49 Management of Toxicities of Targeted Therapies

James Chih-Hsin Yang, Chia-Chi (Josh) Lin, and Chia-Yu Chu

SUMMARY OF KEY POINTS

- Epidermal growth factor receptor (EGFR), anaplastic lymphoma kinase (ALK), BRAF, C-ros oncogene 1 (ROS1), ret proto-oncogene (RET) tyrosine kinase inhibitors (TKIs), several antiangiogenesis agents, and antiprogram death 1 (anti-PD1) immunotherapy are effective targeted treatments for lung cancer patients. Each class of agents has class side effects. In addition, each drug may have its own unique side effects.

- Dermatologic and gastrointestinal side effects are frequently encountered side effects of targeted therapy. These side effects are manageable and preventable.

- Interstitial lung diseases are a unique side effect occasionally encountered in lung cancer patients treated with TKIs or anti-PD1 monoclonal antibodies. Although these pulmonary side effects are rare, they may become fatal if left unnoticed. Patients should be informed about the symptoms of these side effects and seek medical care immediately if in doubt. Early intervention including discontinuation of medication and steroid administration is important to reverse the interstitial lung disease process.

- Physicians should be aware of other infrequent but important side effects such as QTc prolongation associated with some TKIs; hypertension, thromboembolic, or hemorrhage side effects associated with antiangiogenesis agents; autoimmune colitis, hepatitis, thyroiditis, or adrenitis associated with anti-PD1 therapy; and skin tumor associated with treatment with B-raf inhibitors.

- Different incidence of side effects between Asian and non-Asian populations may be due to intrinsic genomic differences or extrinsic differences in clinical practice.

Several classes of targeted agents are effective for the treatment of nonsmall cell lung cancer (NSCLC). EGFR TKIs such as gefitinib, erlotinib, and afatinib are very effective for the treatment of NSCLC in patients with EGFR activating mutations.[1] Novel EGFR TKIs such as osimertinib and rociletinib are efficacious in EGFR-mutant NSCLC patients with acquired EGFR T790M mutation.[1,2] EGFR monoclonal antibodies such as necitumumab enhance chemotherapy drug activity in patients with NSCLC (squamous and non-squamous).[2] ALK inhibitors such as crizotinib, ceritinib (LDK378), alectinib (RO5424802 [CH5424802], AF802), and AP26113 are highly effective treatments for patients with ALK fusion oncoproteins. The most common of these proteins is echinoderm microtubule-associated protein-like 4-ALK, which is detected by ALK immunohistochemical staining or break-apart fluorescence in situ hybridization.[3] V-raf murine sarcoma viral oncogene homolog B (BRAF) inhibitors, such as dabrafenib or vemurafenib, are being tested in patients with BRAF V600E mutation.[4] ROS1 inhibitors such as crizotinib are highly active in patients with ROS1 rearrangements.[5] Foretinib (XL880) may also effectively inhibit ROS1 in patients with NSCLC.[6] These targeted therapies were designed to manage patients with tumors with specific driver mutations, and their side effects often can be predicted by the physiologic pathways that are inhibited. For example, the side effects of EGFR TKIs are diarrhea, skin toxicity, paronychia, hair changes, and mucositis. Rare side effects such as keratitis, nausea, and vomiting can also be linked to the physiologic function of the EGF–EGFR pathway. ALK, ROS1, and ret proto-oncogene (RET) inhibitors produce fewer but unpredictable side effects because less is known about the role of these genes in normal physiology.

Other classes of targeted agents inhibit general pathways that are involved in cancer development and growth. Antiangiogenic agents used in combination with chemotherapy have broad activity in various cancers, including lung cancer. Bevacizumab, a monoclonal antibody that targets vasculoendothelial growth factor (VEGF), improved response and survival in patients with lung adenocarcinoma treated with chemotherapy.[7] Small molecule inhibitors such as vandetanib or nintedanib also have demonstrated anticancer activity in clinical trials.[8] These agents usually cause side effects related to the vascular growth process, such as bleeding and thrombosis, and side effects related to disruption of VEGF pathways such as hypertension, proteinuria, and renal dysfunction.

Heat-shock proteins (HSPs) are chaperones that protect fragile proteins, especially oncoproteins, from disintegration. Inhibition of HSPs may lead to oncoprotein degradation and cancer cell death. HSP90 inhibitors are very effective in cancers such as NSCLC with ALK fusion proteins.[9] Because HSP90 is universally needed in normal physiologic function the consequences of HSP90 inhibition are less clear.

Another class of targeted therapy that has already proven effective in controlling NSCLC is immunotherapy that disrupts the immune checkpoint program death 1 (PD1) on T lymphocytes and its ligands (PD-L1 and PD-L2) on tumor cells. Monoclonal antibodies that target any of these surface proteins can be highly effective in lung cancers harboring PD-L1.[10] The blockage of this checkpoint is more specific on tumor cells than on normal cells. Therefore, these agents may produce fewer immunologic side effects than monoclonal antibodies that target upstream checkpoints such as ipilimumab, which blocks cytotoxic T lymphocyte antigen 4.[10]

Hepatocyte growth factor (HGF) and cMET inhibitors may have a role in inhibiting the growth of NSCLC cells. cMET amplification was noted in up to 20% of individuals with EGFR mutations in whom resistance to EGFR TKIs developed.[11] Monoclonal antibodies that target the ligand (HGF) or the receptor (cMET), as well as small molecule cMET kinase inhibitors, are under active development. The class side effects of HGF and cMET pathway inhibition are not very clear.[12]

Insulin-like growth factor (IGF) and its receptor (IGFR) belong to the insulin receptor family. Overactivity of the insulin signaling pathway has been implicated in tumor progression in several tumor types. Use of the IGFR1 inhibitor figitumumab with chemotherapy has increased response rates in patients with NSCLC.[13] Hyperglycemia and insulin resistance are typical side effects of IGF and IGFR pathway inhibitors.[14]

Phosphatidylinositol 3-kinase, AKT, mitogen-activated and extracellular signal-regulated kinase (MEK), extracellular signal-regulated kinase (ERK), and mammalian target of rapamycin are

the central control molecules for cellular proliferation and apoptosis. Inhibitors of these proteins may lead to tumor control in some people with cancer. Unfortunately, substantial side effects have been reported.[15]

Some side effects from targeted therapy are related to the general molecular structures.[16] For example, infusion reactions, such as chills, fever, hypotension, or even rare anaphylactic reactions, are found with many antibody biologic agents. These side effects often can be alleviated or prevented by pretreatment with a corticosteroid. A unique side effect of many small molecule TKIs is interstitial lung disease, also called interstitial lung fibrosis.[17] Furthermore, similar to many other noncancer drugs or biologics, anticancer agents may have side effects that are not related to known pharmacologic or toxicologic properties. Therefore prescribing oncologists should be familiar with the side effect profiles of each targeted therapy.

DERMATOLOGIC SIDE EFFECTS
EGFR TKIs and Monoclonal Antibodies

Dermatologic side effects develop in a considerable number of patients treated with EGFR TKIs or monoclonal antibodies that target EGFR. A papulopustular (acneiform) eruption is the most frequent side effect; xerosis, eczema, telangiectasia, hyperpigmentation, hair changes, and paronychia may also occur.[18–20] Skin adverse events that result from treatment with EGFR TKIs may affect 45% to 100% of patients, and some of these side effects may be dose dependent.[20] By studying the development of resistance to the reversible EGFR TKIs erlotinib and gefitinib, researchers have learned about the molecular mechanisms underlying the signaling pathways involving EGFR. Novel molecularly targeted therapies have been developed to overcome EGFR T790M resistance. Afatinib is an irreversible ErbB family blocker, and its side effect profile is similar to other EGFR inhibitors, with skin toxicity (and diarrhea) being the most frequently reported adverse events.[21,22] Dacomitinib is another irreversible inhibitor of EGFR and human epidermal growth factor receptor-1 (HER1), HER2, and HER4. The monoclonal antibodies cetuximab and panitumumab also may produce skin toxicities because of their inhibition effect on EGFR.[23]

The common adverse effects of treatment with EGFR inhibitors are papulopustular (acneiform) rash, pruritus, and dry skin; nail, hair, and mucosal changes occur less frequently (Table 49.1).[23] Papulopustular (acneiform) rash associated with anti-EGFR therapy occurs in 43% to 94% of patients, with an incidence of approximately 73% in a 2011 meta-analysis.[24,25] The rash resembles acne vulgaris, but it is characterized by predominantly papular or pustular eruption, is not associated with comedones, and is pathologically and etiologically distinct from acne vulgaris (Fig. 49.1). Commonly affected areas are the face (nose, cheeks, nasolabial folds, chin, and forehead), V-areas of the upper chest and back, and, less frequently, the scalp, arms, legs, abdomen, and buttocks (Fig. 49.2). The palms, soles, and mucosa usually are spared. In general, the papulopustular rash manifests within 1 week to 3 weeks of starting an EGFR inhibitor, often commencing between days 7 and 14 and peaking by weeks 3 to 6.[23] The reaction is reversible, usually with complete resolution within 4 weeks of withdrawal from treatment, but the rash may reappear or worsen once treatment is resumed. Spontaneous improvement with resolution or stabilization of the rash occurs with continued treatment.

The incidence of papulopustular (acneiform) rash was highest among patients with metastatic colorectal cancer treated with cetuximab and in patients with lung cancer treated with afatinib.[21,24,25] The incidences of various cutaneous side effects of anti-EGFR treatments in various studies are hard to compare because the genetic background, clinical condition, treatment schedule, and patient characteristics differ in each trial (Table 49.1).[25] Patients with substantial cutaneous side effects are likely to benefit the most from treatment with EGFR inhibitors. Results from a 2013 systematic review and meta-analysis of 33 eligible trials showed that the presence of skin rash predicted the response to EGFR TKIs and the prognosis for patients with NSCLC.[26]

Among patients taking EGFR TKIs or monoclonal antibodies, 4% to 69% have dry skin with diffuse fine scaling after the onset of papulopustular rash.[21,23,25] Painful paronychial inflammation of the fingers and toes is seen in 6% to 47% of patients after 1 month to 4 months of anti-EGFR treatment.[25] This inflammation is often described as a periungual granulation type of paronychia or pyogenic granuloma-like changes, presenting as

TABLE 49.1 Spectrum of Dermatologic Adverse Effects Associated With Epidermal Growth Factor Receptor Inhibitors

Adverse Effect	Description	Frequency[21,23] (%)	Timing During Treatment
Papulopustular (acneiform) rash	Erythematous papular, follicular, or pustular lesions, which may be associated with mild pruritus Commonly affected areas: face (nose, cheeks, nasolabial folds, chin, forehead), V areas of the upper chest and back; less frequently, on the scalp, arms, legs, abdomen, and buttocks	60–94	Onset: between days 7 & 14 Peak: between weeks 3 & 5
Pruritus	Generalized itching sensation	16–60	Onset: between weeks 2 & 4 Peak: between weeks 3 & 6
Dry skin (xerosis)	Diffuse fine scaling on the whole body, especially the extensor areas	4–38	Onset: after appearance of rash
Paronychia	Painful periungual granulation lesions or friable pyogenic granuloma-like changes, associated with erythema, swelling, and fissuring of lateral nail folds or distal finger tufts	6–12	Onset: 2–4 months after start of treatment
Hair changes	Curlier, finer, and more brittle hair on scalp and extremities; extensive growth and curling of eyelashes and eyebrows	Unknown	Onset: as early as 7–10 weeks to many months after the start of treatment
Hypersensitivity reaction	Flushing, urticaria, and anaphylaxis	2–3	Onset: 1st day of initial dose
Mucositis	Mild to moderate mucositis, stomatitis, aphthous ulcers	2–36	Onset: during treatment, not related to dose or schedule
Fig. 49.1. Papulopustular (acneiform) rash associated with antiepidermal growth factor receptor therapy occurs in 60% to 94% of patients. Commonly affected regions are sun-exposed areas of the face such as the nose, cheeks, nasolabial folds, chin, and forehead.

Fig. 49.3. Paronychia related to treatment with an epidermal growth factor receptor inhibitor often presents as painful periungual granulation lesions associated with erythema, tenderness, swelling, and fissuring of lateral nail folds or distal finger tufts.

Fig. 49.2. Papulopustular rash on the scalp related to treatment with cetuximab.

erythema, tenderness, swelling, and fissuring of lateral nail folds or distal finger tufts (Fig. 49.3).

In patients who take anti-EGFR medications for several months, hair abnormalities may develop, such as curlier, finer, and more brittle hair on the scalp and extremities or slowed growth of beard hair. Androgenetic alopecia-like frontal alopecia has been noted (Fig. 49.4A). Extensive growth of the eyelashes and eyebrows has also been seen in some patients after many months of anti-EGFR therapy (Fig. 49.4B). Patients who report symptoms of eye irritation should be seen by an ophthalmologist because of the risk of trichiasis.[23]

Skin side effects related to EGFR inhibition are generally mild or moderate in severity. However, even mild events may increase the risk of secondary infections, and patients must cope with chronic discomfort, itching, and the disagreeable appearance of the rash. The rash predominantly affects visible areas of the body, which can cause distress, anxiety, negative self-image, and low self-esteem in some patients. Furthermore, high-grade (grade 3 or higher) skin reactions may lead to morbidity, treatment interruption, or dose modifications.[23] Dermatologic side effects may also affect compliance with treatment.[21] Survey results from 110

oncologists who administered EGFR inhibitor therapy indicated that 76% had interrupted therapy because of rash, whereas 32% had discontinued EGFR inhibitor therapy because of rash.[27] Dermatologic reactions also affect a patient's quality of life.[23]

The mechanism underlying the skin toxicities associated with EGFR inhibition is not fully understood, but it is thought to be related to the disruption of physiologic EGFR-mediated signaling processes in the epidermis, especially the basal keratinocytes.[20,21] Inhibition of EGFR-mediated signaling pathways affects keratinocytes in several ways, for example, inducing growth arrest and apoptosis, decreasing cell migration, increasing cell attachment and differentiation, and stimulating inflammation, which result in distinct cutaneous conditions.[20,21] An EGFR-independent pathway, known as c-Jun NH2-terminal kinase activation, may also be related to keratinocyte damage induced by EGFR TKIs.[28]

Several factors have been associated with an increased tendency for the development of rash. Among patients treated with erlotinib, rash is most likely to develop in nonsmokers, individuals with fair skin, and patients older than 70 years.[21] Men younger than 70 years of age are at an increased risk for the development of a rash with cetuximab therapy.[29] When exploring pharmacogenomic and clinical correlations, researchers found that variability in germline polymorphisms in EGFR was a determinant of cutaneous side effects in erlotinib-treated patients.[30]

Symptomatic and preventive treatments are usually helpful for patients. Strategies include use of topical moisturizers or corticosteroids, administration of systemic steroidal medications or antihistamine drugs to palliate pruritus and inflammation, and dose delay or reduction in the case of severe reactions. Although several guidelines for managing cutaneous side effects have been published, they are based mainly on anecdotal evidence and clinical experience.[20,31]

Patients initiating EGFR TKI or monoclonal antibody therapy should take precautions to protect their skin, such as using alcohol-free skin products and minimizing sun exposure by wearing protective clothing, a hat, and sunscreen with a sun protection factor greater than 30 and ultraviolet A and B protection. Some management strategies based on expert opinion have been proposed for the dermatologic side effects associated with anti-EGFR therapies (Tables 49.2–49.5).[21] For papulopustular (acneiform) rash, topical and oral corticosteroids or antibiotics can be used (Fig. 49.5 and Table 49.2). Patients in whom pruritus develops may benefit from topical, oral, or systemic
Fig. 49.4. (A) Hair abnormalities, such as curlier and brittle hair on the scalp, have been found in patients receiving dacomitinib for several months. Androgenetic alopecia-like frontal alopecia has also been reported. (B) Extensive growth of both eyelashes and eyebrows has occurred in some patients taking erlotinib for more than 6 months.

TABLE 49.2 Management of Papulopustular (Acneiform) Rash Associated With Epidermal Growth Factor Receptor (EGFR) Inhibitors

Severity of Side Effect[a]	EGFR Inhibitor Dose	Treatment
Grade 1: macular or papular eruption or erythema without associated symptoms	Continue at current dose	Topical corticosteroid[b] OR tacrolimus ointment, twice daily OR topical antibiotic[b] twice daily
Grade 2: macular or papular eruption or erythema with pruritus or other associated symptoms; localized desquamation or other lesions covering <50% of the body surface area	Continue at current dose	Oral antibiotic[c] for 6 weeks Stop topical antibiotic, if being used Topical corticosteroids[b] OR tacrolimus ointment twice daily
Grade 3 or higher: Severe, generalized erythroderma or macular, papular, or vesicular eruption; desquamation covering ≥50% of the body surface area Generalized exfoliative, ulcerative, or bullous dermatitis	Interrupt treatment; resume at reduced dose when effect is rated grade 2 or lower	Oral antibiotic[c] for 6 weeks Refer to dermatologist If infection is suspected (yellow crusts, purulent discharge, or painful skin or nares): change to a broad-spectrum oral antibiotic with gram-negative coverage Consider skin swab for bacterial culture

[a]Grade according to the National Cancer Institute-Common Terminology Criteria for Adverse Events.
[b]Topical corticosteroids may include (moderate or low strength) triamcinolone acetonide 0.025%, desonide 0.05%, alclometasone 0.05%, fluticasone propionate 0.05%, or hydrocortisone acetate 2.5%. Topical antibiotics include clindamycin 1-2%, erythromycin 1-2%, metronidazole 1%, or fusidic acid 2%.
[c]Oral antibiotics include doxycycline 100 mg twice daily, minocycline 100 mg twice daily, or oxytetracycline 500 mg twice daily.
(Adapted with permission from Lacouture ME, Schadendorf D, Chu CY, et al. Dermatologic adverse events associated with afatinib: an oral ErbB family blocker. Expert Rev Anticancer Ther. *2013;13(6):721–728.)*

agents (Table 49.3). Topical corticosteroids, ammonium lactate, and moisturizing creams are recommended for xerosis (Table 49.4). For paronychia, topical antibiotics or antiseptics and silver nitrate applications can be beneficial (Fig. 49.6 and Table 49.5). Patients with an intolerable grade 2 skin reaction and patients with a severe skin reaction (grade 3 or higher) should be referred to a dermatologist with experience managing patients taking EGFR inhibitors. These patients may also benefit from dose modification (Fig. 49.7). Temporary interruption of EGFR inhibitors may relieve severe skin symptoms but should not last

TABLE 49.3 Management of Pruritus Associated With Epidermal Growth Factor Receptor (EGFR) Inhibitors

Severity of Side Effect[a]	EGFR Inhibitor Dose	Treatment
Grade 1: mild or localized	Continue at current dose	Moderate-strength topical corticosteroid twice daily OR topical antipruritic (pramoxine 1% or doxepin 5% cream) once daily
Grade 2: intense or widespread	Continue at current dose	Moderate-strength topical corticosteroid twice daily OR topical antipruritic (pramoxine 1% or doxepin 5% cream) once daily AND oral antihistamine[b]
Grade 3 or higher: intense or widespread and interfering with activities of daily living	Interrupt treatment; resume at reduced dose when effect is rated grade 2 or lower	Oral antihistamine[b] AND GABA agonist[c] OR aprepitant OR doxepin[d] Refer to dermatologist

[a]Grade according to the National Cancer Institute-Common Terminology Criteria for Adverse Events.
[b]Oral antihistamines include levocetirizine 5 mg once daily, desloratadine 5 mg once daily, diphenhydramine 25 mg to 50 mg three times daily, or fexofenadine 60 mg two or three times daily.
[c]Gamma-aminobutyric acid (GABA) agonists include gabapentin 300 mg every 8 hours, or pregabalin 50 mg to 75 mg every 8 hours. The dose of either drug should be adjusted for patients with renal impairment.
[d]Aprepitant: 125 mg on day 1 and 80 mg on days 2 and 3; doxepin 25 mg to 50 mg every 8 hours.
(Adapted with permission from Lacouture ME, Schadendorf D, Chu CY, et al. Dermatologic adverse events associated with afatinib: an oral ErbB family blocker. Expert Rev Anticancer Ther. 2013;13(6):721–728.)

TABLE 49.4 Management of Xerosis Associated With Epidermal Growth Factor Receptor (EGFR) Inhibitors

Severity of Side Effect[a]	EGFR Inhibitor Dose	Treatment
Grade 1–2: Asymptomatic Symptomatic, not interfering with activities of daily living	Continue at current dose	Over-the-counter moisturizing cream or ointment to face and body twice daily Over-the-counter moisturizing cream or ointment, ceramide-dominant cream, or corneotherapy to face and body twice daily
Grade 3: interfering with activities of daily living	Interrupt treatment; resume at reduced dose when effect is rated grade 2 or lower	Over-the-counter moisturizing cream or ointment, ceramide-dominant cream, or corneotherapy to face and body twice daily AND ammonium lactate 12% cream, urea 10% cream, OR salicylic acid 6% cream to body twice daily[b] AND topical steroid[c] to eczematous areas twice daily

[a]Grade according to the National Cancer Institute-Common Terminology Criteria for Adverse Events.
[b]Avoid ammonium lactate, urea, or salicylic acid creams on erythematous, open skin areas, or fissure wounds.
[c]Topical corticosteroids may include (moderate or low strength) triamcinolone acetonide 0.025%, desonide 0.05%, alclometasone 0.05%, fluticasone propionate 0.05%, or hydrocortisone acetate 2.5%.
(Adapted with permission from Lacouture ME, Schadendorf D, Chu CY, et al. Dermatologic adverse events associated with afatinib: an oral ErbB family blocker. Expert Rev Anticancer Ther. 2013;13(6):721–728.)

TABLE 49.5 Management of Paronychia Associated With Epidermal Growth Factor Receptor (EGFR) Inhibitors

Severity of Side Effect[a]	EGFR Inhibitor Dose	Treatment
Grade 1: nail fold edema or erythema; disruption of cuticle	Continue at current dose	Topical antibiotic[b] AND vinegar soaks[c] AND topical ultrapotent corticosteroid
Grade 2: nail fold edema or erythema with pain, associated with discharge or nail plate separation, limiting instrumental activities of daily living; localized intervention indicated; oral intervention indicated	Continue at current dose	Topical antibiotic[b] AND vinegar soaks[c] AND topical silver nitrate weekly AND topical ultrapotent corticosteroid[d]
Grade 3 or higher: limiting self-care activities of daily living; surgical intervention or intravenous antibiotics indicated	Interrupt treatment; resume at reduced dose when effect is rated grade 2 or lower	Topical antibiotic[b] AND vinegar soaks[c] AND topical silver nitrate weekly; consider nail avulsion AND systemic antibiotic[e] Refer to dermatologist

[a]Grade according to the National Cancer Institute-Common Terminology Criteria for Adverse Events.
[b]Topical antibiotics include clindamycin 1%, erythromycin 1%, tetracycline 1%, or chloramphenicol 1%.
[c]Fingers or toes should be soaked for 15 minutes each day in a 1:1 solution of white vinegar and water.
[d]Topical ultrapotent corticosteroids include clobetasol propionate 0.05%, diflorasone diacetate 0.05%, or betamethasone dipropionate 0.25%.
[e]Systemic antibiotics include tetracycline, doxycycline, minocycline, or cephalexin.
(Adapted with permission from Lacouture ME, Schadendorf D, Chu CY, et al. Dermatologic adverse events associated with afatinib: an oral ErbB family blocker. Expert Rev Anticancer Ther. 2013;13(6):721–728.)

for more than 28 days. Anti-EGFR treatment should be permanently discontinued if dermatologic side effects remain at or above grade 3 despite dermatologic interventions and treatment interruption for 28 days. EGFR TKIs may be reintroduced at a lower dose for patients with a severe skin reaction (grade 3 or higher) that improves (grade 2 or lower) within 28 days of treatment interruption.[21]

Antiangiogenic Agents

Sorafenib, a multikinase inhibitor that targets rapidly accelerated fibrosarcoma (RAF) kinase, VEGF receptors (VEGFR-1 to VEGFR-3), platelet-derived growth factor-alpha, platelet-derived growth factor-beta, c-Kit, and RET, has been approved for use in various malignancies.[32] Hand–foot skin reaction is the
Fig. 49.5. Papulopustular (acneiform) rash (left) may substantially improve after treatment with topical cortico-steroids for 2 weeks (right).

major toxicity of sorafenib treatment requiring clinical management and dose modifications. This reaction is characterized by well-defined, tender palmoplantar hyperkeratotic or blistering lesions, especially in areas of trauma or friction (Fig. 49.8). When sorafenib is used alone, the development of hand–foot skin reaction is associated with dose.[32] However, patients treated with the combination of bevacizumab and sorafenib are at an increased risk of hand–foot skin reaction, suggesting that the pathophysiology may involve VEGF inhibition.[32] Other skin eruptions related to sorafenib therapy include facial or scalp erythema and dysesthesia, alopecia, splinter hemorrhage, keratoacanthoma, leukocytoclastic vasculitis, and epidermal inclusion cysts.

NCI-CTCAE Version 3.0 grade 1 or 2 tolerable skin reaction
Initiate dermatologic treatment

Dose-modification strategy for patients with grade 3 or higher or intolerable grade 2 dermatologic side effects related to treatment with an epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor (TKI). *(Adapted with permission from Lacouture ME, Schadendorf D, Chu CY, et al. Dermatologic adverse events associated with afatinib: an oral ErbB family blocker.* Expert Rev Anticancer Ther. *2013;13(6): 721–728.)* NCI-CTCAE, *National Cancer Institute-Common Terminology Criteria for Adverse Events.*

Fig. 49.8. Hand–foot skin reaction associated with sorafenib therapy is characterized by well-defined, tender palmoplantar hyperkeratotic or blistering lesions, especially in areas of trauma or friction.

Although skin rash (type unspecified) has been reported for some patients after infusion of bevacizumab, it is not a common toxicity of bevacizumab.

GASTROINTESTINAL SIDE EFFECTS OF EGFR INHIBITORS

Diarrhea is a common side effect during the first cycle of treatment with oral EGFR TKIs. The time of onset can vary widely. Diarrheal episodes are usually moderate and are generally well controlled with dose reduction and administration of loperamide.

Mechanism of Diarrhea

The pathophysiology of EGFR TKI-induced diarrhea remains unclear. Diarrhea is related to wild-type EGFR inhibition. Diarrhea is a common side effect for first-generation EGFR TKIs (e.g., gefitinib and erlotinib, which can inhibit wild-type and activating mutation of EGFR) and irreversible, second-generation EGFR TKIs (e.g., afatinib and dacomitinib, which inhibit wild-type, activating mutation, and probably T790M-resistant mutations). Diarrhea is less common in third-generation EGFR TKIs (e.g., osimertinib and rociletinib), which only inhibit wild-type EGFR at high concentrations.[22,33,34] Diarrhea induced by EGFR TKIs is thought to result from excess chloride secretion, causing a secretory form of diarrhea.[35] Little information is available about the histopathology of diarrhea induced by EGFR TKIs. In a phase I trial, microscopic analysis of tissue treated with neratinib (an irreversible EGFR TKI) showed mild duodenal mucosal gland dilatation and degeneration, as well as mild edema and slight villus atrophy in the small intestine.[36]

Incidence and Effect of Diarrhea

In the phase III trials of gefitinib (Iressa Survival Evaluation in Lung Cancer [ISEL] and Iressa Pan-Asia Study [IPASS]), the incidence of diarrhea of all grades was higher with gefitinib (27% to 46.6%) than with placebo (9%) or paclitaxel and carboplatin (21.7%). The incidence of high-grade (grades 3 to 5) diarrhea was greater with gefitinib (3% to 3.8%) than with placebo (1%) or paclitaxel and carboplatin (1.4%).[37,38]

In the phase III trials of erlotinib, the incidence of diarrhea of all grades was 57% in the European Randomized Trial of Tarceva versus Chemotherapy (EURTAC), in which erlotinib

was used as first-line treatment, 19% in the Sequential Tarceva in Unresectable NSCLC (SATURN) trial of maintenance therapy with erlotinib, and 55% in the BR.21 trial in which erlotinib was used as second- or third-line treatment.[39–41] The incidence of high-grade diarrhea in patients receiving erlotinib was 5% in EURTAC, 2% in the SATURN trial, and 6% in the BR.21 trial. In the BR.21 trial, 5% of the erlotinib group required dose reductions because of diarrhea.[41] The incidence and severity of diarrhea were slightly lower in the SATURN trial than in the other studies, possibly because of the better performance status of SATURN trial patients or improved awareness and management of erlotinib-related adverse events by investigators.

Diarrhea is the most common adverse event related to treatment with afatinib. In the phase III trials of afatinib (LUX-Lung 3), the incidence of diarrhea of all grades was substantially higher with afatinib than with chemotherapy (95.2% vs. 15.3%).[42,43] The incidence of high-grade diarrhea was also much higher with afatinib than with chemotherapy (14.4% vs. 0%). Diarrhea led to treatment discontinuation in 1.3% of patients receiving afatinib. The incidence of grade 3 or grade 4 diarrhea was lower in an afatinib phase II study (7%) and another phase III study (5%).[44] The lower incidence of severe diarrhea may be a result of better management and prevention in the few centers that participated in these clinical trials. In the randomized phase II trial of dacomitinib, the incidence of all-grade diarrhea was higher with dacomitinib than with erlotinib (73.1% vs. 47.9%).[45] The incidence of high-grade diarrhea was higher with dacomitinib than with erlotinib (11.8% vs. 4.3%). Grade 2 diarrhea led to treatment discontinuation for one (1.1%) of 94 patients receiving dacomitinib. In the randomized phase II trial of afatinib versus gefitinib (LUX-Lung 7), all-grade diarrhea occurred more frequently in afatinib (90% vs. 61%). Grade 3 diarrhea was also more common with afatinib treatment (11.9% vs. 1.3%). Drug-related adverse events leading to discontinuation occurred in 6.3% and 6.3% of patients, respectively. However, the most common reason to discontinue afatinib was diarrhea in five patients (3.1%), whereas gefitinib increased alanine transaminase in five patients (3.1%).[45a]

Consequences and Management of Diarrhea

Severe diarrhea may result in fluid and electrolyte losses that lead to dehydration, electrolyte imbalances, and renal insufficiency.[22] Patients should be advised to take loperamide, 2 mg to 4 mg, after the first incidence of watery diarrhea. Two milligrams of loperamide can be taken every 4 hours to a maximum of 20 mg/day until diarrhea improves to grade 1. Patients with high-grade diarrhea or grade 2 diarrhea for more than 48 hours should temporarily discontinue the EGFR TKI therapy. Patients should consume enough water and electrolytes to prevent dehydration and renal damage. Because diarrhea is a common side effect of many cancer treatment regimens, guidelines for its management are well established.[46] Patients should be advised to discuss any symptoms of diarrhea with their health-care team immediately to facilitate early and effective management and prevent dose reductions or treatment discontinuation. Patients with frequent diarrhea should consume a light diet without dairy products. Dose reduction of EGFR TKIs should be considered for severe or recurrent diarrhea that affects the patients' quality of life.

PULMONARY SIDE EFFECTS: INTERSTITIAL LUNG DISEASE

Acute interstitial lung disease is an adverse event seen with all EGFR TKIs: gefitinib, erlotinib, afatinib, and osimertinib. More than one-third of reported cases are fatal. Patients with preexisting lung disease are at an increased risk.[47]

Mechanism of Interstitial Lung Disease

The development of EGFR TKI-induced interstitial lung disease is most likely related to decreased alveolar regeneration, a process normally regulated by EGFR, in a population with a high prevalence of preexisting pulmonary disease. Patients typically present with acute onset of dyspnea, cough, and pyrexia. In a series of Japanese patients, chest computed tomography images showed diffuse ground-glass opacities and evaluation of tissue samples indicated that there was diffuse alveolar damage with hyaline membrane formation.[48]

Incidence of Interstitial Lung Disease

Interstitial lung disease usually develops within 3 weeks to 7 weeks after the start of gefitinib therapy, and one-third of cases are fatal. The US Food and Drug Administration reported a 1% incidence of interstitial lung disease among 50,000 patients who received gefitinib worldwide.[49] In the ISEL trial, the frequency of interstitial lung disease events was similar in the two treatment groups (1%).[37] In IPASS, interstitial lung disease events occurred in 16 (2.6%) of 607 patients treated with gefitinib, three of whom died, and in eight (1.4%) of 589 patients treated with paclitaxel and carboplatin, one of whom died.[38] The incidence of interstitial lung disease has been reported to be higher in Japan (2%) than in the United States (0.3%).[49] In a review of data from more than 1900 Japanese patients with NSCLC treated with gefitinib over a 4-month period (3.5%) cases of interstitial lung disease were reported, of which 44% were fatal. Other than Japanese ethnicity, risk factors for the development of interstitial lung disease include male gender, a history of smoking, and a presence of interstitial pneumonia (odds ratios, 3.1, 4.79, and 2.89, respectively).[50] In addition, interstitial lung disease develops in 6.6% of men with a history of smoking. Approximately 90% of patients in whom gefitinib-induced interstitial lung disease develops have received prior radiotherapy or chemotherapy.[48]

Interstitial lung disease occurs in 1.1% of patients receiving erlotinib.[51] The onset of symptoms may range from 5 days to more than 9 months (median, 39 days) after initiating erlotinib therapy. The incidence of pneumonitis or pulmonary infiltrates of all grades was 1% when erlotinib was used as first-line treatment in EURTAC and 3% when it was used as a second- or third-line treatment in the BR.21 trial.[39,41] The incidence of grade 3 to grade 5 interstitial lung disease was 1% in EURTAC and less than 1% in the BR.21 trial. Serious interstitial lung disease, including fatal cases, can occur with erlotinib treatment. In the SATURN trial, the most frequently reported serious adverse event was pneumonia: seven (2%) cases were reported in the erlotinib arm, compared with four (less than 1%) in the placebo arm.[40] In the BR.21 trial, one of 485 patients in the erlotinib arm and one of 242 patients in the placebo arm died from pneumonitis.[41] Risk factors for the development of interstitial lung disease with erlotinib were similar to the risk factors identified in trials of gefitinib.

In a phase II study of afatinib that included 129 patients with EGFR mutations, four patients discontinued afatinib because of possible interstitial lung disease.[43] In the phase III randomized study, possible interstitial lung disease developed in three of 230 patients with lung adenocarcinoma positive for EGFR mutation who received frontline afatinib.[42]

Management of Interstitial Lung Disease

In most interstitial lung disease case series reports, the authors indicate that drug discontinuation, supportive therapy with mechanical ventilation, and high-dose corticosteroids are the only useful interventions and that up to 40% of cases are fatal.[48,50] Resuming EGFR TKIs after resolution of symptoms has been

associated with recurrence of interstitial lung disease. EGFR TKIs should be withheld for acute onset of new or progressive unexplained pulmonary symptoms, such as dyspnea, cough, and fever. EGFR TKIs should be permanently discontinued if interstitial lung disease is diagnosed.[49,51] The best strategy for preventing severe interstitial lung disease seems to be early diagnosis and EGFR TKI discontinuation. Frequent chest radiography for a few weeks after initiating EGFR TKIs and patient education for early signs of interstitial lung disease are important steps to prevent complications in populations with a high prevalence of EGFR TKI-induced interstitial lung disease.[52]

BEVACIZUMAB AND RAMUCIRUMAB SIDE EFFECTS

Bevacizumab causes a wide range of class-related adverse effects. A noteworthy concern with this class of agents is the potential for vessel injury and bleeding, which has been seen in patients with squamous cell lung cancer.[53] Bevacizumab is contraindicated for patients with a history of hemoptysis, brain metastasis, or a bleeding diathesis, but in appropriately selected patients, the rate of life-threatening pulmonary hemorrhage is less than 2%.[7]

The safety of operating on patients treated with bevacizumab continues to be a major concern because of the risk of bleeding and poor wound healing. In a pooled analysis of two large clinical trials in patients with colon cancer, individuals who needed surgery while being treated with bevacizumab had a higher frequency of serious wound healing complications than individuals treated with placebo (13% vs. 3.4%).[54] In light of these data and because of the long half-life of bevacizumab, elective surgery should be delayed for at least 4 weeks from the last dose of antibody, and treatment should be not resumed for at least 4 weeks after surgery.[55]

Other toxicities characteristic of antiangiogenic drugs include hypertension and proteinuria. A majority of patients receiving bevacizumab require antihypertensive therapy, particularly patients receiving higher doses and more prolonged treatment.[7,56] The mechanism of bevacizumab-related hypertension is still unclear but may relate in part to decreased endothelial nitric oxide production.[57] Physicians should carefully monitor the blood pressure of all patients on bevacizumab and intervene with antihypertensives when appropriate. In some studies, reversible posterior leukoencephalopathy developed during bevacizumab treatment in patients with poorly controlled hypertension.[58–60] Bevacizumab has also been associated with congestive heart failure, probably secondary to hypertension.[61] Proteinuria often develops during bevacizumab treatment, but it is usually an asymptomatic finding and rarely associated with nephrotic syndrome.[62]

Arterial thromboembolic events (i.e., stroke or myocardial infarction) are serious concerns with antiangiogenic agents.[63] The authors of a meta-analysis reported that the incidence of arterial thromboembolic events was 3.8% in patients receiving bevacizumab-containing regimens compared with 1.7% in the control group.[63] To reduce the risk of arterial thromboembolic events, clinicians should carefully evaluate a patient's risk factors (e.g., age older than 65 years, clotting diathesis, a history of arterial thromboembolic events) before initiating treatment.

Gastrointestinal perforation, a potentially life-threatening complication of bevacizumab, has been reported in up to 11% of patients with ovarian cancer, perhaps related to the presence of peritoneal carcinomatosis and to prior abdominal surgery.[64] Colonic perforation is rare during bevacizumab treatment for colon cancer, but it occurs most frequently in patients with intact primary colonic tumors, peritoneal carcinomatosis, peptic ulcer disease, chemotherapy-associated colitis, diverticulitis, or a history of abdominal radiotherapy. The rate of colonic perforation is less than 1% in patients with breast or lung cancer who receive the antibody.[55,64] Gut perforation is an infrequent side effect of bevacizumab in patients with lung cancer. However, special caution should be taken for patients with lung cancer and peritoneal metastasis who are receiving bevacizumab.

Ramucirumab is a fully human immunoglobulin G1 monoclonal antibody that specifically binds to VEGFR-2. A randomized phase III trial of docetaxel plus ramucirumab versus docetaxel plus placebo as the second-line therapy in patients with NSCLC was reported. Incidence of febrile neutropenia was higher in patients treated with ramucirumab than in controls (grade 3: 10% vs. 6%; grade 4: 6% vs. 4%). Patients in the ramucirumab group had more bleeding events of any grade (29% vs. 15%), although rates of grade 3 or worse events were the same. Incidence of epistaxis of any grade was significantly higher in the ramucirumab group than in the control group, but few grade 3 or worse events occurred. Of note, this trial enrolled patients with both squamous cell and nonsquamous cell carcinoma excluding major blood vessel involvement and intratumor cavitation. Hypertension occurred more frequently in the ramucirumab group than in the control group, with one grade 4 hypertension event occurring in the ramucirumab group.[65]

ANAPLASTIC LYMPHOMA KINASE INHIBITOR SIDE EFFECTS

The most common adverse reactions to crizotinib, an ALK and MET inhibitor, are vision disorders, nausea, diarrhea, vomiting, edema, and constipation, which occur in 25% of patients or more.[66,67]

Given the role of ALK in the development of the visual system and gut, it is tempting to speculate that several of the common adverse effects result from direct anti-ALK effects on the native protein. Peripheral edema may be a notable exception, as this adverse effect also has been reported with MET inhibition.[68] Other ALK-specific inhibitors (e.g., AP26113, ASP3026, alectinib, ceritinib) are not associated with peripheral edema.[69] The visual disturbances associated with crizotinib include brief light trails, flashes, or image persistence occurring at the edges of the visual field, and these effects usually begin within days after treatment has started. The disturbances occur most commonly with changes in lighting. Studies in rats have demonstrated that crizotinib causes reductions in the rate of retinal dark adaptation but not the ability to achieve full dark adaptation, offering a partial explanation for these clinical findings. Severe side effects associated with crizotinib are rare. Drug holidays followed by rechallenge at a lower dose have allowed ongoing treatment in some cases of severe neutropenia or transaminitis, but permanent drug discontinuation is occasionally required.[70]

Crizotinib-induced hepatotoxicity has occurred with fatal outcomes. Biweekly monitoring of transaminases for the first 2 months of treatment is recommended. Severe, including fatal, treatment-related pneumonitis has occurred. Patients should be monitored for pulmonary symptoms indicative of pneumonitis. In patients with a history of or predisposition for QTc prolongation, or for patients who are taking medications known to prolong the QT interval, clinicians should consider periodic monitoring with electrocardiography and determination of serum electrolyte levels.[70]

Given reports that rapid-onset hypogonadism occurs in the majority of men taking crizotinib, serum testosterone levels should be routinely checked and replaced as appropriate during therapy.[71,72] Case reports of crizotinib-induced asymptomatic profound bradycardia and renal cysts were published between 2011 and 2013, the clinical significance of which remains uncertain.[70,73,74]

HEAT-SHOCK PROTEIN 90 INHIBITOR SIDE EFFECTS

HSP90 inhibitors (e.g., ganetespib [STA-9090], retaspimycin [IPI-504], luminespib [AUY922]) are currently being tested

in patients with certain molecular subtypes of NSCLC, such as ALK fusion.[75,76] The side effect profile of the *N*-terminal-binding radicicol and geldanamycin analogs (e.g., retaspimycin) differs from that of the next-generation synthetic resorcinol-containing chemo-type agents (e.g., AUY922) because of structural differences.[77] For example, reversible visual disturbance has been reported in patients receiving AUY922 but not retaspimycin.[78]

BRAF INHIBITOR SIDE EFFECTS

BRAF inhibitors (e.g., vemurafenib, dabrafenib) have been approved in BRAF-mutated malignant melanoma and are currently being tested in clinical trials for BRAF-mutated NSCLC.[4,79,80] BRAF mutations occur in 1% to 2% of lung adenocarcinoma cases.[81–83] Cutaneous squamous cell carcinoma is a class side effect of BRAF inhibitors. Febrile reaction is unique to dabrafenib.

Skin tumors, especially keratoacanthoma and cutaneous squamous cell carcinoma, have developed in a high percentage of patients in clinical trials of vemurafenib or dabrafenib.[84] Experience from clinical trials of melanoma has shown that the most common grade 2 or higher toxicities were cutaneous squamous cell carcinoma or keratoacanthoma (5% to 11%), fatigue (8%), and pyrexia (3% to 6%). Palmoplantar hyperkeratoses and actinic keratoses were also common but mild. Phototoxicity was rare (3%).[85] Studies have shown that different RAF inhibitors activate the ERK pathway in cells with wild-type BRAF via a mechanism involving dimerization of BRAF and RAF proto-oncogene serine/threonine-protein kinase (CRAF) and transactivation of the inhibitor-free promoter in a RAS–guanosine triphosphate-dependent manner.[84] These findings provide the most likely explanation for the development of skin tumors during RAF inhibitor treatment. Cutaneous toxicities such as rash, hyperkeratosis, cutaneous squamous cell carcinoma, and keratoacanthoma occur with both vemurafenib and dabrafenib, but have been reported to occur to a lesser degree with dabrafenib. Of note, cutaneous squamous cell carcinoma has occurred in 19% of patients with vemurafenib and in only 5% of patients with dabrafenib.[85]

In a 2013 systematic dermatologic study of 42 patients, 100% of patients treated with vemurafenib presented with at least one adverse skin reaction.[86] The most common cutaneous side effects were verrucous papillomas (79%) and hand–foot skin reaction (60%). Other common cutaneous toxic effects were a diffuse hyperkeratotic perifollicular rash (55%), photosensitivity (52%), and alopecia (45%). Keratoacanthoma and cutaneous squamous cell carcinoma occurred in 14% and 26% of the patients, respectively.[86]

Several surgical approaches are available to manage keratotic growths. For small and superficial lesions, destructive modalities such as curettage and electrodessication or cryosurgery may be sufficient.[87] Mohs micrographic surgery may be needed for larger lesions. When surgical treatment is either impractical or undesirable, other strategies such as topical 5-fluorouracil may be used.[87] Reduction of vemurafenib or dabrafenib dose is another potential management strategy. Bexarotene and other systemic retinoids may be helpful for vemurafenib-associated cutaneous squamous cell carcinoma and keratoacanthoma.[87] Use of a MEK inhibitor in combination with vemurafenib or dabrafenib may block paradoxical mitogen-activated protein kinase signaling downstream of CRAF in keratinocytes.[86,87]

In the pivotal trial of vemurafenib in melanoma, cutaneous squamous cell carcinoma occurred in 40 (12%) of 336 patients treated with vemurafenib and in 1 (<1%) of 282 patients treated with chemotherapy.[88] In the pivotal trial of dabrafenib in melanoma, cutaneous squamous cell carcinoma and keratoacanthoma occurred in 14 (7%) of 187 patients treated with dabrafenib and in none of the patients treated with chemotherapy.[89] Across clinical trials of dabrafenib (586 patients), the incidence is between 6%

and 10%.[89–91] The median time to the first cutaneous squamous cell carcinoma was 9 weeks (range, 1 week to 53 weeks). Among patients in whom a cutaneous squamous cell carcinoma developed, at least one additional cutaneous squamous cell carcinoma developed in approximately 33% with continued dabrafenib. The median time between diagnosis of the first and second cutaneous squamous cell carcinoma was 6 weeks.[89–91]

Serious febrile drug reactions have occurred only with dabrafenib. In a melanoma trial, serious febrile drug reactions—defined as serious cases of fever or fever of any severity accompanied by hypotension, rigors or chills, dehydration, or renal failure in the absence of another identifiable cause (e.g., infection)—occurred in 7 (3.7%) of 187 patients treated with dabrafenib and in none of the patients treated with dacarbazine. The incidence of fever (serious and nonserious) was 28% in patients treated with dabrafenib and 10% in patients treated with dacarbazine.[89] In patients treated with dabrafenib, the median time to initial onset of fever (any severity) was 11 days (range, 1 day to 202 days) and the median duration of fever was 3 days (range, 1 day to 129 days).[89]

MEK INHIBITOR SIDE EFFECTS

MEK inhibitors (e.g., refametinib, selumetinib, trametinib, cobimetinib) have been tested in clinical trials for the treatment of NSCLC.[92] The most common adverse effects of MEK inhibitors (e.g., trametinib) are rash, diarrhea, peripheral edema, fatigue, and dermatitis acneiform.[93] MEK inhibitors also have unique cardiac and ophthalmologic side effects.[94]

Central serous retinopathy can occur during treatment with trametinib. In a melanoma trial, ophthalmologic examinations including retinal evaluation were performed at baseline and at regular intervals during treatment; central serous retinopathy developed in one patient (less than 1%) who received trametinib; however, no cases of central serous retinopathy were identified in chemotherapy-treated patients. In addition, no cases of retinal vein occlusion had been reported at the time of analysis.[94] Ophthalmologic evaluation should be performed any time a patient reports visual disturbances, and the results should be compared with baseline, if those data are available. If central serous retinopathy is diagnosed, trametinib should be withheld. If repeat ophthalmologic evaluation indicates resolution of the central serous retinopathy within 3 weeks, the patient may resume trametinib at a reduced dose.

