased HRV typically is associated with morbidity, including pain disorders (see Chapters 23 and 133 for more information). In FMS, a pain condition characterized by widespread tender spots, decreased pain threshold, fatigue, and unrefreshing sleep (see also Chapter 131 on fibromyalgia in this volume), affected persons have lower HRV than control subjects both during wakefulness and during sleep.[35,87] Sympathetic hyperactivation during wakefulness also is associated with tension-type headache, migraine, sleep-related migraine,[88,89] irritable bowel syndrome,[90] and TMD.[91]

In the OPPERA case-control study of chronic TMD (described earlier), HRV in the TMD group was diminished at rest and in response to orthostatic and psychological challenges.[91] TMD cases also had a higher heart rate, another marker of sympathetic hyperactivity, in response to these orthostatic and psychological activities. The fact that cases showed a decrease in low-frequency band values at rest and during the orthostatic and Stroop activities provides further support of possible SNS dysfunction. Taken together, these autonomic measures imply a shift away from parasympathetic tone toward greater sympathetic tone in TMD cases relative to control data.[91]

The findings build on polysomnographic evidence[92] that subjects with myofascial TMD had a lower RMS successive difference of R-R intervals and lower HRV during sleep than pain-free control subjects. In addition, participants with TMD had lower high-frequency spectral power than control subjects, and the ratio of the low frequency to the high frequency was higher in subjects with TMD, suggesting a sympathetic cardiac dominance. Evidence of diminished nocturnal HRV was independent of sleep continuity and architecture, age, and psychological distress and was consistent with an SNS imbalance characterized as sympathetic hyperactivity.[92]

Hence, although separate lines of evidence indicate that intermittent hypoxia increases SNS activity and that sympathetic hyperactivity is associated with pain conditions including TMD, single studies have yet to combine these findings to show that sympathetic hyperactivity secondary to hypoxia from SDB increases risk of TMD onset or persistence.

Intermittent Hypoxia, Oxidative Stress, and Pain

Oxidative stress is a relatively less-studied mechanism through which intermittent hypoxia may contribute to TMD. Exposure to repeated episodes of hypoxia and normoxia stimulates overproduction of reactive oxygen species that overwhelms the protective capacity of antioxidant mechanisms, giving rise to oxidative stress.[93]

Elevated oxidative load is observed in several pain disorders. Patients with FMS have elevated oxidative stress, greater free radical damage, and lower total antioxidant capacity compared with control subjects.[94-97] Likewise, migraineurs have elevated oxidative stress[98,99] and lower levels of the antioxidant enzyme superoxide dismutase[100] than in control subjects. TMD cases with myofascial pain syndrome have lower total antioxidant capacity, higher total oxidative stress, and higher oxidative stress index values than in healthy control subjects, indicative of an imbalance in oxidative metabolism in the pain group.[101] In a clinical study that compared oxidative stress profiles in patients with TMD and control subjects,[102] the patient group showed higher levels of malondialdehyde, indicative of greater oxidative load, and higher levels of 8-hydroxydeoxyguanosine, indicative of greater oxidative damage. Furthermore, the patients with TMD had lower levels of total antioxidant status, consistent with a reduced antioxidant defense capacity.[102]

The evidence that intermittent hypoxia leads to oxidative stress is well established, whereas evidence linking oxidative stress to TMD and related pain disorders is still developing. Although the developing literature is small, it is noteworthy that studies show directional consistency in finding higher oxidative load in pain disorders. As is the status with SNS hyperactivity, single studies with strong designs are required to demonstrate clear pathways linking sleep disorders to oxidative stress and the development or persistence of pain.

Intermittent Hypoxia, Activation of Proinflammatory Pathways, and Pain

Intermittent hypoxia may influence pain through activation of the inflammatory process (see also Chapter 19, on sleep and host defense). A systematic review[103] of pooled data from 51 studies of 2952 OSA cases and 2784 control subjects found that inflammatory markers of C-reactive protein, tumor necrosis factor alpha, interleukins IL-6 and IL-8, intercellular adhesion molecule, vascular cell adhesion molecule, and selectins were significantly elevated in OSA cases compared with

the control group, with a dose-response relationship of higher levels of inflammation with greater OSA severity.[103]

Several animal and human studies have observed elevated secretion of inflammatory proteins in temporomandibular joint synovial fluid, secondary to sleep disturbance. For example, sleep deprivation in rodents induces activation of nuclear factor kappa B, which in turn leads to increased expression of several inflammatory proteins.[104] Although such reports confirm local inflammation in the temporomandibular joint, they fall short of demonstrating that TMD may be associated with systemic inflammation. Addressing this limitation is one such case-control study of 344 women, in which investigators compared circulating plasma levels of 22 cytokines and activity of 48 transcription factors in the women with TMD and in pain-free control women.[105] Levels of the proinflammatory monocyte chemotactic protein-1 and the antiinflammatory interleukin-1 receptor antagonist (IL-1ra) were significantly elevated in the TMD group.

If inflammation mediates a relationship between SDB and TMD, the finding is clinically important because inflammation can be lowered by treating SDB. A study of patients with OSA[106] showed that nasal CPAP decreased circulating intercellular adhesion molecule-1 and IL-8 levels, suggesting that the putative effects of intermittent hypoxia on inflammation can be reversed by treating OSA. Similarly, treatment of OSA with oral appliance therapy appears to lower circulating levels of inflammatory markers.[107] A logical conclusion of these studies is that lowering inflammation may be therapeutic or protective against pain.

Independent Effect of Intermittent Hypoxia

Intermittent hypoxia may influence pain independently of sympathetic hyperactivity, oxidative stress, and inflammation. Analysis of PSG oxygenation data for 634 Cleveland Family Study participants with SDB showed that a decrease in nadir oxyhemoglobin desaturation was associated with morning headache, headache disrupting sleep, and chest pain in bed, independently of proinflammatory protein levels and sleep fragmentation.[108] This finding is of particular interest and needs to be confirmed. (Additional information on sleep and pain interaction is available in Chapter 133.)

Respiratory Effort–Related Arousals, Sympathetic Tone, and Pain

Arousal from respiratory events may contribute to pain mechanisms independently of any intermittent hypoxia. In fact, even mild levels of airway resistance are sufficient to initiate RERAs in some susceptible people, and these have been associated with TMD and fibromyalgia (see earlier). One interesting suggestion is that apneas-hypopneas and RERAs evoke different responses to autonomic nervous system activity.[109] Although the arousals of apneas-hypopneas increase the ratio between low and high frequencies (in favor of a sympathetic tone dominance), one study found that abnormal inspiratory effort associated with RERAs lead to a decrease in the high-frequency component.[109] This finding is consistent with a stronger sympathetic influence in OSA and a stronger parasympathetic influence in UAR. Again, RERA and UAR are not fully comparable, but both are close proxies for breathing events that disturb sleep continuity.

It is becoming clear that RERAs are associated with pain conditions that overlap with TMD, including headache,[110] fibromyalgia,[30] and irritable bowel syndrome.[111] This correlation was demonstrated in a study, described earlier in this chapter, that compared sleep abnormalities on two-night PSG inpatients with myofascial TMD and healthy control subjects.[23] Although the two groups did not differ in daytime sleepiness or AHI values, the patients had a greater percentage of time in NREM stage 1 sleep and experienced almost twice as many respiratory arousals associated with apnea, hypopnea, and RERA events and a greater frequency of RERA events, independently of body mass index and demographic characteristics.

OTHER CONSIDERATIONS REGARDING AN ASSOCIATION BETWEEN SLEEP-DISORDERED BREATHING AND TEMPOROMANDIBULAR JOINT DISORDERS

The association between SDB and TMD is not limited to factors that might contribute to the initiation or persistence of the pain condition, as discussed previously. For example, insomnia is common in patients with TMD and is characterized by hyperarousability.[17,112] A lowered arousal threshold in the insomniac patient with TMD, coupled with the presence of pain, could evoke respiratory instability during sleep realized as RERAs or OSA.[113] Indeed, in one study described earlier, the frequency of RERAs was found to be directly related to the subjective ratings of myofascial pain during the night of the sleep study by participants with TMD.[23]

Another possibility is that both SBD and TMD are independent outcomes in the setting of unfavorable craniofacial anatomy. Although the correlation is highly controversial, some studies have reported anatomic risk factors for TMD.[114-116] Of interest, the major features identified (e.g., retrognathia, long or hyperdivergent face) also have been associated with OSA.[117-119]

CLINICAL PEARLS

- In clinical populations, a high prevalence of SDB has been observed in patients with TMDs and comorbid chronic pain conditions such as fibromyalgia syndrome. Patients with these idiopathic chronic pain conditions should be screened for SDB and treated as indicated.
- Both patients with SDB and those with TMD may report clenching or grinding their teeth during sleep. However, polysomnography that includes EMG of the masticatory muscles does not confirm the presence of SB in either group.
- Background masticatory muscle activity during sleep, outside of SB periods, which is similar to low-intensity clenching or tooth-to-tooth contact during the day, may be of pathogenic significance in the persistence of TMD pain and thus represent a putative risk factor for TMD.

SUMMARY

The widely held belief that bruxism, either sleep or awake, plays a major role in the development or persistence of TMD pain is not strongly supported by scientific evidence. Moreover, there is little evidence to support the premise of a cascade in time, in which SDB leads to SB, which in turns leads to TMD. Generalization of such beliefs, or a cause-and-effect

relationship, does not stand in large population studies or in studies using optimal assessment methods.

As various lines of evidence unfold, a much more complex set of interrelationships is emerging that may explain an association between SDB and TMD. Pathophysiologic mechanisms may involve elevated background levels of activity in the masticatory muscles during sleep and wakefulness, intermittent hypoxia during sleep, altered autonomic nervous system function, oxidative stress, and inflammation. Readers are cautioned that although the evidence in support of these mechanisms is growing, at this time the evidence base remains rudimentary and causal associations are not yet established. Identification of the roles of stress, anxiety, and/or cognitive arousal in patients with TMDs, and their influences on sleep continuity and breathing, are other research avenues of major interest. Findings not only will affect clinicians' ability to care for patients with TMD but also will strengthen the current understanding of the interaction of pain and poor sleep.

Chapter 147

Oral Appliances for the Treatment of Obstructive Sleep Apnea–Hypopnea Syndrome and for Concomitant Sleep Bruxism

Christopher J. Lettieri; Fernanda R. Almeida; Peter A. Cistulli; Maria Clotilde Carra

Chapter Highlights

- Oral appliances are an accepted and reliable treatment option for patients with snoring and obstructive sleep apnea–hypopnea syndrome (OSAHS). They are currently indicated for patients with mild to moderate OSAHS; however, they have been shown to be effective in patients with more severe disease. Oral appliances are most effective in younger, thinner patients with mild to moderate OSAHS. They are less likely to be effective in obese patients.
- In general and especially for more severe disease, custom-made titratable devices offer superior treatment and a greater likelihood for successful therapy than other types of oral devices. Successful therapy is more likely to be achieved by performing an at-home progressive titration using a custom-made titratable device. This may be further enhanced by the application of adjunctive means to monitor the therapeutic response.
- Oral appliances are not as effective as positive airway pressure devices for reducing the apnea-hypopnea index and other sleep measures. However, short- and long-term improvements in daytime somnolence, quality of life, neurocognitive function, and cardiovascular outcomes (primarily blood pressure) appear to be similar with both treatments.
- Oral appliances are generally well tolerated, and serious side effects or adverse consequences resulting in discontinuation of therapy are uncommon. Malocclusion is the most common long-term effect. However, this typically does not lead to discontinuation of therapy and may be mitigated by simple exercises each morning after removal of the device.
- Concomitant sleep bruxism (SB) with OSAHS is common. Although the true etiologic nature of these disorders is not fully understood, there appears to be a modest causal relationship. Patients with SB and symptoms of OSAHS should be assessed for underlying sleep-disordered breathing as common SB occlusal splint therapies may, in some cases, worsen obstructive events if they are not recognized.
- Oral appliances appear to provide adequate therapy for both OSAHS and SB alone or in comorbidity.

Currently, positive airway pressure (PAP) remains the most accepted, common, and efficacious management tool for obstructive sleep apnea–hypopnea syndrome (OSAHS). In this chapter, we use the word *treatment*, although we recognize that most devices or appliances do manage sleep-disordered breathing (SDB), in the whole spectrum from snoring to severe OSAHS, whereas some residual apnea and hypopnea, oxygen desaturation, high blood pressure, inflammation, sleepiness, and cognitive alterations, although improved, may persist over time. However, given the ongoing challenges related to the acceptance of and adherence to PAP therapy, there remains an increasing need for reliable and effective treatment alternatives (e.g., appliance, nerve stimulation, sleep positioning devices). Oral appliances (OAs) of various designs are a solid alternative used to manage OSAHS, sleep bruxism (SB), and both when they are concomitant.

The main objective of this review is to describe the use of OAs for OSAHS, with special attention to SB. Other management tools for OSAHS are described in more detail in Chapters 115 and 116 for devices and medications, Chapter 149 for surgeries, and Chapter 150 for other alternatives. SB and orofacial pain are conditions, although they can be concomitant with SDB and obstructive sleep apnea, and are further described in Chapters 144 to 146.

WHY USE ORAL APPLIANCES FOR SLEEP-DISORDERED BREATHING AND OBSTRUCTIVE SLEEP APNEA–HYPOPNEA SYNDROME?

OAs offer effective therapy for many patients with simple (primary) snoring and OSAHS and have become a proven, validated, and accepted treatment option. With the release of

numerous clinical trials and published practice parameters establishing their efficacy and the expanded availability of these devices, OAs have become an increasingly common treatment modality for patients with SDB.

OAs offer several advantages over PAP. They are generally well tolerated in most individuals, and published reports have consistently shown that therapeutic adherence and patient preferences are as good as if not superior to those with PAP.[1,2] In addition, these devices do not require a ready and reliable source of electricity and may be easier to use, especially during travel or for people who live in an area with restricted access to electricity (e.g., sailors, fishermen, humanitarian workers, military).

As published in the American Academy of Sleep Medicine's "Practice Parameters for the Treatment of Snoring and Obstructive Sleep Apnea with Oral Appliances: An Update for 2005," these devices are recommended as primary therapy for patients with snoring and mild to moderate OSAHS or as a reasonable treatment alternative in patients who prefer these devices to PAP or are intolerant of other therapies.[3] An update to these Practice Parameters is scheduled to be published by the American Academy of Sleep Medicine in 2015.

The route to the current best accepted practices encompasses the role of the physician and dentist[4] in the proper selection of the patient and device and the need for an interdisciplinary approach to the appropriate application and ongoing care of OA therapy.

TYPES OF ORAL APPLIANCES FOR SLEEP-DISORDERED BREATHING AND SLEEP BRUXISM

For SDB and OSAHS management, two broad OA types in common clinical use are mandibular repositioning appliances and tongue-repositioning devices. Mandibular repositioning appliances, also known as mandibular advancement splints (MAS) or mandibular advancement devices, are the focus of this chapter as they are more widely used in clinical practice and have a greater evidence base. Numerous design types are available, but these devices generally fall into either one-piece (monobloc) or two-piece (duobloc) configurations. They can differ substantially in size, type of material, degree of customization to the patient's dentition, and coupling mechanisms. In addition, the amount of occlusal coverage, adjustability of mandibular advancement, degree of mandibular mobility permitted (vertical and lateral), and allowance for oral respiration also vary between the different available devices.

This chapter focuses on customized OAs for managing OSAHS. Although prefabricated MAS exist, many of which are available over the counter, there is a paucity of outcome measures validating their clinical use. Whereas these devices may offer a reasonable and cost-effective treatment, particularly for simple snoring, the existing data show limited efficacy and lower acceptance rates compared with customized OAs.[5,6] As such, prefabricated devices are not recommended for clinical use in patients with OSAHS.

Two-piece OAs have become more commonly used in clinical practice and consist of removable upper and lower plates that are coupled together to promote advancement of the mandible and to mitigate subluxation during sleep. There are a variety of modes of coupling between the upper and lower plates, including elastic or plastic connectors, metal pins and tube connectors, hook connectors, acrylic extensions, and magnets. Duobloc splints offer advantages over monobloc devices by allowing adjustability, which facilitates achievement of the most comfortable and efficient position of the mandible and greater degree of lower jaw movements. OAs that permit lateral jaw movement or opening and closing while maintaining mandibular advancement may offer additional advantages by reducing the risk of complications and improving the patient's comfort and acceptance. Because the patient's tolerance to the amount of protrusion increases over time, splints capable of incremental advancement seem to have a clear practical advantage. These adjustable devices also facilitate improved efficacy as they can be titrated to a more optimal setting needed to ablate obstructive events. Although prefabricated appliances ("off the shelf") are commercially available, their efficacy and potential role as a "trial" device have been called into question.[6] The best retention, comfort, and efficacy are achieved with custom-made, titratable OAs. Further comparisons between the different available types of OAs and potential advantages in the management of patients with SDB are discussed later in this chapter.

The most frequently used OA for SB management (i.e., preventing grinding sound and tooth wear and possibly reducing pain) is the occlusal splint (a one-piece monobloc) that can be custom made to fit either the upper or lower jaw. The efficacy in the short term is recognized, but in patients with OSAHS, it is to be used with caution because, as described later, it may exacerbate their condition. In some subgroups of patients, in their lifetime course, it is possible that SB and OSAHS coexist. Although some association was found, as described later and in Chapters 145 and 146, it is premature to conclude that SB causes SDB or the reverse, that SDB causes SB; association is not causality.

ORAL APPLIANCE MECHANISM OF ACTION

Current evidence suggests that OSAHS pathogenesis reflects reduced upper airway size and altered upper airway muscle activity, resulting in diminished patency and airflow obstruction (see Sections 3 and 14 in this volume for more information). Although it has been thought that the primary mechanism of action of OAs arises from the anterior movement of the tongue and consequent increase in the anteroposterior dimensions of the oropharynx, it appears that this is an overly simplistic view. Many studies using a range of imaging modalities, including computed tomography, magnetic resonance imaging, and nasoendoscopy, suggest that OAs induce more complex anatomic changes.[7-10] An increase in airway volume appears to result, in large part, by an increase in cross-sectional area of the velopharynx, in both the lateral and anteroposterior dimensions, and increases in the lateral dimension of the oropharynx. Figure 147-1[10] illustrates the effects of an OA and tongue-stabilizing device on the upper airway. These changes are thought to be mediated through the palatoglossal and palatopharyngeal arches, which link the muscles of the tongue, soft palate, lateral pharyngeal walls, and mandibular attachments. Interindividual variability in the airway configurational changes that occur with mandibular advancement may reflect variations in anatomy, and this is likely to have major relevance to the variable clinical response associated with this treatment modality.

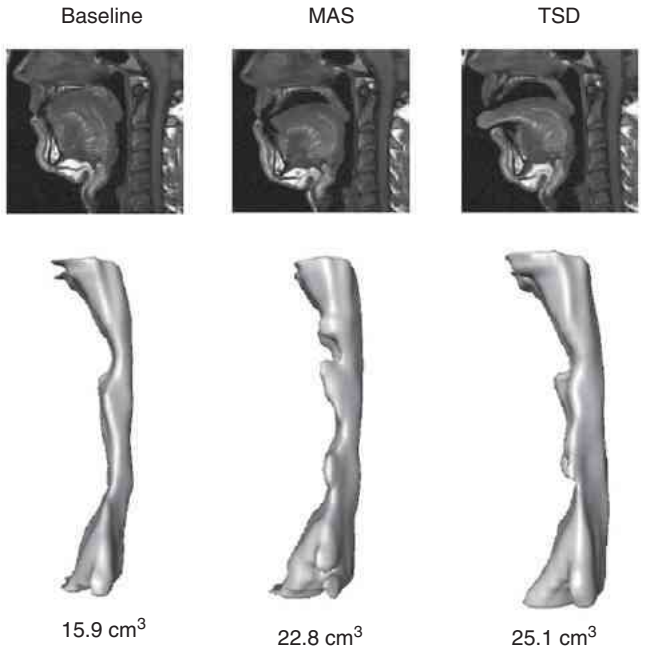

Figure 147-1 Modes of action of mandibular advancement splint (MAS) and tongue-stabilizing device (TSD). Magnetic resonance imaging representation of the increase in upper airway volume while patients have the appliance in place. (From Sutherland K, Deane SA, Chan AS, et al. Comparative effects of two oral appliances on upper airway structure in obstructive sleep apnea. *Sleep* 2011;34:469–77.)

Anatomic imbalance has been proposed as an underlying mechanism in the pathogenesis of OSAHS.[11] In this model, excess tissue within the bony enclosure must be present to generate sufficient tissue pressure to collapse the airway lumen. This extraluminal tissue pressure occurs in the context of either an excess of soft tissue within a normal bony enclosure size or a normal amount of tissue compressed into a reduced bony enclosure. Mandibular advancement delivered by OAs effectively enlarges the bony enclosure and appears to improve anatomic balance.[12]

The effects of OAs on upper airway neuromuscular pathways have not been well studied to date. Whereas some studies indicate that these devices stimulate genioglossus muscle activity,[13,14] studies using inactive "sham" OAs have shown little change in SDB.[15,16] This suggests that mechanical advancement of the mandible is the primary mechanism of action of these devices. This mechanical effect results in greater airway stability, which is evidenced by a reduced upper airway closing pressure during sleep.[17] This effect was demonstrated in a study of anesthetized OSAHS patients by Kato et al,[18] who observed dose-dependent reductions in closing pressure of all pharyngeal segments with progressive mandibular advancement.

CLINICAL OUTCOMES AND MEASURES OF SUCCESS

Since the last published guidelines on the use of OAs in the treatment of OSAHS,[15,16,18-23] there has been a substantial increase in the quantity and quality of clinical trials evaluating the efficacy and effectiveness of OA therapy[2,24-27] (see Figure 147-2). Several trials, including prospective designs using placebo arms and sham comparisons, have produced a high level of evidence and have allowed stronger treatment recommendations. In addition, trials assessing the treatment response between OAs and other primary therapies for OSAHS focusing on clinically important outcomes help further the understanding of appropriate patient selection and the expected therapeutic effect. In short, OAs have been shown to have a good level of efficacy in improving polysomnographic measures, daytime somnolence, quality of life, cardiovascular outcomes, and neurocognitive function for patients with both simple (primary) snoring and OSAHS.

Snoring

Several placebo-controlled trials have found that OAs reduce both subjective and objective measures of snoring frequency and intensity among nonapneic patients with habitual (primary) snoring.[17,19,22,23,28,29] OAs have also been shown to improve quality of life measures in nonapneic snorers. In one trial, the use of OAs produced a mean improvement in Functional Outcomes of Sleep Questionnaire (FOSQ) scores by 3.21 (95% confidence interval, 2.82–3.60; $P < .001$) among patients with habitual snoring.[29]

Polysomnographic Variables and Reduction of the Apnea-Hypopnea Index

OAs have been well established as an effective treatment in the management of OSAHS. There is strong evidence from randomized, controlled trials that these devices produce a significant reduction in the apnea-hypopnea index (AHI) across the full spectrum of OSAHS severities. Abolition of obstructive events to an AHI less than 5 events/hour is achieved in 36% to 70% of patients.[15,16,26,30-32] With use of an AHI threshold of less than 10/hour, OAs provide successful therapy in 30% to 86%.[2,18,30] The likelihood of successful treatment is progressively greater with lower severities of disease. Table 147-1 illustrates success rates with OA therapy according to different disease severity at baseline.