PD1 AND PD-L1 MONOCLONAL ANTIBODY SIDE EFFECTS

NSCLC is now known to be an immunologically targetable cancer. Anti-PD1 antibodies (e.g., nivolumab, pembrolizumab [MK-3475]) and anti-PD-L1 antibodies (e.g., atezolizumab [MPDL3280A], durvalumab [MEDI4736]) have shown effectiveness in treating NSCLC.[95,96]

In a phase I trial, 296 patients were treated with nivolumab at 1 mg/kg to 10 mg/kg.[96] Treatment-related adverse events occurred in 70% of patients. As many as 14% of patients had grade 3 or grade 4 treatment-related adverse events, the most common of which was fatigue. Immune-related adverse events of all grades, including rash (12%), pruritus (9%), diarrhea (11%), transaminitis (3% or less), thyroid abnormalities (3% or less), and infusion-related reaction (3% or less), occurred in 41% of patients. Grade 3 or grade 4 immune-related adverse events occurred in 6% of patients, which mainly included diarrhea, rash, transaminitis, and thyroid abnormalities. Pneumonitis (any grade) developed in nine patients (3%); grade 3 or grade 4 pneumonitis developed in three (1%). Three patients died of pneumonitis.

Among 135 patients with melanoma who were treated with pembrolizumab (MK-3475), 2 mg/kg or 10 mg/kg, in a phase

I trial, adverse events occurred in 72% of patients.[97] As many as 9% of patients had grade 3 to grade 5 treatment-related adverse events, most commonly fatigue. Immune-related adverse events of any grade occurred in 15.9% of patients; these events included rash (4.5%), influenza (3.0%), pruritus (2.2% or less), eczema (2.2% or less), vitiligo (2.2% or less), and hypothyroidism (2.2% or less). Grade 3 or grade 4 immune-related adverse events occurred in 5.3% of patients, mainly thyroid abnormalities. Grade 1 or grade 2 pneumonitis developed in four patients (3%). Of note, no cases of pneumonitis were reported in the clinical trials of the anti-PD-L1 antibodies BMS-936559 and MPDL3280A.[98]

ETHNIC DIFFERENCES IN SIDE EFFECTS OF TARGETED THERAPY

Differences in drug-related side effects by patient ethnicity are a source of concern.[52] Several factors contribute to the different experience patients have in drug-related efficacy and toxicities. Extrinsic factors included medical practice pattern, patients' access to health care, dietary patterns, and living environment, among others. Intrinsic factors include body size, body composition, and, most importantly, genetic differences related to drug absorption, distribution, metabolism, and excretion. For most drugs, interpatient variability is usually higher than interethnic variability.

Interstitial lung disease is an important example of the effect of ethnicity on adverse event frequency. The frequency of treatment-induced interstitial lung disease reported in Japanese studies is 3.5% to 5.8% for patients managed with gefitinib or erlotinib; mortality from interstitial lung disease is 1.6% to 3.6%.[50,52] An independent review committee reported that in a postmarketing surveillance study of 3488 Japanese patients, interstitial lung disease occurred in 4.5% of erlotinib-treated individuals, of whom 55 (1.6%) died.[99] Interstitial lung disease developed in 42 of 1080 Taiwanese patients treated with gefitinib, and the condition was considered to be gefitinib related in 25 (2.3%) of them.[100] However, the frequency of interstitial lung disease among patients treated with EGFR TKIs outside Asia is around 1%.[49,51] It is unclear what factors contribute to this striking disparity. In the ISEL study, the frequencies of gefitinib-related side effects were not formally compared between the group of Asian patients and the overall study population, but there were no apparent differences in most side effects, including diarrhea or skin rash. A higher percentage of severe grade 3 and grade 4 pneumonia was seen among the 235 (6.4%) Asian patients compared with 891 (1.7%) non-Asian patients.[101]

In the LUX-Lung 3 study of afatinib compared with pemetrexed and cisplatin in patients with EGFR mutation, the frequency of grade 3 diarrhea was higher in Japanese patients (20%) than in white patients (11%). This result could be due to the low dosages of loperamide typically used in Japan or to the smaller body size of Japanese patients using the same 40-mg dose of afatinib.[42]

Preliminary data show that crizotinib concentration is higher in Asian patients than in other patients taking the same dosage. However, there were no differences in crizotinib-related side effects by ethnicity in phase II studies.[102]

Cytochrome P450 polymorphisms are distributed unequally among ethnic groups and may contribute to differences in the frequency of drug-related side effects. For example, tivantinib (ARQ197), a cMET inhibitor, is metabolized by 2C19, which has extensive-metabolizer and poor-metabolizer forms. Patients with the poor-metabolizer 2C19 polymorphism may have excessive hematologic toxicity if given the same dose of tivantinib as an individual with the extensive-metabolizer polymorphism (360 mg, twice daily). The 2C19 poor-metabolizer polymorphism is rare among white individuals but is present in 20% of Asian individuals. Therefore it is necessary to test for 2C19 polymorphisms in Asian patients to determine appropriate dosing.[103]

CONCLUSION

Targeted therapies are effective treatment options for patients with advanced lung cancer. Given rapid advances in molecular classification of lung cancers, targeted therapies have demonstrated increasingly good anticancer activity. The side effects of targeted therapy are different from the effects of chemotherapy. Most, if not all, side effects are manageable, preventable, and treatable. Early identification of the side effects followed by appropriate treatment is important to maximize the benefit of targeted therapy for patients with lung cancer.

50 Immunotherapy and Lung Cancer

Leena Gandhi, Johan F. Vansteenkiste, and Frances A. Shepherd

SUMMARY OF KEY POINTS

- Immunotherapy has entered a new era in lung cancer and is rapidly changing the standard of care.
- Vaccines as monotherapies have shown marginal efficacy in certain settings.
- Program death-1 (PD1) and PD1 ligand (PDL1) inhibitors have showed marked and durable responses for a broad subset of lung cancer patients with overall survival rates that far exceed what has been seen with chemotherapy. In addition, the overall toxicity rate is lower than what has been seen with chemotherapy.
- PDL1 is a potential but imperfect biomarker of response in nonsmall cell lung cancer.
- Combination therapies (with other immunomodulators, vaccines, chemotherapy, and radiation) are actively being explored to extend the benefit of PD1 inhibition to more patients.

Lung cancer is the leading cause of cancer-related death, and 85% of patients with this condition are diagnosed with nonsmall cell lung cancer (NSCLC). Modest improvements in cure rates have been observed among patients with early and locally advanced disease; nevertheless, the majority of patients die as a result of a metastatic progression of the cancer.[1] Patients with advanced-stage NSCLC have a median overall survival (OS) of 10 months and a 1-year survival rate of about 40% when treated with modern platinum-doublet chemotherapy, although this time frame has somewhat been extended to a median OS of 13.9 months with maintenance pemetrexed following cisplatin–pemetrexed in nonsquamous lung carcinoma.[2] Tumors with specific oncogenic drivers are particularly sensitive to specific tyrosine kinase inhibitors that represent significant improvements over chemotherapy for these subgroups. Such therapy is approved for tumors with activating epidermal growth factor receptor (EGFR) mutation, anaplastic lymphoma kinase translocation, or c-ros oncogene (ROS) translocation, and several other oncogenic drivers have targeted therapies in development. However, there are still large populations of NSCLC without any targeted therapy available to them.

Immunotherapy using programmed death receptor (PD1) or PD1 ligand (PDL1) inhibitors has already changed the outcomes for advanced NSCLC patients, in some cases more than doubling survival times, and the survival improvements that are possible with combination therapy are still to be determined. As in many tumor types, the rapid advent of immunotherapy-based regimens built on a backbone of PD1 or PDL1 inhibition is rapidly changing our standards of care. Many trials of PD1/PDL1 inhibitors are ongoing in patients in different stages of lung cancer, in combination with vaccines, chemotherapy, radiation, targeted therapy, and with novel immunotherapeutics, suggesting that more change is yet to come.

IMMUNOLOGIC DYSFUNCTION IN PATIENTS WITH LUNG CANCER

The principle of immunosurveillance, that is, the ability of the immune system to recognize malignant cells as foreign and, possibly, to eliminate them, has long been accepted, but the many potential mechanisms of tumor evasion from immune surveillance are now beginning to be targeted with therapeutic agents.[3]

Normal immunosurveillance starts with uptake of tumor antigens by antigen-presenting cells (APCs), particularly dendritic cells (Fig. 50.1). The antigens are internalized, processed into small peptide sequences, and displayed on the extracellular surface of the APC in the presence of the class I and class II major histocompatibility complex (MHC). The dendritic cell with antigenic peptides on its surface circulates to the draining lymph nodes and matures, leading to interaction with naive T lymphocytes.[4]

This interaction results in activation of the CD4+ T-helper lymphocytes—with liberation of several cytokines, for example, interleukin-2 (IL-2; Th1 cells), IL-12 (dendritic cells), and interferon gamma (Th1 cells)—and subsequent activation of CD8+ T cells into cytotoxic T lymphocytes.[5] For this T-cell activation to occur, there must be an interaction between the specific T-cell receptor on naive T cells and the antigen presented by the APC on an MHC molecule. A required costimulatory event is the interaction between the B7 molecules (B7-1 [CD80], B7-2 [CD86]) on the APCs and CD28 on the T cells (Fig. 50.2).[6] Finally, activated cytotoxic T lymphocytes will recognize tumor cells (TCs) that display the complementary peptide–MHC class 1 complex on their cell surface and induce apoptotic cell death.[3,7]

To prevent excessive reactions with autoimmunity and damage to normal host tissue, modulation of activated CD8+ cells is required. Activated CD8+ T cells also express cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) on their surface. Binding of CTLA-4 with CD80 or CD86 on APCs provides an inhibitory signal and limits further T-cell activation. This mechanism against autoimmunity also may be responsible for the tolerance of tumor antigens.[8] Although PD1 was identified on exhausted T cells in 1992, it was after the discovery of the PDL1 ligand (B7-H1) on lymphoid and nonlymphoid tissues that the role of PDL1:PD1-mediated downregulation of immune activation in peripheral tissues was clarified.[9,10] Interaction of PD1 with its ligand results in downregulation of T-cell mediated cell killing, altered cytokine production, and ultimately apoptosis.[10–14] PDL1 is expressed in various normal tissues in response to inflammatory cytokine signaling to maintain self-tolerance. This same mechanism can be co-opted by TCs to avoid an acquired immune response to tumor-associated antigens.[15,16]

Overall, lung cancer and other tumors can induce major immunologic dysfunction through a variety of mechanisms. Downregulation of antigens and decrease of expression of MHC class I molecules and costimulatory molecules lead to failure of T-cell recognition and activation. Inhibitory cytokines such as indoleamine 2,3-dioxygenase and transforming growth factor-beta (TGF-β) impede the maturation of dendritic cells and promote the development of T-regulatory cells and myeloid-derived suppressor cells, which have a powerful immunosuppressive action. Inhibition of T-cell activation by the CTLA-4 interaction
Fig. 50.1. Vaccines for the treatment of non-small cell lung cancer: investigational approaches and clinical experience.* Lung Cancer. *2011;73:11–17.)*

with B7 and PDL1–PD1 interactions to suppress effector T-cell function can contribute centrally and locally to immune suppression. Lastly, the failure to activate apoptotic mechanisms in response to the effect of cytotoxic T lymphocytes may render the lung cancer cells insensitive to immune control.[17]

SUPPORTING EVIDENCE FOR THE USE OF IMMUNOTHERAPY FOR LUNG CANCER

Although lung cancer historically was not considered to be an immunogenic malignancy, there is evidence suggesting that there may be important immune responses in patients with lung cancer. The LACE-Bio group, in a study of 1600 patients with resected early-stage NSCLC, found that marked infiltration of the tumor by lymphocytes was associated with significantly longer disease-free survival and OS (hazard ratio [HR], 0.57 [p = 0.0002] and 0.56 [p = 0.0003], respectively).[18] Other studies also have shown that increased stromal infiltration of CD4+/CD8+ T cells is independently associated with better prognosis in cases of early-stage NSCLC.[19,20] By contrast, high expression of tumor-infiltrating T-regulatory cells—that is, reduced antitumor immunity—has been associated with recurrence of disease.[21,22] Patients with advanced-stage NSCLC, in whom tumors have higher numbers of macrophages and CD8+ T cells compared with the surrounding stroma, have better survival rates.[23] The overexpression of PDL1 by TCs in NSCLC has been demonstrated in several retrospective studies, which have reported rates of 27% to 58%. Several of these studies report an increased

inflammatory infiltrate associated with PDL1 overexpression.[24–29] The expression of PDL1 by TCs may also be mediated by the activation of specific oncogenes associated with NSCLC including EGFR.[24,30–32] Smoking status has also been correlated with elevated PDL1 expression.[32] However, the association between OS and PDL1 expression remains controversial with reports of both an associated improvement and decrease in OS.[24–27] PDL1 overexpression and associated activation of the PD1 pathway thus appear to be broadly exploited by TCs in NSCLC as a means to evade T-cell-mediated antitumor activity. These findings support the strategy to use or manipulate the immune system to generate antitumor effects to improve the outcomes for patients with lung cancer.

The approaches toward therapeutic modulation of immune responses fall into two primary categories. The first, "active" immunotherapy includes modes of stimulating the immune response, such as ILs, interferons, or antigen-specific immunotherapy. Historically, and even in some recent large phase III trials, "active" immunomodulatory agents that stimulate immune response have been associated with disappointing results in lung cancer. Historical examples include trials investigating bacillus Calmette-Guérin,[33] levamisole,[34] or interferons and ILs.[35] More recent examples include trials investigating PF-3512676 (ProMune), an agonist of the toll-like receptor 9 that enhances maturation of dendritic cells,[36,37] and talactoferrin alpha, an oral recombinant human lactoferrin, acting by dendritic cell recruitment and activation in the gut-associated lymphoid tissue.[38]

Therapeutic cancer vaccination is a mode of antigen-specific "active" immunotherapy in which the immune system is primed to produce antigen-specific antibodies, CD4+ T-helper cells, and CD8+ cytotoxic T lymphocytes against relevant tumor-associated antigens. This has been an active area of research in lung cancer, but one that has had largely marginal benefits seen as monotherapies to date, which are reviewed in the following sections.

The second approach, "passive immunotherapy," involves blocking inhibitory signals that suppress immune responses against cancer. Examples of the latter include monoclonal antibodies that modulate T-cell activity by inhibiting CTLA-4, PD1, or PDL1, also known as immune checkpoint inhibitors. It is this latter category of therapy, specifically PD1 and PDL1 antibodies, that has galvanized the field of immunotherapy in lung cancer by demonstrating marked clinical benefit in subsets of patients and this, therefore, will constitute the majority of the discussion here.

VACCINES

Antigen-specific immunotherapeutic agents always have two major components. The first component consists of immunogenic tumor-associated antigens, which can be DNA, RNA, peptides, recombinant proteins, gangliosides, or whole TCs. However, the presence of tumor-associated antigens alone is insufficient for a therapeutic cancer vaccine as the immune system already has failed to control the cells expressing these antigens; otherwise, the tumor would not have grown to a clinical level. Therefore, a strong adjuvant is added to potentiate the immune response.[39] This immunoadjuvant can be a phospholipid or aluminum formulation, a viral vector, a dendritic cell, or a liposome preparation. There are many vaccination strategies and compounds in development. Most have been evaluated either in the adjuvant setting or following first-line chemotherapy in the advanced setting to determine whether they can stave off progression of disease. We will review some of the agents that are still in clinical development and the change in direction now being taken with the success of immune checkpoint inhibitors.

Melanoma-Associated Antigen-A3 Vaccine

Melanoma-associated antigen (MAGE)-A3 is expressed almost exclusively on TCs and is not expressed in normal tissue, except in

male germ line cells; however, such cells do not present the antigen as they lack MHC molecules.[40] The function of MAGE-A3 is unknown, but its expression has been associated with worse prognosis in cases of lung cancer.[41] Expression has been documented in 35% of early-stage NSCLC.[42]

The vaccine contains a recombinant fusion protein (MAGE-A3 and protein D of *Haemophilus influenzae*) in combination with an immune response-enhancing adjuvant (AS02B in the phase II study and AS15 in the phase III study).[43]

For NSCLC, the proof-of-concept study was a double-blind, placebo-controlled randomized phase II trial.[44] Patients with completely resected MAGE-A3-positive stage IB to stage II NSCLC were randomly assigned to receive MAGE-A3 vaccine (122 patients) or placebo (60 patients). No adjuvant chemotherapy was given, as this therapy was not recommended at the time of the study. The disease-free interval was the primary end point of the study and, at a median of 70 months after resection, there was a nonsignificant trend in favor of MAGE-A3 (HR for disease-free interval, 0.75; 95% confidence interval [CI], 0.46–1.23; *p* = 0.254). A potential gene signature, which was found to be predictive of the clinical activity of the MAGE-A3 vaccine in a trial involving patients with metastatic melanoma,[45] was further validated in a separate study in early-stage NSCLC.[46] The disease-free interval was better for actively treated patients with NSCLC and a positive gene signature compared with patients who received placebo (HR, 0.42; 95% CI, 0.17–1.03; *p* = 0.06); among patients with a negative gene signature, no benefit was found (HR, 1.17; 95% CI, 0.59–2.31; *p* = 0.65).

On the basis of these data, a large double-blind, randomized placebo-controlled phase III trial (MAGE-A3 as Adjuvant NSCLC Immunotherapy Trial [MAGRIT]) was conducted from 2007 to 2012 and reported in 2016.[47] Patients with MAGE-A3 overexpression (4210 of 13,489 originally screened) who had completely resected stage IB to stage IIIA NSCLC and adjuvant chemotherapy as clinically indicated were randomly assigned (in a 2:1 ratio) to receive MAGE-A3 vaccine or placebo. There was no difference in disease-free survival between the two groups: median 60.5 months in the vaccinated group and 58.0 months in the placebo group (HR, 0.97; 95% CI, 0.80–1.18; *p* = 0.76). In the absence of any treatment effect, no gene signature predictive of response could be evaluated or validated. Further development of the MAGE-A3 vaccine in NSCLC has been stopped.

Mucinous Glycoprotein-1 Vaccines

Tecemotide (L-BLP25)

Mucinous glycoprotein-1 (MUC1) is a highly glycosylated transmembrane protein that is present in normal tissue only at the apical surface of the epithelial cell.[48] Its exact function remains unclear, but MUC1 may promote cell growth and survival.[49] In cancer cells, MUC1 is overexpressed with loss of polarity of expression and is underglycosylated or aberrantly glycosylated, which results in unmasking of its peptide epitopes, thus identifying a potential target for immunotherapy.[50]

Tecemotide (L-BLP25) is a peptide vaccine based on a 25-amino-acid sequence from the MUC1 protein in a liposomal delivery system (consisting of cholesterol, dimyristoyl phosphatidylglycerol, and dipalmitoyl phosphatidylcholine), which facilitates uptake by APCs, and monophosphoryl lipid A, which is added to enhance immune stimulation.[51]

In an open-label phase II randomized study, 171 patients with stage IIIB to stage IV NSCLC who had a response or stable disease after first-line therapy were randomly assigned to best supportive care plus tecemotide (88 patients) or best supportive care alone (83 patients).[52] The median OS was not significantly different in patients who were treated with tecemotide, compared with those treated with best supportive care alone (13.0 months; HR, 0.739; 95% CI, 0.509–1.073; *p* = 0.112). In a post hoc analysis by stage, tecemotide did not provide benefit to patients with stage IV disease but it did provide some benefit to patients with stage IIIB disease who were treated with chemoradiation therapy (HR, 0.524; 95% CI, 0.261–1.052; *p* = 0.069).

A phase III, double-blind study was conducted in stage III patients and confirmed these findings,[53] showing no significant survival benefit in those treated with vaccine (829 patients; median OS, 25.6 months; 95% CI, 22.5–29.2) compared with those treated with placebo (410 patients; median OS, 22.3 months; 95% CI, 19.6–25.5 months; adjusted HR for modified intention-to-treat population, 0.88; 95% CI, 0.75–1.03; *p* = 0.123). Again, in the subgroup of patients who received concurrent chemotherapy plus radiation (as opposed to sequential) prior to vaccination, there was a statistically significant benefit. The OS in the vaccinated group was 30.8 months (95% CI, 25.6–36.8) compared with 20.6 months (95% CI, 17.4–23.9) for those who received placebo (adjusted HR, 0.78; 95% CI, 0.64–0.95; *p* = 0.016). A follow-up report with longer follow-up confirmed these findings and suggested that high levels of serum MUC1 and antinuclear antibodies (ANA), correlated with a possible survival benefit (interaction *p* = 0.0085 and 0.0022) for tecemotide.[54] Further development of this vaccine as a monotherapy has been stopped.

TG4010 Vaccine

The TG4010 vaccine also targets MUC1 as well as IL-2. It uses a viral vector—attenuated Ankara virus—that has been genetically modified to express the full MUC1 protein and IL-2 and exogenous IL-2 used as an immunoadjuvant to try to overcome the T-cell suppression caused by the cancer-associated MUC1 mucin.[55] This vaccine was tested in a slightly different setting, given not as "adjuvant" therapy after chemotherapy, but in combination therapy in the metastatic setting.

In an open-label phase II randomized study, 148 untreated patients with MUC1-expressing stage IIIB to stage IV NSCLC were randomly assigned to receive up to six cycles of cisplatin and gemcitabine with or without TG4010. The 6-month rate of progression-free survival (PFS) was not statistically different between the two arms (43% vs. 35%; *p* = 0.13), but higher response rate was seen in the experimental arm (43% vs. 27%; *p* = 0.03). In a subgroup analysis, the level of activated natural killer (NK) cells acted as a possible predictive factor. In patients with normal levels of NK cells, the PFS rate at 6 months was 58%, compared with 38% for placebo (*p* = 0.04), and OS was significantly better (18 vs. 11.3 months; *p* = 0.02).[56] Side effects related to TG4010 were mild and most commonly included injection-site reactions, fever, and abdominal pain.

A phase IIb randomized, double-blind, placebo-controlled trial to evaluate first-line chemotherapy with or without TG4010 for patients with MUC1-positive (at least 50% expression on TCs) stage IV NSCLC was reported in 2016.[57] In this trial, patients received four to six cycles of a platinum-based doublet chemotherapy (bevacizumab allowed) and TG4010 or placebo until disease progression or treatment discontinuation for any reason. The primary end point was PFS to validate the predictive value of the previously identified TrPAL biomarker (CD16, CD56, and CD69 triple-positive activated lymphocytes) as a marker of benefit. From 2012 to 2014, 222 patients were randomized to TG4010 and chemotherapy and 111 to placebo. The median PFS in the vaccinated group was 5.9 months versus 5.1 months in the placebo group (HR, 0.74; 95% CI, 0.55–0.98; one-sided *p* = 0.019). The primary end point was met because in patients with the TrPAL biomarker less than the upper limit of normal, the HR for PFS was less than 1 (HR, 0.75; 95% CI, 0.54–10.3), although notably the

CI crosses 1. The phase III portion of the study is continuing with OS as the primary end point.

Belagenpumatucel-L

Belagenpumatucel-L is an allogeneic whole-tumor-cell vaccine derived from four irradiated NSCLC cell lines (two adenocarcinomas, one squamous cell carcinoma, and one large cell carcinoma) that have been transfected with a plasmid containing a TGF-β2 antisense transgene, which downregulates TGF-β2. Elevated levels of TGF-β2 are known to be linked to immunosuppression in patients with cancer, and TGF-β2 levels are inversely correlated with prognosis in patients with NSCLC.[58]

Whole-tumor-cell vaccines can expose the host immune system to a wide range of tumor antigens. Although autologous TCs generally are thought to provide the panel of antigens most representative of the tumor in an individual patient, their practical use is limited by the complex production process. The G-VAX vaccine initially was associated with promising findings in a phase II study involving 83 patients with NSCLC, but further development was abandoned because of logistic problems.[59]

Belagenpumatucel-L was investigated in a phase II single-arm dose-range study involving 75 patients with NSCLC of various stages that suggested improved survival among advanced-stage patients treated at high dose.[58] This vaccine was further studied in the phase III randomized STOP trial.[60] Patients with stage IIIA (T3 N2), stage IIIB, and stage IV disease, without progression after first-line chemotherapy, were randomly assigned to treatment with intradermal belagenpumatucel-L (270 patients) or placebo (262 patients), once monthly for 18 months and then once at 21 months and 24 months. There was no difference in survival for the vaccinated group (median OS, 20.3 months), compared with the placebo group (17.8 months; HR, 0.94; p = 0.594). There were also no differences in PFS. However, a prespecified Cox regression analysis demonstrated that time from chemotherapy (<12 weeks) and the receipt of radiation were associated with benefit, suggesting that there still may be a role for this vaccine in certain settings.[60]

Epidermal Growth Factor Vaccine

Given the prevalence of EGFR overexpression in NSCLC and the importance of EGFR signaling in multiple subtypes of NSCLC, an EGF vaccine (CimaVax) was developed in Cuba with recombinant human EGF coupled to a carrier protein (P64K *Neisseria meningitidis* protein) and emulsified in Montanide ISA-51.[61] A randomized phase III trial conducted in Cuba in 405 NSCLC patients with stage IIIB/IV disease who had completed first-line chemotherapy demonstrated a nonsignificant improvement in median survival for the vaccinated group (10.83 months, 95% CI, 8.85–12.71 months) versus the control group (8.86 months, 95% CI, 6.69–11.03 months).[62] When a weighted log rank was used, given the late separation of curves, the survival difference became significant. High baseline EGF levels were associated with poorer survival overall, but for those with high baseline EGFR, vaccination was associated with improved survival (HR, 0.41; 95% CI, 0.25–0.67; p = 0.0001); however, the CIs for median survival in each arm were very wide. A new international randomized trial, comparing best supportive care alone with best supportive care plus this vaccine after conventional first-line treatment for advanced NSCLC, was started in 2011 and is still ongoing (ClinicalTrials.gov identifier: NCT01444118).

Racotumomab

This compound, formerly known as 1E10, is an anti-idiotype ganglioside vaccine. Gangliosides are involved in cell–cell recognition, cell matrix adhesion, and cell differentiation and are expressed on the surface of TCs. The compound targets Neu-glycosylated sialic acid-containing ganglioside (NeuGc-GM3), a variant of the normal Neu-acetylated sialic acid ganglioside, which is identified almost exclusively in transformed cells, making NeuGc-GM3 an attractive target for immunotherapy.[63,64]

Racotumomab was evaluated in a prospective, randomized, open-label study in Cuba in 176 patients with stage III/IV NSCLC with objective response or stable disease after standard first-line treatment.[65] The intent to treat median OS was 8.2 months versus 6.8 months in the placebo arm (HR, 0.63; 95% CI, 0.46–0.87; p = 0.004), but the OS in both arms was notably low. Fewer than 30% of patients were evaluated for immune response. A confirmatory randomized phase III multinational trial is still ongoing (ClinicalTrials.gov identifier: NCT01460472).

Overall, strategies using vaccine in early- or later-stage lung cancer have proved disappointing, with marginal improvements in survival in select circumstances that require validation. However, one explanation for the lack of effectiveness of vaccines is the possibility that local immune suppression around the tumor prevents the mounting of a sufficient immune response to actually shrink tumors and halt growth. The advent of checkpoint inhibition may alter the potential for vaccines through combination strategies as described in the following section.

IMMUNE CHECKPOINT INHIBITORS: AGENTS AND CLINICAL DEVELOPMENT

Far more promising than the "active immunotherapy" agents studied to date is the recent experience with "passive immunotherapy," such as monoclonal antibodies that modulate T-cell activity by inhibiting CTLA-4, PD1, or PDL1 (immune checkpoint inhibitors).

CTLA-4 is an immunomodulatory molecule that acts as a negative regulator in the early phase of T-cell-mediated immune responses. With CTLA-4, immune activation takes place when there is binding between the antigen presented on the dendritic cell and the T-cell receptor in the presence of costimulatory binding of B7 and CD28, whereas inhibition takes place when coexistent B7 binding is with CTLA-4 (see Fig. 50.2 left panel). Anti-CTLA-4 antibodies prevent interaction between CTLA-4 and its ligands, resulting in relief of the inhibitory signal provided by CTLA-4 and consequent enhancement of activation and proliferation of tumor-specific T cells.[66,67]

In the later phase, immune effector functions take place when there is binding between an antigen presented on tumor tissue and the T-cell receptor. The normal role of PD1 and its ligands is to limit the activity of T cells in peripheral tissues at the time of an inflammatory response to limit autoimmunity.[68] In the context of antitumor activity of CD8[+] lymphocytes, however, this same blockade does not allow efficient TC kill (see Fig. 50.2 right panel). Anti-PD1 and anti-PDL1 antibodies reverse this inhibition, and thus they restore antitumor immune effector functions.[69]

Checkpoint Inhibitors

Anti-CTLA-4 Antibodies

Ipilimumab. Ipilimumab is a humanized immunoglobulin G1 (IgG1) anti-CTLA-4 monoclonal antibody, which is an effective and approved agent for the treatment of melanoma but has had no clear single-agent activity in NSCLC or SCLC.[70,71] In a phase II trial in both NSCLC and SCLC, patients received six cycles of carboplatin–paclitaxel chemotherapy plus placebo or plus ipilimumab in two different sequences: either concurrent (four cycles of chemotherapy plus ipilimumab followed by two cycles plus placebo) or phased ipilimumab (two cycles of chemotherapy plus placebo followed by four cycles plus ipilimumab). For eligible patients, ipilimumab or placebo was administered every 12 weeks as maintenance therapy after chemotherapy and the
Fig. 50.2. Blockade of PD-1 or CTLA-4 signaling in tumor immunotherapy. T cells recognize antigens presented by the major histocompatibility complex (MHC) on the surface of cancer cells through their T-cell receptor (TCR). This first signal is not enough to turn on a T-cell response, and a second signal delivered by the B7 costimulatory molecules B7-1 (or CD80) and B7-2 (or CD86) is required. Cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4) is up-regulated shortly after T-cell activation and initiates negative regulation signaling on T cells during ligation with the B7 costimulatory molecules expressed by antigen-presenting cells. When these molecules bind to CD28, they provide activation signals; when they bind to CTLA-4, they provide inhibitory signals. The interaction between CTLA-4 and the costimulatory molecules happens primarily in the priming phase of a T-cell response within lymph nodes. Programmed death 1 (PD-1) inhibitory receptor is expressed by T cells during long-term antigen exposure and results in negative regulation on T cells during ligation with PD-L1 and PD-L2, which are primarily expressed within inflamed tissues and the tumor microenvironment. The PD-1 interaction happens in the effector phase of a T-cell response in peripheral tissues. Its blockade with antibodies to PD-1 or PD-L1 results in the preferential activation of T cells with specificity for the cancer. *(Reprinted with permission from Ribas A.,* N Eng J Med. *2012;366:2517–2519.)*

primary end point was immune-related PFS (irPFS) as defined by Wolchok and colleagues.[72] In the NSCLC study, the irPFS was significantly better for patients treated with phased ipilimumab than for controls (HR, 0.72; $p = 0.05$), but it was not significantly better for patients treated with concurrent ipilimumab than it was for controls (HR, 0.81; $p = 0.13$, but in the small squamous cell subgroup, HR was 0.55).[70] Median irPFS rates were 5.7 months, 5.5 months, and 4.6 months for the phased ipilimumab, concurrent ipilimumab, and control groups, respectively. There was no significant difference in OS, and the rates of grade 3 and grade 4 immune-related adverse events were high (15%, 20%, and 6%, respectively).

The results of the SCLC study were similar.[73] Phased ipilimumab improved irPFS compared with the control (HR, 0.64; $p = 0.03$) but concurrent ipilimumab did not (HR, 0.75; $p = 0.11$). The median irPFS rates for the phased ipilimumab, concurrent ipilimumab, and control groups were 6.4 months, 5.7 months, and 5.3 months, respectively. There was no significant improvement in OS (HR, 0.75; $p = 0.13$). The overall rates of grade 3 and grade 4 immune-related adverse events were 17%, 21%, and 9%, respectively.

On the basis of these results, two phase III trials using phased ipilimumab were initiated with OS as the primary end point: one in squamous cell carcinoma and one in SCLC. Both studies showed absolutely no OS benefit or PFS benefit with increased rates of toxicities for the ipilimumab arm (squamous study [unpublished] and SCLC study).[73] In the squamous cell study, among 388 patients treated with blinded therapy with chemotherapy plus ipilimumab, the median OS was 13.4 months compared with 12.4 months in 361 patients treated with chemotherapy plus placebo (HR, 0.91; 95% CI, 0.77–1.07; $p = 0.25$; results not published but are presented on ClinicalTrials.gov [NCT01285609]). In the SCLC study, median OS was 11 months for the ipilimumab-containing arm and 10.9 months for the placebo plus chemotherapy arm (HR, 0.94; 95% CI, 0.81–1.09; $p = 0.38$).[73]

Anti-PD1 and Anti-PDL1 Antibodies

Several monoclonal antibodies are in various stages of research. We focus here on the antibodies currently approved for treatment of NSCLC, including nivolumab, pembrolizumab, and atezolizumab. Other agents, such as durvalumab and avelumab,

TABLE 50.1 First-Line Randomized Studies of Checkpoint Inhibition

Compound	Trial	Design	No. of Patients	Study Population	Treatment Arms	Primary End Point
Nivolumab[74]	Phase III CheckMate 026 NCT02041533	Randomized vs. first-line platinum-based chemotherapy	541	Treatment-naive metastatic NSCLC	Nivolumab vs. platinum-based chemotherapy	PFS in prespecified subset of those with ≥5% PDL1 expression
Pembrolizumab[75]	Phase III (KEYNOTE-024)	Randomized vs. first-line platinum-based chemotherapy	305 (randomized population)	Treatment-naive metastatic NSCLC with ≥50% PDL1 tumoral expression	Pembrolizumab vs. platinum-based chemotherapy	PFS: 10.3 months vs. 6.0 months for chemotherapy (HR, 0.50; 95% CI, 0.37–0.68; $p < 0.001$)
Pembrolizumab[76]	Phase III (KEYNOTE-042) NCT02220894	Randomized open-label	1240	Treatment-naive metastatic NSCLC with ≥1% PDL1 positivity	Pembrolizumab vs. platinum-based chemotherapy	OS
Atezolizumab[77]	Phase III: Several ongoing studies IMpower110 NCT02409342 (others ongoing as well)	Randomized open-label	570	Treatment-naive metastatic NSCLC	Atezolizumab vs. platinum + pemetrexed (nonsquamous) or platinum + gemcitabine (squamous)	PFS and OS
Nivolumab/ ipilimumab	Phase III CheckMate 227 NCT02477826	Randomized open-label	2220	Treatment-naive metastatic NSCLC	Nivolumab vs. nivolumab/ ipilimumab vs. platinum-based chemotherapy ± nivolumab	OS and PFS of the monotherapy vs. chemotherapy or combination vs. chemotherapy
Durvalumab/ tremelimumab	Phase III (MYSTIC) NCT02453282	Randomized open-label	810	Treatment-naive metastatic NSCLC in subgroups (PDL1 positive and PDL1 negative)	Durvalumab vs. durvalumab/ tremelimumab vs. platinum-based chemotherapy	PFS and OS of the combination vs. platinum-based chemotherapy
Durvalumab/ tremelimumab	Phase III (NEPTUNE) NCT02542293	Randomized open-label	800	Treatment-naive metastatic NSCLC in stratified subgroups (PDL1 positive and PDL1 negative)	Durvalumab/ tremelimumab vs. standard of care platinum-based chemotherapy	OS

are also in clinical development in lung cancer, although the focus for these agents has been on combination studies, which are still in the early stage and ongoing at this time and so are beyond the scope of this chapter. Table 50.1 outlines some of the major completed and ongoing studies evaluating checkpoint inhibitors as an alternative to standard therapy. Table 50.2 outlines major trials completed and ongoing combining checkpoint inhibitors with standard chemotherapy.

Initial Phase I Studies

Nivolumab (BMS-936558, MDX-1106/ONO-4538, OPDIVO)

Nivolumab is a fully human IgG4 antibody targeting PD1. The proof-of-principle study was a phase I dose-escalation study involving 296 patients with refractory solid tumors who received intravenous nivolumab at a dosage of 1 mg/kg, 3 mg/kg, or 10 mg/kg every 2 weeks for 8 weeks.[80] Response was evaluated according to Response Evaluation Criteria in Solid Tumors (RECIST), and patients with nonprogressive disease or clinically stable disease (even with progression according to RECIST) could continue for as many as 12 8-week cycles or until disease progression or complete response occurred. The cumulative response rate was 18% (14 of 76) among patients with NSCLC. Responses were durable and lasted for more than a year in many cases. Clinical response was related to expression of PDL1 in tumor biopsy specimens (as determined using the 28-8 antibody on a DAKO platform),

which were available for only a small subset of 42 patients. The rate of grade 3 or grade 4 treatment-related adverse events was 14%, and there were three drug-related deaths from pneumonitis. Longer follow-up data demonstrated a median OS of 9.6 months for pretreated patients, with 1- and 2-year survival rates of 42% and 14%, respectively.[81]

Pembrolizumab (MK-3475, Keytruda)

Pembrolizumab is a fully humanized IgG4 antibody targeting PD1 that was also initially tested in lung cancer as part of a broader phase I study in multiple tumor types (KEYNOTE-001). Initial lung cancer data in 495 patients established a role for PDL1 as a predictive biomarker of response.[82] Patients treated at different doses and dosing schedules were pooled for the biomarker analysis but divided into a training and validation cohort to establish a cutoff for tumor PDL1 expression that was predictive of response to pembrolizumab. Tumor PDL1 expression was evaluated in a contemporaneous biopsy specimen (as opposed to nivolumab studies) using a distinct, proprietary IHC assay and PDL1 antibody (clone 22C3, Merck), also on a DAKO platform.

Overall, the study demonstrated a relative risk (RR) of 19.4% and a median duration of response of 12.5 months. In the overall study population, the median PFS was 3.7 months and the median OS was 12.0 months. A cutoff for tumor PDL1 positivity of 50% or greater was selected as a cutoff for predictive value based on receiver-operating-characteristic curve analysis of the

TABLE 50.2 First-Line Randomized Studies of Checkpoint Inhibition Plus Chemotherapy

Compound	Trial	Design	No. of Patients	Study Population	Treatment Arms	Primary End Point
Nivolumab (Rizvi et al. 2016)[78]	Phase I, CheckMate 012 NCT01454102	Open-label combination of nivolumab with platinum-based chemotherapy	56	Treatment-naive metastatic NSCLC	A. Nivolumab (5 mg/kg) + carboplatin + paclitaxel	**Safety RR** A. 33%; B. 47%; C. 47%; D. 43% **24-week PFR** A. 51%; B. 71%; C. 38%; D. 51% **2-year OS** A. 25%; B. 33%; C. 27%; D. 62%
Nivolumab	Phase III, CheckMate 227 NCT02477826	Randomized first-line platinum-based chemotherapy ± nivolumab vs. nivolumab alone vs. nivolumab + ipilimumab	2220	Treatment-naive metastatic NSCLC	Platinum-based chemotherapy ± nivolumab OR nivolumab/ipilimumab OR nivolumab alone	PFS and OS of nivolumab and nivolumab/ ipilimumab vs. chemotherapy alone
Pembrolizumab (Langer et al. 2016)[79]	Phase II (KEYNOTE-021) NCT02039674	Open-label, randomized phase II pembrolizumab ± cisplatin/ pemetrexed	123	Treatment-naive metastatic nonsquamous NSCLC	Cisplatin + pemetrexed ± pembrolizumab	RR: 55% RR in combination vs. 29% with chemotherapy alone PFS: 13 months vs. 8.9 months (HR, 0.53; 95% CI, 0.31–0.91; p = 0.0102)
Pembrolizumab	Phase III (Merck 189, NCT02578680 and Merck 407, NCT02775435)	Randomized first-line platinum-based chemotherapy ± pembrolizumab	570 (189) and 560 (405)	Treatment-naive metastatic NSCLC	Pembrolizumab vs. platinum–pemetrexed in nonsquamous NSCLC (189) or platinum–nab-paclitaxel in squamous NSCLC (405)	PFS
Atezolizumab	Phase III Several ongoing studies IMpower110 NCT02409342 (others ongoing as well)	Randomized open-label	570	Treatment-naive metastatic NSCLC	Platinum + pemetrexed (nonsquamous) or platinum + gemcitabine (squamous) ± atezolizumab	PFS and OS

CI, confidence interval; *HR,* hazard ratio; *NSCLC,* nonsmall cell lung cancer; *OS,* overall survival time; *PFR,* progression-free rate; *PFS,* progression-free survival; *RR,* response rate.

training cohort. Patients with tumor PDL1 expression levels above this threshold exhibited an RR of 45.2% in the validation cohort. The median PFS of patients above this threshold was 6.3 months and the median OS was not yet reached at the time of the publication; there was a clear separation of PFS and OS curves for the 50% or more subset compared with 1% to 49% or less than 1% curves (which tracked together). Treatment-related grade 3 to grade 5 adverse events occurred in 10% of patients with one death from pneumonitis.

Atezolizumab (MPDL3280A, Tecentriq)

Atezolizumab is a humanized IgG1 monoclonal antibody targeting PDL1. There may be benefits to targeting PDL1 rather than PD1 as this spares interruption of PDL2–PD1 interactions and therefore theoretically may have fewer side effects. In a phase I expansion study, pretreated patients with NSCLC were treated at doses of 1 mg/kg, 10 mg/kg, 15 mg/kg, or 20 mg/kg.[83] An objective response was noted in 12 (23%) of 53 evaluable patients with NSCLC. There were additional delayed responses after RECIST-determined progressive disease. Treatment-related grade 3 or grade 4 adverse events were reported in 11% of patients, with no patient having grade 3 or higher pneumonitis and only 1% of patients having diarrhea. Responses were

evaluated in the context of PDL1 expression (based on an assay using the Sp142 antibody on a VENTANA platform) on TCs and immune cells (ICs). There was a statistically significant improvement in response rate with higher PDL1 expression (p = 0.015) on ICs, but not with tumoral PDL1 expression (p = 0.920).[84] A T-helper type 1 like gene signature was also associated with response.

Second-Line Randomized Studies Establishing PD1/PDL1 Inhibition as a Standard of Care

Nivolumab (MDX-1108, OPDIVO)

Two separate phase III studies were conducted in patients with either nonsquamous (CheckMate 057) or squamous (CheckMate 017) advanced NSCLC after progression on initial chemotherapy.[85,86] The CheckMate 017 study randomized 272 squamous NSCLC patients to nivolumab versus docetaxel and met its primary end point of demonstrating improved OS with nivolumab (median 9.2 months) compared with docetaxel (median 6.0 months; HR, 0.59; 95% CI, 0.44–0.79; p < 0.001). The median PFS was higher in the nivolumab group (3.5 months vs. 2.8 months; HR, 0.62; 95% CI, 0.47–0.81; p < 0.001) as well as the objective response rate (ORR; 20%

vs. 9%; p = 0.008). No significant association between tumor PDL1 status and OS, PFS, or ORR was noted in patients treated with nivolumab with an ORR of 19% in those with 10% or more tumor PDL1 expression compared with 16% in those with 10% or less expression. However, a trend toward improved OS and PFS was noted when comparing high and low PDL1 expressing tumors.[59]

The CheckMate 057 study randomized 582 patients with nonsquamous NSCLC to receive either nivolumab or standard docetaxel in a similar trial design.[85] A similar improved OS of 12.2 months with nivolumab versus 9.4 months with docetaxel was seen. However, the benefit was not apparent early on in the study (<3 months into treatment), during which time nivolumab performed slightly worse than docetaxel, with a resulting lower median PFS (2.3 months vs. 4.2 months). Both the 1-year PFS (19% vs. 8%) and ORR (19% vs. 12%, p = 0.02) were superior with nivolumab. Unlike the squamous cell carcinoma study, this study showed a clear relationship between increasing PDL1 expression and improved outcome with an HR of 0.40 (95% CI, 0.26–0.59) for those with over 10% expression but an HR of 1.00 (95% CI, 0.76–1.31; p < 0.001) for those with less than 10% PDL1 expression.

Both studies examined tumor PDL1 expression with an IHC assay using a rabbit antihuman PDL1 antibody (clone 28-8, Epitomics) on a DAKO platform and used prespecified cutoffs for PDL1 positivity of over 1%, over 5%, and over 10%.[85,86] These thresholds for PDL1 positivity were derived from the initial phase I study of nivolumab and were subsequently evaluated in a phase II study of 117 advanced NSCLC patients (CheckMate 063), which demonstrated an ORR of 14% (7/51) among PDL1 positivity less than 5% of tumors and 24% (6/25) among PDL1 positivity in 5% or more tumors.[80,87]

Notably, based on the results from CheckMate 017, the Food and Drug Administration (FDA) granted approval to nivolumab in March 2015 for second-line treatment of squamous cell carcinoma, irrespective of PDL1 status. In October 2015, after the results of CheckMate 057 were published, the FDA expanded approval of nivolumab to include all NSCLCs. This updated approval also included new approval of the "complementary" PDL1 28-8 DAKO diagnostic test to "help physicians determine which patients may benefit most from treatment." However, there was no mandated PDL1 testing for any group, which led to rapid uptake of nivolumab as a standard second-line therapy.

Pembrolizumab

The KEYNOTE-010 study randomized 1034 advanced NSCLC patients to receive either second-line docetaxel or pembrolizumab at 2 mg/kg or 10 mg/kg.[88] This study enrolled patients with a minimum tumor PDL1 expression of 1% on an archival or contemporaneous biopsy (similar to nivolumab studies) using the Merck proprietary antibody. A significant improvement in OS was observed for pembrolizumab (2 mg/kg) over docetaxel (10.4 months vs. 8.5 months; HR, 0.71; 95% CI, 0.58–0.88; p = 0.0008) and pembrolizumab (10 mg/kg) over docetaxel (12.7 months vs. 8.5 months; HR, 0.61; 95% CI, 0.49–0.75; p < 0.0001). This effect was amplified among patients with tumor PDL1 expression of 50% or more in both pembrolizumab (2 mg/kg) to docetaxel (14.9 months vs. 8.2 months; HR, 0.54; 95% CI, 0.38–0.77; p = 0.0002) and pembrolizumab (10 mg/kg) to docetaxel (17.3 months vs. 8.2 months; HR, 0.50; 95% CI, 0.36–0.70; p < 0.0001) groups. Similarly, radiographic responses occurred at a higher rate among patients with 50% or more PDL1 expression treated with pembrolizumab at 2 mg/kg (30% vs. 18%) or 10 mg/kg (29% vs. 18%) but not docetaxel (8% vs. 9%).