Daytime Somnolence and Quality of Life Measures

OAs have been shown to improve daytime sleepiness and quality of life in patients with OSAHS. In one trial, improvements in daytime somnolence were significantly better with customized OAs compared with nontherapeutic devices.[33] Specifically, the Epworth Sleepiness Scale (ESS) score decreased from 14.7 ± 5.1 to 5.1 ± 1.9 ($P < .05$) in those receiving OA therapy compared with 16.3 ± 2.5 to only 13.6 ± 6.7 (P = NS) in the nontherapeutic group. Similarly, in a long-term follow-up study, OAs produced a decrease in ESS from 13.9 ± 1.3 to 9.3 ± 1.2.[28] OAs have also been shown to improve objective measures of sleepiness. In a placebo-controlled trial, 4 weeks of OA therapy led to an additional improvement in the mean sleep latency on the Multiple Sleep Latency Test of 1.2 minutes compared with an inactive control oral device.[28] Two additional trials evaluating objective measures of wakefulness found that the improvements in Maintenance of Wakefulness Test were similar between both PAP and OA therapy.[1,34] Across numerous published studies, the improvement in both subjective and objective measures of somnolence achieved with OAs appears to be similar to that reported with PAP therapy. However, as with PAP, whereas OAs are shown to improve daytime somnolence,

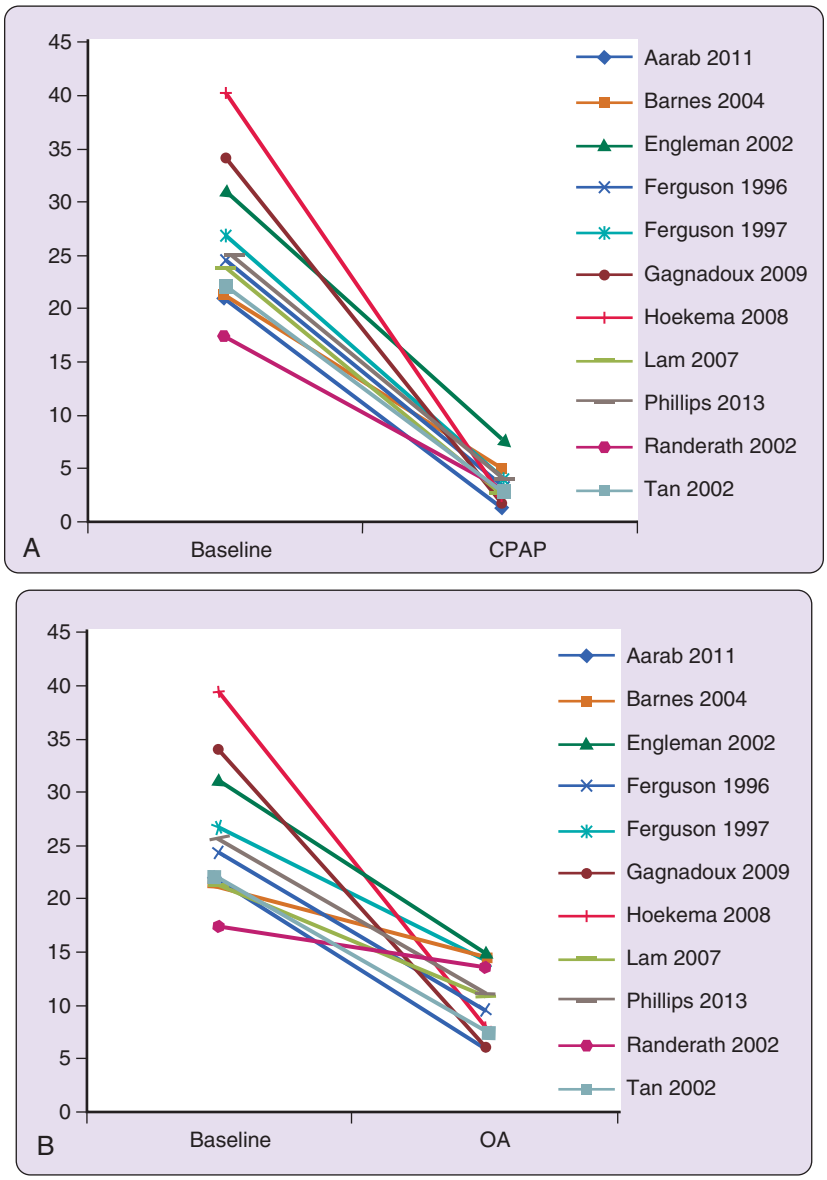

Figure 147-2 Average decrease in apnea-hypopnea index (AHI) from published randomized controlled trials. CPAP, Continuous positive airway pressure; OA, oral appliance.

residual sleepiness may persist despite otherwise adequate therapy.

Compared with no treatment or nontherapeutic (sham) therapy, OAs have also been shown to significantly improve quality of life measures in patients with OSAHS. In one trial, overall FOSQ scores improved by 27.1% from baseline ($P < .001$; effect size, 0.90) in those using a customized OA compared with a –1.7% decline in those using a nontherapeutic sham device.[33] In a randomized, controlled trial comparing OA therapy with a placebo tablet, mandibular advancement produced superior improvements in quality of life as measured by the FOSQ and 36-Item Short Form Health Survey overall health score.[1] The magnitude of improvement was similar to that found with PAP.

Cardiovascular Outcomes

Several studies have addressed the impact of OA therapy on measures of systolic blood pressure.[1,2,29,32,35-39] Overall, OAs were found to lower the systolic, diastolic, and mean blood pressure (Table 147-2). Further, the results from three randomized trials suggest that OAs are as effective as PAP in reducing blood pressure measures.[1,2,32] These studies are largely limited to custom-made, titratable devices. One small, randomized, controlled trial of 36 patients using nontitratable OAs failed to observe significant changes in either the systolic or diastolic blood pressure.[35]

OAs have also been shown to produce significant improvements in endothelial function and markers of oxidative stress similar to those observed with PAP therapy.[1,2,27,32,40] However, as with PAP therapy, the available data suggest that OAs produce only modest reductions in blood pressure recordings and other cardiovascular end points.

Whereas blood pressure and other markers of cardiovascular health have shown small but significant improvements, two studies evaluating cardiovascular morbidity and mortality noted a marked cardiovascular risk reduction with OA

therapy.[41,42] In a study of patients with mild to moderate OSAHS receiving either OA or PAP therapy, there was a marked cardiovascular risk reduction of at least 38%.[42] Recently, a study focused on severe sleep apnea patients described no difference in the cardiovascular death rate of those receiving either treatment.[41]

Despite the limited literature and the presence of residual apneas with OA therapy, the current studies available have shown continuous PAP (CPAP) and OA to be equally effective in the reduction of cardiovascular events.

Neurocognitive Outcomes

OA therapy has been shown to improve neuropsychological functioning. In a trial comparing OAs, PAP, and a tablet placebo for mild to moderate OSAHS, OA therapy improved tension-anxiety, divided attention, and executive functioning compared with placebo.[1] However, PAP was superior to OAs in improving psychomotor speed and mood. Similarly, treatment with an OA was found to significantly improve attention, vigilance, and motor speed, as measured by the distraction–working memory test and continuous performance.[43] In contrast, other trials have failed to demonstrate improved neurocognitive function after OA therapy despite improvements in other measured end points.[1,34,44]

Despite the similarity to PAP, the existing literature shows mixed results with only modest improvements in neurocognitive measures for patients undergoing OA therapy.

Table 147-1 Success Rates with Oral Appliance Therapy according to Different Disease Severity at Baseline

OSA Severity at Baseline	Mild	Moderate	Severe
Success			
Study A	62.3%	50.8%	39.9%
Study B	56.6%	48.1%	21.2%
Partial success			
Study A	13%	25%	24.3%
Study B			
Failure			
Study A	30.4%	26.9%	54.5%
Study B			

The results are expressed in percentage from two trials using custom-made titratable oral appliances: Study A, Holley et al[60] and Study B, Phillips et al.[2] Success is described as an apnea-hypopnea index (AHI) <5 with oral appliance therapy; partial success is at least 50% reduction in AHI but AHI >5; and failure represents <50% reduction in AHI.

OUTCOME COMPARISON BETWEEN TYPES OF ORAL APPLIANCES AND POSITIVE AIRWAY PRESSURE THERAPY

Fixed versus Adjustable Appliances

Customized, individually fabricated MAS are either fixed (nonadjustable) or titratable (adjustable). Nonadjustable devices are monobloc or single-piece appliances in which the degree of mandibular advancement is permanently fixed. Titratable appliances (adjustable or duobloc) allow adjustments in the degree of mandibular protrusion to optimize treatment efficacy. This is an important distinction both in selection of the most effective treatment and in understanding the published literature. Published studies using fixed or single-jaw position appliances may underestimate the impact of OA therapy compared with titratable appliances.[1,25,27,34,45] Titratable or adjustable appliances allow progressive protrusion of the mandible, and the amount of anteroposterior mandibular movement varies considerably among patients. Previous studies have shown that OA efficacy is related to the amount of mandibular advancement.[18,46,47] Determining the optimal degree of mandibular advancement is the most

Table 147-2 Impact of Oral Appliance Therapy on Blood Pressure Measurements in Different Clinical Trials

Author	Mean ΔSBP	Mean ΔDBP	Mean Δ24-h SBP	Mean Δ24-h DBP	Mean ΔNight SBP	Mean ΔNight DBP

Measurements are in millimeters of mercury. Some studies have only clinical blood pressure, whereas some also describe 24-hour blood pressure. A negative change (Δ) in blood pressure refers to a reduction of the blood pressure.
*Refers to a nighttime clinical blood pressure, not 24-hour assessment.
SBP, Systolic blood pressure; DPB, diastolic blood pressure.

important step in using OA therapy successfully.[48,49] As an analogy, titration of OAs is similar to PAP. The amount of pressure (or degree of mandibular advancement) required for each patient cannot be predetermined on the basis of OSAHS severity or patient-specific characteristics. Objective assessment of the treatment response at progressive increases in the delivered pressure (or advancement) is needed to determine the optimal treatment for each individual patient to optimize the ablation of obstructive events. A systematic review of different types of MAS concluded that there is no one MAS design feature that influences treatment efficacy, although efficacy does depend on the degree of mandibular protrusion and whether the device is a fixed or titratable appliance.[50] The comparison of the efficacy rates between fixed and titratable appliances has demonstrated titratable devices to be superior in their ability to reduce the AHI for patients at all levels of OSAHS severity.[51] Although fixed devices were frequently effective in patients with mild sleep apnea, they had high failure rates in those with moderate or severe disease. These studies reinforce that in future meta-analysis of treatment outcomes, fixed single-jaw positioners should not be evaluated together with titratable devices as these therapies have different treatment outcomes.

Oral Appliances versus Positive Airway Pressure Therapy

Several published randomized controlled trials and crossover studies have compared the efficacy of OAs to PAP in the treatment of OSAHS.[52] As seen in Table 147-3, although both PAP and OAs led to improvements in objective sleep measurements such as AHI, arousal index, and minimum arterial oxygen saturation, the magnitude of improvement in AHI is significantly greater with PAP. Although statistically superior, these differences are not necessarily clinically significant. OAs decrease both subjective and objective measurements of snoring in the majority of the patients.[15,31,53] This reduction is less robust than with PAP, which frequently uses the elimination of snoring as an objective assessment of treatment efficacy. Subjective and objective measurements of sleepiness are similarly improved with both forms of therapy.

Both OAs and PAP have been shown to be superior to placebo or no treatment in improving quality of life measures.[24] With a disease-specific questionnaire, the FOSQ, both treatments similarly improved quality of life. Direct comparative studies (randomized controlled trials) demonstrated that both OAs and PAP are effective in improving quality of life, with each treatment providing certain advantages in specific subcategories.[2] Whether this reflects a true difference between the effects of each treatment or is a product of differing study designs and data collection is uncertain. Regardless, it appears that both forms of therapy are similarly effective, and both are highly dependent on the patient's compliance. Given that adherence with OAs is typically superior to that with PAP, outcomes in clinical practice may favor these devices over PAP, particularly for mild and moderate OSAHS.