Initially, the accelerated FDA approval of pembrolizumab as second-line therapy in NSCLC was based on KEYNOTE-001

and limited to the subset of patients with over 50% PDL1 expression as determined by the DAKO 22C3 PDL1 companion diagnostic assay.[82] Following the KEYNOTE-010 publication, approval was expanded to include all patients with at least 1% PDL1 expression (which has a prevalence of 66% based on that publication).[88] Notably, the incidence of treatment-related grade 3 to grade 5 adverse events was higher in this study (13% to 16%) than in the phase I study, although still significantly less than with docetaxel (35%).

Atezolizumab

The POPLAR trial was a randomized phase II trial of atezolizumab versus docetaxel in previously treated NSCLC patients, which also looked at outcomes relative to both TC expression of PDL1 and IC expression of PDL1.[89] Expression that was less than 1% was called TC0 or IC0, expression between 1% and 4% was called TC1 or IC1, expression between 5% and 49% was called TC2 or IC2, and expression over 50% was called TC3 or IC3. Expression was evaluated using the Sp142 VENTANA assay. OS was greater with atezolizumab (12.6 months; 95% CI, 9.7–16.4 months) compared with docetaxel (9.7 months; 95% CI, 8.6–12.0 months) with an HR of 0.73 (95% CI, 0.53–0.99; p = 0.04). Increasing improvement in OS was seen with increasing PDL1 expression in either the TC or IC compartment. At the highest level of expression, TC3 or IC3 (which were mostly non-overlapping), the HR was 0.49 (95% CI, 0.22–1.07; p = 0.068). However, without PDL1 expression, the HR crossed 1 (1.04; 95% CI, 0.62–1.75; p = 0.871).

The OAK trial was a randomized phase III trial of similar design to POPLAR that was published in 2016.[90] Notably this trial showed an improvement in OS for atezolizumab versus docetaxel in all groups, including those with IC0 or TC0. OS with atezolizumab was 13.8 months (95% CI, 11.8–15.7 months) versus 9.6 months with docetaxel (95% CI, 8.6–11.2 months) with an HR of 0.73 (95% CI, 0.62–0.87; p = 0.0003) similar to the POPLAR trial. In addition, the HR in the TC0 or IC0 group was similar (HR, 0.75; 95% CI, 0.59–0.96; p = 0.0102), although the HR for the TC3 or IC3 group was still better than the other subgroups (HR, 0.41; 95% CI, 0.27–0.64). This was the only group to show a PFS benefit as well. Between the POPLAR study and the OAK study, the vendor for the PDL1 assay changed, but the assay remained the same. However, it is notable that the percentage of IC0 and TC0 patients was discrepantly high in this study (45%) compared with 32% in the POPLAR study and rates close to 30% in other studies with other agents. Therefore it is unclear whether the beneficial effect seen in this subgroup was truly indicative of benefit in true PDL1 "negative" patients. However, these findings led to the FDA approval of atezolizumab in the second-line treatment of NSCLC patients, regardless of PDL1 status in December 2016.

In addition to showing improved outcomes, all of these drugs showed far lower toxicity rates than docetaxel although serious immune-related adverse events were seen with all drugs and it is not clear whether atezolizumab, a PDL1 inhibitor, has a lower toxicity rate than the PD1 inhibitors nivolumab and pembrolizumab.

First-Line PD1 Inhibition

Pembrolizumab

There are two first-line studies of pembrolizumab compared with standard first-line therapy: KEYNOTE-042, which enrolled patients regardless of PDL1 status, and KEYNOTE-024, which enrolled only those with PDL1 expression of over 50% by the 22C3 antibody DAKO assay. KEYNOTE-024 was reported in 2016 and showed a clearly superior PFS with pembrolizumab,

compared with platinum-based therapy (HR, 0.5; 95% CI, 0.0.37–0.68; $p < 0.001$).[75] The median OS for the pembrolizumab subgroup has not been reached but the OS at 6 months was superior for the pembrolizumab arm (HR, 0.60; 95% CI, 0.41–0.89; $p = 0.0005$). Treatment-related grade 3 to grade 5 adverse events in the pembrolizumab subgroup were lower than with platinum-based therapy (26.6% vs. 53.3%), although arguably, this rate is higher than some earlier studies had shown. These findings have led to a rapid change in the standard of care for this subgroup of patients with the FDA approval coming shortly on the heels of the publication and presentation (October 24, 2016). As a by-product of this study, the standard of care has also changed in terms of testing for PDL1. Although two of the three approved drugs in second-line therapy have unrestricted approvals (no PDL1 threshold required) and results from studies of all three approved drugs suggest that there is a likely benefit among all patients (even though pembrolizumab was not tested in patients with no PDL1 expression), results at low-level PDL1 expression suggest identical outcomes to those with no expression from the phase I KEYNOTE-001 study.[82] However, in the absence of data in patients with less than 50% PDL1 expression, the FDA approval in a subset of patients will likely spark more widespread testing for PDL1 at diagnosis of metastatic disease.

Nivolumab

The CheckMate-026 study randomized untreated patients to receive nivolumab monotherapy versus first-line therapy with a platinum doublet (investigator's choice).[74] A prespecified analysis of tumors with over 5% PDL1 expression using the DAKO 28-8 assay showed no benefit in terms of PFS to nivolumab over chemotherapy. In fact, there was no benefit at any level of expression, including in those with over 50% expression. However, there were issues of imbalances that may have played a role including increased numbers of patients with high PDL1 expression randomized to the control arm and a greater number of women on the chemotherapy arm. These results were quite surprising given the very positive results of the KEYNOTE-024 study. Until now, the two drugs have been considered very similar in terms of efficacy and safety. The results from the ongoing KEYNOTE-042 study,[76] which is closer in patient population to the CheckMate 026 study, are eagerly awaited to better understand the appropriate group to receive first-line PD1 inhibitors.

Atezolizumab

The comparison of first-line atezolizumab with platinum-based chemotherapy is also ongoing (see Table 50.1).[91] Results from a cohort of a nonrandomized monotherapy study (BIRCH) that have been presented but not published suggest increasing response rates to atezolizumab in either the first- or second-line setting among those with higher levels of PDL1 expression.[77]

PDL1 Expression and Association With Response. The dependence on PDL1 expression for increased efficacy for all of these drugs has been hotly debated and is confounded by the use of different assays, different PD1 level cutoffs, and different biopsy requirements in studies of these different agents. In addition, heterogeneity of expression within the tumor is an important confounding factor as there is frequent geographic variation of expression.[92] An international effort at "harmonization" is ongoing through the IASLC, and a first publication reporting on the performance of four different antibodies on a set of 39 NSCLC specimens showed good concordance between three of the four antibodies:[93] the VENTANA Sp142 assay was an outlier (lower sensitivity). It is not clear whether this lower sensitivity may be a

factor in the high rate of PDL1 negatives seen in the OAK study. IC staining was more variable between all of the antibodies. A second study tested three of the same antibodies—the VENTANA Sp263 (used with durvalumab), DAKO 22C3 (pembrolizumab), and DAKO 28-8 (nivolumab)—in 500 NSCLC samples obtained commercially and showed an agreement of over 90% between the three antibodies.[94] Overall, all antibodies show some improvement in response to increasing PDL1 expression, but PDL1 IHC remains an imperfect biomarker, not only because of the aforementioned issues, but also because its predictive value is limited (at best, >50% expression predicts for about a 50% benefit with pembrolizumab, but for most of these, there can be benefit rates of 5% to 15% in those with negative expression as well). Alternative predictive biomarkers are an area of very active investigation. For instance, nonsynonymous mutation burden has been demonstrated to be a predictive biomarker for pembrolizumab benefit.[95] Although it does not necessarily perform better than PDL1 IHC, a quantitative measurement of mutation burden would not be subject to the same assay and geographic variation. Other measures, such as mass spectrometry, RNA sequencing, and neoantigen burden (and specific neoantigens), as well as cytokine or other immune signatures, continue to be areas of study.

COMBINATION STRATEGIES

A myriad of combination studies has been launched in the wake of the initial findings of activity of PD1/PDL1 inhibitors to improve upon the chances for durable response among the close to 80% of patients who do not respond to monotherapy. These strategies include combinations with other immune-oncology agents that either act to stimulate T-cell activation (OX40, 41BB, or GITR agonists) or block other inhibitors of T-cell activation (Lag3, Tim3, CTLA-4; reviewed by Mahoney et al.[96] Strategies to boost neoantigen production to stimulate an immune response or expression of genes associated with immune response with the use of histone deacetylase inhibitors or other epigenetic modifiers are active areas of study. Studies using blocking antibodies for inhibitory signals to NK cell activity (anti-KIR and others) as well as modified IL-15L ligand–receptor complexes are currently in clinical development in lung cancer.[97] Many other areas are being explored broadly in solid tumors including chimeric antigen receptor T cell or NK cell adoptive cell therapies that have shown great promise in hematologic malignancies.

In addition, combinations with chemotherapy (see Table 50.2) or radiation with the idea that cytotoxicity will expose more neoantigens and stimulate an immune response or using radiation's role in causing local inflammation to boost systemic immune responses are actively ongoing. Targeted therapy combinations are also actively being explored. Finally, the effectiveness of PD1 inhibition has reinvigorated the vaccine field given the potential of these drugs to block local immune suppression that can limit the effectiveness of vaccines. Multiple vaccine-PD1/PDL1 combination studies are currently in development or ongoing and will provoke a reevaluation of multiple vaccines that have ceased development.

The combination strategy that is furthest in development is the combination of CTLA-4 inhibition with PD1 or PDL1 inhibition. This strategy (using nivolumab, a PD1 inhibition, combined with ipilimumab, a CTLA-4 inhibitor) is already an approved combination for melanoma treatment, with notably superior activity to nivolumab alone in those whose tumors have low or no PDL1 expression.[98] In lung cancer, initial cohorts of a combination study (CheckMate 012) using doses similar to those used for melanoma (nivolumab [3 mg/kg] + ipilimumab [1 mg/kg] or nivolumab [1 mg/kg] + ipilimumab [3 mg/kg] every 3 weeks) showed unacceptable toxicity with 51% experiencing (25 of 49 patients) grade 3 to grade 4 toxicity.[99] The study was modified

to evaluate much lower and infrequent doses of ipilimumab (1 mg/kg every 6 or 12 weeks) in combination with standard-dose nivolumab (3 mg/kg every 2 weeks). These cohorts were better tolerated, with grade 3 to grade 4 treatment-related adverse effect rates of 32% (every 12-week cohort) or 28% (every 6-week cohort). The ORR in the every 6-week and 12-week cohorts was 47%,[52] which is substantially higher than the 18% to 20% RR seen with monotherapy. Unexpectedly, response rates were higher with increasing PDL1 expression, with a 92% RR in those with over 50% expression, although the sample size was very small (13 patients). By contrast, a phase I study combining durvalumab with tremelimumab demonstrated the lowest grade 3–4 toxicity (17%) in a combination of 20 mg/kg durvalumab plus 1 mg tremelimumab every 4 weeks, which was chosen as the phase II dose.[100] In a group of 26 patients with over 24 weeks of follow-up treated with durvalumab (10–20 mg/kg) plus tremelimumab (1 mg/kg), the response rate was 23% and did not appear to be dependent on PDL1 status.

CONCLUSION

Modulation of the immune system as a treatment modality for lung cancer has entered a new era with the success of PD1/PDL1 inhibition in generating marked and durable response rates. Because of this success, the path forward for other immunotherapies such as vaccines, adoptive cell therapy, and other immunomodulators has been invigorated as well with the opportunity for synergistic combination. There is still much to learn about how we can best identify the right patients who will get durable benefit from monotherapy with PD1/PDL1 inhibitors (only about 20% of patients) and who will require alternative means to "activate" the immunogenicity of the tumor to generate a long-term response. In addition, the best way to optimize combination therapy with existing cytotoxic and targeted therapies remains poorly understood and will require carefully nuanced sequencing studies and robust biomarker evaluation to understand the best path forward. However, we have come a long way from platinum-doublet therapy for all patients in a very short time, so given the potential for combination therapies we can hopefully look forward to significant further improvement ahead.

51 Adjuvant and Neoadjuvant Chemotherapy for Early-Stage Nonsmall Cell Lung Cancer

Giorgio V. Scagliotti and Everett E. Vokes

SUMMARY OF KEY POINTS

- Surgery remains the most effective curative approach for early-stage (IA–IIB) NSCLC. Selected cases with clinical stage IIIA disease equally benefit from radical resection.
- Stereotactic radiotherapy may be an alternative for selected medically inoperable patients.
- Long-term survival after surgical resection is stage-related, with the likelihood of recurrence increasing with advancing cancer stage (of course this is what staging is all about).
- Two comprehensive systematic reviews and meta-analyses, recently updated, showed a significant benefit of adding chemotherapy after surgery, with an absolute increase in survival of 4% at 5 years. The other meta-analysis in which surgery plus radiotherapy and chemotherapy was compared with surgery and radiotherapy showed indeed a significant benefit, representing an absolute improvement in survival of 4% at 5 years.
- The role of adjuvant radiotherapy for patients with N2 disease remains unclear, and an ongoing study is addressing the issue.
- The role of molecular targeted therapies currently remains generally unproven; studies investigating bevacizumab and epidermal growth factor receptor inhibitors in an imprecisely defined patient population did not show meaningful benefit.
- There is no clear role for molecular prognostic and predictive biomarkers or molecular signatures to assist in treatment selection.

Lung cancer is the most common fatal malignant disease among men and women worldwide.[1,2] Approximately 90% of lung cancers are tobacco-related. Primary prevention of lung cancer through smoking cessation is the first goal in reducing the incidence of lung cancer. However, tobacco consumption is increasing worldwide and the risk of lung cancer is higher for former smokers than for never-smokers; in the United States, more than 50% of lung cancers occur in former smokers.[3] Consequently, lung cancer will continue to be a relevant health problem for the foreseeable future.

More than 80% of all newly diagnosed cases of lung cancer are nonsmall cell lung cancer (NSCLC). Surgery is the main curative therapeutic approach for early-stage NSCLC (stages IA to IIB), but early-stage NSCLC is only a minority (20% to 25%) of all cases. Some groups of patients with stage III disease also benefit from pulmonary resection, usually in combination with other treatment modalities.

Long-term survival after surgical resection is stage-related, with the likelihood of recurrence increasing with advancing cancer stage. One-third of patients with stage IA will relapse and die of the disease within 5 years. Relapse occurs after resection in more than 50% of patients with stage II NSCLC.[4] The majority of these relapses are distant metastases, with a 10% risk of a local recurrence after complete resection. The brain is the most common site of metastatic recurrence, followed closely by bone, ipsilateral and contralateral lung, the liver, and adrenal glands. Histology influences the pattern of recurrence; local recurrence is more common in patients with squamous cell carcinoma and distant metastases are more likely in patients with adenocarcinoma (Table 51.1).[5–8] More than 80% of recurrences occur within 2 years after radical surgery. A 2010 investigation of the timing of local and distant failures showed that among 975 patients with stage I or II disease, recurrent disease developed in 250 patients: 43 at local sites, 110 at distant sites, and 97 at both local and distant sites.[9] The median times to local and distant failure were 13.9 months and 12.5 months, respectively (range, 1 to 79 months for both types of failure). In most patients who had both local and distant recurrence, the failure occurred at both sites simultaneously. This finding is important because only time to first failure has been reported in many trials, and additional sites of failure have not been subsequently analyzed. These results support the integration of local treatment modalities with systemic therapies.

Micrometastatic dissemination of cancer cells at levels that are undetectable with currently available imaging techniques seems to affect the prognosis of patients with clinical early-stage NSCLC. It has been shown consistently that positron emission tomography (PET), which is now routinely included in the staging workup for NSCLC, detects metastatic disease in 11% to 14% of cases otherwise cleared for resection using conventional screening methods and also better detects unsuspected disease in the mediastinal and hilar nodes.[10–12] Despite improved detection with PET, micrometastases are missed. In small retrospective studies, researchers have attempted to detect micrometastatic lymph node disease with immunohistochemistry (IHC) and real-time polymerase chain reaction to identify cytokeratins and carcinoembryonic antigens.[13–16] Patients with positive findings in otherwise morphologically normal lymph nodes were almost invariably more likely to have adverse outcomes than patients without occult micrometastatic disease. Quantification of free circulating DNA has been proposed as a potential additional diagnostic tool for use in patients with resected or persisting neoplastic disease.[17]

As screening techniques are incorporated into preventive and primary care models, it is hoped that the pattern of lung cancer diagnoses can be shifted from stage IV to earlier stages, leading to further interest in the use of systemic adjuvant therapies. This stage migration will be important for decreasing the mortality of lung cancer; however, as we increase the number of patients detected with stage I disease, we must also be able to have some noninvasive molecular or imaging modalities that will help to identify patients with stage I disease who may benefit from additional local and systemic treatments after a complete resection to improve long-term survival.

RATIONALE FOR ADJUVANT THERAPY

The use of adjuvant (postoperative) therapy for the treatment of various solid tumors is well established and is based on theoretical models and clinical observations. After complete resection, a patient's tumor load should be nonexistent or minimal. Any residual neoplastic cells present in micrometastatic deposits should contain few clones resistant to chemotherapy or radiotherapy. Experimental and clinical data support the Gompertzian model of tumor growth and regression in most human solid cancers: when a tumor is present microscopically but is clinically undetectable, its growth rate should be at its highest. Therefore, although the numerical reduction of malignant cells induced by cytotoxic chemotherapy is small, the fractional cell kill from an effective dose of chemotherapy should be high.

The decision to use adjuvant therapy involves balancing the need to treat a large number of patients who may be cured by surgery alone against the need for additional systemic therapy to eradicate remaining cancer cells in only a subset of these patients. Thus, if survival is increased for 10% of patients, the other 90% are exposed unnecessarily, either because they did not need the adjuvant treatment or because adjuvant therapy was ineffective in eradicating residual disease. Because no tools exist that determine prospectively who will benefit from adjuvant therapy, it is very important to select a tolerable regimen and limit the length of treatment (Fig. 51.1). In addition, careful pathologic staging enables better prediction of prognosis, facilitates patient selection, and permits comparison of treatment outcomes among trials.

The most appropriate treatment or regimen for the adjuvant setting has not been established. At a minimum, the chosen agent or agents should have proven activity in advanced disease and should be generally well tolerated.[18] Thus, in the case of cytotoxic chemotherapy, a platinum-based doublet regimen should be selected, initiated sufficiently early after radical surgery, and administered for at least three or four cycles.[19]

ROLE OF ADJUVANT RADIOTHERAPY

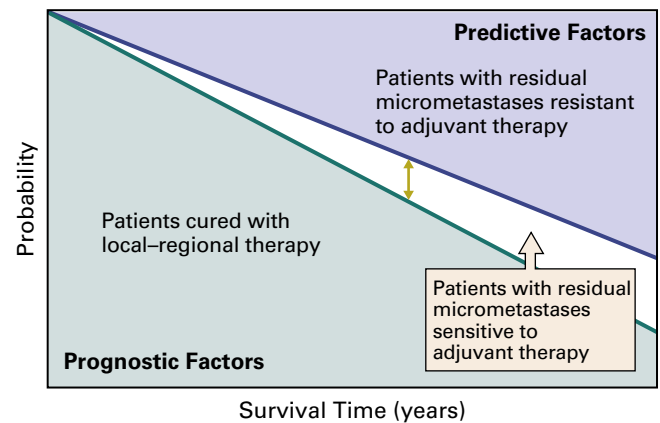
Before effective chemotherapy regimens were established, postoperative thoracic radiotherapy was the preferred adjuvant treatment. Although radiotherapy may improve local–regional control, it is unlikely to reduce systemic recurrence. Use of radiotherapy has been evaluated in many retrospective and prospective studies. Data from nine of these studies (2128 patients) were included in the Postoperative Radiation Therapy (PORT) meta-analysis. The authors of this meta-analysis concluded that postoperative radiotherapy had a significant detrimental effect on survival, especially for patients with stage I and II disease.[20] These results were


Fig. 51.1. Benefit of adjuvant chemotherapy in an unselected patient population and the role of potential prognostic and predictive factors in the adjuvant setting.

confirmed by a Cochrane systematic review and meta-analysis in 2000 and substantially updated in 2005, which demonstrated that postoperative radiotherapy may have a significant adverse effect on survival (hazard ratio [HR], 1.18).[21] The 18% relative increase in the risk of death is equivalent to an absolute detriment of 6% at 2 years (95% CI, 2% to 9%), reducing overall survival (OS) from 58% to 52%. Exploratory subgroup analyses indicate that this detrimental effect was most pronounced for patients with stage I or II disease. For patients with stage III N2 disease, there was no clear evidence of an adverse effect or potential benefit. This outcome is plausible because increased frequency of local–regional failure is associated with the bulky disease often seen in stage III NSCLC.

In most of the studies included in the PORT meta-analysis, patients were treated with older radiotherapy technology (e.g., cobalt 60) and outdated dosimetry, which are less effective than current treatment approaches, and the higher mortality rate in the radiotherapy groups can be attributed in part to an excess of deaths related to intercurrent disease. In a retrospective review, it was reported that use of new technologies and improved dosimetry for postoperative radiotherapy does not excessively increase the risk of death related to intercurrent disease.[22] Another shortcoming of the PORT meta-analysis is that it failed to include sufficient data on mediastinal lymph node dissection, and, additionally, the surgical procedure varied substantially across studies and centers.

Using data from the United States Surveillance, Epidemiology and End Results (SEER) database, researchers evaluated the

relation between survival and postoperative radiotherapy.[23] Factors with a negative effect on OS were older age, T3 or T4 tumor stage, N2 node stage, male gender, fewer lymph nodes sampled, and a greater number of involved lymph nodes. In this study, the use of postoperative radiotherapy was associated with increased survival for patients with N2 disease, but not for patients with N1 or N0 disease.

The role of radiotherapy for patients with N2 disease remains unclear, as no definitive conclusions can be drawn from the available literature. The Lung Adjuvant Radiation Therapy trial in Europe, still ongoing, includes patients with N2 NSCLC who have had surgery, with or without adjuvant chemotherapy.[24] Patients are randomly assigned to postoperative radiotherapy (54 Gy) or no radiotherapy, and it is hoped that results from this trial will define the role of adjuvant radiotherapy for patients with N2 NSCLC.

EARLY STUDIES OF ADJUVANT CHEMOTHERAPY

In the 1960s and 1970s, alkylating agents and nonspecific immunotherapies (e.g., levamisole and bacillus Calmette–Guerin vaccine) universally failed, and detrimental effects of these agents were occasionally reported.[25] These drugs are now known to have very limited or no activity in advanced NSCLC. Subsequently, the use of cisplatin-based chemotherapy was extensively tested in all stages of resectable NSCLC.[26–32] In all but one of these early studies, adjuvant therapy failed to show clinical benefit. Common flaws in the design of these trials were overestimation of the potential benefit of adjuvant chemotherapy, imbalance in relevant patient and treatment characteristics (for instance, the rate of incomplete mediastinal lymph node dissection), and unrealistic patient accrual goals. In addition, in most of the trials, chemotherapy dose delivery (total dose and dose intensity) was often inadequate, with only 50% of patients, on average, receiving the intended course of treatment. Given the toxicity of these regimens in the absence of good antiemetic supportive care and the lack of proven survival benefit from adjuvant therapy, physicians

were reluctant to offer participation in adjuvant trials to their patients.

Nevertheless, the authors of a large meta-analysis, which included these trials, reported a 13% reduction in the risk of death with adjuvant cisplatin-based chemotherapy, a result of borderline significance (*p* = 0.08).[33] There was a 6% reduction in the risk of death among patients who received postoperative radiotherapy and cisplatin-based chemotherapy compared with patients who received postoperative radiotherapy only (*p* = 0.46). In contrast, adjuvant chemotherapy with alkylating agents was shown to be significantly detrimental (HR, 1.15; *p* = 0.005).

These findings failed to have an effect on clinical practice because they were of only borderline significance and were based on several flawed studies. In addition, the heterogeneity of surgical procedures and the difference in the staging modalities limited the applicability of the results. Nevertheless, the findings strongly supported a potential role for adjuvant chemotherapy and the need for a large, well-designed confirmatory trial.

LARGE-SCALE STUDIES ON PLATINUM-BASED ADJUVANT CHEMOTHERAPY

Given the evidence of a marginal benefit of adjuvant systemic treatment, several randomized studies were conducted to evaluate the role of modern, platinum-based regimens in all stages of resectable NSCLC (Table 51.2). Some of the trials were initiated prior to the publication of the PORT meta-analysis and thus included postoperative radiotherapy.

The first of these studies to be reported was an Eastern Cooperative Oncology Group (ECOG) trial, which compared the efficacy of four cycles of adjuvant cisplatin and etoposide plus concomitant thoracic radiotherapy (total dose of 50 Gy) with postoperative radiotherapy alone for 488 patients with stage II and IIIA disease.[34] There was no significant difference between the two treatment arms in terms of median time to progression. The median survival was 38 months for the concurrent chemoradiation therapy arm and 39 months for radiotherapy alone arm

TABLE 51.3 Five-Year Survival Rates Overall and by Disease Stage in Landmark Studies of Adjuvant Chemotherapy

[a]Early data, collected after a median follow-up of 34 months.
ALPI/EORTC, Adjuvant Lung Project Italy/European Organisation for Research and Treatment of Cancer; *ANITA*, Adjuvant Navelbine International Trial Association; *BLT*, Big Lung Trial; *CALGB*, Cancer and Leukemia Group B; *IALT*, International Adjuvant Lung Cancer Trial; *NCIC*, National Cancer Institute of Canada; *NI*, not included; *NT*, not tested.

(HR, 0.93; 95% CI, 0.74–1.18). The lack of efficacy may have been due to the toxicity of radiation with concomitant administration of cytotoxic agents; this effect was more striking in patients with stage II disease. In a biologic correlative study of 197 tumors from this trial, neither p53 protein expression nor Kirsten rat sarcoma viral oncogene homolog (*KRAS*) mutation showed any relation to outcome.[35]

In a joint effort, the Adjuvant Lung Project Italy (ALPI) and the European Organisation for Research and Treatment of Cancer (EORTC) enrolled 1209 patients with completely resected stage I, II, or IIIA NSCLC between 1994 and 1999.[36] Patients were randomly assigned to either three cycles of chemotherapy with mitomycin, vindesine, and cisplatin (MVP) or to observation. Sixty-nine percent of patients completed the three cycles of MVP, with half of those patients needing dose reductions. Radiotherapy was administered sequentially according to the policy at each center, and 43% of patients received postoperative radiotherapy. There was no significant difference in OS between the two groups (HR for death, 0.96). The median OS was 55 months in the chemotherapy arm and 48 months in the observation arm (HR, 0.96; 95% CI, 0.81–1.13; $p = 0.59$). Subset analysis by stage showed that 5-year survival was better for patients with stage II disease than for patients with stage I or III disease (Table 51.3). Even though the HR for patients with stage II NSCLC was not significant, it is notable that, in this subset of patients, there was a 10% survival advantage at 5 years for patients who received chemotherapy. No significant association was found between *p53* or *Ki67* expression, and disease stage or tumor histology. The relation of *KRAS* mutation status to survival was analyzed using specimens from adenocarcinomas and large-cell carcinomas; mutations were found in 22% of 117 samples, with no relation to survival.

The International Adjuvant Lung Cancer Trial (IALT) was the first large trial to demonstrate a significant benefit of adjuvant chemotherapy. A total of 1867 patients with completely resected NSCLC were randomly assigned to cisplatin plus a second drug (vindesine, vinblastine, vinorelbine, or etoposide) or to observation.[37] Approximately 10% had stage IA disease, 27% had stage IB, 24% had stage II, and 39% had stage III. In the chemotherapy arm, 74% of patients received at least 240 mg/m² of cisplatin and 27% of patients received postoperative radiotherapy. Grade 3 or 4 toxicity was reported for 23% of patients (0.8% of toxicity-related deaths). Survival was significantly longer in the chemotherapy arm (HR, 0.86; 95% CI, 0.76–0.98; $p < 0.03$): 5-year survival in the chemotherapy and observation arms were 44.5% and 40.4%, respectively. The median survival was 50.8 months and 44.4 months, respectively, and the median disease-free survival was 40.2 months and 30.5 months (Table 51.3).

In the Big Lung Trial (BLT), 381 patients with resected stage I–III NSCLC were randomly assigned to three cycles of postoperative chemotherapy (cisplatin and vindesine; cisplatin, mitomycin, and ifosfamide; cisplatin, mitomycin, and vinblastine; or

cisplatin and vinorelbine) or to surgery alone.[38] Sixty-four percent of patients received all three courses of chemotherapy, and 40% of them needed dose reductions. Postoperative radiotherapy was used for only 14% of patients. No significant differences in survival were noted between the two groups. However, this trial was underpowered, had a short follow-up (29 months), and a 15% rate of incomplete resection.

In the Adjuvant Navelbine International Trial Association (ANITA) trial, 840 patients with resected stage IB–IIIA NSCLC were randomly assigned to cisplatin (100 mg/m²) every 4 weeks and vinorelbine (30 mg/m²) weekly or to observation; 301 patients (36%) had stage IB disease, 203 (24%) had stage II disease, and 325 (39%) had stage IIIA disease.[39] After a median follow-up of 76 months, the median survival was 65.7 months in the chemotherapy group and 43.7 months in the observation group. Overall, chemotherapy significantly reduced the risk of death (HR, 0.80; 95% CI, 0.66–0.96; $p = 0.017$) and conferred a survival advantage of 8.6% at 5 years, which was maintained at 7 years (8.4%). The 5-year survival rate was better for patients with stage III disease than for patients with stage I or II disease (Table 51.3). Grade 3 or 4 neutropenia was documented for 85% of patients, febrile neutropenia for 9%, and severe infection for 11%. The most common nonhematologic adverse effects were asthenia (28%), nausea and vomiting (27%), and anorexia (15%). As in many of the other studies of adjuvant chemotherapy already described, postoperative radiotherapy was administered according to the policy of individual centers. Radiotherapy was beneficial for patients with N2 disease and harmful for patients with N1 disease when combined with chemotherapy.

The role of adjuvant chemotherapy in the treatment of stage I and II NSCLC was investigated in the National Cancer Institute of Canada Clinical Trials Group JBR.10 trial, which was powered to detect a 10% improvement in 3-year survival.[40] Four hundred and eighty-two patients with resected stage IB and II NSCLC (excluding T3 N0) were enrolled and randomly assigned to receive four cycles of cisplatin (50 mg/m²) on days 1 and 8 every 4 weeks and vinorelbine (25 mg/m²) weekly for 16 weeks or observation. Patients did not receive postoperative radiotherapy, and they were stratified by node status (N0 or N1) and *KRAS* mutation status. OS was significantly longer in the chemotherapy arm (94 vs. 73 months; HR, 0.69; 95% CI, 0.52–0.91; $p = 0.04$), as was recurrence-free survival (not reached vs. 47 months; HR, 0.60; $p < 0.001$). The 5-year survival rate was 69% in the chemotherapy arm and 54% in the observation arm ($p = 0.03$), with an absolute gain of 15% at 5 years. In the subset analysis by stage, patients with stage II disease had a greater survival benefit at 5 years (difference of 20% between study arms, $p = 0.004$) than patients with stage I disease (7% difference between study arms; not significant) (Table 51.3). Fifty-eight percent of the 231 patients who received chemotherapy received three cycles of cisplatin and vinorelbine. Nineteen percent of patients were hospitalized for problems related to chemotherapy toxicity. In

an updated analysis of this study with a median follow-up of 9.3 years, adjuvant chemotherapy continued to produce a significant survival benefit ($p = 0.04$), with an absolute improvement of 11% in 5-year survival (67% in the chemotherapy arm vs. 56% in the observation arm) (Table 51.4). The benefit was particularly pronounced for patients with stage II disease (median survival, 6.8 vs. 3.6 years), and there was no survival benefit for patients with stage IB disease (median survival, 11.0 vs. 9.8 years). However, within the population with stage IB disease, tumor size was predictive of chemotherapy effect, with chemotherapy of benefit for patients with tumors 4 cm or larger (HR, 0.66) compared with patients with smaller tumors (HR, 1.73). The 5-year survival for patients with tumors 4 cm or larger was 79% for patients in the chemotherapy arm compared with 59% for patients in the observation arm. *KRAS* mutation was not associated with a differential effect of chemotherapy.[41]

Similarly, long-term data from the IALT trial were reported at a median follow-up of 7.5 years and the OS advantage was no longer significant ($p = 0.1$) (Table 51.4).[42] This late loss of survival benefit appears to be due to an excess of noncancer-related deaths in the chemotherapy arm.

Unfortunately, JBR.10 and ANITA, two of the positive studies, used chemotherapy doses and schedules that are not routinely used in current clinical practice. The most common dose of cisplatin currently used is 75 mg/m^2 on day 1; cisplatin on days 1 and 8 (as in the JBR-10 trial) is unusual and weekly vinorelbine for 16 weeks is associated with high toxicity and a challenge to safely administer in the adjuvant setting. These trials provide the necessary clinical evidence for adjuvant chemotherapy and may justify the use of other cisplatin-based doublets with similar activity for stage IV NSCLC at the same doses and schedules.

The Cancer and Leukemia Group B (CALGB) 9633 trial was unique in limiting enrollment to patients with resected stage IB disease and is the only large trial to have used a carboplatin-based regimen. The study was powered to detect a 13% improvement in OS at 5 years.[43] In this study, 344 patients were randomly assigned to receive carboplatin (AUC 6) and paclitaxel (200 mg/m^2) every 3 weeks for a total of four cycles, and the trial was closed early (90% of patients recruited) when an interim analysis showed a 12% absolute improvement in OS at 4 years (71% vs. 59%; HR, 0.62; $p = 0.028$). Chemotherapy delivery was excellent, with nearly 85% of patients receiving four cycles of chemotherapy. Toxicity in this group of patients was minimal, with 36% of patients having grade 3 or grade 4 myelosuppression and no treatment-related deaths.

Following initial closure and early reporting, the final analysis of the results of this trial could not confirm a significant favorable outcome. After an extended follow-up (74 months), there was only a nonsignificant trend toward improvement in survival (59% vs. 57%; $p = 0.125$) (Table 51.4).[44] It should be noted that the small sample size did not allow for adequate power to detect small differences in survival. The 3-year failure-free survival (66% vs. 57%) and the 3-year OS (79% vs. 70%; $p = 0.045$) continued to favor the chemotherapy group.

A pooled analysis of data from JBR.10 and CALGB 9633 was done to evaluate survival according to tumor size. The authors

found that the effect of chemotherapy seemed to increase with tumor size.[45] Thus, current entry criteria for adjuvant chemotherapy trials in North America specify a tumor size of 4 cm or larger. The impact of adjuvant chemotherapy use and tumor size on outcomes in stage I has been reviewed from 2003 to 2006 in the National Cancer Database in the United States. The results of the study indicate an increased use over time of adjuvant chemotherapy although it continues to frequently not be used. The analysis also supports the guidelines indicating adjuvant chemotherapy for stage I NSCLC tumors larger than 4 cm with a positive survival impact for patients whose tumors ranged from 3.0 to 8.5 cm.[46]

Overall three studies showed a positive impact of adjuvant chemotherapy in resectable NSCLC, with a survival benefit ranging from 4.1% (IALT) to 15% (JBR.10).[36,39,40] A few factors may help to explain the difference in survival among the landmark adjuvant studies (Table 51.3). First, the sample size differed substantially among the studies (from less than 500 patients to 3300 according to the planned sample sizes) to assess the same expected therapeutic effect in the same patient population. Effectively, the only two studies designed to detect a reasonable survival advantage were the ALPI and IALT trials, which, not surprisingly, demonstrated a relatively similar survival benefit: 3% and 4.1%, respectively.

Second, most of the landmark adjuvant studies do not include information about the proportion of patients who had systematic lymph node dissection or lymph node sampling. This detail is important, as one randomized clinical study showed that systematic lymph node dissection significantly influenced survival for every stage of resectable NSCLC.[47] Third, patients with lung cancer frequently have comorbidities, including chronic obstructive pulmonary disease and cardiovascular diseases, which can affect survival substantially.[48,49] Lastly, an unbalance in the proportion of patients who quit smoking after radical surgery may potentially account for survival differences, as was shown in two retrospective studies.[50,51] A common feature of most of these landmark studies, with the exclusion of the CALGB 9633, is the less than optimal compliance with adjuvant regimens. Because of treatment delays and dose reductions, the delivery of three cycles of adjuvant chemotherapy ranged from 58% to 74% in studies of cisplatin-based chemotherapy.[36–40,43] Reasons for low rates of treatment compliance may be related to the time needed to fully recover from the surgical procedure for lung cancer (which is longer than the time to recover from breast cancer surgery, for example). The rate of pneumonectomy in some of these studies far exceeded the rate in consecutive surgical series; pneumonectomy was done in 26% of patients in ALPI, in 35% of patients in IALT, and in 41% of patients in ANITA, and a subset analysis of the tolerability of chemotherapy in these subgroups has not been performed. Of note, in breast cancer, the survival benefit of adjuvant therapy has been more striking in patients who receive more than 85% of the intended total dose of chemotherapy.[52]

The impact of platinum-based adjuvant chemotherapy on survival has also been specifically evaluated in Asian patients with stage I–IIIA NSCLC. Among 2231 patients in the Taiwan cancer registry who had resection in 2004 to 2007, the mortality rate was lower for patients treated with chemotherapy for both stage II and IIIA disease. Multivariate analysis demonstrated that platinum-based adjuvant chemotherapy was an independent prognostic factor for OS for patients with stage II disease ($p = 0.024$), including both men and women and patients older than 70 years of age.[53]

Quality of Life and Adjuvant Cisplatin-Based Chemotherapy

The impact of adjuvant chemotherapy on quality-of-life outcomes has also been investigated. This specific outcome was evaluated in the JBR.10 trial through the EORTC quality-of-life

TABLE 51.4 Impact of Adjuvant Chemotherapy on Overall Survival in Studies With Prolonged Follow-Up

Study	Follow-Up (Y)	Hazard Ratio for Overall Survival (95% CI)
NCIC JBR.10[41]	9.3	0.78 (0.61–0.99) $p = 0.04$
IALT[42]	7.5	0.91 (0.81–1.02) $p = 0.1$
CALGB 9633[44]	6.2	0.83 (0.64–1.08) $p = 0.125$

questionnaire C30 and a trial-specific checklist at baseline and at weeks 5 and 9 for patients who received chemotherapy and for all patients at regular follow-up visits.[40] The impact of initial surgery on quality of life was similar for the two treatment arms (chemotherapy and observation), whereas the quality of life during chemotherapy was only modestly affected, (in particular, for fatigue, nausea, and vomiting), but without associated changes in global quality of life. These symptoms improved considerably at 3 months of follow-up, with more permanent side effects being limited to sensory neuropathy and chemotherapy-associated hearing loss. Thus, negative effects on quality of life appear to be modest and fairly short-lived. Investigators further followed up on these findings by assessing quality-adjusted time without symptoms or toxicity and reported that adjuvant chemotherapy was preferred for relapse and toxicity and had an overall better quality-adjusted time in the range of 5 to 6 additional months.[54,55]

STUDIES OF ADJUVANT TREATMENT WITH ORAL UFT

UFT, an oral fluoropyrimidine combining uracil and tegafur, has been extensively studied in Japan as adjuvant treatment as a single-agent or in combination with intravenous cytotoxic agents. In the largest trial of postoperative UFT therapy in resected NSCLC, by Kato et al.,[56] 979 patients with completely resected stage I adenocarcinoma were randomly assigned to either oral UFT (250 mg/m^2) for 2 years or to observation. OS favored the UFT arm (HR, 0.71; 95% CI, 0.52–0.98; p = 0.04) and the 5-year survival was 88% in the UFT arm compared with 85% in the observation arm. Subset analyses showed that the benefit was greatest for the subgroup of 263 patients who had T2 N0 disease (HR, 0.48; 95% CI, 0.29–0.81; p = 0.005) but not for the 716 patients who had T1 N0 disease (HR, 0.97; 95% CI, 0.64–1.46; p = 0.87). Compliance was limited to 74% at 12 months and 61% at 24 months. One questionable point in this trial is the absence of any advantage in disease-free survival for the patients in the UFT arm, and this finding clearly contrasts with the results of the positive studies of cisplatin-based adjuvant therapy (IALT, JBR.10, and ANITA), in which improvement in OS for patients receiving adjuvant chemotherapy was invariably associated with disease-free survival that was similar or of greater magnitude.

The results of other published studies of adjuvant UFT in smaller patient cohorts were completely or partially inconsistent with the data found in the study by Kato et al.,[56] and confirmatory data for white patients are lacking.[57–59] Additionally, questions regarding a specific genetic sensitivity to UFT in Japanese patients remain unanswered.

EFFICACY OF ADJUVANT CHEMOTHERAPY ACCORDING TO SYSTEMATIC REVIEWS, META-ANALYSES, AND CANCER REGISTRY DATA

Several systematic reviews and meta-analyses have confirmed the value of adjuvant cisplatin- or UFT-based chemotherapy for resected NSCLC (Table 51.5).[60–65] All of these reviews have consistently shown a benefit from adjuvant chemotherapy, with HRs ranging from 0.72 for adjuvant UFT to 0.89 for cisplatin-based chemotherapy.

Four of these meta-analyses are based on individual patient data rather than published study reports. In a meta-analysis comparing the outcomes for 2003 patients (in six studies) treated with adjuvant oral UFT as a single agent or in combination with other cytotoxic agents, UFT significantly improved OS (HR, 0.74; 95% CI, 0.61–0.88), corresponding to a 4.6% benefit at 5 years (p = 0.001) and 7% at 7 years (p = 0.001).[63]

A further analysis of randomized trials of UFT specifically evaluated the effect of the drug on stage I (T1a and T1b) disease in 1269 patients.[66] Among the 670 patients with T1a disease, the 5-year survival rate was 85% for patients who had surgery only and 87% for patients who received adjuvant UFT. Among the 599 patients with T1b disease, the 5-year survival rate was 82% for patients who had surgery only and 88% for patients who received adjuvant UFT (p = 0.011).

The Lung Adjuvant Cisplatin Evaluation (LACE) is a pooled analysis of data from 4584 patients in five randomized clinical trials of adjuvant therapy (ALPI, ANITA, BLT, IALT, and JBR.10).[64] The analysis demonstrated a significantly positive effect of chemotherapy in terms of OS (HR, 0.89; 95% CI, 0.82–0.96) and disease-free survival (HR, 0.84; 95% CI, 0.78–0.90), with a relative reduction in the risk of death of 11% (HR, 0.89; 95% CI, 0.82–0.96). For patients with stage II–III NSCLC, the gain in OS was 5.3% at 5 years (48.8% vs. 43.3%; HR, 0.83; 95% CI, 0.83–0.95). A small, insignificant survival gain was also evident for patients with stage IB disease (HR, 0.92; 95% CI, 0.78–1.10), and a detrimental effect was found for patients with stage IA disease (HR, 1.41; 95% CI, 0.96–2.1). The most active regimen seems to be cisplatin and vinorelbine, mainly because of the greater number of patients treated (1888 patients; HR, 0.80) and higher total doses of cisplatin administered in combination with that drug (320 to 400 mg/m^2).

Two comprehensive systematic reviews and meta-analyses were published in 2010[65,67] and recently updated.[68] One of these meta-analyses was based on 34 trials (8447 patients) in which surgery plus chemotherapy was compared with surgery alone. The data showed a significant benefit of adding chemotherapy after surgery, with an absolute increase in survival of

TABLE 51.5 Systematic Reviews and Meta-Analyses or Individual Patient Data Meta-Analyses of Trials Evaluating Cisplatin-Based or UFT-Based Adjuvant Treatment

Author	Adjuvant Treatment	Number of Studies (Patients)	Hazard Ratio (95% CI) for Overall Survival
Hotta et al.[59]	Cisplatin-based chemotherapy	8 (3786)	0.89 (0.81–0.97)
	Single-agent UFT	5 (1751)	0.79 (0.67–0.96)
Sedrakyan et al.[60]	Cisplatin-based chemotherapy	12	0.89 (0.82–0.96)
	Single-agent UFT	7 (total = 7200)	0.83 (0.73–0.95)
Bria et al.[61]	Cisplatin-based chemotherapy	12 (6494)	0.93 (0.89–0.95)[a]
Hamada et al.[62b]	UFT (single agent or combined with chemotherapy)	6 (2003)	0.74 (0.61–0.88)
Pignon et al. (LACE Collaborative Group)[63b]	Cisplatin-based chemotherapy	5 (4584)	0.89 (0.82–0.96)
NSCLC Meta-analyses Collaborative Group[64b]	Cisplatin-based chemotherapy	17 (4406)	0.90 (0.82–0.98)
	Single-agent UFT	16 (3848)	0.80 (0.71–0.90)

Adjuvant chemotherapy, with or without postoperative radiotherapy, in operable non-small-cell lung cancer: two meta-analyses of individual patient data. Lancet. 2010;375(9722):1267–1277.)*

4% (95% CI, 3% to 6%) at 5 years (from 60% to 64%) (Fig. 51.2).[65] The other meta-analysis was based on 13 trials (2660 patients) in which surgery plus radiotherapy and chemotherapy was compared with surgery and radiotherapy. Again, adding chemotherapy was of significant benefit, representing an absolute improvement in survival of 4% (95% CI, 1% to 8%) at 5 years (from 29% to 33%) (Fig. 51.2).[67] In both meta-analyses, it was noted that there was little variation in effect according to the type of chemotherapy, other trial characteristics, or patient subgroup.

Douillard et al.[69] specifically evaluated cisplatin and vinorelbine compared with other regimens in four trials (IALT, BLT, JBR.10, and ANITA). Survival associated with cisplatin and vinorelbine was superior to that associated with other regimens, with improvement at 5 years of 8.9%.

Additional analyses support the safety and efficacy of adjuvant chemotherapy in standard clinical practice. Booth et al.[70] evaluated outcomes for patients with surgically resected NSCLC registered in the Ontario Cancer Registry and compared outcomes for patients treated in 2001–2003 with outcomes for a second cohort treated in 2004–2006. The proportion of patients receiving adjuvant chemotherapy increased from 7% to 31%, and postoperative admissions remained stable at 36% and 37%, respectively, within 6 months after surgery. Of note, there was a 33% reduction in the proportion of patients admitted to the hospital for subsequent metastatic disease and there was substantial improvement in the 4-year survival among patients who had surgical resection, increasing from 52.5% for the initial cohort to 56.1% for the second cohort. This analysis supports the use of adjuvant chemotherapy, with evidence of a survival benefit in clinical practice.

Overall, adjuvant chemotherapy has been shown, to a limited extent, to significantly increase survival rates, particularly for patients with stage II and early stage III disease, whereas its effect on stage I disease is not yet clearly established, specifically, for tumors of 4 cm or less.[71,72]

Miksad et al.[73] further evaluated the statistical evidence for a positive effect of adjuvant chemotherapy in a bayesian analysis. Using this approach, the probability of a 4% survival benefit was found to increase from 33% before IALT to 64% after IALT, and after sequential updating of the analysis with data from JBR.10

and ANITA, the probability increased to 82%. IALT produced the largest decrease in variance (61%) and decreased the chance of a survival decrement to 0%. However, sensitivity analyses did not support a survival benefit after IALT, and only the sequential updating substantiated a more than 90% probability of a 6% survival benefit and a 50% probability of a 12% benefit for patients with resected stage II and III NSCLC.

To date, no specific prognostic or predictive biomarkers have been identified that could assist in routine selection of patients for chemotherapy, including *KRAS* mutation, which was evaluated as a prognostic or predictive biomarker in four trials.[74]

ADJUVANT CHEMOTHERAPY FOR OLDER PATIENTS

More than 50% of lung cancers are diagnosed in patients older than 65 years, and approximately 30% of lung cancers are diagnosed in patients older than 70 years of age.[75] The favorable data on efficacy of adjuvant chemotherapy have been largely derived in younger patient cohorts, and separate data supporting its use in an older population would assist physicians in better advising such patients on the utility of adjuvant chemotherapy.

It is well known that older patients tolerate chemotherapy poorly because of comorbidities, mainly respiratory and cardiovascular diseases that are more prevalent in this population, and organ failure, especially declining renal function, which alters drug pharmacodynamics. Moreover, after a demanding surgery such as lobectomy or pneumonectomy, the risk of chemotherapy-induced toxicity is increased because of associated comorbidities in an older population. Higher toxicity or reduced compliance may diminish the potential survival benefit obtained with adjuvant chemotherapy.

A retrospective analysis was designed to evaluate the influence of age on survival, chemotherapy compliance, and toxicity in the JBR.10 trial.[76] Data for 155 patients 65 years or older and 327 younger patients were analyzed. Adenocarcinoma histology and better performance status were more common among the younger patients. The older patients received significantly fewer doses of chemotherapy ($p = 0.0004$ for vinorelbine, and $p = 0.001$ for cisplatin), with no significant difference in toxicities. Among the older patients, OS was significantly better with chemotherapy than with observation (HR, 0.61; $p = 0.04$), but survival was significantly shorter for the 23 patients older than 75 years compared with the patients 66 to 75 years old. These data suggest that, in clinical practice, older fit patients should not be denied adjuvant platinum-based chemotherapy.

Similarly, a pooled analysis was undertaken to assess patients older than 70 years in five large trials of cisplatin-based chemotherapy that were included in the LACE analysis.[77] Specifically, patients were divided into three groups according to age: younger than 65 years, 65 to 69 years old, and older than 70 years. Survival HRs for the three groups were 0.86, 1.01, and 0.9 respectively. More older patients died from noncancer-related causes. Similarly, older patients received lower total doses of cisplatin and fewer chemotherapy cycles.

A population-based study in Canada involving data from the Ontario Cancer Registry compared the uptake of adjuvant chemotherapy among patients 70 years or older with that among younger patients.[78] When data for 2001–2003 were compared with data for 2004–2006 (when adjuvant chemotherapy was introduced into practice), the 4-year survival rate for older patients increased significantly. In essence, more patients, including older ones, were offered adjuvant chemotherapy in the second time period (16.2% vs. 3.3%).

The impact of adjuvant chemotherapy for stage I NSCLC elderly patients with tumors >4 cm was investigated in the SEER Medicare database from 1992 to 2009. Overall, 84% of the patients were treated with resection alone, 9% received platinum-based adjuvant chemotherapy, and 7% underwent PORT

with or without adjuvant chemotherapy. Platinum-based chemotherapy was associated with improved survival but also with an increased amount of serious adverse events especially in terms of hematologic toxicity.[79]

A study from South Korea investigated the quality of life for patients younger or older than 65 who were treated with postoperative chemotherapy and found no significant difference between the age groups in terms of quality of life.[80] Thus, based on the available data, it appears that adjuvant chemotherapy can be offered to older patients who have good performance status and good end-organ function, although age-specific prospective data have not been generated to date.

NEW CHEMOTHERAPY REGIMENS AND TARGETED THERAPY

In recent years, much has been learned about the activity of new chemotherapy regimens in stage IV disease that is relevant to adjuvant trials. In 2002, the ECOG 1594 trial directly compared four commonly used platinum-based doublets, and no difference was found among them in terms of response or survival.[81] In another trial, cisplatin and gemcitabine was compared with cisplatin and pemetrexed, and both regimens were shown to be of equal activity in the entire patient cohort.[82] However, a predefined subset analysis according to tumor histology showed that patients who had tumors with nonsquamous cell histology benefited significantly from the pemetrexed-based regimen, whereas patients who had tumors with squamous cell histology had longer survival when treated with gemcitabine. These results have influenced the choice of treatment for stage IV disease and can similarly be applied to both standard practice and investigational trial design in the adjuvant setting.

Few specific data for adjuvant chemotherapy with cisplatin and docetaxel or cisplatin and pemetrexed exist. However, some preliminary clinical experience has been published. For example, a chart review of 54 patients treated with adjuvant cisplatin and docetaxel (75 mg/m^2 for each drug in 3-week intervals) demonstrated that 85% of patients received all four planned cycles, usually at full dose.[83] The data suggested good dose delivery and patient convenience for this regimen. In a randomized phase II trial, 132 patients with completely resected NSCLC (10% stage IA, 38% stage IB, and 47% stage IIB) were randomly assigned to four cycles of cisplatin and either vinorelbine or pemetrexed, and having drug delivery and efficacy are end points. The feasibility of administering the combinations was 95.5% for cisplatin and pemetrexed and 75.4% for cisplatin and vinorelbine.[84] The pemetrexed based-regimen had significantly fewer hematologic grade 3 or 4 side effects ($p < 0.001$), whereas the rates of nonhematologic toxicities were similar.

Researchers have tried to enhance the efficacy of adjuvant chemotherapy by combining it with targeted therapy, including vascular endothelial growth factor (*VEGF*) inhibitors and epidermal growth factor receptor (*EGFR*) tyrosine kinase inhibitors (TKIs). *VEGF* is the most potent and specific angiogenic factor that has been identified, with a well-defined role in normal and pathologic angiogenesis. A correlation has been noted between the degree of tumor vascularization and the level of *VEGF* mRNA expression, and in virtually all specimens examined, *VEGF* mRNA is expressed in tumor cells but not in endothelial cells, whereas mRNAs for the two *VEGF* receptors, Flt-1 and KDR, are upregulated in endothelial cells associated with the tumor.[85] *VEGF* is also a strong prognostic indicator in NSCLC and is associated with early postoperative relapse and decreased survival.[86]

ECOG 4599 demonstrated that adding the antiangiogenic bevacizumab to carboplatin and paclitaxel for advanced NSCLC increased median survival time (12 vs. 10 months).[87] Therefore, the question of adding bevacizumab to chemotherapy in the

adjuvant setting is of great current interest. In general, bevacizumab is administered only to patients who have tumors with nonsquamous cell histology, given the increased risk of pulmonary hemorrhage reported in early trials for patients with squamous cell carcinoma. However, in the adjuvant setting, because there is no remaining macroscopic disease, the bleeding risk is eliminated and bevacizumab may be added to a doublet regimen of choice, usually cisplatin and pemetrexed for adenocarcinoma and large cell carcinoma and cisplatin combined with paclitaxel, docetaxel, or gemcitabine for patients with squamous cell histology. ECOG 1505 was a phase III study that evaluated the addition of bevacizumab to adjuvant chemotherapy in patients with resected stage IB, II, or IIIA NSCLC (ClinicalTrials.gov identifier: NCT00324805) having OS as the primary end point. Chemotherapy was investigator-selected and included cisplatin/vinorelbine, cisplatin/docetaxel, cisplatin/gemcitabine, and cisplatin/pemetrexed. From July 2007 to September 2013, 1501 patients were enrolled and at the median follow-up time of 41 months the IDMC recommended releasing the trial results due to futility. The HR for disease-free survival was 0.98 (95% CI, 0.84–1.14) and for OS was 0.99 (95% CI, 0.81–1.21).[88] In subset analysis none of the four specific chemotherapy regimens was shown to be superior to control or another regimen.

In advanced NSCLC, *EGFR* TKIs such as gefitinib, erlotinib, and afatinib have been shown to increase progression-free survival for patients with sensitizing *EGFR* mutations when administered as a single agent in the first-line setting and in unselected patients in the second or third line (erlotinib only). Other targets with activity in NSCLC have been identified, in particular the echinoderm microtubule-associated protein-like 4 (*EML4*)-anaplastic lymphoma kinase (*ALK*) fusion gene and C-ros oncogene 1, receptor tyrosine kinase (*ROS1*) rearrangements. To date, the role of these targeted agents as adjuvant therapy has not been investigated. The clinical experience with *EGFR* TKIs in this setting is very limited, and most trials to date have not required that patients have molecular testing for a drug-specific molecular predictive factor. It has been shown that patients with sensitizing mutations appear to derive more benefit from adjuvant chemotherapy and that chemotherapy may reduce the frequency of *EGFR* mutations, suggesting a preferred response of those subclones to chemotherapy.[89,90]

A Japanese phase III study planned to randomly assign patients with completely resected NSCLC (stage IB–IIIA) to receive either adjuvant gefitinib at 250 mg/day or placebo 4 to 6 weeks following surgery, for 2 years, until recurrence or trial withdrawal. However, recruitment was stopped after 38 patients had been randomly assigned, because interstitial lung disease–type events were being increasingly reported in Japan in the advanced disease setting. Safety data for 38 recruited patients (18 who received gefitinib and 20 who received placebo) showed no unexpected adverse drug reactions, with the most common being grade 1 or gastrointestinal and skin disorders in 12 and 16 patients receiving gefitinib, respectively, and in 5 and 6 patients receiving placebo, respectively. Grade 3 or 4 adverse events occurred in 4 patients receiving gefitinib and in 1 patient receiving placebo. Interstitial lung disease–type events were reported in 1 patient receiving gefitinib (concomitantly with other interstitial lung disease–inducing drugs) who died and in 2 patients receiving placebo. Adverse events associated with surgical complications were reported in 6 patients receiving gefitinib and in 4 patients receiving placebo.[91]

In the same patient population, another phase III trial from the National Cancer Institute of Canada (JBR.19) compared gefitinib and placebo after four courses of cisplatin-based chemotherapy, but the trial was prematurely closed after accrual of only 503 patients as a consequence of the negative outcome of other phase III studies, such as Southwest Oncology Group (SWOG) S0023 (gefitinib compared with placebo for patients

with nonprogressive stage IIIB disease after concurrent chemo-radiation therapy and maintenance docetaxel) and the Iressa Survival Evaluation in Lung Cancer trial (second-line gefitinib compared with placebo).[92–94] Data from JBR.19 showed no advantage for the addition of maintenance gefitinib after adjuvant chemotherapy.[92] Few patients in this trial had documented *EGFR* mutations, and they also did not seem to derive benefit from gefitinib.

The Randomized Double-Blind Trial in Adjuvant NSCLC With Tarceva (RADIANT) trial compared adjuvant erlotinib with placebo after adjuvant platinum-based chemotherapy in patients with stage IB–IIIA NSCLC positive for *EGFR* expression according to IHC and/or fluorescence in situ hybridization [FISH]. The primary end point was disease-free survival (DFS); key secondary end points were OS and DFS and OS in patients whose tumors had *EGFR*-activating mutations (EGFRm-positive). A total of 973 patients were randomly assigned and there was no statistically significant difference in DFS (median, 50.5 months for erlotinib and 48.2 months for placebo; HR, 0.90; 95% CI, 0.74–1.10; $p = 0.324$). Among the 161 patients (16.5%) in the EGFRm-positive subgroup, DFS favored erlotinib (median, 46.4 vs. 28.5 months; HR, 0.61; 95% CI, 0.38–0.98; $p = 0.039$), but this was not statistically significant because of the hierarchical testing procedure and no effect on survival was demonstrated. The most common grade 3 adverse events in patients treated with erlotinib were rash (22.3%) and diarrhea (6.2%).[95] Potential limitations of the study are the relative unselected patient population, as FISH is positive in a large proportion of patients and a less sensitive biomarker than mutation testing, and thus, the role of FISH in early-stage disease is unproven. The onset of resistant secondary mutations or other resistance mechanisms may be another concern, as these mutations and resistance mechanisms have been noted frequently in stage IV disease.

Analysis of data from a surgical database of 167 patients with completely resected stage I–III NSCLC harboring sensitizing mutations and treated with adjuvant TKIs showed a 2-year survival of 89% compared with 72% for nontreated patients.[96] The findings support evaluation in prospective studies.

In another study, 36 patients with surgically resected stage IA–IIIA NSCLC harboring activating *EGFR* mutations were treated with 150 mg/day of erlotinib for 2 years after completion of any standard adjuvant chemotherapy and/or radiotherapy. After a median follow-up of 2.5 years, the 2-year disease-free survival was 94% (95% CI, 80% to 99%), suggesting an improvement over the historically expected rate of 70%.[97]

A definitive trial evaluating erlotinib and crizotinib in patients selected according to molecular testing was close to starting in the United States at the time of publication. This trial, Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trial (ALCHEMIST), will initially focus on patients with tumors with *EGFR* mutations and *EML-ALK* fusions, but it is designed to allow for inclusion of additional targets, as active agents for them are identified.

Another recent randomized trial evaluated the efficacy of an anti-MAGE-A3 cancer immunotherapeutic as adjuvant therapy. Patients with completely resected stage IB–IIIA MAGE-positive NSCLC were randomly assigned to either receive intramuscular injections of recombinant MAGE-A3 with an added immunostimulant or placebo in a 2–1 randomization design. A total of 13,849 patients were screened for MAGE-A3 expression, and 4210 had a MAGE-positive tumor; 2312 of these patients met all eligibility criteria and were randomly assigned to treatment. Median DFS was 60.5 months for the MAGE group and 57.9 months for placebo (not significant). Thus, further development of this approach has been halted. It should be noted, however, that high interest currently exists to further study immune stimulatory approaches. These are now focused on inhibitors of the PD-1 mechanism.[93,98]

NEOADJUVANT CHEMOTHERAPY

Neoadjuvant (preoperative) chemotherapy offers potential advantages over postoperative chemotherapy, including greater therapeutic compliance and the ability to treat micrometastatic disease, to analyze the treatment-related effect on the primary tumor, and to select patients with responsive disease; patients with disease progression during chemotherapy will most likely not benefit from surgery.

Platinum-based doublets confer response rates in the preoperative setting that exceed rates achieved in advanced NSCLC,[99–102] and consequently, tumor downstaging may potentially lead to a higher percentage of radical resections. Disadvantages of neoadjuvant chemotherapy include the delay of surgery, less accurate staging (the pathologic staging is confounded by the induction treatment), and, potentially, increased surgical morbidity and mortality after chemotherapy, with a decrease in the quality of life.

In the 1990s, two small, randomized phase III trials, mainly designed for patients with stage III (N2) NSCLC, were terminated early based on interim analyses that showed significant improvements in OS for the combined approach of perioperative chemotherapy plus surgery compared with surgery alone.[103,104] However, results from these early trials may have been biased by imbalances between treatment groups in important prognostic factors. A large, randomized study by Depierre et al.[105] showed an 11-month improvement in survival with neoadjuvant chemotherapy compared with surgery alone for patients with stage I–IIIA disease (median, 37 vs. 26 months, $p = 0.15$).[105] The difference in OS between the treatment arms increased to 10.4% at 3 years, favoring neoadjuvant chemotherapy, with a significant reduction in the rate of disease-free survival ($p = 0.033$). In a subset analysis, the benefit of chemotherapy was confined to patients with N0 and N1 disease, with a relative risk of death of 0.68 ($p = 0.027$).

All of the aforementioned studies were conducted with doublet or triplet combinations that are not currently used. The feasibility and safety of neoadjuvant chemotherapy with carboplatin and paclitaxel for early-stage NSCLC were prospectively established in the Bimodality Lung Oncology Team trial.[106] This phase II trial enrolled two sequential cohorts of patients with clinical stage IB, II, and IIIA disease. Clinical staging was defined by CT imaging, and mediastinoscopy was required for all patients. Patients with mediastinoscopy-proven N2 disease or superior sulcus tumors were excluded from the trial. Patients were treated with paclitaxel and carboplatin before and after surgery; patients in cohort 1 received two cycles before surgery and three cycles after surgery, and patients in cohort 2 received three cycles before surgery and four cycles after surgery. For all the patients in both cohorts, the radiographic response rate was 51%, the complete resection rate was 86%, and the pathologic complete response rate was 5%. Three-year and 5-year survival rates were 61% and 45%, respectively, which are comparable to the rates in historical series. There were no significant differences in patient characteristics or outcome between the two cohorts. A detailed analysis showed a lack of correlation between radiographic and pathologic responses, with 50% of patients who were found to have equivalent or more extensive disease at surgery having a major response to chemotherapy. Two patients died postoperatively. Ninety-six percent of patients received the planned preoperative chemotherapy, and 45% received postoperative chemotherapy. A subsequent phase III study, SWOG S9900, compared the same induction chemotherapy for three cycles followed by surgery with surgery alone for patients with clinical stage IB, II, and IIIA NSCLC (excluding superior sulcus and N2 disease).[107] Mediastinoscopy was performed when a mediastinal lymph node was bigger than 1 cm, and the original statistical plan called for 600 patients in order to detect a 33% increase in median survival or a 10% increase in 5-year survival. This trial closed prematurely

in June 2004 when new evidence demonstrated the superiority of adjuvant chemotherapy over surgery alone, making the accrual to the control arm of the study flawed. At the time of study closure, 336 of the planned 600 eligible patients had been enrolled. Neoadjuvant chemotherapy was well tolerated, with 79% of patients receiving all three cycles. Objective response was documented in 41%, and 7% had progressive disease. Seven patients in the chemotherapy arm died postoperatively, compared with four patients in the surgery alone arm. With a median follow-up of 53 months, the median survival was 75 months for the chemotherapy arm compared with 46 months for the surgery alone arm; the 5-year survival rates were 50% and 43%, respectively. Although the use of chemotherapy was associated with a 19% reduction in the risk of death (HR, 0.81), this difference did not achieve significance ($p = 0.19$). Progression-free survival trended in favor of perioperative chemotherapy (median, 33 vs. 21 months, $p = 0.07$).

The Neoadjuvant Taxol Carboplatin Hope (NATCH) trial compared surgery alone to either chemotherapy followed by surgery or surgery followed by chemotherapy.[108] A total of 624 patients with stage I (greater than 2 cm), II, and T3 N1 disease according to the sixth edition of the TNM staging classification for lung cancer were randomly assigned to the three arms. The primary end point of the study was DFS. In the preoperative arm, 97% of patients started the planned chemotherapy, and the radiographic response rate was 53.3%. In the adjuvant arm, 66.2% started the planned chemotherapy. Surgery was performed in 94% of patients; surgical procedures and postoperative mortality were similar across the three arms. There was a trend toward longer DFS for patients in the preoperative arm compared with patients in the surgery alone arm (5-year DFS, 38.3% vs. 34.1%; HR for progression or death, 0.92; $p = 0.176$). The 5-year DFS rate was 36.6% in the adjuvant arm (HR for comparison with surgery alone arm, 0.96; $p = 0.74$). Overall, this study failed to show significant differences in DFS with the addition of preoperative or adjuvant chemotherapy to surgery. In this trial, in which the treatment allocation was made before surgery, more patients were able to receive preoperative than adjuvant treatment.

Another phase III trial promoted by the Medical Research Council (MRC), with the participation of European cooperative groups (MRC LU22, NVALT 2, EORTC 08012), randomly assigned 519 patients with early-stage NSCLC to receive either surgery (261 patients) or three cycles of platinum-based chemotherapy followed by surgery (258 patients).[109] Before randomization, clinicians chose the chemotherapy that would be given from a list of six standard regimens. The primary outcome measure was OS, which was analyzed on an intent-to-treat basis. Most of the patients (61%) had clinical stage I disease; 31% had stage II disease, and 7% had stage III disease. Seventy-five percent of patients received all three cycles of chemotherapy. The overall response rate was 49% (95% CI, 43% to 55%) and disease was downstaged in 31% (range, 25% to 37%) of patients. The rate of postoperative complications was not higher in the combined-modality arm and no impairment of quality of life was noted. However, there was no evidence of a benefit in terms of OS (HR, 1.02; 95% CI, 0.80–1.31; $p = 0.86$).

In another pan-European phase III study, Chemotherapy for Early Stages Trial (ChEST), patients with chemotherapy- and radiotherapy-naïve NSCLC (stage IB, II, or IIIA) were randomly assigned to either treatment with three cycles of gemcitabine (1250 mg/m^2 on days 1 and 8, every 3 weeks) plus cisplatin (75 mg/m^2 on days 1 or 2, every 3 weeks) followed by surgery, or to surgery alone.[110] Randomization was stratified by center and disease stage (IB/IIA vs. IIB/IIIA). The primary end point was 3-year progression-free survival. The study was closed prematurely after the random assignment of 270 patients, 129 to combined therapy and 141 to surgery alone. Slightly more patients in the surgery alone arm had stage IB–IIA disease (55.3% vs. 48.8%). The chemotherapy response rate was 35.4%. The combined modality was

associated with significantly better progression-free survival (HR, 0.70; $p = 0.003$) and OS (HR, 0.63; $p = 0.02$). Preoperative chemotherapy had a significant impact on outcomes in the stage IIB–IIIA subgroup (3-year progression-free rate, 36.1% vs. 55.4%; $p = 0.002$). These findings are not consistent with the results of S9900, which found no difference in treatment effect by stage,[107] and the results of the trial by Depierre et al.,[105] in which the benefit of chemotherapy was greater for patients with earlier stages of disease. The NATCH trial, however, demonstrated greater benefit of chemotherapy among patients with clinical stage II (T3 N1) disease.[108]

A systematic review and meta-analysis not based on individual patient data was reported in 2006 by Burdett et al.[111] and updated to include results from the MRC trial.[109] The original meta-analysis included data from seven randomized trials published between 1990 and 2005 (988 patients globally). Neoadjuvant chemotherapy improved survival (HR, 0.82; 95% CI, 0.69–0.97), equivalent to an absolute benefit of 6% at 5 years. The update documented a shift of the HR to 0.87 (95% CI, 0.76–1.01), with loss of the significance of the improvement in outcome. In 2014, the NSCLC Meta-analysis Collaborative Group performed a systematic review and individual participant data meta-analysis to establish the effect of preoperative chemotherapy for patients with resectable NSCLC.[112] Analyses of 15 randomized controlled trials (2385 patients) showed a significant benefit of neoadjuvant chemotherapy on survival (HR, 0.87; 95% CI, 0.78–0.96; $p = 0.007$), a 13% reduction in the relative risk of death (Fig. 51.3). This finding is remarkably similar to the results of the LACE Collaborative Group, which further updated the data in the meta-analysis with the results of the phase III studies NATCH and ChEST. Consisting of nearly 2200 total patients from 10 trials, the combined analysis produced a HR favoring neoadjuvant chemotherapy and surgery of 0.89 (95% CI, 0.81–0.98; $p = 0.02$) (unpublished data). The combined HR from these meta-analyses suggests that the estimated benefit from neoadjuvant chemotherapy is similar in magnitude to that expected with adjuvant chemotherapy.

A French multi-institutional trial first compared in an open-label, randomized trial with a 2 × 2 factorial design preoperative versus postoperative chemotherapy, then two chemotherapy regimens (gemcitabine-cisplatin versus paclitaxel-carboplatin). The preoperative group received two preoperative cycles followed by two additional preoperative cycles, while the postoperative group underwent two preoperative cycles followed by two postoperative cycles, the third and fourth cycles being given only to responders in both cases. A total of 528 patients were randomized and the 3-year OS did not differ between the two groups (67.4% and 67.7%, respectively; HR, 1.01 [0.79–1.30], $p = 0.92$), nor did 3-year DFS, response rates, toxicity, or postoperative mortality. Chemotherapy compliance was significantly higher in the preoperative group.[113]

In summary, perioperative chemotherapy is a feasible and ethical approach for patients with stage II–IIIA NSCLC, and modern chemotherapy regimens produce a benefit in the neoadjuvant setting similar to the benefit in the adjuvant setting although the supportive database is smaller. Tumor response occurs in 40% to 50% of patients, with treatment compliance that is generally better than that for adjuvant chemotherapy. However, the tumor is downstaged in fewer than 20% of cases and the rate of complete response is low.

BIOMARKERS TO INDIVIDUALIZE ADJUVANT CHEMOTHERAPY

Current research efforts aim to identify subsets of patients who will derive the greatest benefit from adjuvant chemotherapy by using gene expression profiling and pharmacogenomic approaches.

Microarray technologies allow researchers to explore the prognostic significance of thousands of markers using high-throughput and computational approaches. To date, more than 30 studies in lung cancer have been reported, showing that gene expression signature may stratify patients with early-stage NSCLC into different groups based on prognosis or survival.[114] Although most of these signatures have been validated in one or more independent patient cohorts, overlap of gene sets in the microarray datasets has been minimal. Thus, there is a strong possibility that sample collection methods, processing proto-cols, single-institution patient cohorts, small sample sizes, and peculiarities of the different microarray platforms are contributing substantially to the results. To address these issues, a multi-institutional collaborative study was conducted to generate gene expression profiles from a large number of samples with a priori determined clinical features, useful to evaluate proposed prognostic models for potential clinical implementation. A large series of lung adenocarcinomas was tested to determine whether microarray measurements of gene expression, either alone or combined with basic clinical covariates (stage of disease, age, and gender of the patient), can be used to predict OS. The risk scores produced correlated strongly with actual outcomes, especially when clinical and molecular information were combined to build prognostic models for early-stage lung cancer.[115]

A 14-gene expression assay based on quantitative polymerase chain reaction (PCR) that used formalin-fixed paraffin-embedded tissue samples and differentiated patients with heterogeneous statistical prognoses was developed in a cohort of 361 patients with resected nonsquamous NSCLC. The assay was validated in two different cohorts: 433 patients with resected stage I nonsquamous NSCLC and 1006 patients with resected stage I–III nonsquamous NSCLC from several leading Chinese cancer centers.[116] The signature segregated patients according to risk (low, intermediate,

and high), with 5-year survival rates of 71.4%, 58.3%, and 49.2%, respectively (*p* = 0.0003). Multivariate analysis in both cohorts indicated that no standard clinical risk factors could account for or provide the prognostic information derived from tumor gene expression. These data suggest that quantitative-PCR-based assays could reliably identify patients with early-stage nonsquamous NSCLC at high risk for mortality after surgical resection.

A DNA methylation microarray that analyzes 450,000 CpG sites was used to investigate tumoral DNA obtained from 444 patients with NSCLC that included 237 stage I tumors. The prognostic DNA methylation markers were validated in an independent cohort of 143 patients with stage I NSCLC. Unsupervised clustering of the 10,000 most variable DNA methylation sites in the discovery cohort identified patients with high-risk stage I NSCLC who had shorter relapse-free survival (RFS; HR [HR], 2.35; 95% CI, 1.29–4.28; *p* = 0.004). The study in the validation cohort of the significant methylated sites from the discovery cohort found that hypermethylation of five genes was significantly associated with shorter RFS in stage I NSCLC: *HIST1H4F, PCDHGB6, NPBWR1, ALX1,* and *HOXA9.* A signature based on the number of hypermethylated events distinguished patients with high- and low-risk stage I NSCLC (HR, 3.24; 95% CI, 1.61–6.54; *p* = 0.001).[117]

Although these types of molecular tools may add prognostic information beyond stage in early NSCLC or may serve as a stratification tool for future adjuvant studies, they are not routinely used in clinical practice.

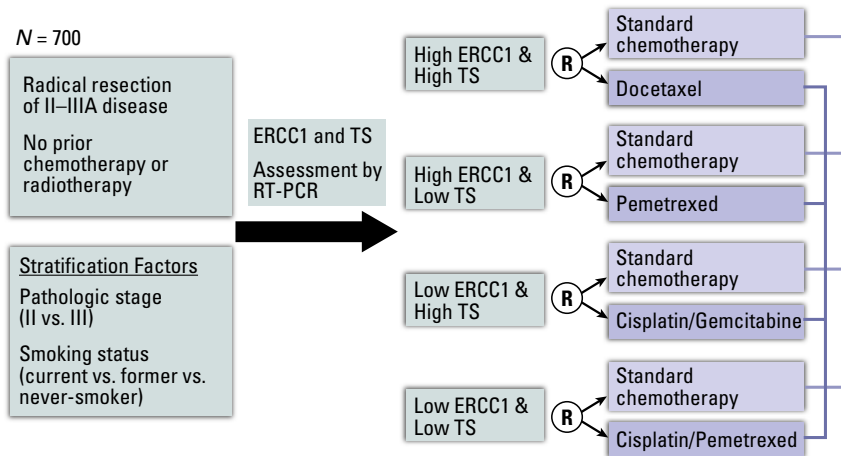
Another approach that has been evaluated as a method for selecting patients for adjuvant chemotherapy is to identify a predictive molecular determinant for cisplatin. Cisplatin inhibits replication by binding to DNA and forming platinum–DNA adducts, causing strand breaks when the DNA helices unwind in preparation for replication. The nuclear excision repair (NER)


Fig. 51.4. The International Tailored Chemotherapy Adjuvant Trial, an ongoing phase III multicenter randomized trial comparing adjuvant pharmacogenomic-driven chemotherapy with standard adjuvant chemotherapy for completely resected stage II–IIIA nonsmall cell lung cancer. *ERCC1*, excision repair cross–complementation group 1; *RT-PCR*, real-time polymerase chain reaction; *TS*, thymidylate synthase.

family of genes is involved in repair of these DNA strand breaks.[118] The excision repair cross–complementation group 1 (ERCC1) enzyme is one of the proteins involved in the final step of the NER pathway that recognizes and removes cisplatin-induced DNA adducts. ERCC1 is also important in the repair of interstrand cross-links in DNA and in recombination processes. The removal of platinum-DNA adducts by the proteins of the NER pathway reverses the tumoral DNA damage induced by cisplatin, leading to cisplatin resistance. High tumoral *ERCC1* expression, therefore, was predicted to be associated with cisplatin resistance and hence serve as a predictive molecular determinant for this chemotherapy agent.

Exploratory studies in advanced disease confirmed this hypothesis,[119,120] but a later phase III trial failed to prove the superiority of this approach.[121] *ERCC1* expression may be investigated either at the protein level, with use of IHC, or at the mRNA level, with use of quantitative PCR. Initial data from the IALT Biology study appeared to confirm ERCC1 as assessed by IHC as a positive prognostic factor and negative predictive factor for benefit from chemotherapy in a sample of 761 tumor specimens obtained before administration of chemotherapy.[122] Thus, patients with tumors that overexpressed *ERCC1* had longer survival than patients with tumors that did not, but the addition of chemotherapy was of no additional benefit. Among patients with no ERCC1 protein detected in the tumor, the median survival was 14 months longer for patients who received chemotherapy than for patients who did not receive chemotherapy. Among patients with *ERCC1*-positive tumors, there were no differences in survival with or without chemotherapy. This observation prompted the initiation of a phase II study that enrolled 150 patients with completely resected nonsquamous cell stage II or IIIA (non-N2) tumors. Patients in the control arm (*n* = 74) were treated with four standard-dose courses of cisplatin plus pemetrexed (CP). In the customized treatment arm (*n* = 76), patients with activated *EGFR* mutations received erlotinib 150 mg for 1 year; *ERCC1*-negative patients received four CP courses, whereas *ERCC1*-positive patients underwent follow-up. The trial sought to demonstrate the feasibility of customized adjuvant chemotherapy based on timely biomarker analysis within a 2-month postsurgery delay.

The primary end point of the study was met but the subsequent phase III study was cancelled because the unreliability of the ERCC1 immunohistochemical read-outs became evident.[123] In fact in a further analysis of a larger number of samples, original results about the predictive role of ERCC1 IHC were not confirmed,[124] likely due to the fact that currently available monoclonal antibodies could not distinguish among the four ERCC1 protein isoforms, whereas only one isoform produced a protein that had full capacities for nucleotide excision repair and cisplatin resistance.[116,125] Thus, ERCC1 testing is not currently used in routine practice. Other genomic markers being investigated in ongoing randomized clinical trials in early disease to tailor adjuvant treatment include *BRCA1*, another gene involved in both homologous recombination repair and nonhomologous end joining,[125] and thymidylate synthase, a putative marker for pemetrexed sensitivity.[126]

In a Spanish multicenter study, completely resected stage II–III NSCLC patients were randomized to receive standard adjuvant chemotherapy or, in the experimental arm, three different treatment options based on the level of tumor *BRCA1* expression. The study failed to show a significant benefit from treatment customization, but a longer follow-up time is needed to conclude definitively in favor of a completely negative study. The study does not support the hypothesis of cisplatin-resistance in high *BRCA1* tumors, and cisplatin-based CT remains the standard of care.

Another phase III trial, the International Tailored Chemotherapy Adjuvant Trial, compared adjuvant pharmacogenomic-driven chemotherapy versus standard adjuvant chemotherapy in completely resected stage II–IIIA NSCLC by evaluating *ERCC1* and thymidylate synthase expression (Fig. 51.4) The trial has fully completed the accrual in 2014 and final results are eagerly awaited.

CONCLUSION

Randomized studies testing the efficacy of current standard adjuvant chemotherapy regimens have demonstrated a positive impact on DFS and OS. A precise quantitative estimate of the survival gain is not known, but meta-analysis suggests it is approximately 5% at 5 years. The findings of two randomized clinical trials conducted with selected patient populations support the use of adjuvant treatment after complete resection of stage IB–II NSCLC, and two other, larger, randomized clinical trials (one marginally positive and one marginally negative) support the use of adjuvant treatment after complete resection of all stages of NSCLC. A new meta-analysis that includes the most recent generation of these positive and negative randomized clinical studies will substantially contribute to determining the role of adjuvant chemotherapy.

There is a need, however, for reliable predictive and prognostic factors that stratify patients who do or do not need adjuvant therapy in order to avoid the exposure of most patients to unnecessary treatments. In the near future, genomic (or pharmacogenomic) and proteomic assays may drive the identification of patients who are ideal candidates for adjuvant therapy.

Neoadjuvant chemotherapy may be better suited than adjuvant therapy for evaluating novel agents, as the effect of the drug on the target can be assessed by pretreatment biopsy (at diagnosis) and after chemotherapy (at surgery). However, targeted agents matched to specific mutations may need to be administered for long periods of time, which is better accomplished in the adjuvant setting, where a curative resection option is not jeopardized in patients who fail to respond preoperatively. The duration of the administration of novel agents postoperatively, for example, in patients who have an initial response, will need careful evaluation in randomized trials. It is hoped that better patient selection and better matching of individual patients to a specific treatment regimen based on molecular profiling can lead to more effective treatment.

Smoking cessation and early detection of lung cancer remain of high importance. It is hoped that newer radiographic methodologies will allow for better characterization and even earlier detection of malignancies to decrease the number of diagnostic procedures performed to remove small lesions that are not malignant. In the long run, improved molecular technologies are likely to also allow for earlier detection by nonradiographic methods.

52 Treatment of Extensive-Stage Small Cell Lung Cancer

Mamta Parikh, Karen Kelly, Primo N. Lara, Jr., and Egbert F. Smit

SUMMARY OF KEY POINTS

- Performance status is universally recognized as an independent prognostic factor and typically correlates with the extent of tumor burden.
- As first-line therapy, platinum agent plus etoposide or irinotecan remains the standard of care for the treatment of small cell lung cancer (SCLC).
- The ideal number of chemotherapy cycles for SCLC has not been defined; however, four to six cycles are considered the standard based on results from randomized trials.
- Despite an initially high response rate to frontline platinum-based chemotherapy, extensive-stage SCLC will universally relapse, often within 3 to 6 months.
- Alternative chemotherapy strategies have focused on modifying the dosage and schedules of established regimens.
- Dose-dense regimens have shown mixed results.
- Most trials employing a dose-intensification strategy did not show a survival advantage over standard therapy for patients with extensive-stage SCLC, and higher doses were typically associated with greater toxicity.
- Patients who receive no further therapy have a median survival of less than 3 months.
- Patients who have previously received platinum-based therapy are grouped into two general categories reflecting the platinum-sensitivity status of their disease: platinum sensitive and platinum refractory.
- Topotecan is approved as second-line treatment for patients with platinum-sensitive, relapsed disease based on symptom control. An oral formulation of topotecan was also developed for patients' convenience.
- Despite progress in the understanding of genomic alterations and signaling pathways in SCLC, clinical experiments with tyrosine kinase inhibitors, other small-molecule inhibitors, and antiangiogenic agents have been disappointing Other therapeutic areas of interest more recently evaluated include epigenetic modifiers, inhibitors of DNA repair and the cell cycle, immunocheckpoint inhibitors and inhibitors of the Notch pathway.

The chemosensitivity of small cell lung cancer (SCLC) was first identified 50 years ago with the recognition that methyl-bis-β-chloroethyl amine hydrochloride could cause tumor regression in more than 50% of patients.[1] Since then, numerous antineoplastic agents have been shown to produce objective response rates of at least 20% in previously untreated patients. Older active agents included nitrogen mustard, doxorubicin, methotrexate, ifosfamide, etoposide, teniposide, vincristine, vindesine, nitrosureas, and cisplatin and its analog carboplatin.[2] In the 1990s, six new agents were discovered to have activity against SCLC in untreated patients, including paclitaxel, docetaxel, topotecan, irinotecan, vinorelbine,

and gemcitabine.[3–11] In this century, two additional cytotoxic agents were evaluated: pemetrexed, a multitargeted antifolate agent evaluated as monotherapy in the relapse setting, and amrubicin, a topoisomerase II inhibitor that has produced impressive responses as first-line therapy.[12,13] This chapter discusses first-line and second-line therapy for patients with extensive-stage SCLC.

FIRST-LINE CHEMOTHERAPY

Combination Chemotherapy

Given the large number of active agents in SCLC, the evaluation of combination regimens quickly ensued. In the 1970s, randomized trials demonstrated the superiority of combination chemotherapy over single-agent therapy.[14] Furthermore, studies showed that simultaneous administration of multiple agents was more efficacious than the sequential administration of the same agents.[15,16] Cyclophosphamide-based regimens were commonly used to treat SCLC, including cyclophosphamide, doxorubicin, and vincristine (CAV); cyclophosphamide, doxorubicin, and etoposide (CDE); and cyclophosphamide, etoposide, and vincristine (CEV).

After the introduction of cisplatin, randomized trials with a regimen of cisplatin and etoposide showed that this combination was as effective as CAV and less toxic.[17,18] A meta-analysis of 36 trials demonstrated that regimens containing cisplatin and/or etoposide offered a significant survival advantage to patients with SCLC.[19] Thus cisplatin and etoposide became the preferred regimen for the treatment of extensive-stage SCLC, yielding overall response rates of 65% to 85%, complete response rates of 10% to 20%, and a median survival of 8 months to 10 months.[16–18] For patients with limited-stage SCLC, cisplatin and etoposide plus twice-daily thoracic radiotherapy was also considered the treatment of choice, producing an 87% overall response rate, a 56% complete response rate, a median survival of 23 months, and a 5-year survival rate of 44%.[20] Carboplatin is frequently substituted for cisplatin because of its more favorable toxicity profile. One small randomized trial comparing cisplatin and etoposide with carboplatin and etoposide in patients with limited- and extensive-stage disease showed similar efficacy, but the carboplatin-based combination was significantly less toxic.[21] A meta-analysis of individual data from 633 patients who participated in four clinical trials did not demonstrate any difference in efficacy between cisplatin- and carboplatin-based regimens, with a median survival of 9.6 months and 9.4 months, respectively.[22] Significant differences in toxicity were found; more neutropenia, anemia, and thrombocytopenia occurred with carboplatin-based regimens, whereas more nausea, vomiting, neurotoxicity, and renal toxicity developed with cisplatin-based regimens.

Years elapsed before the discovery of newer cytotoxic agents such as the topoisomerase II inhibitors, taxanes, gemcitabine, and vinorelbine, which were shown to have antitumor activity in SCLC. Many studies have summarized the results from novel combinations that were evaluated in phase III trials (Table 52.1).[23–55] Enthusiasm for the combination of cisplatin and irinotecan (PI) arose when Japanese researchers halted their phase III trial prematurely after an interim analysis showed a survival benefit for PI over cisplatin and etoposide.[23] One hundred and fifty-four patients were randomly assigned to receive either four

cycles of etoposide (100 mg/m²) on days 1, 2, and 3 with cisplatin (80 mg/m²) on day 1 every 3 weeks or four cycles of irinotecan (60 mg/m²) on days 1, 8, and 15, and cisplatin (60 mg/m²) on day 1. Patients treated with PI had a significantly better overall response rate (84.4% vs. 67.5%; $p = 0.02$), median survival (12.8 months vs. 9.4 months), and 1-year survival rate (58.4% vs. 37.7%; $p = 0.002$) than patients treated with cisplatin and etoposide. The PI combination was associated with a higher rate of grade 3 or grade 4 diarrhea ($p = 0.01$), whereas cisplatin and etoposide were associated with a higher rate of myelosuppression ($p = 0.0001$). The Southwest Oncology Group (SWOG) conducted a confirmatory trial using the identical study design but found no survival benefit for PI.[24] In this large trial of 651 patients, all efficacy parameters were very similar except for a trend toward improved progression-free survival time for PI (5.7 months vs. 5.2 months for cisplatin and etoposide; $p = 0.07$). Grade 3 or grade 4 neutropenia and thrombocytopenia were higher in the cisplatin and etoposide arm, whereas grade 3 or grade 4 nausea/vomiting and diarrhea were higher in the PI arm. A phase III superiority trial comparing a novel dose and schedule of the PI regimen (irinotecan [65 mg/m²] with cisplatin [30 mg/m²] given on days 1 and 8) with standard cisplatin and etoposide produced similar survival in both arms.[25] In Europe, a different schedule of PI (irinotecan [65 mg/m²] on days 1 and 8 with cisplatin [80 mg/m²] on day 1) was assessed in comparison with standard cisplatin and etoposide.[26] The data showed that the PI regimen was noninferior to cisplatin and etoposide, as hypothesized. The median overall survival rates were 10.2 months and 9.7 months, respectively, with a hazard ratio (HR) of 0.81 (95% confidence interval [CI], 0.61–1.01; $p = 0.06$). Overall response rates were 39% for PI and 47% for cisplatin and etoposide, and time to progression was 5.4 months and 6.2 months, respectively. The number of grade 3 or grade 4 adverse events was similar between the arms, but more patients in the PI arm had gastrointestinal toxicity and more patients in the cisplatin and etoposide arm had neutropenia. In 2013, Korean investigators reported the results from a phase III trial comparing PI with cisplatin and etoposide.[27] Irinotecan was administered on days 1 and 8 with cisplatin on day 1, and cisplatin and etoposide

were given in the standard fashion. The trial, however, did not demonstrate the superiority of PI (HR, 0.88; 95% CI, 0.73–1.05; p = 0.12). The median overall survival was 10.9 months for PI and 10.3 months for cisplatin and etoposide. The overall response rate was significantly higher for PI (62.3% vs. 48.2%; p = 0.0064), but progression-free survival was not significantly different (6.5 months vs. 5.8 months, respectively). The frequency of anemia, nausea, and diarrhea was greater with PI.

Irinotecan has also been evaluated in combination with carboplatin. The IRIS study demonstrated superior survival for irinotecan plus carboplatin compared with oral etoposide plus carboplatin; however, overall survival in both study arms was low, at less than 9 months.[28] Drug dosages and schedules were unconventional and lower than other published regimens, with irinotecan (175 mg/m^2) and carboplatin (area under the curve [AUC] 4) administered on day 1, and etoposide (120 mg/m^2) orally on days 1–5 with carboplatin (AUC 4) on day 1. Another trial, conducted in Germany, randomly assigned 216 patients to receive either irinotecan (50 mg/m^2) on days 1, 8, and 15 with carboplatin (AUC 5) or intravenous (IV) etoposide (140 mg/m^2) on days 1–3 with carboplatin (AUC 5).[29] The irinotecan regimen was not found to be superior to the etoposide regimen in terms of overall survival (HR, 1.34; 95% CI, 0.97–1.85; p = 0.072). The median survival was 10 months and 9 months, respectively. The overall response rate and progression-free survival were similar for both treatment arms.

A meta-analysis of seven randomized trials including 2027 patients that compared irinotecan plus a platinum agent with etoposide plus a platinum agent showed a survival advantage for irinotecan regimens (HR, 0.81; 95% CI, 0.71–0.93; p = 0.003).[30] No significant differences in progression-free survival or overall response rate were noted. Irinotecan regimens produced significantly less hematologic toxicity but more gastrointestinal toxicity than etoposide regimens. Overall, the data suggest that combinations of irinotecan or etoposide plus a platinum compound are reasonable options as first-line therapy for patients with extensive-stage SCLC.

Topotecan, a drug with activity for disease relapse, was evaluated in the frontline setting. Two large phase III trials with oral or IV topotecan plus cisplatin did not show a survival advantage over standard cisplatin and etoposide. Efficacy parameters were similar between the regimens, with median survival times of 9 months to 10 months.[31,32] The IV topotecan regimen did produce a significantly higher overall response rate (56% vs. 46%; p = 0.01) and prolonged progression-free survival (7 months vs. 6 months; p = 0.004), but was associated with more hematologic toxicity.

Several other novel platinum combinations have been studied. One trial comparing paclitaxel plus carboplatin with CDE showed no benefit of the doublet over the standard regimen, but survival was modest in both arms, at less than 7 months.[33] A phase III trial of the combination of pemetrexed and carboplatin unexpectedly showed inferior efficacy to standard treatment. In a previous randomized phase II study of pemetrexed plus cisplatin or carboplatin, the carboplatin arm produced a median survival of 10.4 months and was well tolerated.[34] A phase III study, the Global Analysis of Pemetrexed in SCLC Extensive Stage, was designed to show noninferiority of pemetrexed (500 mg/m^2) and carboplatin (AUC 5) compared with etoposide and carboplatin. With 733 patients randomly assigned to treatment, the study was terminated prematurely when the predefined futility end point for progression-free survival showed inferiority of the experimental arm.[35] In the final analysis, overall survival was inferior (HR, 1.56; 95% CI, 1.27–1.92; p < 0.01). The median overall survival was 8.1 months for pemetrexed and carboplatin and 10.6 months for etoposide and carboplatin. The median progression-free survival was 3.8 months for pemetrexed and carboplatin and 5.4 months for etoposide and carboplatin (p < 0.01), and the

overall response rate also favored the etoposide and carboplatin combination (52% vs. 31%; p < 0.001). Significant neutropenia and more febrile neutropenia were seen in the etoposide arm. By contrast, death during therapy or within 30 days was higher for the pemetrexed arm than for the etoposide arm (16% vs. 10%; p = 0.032), and the rate of toxicity-related death was higher (1.4% vs. 0%; p = 0.028).

Another novel cytotoxic agent with promising early results that failed to show a survival advantage in the phase III setting was amrubicin. A phase III randomized study showed that amrubicin plus cisplatin was inferior to PI.[36] Two hundred and eighty-four patients were randomly assigned to receive either amrubicin (35 mg/m^2 to 40 mg/m^2) on days 1–3 and cisplatin (60 mg/m^2) every 3 weeks or cisplatin (60 mg/m^2) on day 1 and irinotecan (60 mg/m^2) on days 1, 8, and 15 every 4 weeks. The median overall survival for amrubicin plus cisplatin was 15 months, compared with 18.3 months for PI (HR, 1.33; 95% CI, 1.01–1.74; p = 0.681), and this result exceeded the noninferiority margin. The progression-free survival was 5.1 months for amrubicin plus cisplatin and 5.7 months for PI with an overall response rate of 78% and 72%, respectively. An increased incidence of grade 4 neutropenia (79% vs. 23%) and febrile neutropenia (32% vs. 11%) was found in the amrubicin plus cisplatin arm.