Whereas both OAs and PAP significantly reduce the AHI, PAP has been consistently shown to be superior in this measured outcome. Table 147-3 shows the results of randomized controlled trials and their average reduction in AHI. However, there is equivalence in overall health outcomes with both therapies. This may reflect that the greater efficacy of PAP is offset by inferior compliance relative to OAs, resulting in similar effectiveness. In other words, higher adherence rates with OAs likely translate into a similar mean disease alleviation and consequently similar effectiveness compared with PAP.[54] These findings strongly challenge current practice parameters recommending that OA treatment should be considered only in patients with mild to moderate OSAHS or in those who have failed to respond to or refuse PAP treatment. Long-term comparative effectiveness studies of these two treatment modalities are clearly needed.

PATIENT AND DEVICE SELECTION

Proper selection of the patient and device can increase the likelihood of success, improve the therapeutic effect, and enhance outcomes. There are multiple factors that should be considered in determining which patients are ideal candidates for OA therapy. Similarly, there are multiple different types, designs, and brands of OA devices, each with its inherent advantages and limitations. Understanding these factors can aid clinicians in making appropriate treatment decisions.

Indications and Contraindications

The American Academy of Sleep Medicine's Practice Parameters on OAs in the treatment of SDB advocate the use of these devices in patients with mild to moderate OSAHS who prefer this form of treatment to PAP or who do not respond to or are unable to tolerate PAP.[3] Since these guidelines were published, the evidence base supporting the use of OA therapy has grown considerably and suggests that clinicians should use custom-made titratable OAs as first-line therapy or as an alternative to PAP as an effective and reliable means to improve physiologic sleep measures, daytime sleepiness, and quality of life in adult patients with OSAHS.

Selection of appropriate patients for OA therapy, based on the likelihood of successful treatment, remains a somewhat elusive goal at present. Whereas considerable research has attempted to identify the factors that predict a good response, the clinical utility of such approaches remains to be proven. In general, younger, thinner patients with positional OSAHS and an overall lower AHI appear to be the preferred candidates for OA therapy. However, in the absence of clear selection criteria, the clinician should rely on clinical judgment and the patient's preference when choosing the appropriate therapeutic approach.

Dentists experienced in dental sleep medicine have a prominent role in determining whether a patient is an ideal candidate for OA therapy. Patients require a sufficient number and location of healthy teeth to retain the device and to promote mandibular advancement. Specifically, patients require a minimum of eight teeth in the upper jaw and in the lower jaw, with at least two teeth in each quadrant.[55] In addition, the patient should have the ability to protrude the mandible forward to achieve a therapeutic result.

Not all patients are suitable candidates for the use of OAs because of associated medical or dental conditions and factors. In general, PAP affords a more prompt initiation of therapy. A major clinical limitation of OA therapy is in circumstances in which there is an imperative to commence more immediate treatment as there are inherent delays to attaining optimal therapy with use of these devices. This includes situations involving severe symptomatic OSAHS (e.g., concern about

Table 147-3 Summary of the Outcomes of Randomized Controlled Trials Comparing Oral Appliances with Continuous Positive Airway Pressure

Study	Design	No. of Subjects (% Male) [Withdrawals]	Inclusion	Oral Appliance	Treatment [Washout] Duration	Baseline AHI	Treatment AHI		OA vs. CPAP		
							CPAP	OA	AHI	ESS	Patient Preference
Aarab, 2010[27]	Parallel (*placebo group included*)	57 (74%) (20 OA/18 CPAP) [7]	AHI 5–45 + ESS ≥ 10	Customized, two-piece, set 25%, 50%, or 75% advancement, depending on sleep study results at each level	24 weeks	CPAP: 20.9 ± 9.8 OA: 22.1 ± 10.8	1.4 ± 13.1	5.8 ± 14.9	↔ (*P* = .092)	↔	N/A—parallel groups

driving risk or profound daytime impairments) and coexistent medical comorbidities, such as ischemic heart disease. Moreover, this treatment modality has no known role in treating central sleep apnea or hypoventilation states. In addition, some case reports have shown worsening of OSAHS severity in some patients using OAs.[22,56] This, together with the known potential for a placebo response, highlights the need for objective verification of treatment outcome using in-laboratory or home sleep testing with an OA in place at its prescribed, therapeutic position.[15,16] Patients with temporomandibular joint (TMJ) problems may require concomitant use of exercises to be able to adhere to OA therapy.[57] Long-term use of OAs results in few or no TMJ problems.[58] The presence of periodontal disease may promote excessive tooth movement or worsening of dental caries with an OA. These factors tend to limit the scope and application of this form of therapy; it is therefore highly important that a dentist with expertise in sleep medicine assess dental and TMJ health before initiation of therapy.

Predictors of Successful Oral Appliance Therapy

An important and currently unresolved issue limiting the role of OAs for the treatment of OSAHS is the inability to reliably predict an effective response to treatment. Ultimately, the response to therapy is likely to be related to multiple patient factors, device features, and clinical expertise of the treating provider. Patient factors, including anthropomorphic and polysomnographic variables, have been the subject of numerous studies. Clinical features reported to be associated with better outcomes and greater likelihood of success include younger age, lower body mass index, supine-dependent OSAHS, lower AHI, smaller oropharynx, less overjet, shorter soft palate, and smaller neck circumference.[59] In general, it is considered that a good response is more likely in mild to moderate OSAHS, although benefit in severe OSAHS has been reported.[2,60,61] Cephalometric measures, such as a shorter soft palate, longer maxilla, and decreased distance between mandibular plane and hyoid bone, either in isolation or in combination with other anthropomorphic and polysomnographic variables, are thought to provide some predictive power regarding successful therapy with OAs.[16,61]

Physiologic studies indicate that retroglossal rather than velopharyngeal collapse during sleep is highly predictive of OA success.[62] Physiologic measurements during wakefulness, including nasal resistance and flow-volume loops, have been reported to differ between OA responders and nonresponders.[63,64] However, upper airway imaging during wakefulness may aid in predicting the treatment response. Upper airway magnetic resonance imaging studies suggest that although baseline airway and soft tissue anatomic characteristics may not differ between responders and nonresponders, the changes consequent to mandibular advancement do differ such that increases in airway volume are reasonably predictive of a favorable outcome.[65] Furthermore, computational modeling techniques further add to the information that can be derived from sophisticated imaging and appear to enhance these predictions.[66] Whereas such studies are helpful in understanding fundamental mechanisms of airway collapse during sleep and the mechanism of OA therapy, the clinical utility of such approaches is limited by cost and accessibility. Nasoendoscopy offers a more clinically accessible imaging modality. Studies during both wakefulness and drug-induced sleep[67,68] have established the predictive potential of this technique. Lateral widening of the velopharynx during awake endoscopy in the supine position is associated with a higher response rate with OAs.[67] Drug-induced sleep endoscopy has shown good sensitivity for predicting treatment success by allowing visualization of the magnitude and patterns of pharyngeal collapse and identifying patients with greater improvements in pharyngeal patency with mandibular advancement.[69] See Chapter 148 for more information.

Remotely controlled mandibular positioning devices offer a relatively novel approach to identifying individuals who will or will not respond to OA therapy.[70-72] During a single-night titration procedure, these devices use hydraulic or electronic means to incrementally advance the mandible during sleep to determine both the treatment responsiveness and the required degree of advancement to ablate obstructive events. In addition, this may help establish tolerability for OA devices before costly acquisition. A prospective study using a commercially available system demonstrated that it is feasible both to predict treatment outcome and to determine the required "dose" of mandibular advancement during a single-night titration polysomnographic study.[71]

Appliance Selection

It is the sleep dentist's role to determine the most appropriate type of appliance based on specific clinical features to ensure that the patient is provided the most efficacious and cost-effective therapy. Given the wide variability in the reported efficacy across different studies, there is a strong suggestion that OA design has an important influence on treatment outcomes. Duobloc OAs, consisting of upper and lower plates, offer the advantage of a greater degree of mandibular movement (vertical and lateral) and adjustability (advancement), permitting attainment of the most comfortable and efficient position of the mandible. It is generally considered that the best retention is achieved with OAs that are customized and individually fabricated from the patient's dental impressions.[73]

Associated dental conditions, such as bruxism, may influence the choice of appliance design. As discussed later in this chapter, sleep bruxism/tooth grinding is common in patients with OSAHS,[74] although the causal relationship between the two conditions is unclear[31] (see Chapters 144–146). Patients who experience jaw discomfort after wearing a rigid monobloc OA may benefit from using an appliance that allows lateral and vertical jaw movement.

Another important consideration is the vertical dimension of the OA. Minimum vertical opening depends on the amount of overbite. There are conflicting data on the effect of the degree of bite opening induced by OAs on treatment outcomes, although most patients appear to prefer minimal interocclusal openings.[75] In mouth-breathing patients, the selected OA design should have an anterior opening to permit comfortable breathing. In the case of edentulous patients wearing partial dentures, the splint design selected for that patient should adapt to the remaining natural dental structures when the dentures are removed. Whereas tongue-repositioning devices have a limited role in the treatment of OSAHS, they may play a role in individuals with insufficient teeth who fail to respond to or are not tolerant of other therapies.

A number of studies comparing the efficacy of different OA designs have emerged recently.[28,76,77] A retrospective analysis of 805 patients using either an adjustable OA or a fixed device found a higher treatment response rate for adjustable devices (56.8% vs. 47.0%).[77] Two crossover studies have compared two-piece adjustable appliances with different advancement mechanisms and found similar improvements in AHI, symptoms, and side effects.[28,76] One study assessing the addition of tongue protrusion using an anterior tongue bulb on an existing OA device showed further reductions in AHI compared with mandibular advancement alone.[78] These studies suggest that appliance design features are relevant to treatment efficacy, patient tolerance, and use and highlight the need for further research to differentiate the advantages of different OA designs and to aid in the appropriate appliance selection in clinical practice.

OPTIMIZATION OF TREATMENT

Although similar in concept, the optimization of OA treatment is different from that of PAP, which can be performed either during polysomnography or with an automatic/autotitrating PAP platform. One of the main differences is that patients may not be able initially to tolerate the degree of mandibular advancement required to completely relieve obstructive events and may require several months of progressive mandibular advancement to achieve a therapeutic position.[18,46,47,79] Several studies have evaluated whether titration of mandibular advancement during polysomnography could be used to optimize OA treatment, similar to PAP titrations.[47,70,80,81] These protocols have mixed results and only a fair sensitivity in predicting the amount of mandibular advancement needed for successful OA therapy. A remotely controlled mandibular positioner[80] using a success criterion of less than 10 events/hour and 50% improvement with a 4% oxygen desaturation criterion showed a positive and negative prediction value for subsequent successful OA therapy of 94% and 83%, respectively. These studies are promising, but non–industry-supported studies are required to further assess the prediction of treatment outcome with this tool.

The use of a systematic, home-based titration in which patients incrementally advance their devices until subjective improvements in sleep quality and daytime symptoms are achieved is significantly more likely to render more effective OA therapy. Studies have shown that although 55% of patients achieve successful self-titration at home, another 32% can reach success with further polysomnography-guided titration.[48,82] Similarly, the use of home oximetry during titration does help titrate OAs.[49,82] Interestingly, 25% of the patients required additional mandibular advancement because of an abnormal oxygen desaturation index despite resolution of symptoms, whereas 20% of patients required further titration because of persistent symptoms despite a normal oxygen desaturation index.

Similar to PAP, appropriate OA titration is vital to achieve optimum therapeutic efficacy. Successful therapy requires both a dentist with experience in OA treatment to ensure proper adjustments of these devices and a sleep physician who should conduct follow-up evaluations and sleep testing to confirm that effective treatment is achieved. The dentist should observe patients on a yearly basis and may advance/titrate the appliance further if symptoms recur. If maximum mandibular advancement is reached and symptoms are still present, the patient should be referred to the referring physician for further evaluation and consideration of adjunctive or alternative therapies.

The other concept of optimization of treatment is the combination of treatment modalities. One study included patients who were unable to tolerate CPAP because high pressure was required to abolish the apneas. The combination of CPAP with an OA, not interconnected but used simultaneously, resulted in a CPAP pressure reduction of about 2 cm H_2O.[83] Another form of combination is to use the treatments interchangeably. Interestingly, when patients have the opportunity to use either treatment on a regular basis, patients tend to fluctuate between therapies. When patients compared the sleepiness while receiving CPAP only, they showed a significant decrease in their ESS score when they were able to use both treatments. One could hypothesize that patients were less likely to occasionally drop treatment, and therefore the long-term effects on sleepiness were further consolidated.[84] The combination of positional therapy with OA therapy has also been shown to improve clinical outcomes.[85]

Optimization of OA treatment, as described here, is indeed important and can be related to proper titration of the appliance and also the ability to offer combination therapies.

SIDE EFFECTS AND COMPLICATIONS

The primary reasons for discontinuation of OA treatment are an insufficient reduction of snoring, the persistence of apneic events, and the development of treatment-related side effects.[21] The most common reasons that patients completely discontinue OA therapy are device discomfort/cumbersome and limited perceived efficacy, and about 45% of nonadherence occurs within the first 6 months of therapy.[53]

Most side effects caused by OA are typically mild and transient. The most frequently reported events are excessive salivation, dry mouth, mouth or teeth discomfort, muscle tenderness, and jaw stiffness. Device adjustment can decrease short-term side effects by reducing pressure on the anterior teeth and excessive mandibular advancement. The clinical importance of short-term OA side effects has been compared with PAP published observations. By use of the same visual analog scale to categorize side effects of either OA or PAP, the two treatment modalities had a similar side effect score.[25] More persistent and severe side effects, including TMJ dysfunction and dental crown damage, are uncommon.[21] OAs in the titrated position appear to be innocuous to the TMJ in OSAHS patients.[53] Whereas existing TMJ disorders were typically considered a contraindication to OAs, a study of patients with known or prior TMJ dysfunction found that these patients can become eligible for OA therapy after simple physiotherapy exercises.[57,86] Transient and nonserious TMJ pain occurs more frequently with OAs than with PAP, but the risk for development of impairment of the temporomandibular complex is infrequent with long-term MAS use. Therefore, pain related to the initial use of OAs is typically transient and not associated with a significant risk of long-term complications or functional limitations.

Long-term side effects of OA therapy are related to a significant impact on the occlusion. Changes in dentition are

not restricted to OA therapy as the use of nasal masks can also alter the craniofacial structures.[58,87] However, these changes are more prominent in OA users compared with PAP users. Changes observed in craniofacial structures were mainly related to significant dentoalveolar changes (tooth movements).[88-90] There are important concerns about the timing and continuation of dental changes during a long-term period.[91] Importantly, overbite changes were observed to decrease less with time, whereas overjet continuously changed at a constant rate of 0.2 mm per year of OA use. Interestingly, on evaluation of various studies of different appliance designs, such as Herbst, Mobloc, Klearway, SomnoMed, and TAP, it has been shown that the amount of change was related to the duration of therapy and not the type of appliance that was used.[86,89-93]

Although changes in dental occlusion do occur, these are generally not a significant cause of treatment discontinuation. The patient's perceptions do not typically correlate with objective measurements, and occlusal changes often go unnoticed[90]; also, most individuals developed new occlusal contacts resulting from the development of a new occlusal equilibrium over time.[94] In addition, several reports have consistently found that patients perceive dental side effects to be less important than the benefits of improved daytime sleepiness and other sleep apnea symptoms. Therefore, despite the presence of irreversible long-term occlusal changes, OA therapy should be considered a lifelong treatment for patients with OSAHS.

ADHERENCE AND PATIENT PERCEPTIONS

Adherence is defined by the World Health Organization as "the extent to which a person's behavior—taking medications, following a diet, and/or executing lifestyle changes—corresponds with agreed recommendations from a healthcare provider."[95] Numerous factors affect treatment adherence, including social and economic factors, health care system/team, characteristics of the disease, disease therapies, and patient-related factors. The consequences of a nontailored treatment with poor patient adherence are related to poor health outcomes and increased health care costs. As stated before, OSAHS is a chronic disease, and treatment with either PAP or OAs requires cooperation of the patient.

Treatment preference has been correlated to the degree of effectiveness, the impact of treatment on quality of life improvements, and the perceived severity of side effects.[96] Treatment expectations, lifestyle and personality of the patient, marital status, perceived stigma related to the treatment, and cost of treatment may also have an impact on a patient's preferences.[97] It is therefore important to include patients in the decision-making process regarding their treatment choices to promote better acceptance of and adherence with therapy as well as to identify potential barriers of one treatment option over another.

Treatment adherence with OAs appears to be dependent on the type of the appliance, disease severity, and patient supervision.[98,99] For example, adherence rates are greater with custom-made MAS than with tongue-retaining or "boil and bite" type appliances.[100,101] Studies have shown that about 75% of patients remained adherent after 12 months of treatment, which may decrease to 50% after 5 years.[102-105] Table 147-4 summarizes adherence rates in recent studies.[106]

Table 147-4 Adherence Rates of Oral Appliance Therapy in Selected Studies that Evaluated Use after a Minimum of 1 Year

Author	Interval (Months)	No. of Patients	Compliance Rate WCS/BCS
McGown,[99] 2001	22	166	42/56
Dort,[98] 2004	22	110	40/57
Marklund,[103] 2004	12	630	75/76
Almeida,[53] 2005	68	544	30/64
Marklund,[90] 2006	60	450	56/56
Gindre,[150] 2008	17	66	82/82

BCS, Best case scenario, relates to the percentage of patients who responded to the questionnaire only; WCS, worst case scenario, relates to an analysis interpretation of patients who did not return the questionnaires as compliance failures.
From Fleetham J, Almeida FR. Oral appliances. In: McNicholas WT, Bonsignore MR, editors. *European respiratory monograph*. Sheffield, UK: European Respiratory Society Journals; 2010. p. 267–85.

Adherence with OAs is consistently greater than that seen with PAP.[1] Whereas the existing literature strongly suggests that adherence with OAs is superior to that with PAP, most studies are based on subjective reports.[2,25] Recently, devices that provide a means to objectively monitor OA use have been developed.[54] Three microsensors are currently available that can be integrated into OAs: TheraMon (IFT Handels- und Entwicklungsgesellschaft GmbH, Handelsagentur Gschladt, Hargelsberg, Austria), AIR AID SLEEP (AIR AID GmbH & Co KG, Frankfurt, Germany), and Denti-Trac (Braebon Medical Corporation, Kanata, Canada). All three microsensors provide reliability and accurate wear time and can be incorporated into OAs fabricated from different materials.[107]

SLEEP BRUXISM IN PATIENTS WITH OBSTRUCTIVE SLEEP APNEA–HYPOPNEA SYNDROME

Sleep bruxism (SB) is classified as a sleep-related movement disorder in the *International Classification of Sleep Disorders*.[108] For more information on SB, see Chapters 144 to 146.

During sleep, individuals with SB will engage in jaw movements described as tooth clenching and grinding, but on the basis of electromyographic recordings of masseter and temporalis, this has been described as rhythmic masticatory muscle activity (RMMA) to facilitate the recognition of and further refine the specificity of the SB clinical diagnosis.[29,108]

Although the etiology of SB remains unclear, 50% to 80% of SB episodes are associated with sleep arousals in otherwise healthy subjects.[109-114] Sleep arousal precedes the onset of RMMA-SB, and it is characterized by a rise in sympathetic cardiac activation, blood pressure, muscle tone, and breathing amplitude.[111,114-116] Clearly, there is not a single cause for SB, and the role of stress, anxiety, breathing, and cardiac reactivity in relation to wake and sleep hyperarousal is a current question of interest.

SB has been frequently observed with other sleep conditions, such as snoring, upper airway resistance syndrome, and obstructive sleep apnea.[73,113,117-121] It has been estimated that up to 50% of both adults and children with OSAHS may have comorbid SB; in such cases, it is named secondary SB.[73,122,123] In addition, a positive correlation between the severity of OSAHS and the frequency of tooth grinding and clenching has been established.[117,124] A questionnaire-based epidemiologic study by Ohayon et al[120] suggested that OSAHS is a low but significant risk factor for SB (odds ratio, 1.8; 95% confidence interval, 1.2–2.6). All this evidence is derived from questionnaires and lacks power to explain a causative relationship.

A recent population-based community sleep study, which investigated more than 1000 adults using polysomnography, observed no difference in the AHI between individuals with and without SB.[109] This is not surprising; the prevalence of SB, which decreases with age, and the rise in the prevalence of SDB prevent such an association. Furthermore, a recent polysomnographic study failed to show a clear temporal association between RMMA-SB and OSAHS. In one study of OSAHS patients, the majority of SB events were temporally related to apneas and hypopneas, occurring between 0 and 30 seconds after the event. However, 25% of SB episodes showed an opposite temporal relationship (i.e., the SB event occurred before the obstructive event), and 20% had no time correlation with obstructive events.[125] Furthermore, it is possible that SB resulted in some cases from unrecognized or unmeasured respiratory effort–related events. Regardless, this study did demonstrate a significant association of SB in those with SDB and identified a potential dependent relationship between the two conditions in the majority of events.

Given the limited and conflicting existing evidence, the nature of the relationship between SDB and SB remains controversial.

Some authors have suggested that SB-related masticatory muscle activities have a role in reinstating upper airway patency after an episode of respiratory obstruction during sleep.[114,116,125-127] On the basis of this suggestion, it would appear that SB occurs secondary to obstructive events and is a consequence of an OSAHS-related phenomenon similar to sleep arousal or oxygen desaturation. If this is true, treatments of OSAHS would be expected to improve SB.[117,124,128] Indeed, some clinical studies have shown a decrease in SB activity after treatment of OSAHS using different modalities, including adenotonsillectomy, OA, and PAP.[126,129-131] However, as described before, the temporal association between OSAHS events and the masticatory muscle activity has not been confirmed in most of the available studies.[73,125,128,132] Alternatively, SB has been described as masticatory movements required to lubricate the oropharyngeal structures during sleep, which may be particularly dry in snorers and OSAHS patients.[133,134] However, in all cases, the role of sleep arousal and related autonomic sympathetic activation has to be taken into account while investigating the potential relationship between OSAHS and SB.[113,114,116,117,125,132]

The Impact of Bruxism Therapies on the Upper Airway

Management strategies for SB include dental (i.e., OAs and guards), cognitive-behavioral, and pharmacologic approaches (see Chapter 150 for more information).[114] These approaches typically aim to reduce SB detrimental consequences on the teeth (e.g., tooth wear) and dental restorations/prosthesis (e.g., fracture) and to reduce accompanying orofacial complaints (e.g., pain, headache). However, these treatment options largely mitigate the consequences of SB and do not address the SB events or potential underlying etiology or role of comorbidities such as OSAHS.

To protect dental surfaces and to relax the masticatory muscles, various designs and types of OAs are used. The soft vinyl mouth guards or hard acrylic occlusal splints have been extensively used in the management of SB.[114,135-139] These devices are more frequently designed to cover maxillary dentition, and patients are instructed to use them during sleep. The exact mechanism of action is still under debate, and there is no evidence to support their role in halting SB. Their main effect is to protect teeth against damage. Moreover, the lack of well-designed randomized controlled clinical trials and long-term studies makes it difficult to assess their true effectiveness on SB and oropharyngeal functions during sleep.[137] The majority of studies show a decrease in the RMMA-SB index by 40% to 50% during the initial period of treatment (2 to 6 weeks), regardless of the specific design of the occlusal splint.[136,138-140] However, the effect appears to be transitory, with values typically returning to pretreatment levels after a short time, and the outcomes are highly variable between subjects. Indeed, some studies have also reported no effect on or even an increase in electromyographic activities during sleep when an occlusal splint is worn, especially with soft mouth guard designs.[139,141,142]

The Use of Oral Appliances in Patients with Sleep Bruxism and Obstructive Sleep Apnea–Hypopnea Syndrome

Although occlusal splints have been thought to be a safe and conservative option for management of SB, few studies have investigated the effects of OAs designed to treat SB in patients who may have concomitant OSAHS. A pilot study of 10 patients with OSAHS found that a maxillary occlusal splint increased the AHI by more than 50% in half of the patients, likely by reducing the intraoral space and changing the tongue position during sleep.[143] Another group reproduced the direction taken by the pilot study, a risk for exacerbation of breathing in OSAHS patients but with a milder effect due to different morphologic patient characteristics.[144] Although there is a paucity of data, the potential adverse influence of maxillary occlusal splints on snoring and the respiratory disturbance index cannot be ignored, and clinicians should be cautious and consider the potential medical and dental complications of occlusal splints, especially when SB and OSAHS occur in the same patient. Given the potential association between SB and OSAHS in some patients and the potential negative effects of traditional SB therapies with SDB, it is imperative to assess risk of SDB in SB patients with OSAHS mild symptoms to select appropriate treatment options. In general, when SB is concomitant with OSAHS or when SDB is suspected, a mandibular advancement appliance would be preferable.