The favorable toxicity profiles of most of the newer agents led investigators to explore the possibility of integrating them into an active doublet (see Table 52.1). Three randomized trials evaluating the addition of paclitaxel to cisplatin and etoposide or carboplatin and etoposide did not produce a survival benefit over traditional doublets and were associated with increased toxicity.[37–39] French investigators evaluated a four-drug regimen in which they added cyclophosphamide and 4′-epidoxorubicin to cisplatin and etoposide (PCDE). A significant improvement in the complete response rate (13% vs. 21%; p = 0.02) and overall survival (9.3 months vs. 10.5 months; p = 0.0067) was noted for PCDE.[40] However, PCDE was associated with a significantly higher hematologic toxicity rate, with 22% of patients having a documented infection, compared with 8% in the cisplatin and etoposide arm (p = 0.0038). Toxicity-related death rates were similar, at 9% for PCDE and 5.5% for cisplatin and etoposide. Since the early 1990s, there have been no major breakthroughs with newer chemotherapy agents in the first-line setting. A platinum agent plus etoposide or irinotecan remains the standard of care for the treatment of SCLC.

Alternative Chemotherapy Strategies

Alternative chemotherapy strategies have focused on modifying the dosage and schedules of established regimens, including dose intensification, alternating non–cross-resistant chemotherapy, and prolonged treatment durations. However, with the discovery of molecularly targeted agents, investigators have largely abandoned the pursuit of optimizing current chemotherapy regimens.

Dose Intensification

Dose intensity is defined as the dose per meter squared per week. Dose intensification can be accomplished by increasing the dose administered or by shortening the interval between doses (dose density). Results from preclinical tumor models suggested that one of the simplest ways to overcome drug resistance was dose escalation.[41] In the late 1970s, Cohen et al.[42] randomly assigned patients to receive either standard dosages of cyclophosphamide, methotrexate, and lomustine or a higher dose of cyclophosphamide and lomustine plus a standard dose of methotrexate. Patients treated in the high-dose arm had a higher overall response rate that led to prolonged survival, and a subset of these patients were long-term survivors. These data

resulted in a series of seven randomized trials comparing high-dose and conventional-dose chemotherapy in patients with limited-stage and extensive-stage SCLC.[43–49] Most of these trials were conducted in the 1980s and did not show a clinical benefit. The Spanish Lung Cancer Group reexamined this question in 2004.[49] They compared high-dose epirubicin (100 mg/m²) plus cisplatin (100 mg/m²) administered on day 1 with standard cisplatin and etoposide (cisplatin [100 mg/m²] on day 1 and etoposide [100 mg/m²] on days 1–3) in 402 patients with SCLC. Efficacy results were similar between the arms. A study of patients with limited-stage disease published in 1989 showed a superior 2-year survival rate of 43% when the dose of cisplatin and cyclophosphamide was increased by 20% in the first cycle of a PCDE regimen, compared with a 2-year survival rate of 23% for standard PCDE.[50]

Dose-dense regimens have shown mixed results. One such combination was an intense weekly regimen of cisplatin (25 mg/m²) for 9 consecutive weeks, vincristine (1 mg/m²) on even weeks for 9 weeks, and doxorubicin (40 mg/m²) and etoposide (80 mg/m²) on days 1–3 on odd weeks for 9 weeks (CODE). This was the first regimen to be associated with an impressive 2-year survival rate of 30% among 48 patients with extensive-stage SCLC.[51] The investigators were able to administer close to the intended full doses of all four agents, thereby increasing the dose intensity by twofold. The National Cancer Institute of Canada–Cancer Treatment Group (NCIC–CTG) in collaboration with SWOG conducted a phase III trial comparing the CODE regimen and conventional alternating CAV/cisplatin and etoposide for patients with extensive-stage SCLC.[52] Response rates were higher in the CODE arm, but no differences were found in progression-free or overall survival. Although rates of neutropenia and fever were similar, toxicity-related deaths occurred in 9 of 110 patients receiving CODE, compared with one of 109 patients receiving CAV/cisplatin and etoposide (p = 0.42). Given the high toxicity-related death rate and similar efficacy, CODE was not recommended. Japanese investigators subsequently demonstrated that adding granulocyte colony-stimulating factor (G-CSF) to CODE increased the mean total dose intensity received, reduced neutropenia and febrile neutropenia, and significantly prolonged survival (59 weeks vs. 32 weeks; p = 0.0004).[53] This led to a phase III trial of CODE plus G-CSF compared with CAV/cisplatin and etoposide.[54] The response rate was significantly higher for CODE, but there was no survival advantage. The toxicity-related death rate with CODE plus G-CSF was low, with only four reported deaths.

European investigators evaluated the dose-dense strategy with or without colony stimulation in seven phase III trials published between 1993 and 2002.[55–61] Two trials showed a survival advantage for the dose-dense arm, and the other trials reported similar outcomes between the standard and experimental arms. The trial by Steward et al.[58] showed a significant prolongation in survival with dose intensification of vincristine, ifosfamide, carboplatin, and etoposide (ICE) chemotherapy compared with standard dosing of this regimen. The median survival time was 443 days in the dose-dense arm and 351 days in the standard arm (p = 0.0014), with 2-year survival rates of 33% and 18%, respectively. There was no difference in response rate, despite the 26% increase in dose intensity in the experimental arm. The British Medical Research Council randomly assigned 403 patients to receive doxorubicin, cyclophosphamide, and etoposide in two or three weekly schedules.[59] In this trial, a 34% escalation in dose density was achieved. Although the response rates in the two arms were similar, a significant improvement was found in the complete response rate in the dose-dense arm (40% vs. 28%; p = 0.02) that translated into a 2-year survival benefit (13% vs. 8%; p = 0.04). Subgroup analysis showed that the survival advantage among patients with extensive disease was as large as that for patients with limited disease.

A possible explanation for the failure of the previous trials is that the dose intensity was insufficient to produce a survival benefit. To definitively answer the question about dose intensification, studies were conducted using stem cell rescue, which would allow for a 200% to 300% dose escalation of chemotherapy. Multiple small studies have shown this approach to be feasible. The original studies focused on patients who had a response with conventional cytotoxic therapy and then received high-dose consolidation with stem cell rescue. A randomized trial testing this late-intensification strategy was reported by Humblet et al.[62] in 1987. One hundred and one patients received standard induction chemotherapy, and 45 patients with chemotherapy sensitivity were randomly assigned to receive either one additional cycle with high-dose cyclophosphamide, carmustine, and etoposide or conventional doses of the same drugs. In this highly selected group of patients, the median overall survival was 68 weeks for the high-dose arm compared with 55 weeks for the conventional therapy (p = 0.13).

Because of its improved safety and feasibility, peripheral blood stem cell transplantation has largely replaced autologous marrow transplants. Japanese investigators reported promising results from a phase II study of high-dose ICE with autologous peripheral blood stem cell transplantation in 18 patients with limited-stage SCLC after concurrent, hyperfractionated chemoradiation therapy.[63] The complete response rate was 61% and the median survival time was 36.4 months. One toxicity-related death was reported. At the time of publication, a randomized trial based on these results was ongoing. Three randomized trials using high-dose ICE chemotherapy with peripheral blood rescue as first-line treatment for SCLC have also been reported.[64–66] The largest trial included 318 patients with predominantly limited-stage SCLC and compared six cycles of a dose-dense ICE regimen every 14 days, with G-CSF–mobilized whole-blood hematopoietic progenitors, with six cycles of the standard 28-day ICE regimen.[64] Despite doubling of the median dose intensity with the dose-dense regimen (182% vs. 88%, respectively), the median survival time and the 2-year survival rate were comparable (14.4 months and 22% vs. 13.9 months and 19%, respectively). By contrast, an identical study by Buchholz et al.[65] was halted after 70 patients were enrolled. They reported a favorable median survival of 30.3 months (p = 0.001), a 2-year survival rate of 55%, and a time to progression of 15 months (p = 0.0001) for the dose-intense arm compared with a median survival of 18.5 months, a 2-year survival rate of 39%, and a time to progression of 11 months for the standard-dose arm in this small, single-institution study. The European Group for Blood and Marrow Transplant conducted a similar study.[66] The study was closed after 140 of the planned 340 patients were enrolled because of poor accrual. The median dose intensity for the high-dose arm was 293%, but this dose did not yield a survival benefit; the median survival time was 18.1 months and the 3-year survival rate was 18% for the high-dose arm, compared with 14.4 months and 19%, respectively, for the standard ICE arm. None of the subgroups benefited from high-dose ICE.

Overall, most trials using a dose-intensification strategy did not show a survival advantage over standard therapy for patients with extensive-stage SCLC, and the higher doses were typically associated with greater toxicity. This approach should be abandoned in patients with extensive disease. In limited-stage SCLC, the optimal drug doses remain unclear, with several studies suggesting a possible benefit. Continued evaluation of dose intensity in the curative setting is reasonable.

Alternating Non–Cross-Resistant Chemotherapy Regimens

To achieve maximal antitumor effects using multiple active agents, they should be administered simultaneously at their

optimal single-agent dose. However, because drug toxicities often overlap, strict adherence to this approach is often not possible in the clinical setting. In the 1980s, Goldie et al.[67] suggested that alternating two non–cross-resistant chemotherapy regimens of relatively comparable efficacy could minimize the development of drug resistance while avoiding excessive host toxicity. This strategy was particularly appealing for SCLC because both CAV and cisplatin and etoposide are highly active against SCLC and contain agents from divergent drug classes. Three randomized phase III trials were performed to evaluate CAV and CAV alternating with cisplatin and etoposide.[16,17,68] Studies from the United States and Japan showed similar efficacy between the study arms, whereas the NCIC–CTG reported superior efficacy for the alternating regimen, with overall response rates of 80% and 63%, respectively ($p < 0.002$), and survival times of 9.6 months and 8.0 months ($p = 0.03$). Investigators at the NCIC–CTG went on to test this approach in patients with limited-stage SCLC.[69] Patients were randomly assigned between two induction regimens, either alternating CAV/cisplatin and etoposide or sequential therapy with three cycles of CAV followed by three cycles of cisplatin and etoposide. Chemotherapy was followed by radiotherapy in patients with a disease response. The therapeutic outcomes in the study groups were not significantly different. SWOG conducted a similar study and found no advantage for the alternating CAV/cisplatin and etoposide regimen over the etoposide, vincristine, doxorubicin, and cyclophosphamide regimen in patients with limited-stage disease.[70]

The European Organization for Research and Treatment of Cancer reported a trial testing two relatively non–cross-resistant regimens: CDE and vincristine, carboplatin, ifosfamide, and mesna.[71] Patients with extensive-stage SCLC were randomly assigned to receive either a maximum of five courses of CDE or an alternating regimen consisting of CDE in cycles 1, 3, and 5 and vincristine, carboplatin, ifosfamide, and mesna in cycles 2 and 4. The trial accrued only 148 of the 360 planned patients. The median survival time was 7.6 months in the standard arm and 8.7 months in the alternating arm ($p = 0.243$).

Although no survival benefit for the alternating drug hypothesis was demonstrated, the emergence of newer active agents for the treatment of SCLC justified revisiting this strategy. The North Central Cancer Treatment Group conducted a trial of etoposide and cisplatin alternating with topotecan and paclitaxel.[72] The overall response rate was 77%, including four complete responses among 44 evaluable patients. The median survival was 10.5 months, with 1- and 2-year survival rates of 37% and 12%, respectively. This alternating regimen was associated with a high rate of grade 3 and grade 4 neutropenia (95%) despite the use of filgrastim in cycles 2, 4, and 6. The Hellenic Oncology Research Group treated 36 previously untreated patients with extensive-stage SCLC with cisplatin and etoposide alternating with topotecan.[73] The overall response rate was 64%, and 14% of patients had a complete response. Grade 3 and grade 4 neutropenia occurred in 39% of patients during the cycles of cisplatin and etoposide and in 55% after the topotecan treatment. These limited data incorporating newer chemotherapy agents into an alternating strategy were disappointing. Taken together, alternating newer and/or older cytotoxic agents to overcome drug resistance is an unsuccessful strategy and should not be pursued.

Treatment Duration and Maintenance Therapy

The ideal number of chemotherapy cycles for SCLC has not been defined; however, four to six cycles is considered the standard based on the results from the randomized trials described previously. Clinical trials specifically designed to investigate the role of prolonged treatment using a consolidation or maintenance approach have been performed. Three of 14 trials produced positive results.[74–76] All three trials were initiated in 1982.

In two trials of patients with limited-stage SCLC, two cycles to four cycles of consolidation therapy with cisplatin and etoposide were given to patients who had a response after induction CAV with or without thoracic radiotherapy.[74,75] The remaining trial randomly assigned patients with nonprogressing limited or extensive-stage disease to four additional cycles of CEV or observation.[76] Although this trial showed that four cycles of CEV were inferior, a second randomization to salvage chemotherapy compared with palliative care given at the time of disease progression demonstrated that the subset of patients who received eight cycles of CEV with or without salvage therapy did not live longer than patients who received four cycles of CEV and salvage therapy at the time of relapse. The role of consolidation and/or maintenance therapy with topotecan was evaluated by the Eastern Cooperative Oncology Group (ECOG).[77] Two hundred and twenty-three patients with nonprogressing, extensive-stage SCLC were randomly assigned to receive either four cycles of topotecan or observation. Progression-free survival from the date of randomization was significantly better with topotecan than with observation alone (3.6 months vs. 2.3 months; $p < 0.001$), but overall survival from randomization was not significantly different between the arms (8.9 months vs. 9.3 months; $p = 0.43$). A meta-analysis of 14 randomized trials of maintenance chemotherapy involving 1806 patients was published in 2013.[78] Maintenance chemotherapy failed to increase survival when compared with observation alone, with an odds ratio for 1-year mortality of 0.88 (95% CI, 0.66–1.19; $p = 0.414$). Maintenance treatment did, however, significantly prolong progression-free survival for patients with extensive-stage disease (HR, 0.72; 95% CI, 0.58–0.89; $p = 0.003$). This benefit was limited to patients who had switch maintenance therapy. Overall, chemotherapy after four to six cycles of a combination regimen is not warranted. Patients should be followed closely for signs and symptoms of relapse. Clinical trials evaluating maintenance regimens with molecularly targeted agents were ongoing at the time of publication.

In summary, a platinum-based doublet with etoposide or irinotecan remains the standard of care for patients with SCLC. Although extensive research has not altered the standard of care for SCLC in many years, an analysis of the Surveillance, Epidemiology, and End Results database showed a modest but significant improvement in survival with current therapies.[79] In 1973, the 2-year survival rate for extensive-stage SCLC was 1.5%, compared with 4.6% in 2000, whereas the 5-year survival rate for limited-stage SCLC increased from 4.9% to 10% during a similar period (Fig. 52.1). Moreover, the recent genomic characterization of SCLC provides optimism that novel, efficacious agents are forthcoming.

FIRST-LINE CHEMOTHERAPY FOR OLDER PATIENTS

According to the Surveillance, Epidemiology, and End Results database, 42% of patients with SCLC were aged 70 years or older at diagnosis.[80] Similar age distributions are seen worldwide.[81,82] Furthermore, the 5-year survival rate for SCLC was significantly worse for older patients than for younger patients ($p < 0.0001$) and had not changed over the 15 years studied.[80] For the period between 1998 and 2003, 5-year survival rates were 6.5% for patients younger than 70 years of age, 3.4% for patients aged 70 to 79 years, and 2.4% for patients aged 80 years or older.

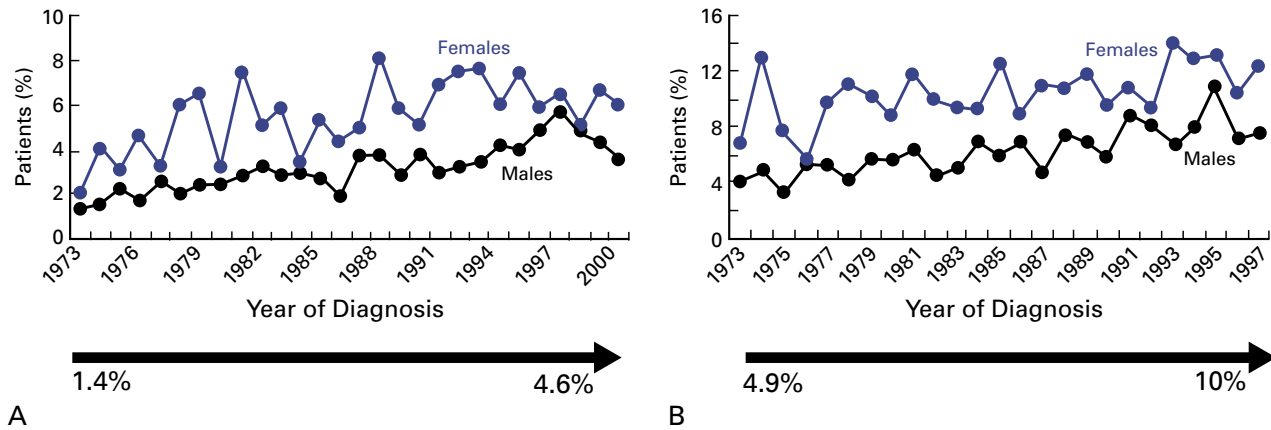
Retrospective reviews to identify prognostic factors in SCLC have shown variable results with regard to age. The largest experience comes from SWOG.[83] An analysis of 2580 patients enrolled in six SWOG studies, of whom approximately 10% were older, showed that patients over the age of 70 years had a significant risk of death, with a HR of 1.5 ($p \le 0.0001$) for limited-stage disease and a HR of 1.3 ($p = 0.006$) for extensive-stage disease. By contrast, a smaller study from 1991 reviewed 614 patients with limited- and extensive-stage disease from the University of Toronto


Fig. 52.1. All-cause survival trends in (A) extensive-stage small cell lung cancer (SCLC) from 1973 to 2000 and (B) limited-stage SCLC from 1973 to 1997. *(Modified with permission from Govindan R, Page N, Morgensztern D, et al. Changing epidemiology of small-cell lung cancer in the United States over the last 30 years: analysis of the Surveillance, Epidemiologic, and End Results database.* J Clin Oncol. *2006;24(28):4539–4544.)*

clinical trial database and showed that age over 70 years was not a significant predictor of a poorer outcome.[84] A meta-analysis published by Pignon et al.[83] in 1992 examined 2140 patients with limited-stage disease from 13 randomized trials that were designed to determine the role of thoracic radiotherapy combined with chemotherapy compared with chemotherapy alone. The relative risk of death in patients older than 70 years of age receiving combination therapy was 1.07, higher than that of older patients receiving chemotherapy alone. Since this meta-analysis, a review of two NCIC–CTG trials, BR.3 and BR.6, involving 618 patients with limited-stage SCLC who received the same chemotherapy regimen, showed no difference in survival between patients aged younger and older than 70 years.[84] In the United States Intergroup study comparing once-daily and twice-daily radiotherapy for limited-stage SCLC, survival of younger patients was better than that for patients older than 70 years of age, with borderline significance ($p = 0.051$).[85]

Advanced age has been perceived as a strong rationale for the use of less aggressive therapies or no therapy, for fear of increasing toxicity. The literature is conflicting on this topic. Some retrospective reviews have reported that older age is associated with an increased risk of chemotherapy-related morbidity and mortality, whereas other studies have shown that despite toxicity and dose reductions, older patients receive a survival benefit with chemotherapy and/or radiotherapy compared with no treatment.[86–93] A review by the Royal Marsden Hospital investigated the survival outcomes of 322 older patients (aged 70 years or older) with SCLC treated with chemotherapy from 1982 to 2003.[94] Patients treated between 1995 and 2003 had a median survival of 43 weeks and a 1-year survival rate of 37%, compared with 25 weeks and 14%, respectively, for patients treated between 1982 and 1994 ($p < 0.001$). Patients who received a platinum combination had significantly better survival ($p < 0.001$) than patients who received single agents or another combination. No survival difference was found between a cisplatin and a carboplatin regimen. In a 2005 analysis of 54 older patients with limited-stage disease who participated in the North Central Cancer Treatment Group phase III trial of cisplatin and etoposide plus twice-daily or once-daily thoracic radiotherapy, survival was not different from that of their younger counterparts despite higher toxicity.[95] These results corroborate the United States Intergroup findings. More data are needed from phase III trials regarding age-specific outcomes.

To formally address the question of dose tolerability among older patients with SCLC, Ardizzoni et al.[96] randomly assigned

patients aged 70 years or older either to four cycles of cisplatin (25 mg/m^2) on days 1–2 with etoposide (60 mg/m^2) IV on days 1–3 every 3 weeks (the attenuated-dose regimen; 28 patients) or to cisplatin (40 mg/m^2) on days 1–2 plus etoposide (100 mg/m^2) IV on days 1–3 with prophylactic G-CSF (the full-dose regimen; 67 patients). Patients treated with the attenuated-dose regimen had a poorer outcome. The response rate was 39% in the attenuated-dose arm and 68% in the full-dose arm, with 1-year survival rates of 18% and 39%, respectively. No grade 3 or grade 4 myelotoxicity was reported in the attenuated-dose group, but 10% was noted in the full-dose group. There was one toxicity-related death in the full-dose arm. The median number of cycles was four in both groups; 75% of patients in the attenuated-dose group and 72% in the full-dose group completed all planned cycles. Japanese investigators conducted a phase III trial to test whether nearly full doses of carboplatin and etoposide were superior to their standard regimen for older patients, which consisted of a split dose of cisplatin and etoposide. Older was defined as an age of 70 years or more with an ECOG performance status of 0 to 2. Patients younger than 70 years of age with a performance status of 3 were also allowed to participate.[97] A total of 220 patients with extensive-stage SCLC were entered in the study, with 110 patients receiving carboplatin (AUC 5) on day 1 and etoposide (80 mg/m^2 IV) on days 1–3 every 3–4 weeks for four cycles, and 109 patients receiving cisplatin (25 mg/m^2) on days 1–3 with etoposide (80 mg/m^2 IV) on days 1–3 every 3–4 weeks for four cycles. G-CSF was recommended in both treatment arms. As many as 92% of the patients met the criteria for older status, and 8% were poor risk. Objective response rates were identical in both treatment arms (73%). The median survival for the carboplatin and etoposide arm was 10.6 months and the 1-year survival rate was 41%, as compared with 9.9 months and 35%, respectively, for the split-dose cisplatin and etoposide arm. The rate of grade 3 or grade 4 neutropenia was high in both arms (95% for the carboplatin and etoposide arm and 90% for the split-dose cisplatin and etoposide arm). A significant difference in the rate of grade 3 or 4 thrombocytopenia was noted (56% for carboplatin and etoposide and 16% for split-dose cisplatin and etoposide; $p = 0.01$). There were four treatment-related deaths, three in the carboplatin and etoposide arm and one in the split-dose cisplatin and etoposide arm. The authors concluded that either regimen was a reasonable treatment option.

The optimal chemotherapy regimen for older patients with SCLC is not known. We have learned that chronologic age

should not be the sole determinant of treatment decisions. Physiologic age determined by comorbidities and performance status provides a clearer framework for guiding treatment decisions. Among patients aged 70 years or older, categories such as fit elderly (performance status of 0 or 1) and frail (performance status of 2–4) are emerging as beneficial terms in both the clinical and research settings. Despite the limited data, we are encouraged that a survival benefit can be achieved in a subset of older patients with acceptable toxicity. As the older population continues to increase, it is crucial that we develop evidence-based treatment plans. Additional clinical research in this population is needed.

FIRST-LINE CHEMOTHERAPY FOR PATIENTS WITH POOR PERFORMANCE STATUS

Performance status is universally recognized as an independent prognostic factor and typically correlates with the extent of tumor burden. Several retrospective studies of large databases have confirmed that shorter survival times among patients with SCLC are associated with poor performance status.[98–100] Despite poor survival, patients with a performance status of 2 have routinely been eligible for clinical trials because our experience has taught us that patients whose poor performance status is attributed to tumor burden can respond to treatment with meaningful symptom palliation, improved performance status, and prolonged survival. However, the number of patients with poor performance status enrolling in clinical trials is low, and outcome data specific to performance status are not available.

Clinical trials specifically including patients with poor performance status are few and were conducted more than 20 years ago. Two trials evaluated the oral formulation of etoposide because it was presumed to be efficacious but less toxic. The first study randomly assigned previously untreated patients with a performance status of 2–4 to either oral etoposide (50 mg twice a day) for 10 days (171 patients) or standard chemotherapy with cisplatin and etoposide or CAV (168 patients).[101] The primary end point was palliation of symptoms at 3 months. The data safety and monitoring board stopped the trial early because of an inferior survival rate with oral etoposide. Survival was 130 days in the oral etoposide arm and 183 days in the standard arm ($p = 0.03$). Palliation rates were similar in both arms (41% vs. 46%, respectively). Grade 2 or greater hematologic toxicity was low in both arms (21% vs. 26%, respectively). The second trial, conducted by the London Lung Cancer Group, enrolled patients younger than 75 years of age with a performance status of 2 or 3 or patients equal to or older than 75 years of age with any performance status to receive 100 mg etoposide orally for 5 days (75 patients) or CAV alternating with cisplatin and etoposide (80 patients).[102] The authors hypothesized that oral etoposide would produce a similar survival rate but with improved quality of life. This study, too, was stopped prematurely because of a significantly inferior survival rate in the oral etoposide arm. The median survival was 4.8 months, with a 1-year survival rate of 9.8% for oral etoposide, compared with 5.9 months and 19.3%, respectively, for CAV/cisplatin and etoposide ($p < 0.05$). Grade 3 and grade 4 toxicities were infrequent and similar between the treatment groups, except that more nausea and vomiting were reported in the CAV/cisplatin and etoposide arm. In another study, the Medical Research Council Lung Cancer Working Party randomly assigned 310 patients with poor performance status either to a four-drug regimen of etoposide, cyclophosphamide, methotrexate, and vincristine (control arm) or to a less intense two-drug regimen of etoposide and vincristine.[103] No differences were found in symptom palliation, response rates, or survival times between the groups; however, more early deaths occurred with the four-drug regimen. Grade 2 or greater hematologic toxicity and mucositis were also worse with the four-drug regimen.

Despite the lack of data, experts generally agree that if a poor performance status is due to the disease itself, patients should be offered standard platinum-based chemotherapy with close monitoring because they have a reasonable chance of symptom palliation and prolonged survival.

SECOND-LINE CHEMOTHERAPY

Despite an initially high response rate to frontline platinum-based chemotherapy, extensive-stage SCLC will universally relapse, often within 3 to 6 months. The precise mechanisms of drug resistance that result in disease progression have not been well defined, but are likely to be multifactorial.[104] Relapse generally heralds a poor outcome. Patients who receive no further therapy have a median survival of less than 3 months.[105] Traditionally, patients who have previously received platinum-based therapy are grouped into two general categories reflecting the platinum-sensitivity status of their disease.[106] These categories include platinum sensitive, referring to relapse 90 days or more after the last dose of platinum; and platinum refractory, referring to relapse within 90 days of the last treatment. A third category, platinum resistant, has sometimes been assigned to patients whose disease progressed during platinum-based therapy; these patients are typically grouped together with the platinum-refractory category. The practice of categorizing disease according to platinum sensitivity arose from seminal observations in a small, single-arm phase II trial of salvage teniposide published in 1988.[107] In that experience involving 50 patients, the response to second-line teniposide appeared to be associated with a previous response to platinum-based therapy and with the length of time between the last line of therapy and the initiation of teniposide. Since then, clinical trials in the second-line setting have routinely stratified patients according to the platinum sensitivity of their disease, resulting in higher sample sizes and increased resource use. More recent data from SWOG among patients treated in a series of phase II trials in the second-line setting and beyond strongly suggest that platinum-sensitivity status may no longer be relevant in the modern era. In a pooled analysis of 329 patients with platinum-treated SCLC enrolled in three SWOG phase II trials, 151 patients had platinum-sensitive disease and 178 had platinum-refractory disease.[108] In this analysis, Cox proportional hazards models adjusted for baseline prognostic factors showed that only an elevated serum lactate dehydrogenase level (HR, 2.04; $p < 0.001$), male gender (HR, 1.36; $p = 0.04$), performance status of 1 (HR, 1.25; $p = 0.02$), and weight loss of at least 5% (HR, 1.53; $p = 0.01$) were independently associated with overall survival. Platinum-sensitivity status was not associated with either progression-free survival (HR, 1.11; $p = 0.49$) or overall survival (HR, 1.25; $p = 0.14$). However, these data must be prospectively validated before clinical use.

As a historic footnote, it is notable that before the establishment of cisplatin and etoposide as the frontline regimen for extensive-stage SCLC, systemic therapy consisted mostly of other multiagent chemotherapy regimens, most commonly CAV. During that era, cisplatin plus etoposide was a typical treatment choice for SCLC that had failed to respond to CAV. In a phase III SWOG trial, 103 patients with disease relapse who were categorized as having good or poor risk were randomly assigned either to cisplatin and etoposide or to a four-drug regimen (carmustine, thiotepa, vincristine, and cyclophosphamide). For good-risk patients, the median survival was 35 weeks with cisplatin and etoposide and 10 weeks with the four-drug regimen. Poor-risk patients in both treatment arms had an unfavorable response rate (9%) and a short median survival (10 to 12 weeks). In addition, CAV had no clear benefit for patients whose disease had failed to respond to cisplatin and etoposide.[16,17,107] Subsequently, several phase III trials of newer approaches have evaluated the role of these systemic therapies in the pretreated setting (Table 52.2).

TABLE 52.2 Phase III Trials of Second-Line Chemotherapy Regimens for Small Cell Lung Cancer

Author (y)	Regimen	No. of Patients	Overall Response Rate (%)	Median Survival	1-Year Survival Rate (%)
von Pawel et al.[109] (1999)	Topotecan CAV	107	24.3	25 wk	14.2
		104	18.3	18.3 wk	14.4
O'Brien et al.[110] (2006)	Topotecan	71	NR	25.5 wk[a]	NR
	Best supportive care	70	7	13.9 wk	NR
Eckardt et al.[111] (2003)	Topotecan (IV)	151	21.9	35 wk	29
	Topotecan (PO)	153	18.3	33 wk	33
Jotte et al.[112] (2011)	Topotecan (IV)	424	31	7.5 mo	28
	Amrubicin	213	17	7.8 mo	25

CAV, cyclophosphamide, doxorubicin, and vincristine; *IV*, intravenous; *NR*, not reported; *PO*, oral.

The topoisomerase-1 inhibitor topotecan became available in the late 1990s and was found in early phase trials to have efficacy in previously treated SCLC. In a small phase III trial of 211 patients who had disease relapse more than 60 days after completion of induction therapy, topotecan (1.5 mg/m^2/day on days 1–5 every 21 days) was found to be comparable in efficacy with conventional CAV.[113] This trial had a primary end point of objective response, with a secondary end point of overall survival. At the final analysis, the overall response rates and median survival were not significantly different between the treatment arms (24.3% vs. 18.3% and 25 weeks vs. 24.7 weeks, respectively). In other words, topotecan failed to demonstrate a clear efficacy advantage over CAV. However, symptoms such as dyspnea, fatigue, anorexia, and hoarseness appeared to have been significantly improved with topotecan, despite a higher rate of grade 3 or grade 4 anemia and thrombocytopenia in that arm. The United States Food and Drug Administration (FDA) approved topotecan as second-line treatment for patients with platinum-sensitive, relapsed disease based on symptom control. An oral formulation of topotecan was later developed for patients' convenience. To evaluate the efficacy of this formulation, 141 patients with disease relapse were randomly assigned to receive either oral topotecan (2.3 mg/m^2/day for 5 days) plus best supportive care or best supportive care alone every 21 days.[109] Oral topotecan was superior to best supportive care, with a median survival time of 25.9 weeks, compared with 13.9 weeks for best supportive care ($p = 0.01$). A survival advantage was recognized in patients who had disease relapse both less than 60 days and more than 60 days from the end of their previous therapy. The most common toxicities with oral topotecan were hematologic events. Grade 3 and grade 4 neutropenia occurred in 61%, thrombocytopenia in 38%, and anemia in 25% of patients. Subsequently, oral topotecan was compared with IV topotecan in patients with platinum-sensitive disease that relapsed more than 90 days after chemotherapy.[110] One hundred and fifty-three patients received oral topotecan (2.3 mg/m^2/day on days 1–5 every 21 days), and 151 patients received standard doses of IV topotecan (1.5 mg/m^2/day on days 1–5 every 21 days). The response rate, median survival, and 1-year survival for the oral agent were 18.3%, 33 weeks, and 33%, respectively, compared with 21.9%, 35 weeks, and 29%, respectively, for IV administration. The incidence of grade 4 neutropenia was 47% with oral topotecan and 64% with the IV formulation. Quality of life appeared comparable between the arms. The FDA subsequently approved oral topotecan for the treatment of both sensitive and resistant/refractory SCLC.

The early years of the 21st century saw a renewed interest in the role of anthracyclines in relapsed SCLC. Specifically, amrubicin was developed principally in Japan, and this agent is currently approved for commercial use in Japan for treating SCLC. Two phase II Japanese trials were initially completed. One trial enrolled 60 patients with relapsed SCLC, 16 of whom had relapse within 60 days of platinum-based therapy (refractory)

and 44 who had relapse after 60 days (sensitive). Patients received amrubicin (40 mg/m^2) for 3 days every 3 weeks.[112] A median of four cycles were delivered. Overall response rates were 50% (95% CI, 25% to 75%) and 52% (95% CI, 37% to 58%) for the refractory and sensitive cohorts, respectively. Overall median survival was 10.3 months and 11.6 months in the refractory and sensitive groups, respectively. Amrubicin resulted in high rates of myelotoxicity, with grade 3 or grade 4 neutropenia occurring in 83%. However, the rate of febrile neutropenia was only 5%, and no toxicity-related deaths were reported. In another phase II trial, 34 Japanese patients with relapsed SCLC (10 refractory, 24 sensitive) received amrubicin (45 mg/m^2) for 3 days every 3 weeks.[114] A median of four cycles were administered. Response rates were 60% (95% CI, 23% to 97%) for patients with refractory disease and 53% (95% CI, 35% to 70%) for patients with sensitive disease. The median survival was 6.8 months for patients with refractory disease and 10.4 months for patients with sensitive disease. Again, rates of myelosuppression were high, with grade 3 or grade 4 neutropenia reported for more than 70% of patients. At the higher amrubicin dose, however, the rate of febrile neutropenia was 35%, with one toxicity-related death from pneumonia.

In a randomized phase II trial from Japan, 60 patients were assigned to receive either amrubicin (40 mg/m^2 on days 1–3) or topotecan (1 mg/m^2 IV on days 1–5) every 3 weeks.[115] Overall response rates were 38% (95% CI, 20% to 56%) for amrubicin and 13% (95% CI, 1% to 25%) for topotecan. Among patients with so-called sensitive relapse, the response rates were 53% and 21% for the amrubicin and topotecan arms, respectively. Among patients with so-called refractory relapse, 17% responded to amrubicin compared with 0% for topotecan. The median progression-free survival was 3.5 months for patients in the amrubicin arm and 2.2 months for patients in the topotecan arm.

In the United States, a randomized phase II study was performed to evaluate the response rate of amrubicin compared with topotecan in patients with so-called sensitive-relapse disease.[116] Seventy-six patients were randomly assigned in a 2:1 fashion to receive the same dose of amrubicin (50 patients) or topotecan (26 patients) at 1.5 mg/m^2 IV on days 1–5 every 3 weeks. Treatment with amrubicin was associated with a higher response rate (44% vs. 15%; $p = 0.021$). The median progression-free survival and overall survival were 4.5 months and 9.2 months, respectively, with amrubicin, and 3.3 months and 7.6 months, respectively, with topotecan. Grade 3 or higher neutropenia and thrombocytopenia appeared to be more frequent in the topotecan group (78% and 61% vs. 61% and 39%, respectively). No evidence of anthracycline-induced cardiotoxicity was reported. In a phase II North American trial of amrubicin in patients with refractory or resistant disease progressing within 90 days,[117] 75 patients received amrubicin at 40 mg/m^2 on days 1–3 every 3 weeks. An overall response rate of 21.3% was reported, with an acceptable safety profile. Notably, no patient had early cardiotoxicity.

Lastly, a large global phase III trial was conducted to compare amrubicin and topotecan.[118] In this study, 637 patients were randomly assigned 2:1 to receive either amrubicin (40 mg/m^2 IV) on days 1–3 (424 patients) or topotecan (1.5 mg/m^2 IV) on days 1–5 (213 patients). The primary end point was overall survival. Patients with refractory relapse represented approximately 45% of the group. Grade 3 or higher adverse events (all $p < 0.05$) in the respective amrubicin and topotecan groups included neutropenia (41% vs. 53%), thrombocytopenia (21% vs. 54%), anemia (16% vs. 30%), infections (16% vs. 10%), and febrile neutropenia (10% vs. 4%). Transfusion rates were 32% in the amrubicin arm and 53% in the topotecan arm ($p < 0.01$). Despite a higher response rate in the amrubicin arm (31% vs. 17%; $p = 0.0002$), no difference was found in overall survival (HR, 0.88; $p = 0.17$). The median survival was 7.5 months and 7.8 months for the amrubicin and topotecan arms, respectively. This pivotal trial thus failed to show a survival benefit for amrubicin, precluding its commercial approval outside of Japan.

Using the same regimen as that in the frontline setting as salvage therapy can also be an option for selected patients. Two small case series totaling 18 patients have reported outcomes on 10 patients who had disease relapse more than 10 months after the end of previous therapy. In this database, durable responses were seen after treatment with the original regimen.[119,120] Thus considering salvage treatment with the original regimen is reasonable, particularly for patients with a long relapse-free interval.

Other agents commonly used in the salvage setting (second line and beyond), often as single agents, are taxanes (docetaxel and paclitaxel), gemcitabine, vinorelbine, ifosfamide, and other topoisomerase inhibitors (irinotecan and oral etoposide).[121] In general, clinical trials of these chemotherapeutic agents have yielded modest clinical benefits in this pretreated population, with response rates ranging from 10% to 20% and median survival of 2 months to 5 months. As expected, rates of response to subsequent therapies tend to be lower for patients with platinum-refractory disease, whereas the likelihood of response is better for patients with platinum-sensitive disease.

In summary, the topoisomerase inhibitor topotecan (whether delivered IV or orally) represents a reasonable standard of care for patients with relapsed SCLC. In Japan, amrubicin is also approved for SCLC therapy. However, efficacy for either of these agents is fairly modest and must be weighed against their known toxicities, particularly myelosuppression. Given the generally poor outcome of patients with relapsed or refractory SCLC, participation in clinical trials with novel approaches represents the principal standard of care.

NEW DRUGS

Improvements in clinical outcome after treatment of patients with extensive-stage SCLC will necessitate more effective systemic treatments. Drug development for extensive-stage SCLC has, however, been slow during the past 20 years. In contrast to treatments for nonsmall cell lung cancer, neither cytotoxic agents with novel mechanisms of action nor targeted agents have entered the clinical arena for SCLC.

Cytotoxic agents that have generated some interest in the past decade include belotecan, a novel camptothecin analog, and picoplatin, a platinum analog. Belotecan has been studied in patients with both untreated and pretreated extensive-stage SCLC. In untreated patients, a single-arm phase II study showed an overall response rate of 54%, a 4.6-month time to progression, and a 10.4-month median overall survival. As with other topoisomerase I inhibitors, myelosuppression was the main toxic effect, with grade 3 or grade 4 neutropenia occurring in more than 70% of patients.[122] Subsequently, the combination of belotecan and cisplatin was investigated in two phase II studies, which found an overall response rate of greater than 70% and a median overall survival of more than 10 months.[123,124] At the time of publication, this doublet was undergoing phase III testing in untreated patients. In pretreated patients, the efficacy of belotecan seems to be no different from that of currently available topoisomerase I inhibitors. Three phase II studies demonstrated an overall response rate ranging from 14% to 24%, a median progression-free survival of 1.6 months to 3.7 months, and a median overall survival of 4.0 months to 13.9 months.[125–127] Of note, all three studies were performed in Asian populations, in whom this class of drugs seems to have more efficacy in SCLC. Taken together, the results obtained with belotecan suggest that this drug will not constitute a major step forward in the treatment of SCLC.

In vitro studies identified picoplatin (ZD0473) as a platinum analog capable of circumventing resistance to both cisplatin and carboplatin. After single-agent phase II studies in which no compelling results were obtained, a randomized phase III study was launched in which 401 patients with SCLC relapse (within 6 months of completing first-line therapy) were randomly assigned in a 2:1 fashion compared with best supportive care. No difference was found in overall survival between the treatment arms.[128]

Despite progress in our understanding of genomic alterations and signaling pathways in SCLC,[129–132] clinical experiments with tyrosine kinase inhibitors, other small-molecule inhibitors, and antiangiogenic agents have been disappointing (Table 52.3). Other therapeutic areas of interest more recently evaluated include epigenetic modifiers and inhibitors of DNA repair and the cell cycle. In a phase II study, romidepsin (a histone deacetylase inhibitor) did not show a meaningful benefit in relapsed extensive-stage disease SCLC (ED-SCLC).[133] Another phase II study of the histone deacetylase inhibitor panobinostat was stopped prematurely as patients did not meet Response Evaluation Criteria in Solid Tumors criteria for partial response.[134] Veliparib, a poly(ADP-ribose) polymerase inhibitor implicated in the DNA damage repair pathway, was recently studied in a small phase I dose-escalation study in combination with cisplatin and etoposide in newly diagnosed ED-SCLC.[135] Of the seven evaluable patients, 14.3% had a complete response, 57.1% had a partial response, and 28.6% had stable disease. As such, veliparib continues to be under investigation, including in one study of the combination of temozolomide, another DNA damaging agent, and veliparib. Inhibition of aurora A kinase, which regulates cell cycle transit from G_2 to cytokinesis, has shown promising preclinical activity and thus a phase I/II trial of alisertib was conducted in a variety of tumor types.[136] One arm enrolled 60 patients with relapsed or refractory SCLC; objective partial responses of 21% (95% CI, 10% to 35%) were seen in this trial. A follow-up phase II trial combining alisertib with paclitaxel in patients with platinum-refractory ED-SCLC has completed accrual.

Investigators hope that novel immune-modulating agents may alter the therapeutic landscape of SCLC. Mounting evidence suggests that these agents may work in concert with classic cytotoxic chemotherapy and, more importantly, with radiotherapy. Although phase III trials examining the role of tumor vaccines, mainly performed in the maintenance setting of responding patients, have been uniformly negative, results of early studies with immune checkpoint modulators have been encouraging.

Ipilimumab, a monoclonal antibody that blocks cytotoxic T-lymphocyte antigen-4, has been studied in a randomized phase II study including 130 patients with extensive-stage SCLC not previously treated with chemotherapy.[156] A total of 135 patients were treated with carboplatin and paclitaxel or the same regimen plus two schedules of ipilimumab. Although no differences were found in progression-free survival or overall survival, the so-called phased schedule of ipilimumab (i.e., administered after two courses of carboplatin and paclitaxel without ipilimumab) resulted in a higher immune-related progression-free survival and numerically increased overall survival (12.9 vs. 9.9 months). Concurrent ipilimumab and carboplatin and paclitaxel provided no benefit even

TABLE 52.3 Selected Targets and Agents Studied for Small Cell Lung Cancer

Target	Agent	Phase	Result	Comment
VEGF-A	Bevacizumab[137]	III	Negative	In combination with cisplatin + etoposide Statistically significant improvement in PFS but not OS
VEGFR-I–III	Cediranib[138]	II	Negative	
VEGFR, PDGFR, Raf-1	Sorafenib[139], thalidomide[140]	II, III	Negative

in numerical terms for progression-free survival or survival. Near doubling of the incidence of grade 3 or grade 4 adverse events was observed when ipilimumab-containing regimens were compared with standard chemotherapy. These findings prompted a phase III clinical trial evaluating the combination with standard platinum and etoposide.[157] In total, 1132 patients with newly diagnosed ED-SCLC were enrolled to randomized, blinded arms, with one arm treated with etoposide and platinum with placebo, and the other arm with etoposide and platinum and ipilimumab. As in the phase II study, ipilimumab or placebo was administered in a phased schedule. Unfortunately, the trial demonstrated no difference in median progression-free survival or overall survival between the arms. Patients treated with the combination of platinum, etoposide, and ipilimumab were found again to have a higher incidence of treatment-related diarrhea, colitis, and rash and more treatment-related deaths. Thus the combination of standard chemotherapy with ipilimumab did not result in improved efficacy in ED-SCLC but did result in added toxicity.

Ipilimumab was also recently studied in combination with a programmed cell death protein 1 (PD1) inhibiting antibody, nivolumab, in the CheckMate 032 trial. This phase I/II trial enrolled patients with limited and extensive-stage SCLC who had progressed after platinum-based chemotherapy.[158] Of the 216 patients enrolled, 98 were treated with nivolumab (3 mg/kg IV) every 2 weeks, with the remainder of patients enrolled into initial treatment with nivolumab (1 mg/kg IV) and ipilimumab (1 mg/kg IV) every 3 weeks. Patients who received the latter regimen could then undergo dose escalation such that 61 patients received nivolumab (1 mg/kg) and ipilimumab (3 mg/kg IV) every 3 weeks, and 54 received nivolumab (3 mg/kg) and ipilimumab (1 mg/kg) every 3 weeks, whereas three patients remained at the initial dose. All arms showed potential benefit, though treatment with nivolumab alone resulted in a modest 10% objective response rate. Although the study was not designed to detect efficacy differences between arms, the combination of nivolumab and ipilimumab did result in higher objective response rates (23% for nivolumab [1 mg/kg] + ipilimumab [3 mg/kg] and 19% for nivolumab [3 mg/kg] + ipilimumab [1 mg/kg], respectively).

However, patients treated with the combination discontinued therapy due to treatment-related adverse effects, and there were more grade 3 and grade 4 adverse effects with combination treatment, most commonly lipase elevation and diarrhea.

In addition to the aforementioned data with nivolumab, PD1 inhibition in ED-SCLC was also investigated in the KEYNOTE-028 trial.[159] This phase Ib trial has screened a cohort of 135 patients with ED-SCLC who had progressed on platinum-based chemotherapy, with 27% of patients subsequently testing positive for greater or equal to 1% PD1 ligand expression. Ultimately, 17 patients with ED-SCLC were treated with pembrolizumab (10 mg/kg IV) every 2 weeks. Of these patients, 25% had a partial response to treatment, with durable responses at greater than 16 weeks. There was also a high rate of drug-related adverse events; although there was only one patient with a greater than or equal to grade 3 drug-related adverse event, 53% of drug-related adverse events were reported. As of this publication, final results of this trial have not been reported. As such, while immune checkpoint inhibition remains of interest, to date modest efficacy findings have been tempered by significant toxicity.

A new target, DLL3, part of the Notch signaling pathway, has been identified due to its high expression in SCLC cells. DLL3 is thought to play a key role in the function and survival of tumor-initiating cells. An antibody–drug conjugate, rovalpituzumab tesirine, has been designed to bind DLL3. In a phase Ia/Ib trial, patients with SCLC who had progressed after first- or second-line therapy were treated with rovalpituzumab tesirine.[160] Although the trial was small and reported a modest partial response of 34% with 31% of patients achieving disease stability, duration of response was more than 178 days with no cases of disease progression. Moreover, although DLL3 status was not required for treatment, patients did require sufficient tumor sample for testing. About 67% of patients had tumor DLL3 expression greater than or equal to 50%; these patients tended to have better responses and an overall survival of 5.8 months. It is hoped that this novel targeted agent will demonstrate efficacy upon further investigation, and a phase II study is currently underway.

CONCLUSION

The optimal first-line treatment for good performance score ED-SCLC, regardless of age, is a platinum doublet with either etoposide or irinotecan. Although poor performance status (ECOG PS 2–4) patients are less able to tolerate platinum doublets, because the disease itself attributes most to the deterioration of performance status, a platinum-based regimen at standard doses should be offered with close monitoring. For second-line treatment, the standard of care consists of the topoisomerase I inhibitor topotecan, and in Japan, damrubicin. Because the therapeutic results of second-line treatments remain poor, enrollment of relapsed ED-SCLC in clinical trials with novel agents is also an acceptable standard of care. No new agents with clinically relevant activity have been identified during the last two decades in ED-SCLC, underscoring the unmet need in this area.

53 Malignant Mesothelioma

Paul Baas, Raffit Hassan, Anna K. Nowak, and David Rice

SUMMARY OF KEY POINTS

- Development of malignant mesothelioma is usually associated with asbestos exposure.
- The most common genetic alterations in mesothelioma are deletion of *CDKN2A/ARF*, inactivation of *NF2*, and mutation or deletion in *BAP1*.
- The eighth edition of the American Joint Commission on Cancer/Union for International Cancer Control staging manual has altered the T and N components for staging from the previous edition.
- Clinical, imaging, and serum biomarkers can contribute to prognostication in pleural mesothelioma.
- First-line palliative chemotherapy is cisplatin (or carboplatin) with pemetrexed; appropriate patients may benefit from the addition of bevacizumab.
- There is no standard second-line chemotherapy for pleural mesothelioma although reintroduction of a pemetrexed-containing regimen, or the use of vinorelbine or gemcitabine, would be considered reasonable.
- Optimal surgical management of malignant pleural mesothelioma remains controversial.
- Immunotherapies including mesothelin-targeted agents and immune checkpoint inhibitors have shown promising efficacy in mesothelioma but further research is required before these are adopted as standard therapy.

All mesothelioma tumors originate from the lining of the pleural cavity, the lung, the pericardium, and the abdominal cavity, including the tunica vaginalis. After transformation of the mesothelium or peritoneum, subtypes of mesothelioma can develop. Malignant mesothelioma (MM) occurs most frequently on one side of the thorax (Malignant Pleural Mesothelioma [MPM]—80%) with the remainder occurring in the abdomen as malignant peritoneal mesothelioma. Although the World Health Organization classification distinguishes three main histologic subtypes of mesothelioma, epithelioid (60%), sarcomatoid (10% to 15%), and biphasic (25% to 30%), there are different subtypes of the epithelioid histology. These subtypes include the papillary, pleomorphic, tubulopapillary, and small cell type. However, these subtypes are not standardly reported.[1]

The main cause of MPM is the exposure to asbestos fibers, which was first described by Wagner et al.[2] Other causes of mesothelioma are endemic erionite exposure in Turkey, ionizing radiation, and chronic inflammation in the pleura.[3,4] Unlike the case with lung cancer, cigarette smoking does not play a role in the development of MPM. MPM is one of the best-known occupational diseases and it is more likely to develop in men than in women (90% vs. 10%), primarily as a result of its association with mining and processing of asbestos fibers. Given the long latency period of 30 to 50 years, the prevalence of mesothelioma is expected to peak for the next decade. Regulations against handling and mining asbestos in Western Europe and the United States were put in place in the 1990s. It is expected that the disease will be increasingly encountered in third-world countries because of the lack of legislation and increased export to these countries.

BIOLOGY OF MALIGNANT PLEURAL MESOTHELIOMA

Considerable progress has been made in understanding the molecular basis of mesothelioma, which has, in turn, led to an abundance of preclinical studies translating these discoveries to treatment.

Some people with mesothelioma have no history of asbestos exposure or prior radiotherapy.[4] In the case of peritoneal mesothelioma, many patients are teenagers or young adults. Good evidence now exists that at least in some people there may be a genetic basis for developing mesothelioma, which could lead to mesothelioma by itself or cause some individuals to be susceptible to asbestos carcinogenesis. Cyclin-dependent kinase inhibitor 2A/alternative reading frame (*CDKN2A/ARF*), neurofibromatosis type 2 (*NF2*), and BRCA1-associated protein 1 (*BAP1*) are the most frequently mutated tumor suppressor genes in mesothelioma.[5]

Cyclin-Dependent Kinase Inhibitor 2A/Alternative Reading Frame

CDKN2A/ARF is the most frequently inactivated tumor suppressor gene in malignant mesothelioma and encodes two important cell cycle regulatory proteins, p16 (*INK4A*) and, in an alternative reading frame, p14 (*ARF*).[6] p16, a cyclin-dependent kinase (CDK) inhibitor, blocks phosphorylation of retinoblastoma protein, and p14 (*ARF*) blocks murine double minute 2 (*MDM2*), thus resulting in a positive regulation of p53. Homozygous deletion of *CDKN2A/ARF* thus results in inactivation of two major tumor suppressing pathways, retinoblastoma protein and p53.[5]

CDKN2A deletion is found in about 70% of primary tumors and nearly all mesothelioma cell lines.[7]

Neurofibromatosis Type 2

The *NF2* gene encodes a tumor suppressor protein Merlin, a member of the band 4.1 family of cytoskeletal linker proteins. Inactivating *NF2* mutations are found in 35% to 40% of MPMs.[8] The mechanisms of Merlin-mediated tumor suppression are not well defined. Merlin mediates contact-dependent inhibition of cell proliferation in normal cells, primarily through inhibition of mammalian target of rapamycin (mTOR) in an AKT-independent manner. mTOR activity is aberrantly upregulated in the absence of Merlin, leading to increased cell proliferation.[5,9]

BAP1

Up to 60% of mesotheliomas have *BAP1* alterations, which include, among others, homozygous deletions of partial or entire *BAP1* and sequence-level mutations.[10] *BAP1* is located

on chromosome 3p21.1, which is also deleted in several human malignancies.[11] Germline *BAP1* mutations were described in 2011 in mesothelioma families in which *BAP1* mutation carriers had an exceptionally high incidence of malignancies, including mesothelioma and uveal melanoma.[12] These malignancies did not develop in family members who did not carry germline *BAP1* mutations. *BAP1* is a nuclear protein that enhances BRCA1-mediated inhibition of breast cancer cell proliferation, acting as a tumor suppressor in the BRCA1 growth control pathway and regulating proliferation by deubiquitinating host cell factor.[1] *BAP1* influences a wide array of cellular functions, and its depletion induces significant changes in the expression of many genes that control various cellular pathways.[4,9]

DIAGNOSIS

Diagnosis of mesothelioma may be achieved by cytologic analysis of pleural effusions sampled by thoracentesis, blind pleural biopsy, computed tomography (CT)-directed fine-needle aspiration or core biopsy, and, increasingly more commonly, via pleuroscopy. However, in a considerable number of cases, evaluations of specimens obtained by these less invasive modalities are inconclusive, necessitating surgical biopsy. Video-assisted thoracoscopic surgery (VATS) is the preferred method for surgical diagnosis of MPM (Fig. 53.1). VATS allows large tissue samples to be obtained from multiple areas of the thoracic cavity, an important consideration, given the considerable tumor heterogeneity within individual mesothelioma tumors. Multiple separate biopsies by VATS increases the likelihood of accurately determining histologic subtype.[13] VATS can also be used to identify whether the tumor involves the visceral pleura as well as the parietal pleura, although this distinction is no longer required for staging with the updated American Joint Commission on Cancer (AJCC)/Union for International Cancer Control (UICC) eighth edition guidelines. VATS is otherwise of limited use for assessment of tumor or node stage. Although VATS is most easily performed in patients with a large effusive component, occasionally tumor burden is such that VATS is impossible due to fusion of the visceral and parietal pleurae and, in such instances, a small, 2-cm cutdown can usually allow access to the underlying pleural tumor under direct vision. A further merit of VATS is that it allows talc pleurodesis to be done at the time of tissue diagnosis, which often obviates the need for additional palliative procedures. Pleurodesis does not influence the ability to perform subsequent cytoreductive surgery (pleurectomy/decortication [PD] or extrapleural pneumonectomy [EPP]). Talc will cause fluorodeoxyglucose (FDG) activity in the pleural distribution and in mediastinal lymph nodes on positron emission tomography (PET) imaging. For this reason, initial staging with PET should be performed before talc pleurodesis.

Thoracotomy is to be avoided as a diagnostic method as it not only causes the patient unnecessary trauma but also hampers the performance of subsequent cytoreductive surgery due to disruption of tissue planes and risks iatrogenic tumor invasion of the chest wall.

STAGING

The AJCC/International Mesothelioma Interest Group staging system is based primarily on pathologic data and is, therefore, of limited use when applied to clinical staging of this disease.[14] Many of the factors that contribute to stage assignment, such as involvement of the pericardium, lung, and diaphragm; involvement of the endothoracic fascia; and lymph node metastases, for example, simply are not possible to determine accurately with current imaging technology. The staging system has recently undergone revision based on an international multicenter prospective data collection of detailed staging information and
Fig. 53.1. (A) Computed tomography (CT) image of a male patient with a pleural effusion and minimal pleural thickening. (B) Image from video-assisted thorascopic surgery shows multiple nodules on chest wall at the level of the CT image. (B) The lung is partly collapsed and shows no involvement.

component descriptors (Table 53.1).[14a] The revision for the eighth edition AJCC/UICC staging system has made a number of important changes, including collapsing T1a and T1b into T1 and revising nodal staging such that any ipsilateral mediastinal involved lymph nodes are all included as N1 disease, whereas nodes previously categorized as N3 and reclassified as N2. PET is useful for identifying occult distant metastatic disease (present in up to 25% of cases), but it is inaccurate for determining T and N stage.[14b,14c,15]

Laparoscopy and Thoracoscopy

Extension of the tumor through the diaphragm into the peritoneal cavity or dissemination to the contralateral side can occur, which will influence the staging and treatment options. Rice et al.[16] reported on 109 patients who had routine laparoscopy before planned EPP and found nine (8.3%) patients with transdiaphragmatic extension of tumor and one (0.9%) with diffuse peritoneal carcinomatosis. Alvarez et al.[17] performed thoracoscopic examination of the contralateral side and found contralateral chest involvement in three (10%) of 30 patients from a selected group.

TABLE 53.1 IASLC Mesothelioma Staging Project: TNM Definitions*

Stage	Definition
Primary Tumor (T)	
TX	Primary tumor cannot be assessed
TO	No evidence of primary tumor
T1	Tumor imited to the ipsilateral parietal± visceral ± mediastinal± diaphragmatic pleura
T2	Tumorinvolving each of theipsi ateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features: • involvement of diaphragmatic muscle • extension of tumor from visceral pleura into the underlying pulmonary parenchyma
T3	Describeslocally advanced but *potentially* resectable tumor. Tumor involving all of theipsilaterat pleuralsurfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features : • involvement of the endothoracic fascia • extension into the mediastinal fat • solitary, completely resectabte focus of tumor extendinginto the soft tissues of the chest wall • nontransmurat involvement of the pericardium
T4	Describes locally advanced *technically* unresectable tumor. Tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features: • diffuse extension or multifocal masses of tumor in the chest wall, with or without associated rib destruction • direct transdiaphragmatic extension of tumor to the peritoneum • direct extension of tumor to the contralaterat pleura • direct extension of tumor to mediastinal organs • direct extension of tumor into the spine • tumor extending through to the internal surface of the pericardium with or without a pericardial effusion, or tumor involving the myocardium
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
NO	No regional lymph node metastases
N1	Metastases in the ipsilateral bronchoputmonary, hilar, or mediastinal (including the internal mammary, peridiaphragmatic, pericardial fat pad, or intercostal lymph nodes) lymph nodes
N2	Metastases in the contralateral mediastinal, ipsilaterat, or contralateral supraclavicutar lymph nodes
Distant Metastasis (M)	
MO	No distant metastasis
MI	Distant metastasis present

Mediastinal Evaluation

Lymph node metastases occur in approximately 50% of patients with MPM undergoing multimodality therapy and portends a poor prognosis. Current imaging modalities are inaccurate for defining N stage, and, therefore, cervical mediastinoscopy has been advocated for pretreatment staging of MPM.[18] The sensitivity, specificity, and accuracy for cervical mediastinoscopy have been reported by two groups and vary from 60% to 80%, 71% to 100%, and 67% to 93%, respectively.[19,20]

Endobronchial ultrasound (EBUS)- and endoscopic ultrasound (EUS)-guided fine-needle aspiration of mediastinal lymph nodes have been highly effective for staging nonsmall cell lung cancer. Rice et al.[21] compared 50 consecutive patients with mesothelioma who had staging cervical mediastinoscopy with 38 patients who had staging EBUS. Sensitivity and negative-predictive value were 28% and 49%, respectively, for cervical mediastinoscopy, and 59% and 57%, respectively, for EBUS. Furthermore, 11 patients had EUS preoperatively, and metastases were found in the infradiaphragmatic nodes in five patients.

Tournoy et al.[22] performed EUS and fine-needle aspiration in 32 patients with presumed early-stage mesothelioma and identified N2 metastases in four patients (12.5%). In 17 patients who subsequently had extrapleural pneumonectomy, one false-negative result (4.7%) was found. Some centers now prefer to stage the mediastinum by combined EBUC and EUS before entering a patient into a multimodality trial.

BIOMARKERS

Biomarkers have the potential to play a key role in current oncology practice. They can be used in diagnosis (screening), measurement of response, and follow-up. The requisites that apply for biomarkers are technical reproducibility, validation, and clinical relevance. Diagnostic biomarkers can underpin screening programs and early detection in high-risk individuals, can help to direct diagnostic procedures, and can provide support for cytologic or histologic diagnoses. Biomarkers can be predictive for a response or can be prognostic. Predictive biomarkers can assist with treatment selection, in particular drug

therapy. Biomarkers of response can accelerate drug development through surrogate end point and provide guidance during routine patient care. Prognostic biomarkers can give patients and clinicians valuable information, in addition to their use as stratification factors in clinical trials. Biomarkers can involve blood measurements (plasma or serum) or molecular genetics or can be based on imaging.

Diagnostic Biomarkers

The development of robust diagnostic serum biomarkers for mesothelioma is important, as exposure to the etiologic agent is often known. A population with heavy asbestos exposure would be rational participants in a screening program. The availability of a blood-based biomarker would facilitate early detection and treatment. The most important candidate diagnostic serum biomarkers are mesothelin (serum mesothelin-related protein), osteopontin, and fibulin-3. Elevated levels of mesothelin are highly specific, unless patients have concurrent renal failure, and add to the diagnostic certainty or direct additional investigations when a diagnosis of mesothelioma is suspected.[23,24] However, mesothelin lacks sensitivity at the time of diagnosis, thus limiting its use in screening.[25,26] Osteopontin does not perform as well as mesothelin.[27] In 2012, Pass et al.[28] reported on fibulin-3 as a blood and effusion biomarker. Plasma levels of fibulin-3 were significantly higher for patients with mesothelioma than in people exposed to asbestos without mesothelioma, with a sensitivity of 100% and specificity of 94% reported. Effusion levels of fibulin-3 were also significantly higher in effusions from mesothelioma than from other etiologies; nevertheless, these findings should be further validated before translation to practice. Carcinoembryogenic antigen is a well-known marker that will not be elevated in case of a MPM. It can be used for quick screening for other tumor types with pleural dissemination.

Prognostic Biomarkers

A number of simple prognostic biomarkers have been well established in the literature for MPM. At pathologic diagnosis, a diagnosis of sarcomatoid or nonepithelioid subtypes of mesothelioma is uniformly associated with poor prognosis.[29,30] The same large retrospective series, mostly based on collections of clinical trial data, has also validated readily available laboratory parameters, including low hemoglobin, thrombocytosis, high white blood cell count, and elevated serum lactate dehydrogenase level as poor prognostic indicators.[31] In 2010, Kao et al.[32] proposed and independently validated an elevated neutrophil-to-lymphocyte ratio as a poor prognostic indicator; however, the patient groups used were heterogeneous and relatively small, and others have been unable to confirm these findings. High serum vascular endothelial growth factor (VEGF) levels have been found to correlate with poor prognosis and advanced stage of disease.[33] A recent publication used a Classification and Regression Tree analysis to group patients into prognostic categories at diagnosis, deriving four prognostic groupings with median survivals ranging from 7.5 months (risk group 4) to 34 months (risk group 1) using readily available clinical indicators including weight loss, hemoglobin level, performance status, histology, and albumin level.[34]

Considering prognostic serum biomarkers more specific to mesothelioma, mesothelin levels at diagnosis may also be prognostic;[34] however, mesothelin levels appear to reflect tumor bulk, as the addition of tumor bulk metrics to the model eliminates the significance of serum mesothelin.[35] No strong evidence exists that serum osteopontin is useful in prognostication, although lower tissue expression of osteopontin may be associated with longer survival and plasma osteopontin as well as mesothelin were found to increase prognostic accuracy in combination with the EORTC and CALGB mesothleioma prognostic indices.[36]

Many candidate tumor molecular and histologic prognostic markers have been reported (phosphatase and tensin homolog, VEGF expression, fibroblast growth factor 2, cyclooxygenase-2, platelet-derived growth factor, epidermal growth factor receptor, epithelial-to-mesenchymal transition, osteopontin, and c-MET expression); however, at the time of publication, none has been sufficiently validated to be entered into routine clinical use worldwide. The anticipation is that the extensive molecular profiling and characterization efforts proceeding worldwide will identify new molecular prognostic biomarkers that will translate to routine clinical practice in addition to providing potential molecular targets for therapy.

Prognostic Imaging Biomarkers

In addition to providing anatomic staging information regarding the sites of disease involvement, a substantial body of evidence indicates that the bulk of tumor as demonstrated on imaging and metabolic characteristics of tumor may be prognostic biomarkers. Tumor volume as measured by CT is a prognostic indicator, but it can be challenging to implement automated volumetric measurements due to the difficulty of distinguishing tumor from pleural fluid and atelectasis.[37,38] Quantitative parameters from FDG-PET may be simpler to implement reproducibly and with less manual input. FDG-PET has consistently shown prognostic value in MPM, although the appropriate metric for quantitative assessment remains the subject of debate. A higher maximum standardized uptake value (SUV) is a poor prognostic indicator.[39] However, the inclusion of volumetric parameters may also be important, with the concepts of total lesion glycolysis or total glycolytic volume incorporating both SUV and a measure of lesion volume and performing better than SUV alone in studies incorporating both measures.[40,41]

CHEMOTHERAPY

First-Line Chemotherapy

Combination cytotoxic chemotherapy remains the mainstay of palliative treatment of patients with MPM, with cisplatin and an antifolate being the most widely used and evidence-based first-line doublet. The authors of two studies reported that the combination of cisplatin and an antifolate produced a survival benefit over cisplatin alone, with a hazard ratio for overall survival of 0.77 and a median survival gain of 3 months.[42,43] Cisplatin and pemetrexed have become the standard of care and the backbone on which subsequent clinical trials in mesothelioma have been constructed.

The combination of cisplatin and either pemetrexed or raltitrexed was associated with better quality of life and symptom control than cisplatin alone, with improvements in pain, dyspnea, fatigue, and cough, as well as global quality of life.[42] The combination of cisplatin and raltitrexed improved dyspnea to a clinically meaningful extent compared with cisplatin alone, although other parameters remained stable.[43] However, selection of patients who are fit for treatment is important, as is supportive care and careful oversight of potential toxicities. Treatment with cisplatin and pemetrexed should be accompanied by supplementary folate and vitamin B12 starting 1 to 2 weeks before the first day of chemotherapy.

Recently, the addition of bevacizumab to cisplatin and pemetrexed has demonstrated further benefits in progression-free and overall survival. Bevacizumab was used in combination with cisplatin and pemetrexed, and with subsequent single agent bevacizumab continuing until disease progression after completion of up to 6 cycles of the combination therapy. This addition gave a hazard ratio for overall survival of 0.7, increasing the median survival from 16.1 to 18.8 months, with manageable toxicities.

The high cost of bevacizumab and modest benefits, as well as the lack of any predictive biomarker, has delayed widespread uptake into international routine clinical practice. However in selected patients without contraindications to anti-VEGF therapy this is an appropriate addition to standard chemotherapy.[44]

Response to first-line chemotherapy should be assessed with serial CT performed at baseline and then after every two or three cycles. FDG-PET to monitor response is not standard, but can supplement information from CT and may provide an indication of response or progression at an earlier time point than CT. Although changes in serum mesothelin levels may parallel tumor volume, the test has not been sufficiently validated in this context to replace or supplement imaging to monitor response.[45] The optimum number of cycles of platinum-based chemotherapy has not been demonstrated in clinical trials; however, four to six cycles of doublet chemotherapy is in keeping with the pivotal clinical trial data, allowing for cessation at four cycles if treatment is poorly tolerated. The spectrum of common cumulative toxicities includes fatigue, progressive anemia, and sensory peripheral neuropathy.

Timing of First-Line Chemotherapy

The timing of initiation of first-line palliative chemotherapy remains a matter of debate. A chemotherapy regimen used in one small randomized clinical trial was subsequently found to be inactive (mitomycin, vinblastine, and cisplatin or carboplatin) in a large, randomized study.[46,47] In this trial,[43] patients who were symptomatically stable were randomly assigned to receive either immediate chemotherapy or delayed treatment after the onset of symptoms. The investigators found a nonsignificant survival benefit for the immediate treatment arm. Nevertheless, in asymptomatic patients with minimal or nonmeasurable disease and epithelioid histology, for example, patients presenting with pleural effusion that has been effectively managed, it is reasonable to defer treatment if surgery is not planned.

Second-Line and Subsequent Chemotherapy

Patients often have a good performance status at progression after first-line chemotherapy and are fit for and desire further treatment. Although uncontrolled studies and anecdotal experience support the potential for second-line chemotherapy to elicit objective treatment responses, at the time of publication, no positive randomized controlled trial of any agent in the setting of uniform previous treatment with cisplatin and pemetrexed had been reported.

In the era before routine first-line treatment with a platinum agent and pemetrexed, authors of a well-conducted randomized clinical trial of second-line single-agent pemetrexed plus best supportive care compared with best supportive care alone in 243 patients reported partial response in 19% of patients receiving pemetrexed and 2% of patients receiving best supportive care alone. The disease control rate was 59% in the pemetrexed arm and 19% in the best supportive care arm, and progression-free survival favored the pemetrexed arm (median, 3.6 vs. 1.5 months) although there was no significant difference in overall survival (p = 0.7434).[46] Patients who had a response to their previous chemotherapy regimen were more likely to have a clinical benefit. Substantially more participants in the best supportive care arm (52% vs. 28%) received postdiscontinuation chemotherapy, which may have obscured any potential difference in overall survival.

Although these results are encouraging, this study does not give firm guidance in the post-pemetrexed setting. To attempt to address this question, patients from the pivotal trial of pemetrexed and cisplatin were evaluated for chemotherapy use after pemetrexed.[49] Eighty-four patients in the pemetrexed and cisplatin arm received subsequent chemotherapy, with 48 patients receiving single-agent treatment and 36 patients receiving combination chemotherapy. Regimens included gemcitabine, vinorelbine, anthracyclines, and platinum agents alone and gemcitabine-based combinations. Although the data available were not suitable to examine response or disease control rates, subsequent chemotherapy was significantly correlated with longer survival ($p < 0.001$), after adjustment for treatment group and prognostic factors. This finding may be explained by a benefit from second-line chemotherapy, but is also likely to be biased by the selection of fitter patients for subsequent treatment lines.

Support for reintroduction of pemetrexed-based chemotherapy for patients who had a previous response can be found in a number of uncontrolled clinical trials and case series (Table 53.2). In an observational study,[31] patients who had response or stable disease to previous pemetrexed-based therapy were further treated with pemetrexed either as a single agent (15 patients) or in combination with carboplatin or cisplatin (16 patients).[50] The overall response rate was 19%, and 52% of patients had progressive disease as their best response. The median progression-free survival was 3.8 months, median overall survival was 10.5 months, and the toxicity was manageable. Predictors of better outcomes included a longer interval between initial pemetrexed-based chemotherapy and additional treatment, previous objective response to therapy, and second-line rather than third-line treatment.

In a large retrospective assessment of patient outcomes with second-line therapy, 181 patients who had received second-line chemotherapy were identified from eight Italian centers.[51] Most (66%) of the patients had received prior pemetrexed-based treatment, of whom 42 patients received further pemetrexed-based therapy and 31 received platinum and pemetrexed. Again, good performance status and more than 12 months since first-line therapy predicted better outcomes after further treatment in all patients. Although the disease control rate was similar for patients who were retreated with pemetrexed alone or in combination with a platinum drug, progression-free survival and overall survival were better for patients retreated with a combination of a platinum agent and pemetrexed. Clear potential biases exist that limit interpretation of these data, in particular, that selection of single-agent chemotherapy over combination chemotherapy is likely to have been influenced by clinician perception of the tolerability of combination chemotherapy for individuals, with single-agent treatment more likely to have been recommended for patients who were less fit.

A number of other nonpemetrexed second-line regimens were used in this retrospective Italian series,[51] either with or without platinum agents. These regimens included combinations of cisplatin or carboplatin with gemcitabine or vinorelbine, as well as vinorelbine and gemcitabine alone or in combination. Overall, the disease control rate, progression-free survival, and overall survival were superior for patients who received repeat platinum-based treatment, however, we should interpret these data with the same potential for bias as just discussed.

The interpretation of these studies has substantial limitations, particularly in view of the heterogeneity of patient populations. In particular, in some studies not all patients had been previously treated with pemetrexed. Selection criteria and tumor measurement metrics were variable. Few studies included evaluation of symptom benefit, quality of life, or functional benefit as measured by lung function.

In recommendations for second-line therapy, it is appropriate to consider reintroduction of a pemetrexed-based regimen for patients who have had a response to first-line pemetrexed-based treatment, and who have had a long interval since previous treatment, with patients treated more than 12 months before reintroduction likely to have the most benefit. An appropriate regimen choice is pemetrexed with the alternative platinum drug or single-agent pemetrexed if the patient is unfit for combination therapy or has a contraindication to the platinum compounds.

TABLE 53.2 Selected Results of Repeat Induction Therapy or Other Regimens Studied in the Second-Line Setting

In patients for whom pemetrexed-based treatment is not recommended, such as patients with a shorter treatment-free interval, vinorelbine, either as a single agent or with gemcitabine, has an acceptable activity and toxicity profile. Treatment discussions should include careful consideration of patient preferences and disclosure regarding the limited data on functional and quality-of-life benefits.

A relative paucity of trials of second-line cytotoxic chemotherapy in malignant mesothelioma has been reported since 2009. Research efforts and enrollment into second-line trials have focused on identifying novel targeted agents that may have activity in mesothelioma and the prospect of molecular predictors of response to such agents. A realistic perception exists that the benefits of cytotoxic chemotherapy have reached a plateau, given the lack of development of new cytotoxic agents in favor of molecularly targeted agents, and there is likely to be limited benefit from further testing of existing cytotoxic agents in this setting. The current generation of clinical trials for second-line therapy in mesothelioma generates debate about an appropriate control arm. Placebo control is still considered appropriate for a phase III study, in the absence of data showing a survival benefit for second-line treatment after pemetrexed. Second-line trials should include testing of quality-of-life and functional parameters in order to draw robust conclusions about patient benefit in this population.

SURGERY

Surgery for MPM is indicated for diagnosis, staging of disease, palliation of symptoms (rarely), and cytoreduction.

Palliative Surgery

Patients with mesothelioma most commonly present with dyspnea, chest wall pain, cough, or constitutional symptoms such as fatigue, fever, and anorexia. Respiratory symptoms may be secondary to atelectasis, with ventilation reduction and shunting caused by the compressive effects of pleural effusion or tumor encasement. Symptoms may also be secondary to altered respiratory mechanics as a result of altered chest wall mechanics and impaired movement of the ribs and diaphragm. Surgical palliation for patients with these symptoms includes treatment of pleural effusion and lung collapse and amelioration of chest wall mechanics.

Pleural Drainage

Treatment of pleural effusion depends on the size of the effusion, the degree to which it is causing atelectasis, and the amount of underlying lung entrapment. Simple thoracentesis is rarely effective in providing long-term relief of pleural effusion; however, it is a reasonable initial procedure to help

dyspnea, to obtain a diagnosis, and to evaluate the degree to which the lung will reexpand. In the absence of complete reexpansion, pleural symphysis is unlikely to occur with sclerotherapy (i.e., talc). In cases of effusion with lung entrapment, placement of an indwelling pleural catheter can be helpful. This simple outpatient procedure does not require complete lung reexpansion to be effective, and, although tumor progression along the catheter tract has been described, it appears to be an uncommon event.[52]

Palliative Pleurectomy

The aim of palliative pleurectomy is to free up an entrapped lung, allowing it to reexpand, to ameliorate the restrictive effect of chest wall tumor, and to reestablish pleural apposition and ultimately pleural symphysis. Palliative pleurectomy should be differentiated from cytoreductive PD, which is performed with the aim of achieving macroscopic complete resection of tumor in the hope of influencing time to recurrence and survival. Quality-of-life improvements after palliative pleurectomy have not been extensively documented, and no prospective comparisons between best supportive care and PD exist. Control of pleural effusion is good, with most reports citing success in 80% to 100% of cases.[53] Improvement in dyspnea and chest wall pain is generally less. Soysal et al.[54] retrospectively reviewed 100 consecutive pleurectomies performed for palliation of MPM. Pleural effusion was controlled in 52 (96%) of 54 patients who presented with symptomatic effusion, chest pain was relieved or improved in 85%, and cough and dyspnea improved in all patients. Most important, symptom relief was achieved for up to 6 months.

Although palliative pleurectomy can achieve excellent control of pleural effusion, it requires a thoracotomy, and the upfront morbidity of this procedure may negate some of its potential advantages, particularly with respect to pain control. VATS debulking has emerged as an alternative option. Waller et al.[55] first described use of VATS pleurectomy in 19 patients with malignant effusion and showed control of pleural effusion in 84% of patients at a median follow-up of 12 months; however, tumor seeding at port sites occurred in 5 (38%) of 13 patients with MPM. A phase III trial comparing VATS pleurectomy with talc pleurodesis (MESOVATS) indicated that the success of VATS pleurodesis was higher than that of talc pleurodesis, but no differences in overall survival were found.[56] The influence of histology on outcome following palliative pleurectomy was evaluated in 51 patients with MPM.[55] Significant improvement in dyspnea and pain score was achieved at 6 weeks and 3 months; however, prolonged benefit was found mainly for patients with epithelioid tumors and for patients without substantial weight loss. The median survival for patients with nonepithelioid tumors in this study was 4.4 months. The 30-day mortality was 8%, but increased to 14% by 6 weeks, calling into question the validity of palliative pleurectomy for patients with sarcomatoid and biphasic tumors.

Cytoreductive Surgery

The aim of cytoreductive surgery is to remove all macroscopic tumor from the hemithorax.[57,58] It is postulated, although unproven, that R0 or R1 cytoreduction prolongs survival for patients, particularly patients with epithelioid tumors and no lymph node metastases. The argument in favor of cytoreduction is supported by several observations. First, a large body of evidence from other disease sites shows a benefit to cytoreductive surgery in stage IV disease; the results of randomized trials support this procedure for advanced ovarian, colorectal, and renal cell cancers. Second, most long-term survivors of MPM have had surgery as a component of their therapy, whereas very few long-term survivors have been treated with nonoperative strategies. In

two studies, both published in 2010, the outcomes for patients with MPM in the Surveillance Epidemiology and End Results database were evaluated. In both studies, survival was longer for patients who had cancer-directed surgery compared with patients whose treatment did not include surgery (11 vs. 7 months).[59,60] Third, the median survival of patients in three phase III trials of chemotherapy was between 10 and 13 months,[42,43,46] whereas in three multicenter trimodality phase II studies that included cytoreductive surgery in the form of EPP, the median survival on an intent-to-treat basis was notably longer than 17 months.[61–63] Lastly, several retrospective studies appear to demonstrate longer survival for patients with mesothelioma who have undergone more complete cytoreduction compared with patients with larger tumor volumes after resection.[64] The two approaches to cytoreductive surgery for pleural mesothelioma are EPP and radical PD (or total pleurectomy).

Extrapleural Pneumonectomy

EPP involves the en bloc resection of the parietal and visceral pleura, lung, ipsilateral pericardium, and diaphragm (Fig. 53.2). The pericardium and diaphragm are usually reconstructed with prosthetic mesh, often polytetrafluoroethylene, although use of polyglycolic acid, polypropylene, and various biologic meshes has also been described. The procedure is extensive and has been associated with a high mortality rate, but in most large-volume centers perioperative mortality is below 8%. Postoperative morbidity is approximately 50% to 60% and most commonly includes supraventricular tachyarrhythmias (44% to 46%), which are easily treated, but also life-threatening events such as major hemorrhage (1%), cardiac herniation (1% to 2%), esophageal perforation (1% to 2%), bronchopleural fistula (1% to 2%), empyema (3% to 6%), acute respiratory distress syndrome (4% to 8%), and pneumonia (5% to 10%). Survival following EPP in the trimodality setting ranges from 10 to 28 months and is dependent on stage, histology, and whether survival is calculated from the date of surgery or from the date of diagnosis. Because the entire lung is removed with EPP, the at-risk area for local recurrence is limited to the inner aspect of the chest wall, the peridiaphragmatic area, and the ipsilateral mediastinum. Local recurrence rates with EPP alone range from 30% to 50%. For this reason, both adjuvant hemithoracic radiotherapy and intrapleural therapies, such as heated intrapleural chemotherapy (HIOC) and photodynamic therapy (described later), have been administered in an effort to reduce local recurrence.

Adjuvant radiotherapy has been a treatment component in several case series. In a phase II trial of adjuvant external-beam radiotherapy reported by Rusch et al.,[65] radiotherapy to the postpneumonectomy space to 50.4 Gy reduced the rate of local failure to 13%.[18] Sites of failure were predominantly in the posterior diaphragmatic sulcus, but authors of later reports suggested higher rates of local recurrences (approximately 30%) using standard anterior-posterior beam techniques.[65] Intensity-modulated radiotherapy (IMRT), which allows for better dose distribution and targeting of the postpneumonectomy space, has been applied in this setting. Unfortunately, systemic metastases remain a major problem. Distant metastases developed in many patients, most commonly in the contralateral lung or in the abdominal cavity. Caution should be maintained when using IMRT after pneumonectomy because of the potential for radiation toxicity to the remaining lung; in some reports, IMRT has been associated with fatal pneumonitis.[66] Lung toxicity can be minimized, however, by ensuring the volume of lung tissue receiving 20 Gy or more is less than 7% and the mean lung dose is less than 8.5 Gy.[19] Newer modalities, such as helical tomotherapy and intensity-modulated proton-beam therapy, show promise to provide good local control while minimizing toxicity to surrounding structures.
Fig. 53.2. Extrapleural pneumonectomy includes removal of all pleural lining, diaphragm, pericardium, and lung. (A) The yellow line indicates the spread of the mesothelioma over the pleural lining. (B) After removal of the lung and stripping of the parietal pleura, diaphragm, and pericardium, patches (white) (C) are placed to cover the abdominal structures and the heart. *(Reprinted with permission from David Rice, MD.)*

Survival following EPP is highly dependent on tumor stage, histology, and tumor volume (Table 53.3).[18,64,67] In a series of 183 patients with MPM treated at the Brigham and Women's Hospital, the median survival was 19 months overall and was 51 months for patients who had negative margins, epithelioid tumors, and negative nodes.[66] Analysis of 34 published reports showed an average survival of 18 months (range, 5 to 47 months).[68] The utility of EPP was questioned following publication of results of the Mesothelioma and Radical Surgery feasibility study, a small pilot study in 50 patients designed to test whether patients could be randomly assigned to receive either EPP or best supportive care following systemic platinum-based chemotherapy.[69] The trial was negative because it showed that it would not be feasible to randomize enough patients to reach the accrual goal of 670 patients, the number estimated to be required to have power to detect a survival difference. The results of this pilot study indicated that overall survival was worse in the EPP arm (14.4 vs. 19.5 months). The study has been criticized for several reasons, including high perioperative mortality (19%) in the EPP arm, small sample size,

failure to standardize chemotherapy regimens, crossover between treatment groups, lack of reporting of final histology, and survival analysis truncation at 18 months.[70,71]

Pleurectomy/Decortication

PD for cytoreduction of mesothelioma removes the involved visceral and/or parietal pleura with the aim of achieving macroscopic complete resection of tumor while preserving the underlying lung parenchyma. When structures such as the diaphragm or pericardium require resection, the procedure is termed extended PD (Fig. 53.2).[72] PD begins with complete extrapleural mobilization of the lung and involved parietal pleura to the level of the hilar structures, similar to that performed during the initial dissection for EPP. If the pleura/tumor is inseparable from the pericardium or diaphragm (as it often is), these structures are resected in a manner similar to that with EPP. Frequently, the pericardium does not require reconstruction because of the limited risk of cardiac torsion with the lung in situ. Once the lung

and overlying pleura have been mobilized, an incision is made in the parietal pleura and taken through the tumor and visceral pleura down to the level of the lung parenchyma. Subpleural tumor deposits that remain adherent to the lung after visceral pleurectomy may be directly removed using sharp dissection or may be ablated using thermal energy. PD is generally associated with less risk than EPP, with perioperative mortality typically in the range of 0% to 5%. Reported complications include atrial arrhythmias (24% to 32%), prolonged air leaks (3% to 21%), pulmonary complications (9% to 11%), and empyema (2% to 8%).[72]

Because the lung is left in situ, PD offers a greater surface area for residual microscopic disease, as reflected in the higher rate of local recurrence compared with EPP, which is generally 1.5 to 2 times higher.[71] Because ipsilateral lung parenchyma remains in situ, the ability to deliver effective postoperative radiotherapy is compromised, which is not a limiting factor after EPP. Gupta et al.[73] reported on 123 patients who received hemithoracic radiotherapy (median, 43 Gy) following PD. Despite a preponderance of patients with early-stage disease (59%), the median survival was 14 months, and local recurrence developed in 56% of patients (Table 53.4).

Intrapleural Therapies

The relatively high local recurrence rate following cytoreductive surgery alone has prompted use of intrapleural therapies at the time of PD and EPP. These therapies have primarily involved intrapleural administration of platinum-based chemotherapy or intracavitary photodynamic therapy. Intrapleural therapies are attractive because they potentially treat the entire at-risk area of the hemithorax and lung. Topical administration of heated platinum agents has been shown to result in permeation of chemotherapy into tissue up to a depth of 5 mm. Most trials of intrapleural chemotherapy have been small phase I and II studies with limited numbers of patients, and the rate of local recurrence has ranged from 17% to 100%.[74] Earlier studies tended to rely on the instillation of the chemotherapeutic agent into the chest cavity via chest drains in the postoperative period, but later investigators employed HIOC, perfusing the cytotoxic agents in the chest at 42°C. Following a phase I/II study by Richards et al.[75] for patients with MPM who had PD and HIOC in which local failure occurred in 57%, Tilleman et al.[76] reported results of

heated cisplatin in 92 patients after EPP. Renal function was preserved by the concomitant administration of sodium thiosulfate and amifostine. Although recurrence within the ipsilateral chest was low (17%) and operative mortality was 4%, the median survival was 13 months. However, nearly half of the patients had stage III disease and 42% had nonepithelioid histology, which may have negatively influenced survival. A 1998 analysis from the same group compared patients with a good prognosis (epithelioid histology, low-volume disease, hemoglobin greater than 13g/dL, or female gender) who received HIOC with a similar group who did not and reported that the HIOC group had a longer interval to recurrence (27 vs. 13 months) and improved survival (35 vs. 23 months).[77]

Photodynamic therapy has been evaluated in a few phase I/II studies.[78–80] Local recurrence rates have varied between 15% and 76% and survival has ranged from 10 to 32 months. Treatment-related toxicity was an issue in some early studies, with reported deaths due to bronchial and esophageal fistulization.[79] A single, randomized study was performed by Pass et al.[81] to evaluate the effect of porfimer sodium after cytoreductive surgery. The study did not show any benefit of the addition of photodynamic therapy. In 2004, Friedberg et al.[80] reported promising results for 38 patients with MPM who had extended PD and intraoperative PDT. The median survival was 32 months, although local failure subsequently developed in 66% of patients and distant recurrence in 47%.

Choice of Extrapleural Pneumonectomy or Pleurectomy/Decortication

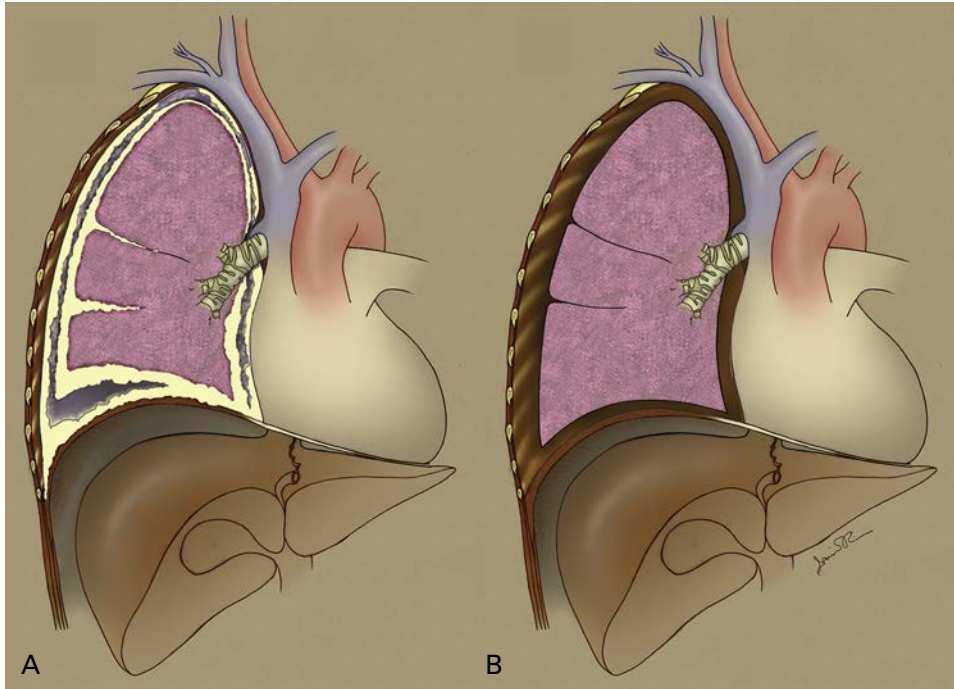
Controversy exists over the selection of the most appropriate surgical procedure (Fig. 53.3). A consensus statement from the International Mesothelioma Interest Group Congress in 2012 concluded that the goal of cytoreductive surgery should be the complete resection of all macroscopic tumor and that whether EPP or PD is applied to achieve this goal is of secondary importance and best left to the discretion of the surgeon based on patient and tumor characteristics.[71] Several comparison series have been published, but all have been retrospective in nature and thus subject to selection bias. The largest study to date was by Flores et al.,[82] who reported on 663 patients from three separate institutions. The overall median survival was 14 months and


Fig. 53.3. Macroscopic complete resection is obtained when all macroscopic tumor (A) is resected, leaving the lung, diaphragm, and pericardium in situ (B). *(Reprinted with permission from David Rice, MD.)*

was significantly longer for the 278 patients who had PD than for the 385 patients who had EPP (16 vs. 12 months, *p* < 0.001). However, it should be recognized that significantly more patients in the PD group had early-stage tumors (35% vs. 25%, *p* < 0.001). In addition, the institutions involved in this study preferentially performed PD for patients with minimal visceral involvement and for patients with low tumor volume. This bias toward performing PD for patients with biologically more favorable tumors makes it difficult to draw firm conclusions from the data. Furthermore, a previous analysis from one of the institutions showed no difference in survival among 222 patients with EPP and 126 patients with PD.[83]

Another controversial topic relates to whether to offer EPP to patients with node metastases, which can occur in up to 50% of patients undergoing cytoreduction and which negatively influence survival. Investigators of a study published in 2007 compared outcomes for patients with node-positive disease who had EPP and PD and found no survival benefit for EPP over PD for patients with N2 disease.[57] However, accurately identifying N2 disease before EPP remains a problem. As already outlined, mediastinoscopy has poor sensitivity (approximately 30% to 40%) and, although EBUS and EUS may offer improved accuracy, a large number of positive nodes occur in locations where preoperative histologic sampling is not possible. Detailed intraoperative lymph node sampling following the initial extrapleural dissection in patients for whom EPP is planned affords the surgeon the ability to perform PD if node metastases are identified on evaluation of a frozen section specimen, thus sparing a patient likely to have a poor prognosis the risk of EPP.

In terms of postoperative quality of life, EPP is generally more deleterious than PD. In a 2012 study by Rena et al.,[84] quality of life for patients undergoing EPP or PD was measured using the validated Cancer Core Questionnaire from the European Organisation for Research and Treatment of Cancer. Patients who had EPP had significantly poorer functional scores at 6 and 12 months compared with patients who had PD and never approached a return to baseline. In terms of symptoms, pain scores increased

and cough and dyspnea scores decreased, although to a lesser extent than for patients who had PD.

Controversy remains regarding the surgical management of MPM. In fit patients with epithelioid tumors and negative nodes, cytoreductive surgery as part of a multimodality regimen appears to improve survival compared with best supportive care or chemotherapy alone, although this result is unproven. Complete resection of all macroscopic disease is considered the goal of any therapeutic cytoreductive procedure, whether EPP or PD. EPP is associated with lower rates of local recurrence, particularly when combined with hemithoracic radiotherapy or HIOC, but it is also associated with higher perioperative morbidity and mortality than is PD. At the time of publication, no convincing evidence supports any major survival difference between the two procedures. Intrapleural therapies appear promising, particularly for patients with a good prognosis. Distant failure remains a substantial issue that limits long-term survival for patients who have undergone cytoreductive surgery, although in the future, it is possible that if micrometastatic disease can be successfully managed with improved chemotherapeutic or immunotherapeutic agents, the local control achievable with cytoreduction may translate into better survival.