Some clinical studies have shown a decrease in RMMA-SB activity by using mandibular advancement devices in the absence of OSAHS.[126,145,146] These duobloc titratable OAs appear to be effective in decreasing SB and have been shown

to reduce up to 70% of bruxism events in otherwise healthy young adult subjects.[126,145,146] Duobloc OAs also appeared to relieve morning headaches and snoring concomitant with SB.[126,147] In an experimental study among adolescents, SB-related symptoms were significantly mitigated and sleep structure and quality were preserved by the use of mandibular advancement OAs during sleep.[126] In general, OAs are well tolerated by SB patients, especially if some range of jaw movements is permitted.[126,145-147] The use of mandibular advancement OAs for the treatment of SB seems promising but probably for cases with SDB symptoms. Intuitively, OAs seem ideally suited to treatment of patients with concomitant SB and OSAHS. However, data on the utility of these devices in patients with both conditions are lacking, and the long-term effectiveness of OAs in patients with both SB and OSAHS has not been established.

FUTURE DIRECTIONS

OA therapy has emerged as the main alternative to PAP in the treatment of OSAHS. There is now a strong evidence base demonstrating the benefits of this therapy for improving physiologic sleep measures, daytime sleepiness, and quality of life in OSAHS patients across the spectrum of disease severity. The existing literature suggests that the superior treatment efficacy of PAP is mitigated by inferior compliance relative to OA therapy, resulting in similar health outcomes. Long-term comparative effectiveness studies, using patient-centered and clinically important outcome measures, are required to verify this. The advent of objective compliance monitors for OA therapy is critical to such studies.[148] Cost-effectiveness studies are also warranted to appropriately inform and direct clinical care. In addition, prospective validation studies are required to evaluate predictors of treatment outcome, and more research is needed to determine optimal titration protocols to increase the effectiveness of OA and to decrease the time taken to attain optimal treatment.

Future studies are needed to compare the effectiveness of different types of appliances and different design features (e.g., the amount of vertical opening). Likewise, these studies ideally would help differentiate which patients should receive custom-made, titratable devices and identify those who could be appropriately managed with less expensive, fixed devices. Ongoing refinements and standardization of appliance design may eventually lead to improved outcomes and will be enhanced by a better understanding of the mechanisms of action of OAs.

Snoring and SDB are chronic and progressive conditions, raising the possibility that early intervention of snoring may retard the development of OSAHS. OA therapy would appear to have a major role in such a preventive approach, and further work is warranted to evaluate this possibility.

OSAHS is increasingly recognized as a heterogeneous disorder with multiple pathophysiologic causes. Currently, PAP represents a "one size fits all" solution by preventing upper airway collapse. However, new concepts in OSAHS pathogenesis and phenotypes have recently emerged and could help the field move toward a future "personalized medicine" approach in which treatment is tailored to the patient. Finally, the use of OAs for SDB in the presence of comorbidities, such as SB, headache, pain, gastroesophageal reflux, and opioid use, needs to be better delineated.

CLINICAL PEARL

OAs provide effective therapy for patients with OSAHS and can be used as primary therapy for mild to moderate cases or as an alternative treatment for individuals who fail to respond to, are not compliant with, or are intolerant of PAP and also for managing SB alone or concomitant with SDB. Several different device designs are available, each with inherent advantages and limitations. Types of OA design have to be selected for patient characteristics, dominance of OSAHS or SB, and comorbidity. This makes interpreting the published literature and understanding the role of OAs in clinical practice somewhat difficult. However, the data strongly suggest that custom-made, titratable devices with a small anterior vertical opening offer the most advantageous therapy for most patients with SDB and OSAHS. Appropriate and valid means to determine the required degree of mandibular advancement are not yet available, and much more work is awaited to improve OA efficacy and effectiveness.

SUMMARY

OAs, occlusal splint on single dental arch, can be used to prevent SB consequences on the teeth and pain, but in the presence of OSAHS, they may be contraindicated. Use of OAs with mandibular advancement is the ideal approach to manage OSAHS, conversely to occlusal splint. The putative mechanism is associated with increase in the anterior-posterior diameter of the upper airway space by advancing the oropharyngeal anatomic trio: the mandible, tongue, and soft palate. OAs with such advancement properties also add one important feature: they prevent posterior retrusion of the mandible during sleep, reducing the upper airway collapse. However, there appears to be a more robust and complex mechanism of improved airway patency and stability of upper airway muscle activity provided by these devices.

Although OAs provide reliable and effective treatment for most individuals with OSAHS, especially those with mild and moderate disease, there is a growing body of literature supporting that OAs are effective across a larger range of OSAHS severity. Nowadays, OAs for OSAHS should be considered an additional first-line treatment option. However, as with most appliances, success with OAs is not optimal. Even with titratable devices, a residual AHI is expected in more than 50% of individuals, and much work is expected to achieve higher success on most relevant outcomes, such as optimal sleep continuity, and reversal of signs and symptoms, such as sleepiness, cognitive alteration, blood pressure, and inflammatory reaction linked to SDB.

We recognize that OAs are not as effective as PAP in reducing the AHI, but they perform equally well compared with other measured variables, plus the OAs are more likely to be preferred by patients with better measures of adherence. Treatment with OAs provides a unique opportunity for interdisciplinary collaboration. Diagnosis and follow-up are performed by sleep medicine physicians; OA selection and follow-up are performed by dental sleep medicine professionals. OAs for either SB or OSAHS cannot be made for patients with gum infection, periodontal disease, or jaw pain without dental supervision. OAs may also induce orthognathic and dental changes in some patients that only a dentist can monitor and manage.

Anesthesia in Upper Airway Surgery for Obstructive Sleep Apnea

David R. Hillman; Peter R. Eastwood; Olivier M. Vanderveken

Chapter Highlights

- This chapter presents an overview of anesthetic considerations relating to upper airway surgery for patients with obstructive sleep apnea.
- Insightful anesthetic management of such cases requires an appreciation of the similarities and differences between the sleep and anesthetic states in relationship to their effects on upper airway and breathing function and on the arousal responses that help protect against disturbance of these essential physiologic functions.
- These issues are discussed in regard to both sedation for preoperative evaluation for obstructive sleep apnea surgery and perioperative management when surgery is undertaken.

Upper airway surgery is an undertaking that requires particularly close cooperation between surgeon and anesthesiologist. Patients presenting for these procedures do so because of compromised upper airway structure or function. In some circumstances, upper airway obstruction is the presenting complaint, as may occur with tumors in the upper airway. In others, the potential for obstruction may be great, as is the case for patients with obstructive sleep apnea (OSA). Managing such airways is challenging in the perioperative period. In anesthesiology terms, they are known as "difficult." A *difficult airway* has been defined by the American Society of Anesthesiologists as one that causes a conventionally trained anesthesiologist difficulty with face mask ventilation delivered to the upper airway, difficulty with tracheal intubation, or both.[1] Patients with OSA are vulnerable in both of these respects. In addition, they are, of course, at increased risk for upper airway obstruction whenever they are asleep or sedated. Whereas the sleeping patient is naturally protected from prolonged asphyxia by a capacity to arouse and reactivate effective breathing function, mild sedation compromises arousal mechanisms, and deep sedation or anesthesia abolishes these responses.[2] Patients with OSA are therefore particularly vulnerable throughout the perioperative period because of their airway compromise, compounded by the effects of anesthetic, opioid, and other sedative drugs and the risk of postoperative hemorrhage or edema associated with upper airway surgery.

In keeping with the orientation of this book toward sleep disorders, the focus of this chapter is on anesthetic considerations relating to upper airway surgery for OSA. Surgery frequently is undertaken to treat OSA in children, in whom tonsillar and adenoidal hypertrophy is a common cause.[3] Upper airway surgery also is regularly undertaken in adults for treatment of OSA, with several specific indications: removal of certain obstructing lesions in the upper airway; correction of abnormalities of the facial skeleton; unacceptability of nonsurgical treatments such as continuous positive airway pressure (CPAP) therapy and oral appliance therapy; and the need to relieve nasal obstruction to allow use of nasal masks for more comfortable, less intrusive delivery of CPAP than that offered by face masks.[4] A variety of procedures are available including nasal, palatal, and tongue base surgery; adenotonsillectomy (if hypertrophy is present); and a variety of orthognathic procedures.[5,6] The choice between them requires careful preoperative evaluation, often involving upper airway endoscopy and radiography including cephalometry, conventional computed tomography (CT), and, increasingly, three-dimensional studies using cone beam CT scans.[7]

Insightful anesthetic management of such cases requires an appreciation of the similarities and differences between the sleep and anesthetic states in relationship to their effect on upper airway and breathing function and on arousal responses that act to protect against disturbance in these functions. One facet of these shared considerations is illustrated by the use of anesthesia to simulate sleep-like conditions during drug-induced sedation endoscopy (DISE), sometimes termed drug-induced sleep endoscopy—a test to evaluate suitability for and type of OSA-related surgery, as described further on. More broadly, anesthetic management of patients with OSA presenting for upper airway surgical procedures must take into account several important factors: the shared influences of sedation, anesthesia, and sleep on upper airway behavior; how surgery can affect this behavior; the potential influences of OSA comorbid conditions including obesity and heart disease; and the early postoperative challenges associated with emergence from anesthesia, pain and its management, and the possibility of airway compromise from edema or hemorrhage.

Children present particular difficulties because of their small airway size and lung volumes relative to body size, predisposing them to upper airway obstruction and to rapid desaturation under such circumstances. Congenital problems associated with airway compromise, such as Down syndrome,

also regularly manifest in childhood, further highlighting the challenges that confront pediatric anesthesiologists.[8] Relatively recently, DISE has been introduced into preoperative evaluation of pediatric patients with OSA, adding to these challenges.[9,10]

PREOPERATIVE EVALUATION OF PATIENTS PRESENTING FOR OBSTRUCTIVE SLEEP APNEA SURGERY

Preoperative evaluation of patients presenting for general anesthesia of any kind should include consideration of the possibility of OSA, in view of its prevalence and the associated perioperative risks.[11] Patients presenting for OSA surgery, however,usually have already had their OSA well characterized by a diagnostic home or laboratory-based sleep study. Often a trial of CPAP to treat the problem may be under way, or CPAP therapy may be a more-or-less established management component. Emergent or subsequent problems with compliance arising from difficulty in accepting or tolerating CPAP, usually because of its intrusive nature, are well documented as a common reason why adults patients with OSA present for upper airway surgery.[12] Other patients may elect nasal surgery to allow easier application of CPAP delivered by means of a nasal mask; otherwise, a more cumbersome face mask is the required interface when there is nasal obstruction.

Often, upper airway surgery for OSA is preceded by a surgeon-initiated investigation to determine the primary site of obstruction (velo-, oro-, or hypopharyngeal) and the nature of the obstructive process (lateral, anteroposterior, or concentric narrowing). This assessment allows the surgeon to determine the best procedure to counteract the problems identified by it.