IMMUNOTHERAPY FOR MESOTHELIOMA

Although mesothelioma is not considered particularly immunogenic, antitumor immune responses, including spontaneous tumor regressions in some patients with mesothelioma, have been reported. However, such spontaneous tumor regressions are rare, which suggests the presence of immune escape mechanisms. Mesothelioma is heavily infiltrated with many immune effector cells, and macrophages, natural killer cells, and T lymphocytes (both T-helper/inducer [CD4] and T-suppressor/cytotoxic [CD8] cells) constitute most of the inflammatory cells in malignant pleural effusions of patients with mesothelioma.[85]

Regulatory T Cells and Immunosuppressive Cytokines

Regulatory T cells are negative regulators of the immune system, which play an important role in maintaining peripheral tolerance. Hegmans et al.[85] demonstrated that mesothelioma tissue sections contained substantial amounts of regulatory T cells characterized by the Foxp3-positive, CD4-positive, CD25-positive immunophenotype. Authors of retrospective studies in a limited number of patients undergoing EPP indicate that the presence of high levels of CD8-positive tumor-infiltrating lymphocytes may be associated with better prognosis.[86] Preliminary evidence also suggests that blockade of regulatory T cells could enhance survival when combined with pemetrexed in established mesothelioma.[87]

Release of immunosuppressive cytokines is yet another mechanism employed by tumors to inhibit immune responses.[88] Transforming growth factor-β2 (TGF-β2) has been detected in the pleural fluid and malignant mesothelioma cell supernatants.[85] Although TGF-β blockade appeared promising in murine models of malignant mesothelioma, objective responses were not found in a phase II trial that evaluated GC1008, an anti-TGF-β monoclonal antibody.[89]

Immune Checkpoint Inhibition

Cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) is a member of the CD28/B7 immunoglobulin superfamily of immune regulatory molecules. It shares its two ligands (B7-1 and B7-2) with its costimulatory counterpart CD28. CTLA-4 and CD28 and their ligands B7-1 (CD80) and B7-2 (CD86) are critically important for the initial activation of naive T cells and regulation of the clonal composition of the responding repertoire following migration of activated dendritic cells to lymphoid organs. The expression of CTLA-4 is upregulated following T-cell activation, and the pathway has been shown to play an important immunomodulatory role in cancer.

Preclinical data suggest synergy between CTLA-4 blockade and cytotoxic chemotherapy, possibly as the result of a variety of mechanisms, including induction of a long-lasting immunologic memory and inhibition of tumor cell repopulation.[90] In a murine mesothelioma model, the combination of gemcitabine and anti-CTLA-4 exerted a far greater antitumor effect than either agent alone, whereas a similar effect was lacking when CTLA-4 blockade was combined with cisplatin.[90] In a different murine mesothelioma model, anti-CTLA-4 monoclonal antibody administered between cycles of cisplatin led to inhibition of tumor cell repopulation and was associated with increased numbers of tumor infiltrating CD4 and CD8 T cells and upregulation of cytokines associated with cytotoxic T-cell function.[91] It is conceivable that the synergy of chemotherapy with CTLA-4 blockade is dependent on the type of cytotoxic agent, the schedule, and immunogenicity, all of which require further evaluation in clinical trials.

Tremelimumab, a monoclonal antibody to CTLA-4, was evaluated in a single-arm, phase II study of 29 patients with malignant mesothelioma who had progressive disease after a first-line platinum-based regimen.[92] Although the study did not reach its primary end point of demonstrating a 17% response rate, 2 (7%) patients had durable partial responses, one lasting 6 months and another lasting 18 months. In a further second-line single-arm study of dose-intensified tremelimumab, 14% partial responses were noted, with a median overall survival of 11.3 months.[92a]

Unfortunately a randomized phase IIb clinical trial of tremelimumab versus placebo did not reach its primary end point, with no evidence of benefit in overall survival or progression-free survival for patients with mesothelioma treated in the second-line setting.[93]

Encouraging early results have been presented for the program death 1 (PD1) targeting monoclonal antibodies, nivolumab and pembrolizumab in early-phase clinical trials. The results of the NivoMes trial in which 34 patients received nivolumab 3 mg/kg every 2 weeks with response evaluation at 6 weeks were recently presented.[94] PDL1 expression by immunohistochemistry was greater than 1% in 29% mostly in epithelial patients, but responses were seen irrespective of PDL1 expression. By 12 weeks, 50% of the patients had disease control, which decreased to 33% at 24 weeks, and median progression-free survival was 110 days. Pembrolizumab, 10 mg/kgm IV every 2 weeks, was delivered to 25 patients after failure of standard therapy as part of the KEYNOTE-28 trial.[95] Response rate was 20% with a median duration of 12 months, and at 6 months or later a clinical benefit rate of 40% was achieved. Progression-free survival was 5.4 months with a median overall survival of 18 months. An interim analysis of another Phase II trial of 35 patients treated at University of Chicago with pembrolizumab 200 mg IV every 21 days (median number of cyles, 9) noted a response rate of 21%, disease control rate of 80%, a median progression-free survival of 6.2 months, and an overall survival of of 11.9 months.[96] Again, PDL1 expression was independent of responses. However, in the largest clinical trial of an immune checkpoint inhibitor reported to date, the response rate was lower than reported with pembrolizumab and nivolumab. Fifty-three patients with heavily pretreated pleural or peritoneal mesothelioma received the anti-PDL1 antibody avelumab at a dose of 10 mg/kg every 2 weeks until disease progression or unacceptable toxicity. The overall response rate was 9.4% and the responses[97] were seen in patients with or without tumor PDL1 expression. Larger studies are needed to confirm efficacy of single agent immune checkpoint inhibitors in malignant mesothelioma. The current generation of clinical trials using immune checkpoint blockade are also exploring combinations of immunotherapies, immunotherapy with chemotherapy, and other PD1 and PDL1 blocking antibodies.

Dendritic Cell–Based Immunotherapy

Dendritic cells are potent antigen-presenting cells that originate from bone marrow precursor cells and are present in peripheral tissues, where they capture, process, and transport antigens to naive T cells in draining lymph nodes. When dendritic cells are immature, antigens are presented to T cells in the lymph node without costimulation, leading to either the deletion of T cells or the generation of inducible regulatory T cells. Immunogenic tumor-associated antigens are secreted or shed by tumor cells or released when tumor cells die and can be taken up by dendritic cells. Upon encountering an antigen, dendritic cells mature and express peptide-major histocompatibility complex (MHC) at the cell surface, as well as appropriate costimulatory molecules (Fig. 53.4). Mature dendritic cells migrate in large numbers to draining lymph nodes where they prime CD4-positive helper T cells and CD8-positive cytotoxic T lymphocytes, activate B cells, and initiate an adaptive immune response. Vaccination with ex vivo generated mature dendritic cells pulsed with tumor-associated antigens has successfully elicited therapeutic immunity in other solid tumors.

Ebstein et al.[98] demonstrated that dendritic cells from healthy donors pulsed with antigen preparations from apoptotic allogeneic mesothelioma cell lines were capable of inducing a class I restricted cytotoxic T-cell response against mesothelioma tumor cells.[98] Hegmans et al.[85] provided in vivo proof of the concept of antitumor immune responses generated by dendritic cell vaccination in mesothelioma and showed that mice who received tumor lysate-pulsed dendritic cells before tumor implantation had prolonged survival. Recently, preliminary results of an off-the-shelf allogenic tumor cell lysate from human mesothelioma cell lines (Pheralys) were reported.[99] Leucopheresis was performed to obtain an enriched monocyte fraction from which immature DC were generated, which were loaded with the allogenic lysate.
Fig. 53.4. Cellular processes involved in the immunomodulation of mesothelioma and potential targets for thera-peutic intervention. The complex interaction between tumor cells and the immune system is presented in a simpli-fied manner. Immunogenic tumor-associated antigens, which are shed by tumor cells or released when tumor cells die, are taken up by dendritic cells. Upon encountering an antigen, dendritic cells mature and express peptide-major histocompatibility complex (MHC) at the cell surface as well as appropriate costimulatory molecules, which lead to cytotoxic T-cell activation. Inhibitory processes from cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), CD28, and program death 1 (PD1) regulate further activation of the immune system. Enhancing host immune system by antibody-mediated inhibition of T-cell coinhibitory receptors (e.g., CTLA-4, PD1) or their ligands (e.g., PDL1, PDL2) offers potential therapeutic opportunities in mesothelioma. Antigen-specific, tumor cell, and dendritic cell vaccines are other immunotherapeutic interventions that are being explored in mesothelioma. *TCR,* T cell receptor.

Immunotherapy with the allogenic tumor cell lysate was safe, and a randomized trial comparing DC therapy with Pheralys versus best supportive care as maintenance treatment after chemother-apy is planned.

Vaccination induced immunologic responses to keyhole lim-pet hemocyanin, and nine patients had increased CD3 and CD8 T cells expressing granzyme B after vaccination, suggesting lymphocyte activation by dendritic cell vaccination.[85,100] How-ever, the measured humoral or cellular immunologic responses did not correlate with clinical responses. A phase I/II clinical trial ongoing at the time of publication is evaluating immune response to autologous RNA-modified dendritic cells engineered to express the WT1 protein for patients with malignant meso-thelioma who have a good response to first-line chemotherapy (ClinicalTrials.gov identifier: NCT01291420). Based on indica-tions from preliminary results (which included one patient with mesothelioma), this approach is feasible and capable of inducing immune responses.[101] The source of the tumor-associated anti-gens for dendritic cell loading, which requires care in identifying and characterizing antigenic epitopes, remains a critical issue that will determine the efficacy of dendritic cell–based vaccination in mesothelioma.[102]

Vaccination Using WT1

The transcription factor WT1 is overexpressed in malignant mesothelioma.[103] Although WT1 is a nuclear protein, it is pro-cessed and presented on the cell surface in the context of MHC molecules. In normal adult tissues, WT1 expression is restricted to low levels in nuclei of normal CD34 hematopoietic stem cells, myoepithelial progenitor cells, renal podocytes, and some cells in the testes and ovaries.[104]

Mesothelin-Targeted Therapies

Mesothelin is a tumor differentiation antigen that is present on normal mesothelial cells lining the pleura, peritoneum, and pericardium but is highly expressed in many solid tumors, including mesothelioma, ovarian and pancreatic cancer, and lung adenocarcinoma. In the case of mesothelioma, almost all epithelioid mesotheliomas express mesothelin, as does the epithelial component of biphasic tumors, but it is absent in sarcomatoid mesotheliomas. The mesothelin gene encodes a precursor protein of 71 kDa that is processed to a 31-kDa shed fragment megakaryocyte-potentiating factor and a 40-kDa fragment, mesothelin that is attached to the cell membrane by a glycosylphosphatidylinositol anchor. Both mesothelin and megakaryocyte-potentiating factor can be detected in serum and can be used as a biomarker of tumor detection or tumor response. The restricted expression of mesothelin on nor-mal tissues makes it a good target for antibody- or cell-based immunotherapy.

Many mesothelin-targeted agents are being evaluated in clinical trials. These agents include an antimesothelin immuno-toxin (SS1P), a chimeric antimesothelin antibody (MORAb-009, amatuximab), a mesothelin-targeted antibody drug conjugate (BAY94-9343), a mesothelin vaccine (CRS-207), and a chimeric antigen receptor (CAR)-based T-cell adoptive therapy.

SS1P

SS1P is a recombinant immunotoxin consisting of an antime-sothelin variable fragment linked to a truncated Pseudomonas exotoxin A, PE38. After binding to mesothelin on the cell surface, SS1P is internalized and undergoes processing in the

endocytic compartment of the cell and leads to inhibition of protein synthesis and, ultimately, cell death. In preclinical studies, SS1P showed significant antitumor activity against mesothelin-expressing tumor cells obtained from patients with mesothelioma.[105,106]

In 2013, a phase I trial was published on the use of SS1P for patients with recurrent MPM and showed promising and long-lasting responses.[107] Further studies will focus on the combination of this compound with chemotherapy.

Amatuximab (MORAb-009)

Amatuximab is a chimeric monoclonal antibody directed to mesothelin that kills mesothelin-expressing tumor cells by antibody-dependent cell-mediated cytotoxicity. In addition, it blocks the interaction between mesothelin and CA-125, which may potentially inhibit tumor metastasis.[108] In a phase I trial, the dose-limiting toxicities were transaminitis and serum sickness and the maximum tolerated dose was 200 mg/m^2.[109] In a phase II nonrandomized trial of chemonaive pleural mesothelioma patients, administration of amatuximab with pemetrexed and cisplatin resulted in overall survival of 14.8 months, which is better than historical controls with pemetrexed and cisplatin alone.[110] Analysis of the pharmacokinetic data showed that serum amatuximab trough concentrations above the population median of 38.2 μg/mL were associated with significant improvement of both progression-free as well as overall survival.[111] Pharmacodynamic modeling shows that administering amatuximab 5 mg/kg weekly will allow 80% of patients to achieve amatuximab trough concentrations above 38.2 μg/mL. Based on these data, a randomized phase II clinical trial of amatuximab plus pemetrexed and cisplatin versus pemetrexed and cisplatin for patients with newly diagnosed unresectable mesothelioma with a primary end point of overall survival has been initiated and is enrolling patients (Clinical trials.gov NCT02357147).

Antimesothelin Antibody Drug Conjugate (Anetumab Ravtansine)

Anetumab ravtansine (BAY94-9343) is a mesothelin-targeted antibody drug conjugate consisting of a humanized immunoglobulin G1 monoclonal antibody to mesothelin conjugated to DM4, a tubulin-binding drug. In preclinical studies, it has been extremely potent against mesothelin-positive cell lines and shows significant antitumor activity against mesothelin-expressing tumor xenografts.[112] In a phase I study, anetumab ravtansine was administered intravenously every 21 days (q3w) in 77 patients: 45 patients in 10 dose escalation cohorts from 0.15 to 7.5 mg/kg (21 mesothelioma, 9 pancreatic, 5 breast, 4 ovarian, 6 other), and 32 patients in two expansion cohorts (12 mesothelioma and 20 ovarian). A total of 38 patients were treated at maximum tolerated dose (MTD) in escalation and expansion cohorts (16 mesothelioma, 21 ovarian, 1 breast). The MTD of anetumab ravtansine given q 3 weeks was 6.5 mg/kg. The dose-limiting toxicity at the highest dose of 7.5 mg/kg was keratitis and neuropathy. The most common side effects included peripheral sensory neuropathy and corneal microdeposits. Out of 16 mesothelioma patients treated at the MTD, 5 (31%) patients had objective tumor responses and 7 (44%) patients had stable disease. However, in patients with pleural mesothelioma who received anetumab ravtansine as second-line therapy, 5 of 10 (50%) had objective partial responses and 4 (40%) had stable disease.[56] More important, the responses were durable with 3 patients having ongoing response at greater than 2 years.[113] Based on these results a randomized phase II registration clinical trial of anetumab ravtansine versus vinorelbine as second-line therapy for pleural mesothelioma, with a primary end point of progression-free survival, has been initiated (Clinical trials.gov NCT02610140).

Mesothelin Vaccine (CRS-207)

Mesothelin is an immunogenic protein and can elicit an antitumor immune response. CRS-207 is the only mesothelin vaccine in clinical trials at the time of publication. It consists of a live attenuated strain of the bacterium *Listeria monocytogenes* encoding human mesothelin. The safety and induction of antimesothelin immune response by CRS-207 were established in a phase I dose-escalation study of patients with mesothelin-expressing cancers.[114] A phase Ib study is evaluating the combination of CRS-207 with pemetrexed and cisplatin for patients with untreated pleural mesothelioma who are not candidates for surgical resection. On this study patients received two doses of intravenous CRS-207 given 2 weeks apart (prime vaccination), followed 2 weeks after the second dose of CRS-207 by pemetrexed and cisplatin administered on the standard dose and schedule for four to six cycles. If patients had stable disease or decreased tumor burden at completion of chemotherapy, they received two more doses of CRS-207 3 weeks apart as boost vaccination. Patients with continuing tumor response or stable disease could get CRS-207 as maintenance vaccination every 8 weeks. A total of 38 patients have been enrolled on this study. The most frequently reported adverse events related to CRS-207 consisted of transient side effects of fever, chills or rigor, and nausea. There were no additive or cumulative toxicities observed from combination treatment of CRS-207 and chemotherapy. Out of the 36 patients evaluable for tumor response, 1 (3%) had complete response, 20 (56%) had partial response, 13 (36%) had stable disease, and 2 (6%) had progressive disease as their best overall response and the median progression-free survival and overall survival were 7.6 (95% confidence interval [CI], 7.1–10.1) and 16.4 (95% CI, 11.0–20.6) months, respectively.[115]

Mesothelin-Directed CAR Therapy

The limited expression of mesothelin on normal tissues makes it a good candidate for CAR-directed T-cell therapies. Clinical trials of mesothelin-directed CAR T-cell agents are currently ongoing.[116] Results of initial clinical trials show that this approach is safe and some activity seen in patients with solid tumors.[117] More recently, preclinical studies have shown increased efficacy when antimesothelin CAR T cells are administered into the pleural cavity, and this approach is now being studied in patients.[118]

Oncolytic Viral Therapies

Oncolytic viruses are replicating microorganisms that have been selected or engineered to grow inside tumor cells.[119] Oncolytic viruses take advantage of tumor-specific mutations, signaling pathways, or antigens, allowing their selective replication in tumor cells leading to tumor cell lysis but sparing normal cells. For example, activation of viral transcription under a regulatory region of the gene that is preferentially transcribed in target tumors is commonly used to achieve tumor specificity. In addition to direct cytotoxicity, therapeutic virus-mediated destruction or damage of tumors can also lead to an antitumor immune response. Phagocytosis of apoptotic measles virus–infected mesothelioma cells induced spontaneous dendritic cell maturation, activation, and a significant amplification of mesothelin-specific CD8 T cells.[120]

A number of oncolytic viruses, which replicate preferentially within tumors, such as adenovirus, measles, retroviruses, Newcastle disease, herpes simplex viruses, and vesicular stomatitis viruses, have been examined for their cytotoxicity and efficacy in mesothelioma.[121]

One of the challenges with oncolytic viral therapy in mesothelioma is tumor penetration of the oncolytic viruses. Extracellular matrix and tumor-associated fibrous tissue hampers the spread of

viruses released from infected tumors. Coexpression of enzymes that destroy extracellular matrix, such as heparanase, has been used successfully in preclinical studies to overcome the resistance from fibrous tissue, which prevents the penetration of oncolytic viruses.[122]

Gene Therapy

With the limited pattern of spread of mesothelioma, which is mostly restricted to the pleural cavity, and the ease of intrapleural delivery, local–regional administration of tumor selective adenoviruses and carrier cells, such as PA1STK cells, has been explored for therapeutic purposes.[123,124] In a phase I study of 21 patients with treatment-naive pleural mesothelioma, intrapleural delivery of Ad.HSVtk, a replication incompetent adenovirus with a transgene encoding herpes simplex virus thymidine kinase gene (HSVtk), was safe and well tolerated.[123] Tumor specificity in this study was achieved by the use of the HSVtk gene, whose protein product is an enzyme that converts ganciclovir into a highly cytotoxic phosphorylated form. Ad.HSVtk was administered into the pleural cavity following which patients received 2 weeks of ganciclovir intravenously. Anti-Ad humoral and cellular immune responses were generated, and posttreatment biopsies indicated presence of intratumoral transgene for patients who received a higher dose of Ad.HSVtk.

Clinical experience with Ad.HSVtk and preclinical data indicating that HSVtk generates a strong Th1-type antitumor immune response suggest that cell kill was primarily due to antitumor immune responses induced by Ad.HSV.tk/ganciclovir, rather than direct cytotoxicity.[125] Subsequently, several studies were conducted to enhance antitumor immune responses using adenoviral vector expressing human interferon (IFN)-β gene, which augments expression of the MHC class I antigens and induces apoptosis.[126] Although these trials demonstrated the safety of Ad.IFN-β and showed induction of antitumor humoral and cellular immune responses, the rapid rise in serum anti-Ad neutralizing antibody titers minimized target-cell transduction and IFN-β gene expression. Although these clinical studies have consistently demonstrated generation of antitumor immune responses, radiographic and clinical antitumor responses have been limited, possibly because of large tumor volumes and the presence of immunoinhibitory networks. At the time of publication, studies were underway to evaluate the combination of Ad.IFN-β gene transfer with chemotherapy and surgery based on preclinical data that have shown markedly enhanced antitumor efficacy of Ad.IFN-β when combined with chemotherapy or with debulking surgery.[127,128]

CONCLUSION

MPM continues to be a controversial and difficult to eradicate tumor. Consensus on the use of surgery and even the type of surgery has not been reached, yet there is a movement toward lung-sparing procedures in these patients. Cisplatin and pemetrexed together remains the standard of care with regard to cytotoxic therapy, but novel therapies are under investigation. There is abundant in vitro evidence for human immune reactivity against mesothelioma. However, such responses are often ineffectual in situ, as the tumor exerts locally immunosuppressive effects. Strategies being explored in mesothelioma to overcome this inhibition include local manipulation of immunoregulatory molecules in the tumor microenvironment (e.g., immune checkpoint inhibitors) and antigen-specific activation of the immune system (e.g., vaccines). A number of investigational strategies focus on mesothelin, a tumor differentiation antigen that is present on normal mesothelial cells, but is highly expressed on mesothelioma.

54 Mediastinal Tumors

Christopher Hazzard, Andrew Kaufman, and Raja Flores

SUMMARY OF KEY POINTS

- Knowledge of the anatomy of the mediastinum is critical to establishing the differential diagnosis and choosing the best diagnostic and therapeutic interventions.
- A wide variety of possible etiologies must be considered including solid and lymphatic malignancies, benign cysts, and benign neoplasms.
- Computed tomography (CT) and magnetic resonance imaging (MRI) are essential tools for the diagnosis and planning of surgical approach and choice of surgical technique.
- Thymoma and lymphoma are common anterior mediastinal masses in adults. Lymphoma and benign cysts are the most common middle mediastinal lesions. Neurogenic tumors are seen only in the posterior mediastinum.
- Vital visceral, vascular, and neurologic structures exist in the mediastinum, and precise surgical technique is paramount to avoid complications.
- Surgical resection of benign cysts should be reserved for bronchogenic or esophageal cysts; pericardial cysts do not warrant invasive tissue sampling or removal.
- Bronchogenic and esophageal cysts can acquire significant adhesions to surrounding structures, making minimally invasive resection challenging in some patients.
- Electrocautery should be used with caution near the spinal foramina to avoid central nervous system injury.
- Known complications from surgery include phrenic nerve injury and paralysis, chyle leak, bronchial or esophageal perforation, and bleeding.

The mediastinum is the region of the thorax between the pleural cavities, commonly described in three compartments: anterior, visceral or middle, and posterior. The anterior mediastinum contains the thymus, lymph nodes, connective tissue, and fat. The visceral mediastinum contains the heart and its vasculature within the pericardium, trachea and proximal bronchi, esophagus, thoracic duct, lymph nodes, and the vagus, phrenic, and recurrent laryngeal nerves. The posterior mediastinum contains the sympathetic chain and proximal intercostal arteries, veins, and nerves. The differential diagnosis for a mediastinal mass is influenced by its anatomic position (Table 54.1).[1]

Mediastinal masses are often asymptomatic and present as an incidental finding during workup, surveillance, or screening for an unrelated condition. Malignant disease is more likely to be symptomatic.[2] Symptoms resulting from local compression and invasion include superior vena cava syndrome, dyspnea, dysphagia, hoarseness, cardiac tamponade, and Horner syndrome. Systemic symptoms may occur because of endocrine tumor activity or fever, chills, and weight loss associated with malignancy (Table 54.2).[1] Certain syndromes have commonly associated tumors and symptoms, including myasthenia gravis and anterior mass with

thymoma or café-au-lait spots and posterior mass with von Recklinghausen neurofibromatosis.

The most common anterior mediastinal masses in adults are thymoma, germ cell tumor (GCT), lymphoma, and displaced thyroid. In the visceral compartment, the most common mass is lymphadenopathy associated with metastatic disease. Other visceral masses are usually congenital cysts. Most posterior masses are neurogenic tumors.[3]

CT can provide information about the size, density, and anatomic relationship of mediastinal masses. Intravenous contrast medium used with CT will usually assist in the definition of mediastinal masses. MRI of the mediastinum is hindered by cardiac and respiratory motion artifacts. MRI of mediastinal masses is normally reserved for assessing intraspinal involvement of paravertebral tumors.[4]

GERM CELL TUMORS

Extragonadal GCTs result from errors in cell migration during embryogenesis (Fig. 54.1). These tumors are most commonly found in the mediastinum, where they account for 15% of anterior mediastinal masses in adults.[5] Most mediastinal GCTs present in the second through fourth decade of life. Approximately 85% of mediastinal GCTs are benign and occur at similar rates in men and women;[6] however, 90% of malignant GCTs occur in men. With malignant GCTs, scrotal ultrasound is necessary to detect possible primary gonadal tumors. Histologically, there are three types of GCTs: benign teratoma, seminoma, and nonseminomatous GCT (NSGCT).[3]

Benign Teratoma

Benign teratomas are composed of multiple germ cell layers, and are also referred to as mature teratomas. These teratomas may contain any type of tissue, including teeth, hair, bone, cartilage, and occasionally higher order structures. Although many patients will be asymptomatic, benign teratomas have the capacity to compress, erode, rupture, and fistulize into surrounding structures.[7] Rarely, these benign tumors undergo malignant transformation.[8] Elevated serum levels of beta-human chorionic gonadotropin (beta-hCG) or alpha-fetoprotein (AFP) may indicate malignant GCT. Total surgical excision of benign teratoma is recommended. The treatment approach for benign teratomas can vary and has included median sternotomy and lateral thoracotomy. The preferred treatment, particularly with GCTs, is the hemiclamshell approach, which is a unilateral extension into the hemithorax. For large masses with bilateral extension, a clamshell incision (a combined upper median sternotomy and anterior thoracotomy) provides excellent exposure. Benign teratomas are often adjacently adherent, which can make dissection challenging, and total resection is not always possible. However, postsurgical prognosis is excellent, even with incomplete excision.[7] There is no indication for chemotherapy or radiotherapy.

Seminoma

Seminomas occur almost exclusively in men and usually present in the third to fourth decade of life. Seminomas often grow quite large before discovery, and metastatic disease is present in 60%

to 70% of cases.[9] The serum AFP level is normal in pure semi-noma and the beta-hCG level can be elevated in some patients. An elevated AFP level implies a nonseminomatous component, but workup and treatment should be the same as for NSGCTs; however, a CT-guided needle biopsy should be considered over surgical biopsy.[10,11] Because of the prevalence of systemic disease, treatment with radiotherapy alone is associated with significantly lower progression-free survival compared with that associated with bleomycin, etoposide, and cisplatin chemotherapy.[12] Even

TABLE 54.1 Differential Diagnosis of Mediastinal Mass by Compartment[1]

Anterior	Middle	Posterior
Thymoma	Lymphoma	Neurogenic tumor
Teratoma, seminoma	Pericardial cyst	Bronchogenic cyst
Lymphoma	Bronchogenic cyst	Enteric cyst
Carcinoma	Metastatic cyst	Xanthogranuloma
Parathyroid adenoma	Systemic granuloma	Diaphragmatic hernia
Intrathoracic goiter		Meningocele
Lipoma		Paravertebral abscess
Lymphangioma		
Aortic aneurysm		

TABLE 54.2 Systemic Symptoms of Mediastinal Tumors[1]

Syndrome	Tumor
Myasthenia gravis, red blood cell aplasia, hypogammaglobulinemia, Good syndrome, Whipple disease, megaesophagus, myocarditis	Thymoma
Multiple endocrine adenomatosis, Cushing syndrome	Carcinoid, thymoma
Hypertension	Pheochromocytoma, ganglioneuroma, chemodectoma
Diarrhea	Ganglioneuroma
Hypercalcemia	Parathyroid adenoma, lymphoma
Thyrotoxicosis	Intrathoracic goiter
Hypoglycemia	Mesothelioma, teratoma, fibrosarcoma, neurosarcoma
Osteoarthropathy	Neurofibroma, neurilemoma, mesothelioma
Vertebral abnormalities	Enteric cysts
Fever of unknown origin	Lymphoma
Alcohol-induced pain	Hodgkin lymphoma
Opsomyoclonus	Neuroblastoma

Fig. 54.1. Anterior mediastinal germ cell tumor with extension into the left hemithorax.

in the case of a residual mass, there is little, if any, role for surgical interventions.[9]

Nonseminomatous Germ Cell Tumor

NSGCTs can include embryonal carcinoma, yolk sac carcinoma, choriocarcinoma, or a mixed histology. Primary mediastinal NSGCT appears to be biologically distinct from testicular NSGCT and is associated with a poor prognosis.[13] Primary mediastinal NSGCTs grow rapidly and metastatic disease is found in 80% of patients.[14] Overall survival after multimodality treatment is 40% to 50%. Hematologic malignancies present with NSGCT in 6% of cases, most commonly in patients with acute megakaryoblastic leukemia, and myelodysplastic syndrome is the most common.[15] The serum AFP level is elevated in 80% of patients and the beta-hCG level is elevated in 30% to 35%. Substantial elevation of tumor marker levels can preclude biopsy.[12] However, if biopsy is performed, fine-needle aspiration can be ambiguous and is discouraged in favor of core-needle biopsy or anterior mediastinotomy.[16]

The standard treatment for NSGCT is four courses of bleomycin, etoposide, and cisplatin; ifosfamide has been recommended over bleomycin to avoid pulmonary complications prior to surgical resection.[12] Residual mass after chemotherapy should be surgically resected, regardless of the serum marker levels; the prognosis is poor for patients with unresectable residual masses. When active germ cell cancer is present in the surgical specimen, two additional courses of chemotherapy should be given. Patients who have no residual tumor should be followed closely with history and physical examination, determination of serum markers, and CT. Patients who have disease recurrence have a particularly poor prognosis, although a small number of patients may benefit from salvage chemotherapy.[13] A 20% survival rate following surgical resection for relapsed primary mediastinal NSGCT has also been reported.[17]

LYMPHOMA

Lymphomas represent a variety of hematologic neoplasms. Proper management of lymphoma depends on subtyping and staging. Approximately 15% of mediastinal masses are lymphomas, typically in the anterior or middle compartment (Fig. 54.2). About 90% of mediastinal lymphomas represent disseminated disease, and one-third are Hodgkin lymphomas. Most patients present with some combination of systemic B symptoms, and symptoms associated with local compression.[18] Positron emission tomography is frequently used to stage and monitor the progress of lymphoma.[19]

Hodgkin Lymphoma

Mediastinal involvement occurs in as many as two-thirds of Hodgkin lymphoma. Diagnosis typically requires tissue quantities only obtainable by surgical biopsy. Typically, video-assisted thoracoscopy (VATS) or anterior mediastinotomy will yield definitive samples; however, mediastinoscopy is not always sufficient.

Fig. 54.2. Lymphoma in the anterior mediastinum.

CD15- and CD30-positive Reed-Sternberg cells, which are diagnostic for Hodgkin lymphoma, can be difficult to identify in a small biopsy.[18] Disease is staged according to the Ann Arbor Staging System;[20] early-stage Hodgkin lymphoma is treated with chemoradiation therapy and late-stage disease is treated with chemotherapy only.[21]

Non-Hodgkin Lymphoma

Large B-cell lymphoma and lymphoblastic lymphoma are the most common forms of non-Hodgkin lymphoma of the mediastinum. As in Hodgkin lymphoma, a sizable biopsy sample is often required for diagnosis. However, lymphoblastic lymphoma is usually first identified in bone marrow and peripheral blood; thus a mediastinal biopsy is not necessary. Lymphoblastic lymphoma is particularly aggressive, and treatment with chemotherapy and possible bone marrow transplant should not be delayed by staging procedures. Large B-cell lymphoma is treated with chemotherapy, and some centers also use radiotherapy for the treatment of B-cell lymphoma and lymphoblastic lymphoma.[18]

NEUROGENIC TUMORS

Approximately three-quarters of posterior mediastinal tumors are neurogenic (Fig. 54.3). These neurogenic tumors arise from the sympathetic chain or intercostal rami, and they most commonly take the forms of nerve sheath tumors (schwannoma and neurofibroma). Nearly all neurogenic tumors are benign, and approximately 30% of neurofibromas are associated with von Recklinghausen disease. Neurogenic tumors may erode osseous structures; this contributes to the development of an intraspinal (dumbbell) extension. MRI is essential if intraspinal involvement is suspected, as failure to recognize involvement can result in devastating spinal cord injury during attempted excision; resection of intraspinal tumor requires neurosurgical expertise. Simple nerve sheath tumors, whether benign or malignant, should be surgically resected, and a VATS approach is usually sufficient. Relative contraindications for complete resection include a mass greater than 6 cm and spinal artery involvement. Chemotherapy and radiotherapy may be used when complete resection is not possible.[4]

BENIGN CYSTIC MASSES

Bronchogenic Cysts

Bronchogenic cysts arise from errors in embryonic budding of the tracheobronchial tree (Fig. 54.4); they are the most
common mediastinal cysts and are frequently found behind the carina. The majority of bronchogenic cysts are discovered before the onset of symptoms, but most do eventually cause symptoms. Bronchogenic cysts can cause local compression and erosion and may become infected.[22] Resection of asymptomatic cysts can be controversial, but because of their potential to cause later complications and the favorable outcomes from early surgical intervention, VATS or mediastinoscopic resection is recommended.[22–24]

Esophageal Cysts

Esophageal cysts, also called esophageal duplications, arise in a similar manner as bronchogenic cysts. Like bronchogenic cysts, esophageal cysts can also cause local compression and may become infected. There is also risk of hemorrhage and rupture into the esophagus or airways. VATS excision is recommended, with care taken to minimize disruption of the esophageal muscularis.[22]

Pericardial Cysts

Pericardial cysts are mesothelium-derived and in close proximity to the pericardium. Pericardial cysts are typically benign and require no intervention. However, a growing pericardial cyst can cause hemodynamic compromise, and excision should be performed for symptomatic patients.[25] VATS is recommended, if feasible.

SUBSTERNAL GOITER

Goiters are enlargements of the thyroid and are deemed substernal when more than half of the gland extends inferior to the sternal notch (Fig. 54.5). Substernal goiters are the most common superior mediastinal tumors, usually found in the anterior mediastinum; however, 10% to 15% of substernal goiters are found in the posterior compartment.[26] The most common symptoms of substernal goiters are caused by local compression and include dyspnea, cough, and hoarseness. Approximately 25% of patients will be asymptomatic. A palpable thyroid is present in 88% of patients, and 16% of patients have hyperthyroidism.[27] Serum levels of thyroid-stimulating hormone, free T4, and total T3 can be useful in the diagnosis and detection of subclinical hyperthyroidism.[28] Spirometry can assess the extent of airway compression and may identify abnormalities in asymptomatic patients. CT is used to determine the extent and position of the goiter. Although malignancy is possible, needle biopsy is not indicated, as the malignant focus may be missed and its presence does not alter the operative indication.[29] Presence of substernal goiter is itself an indication for resection. Further enlargement worsens compression-associated symptoms and can complicate surgical

Fig. 54.3. Paravertebral mass typical of neurogenic tumors.

Fig. 54.4. Bronchogenic cyst in the visceral mediastinum.

treatment that would otherwise be associated with low post-operative morbidity.[27] Total thyroidectomy is recommended and can usually be accomplished by a collar incision. When the extent of thoracic involvement does not permit resection by a collar incision, possible approaches include manubrial split, sternotomy, and thoracotomy. Postoperative complications are infrequent and include hypoparathyroidism and recurrent laryngeal nerves paralysis.[29]

PARATHYROID ADENOMA

Primary hyperparathyroidism is most commonly a result of adenoma of the parathyroid glands (Fig. 54.6). Approximately 22% of parathyroid adenomas are found in a mediastinal parathyroid gland.[30] Resection of the tumor is curative in nearly every case.[31] The preferred surgical approach is minimally invasive and relies on precise preoperative localization. The mainstay of parathyroid adenoma localization is technetium-99m sestamibi scintigraphy; when combined with three-dimensional single-photon emission CT, the sensitivity and specificity are high.[32] Ultrasound is often used to complement other modalities. Localization has no diagnostic role and is used only for preoperative planning in biochemically proven cases. Most mediastinal parathyroid tumors can be resected transcervically, and videomediastinoscopy may be useful in difficult cases. VATS has also been used for the resection of parathyroid adenomas, but precise localization is particularly important with this approach. Intraoperative monitoring of the parathyroid hormone level is used to confirm systemic cure.[33]

LEIOMYOMA

Leiomyoma in the mediastinum usually arises from the esophagus or large vessels (Fig. 54.7). Primary mediastinal leiomyoma not associated with adjacent organs is exceedingly rare.[34] These lesions are firm and well circumscribed, and symptoms are typically due to local compression. Complete excision is the definitive treatment;[35] esophageal leiomyoma is treated using VATS enucleation.[36]

SURGICAL APPROACH

The appropriate surgical approach depends on the nature and position of the lesion within the mediastinum. A minimally invasive approach is often possible for uninvolved benign masses. More aggressive exposure is used for large and/or malignant tumors, for which complete resection is crucial and dissection is potentially challenging.

Access to small anterior midline tumors is commonly approached by a median sternotomy, with the patient in the supine position with the arms tucked to the side. In this position, the mediastinal vasculature, left and right hemithoraces, and lung hila are well exposed; however, exposure of the left lower lobe and posterior aspect of the lungs is poor. In some cases, a partial sternum-sparing approach will allow for sufficient exposure, such as a manubrial split for superior mediastinal mass. A collar incision may also provide sufficient access to the superior mediastinum if the mass can be accessed through the neck.

For large tumors extending into either of the hemithoraces, a hemiclamshell incision provides good exposure.[37] The patient should be placed in the supine position, with a longitudinal roll

Fig. 54.5. Substernal goiter in the superior mediastinum.
Fig. 54.7. Leiomyoma of the thoracic esophagus.

elevating the thoracotomy side by 30 degrees and the arms tucked to the side. The ipsilateral lung may be collapsed to allow for anatomic resection of involved lobes, if necessary, and access to the posterolateral aspect of the tumor. If the tumor has substantial cervical extension, the upper sternotomy may be extended superiorly along the anterior border of the sternocleidomastoid.[38] This approach exposes the carotid and jugular vessels if vascular dissection is necessary. Rarely, resection of the subclavian vessels will be needed for a GCT. In these cases, a so-called trap door incision, created by extending the upper sternotomy along the superior margin of the clavicle, will allow for appropriate exposure. Excision of the medial third of the clavicle may also assist in exposure of the tumor.

A large tumor that extends into both right and left hemithoraces may be resected through a bilateral clamshell incision, with the patient in the supine position and the arms abducted or flexed over the forehead. A curvilinear incision should be made along the inframammary crease from the right to left anterior axillary lines for access to the fourth intercostal space; the mammary vessels are then ligated, and the sternum is divided transversally. Retraction is provided by two Finochietto retractors. An upper sternal split may be made in the event that an initial clamshell approach provides inadequate exposure of the superior mediastinum.

CONCLUSION

The mediastinum is dense with multiple organ systems, and the tumors thereof are equally varied. Appropriate management and surgical approach require careful assessment of each case. Indications for chemotherapy, radiotherapy, and surgical treatment of mediastinal GCTs vary according to the histologic subtypes. Surgical exposure of large mediastinal GCTs is often best approached by hemiclamshell or bilateral clamshell incision. Lymphoma of the mediastinum is usually a disseminated disease. Surgical biopsy provides sufficient tissue for diagnosis, but treatment is nonsurgical and based on the subtype and stage. Posterior masses are typically neurogenic tumors. MRI is essential for assessment of intraspinal involvement. Small uninvolved neurogenic tumors should be treated by VATS. Congenital cystic masses of the bronchial tree and esophagus should be resected by minimally invasive approach. Resection of pericardial cysts is reserved for symptomatic patients. A substernal goiter is an indication for total thyroidectomy. A collar incision is often sufficient, but more involved goiters can require a sternal split. Parathyroid adenomas causing primary hyperparathyroidism should be resected with a minimally invasive approach. Precise preoperative localization of parathyroid adenoma is crucial to successful resection. Leiomyomas are typically of the esophagus or large vessels and should be excised.

55 Neuroendocrine Tumors of the Lung Other Than Small Cell Lung Cancer

Krista Noonan, Jules Derks, Janessa Laskin, and Anne-Marie C. Dingemans

SUMMARY OF KEY POINTS

- Neuroendocrine cancers of the lung share some fundamental pathology features but span a broad range of clinical behaviors.
- The clinical behavior varies with the degree of differentiation: typical carcinoids are more indolent and localized, atypical carcinoids are intermediate and tend to spread systemically, and large cell neuroendocrine cancers are high grade and aggressive similar to small cell cancers.
- Unlike midgut carcinoids, bronchial carcinoids seldom present with carcinoid syndrome.
- Surgical resection is the preferred treatment for early-stage disease.
- Standard chemotherapy treatments for metastatic disease are platinum based but little phase III evidence exists to support a specific regimen.
- Clinical trials of molecularly targeted therapy are urgently needed.

Pulmonary neuroendocrine tumors represent a spectrum of tumors that develop from neuroendocrine cells of the bronchopulmonary (BP) epithelium. Although neuroendocrine tumors have similar morphologic and immunohistochemical (IHC) features, they span a broad clinical–pathologic spectrum and are characterized by differing biologic behavior. Typical carcinoids are low-grade, slow-growing malignancies that rarely metastasize; atypical carcinoids are intermediate-grade malignancies; and large cell neuroendocrine carcinoma (LCNEC) and small cell lung cancers (SCLCs) are high-grade carcinomas.[1]

BP carcinoid tumors are part of a heterogeneous group of neuroendocrine tumors arising from the Kulchitzky cells present in the bronchial mucosa and account for approximately 1% to 2% of all lung malignancies in adults. The incidence of BP carcinoid tumors in the United States has increased by approximately 6% per year over the past 30 years, with rates ranging from 0.2 to 2 per 100,000 individuals per year.[2–5]

LCNEC is an uncommon tumor of the lung with an incidence of approximately 3%, as reported in surgical case series.[6] LCNEC has only recently been described as a form of high-grade lung cancer that expresses neuroendocrine features. Because of the low incidence, evolving classification, and high degree of diagnostic difficulty, many aspects of LCNEC are still unknown.

CLASSIFICATION

Although neuroendocrine tumors of the lung exhibit divergent behavior, they share similar morphologic and biochemical characteristics, including an ability to secrete neuropeptides, and the presence of neuroendocrine granules. Of the pulmonary carcinoids, 80% to 90% are typical carcinoids, whereas 10% to 20% are atypical carcinoids.

Before the introduction of LCNEC, neuroendocrine tumors of the lung were subdivided into three classes: typical carcinoids, atypical carcinoids, and SCLC. In 1991, after reviewing a set of neuroendocrine tumors (typical and atypical carcinoids and SCLC), Travis et al.[7] found a group of tumors that deviated from the known classification in prognosis and morphology. They classified this new group as a high-grade neuroendocrine non small cell lung cancer (NSCLC) and placed it in between atypical carcinoid and SCLC.

In 1991, LCNEC was recognized in the World Health Organization (WHO) classification of lung tumors as a large cell carcinoma (LCC) based on its cytologic parallels (large cell size and abundant cytoplasm).[7] LCNEC is different from other LCCs because of its combination of neuroendocrine differentiation and morphology. Other LCC histologies can express neuroendocrine morphology, but not in combination with neuroendocrine differentiation.

Other regularly used terms referring to LCNEC are neuroendocrine carcinoma (NEC) grade 3, poorly differentiated NEC, and high-grade NSCLC; however, these terms are also used for SCLC and thus may include tumors with SCLC and/or LCNEC histology.

The most recent WHO/International Association for the Study of Lung Cancer classification of neuroendocrine lung tumors was established in 2004 by Travis et al.[8] (Table 55.1).[9]

DIAGNOSIS

Histology

Bronchopulmonary Carcinoids

A diagnosis of BP carcinoid can be challenging because of small biopsies, crush artifacts, and poor fixation of the specimens. BP carcinoids are composed of cells containing round to oval nuclei, a moderate amount of eosinophilic cytoplasm, finely granular chromatin, and indistinct or absent nucleoli. The cells tend to be uniform and can be arranged in a variety of patterns, including trabecular, palisading, spindle cell, glandular, follicular, rosette-like, sclerosing, clear cell, and papillary.[7,10] Rarely, BP carcinoids can show oncocytic or melanocytic features.[7,11,12] Stromal hyalinization, calcification, ossification, and amyloid deposition can also occasionally be seen.[13,14] Two features that distinguish atypical from typical carcinoids are the presence of necrosis and number of mitoses per square millimeter. Typical carcinoids must have no necrosis and fewer than 2 mitoses/ 2 mm² (10 high-power fields [HPFs]; Fig. 55.1). Atypical carcinoids should have either punctate necrosis or 2 mitoses to 10 mitoses/2 mm² (10 HPFs; Fig. 55.2),[15] and exhibit neuroendocrine differentiation, confirmed by more than 10% of positive cells for a neuroendocrine marker, such as chromogranin, synaptophysin, and/or neural cell adhesion molecule (NCAM; CD56).

TABLE 55.1 Criteria for Diagnosis of Neuroendocrine Tumors From the World Health Organization Guidelines[8,9]

Neuroendocrine Tumor	Criteria for Diagnosis
Typical carcinoid	Tumor with carcinoid morphology and <2 mitoses/ 2 mm² (10 HPFs), lacking necrosis, and ≥0.5 cm
Atypical carcinoid	Tumor with carcinoid morphology with 2–10 mitosis/2 mm² (10 HPFs) OR necrosis (often punctate)
Large cell neuroendocrine carcinoma	Tumor with a neuroendocrine morphology (organoid nesting, palisading, rosettes, trabeculae)
	High mitotic rate: ≥11/2 mm² (10 HPFs), median of 70/2 mm² (10 HPFs)
	Necrosis (often large zones)
	Cytologic features of a nonsmall cell carcinoma (NSCLC): large cell size, low nuclear-to-cytoplasmic ratio, vesicular, coarse or fine chromatin, and/or frequent nucleoli. (Some tumors have fine nuclear chromatin and lack nucleoli, but qualify as NSCLC because of large cell size and abundant cytoplasm.)
	Positive immunohistochemical staining for one or more neuroendocrine markers (other than neuron-specific enolase) and/or neuroendocrine granules by electron microscopy
Small cell carcinoma	Small size (generally less than the diameter of three small resting lymphocytes)
	Scant cytoplasm
	Nuclei: finely granular nuclear chromatin, absent or faint nucleoli
	High mitotic rate: ≥11/2 mm² (10 HPFs), median of 80/2 mm² (10 HPFs)
	Frequent necrosis often in large zones

HPFs, high-power fields.