Apart from radiographic imaging (such as cephalometry and CT scans), such evaluations usually involve endoscopic visualization of the upper airway under conditions conducive to obstruction. Early methods involved the performance of Mueller maneuvers (inspiratory effort against an obstruction—the opposite of the Valsalva manuever) during awake endoscopy or with the patient under mild sedation.[13] However, this approach is far removed from sleep-like conditions, in which the upper airway muscles are relaxed and obstruction occurs without exaggeratedly negative intraluminal pressures, so it has limited validity as an assessment of site and nature of upper airway collapse during sleep.[14]

Drug-Induced Sedation Endoscopy

To better simulate the conditions of sleep, DISE has evolved as a test to help determine suitability for surgery and the type of surgical procedure to be undertaken.[15,16] This procedure directly involves anesthesiologists because drugs are administered (usually intravenous propofol with or without midazolam) to produce sedation and sleep-like muscle relaxation, which induces snoring and upper airway obstruction (partial or complete) in predisposed patients. A recent European position paper on DISE provides an overview of the possible protocols for sedation during DISE, the indications for the procedure, and how the findings might be reported.[17]

Of note, with use of mild (wakeful) sedation, the upper airway muscles remain quite active, and sleep-like conditions cannot be assumed.[18] It is only if sleep itself supervenes or if sedation is deepened to a level at which consciousness is lost through a direct drug effect that behavior of the relaxed upper airway is observed. Indeed, a steplike reduction in phasic genioglossus muscle activity, a major upper airway dilating force, is seen at the transition to unconsciousness at sleep onset and with anesthetic induction.[18,19]

Observations made under the relaxed conditions of DISE will help determine suitability for non-CPAP treatment such as upper airway and skeletal surgery and for oral appliance therapy, as well as guiding the choice of surgical procedure to be undertaken. Resolution of pharyngeal collapse at all levels of the upper airway is necessary to achieve successful treatment in the individual patient. Indeed, it has been demonstrated that multilevel collapse is present in a majority of patients with OSA, and that the prevalence of complete collapse and multilevel collapse increases with increasing OSA severity and overweight and obesity.[20,21]

The use of DISE is based on the concept that upper airway behavior during drug-induced unconsciousness is similar to that in natural sleep, with similar reductions in muscle activation, respiratory drive, and reflex gains at transition to unconsciousness in each state.[18,19] The results of a study evaluating polysomnography with or without propofol administered by continuous target-controlled intravenous infusion demonstrated that although propofol significantly changes sleep macroarchitecture, the main respiratory parameters, apnea-hypopnea index and mean arterial oxygen saturation, remain unaffected.[22]

However, a critical difference that is highly relevant to the considerations that follow (and to recovery after the DISE procedure) is that with sleep, the capacity for spontaneous arousal is preserved, whereas with drug-induced unconsciousness, a dose-dependent depression of arousal responses prevails. This depression persists until physiologic drug elimination allows return of consciousness, so the anesthetized patient is highly vulnerable to asphyxia if upper airway obstruction occurs and is not detected by and dealt with by attending medical or nursing staff.

ANESTHESIA FOR SURGERY TO TREAT OBSTRUCTIVE SLEEP APNEA

Patients with OSA present the anesthesiologist with many challenges. The problems they experience during sleep signify the presence of a narrow airway predisposed to obstruction when the upper airway (and other) muscles relax with onset of anesthesia. Obesity and presence of other comorbid conditions (such as hypertension—systemic and pulmonary, cardiovascular disease, cerebrovascular disease, metabolic syndrome, atrial fibrillation, or heart failure) may be contributing factors. If sufficiently severe, obesity also may predispose the patient to atelectasis under anesthesia and to hypoventilation if spontaneous ventilation is preserved.[23,24]

A reduction in functional residual capacity (FRC) is another phenomenon that occurs with the muscle relaxation (in this case of chest wall muscles) that accompanies onset of anesthesia (and of sleep). The decrease can be profound in the morbidly obese, with FRC dropping to near residual volume.[24] This reduction in FRC is associated with atelectasis in the dependent parts of the lung with consequent shunt and hypoxemia. The loss of lung volume also is a significant contributor (along with upper airway muscle relaxation) to the

Table 148-1 Obstructive Sleep Apnea (OSA) and Perioperative Risk*

Risk Factor	Potential Perioperative Consequences	Identification of Risk	Reducing Risk
OSA	Upper airway obstruction with asphyxiation if unrecognized and untreated	Clinical evaluation Screening tools (e.g., STOP-Bang) Sleep study when indicated	Early identification Preparation for potential difficulties with airway management (including intubation) Techniques to minimize postoperative sedation Perioperative use of CPAP therapy Intensive monitoring until sentient and arousal responses unimpaired Referral for definitive diagnosis and treatment when OSA is first suspected perioperatively
OSA-predisposing factors Obesity Familial Craniofacial Mandibular retrusion Maxillary hypoplasia Other indicators of difficult intubation	OSA-related problems (above) Difficult tracheal intubation Difficult airway management Delayed extubation/ reintubation Atelectasis, hypoventilation when patient is morbidly obese	Clinical evaluation Endoscopy Cephalometry Upper airway imaging (CT, MRI)	Awareness of predisposition and associated risks Monitoring for these risks Preparation for potential risks, including availability of appropriate equipment to manage them Techniques to minimize postoperative sedation
OSA comorbid conditions Hypertension Cardiovascular/ cerebrovascular disease Metabolic syndrome Depression	Worsening of comorbid condition Delayed recovery	Clinical evaluation Biochemical testing when indicated	Optimize control preoperatively Careful perioperative management

*See text for further details.
CPAP, Continuous positive airway pressure; CT, computed tomography; MRI, magnetic resonance imaging.

increased airway collapsibility observed during anesthesia, because of associated loss of longitudinal traction on the upper airway.[25] Conveniently, CPAP counteracts both problems, providing a pneumatic splint to the upper airway and increasing FRC, helping to prevent or recruit atelectatic lung, and offsetting the negative influence of volume loss on upper airway patency.

When hypoventilation is a prominent feature, bilevel ventilatory assistance is a preferred form of positive airway pressure therapy for obese patients, because it combines a background level of pressure to provide the benefits of CPAP with inspiratory pressure support to counteract the inadequate inspiratory flow.[26]

OSA is not restricted to the obese, however, and other pathogenetic factors are involved that are relevant to anesthesia. These include facial skeletal characteristics such as retrognathia and maxillary hypoplasia.[27] Such anatomic configurations, perhaps more than obesity itself, can present substantial challenges to the anesthesiologist. Potential problems include difficulty in performing endotracheal intubation and/or in maintaining airway patency during mask ventilation. Patients presenting such problems are said to have a "difficult airway." The presence of a difficult airway under anesthesia is an indicator of vulnerability to OSA.[28] Conversely, OSA is a risk factor for difficult intubation and/or difficulty with airway maintenance during the anesthetic procedure.[29] Hence the anesthesiologist should approach patients with OSA prepared for a difficult intubation. It is likely that in the assessment of such patients, other factors indicating this possibility will be present, such as oropharyngeal crowding with high Mallampati scores, retrognathia with reduced thyromental distances and/or increased mandibular angulation, or increased neck circumference.[28] Increased neck circumference is a risk factor for OSA that is independent of obesity, although it reflects central fat deposition. Patients with large muscular necks also are at increased risk for OSA and may present additional airway management difficulties under anesthesia.[30] Apart from clinical evaluation, the anesthesiologist also should take advantage of the various radiographic and endoscopic preoperative investigations undertaken by the surgical team to assess upper airway structure and function in preparation for surgery (as outlined previously), to develop greater insights into the challenges ahead (Table 148-1).

Tracheal Intubation

Although some upper airway surgery procedures relevant to OSA can be done using local anesthesia (such as minor nasal surgery undertaken to improve the prospects of successful nasal CPAP delivery in patients with OSA along with nasal obstruction), most cases require general anesthesia. In such cases, the patient is almost always tracheally intubated. The

presence of an endotracheal tube allows the anesthesiologist to step back from immediate proximity to the head, to allow surgical access, while ensuring airway patency and, in addition, ensuring protection of the lower airway from aspiration of blood and other material during the course of the procedure. The principal challenges in dealing with patients with obstruction-prone upper airways lie in placing the tracheal tube at the start of the procedure and in ensuring airway patency after removal of the tube on completion of anesthesia.

Airway Patency after Extubation

Several measures are required to ensure airway patency after extubation. First, apart from adequate reversal of any neuromuscular blockade if such drugs have been used, it is prudent to ensure that the patient has regained consciousness before extubation. Early return of consciousness requires the choice of appropriate anesthetic drugs and titration of doses to facilitate this outcome. Second, extubation in the lateral posture should be considered when practicable, with the patient maintained in this position during sleep for the postoperative period in the hospital. Third, CPAP or other positive airway pressure therapies should be readily available and used during sleep or sedation in patients with threatened or actual upper airway obstructive episodes. This is not a problem with CPAP-compliant patients, who expect the continuation of such therapy. It is more problematic in noncompliant patients, which is a good reason for preoperative induction of CPAP therapy when possible. Although the nose is the favored route of administration of CPAP for a majority of users, a face mask may be required perioperatively, particularly in the presence of edema or other conditions causing nasal obstruction. In the case of nasal surgery, nasal packs should be avoided when possible. Furthermore, an important caveat is that CPAP therapy may be needed in the early postoperative period despite the fact that the aim of surgery was to restore airway patency. This is because edema, secretions, blood, and clots can temporarily worsen airway patency. Although CPAP is a mainstay, use of other devices to improve airway patency, such as mandibular advancement devices, may have a perioperative role. Available literature to guide the perioperative use of these other devices is limited at present, however.

Early Postoperative Care

Finally, the patient must be closely monitored while he or she remains at increased risk. Clinical care thus requires a higher nurse-to-patient ratio than in the general ward and continuous monitoring of oxygenation (oximetry) and ventilation (capnography, oronasal airflow). Such facilities are available in the postanesthetic care unit and other high-dependency areas. Oxygen therapy should be used with caution because it can conceal obstructive events, potentially leading to their prolongation. It is for this reason that monitoring oronasal airflow, either directly or with capnography, adds value to oximetry monitoring.[31] Attending staff members must be expert in the use of CPAP and noninvasive ventilation. Discharge of the patient from such an environment demands return of consciousness and subsequent unimpeded arousal responses to threatened airway compromise. To ensure this outcome, it is highly desirable to avoid opioids and other drugs with sedative potential whenever possible. Alternative analgesic techniques include use of nonsteroidal anti-inflammatory drugs and acetaminophen and analgesic-sparing strategies such as use of corticosteroids. There also is a place for use of topical anesthesia and nerve blocks in the perioperative setting.[32]

Postoperative edema and secretions can temporarily compromise airways in which procedures have been undertaken to ultimately improve patency. Hemorrhage also is a risk, particularly in the early postoperative period.

Postoperative Sleep

Owing to the aforementioned considerations, the perioperative period is one of vulnerability. Added to these potential airway and ventilatory impairments is the disruption to sleep that occurs during the first few days postoperatively. Such sleep impairment increases the risk of postoperative delirium. Furthermore, as this early sleep disruption settles, a night or two of rapid eye movement (REM) sleep rebound may follow, with an increased proportion of sleep spent in the REM stage. This is of relevance because REM is the stage of sleep during which muscle activation and respiratory drive are most depressed and, consequently, the risk of upper airway obstruction and hypoventilation is greatest.[33]

Discharge Requirements

The ideal circumstances for discharge of these patients from high-dependency care and from the hospital are achieved with the following clinical objectives: return of consciousness with no plan for subsequent use of opioids or sedatives that may impair arousal responses; resolution of edema and of the particular risk of hemorrhage; and, when indicated, ability to self-administer CPAP, with willingness to use it when asleep. In some settings, these conditions may be met in the early postoperative period, depending on the nature of the procedure and the anesthetic technique used. If so, and if any comorbid conditions are well controlled, same-day discharge from the hospital after surgery is possible.

These recommendations are consistent with current published guidelines for perioperative care of patients with OSA.[32,34] It must be recognized, however, that this is an evolving area, and such guidelines currently are based largely on expert opinion. An evidence base developed from careful study and analysis of methods to improve perioperative outcomes is slowly accumulating and can be expected to eventually result in well-supported recommendations. Much work in this area remains to be done.

CONCLUSIONS

Anesthesia for upper airway surgery to treat OSA is challenging. The surgery often is undertaken in patients who have been unable or unwilling to tolerate CPAP therapy or in those who have surgically correctable upper airway or craniofacial abnormalities. Sometimes it is undertaken to improve CPAP compliance by relieving nasal obstruction. Anesthetic management requires careful preparation, allowing for the possibility of difficult intubation, and careful management of extubation and emergence to ensure maintenance of airway patency particularly in the period that precedes full return of consciousness and ability to promptly arouse from subsequent sleep in response to hypopneic or apneic events.

CLINICAL PEARLS

- The similar effects of anesthesia and of sleep in reducing muscle activation and ventilatory drive mean that vulnerability to upper airway obstruction in one state indicates high risk of problems in the other.
- The anatomic features (e.g., retrognathia) that predispose to airway obstruction also increase difficulties with tracheal intubation and mask ventilation performed with the patient under anesthesia.
- A key difference between the states is suppression of the arousal responses that protect the sleeping patient by anesthetic agents, with increased risk of asphyxia in those with obstruction-prone airways, such as patients with OSA. Postoperative use of opioid and sedative drugs may extend these risks beyond the immediate postoperative period, and caution with use of these agents is mandatory.
- Postoperative edema further compounds potential problems for patients who have undergone surgery for OSA.
- Close peri- and postoperative monitoring and management must take these matters into account.

SUMMARY

Anesthesia for upper airway surgery to treat OSA is challenging. Often such surgery is undertaken in patients who have been unable or unwilling to tolerate CPAP therapy. Sometimes it is undertaken to improve CPAP compliance by relieving nasal obstruction. Preoperative surgical evaluation often entails DISE to assess suitability for and determine the optimal type of surgery. This procedure requires an appreciation of the relationships between drug-induced sedation and sleep in terms of muscle relaxation, ventilatory depression, and reflex suppression to ensure that airway behavior is observed under sleep-like conditions. Anesthetic management for the upper airway surgery requires careful preparation, allowing for the possibility of difficult intubation, and careful management of extubation and monitoring of emergence to ensure maintenance of airway patency, particularly in the period that precedes full return of consciousness and the capability for prompt arousal from subsequent sleep in response to hypopneic or apneic events.

Chapter 149

Upper Airway Surgery to Treat Obstructive Sleep-Disordered Breathing

Olivier M. Vanderveken; Aarnoud Hoekema; Edward M. Weaver

Chapter Highlights

- Management with continuous positive airway pressure (CPAP) remains the treatment of choice for moderate to severe obstructive sleep apnea (OSA). Some patients cannot or will not accept CPAP therapy, or CPAP may not be effective in certain cases, so use of other therapies may be indicated.
- Objective sleep testing is always required before the decision for surgical treatment, to identify those patients at risk for complications of OSA, to guide selection of appropriate management, and to provide a baseline to establish the efficacy of treatment.
- Surgical treatments for OSA fall into the following categories: surgical upper airway modifications including tongue suspension techniques, upper airway neurostimulation therapy, tracheostomy, skeletal modifications, and bariatric surgery.
- Objective sleep testing is always required after surgical treatment, to document efficacy.

OVERVIEW AND BACKGROUND

Management with continuous positive airway pressure (CPAP) remains the treatment of choice for moderate to severe obstructive sleep apnea (OSA).[1] Adequate CPAP treatment improves blood pressure to combat hypertension and reduces the risk of nonfatal and fatal cardiovascular events, and successful CPAP treatment has been shown to prolong survival.[2-5]

The clinical effectiveness of CPAP often is hampered and limited by important patient-specific factors: low rate of acceptance, poor tolerance, and suboptimal adherence.[6] Therefore many patients with OSA remain inadequately treated owing to inconsistent CPAP adherence,[6,7] with consequent reduced clinical effectiveness of therapy.[5,6,8-12] When the response to CPAP is considered inadequate as indicated by both symptom evaluation and objective monitoring data, despite intensive efforts to improve adherence to the CPAP regimen including trials of combination therapies, non-CPAP alternatives for the management of OSA need to be considered.[13,14] At this stage, proper and careful selection of the right patient for the right treatment option(s) is of utmost importance.[13]

The focus of this chapter is on upper airway surgery to treat OSA. Sometimes surgery is most helpful to facilitate CPAP or oral appliance therapy, such as with surgical correction of nasal obstruction. Alternatively, surgical management may be indicated in place of these other therapies—for example, when factors including unfavorable anatomy or patient intolerance preclude their use. It is important to recognize that often multimodality therapy is the best strategy, and surgery can be combined with any and all other OSA treatments including CPAP and non-CPAP approaches when indicated.[15]

Surgical modifications for treating OSA fall into five main categories: upper airway bypass procedure, surgical upper airway modifications including tongue suspension techniques, upper airway neurostimulation therapy, skeletal modifications, and bariatric surgery.

Objective sleep testing is required before initiation of surgical treatment, to identify those patients at risk for complications of OSA, to guide selection of appropriate management, and to provide a baseline to establish the physiologic efficacy of subsequent treatment.[14] Follow-up sleep studies are routinely indicated to monitor the response to surgery for OSA.

PREOPERATIVE EVALUATION

The comprehensive diagnostic workup of the patient with OSA should include a complete medical and thorough sleep history. Previous OSA treatments and their clinical and polysomnographic results also should be evaluated and documented in this workup, as described in later chapters (see Section 14 and Chapter 143 for orthodontic management). Before proceeding with surgery, the medical workup should identify complicating factors that can increase the medical, anesthetic, and surgical risk of the surgical procedure. A thorough upper airway examination should be performed, including assessment of the anatomy and functional status of the nose, mouth, pharynx, larynx, and related structures (e.g., craniofacial, dental, and airway structures). The OSA examination often includes upper airway endoscopy to visualize all the levels of the pharynx, larynx, and related structures—the palate, tongue base, the lateral pharyngeal walls, the vallecula, the pyriform sinuses, the larynx, and the epiglottis. The diagnostic pretreatment assessment needs to include a baseline sleep study. The polysomnographic recording should be recent

enough that it represents the current status of the OSA and ideally consists of a full-night diagnostic study.

The option of surgical interventions for OSA is based in part on the demonstration that the upper airway is significantly smaller in patients with OSA than in normal subjects, especially at the retropalatal and retroglossal levels.[16,17] The upper airway is described as a structure with a rigid support in its proximal (laryngeal) and distal (nasal) segments, with a collapsible portion in between. This collapsible anatomic portion extends from the soft palate to the epiglottis, with the size of its lumen subject to the influence of surrounding anatomy, presence of fat tissue, pressures gradients, tissue laxity, and dilator muscle activity. The potential loss of upper airway patency during sleep in patients with OSA is therefore usually localized to this so-called collapsible segment (Figure 149-1).

In the early days of OSA therapy, tracheostomy, or "upper airway bypass surgery," offered the only effective management, and it often was used in patients with profound OSA.[18] Tracheostomy, however, does not address the collapse directly in the vulnerable segment of the upper airway but instead successfully bypasses the obstruction, thereby moderating OSA. Tracheostomy is thus a highly effective treatment for OSA. On the other hand, tracheostomy is a physically and socially invasive procedure that may substantially reduce perceived quality of life.[18] The more commonly used upper airway surgical procedures nowadays have greater acceptance but are less effective.[19]

The decision process to select the appropriate upper airway surgical procedures for any specific patient are determined by the site(s), the degree, and the pattern of upper airway obstruction[13] (Figure 149-2). Indeed, most upper airway surgical approaches, apart from surgical treatments with a global effect (i.e., tracheostomy bypass, bariatric surgery, and maxillomandibular advancement [MMA]) (Table 149-1), ideally strive to intervene at the specific anatomic region(s) that become obstructed during sleep. In addition to the history, examination, and in-office awake upper airway endoscopy, a variety of other modalities may be used to assess sites, degree, and pattern of obstruction. Pharyngeal pressure measurements, imaging and endoscopic techniques can be used to gain insight into the pathogenesis of this disease, as well as to identify appropriate therapeutic options.[20-23] Imaging techniques available for the preoperative evaluation include radiography, fluoroscopy, conventional computed tomography

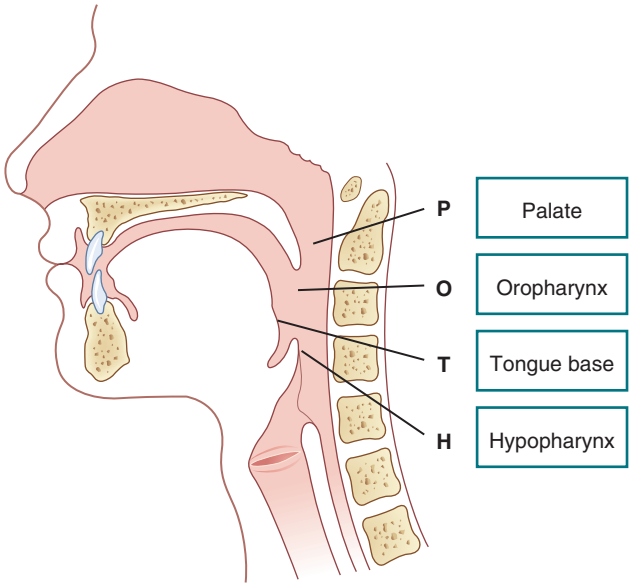

Figure 149-1 Sagittal cross section of the upper airway with the different levels prone to upper airway collapse during sleep within the "collapsible segment": the velopharynx with the palate as the most relevant structure; the oropharynx, including both the palatine tonsils and the lateral oropharyngeal walls; the level of the tongue base, including the lingual tonsils; and the hypopharynx, including the epiglottis and the hypopharyngeal lateral walls. The upper airway has rigid support in its proximal and distal segments but has a collapsible portion, the so-called "collapsible segment" extending from the soft palate to the epiglottis, with the size of its lumen subject to the influence of surrounding pressures and the activity of dilator muscles.

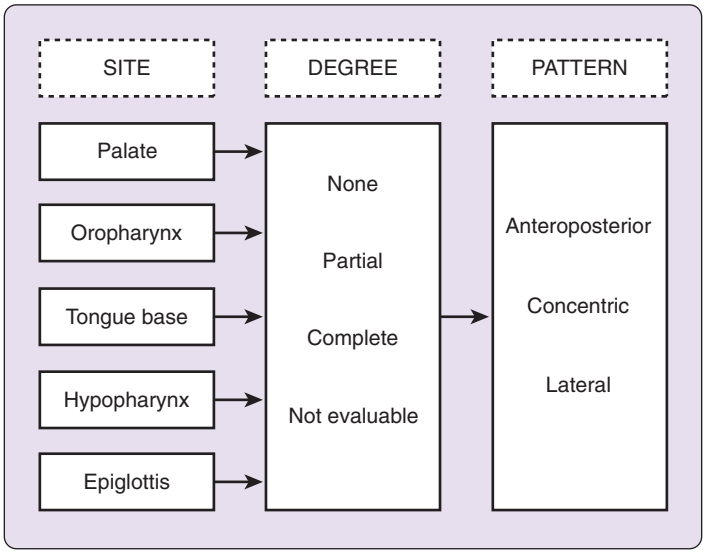

Figure 149-2 Scoring form for drug-induced sedation endoscopy (DISE): Reporting of the assessment of the site, the corresponding degree, and pattern of upper airway collapse. (From Vroegop AV, Vanderveken OM, Wouters K, et al. Observer variation in drug-induced sleep endoscopy: experienced versus nonexperienced ear, nose, and throat surgeons. *Sleep* 2013;36:947–53.)

Table 149-1 Treatment Options Other than Continuous Positive Airway Pressure (CPAP) for Patients with Obstructive Sleep Apnea

Category	Intervention/Procedure
General measures	Avoidance of sedatives Avoidance of alcohol Sleep hygiene Weight loss in case of overweight or obesity Avoidance of supine position during sleep in case of positional sleep apnea