On slides stained with hematoxylin and eosin, these neuroendocrine growth patterns are recognized as organoid nesting, trabeculae, rosette-like structures, or palisading cells (Fig. 55.3). All LCNECs have a high proliferative rate, with more than 10 mitoses/mm² on HPF examination. Total HPF examination should include an area of 2 mm², preferably in the regions with the highest mitotic activity and viable cells. Besides high mitotic activity, areas of necrosis are frequently noted. By definition, all LCNECs express neuroendocrine differentiation, which is immunohistochemically confirmed when focal activity (more than 10% positive cells) is found with use of neuroendocrine markers (chromogranin, synaptophysin, or NCAM [CD56]) (Fig. 55.4). The presence of neuroendocrine granules on electron microscopy examination is also sufficient for diagnosis of LCNEC. The morphologic features of LCNEC resemble those of NSCLC, because the cells are large with abundant eosinophilic cytoplasm and a low nuclear-to-cytoplasmic ratio. The nuclei are round to oval shaped with granular chromatin (so-called salt and pepper). Nucleoli are also frequently seen (Fig. 55.3).

Cytology

It can often be challenging to make a diagnosis of atypical or typical carcinoid on cytologic examination, given the limited number of cells and the absence of tissue structure. BP carcinoids present as small, polyhedral-shaped cells with oval or round nuclei. The cells are arranged in a regular fashion, consisting of nests, sheets, ribbons, or spindle structures, separated by a fibrovascular stroma; however, a spindle-cell variant exists.[10,16–18] Necroses are only seen in atypical carcinoids,[15,19] which have 2 mitoses to 10 mitoses/10 HPFs. Typical carcinoids have less than 2 mitoses/10 HPFs. Nucleoli are common in atypical carcinoids and are occasionally seen in typical carcinoids; both typical and atypical carcinoids have finely granular chromatin.

Although cytologic smears are not suitable for establishing a diagnosis of LCNEC, cytologic examination can be useful during the initial evaluation of a tumor. On cytologic smears, the presentation of LCNEC is medium-to-large round or polygonal cells arranged in groups or as a single cell. The LCNEC cells can be arranged in rosette-like structures or peripheral palisading cells, and nuclear molding can be seen. In the background of the cytologic smears, necrosis and nuclear streaking are commonly seen. LCNEC cells have scant or moderate amounts of cytoplasm with a high nuclear-to-cytoplasmic ratio, which is dependent on the fixation material (air dried vs. alcohol

Fig. 55.1. Typical carcinoid shows an organoid nesting growth pattern and is composed of a homogeneous population of cells with finely granular cytoplasm chromatin and eosinophilic cytoplasm. No necrosis is seen, and if present, mitoses are rare. *(Courtesy Brenda Smith, British Columbia Cancer Agency, Vancouver, BC, Canada.)*

Large Cell Neuroendocrine Carcinoma

The diagnosis of LCNEC is also complex and often requires a large surgically resected lung biopsy specimen, mainly because small biopsy specimens are susceptible to crushing artifacts that may disturb the neuroendocrine morphology and cell size, two features that are critical for the diagnosis of LCNEC. To establish a LCNEC diagnosis, several histologic criteria have to be confirmed (Table 55.1). LCNECs express a neuroendocrine growth pattern (morphology) that is similar to that seen in low-grade neuroendocrine tumors (carcinoids).

Fig. 55.3. (A) Large cell neuroendocrine carcinoma (hematoxylin and eosin, 100×). Nests of tumor cells with peripheral palisading and central necrotic foci and rosette-like structures. (B) High-magnification view (hematoxylin and eosin, 400×). Note large cells with abundant eosinophilic cytoplasm and round to oval nuclei with a fine granular (so-called salt-and-pepper) to more clumped chromatin with occasional nucleoli. Numerous mitotic figures and necrosis *(upper left corner)* are present. *(Courtesy Dr M. Béndek, Maastricht University Medical Centre, the Netherlands.)*
Fig. 55.4. Immunohistochemistry of a pulmonary large cell neuroendocrine carcinoma. (A) Granular cytoplasmic staining with chromogranin-A (100×); and (B) diffuse membrane positivity of CD56 (neural cell adhesion molecule, 100×) can be seen. *(Courtesy Dr M. Béndek, Maastricht University Medical Centre, the Netherlands.)*

fixated).[20] Most often, the nuclear shape is round or oval, and nuclear mitoses are frequently found. Nuclear pleomorphism and nucleoli are occasionally present.

Differential Diagnosis

Histology

Diagnosing LCNEC is a highly complex process and was addressed in interobserver studies on resected pulmonary neuroendocrine tumors. In a study performed by a panel of expert lung pathologists, a moderate interobserver variation with κ ranging from 0.35 to 0.81 was reported.[21–23] The most common overlapping diagnoses with LCNEC were SCLC, LCC, atypical carcinoid, basaloid carcinoma, and the poorly differentiated NSCLC tumors expressing a neuroendocrine phenotype.[6,21] Undoubtedly, these uncertainties are secondary to the morphologic and cytologic similarities of lung tumors with LCNEC. In the interobserver studies of BP carcinoids, there was a variability of results, from substantial agreement (κ > 0.7) in one study[21] to fair to moderate (κ = 0.39–0.87) in another study by Lee et al.[24] The fact that there were only two pulmonary pathologists in the Lee et al.[24] study may have had an influence on the results.

Although differentiating pulmonary NEC from overlapping tumors can be a challenge, several criteria may help guide the diagnosis. The differentiation of atypical carcinoid from high-grade NEC can be achieved with the help of the mitosis count; on average, 2 mitoses to 10 mitoses/2 mm^2 are expressed in atypical carcinoid compared with more than 11 mitoses/2 mm^2 in high-grade NEC. Moreover, necrosis in atypical carcinoid predominantly consists of punctate foci, whereas necrosis is more prominent in LCNEC.[15]

A distinction between LCNEC and SCLC can be established only with the help of cytology-based criteria. Compared with

LCNEC, SCLC has a smaller cell size (less than the diameter of three lymphocytes), a higher nuclear:cytoplasmic ratio, and absent or faint nucleoli. Although it was demonstrated in several studies that LCNEC and SCLC had a considerably different mean cell size, the standard deviations did overlap. Therefore whether cell size is the most adequate criteria to differentiate LCNEC from SCLC should be questioned.[25–27] The mitosis count, which is useful in atypical carcinoid, is not helpful in differentiating LCNEC from SCLC.

Both SCLC and typical carcinoid cells may be similar in size and shape and may appear uniform. Variation in size may be a helpful distinguishing feature, from less than onefold (mild) in typical carcinoid to more than twofold to threefold in atypical carcinoid and high-grade neuroendocrine tumors.[28–30] In addition, SCLC cells are arranged in more cohesive groups and three-dimensional clusters, which are not present in bronchial carcinoids.[31–33] Ki-67 (MIB-1) staining may also be useful because SCLC will show a proliferation index of more than 50%, whereas carcinoids have a proliferation index of less than 20%.[34]

In addition to atypical carcinoid and SCLC, other forms of nonsmall carcinomas—such as the basaloid carcinoma—must be distinguished from LCNEC. The morphology of basaloid carcinoma is comparable to that of LCNEC; differentiation is possible with the help of IHC with neuroendocrine markers, which are negative in basaloid carcinomas.[8]

As for the basaloid carcinoma, poorly differentiated adenocarcinomas or squamous cell carcinomas can also be distinguished from LCNEC with the help of IHC markers, which are addressed later in the chapter.

Cytology

The value of cytology in the diagnosis of BP carcinoids has been examined in several studies. The main factor in distinguishing typical carcinoid from high-grade neuroendocrine neoplasms or other carcinomas is adequate evaluation of nuclear features. Typical carcinoids tend to have fine, evenly dispersed granular chromatin with inconspicuous or undetectable nucleoli; SCLC has coarsely granular chromatin and occasional chromatin clumping, and poorly differentiated carcinoma has more clumped chromatin in a vesicular nucleus.[29,35,36] The cytologic diagnosis of atypical carcinoid can be quite difficult, as it has features that may be found in typical carcinoid or SCLC. In atypical carcinoid, tumor cells tend to be larger than those noted in typical carcinoid or SCLC, and nuclear pleomorphism and atypia are also common. The finely granular chromatin is present, and mitoses range from 2 HPF to 10/10 HPFs.[37]

Compared with histology, misdiagnoses are even more common when LCNEC is diagnosed on cytology specimens. Preoperatively obtained cytologic smears from confirmed resected LCNEC have been reviewed in several studies.[20,38,39] In about 80% of smears, the cytology was initially diagnosed as NSCLC, SCLC, LCC with neuroendocrine features, poorly differentiated adenocarcinoma or squamous cell carcinoma, or combined SCLC. However, during the period between 1990 and the beginning of 2000, when the majority of the series in these studies were diagnosed, LCNEC was a new entity and pathologists may have been unaware of it. In 2005, a study was published in which 9 (90%) of 11 LCNEC cases ($N = 11$) were correctly diagnosed before surgery.[40]

Cytokeratin Markers. High-molecular-weight cytokeratin (CK) types 1, 5, 10, and 14 (antibody clone 34E1β2) are almost solely expressed in non-NECs such as basaloid carcinoma and poorly differentiated adenocarcinoma or squamous cell carcinoma. In tissue microarray panel studies, 3% to 17% of pure LCNEC[41] showed positive staining for clone 34E1β2.[26,40,42] Other commonly used high-molecular-weight CK types such as CK5/6,

CK7, and CK20 were positive in 2% to 13%, 57% to 77%, and 2% to 10% of LCNECs, respectively.[43,44] CK18 and CK19 were positive in 97% and 59%, respectively.[44,45] In combined LCNEC, expression of 34E1β2 has been noted in the adenocarcinoma/squamous cell carcinoma component.[40]

Markers for Differentiating Atypical From Typical Carcinoid. Counting mitoses may be challenging, especially if there is crush artifact or poor sample fixation. Ki-67 expression may be used as a surrogate to help differentiate between atypical and typical carcinoids. In a study by Warth et al.,[46] a low interobserver agreement was demonstrated when using mitotic count (median κ = 0.213) to distinguish between atypical and typical carcinoids, and the overall κ for Ki-67 was higher (0.746). Ki-67 expression is also prognostic; carcinoids with Ki-67 expression higher than 5% were associated with a worse overall survival.[37,47,48]

Markers for Differentiating Large Cell Neuroendocrine Carcinoma From Squamous Cell Carcinoma. In addition to high-molecular-weight CKs, markers such as desmocollin-3 and p63 may be useful in discriminating poorly differentiated squamous cell carcinomas from LCNEC. Desmocollin-3 was negative in 99% of all pure LCNECs and therefore appears to be a promising specific marker but requires further validation.[43] Expression of p63, a highly sensitive and specific marker for diagnosing squamous cell carcinomas, was detected in 0% to 18% of LCNECs. Therefore p63 may not be appropriate as a specific marker for poorly differentiated NSCLC when LCNEC is a possibility in the differential diagnosis.[26,43,49] When compared with p63, the nontransactivating isoform of the p63 gene, delta Np63 (p40), was found to be a more reliable marker for squamous differentiation. Expression of p40 was lower compared with p63 in LCNEC and therefore more accurate.[50] These results were confirmed in a study subtyping LCC with IHC; none of the confirmed LCNECs stained for p40.[51]

Markers for Differentiating Large Cell Neuroendocrine Carcinoma From Adenocarcinoma. Thyroid transcription factor-1 (TTF-1), a marker commonly used in defining the appropriate histotype of lung cancer and that is also sensitive and specific for lung adenocarcinoma, is expressed in about 50% of all resected lung LCNEC. The expression ranges of TTF-1 mainly depend on the antibody used. The more sensitive clone, SPT24, is positive in 23% to 77% of LCNECs,[43,44,52] and the 8G763 clone is positive in 23% to 48%.[42,43,53,54] Therefore TTF-1 is not useful in differentiating LCNEC from poorly differentiated NSCLC (adenocarcinoma).

A new marker named Napsin-A, specific to adenocarcinomas, was negative in 100% of LCNECs, but further validation of this marker is required.[43] In addition, collapsin response mediator protein (CRMP) is known to be involved in neurogenesis and was studied in a group of lung tumors. CRMP was expressed in 4 (100%) of 4 LCNECs and in 54 (100%) of 54 SCLCs. The expression of CRMP was negative in 0% of 22 adenocarcinomas and positive in 1 (8%) of 12 squamous cell carcinomas. The number of LCNECs studied was very small, but CRMP was shown to be a promising marker that also requires further validation.[55]

Markers for Differentiating Bronchopulmonary Carcinoid From Small Cell Lung Cancer. Ki-67 staining may be of value because SCLC shows a proliferation index of more than 50%, whereas carcinoids have a proliferation index of less than 20%.[34,56,57] K homology domain (KOC) protein and paired box gene 5 (PAX5) expressions have been evaluated in small samples.[58,59] The KOC protein was strongly positive in 90% of SCLCs and negative in 20 of 21 cases of typical and atypical carcinoids. PAX5 expression was present in 29 (78%) of 37 high-grade neuroendocrine tumors and 0 of 51 typical and atypical

carcinoids. Validation in larger samples is required before such markers are used routinely for differentiation.

Markers for Differentiating Large Cell Neuroendocrine Carcinoma From Small Cell Lung Cancer. As of the time of publication, distinguishing LCNEC from SCLC by IHC is not feasible. Several markers have been proposed, but lack practical usefulness. Both CK7 and 18 are commonly expressed in LCNEC and were reported in several studies to have a considerably higher expression intensity in LCNEC compared with SCLC.[44,60] These results were similar in studies comparing the expression intensity of E-cadherin and β-catenin in LCNEC and SCLC, where both markers were shown to have considerably higher expression intensity in LCNEC.[44,60] Villin1, a promising marker located in the brush border of epithelial cells, was found to be expressed in 62% of LCNECs and 4% of SCLCs.[45,60] However, these results must be confirmed in larger studies. In a smaller study, IHC expression of neuronatin was examined in LCNEC and SCLC after an increased complementary DNA transcription of neuronatin in LCNEC was noted. Among the SCLC samples, 8% were positive for neuronatin with IHC staining compared with 43% among the LCNEC samples.[61] A neurogenesis-regulating gene (NeuroD) was also found to be differentially expressed between LCNEC and SCLC.[26] NeuroD was expressed in 53% of LCNECs and 13% of SCLCs. Therefore several markers may differentiate LCNEC from SCLC, but none of these is very specific or sensitive and further validation is required.

Markers for Differentiating Atypical and Typical Carcinoids From Large Cell Neuroendocrine Carcinoma. Separating atypical and typical carcinoids from LCNEC is possible with the Ki-67 index. The expression index in LCNEC is approximately 40% (range, 25% to 52%); for carcinoids, the expression index is reported to be below 20% (typical carcinoid, less than 2%; atypical carcinoid, less than 20%, typically ± 10%).[34,56,57,62] Consequently, Ki-67 may be useful in differentiating LCNEC from atypical and typical carcinoids, although the diagnosis has to be confirmed with a mitoses count.

Immunohistochemical on Cytology. IHC neuroendocrine markers such as chromogranin, synaptophysin, and NCAM were found to be positive in 28% to 31%, 64% to 75%, and 45% of cytologic smears, respectively.[20,63]

MOLECULAR BIOLOGY

Approximately 5% of BP carcinoids may occur as a result of the multiple neuroendocrine neoplasia type 1 gene (MEN1); 95% are sporadic tumors of uncertain etiology. Various techniques have been used to evaluate the molecular biology of BP carcinoids, including in vitro cell line studies, chromosomal evaluation, comparative genomic hybridization (CGH), polymerase chain reaction, and, most recently, whole genome sequencing. Swarts et al.[64] performed an extensive review of the molecular biology of neuroendocrine lung tumors, and Cakir and Grossman[65] examined the molecular pathogenesis of BP carcinoids. The molecular basis of LCNEC is also still unknown. SCLC and LCNEC are known as highly undifferentiated pulmonary tumors that express similar characteristics. However, according to WHO classification, LCNEC is categorized as a subtype of LCC. The molecular biology of LCNEC, determined by different techniques, has been addressed in several studies and the findings were compared with SCLC and LCC.

Loss of Heterozygosity

BP carcinoids may have loss of heterozygosity (LOH) on a variety of different chromosomes. LOH at 11q has been seen in 27% to 55.5% of typical carcinoids and 0% to 73% of atypical carcinoids.[66,67] LOH at 11q13, the locus of the MEN1 gene, was detected in 50% to 63.6% of atypical carcinoids and 22% to 73% of typical carcinoids.[66,68] In several other small studies, LOH was found on several chromosomes in bronchial carcinoids, including 3p14.2 (fragile histidine triad gene);[68,69] 5q;67 5q21 (adenomatous polyposis coil/mutated in colon cancer gene);68 9p;67,70 9p21 (p16);68 9q;67 13q;67 13q14.1–14.2 (retinoblastoma [Rb]);68 17p;67 17q13.1 (p53);[68,70] and X (microsatellite markers).[71]

In an evaluation of LOH with microsatellite markers at chromosomes 3p, 5q, 9p, 11q, and 13q, several similarities between SCLC and LCNEC were demonstrated.[68] These chromosomal findings were in accordance with the results from another study that compared LOH in LCC, LCNEC, and SCLC.[72] LOH was examined for chromosomes 3p, 5q, 9p, 10p, 10q, and 13q. Significant differences were noted between all three tumor types except for SCLC and LCNEC, emphasizing the close relation between these high-grade neuroendocrine tumors.

LOH has also been examined in combined SCLC and LCNEC tumors. Depending on the region being examined, combined tumors can express an SCLC or LCNEC phenotype. Investigators separately studied SCLC and LCNEC regions and found a high degree of similarity in the genetic profile. These findings suggest that there is a common origin of combined SCLC and LCNEC tumors.[71]

Chromosomal Aberrations

CGH and other genetic analyses to assess chromosomal aberrations in BP carcinoids,[73–79] high-grade pulmonary NECs,[80–85] or both have been examined in several studies.[85–88] Swarts et al.[64] performed a meta-analysis of these studies, which included typical carcinoids, 38 atypical carcinoids, 33 LCNECs, 48 SCLCs, and 11 unclassified high-grade neuroendocrine tumors. Chromosomal aberrations more than 10 Mb were much more frequent in LCNEC (average 13.7 aberrations per tumor) and SCLC (18.8 aberrations per tumor), as compared with atypical carcinoids (6.1 aberrations per tumor) and typical carcinoids (2.8 aberrations per tumor). The investigators assumed that smoking habit may explain the differences. The most frequent aberrations for bronchial carcinoids are –11q, +19P, –13q, +19q, +17q, –11p, –6q, +16p, +20p, and –3p. These aberrations differ from those present in the high-grade neuroendocrine tumors, with the exception of 3p and 13q losses.

Chromosomal aberration in LCNEC and SCLC has also been studied. Through CGH, loss of chromosomes 3p, 4, 5p, 6q, 8p, 9p, and 21q, and gain in 5p, 8q, 12p, and 22 was found in three patients with LCNEC. Similarities between chromosomal aberrations in LCNEC and SCLC included loss of 3p, 4q, 5q, and 13q and gain of 5p. Noticeable chromosomal aberrations between SCLC and LCNEC were found at chromosomal arms 3q (gain), 10q (loss), and 17p (loss) in favor of SCLC, and gain of 6p in favor of LCNEC.[82] Compared with atypical carcinoid, no similarities were detected.[86] In a study by Peng et al.,[85] several similarities between LCNEC and SCLC were found when the genetic profiles were analyzed with high-density bacterial artificial chromosome array. Frequently gained loci were located at 1q, 2q, 3q, 5p, 7q, 8q, 12q, and 18q; lost loci were located at 1p, 3p, 4q, 5q, 10q, 13q, 16q, 17p, and 22q. Considerably different chromosomal aberrations compared between all stages of SCLC and LCNEC were located at 2q (gain), 3p (loss), 4q (loss), and 6p (loss). Although it may appear that SCLC and LCNEC share a common genetic profile, the majority of similarities may not be very specific, because numerous chromosomal aberrations are commonly encountered in other forms of lung cancer, including pulmonary NEC.

Microarray Comparison

Anbazhagan et al.[89] performed hierarchical clustering of gene expression profiles of two carcinoids, two SCLCs, and two brain tumors. Although the carcinoids clustered together with the brain tumors, SCLC was more closely related to normal bronchial epithelial carcinoma. Swarts et al.[90] used gene expression profiling to explore pathways involved in lung carcinoid progression and found that in carcinoids with poor prognosis, a significantly higher number of downregulated genes were located at chromosome 11q (p = 0.00017). In addition, a number of upregulated genes were found to be involved in the mitotic spindle checkpoint, the chromosomal passenger complex, mitotic kinase CDC2 activity, and the *BRCA*/Fanconi anemia pathway. At the individual gene level, BIRC5 (survivin), BUB1, CD44, IL20RA, KLK12, and OTP were independent predictors of patient outcome. For BIRC5, the number of positive nuclei was also related to poor prognosis within the group of carcinoids. Aurora B kinase and BIRC5, major components of the chromosomal passenger complex, were particularly upregulated in high-grade carcinomas and may therefore be indicative of therapeutic targets for these tumors.[90]

When examining the clinical behavior of high-grade neuroendocrine tumors, classification based on genetic profiling may be more appropriate than histologic classification. Jones et al.[91] examined complementary DNA microarray data obtained from neuroendocrine lung tumors (8 LCNECs [2 combined with SCLC], 17 SCLCs [2 combined with LCNEC], and 13 LCCs). Surprisingly, neither SCLC nor LCNEC clustered as single entities in the way that LCCs did. In support of this molecular description of neuroendocrine lung tumors, Shibata et al.[92] found three high-grade neuroendocrine subclasses when data from comparative genome hybridization were hierarchically clustered (8 SCLC and 15 LCNEC). The three subclass branches were subdivided into groups named BR1, BR2, and BR3. Patients in the BR2 group had a significantly different survival compared with the BR1 and BR3 groups (p = 0.028). However, contrary to findings from Jones et al.,[91] almost all SCLCs clustered.[92]

Mutation Analysis

In a recent study by Sachithanandan et al.[93] of patients with MEN1, 5% had been diagnosed with BP carcinoids. MEN1 is an autosomal dominant disorder associated with mutations in the gene locus on 11q13. MEN1 gene activation is evident in 70% of patients with atypical carcinoid, 47% with typical carcinoid, 52% with LCNEC, and 41% with SCLC. A single mutation was found in a small study of MEN1 in LCNEC.[94]

Capodanno et al.[95] assessed 190 patients with bronchial neuroendocrine tumors (75 typical carcinoids, 23 atypical carcinoids, 17 LCNECs, and 75 SCLCs) and found that there was an increasing frequency of phosphatidylinositol 3-kinase (PI3K) mutations, with increased biologic aggressiveness of the bronchial neuroendocrine tumors, except in LCNECs. PIK3CA mutations were present in 13% of typical carcinoids, 39% of atypical carcinoids, 31% of SCLCs, and only 12% of LCNECs.[95]

Mutations in LCNEC that are commonly encountered in lung cancer have been examined in several studies (Table 55.2). Kirsten rat sarcoma viral oncogene homolog (KRAS) and epidermal growth factor receptor mutations are uncommon in LCNEC, although there have been published reports in cases of combined LCNEC and adenocarcinomas.[68,96,97] Aberrant expression of anaplastic lymphoma kinase (ALK) by IHC was demonstrated in a single case of LCNEC. No ALK rearrangement or mutation was noted in further analyses.[98] Two PIK3CA mutations have been found at c.3145 G>A and c.3140 A>G.[95] In 29% of resected LCNECs, a mutation in the neurotropic tyrosine receptor kinase gene family was demonstrated.[96]

TABLE 55.2 Overview of Mutations Analyzed in Pure and Combined Large Cell Neuroendocrine Carcinoma of the Lung[a]

| Mutation | Type of LCNEC (Number of Samples With Mutation/Total Number of Samples) | | | |
	Pure	With SCLC	With Squamous Cell Carcinoma	With Adenocarcinoma
ALK	0/106[b]	ND	ND	ND
BRAF	0/24	2/9	0/3	ND
EGFR	1/62	0/10	0/3	0/8
KRAS	2/83	1/10	ND	1/9
NRAS	0/34	0/6	ND	ND
PIK3CA	2/43	1/10	ND	ND
ROS1	ND	ND	ND	ND
HRAS	1/17	0/8	0/3	ND
MEN1	1/13	ND	ND	ND

[a]Published data only.
[b]By immunohistochemical analysis.
LCNEC, large cell neuroendocrine carcinoma; *ND*, no data have been reported on this mutation in the specified type of lung carcinoma; *SCLC,* small cell lung cancer.

In a 2013 study, a large group of molecularly analyzed lung tumors was reported by the Clinical Lung Cancer Genome Project and Network Genomic Medicine.[99] A total of 261 lung tumors (31 LCCs) were included for unsupervised hierarchical clustering of gene expressions. Although the analyzed carcinoid tumors harbored no noteworthy mutations, a number of mutations were identified in pure LCNEC and the combination of SCLC and LCNEC (Table 55.2). Based on genetic modeling, the authors of the study were able to classify the majority of all LCCs as adenocarcinoma, squamous cell carcinoma, or SCLC. Thereby, the diagnosis of LCC as a separate entity was brought into question. Whole-exome (15 tumors) and transcriptome (10 tumors) sequencing of LCNEC showed overlapping mutations between LCNEC and SCLC (T53, RB1, and EP300). Several mutations typically found in adenocarcinomas or squamous cell carcinomas were detected in LCNEC, but these findings were not significant. Additional information about the whole-exome and transcriptome sequencing of LCNEC is expected to be published in the near future.[99]

Pathways

The p53 gene, which helps to maintain genomic stability, is mutated in approximately 4% of typical carcinoids, 29% of atypical carcinoids, 80% of LCNECs, and 75% of SCLCs.[68,70,100–104]

The p16/cyclin D1/Rb pathway is affected in 9% to 20% of typical carcinoids, 22% of atypical carcinoids, 62% of LCNECs, and 71% to 90% of SCLCs.[62,78,79,104–109] The Rb gene is a tumor suppressor with a critical role in cell cycle control through the regulation of the G_1 growth arrest. p16 is a cyclin-dependent kinase inhibitor that inhibits binding of cyclin-dependent kinases

to cyclin D1 and prevents phosphorylation (inhibition) of Rb. Therefore downregulation of p16 and Rb may lead to uncontrolled cell growth. Loss of Rb expression was demonstrated in 47% to 91% of LCNECs. Loss of p16 expression and overexpression of cyclin D1 were found more frequently in LCNEC than in SCLC.[26,57,62,72,110]

The intrinsic apoptosis pathway, including Bcl2, Bcl2L1, and BAX genes, has been found in several studies to be inhibited in high-grade neuroendocrine tumors, moderately affected in atypical carcinoids, and almost intact in typical carcinoids.[111,112]

The expression of AKT and mammalian target of rapamycin (mTOR) as part of the PI3K/AKT/mTOR pathway in a group of neuroendocrine lung tumors has also been evaluated in several studies; however, there were contradicting results for AKT expression (19% to 82%) and mTOR expression (50% to 77%) in these tumors.[113,114] Righi et al.[115] described a pattern of mTOR intensity expression that decreased from low- to high-grade neuroendocrine tumors. The authors also noted that mTOR expression correlated with SSRT-2/3 expression and hypothesized that mTOR may be a possible regulator of SSRT expression.

CLINICAL CHARACTERISTICS

BP Carcinoids

As a result of endobronchial obstruction and tumor ulceration, approximately 58% of patients with BP carcinoids present with symptoms including cough (32%), hemoptysis (26%), and pneumonia (24%).[1,116–123]

Contrary to midgut carcinoids, BP carcinoids produce less serotonin and thus patients with BP carcinoids have a lower rate of carcinoid syndrome. Carcinoid syndrome, which occurs in 1% to 3% of BP carcinoid cases, may be atypical, with episodes of flushing accompanied by disorientation, tremor, periorbital edema, lacrimation, salivation, hypotension, tachycardia, diarrhea, dyspnea, asthma, and edema.[116,123] In addition, the risk of carcinoid crisis with BP carcinoids is so low that routine prophylaxis with octreotide prior to tumor manipulation is not typically recommended.

Approximately 1% to 2% of BP carcinoids are associated with ectopic adrenocorticotropic hormone production.[12] Even more rare is the production of growth hormone-releasing hormone from BP carcinoids causing acromegaly,[124,125] hypoglycemia,[126] and hypercalcemia.[127,128]

Large Cell Neuroendocrine Carcinoma

Because of the difficulty in diagnosing LCNEC on small biopsy specimens and cytology samples, most clinical data come from surgical series, which may bias the results (i.e., selection of younger patients with less comorbidity). Reported symptoms at initial presentation often include coughing, weight loss, hemoptysis, chest pain, and fever.[129–131] Classic paraneoplastic syndromes, such as Cushing syndrome seen in SCLC or the carcinoid syndrome rarely associated with lung carcinoids, are seldom diagnosed in LCNEC.[132,133]

The incidence of LCNEC is about 3% in reviewed case series of resected pulmonary malignancies.[6] In these LCNEC series, the average age of initial presentation was 64 years (range, 30 years to 88 years) with the majority of patients being male (mean, 80%; range, 54% to 89%) and former heavy smokers (89% to 100%; Table 55.3). Data from two studies have challenged that the incidence of LCNEC is substantially higher in men. In 100 cases of confirmed resected LCNEC, the female-to-male ratio was 5:9 (46%:54%).[134] In a study of clinical characteristics extracted from the Surveillance, Epidemiology, and End Results

database, the findings were similar, with a female-to-male ratio of approximately 5:9 (45%:55%).[135]

STAGING

No classification staging system currently exists that specifically addresses BP carcinoids or LCNEC; therefore the seventh edition of the tumor, node, and metastasis (TNM) staging for NSCLC is used for staging LCNEC.[136]

IMAGING

Computed Tomography

Computed tomography (CT) and magnetic resonance imaging are recommended for staging of BP carcinoids. Typical carcinoids are well-defined, spherical, or ovoid masses that may narrow or obstruct airways and may result in secondary atelectasis.[137] Although typical carcinoids tend to be centrally located, atypical carcinoids are usually peripherally located. Davila et al.[138] noted that 15% of BP carcinoids were located peripherally, with 10% in the mainstem bronchi and 75% in the lobar bronchi. Calcification may be present in 30% of BP carcinoids.[118]

Most typical carcinoids present as stage I tumors, with 87% of patients having no lymph node metastases. In one series, 10% of patients with typical carcinoids had N1 disease; 3% had N2; and no patients had N3 disease. By contrast, the presence of N0, N1, N2, and N3 disease in patients with atypical carcinoids was 43%, 29%, 14%, and 14%, respectively.[116]

Large Cell Neuroendocrine Carcinoma

Findings of LCNEC on CT are nonspecific and comparable to that of other solid pulmonary malignancies. LCNEC is predominantly situated in the periphery (67% to 97%) of the lungs but, like SCLC, can also be centrally located (3% to 33%).[129,130,139,140] In radiologic and surgical case series, LCNEC had a slight tendency to be situated in the upper lobes. The border of the tumor is usually lobulated, but can be spiculated. On CT evaluation, the average diameter of the primary tumor is approximately 40 mm (range, 7 mm to 100 mm).[129,130,139,140] Necrosis is commonly seen and can present as an inhomogeneous enhancement, especially in larger nodules.[129] Calcification has been reported in 7% to 21% of all primary LCNEC tumors, and it has been hypothesized that these are dystrophic calcifications that can arise in areas of necrosis.[130,139,141]

Positron Emission Tomography

Imaging studies in which the effectiveness of positron emission tomography (PET) is evaluated are scarce. ^{68}Ga-DOTATOC PET, which targets the somatostatin receptor, was evaluated in neuroendocrine tumors and had a specificity of 90% to 92%, a sensitivity of 81% to 97%, and an accuracy of 87% to 96%.[142,143] ^{11}C-5-hydroxytryptophan, a radiolabeled precursor of 5-hydroxytryptophan synthesis, may be more specific for bronchial carcinoids. In one study, ^{11}C-5-hydroxytryptophan scanning was compared with CT for the identification of tumor lesions; ^{11}C-5-hydroxytryptophan identified tumor lesions in 95% of patients and detected more lesions than CT and somatostatin receptor scintigraphy (SRS) in 58% of patients.[144] The available data suggest that LCNEC has a high uptake of fluorine ^{18}F-2-deoxy-D-glucose (FDG) with a mean standardized uptake value of 12.0 (range, 3.9 to 25.6),[139,145] comparable with results found in SCLC.[146] The use of FDG is controversial for the imaging of BP carcinoids as they usually have low metabolic activity and therefore tend to have less FDG uptake compared with LCNEC and SCLC.[147]

LCNEC, large cell neuroendocrine carcinoma; *NA,* not available; *NR,* not reported.

Somatostatin Receptor Scintigraphy

Expression of somatostatin is frequently found in neuroendocrine tumors and is known for its regulation of hormones including glucagon, gastrin, insulin, and the growth hormone. Currently, five somatostatin subtype receptors (SSTRs) are known and classified as SSTR-1 through SSTR-5. In a surgical series, the different receptors were found to be present to varying degrees in typical carcinoid, atypical carcinoid, and LCNEC. With the exception of SSTR-5, there was a tendency toward decreased expression in well- to poorly differentiated NECs.[148,149]

Radiographic detection of SSTR in tumors is possible with indium-111 pentetreotide scintigraphy (octreotide scan). An octreotide scan detects radiolabeled octreotide, a synthetic analog of somatostatin, which binds with a high affinity to SSTR-2, SSTR-3, and SSTR-5 after intravenous injection.

Approximately 80% of bronchial neuroendocrine tumors can be imaged with octreotide scanning.[150] In a study by Rodrigues et al.,[151] results from two different radioligands—^{111}In-DOTA-D: Phe(1)-Tyr(3)-octreotide and ^{111}In-DOTA-lanreotide—were compared and the overall sensitivity was 93% and 87%, respectively. The sensitivity of SRS to detect the primary malignancy instead of metastatic disease can vary. Granberg et al.[152] identified a sensitivity of approximately 80% for primary bronchial carcinoids and 60% for liver metastases; however, the main limitation of SRS is its specificity, as it detects positivity in many other tumors, granulomas, and autoimmune diseases. The role of SRS in preoperative staging is controversial, taking into account that extrathoracic metastatic disease is rare.[153]

Although SRS is commonly used for detection of BP carcinoids, studies of LCNEC are scarce. In a small study evaluating LCNEC preoperatively, 55% of primary lesions (10 of 18) showed activity on octreotide scan.[154] In another study, the use of technetium-99m ethylene diamine diacetic acid/hydrazinonicotinyl-Tyr^3-octreotide (99mTc-TOC) scintigraphy was evaluated for the detection of LCNEC.[155] A high sensitivity was found for primary lesions (100%) and supradiaphragmatic metastases (83%), whereas none of the infradiaphragmatic (adrenal glands) metastases was detected and only 11% of all skeletal metastases were detected. Table 55.4 provides a summary of the clinical, pathologic, and imaging findings in neuroendocrine cancers of the lung.

THERAPY

Surgery

Bronchopulmonary Carcinoids

The standard of care for BP carcinoids is surgical resection, with the approach dependent on location, size of tumor, and tissue type. For central, localized typical carcinoid, lung preservation resection, such as sleeve resection, wedge, or segmental resection, is preferred.[156] The optimal treatment of atypical carcinoid with or without lymph node metastases is controversial, and the use of conservative resection in these two scenarios has been called into question. Typically, a more extensive resection, such as lobectomy, bilobectomy, and pneumonectomy, is recommended.[121,138,157,158] The goal is en bloc resection with preservation of as much normal lung as possible. Surgical margins that are as narrow as 5 mm are considered adequate, as bronchial carcinoids do not tend to spread submucosally.

Because 5% to 20% of typical carcinoids and 30% to 70% of atypical carcinoids metastasize to lymph nodes, a complete mediastinal lymph node sampling or dissection is indicated.[159–161] If the mediastinal lymph nodes are positive, a full dissection is recommended, as this does not preclude the possibility of cure.

It is possible to attempt a bronchoscopic resection of an intraluminal typical carcinoid. A variety of bronchoscopic strategies have been utilized, including neodymium:yttrium aluminum garnet laser, with or without photodynamic therapy, an approach

TABLE 55.4 Comparison of Clinical, Pathologic, and Imaging Findings in Neuroendocrine Tumors of the Lung

	Typical Carcinoid	Atypical Carcinoid	Large Cell Neuroendocrine Carcinoma	Small Cell Lung Cancer

that has been shown in several small series to be feasible.[162] This strategy may be effective for patients who are deemed inoperable because of comorbidities, or for patients who refuse surgery. New radiation technologies such as stereotactic ablation radiotherapy may also be useful in this setting, but definitive evidence is lacking and surgery, when possible, remains the standard of care.

Large Cell Neuroendocrine Carcinoma

Surgical treatment of LCNEC may be indicated for stage I and II disease, similar to other NSCLC histologic types. However, surgical treatment is rarely an option, as approximately 45% of patients present with metastatic disease (Table 55.4).[135,163] In addition, evidence regarding surgical treatment for LCNEC is rare because no randomized trials have been conducted on the subject.

In a selection of studies, surgical case series of LCNEC were reported, spanning the period from 1982 to 2010 (Table 55.3). The majority of the studies included a pathologic review of all resected tissues. Lobectomy was the most frequently used surgical treatment modality (48% to 95% of patients with LCNEC), although several patients received a pneumonectomy or bilobectomy. Systematical node dissection was performed in most cases, and the reported resection status, R0, was 84% to 100%. The stage of disease was recorded according to pathologic TNM staging editions IV to VII. There was no lymph node involvement in 46% to 75% of patients, but metastasis after resection was reported in 0% to 7% of the cases studied. After resection, 14% to 34% of the patients were treated with adjuvant chemotherapy, although the majority of the postsurgical data were missing.

The reported 5-year survival of patients with resected LCNEC ranged from 28% to 57%, with an average overall survival rate of 43%; however, it should be considered that the vast majority of the patients had stage I to III disease. Five-year survival of patients ranged from 33% to 67% for those with stage I disease and 23% to 75% for those with stage II disease. However, any conclusion is limited by the use of different TNM staging systems, and the adoption of adjuvant chemotherapy varied considerably from one study to another. Recurrence of disease was reported in 40% to 62% of patients.

Adjuvant Treatment

Bronchopulmonary Carcinoids

No prospective trials have directly addressed the benefit of adjuvant therapy for patients with BP carcinoids, although several single-institution retrospective series have evaluated the use of adjuvant radiation and/or chemotherapy. However, these studies tend to be small and had apparently discordant results.[118,156,164–167] Carretta et al.[164] reviewed 44 patients treated with surgical resection, and one patient with clinical stage IIIA disease received neoadjuvant mitomycin-c, vinblastine, and cisplatin and had a partial response, but disease recurred 2 months postoperatively. Of the five patients with N1 disease who received postoperative radiotherapy, none of them had local recurrence.[164] In the study by Paladugu et al.,[168] seven patients with atypical carcinoid who had distant metastases were treated with surgery followed by chemotherapy and all were alive at follow-up (range, 23 months to 127 months). By contrast, Mills et al.[169] did not detect any difference in survival when they compared seven patients with atypical carcinoid treated with adjuvant chemotherapy and radiotherapy with six patients who had a surgical procedure only. Thus adjuvant therapy for completely resected typical or atypical carcinoid, with or without regional node involvement, remains controversial. Despite these limited data, the National Comprehensive Cancer Network suggests the use of chemotherapy with or without radiotherapy for resected stage II or III atypical carcinoid and for stage

IIIb typical carcinoid. The North American Neuroendocrine Tumor Society guidelines indicate that there are insufficient data to recommend adjuvant therapy,[159] whereas the European Society for Medical Oncology clinical practice guidelines do not specifically address adjuvant therapy.[170]

Large Cell Neuroendocrine Carcinoma

Evidence regarding adjuvant chemotherapy and radiotherapy for resected LCNEC is limited. Several retrospective case series and one prospective study have been reported. In this chapter, only studies in which treatment for pure or mixed LCNEC were assessed are reviewed. Studies that include LCC with neuroendocrine morphology without neuroendocrine differentiation are not addressed.

In 2006, Iyoda et al.[171] conducted a single-arm, nonrandomized, unblinded prospective trial of patients with resected LCNEC who were treated with postoperative adjuvant cisplatin and etoposide (two cycles). Fifteen patients with resected LCNEC (13 with stage I disease and 4 with stage II or higher), including radical lymph node dissection, were included. The results of the prospective study were compared with the results from a retrospective cohort of 23 patients treated with resected LCNEC without adjuvant chemotherapy; clinical characteristics of the two series were comparable. The authors reported a difference in overall survival, however, with an advantage for the cohort that received adjuvant treatment. The 2-year and 5-year overall survival was 88.9% and 88.9%, respectively, in the treatment group compared with 65.2% and 47.4% in the control group, respectively.

Rossi et al.[172] examined a cohort of 83 patients with resected LCNEC, including 28 patients who received adjuvant chemotherapy. The chemotherapy consisted of SCLC regimens (13 patients) and NSCLC regimens (15 patients), including cisplatin and gemcitabine, carboplatin and paclitaxel, and cisplatin and vinorelbine. Multivariate regression analysis for survival showed that treatment with an NSCLC adjuvant chemotherapy regimen resulted in a relative risk of 15.52 compared with an SCLC regimen, favoring the SCLC regimen ($p = 0.0001$). Stage and tumor size had a relative risk of 2.31 ($p = 0.029$) and 2.15 ($p = 0.013$), respectively. The chemotherapy regimens were not analytically reported. The results were similar in the study by Tanaka et al.[173] of 63 patients with completely resected (R0) LCNEC. Twenty-three (37%) of 63 patients were treated with induction chemotherapy (3 patients) or adjuvant chemotherapy (20 patients). Regimens differed, although all contained a platinum agent (combinations of carboplatin or cisplatin with etoposide, paclitaxel, docetaxel, or vinorelbine). Multivariate analyses showed improved survival for patients treated with adjuvant chemotherapy (hazard ratio [HR], 0.323; $p = 0.037$). Pathologic stage (I vs. II/III) was not a predictor for survival (HR, 0.645; $p = 0.29$). The authors also reported possible chemotherapy resistance in patients with LCNEC who were positive for three neuroendocrine markers (NCAM+, chromogranin A+, and synaptophysin+). In this group of patients with triple-positive LCNEC, chemotherapy did not contribute to increased survival.

Sarkaria et al.[134] evaluated 100 patients with surgically resected LCNEC (and combined LCNEC). Twenty-four patients received induction chemotherapy with a response rate of 63% (15 with partial response, 8 with stable disease, and 1 with progressive disease); 22 (92%) of the 24 patients received a platinum-based chemotherapy regimen. A total of 25 patients received adjuvant chemotherapy, mostly consisting of platinum-based regimens (80%), and 60% received a platinum-based regimen combined with etoposide. Adjuvant radiotherapy was administered to 15 patients. Forty-two patients received both induction chemotherapy and adjuvant chemotherapy. In patients with completely resected IB–IIIA disease, treatment with platinum-based chemotherapy correlated with a

nonsignificant trend in increased survival. Multivariate analysis for survival was significant for stage (HR for stage III/IV vs. stage I/II, 2.21; *p* = 0.011), gender, and pulmonary comorbidities. In a study by Veronesi et al.,[174] in which patients with resected LCNEC were evaluated in a retrospective and multicenter setting, 21 patients received induction chemotherapy; among the 15 patients evaluable for response, the response rate was 80% (1 complete response, 11 partial responses, 2 stable disease, and 1 progressive disease). In addition, several patients received radiotherapy postoperatively. Chemotherapy combined with surgery compared with surgery alone was not a significant predictor in the multivariate analysis for survival (HR, 0.6; *p* = 0.274). Stage of disease, age, and type of surgery were significant independent prognostic factors.

Iyoda et al.[175] found that recurrence of disease occurred less frequently among 30 patients who received platinum-based adjuvant chemotherapy compared with 42 patients who received nonplatinum-based adjuvant chemotherapy; disease recurred in 33% of patients who received platinum-based chemotherapy compared with 62% of patients who received nonplatinum-based treatment (*p* = 0.017). However, no information was reported about the type of node dissection, the status of surgical margins (R0, R1, and R2), the exact type of chemotherapy, and the median follow-up of patients.

Preliminary results of neoadjuvant therapy in potentially surgically resectable patients with LCNEC who had a preoperative octreotide scan have been reported in only one study. All patients with positive findings on the scan received the somatostatin analog octreotide, and several patients also received radiotherapy. The results of this study were promising: a significant survival difference (*p* = 0.0007) was found for patients treated with octreotide compared with nontreated patients. Limitations of the study included small sample size (total of 18 patients, 10 of whom were treated) and its retrospective nature.[154]

Currently, in two prospective studies, the efficacy of adjuvant chemotherapy for resected LCNEC is being evaluated. The UMIN000001319 trial is a Japanese single-arm, multicenter, nonblinded randomized phase II study in which the effect of four cycles of cisplatin and irinotecan in both LCNEC and limited-disease resected SCLC is being assessed. Preliminary results from this study showed an overall and recurrence-free survival rate at 3 years of 86% and 74%, respectively, for the LCNEC cohort. Patients were classified as having IA to IIIA disease, and 83% of patients completed chemotherapy.[176] The other prospective study, also from Japan (Trial identifier: UMIN000010298), is a two-arm, randomized double-blind phase III trial in progress that is comparing adjuvant cisplatin and irinotecan with cisplatin and etoposide for stage I–IIIA resected LCNEC.[177]

Therapy for Metastatic Disease

Although there are no definitive guidelines for the treatment of BP carcinoids, the European Neuroendocrine Tumor Society has suggested treatment options according to prognosis. Patients with a good prognosis, including asymptomatic patients with typical carcinoid and no growth within 6 months to 12 months, may be treated with active surveillance, locoregional therapy, or somatostatin analogs. Patients with a poor prognosis (atypical carcinoid or growth within 6 months to 12 months) may be treated with peptide-receptor radiotherapy or palliative chemotherapy, such as temozolomide, streptozotocin (streptozocin) plus interferon, or everolimus.

Palliative Chemotherapy

As BP carcinoids are relatively rare and include a spectrum of pathologic features, there is a lack of robust clinical trial evidence to guide treatment choices. In general, treatment recommendations

stem from the experience of treating gastrointestinal carcinoids or extrapolating information from trials on SCLC.

Sun et al.[178] conducted a phase II/III trial in symptomatic carcinoids, randomly assigning patients to 5-fluorouracil (5-FU) and streptozocin or 5-FU and doxorubicin. Response rates were nearly identical at 16% and 15.9% in the two arms, respectively, but the median progression-free survival associated with 5-FU and streptozocin was superior (24.3 months vs. 15.7 months; *p* = 0.0267). At the time of progression, patients received dacarbazine, with a resulting response rate of 8.2%.[178]

In retrospective studies, cisplatin and etoposide have been assessed for the treatment of atypical carcinoid, and the objective response has ranged from 7% to 39%, with a median duration of response ranging from 4 months to 102 months.[177,179–184] Guigay et al.[185] performed a retrospective study in 37 patients with progressive atypical carcinoid, 34 of whom had liver or bone metastases. Patients were treated with either cisplatin and etoposide or 5-FU and streptozocin or other regimens combining 5-FU or doxorubicin. The overall response rate to first-line chemotherapy was 32%; 5-FU and streptozocin resulted in a partial response in six (35%) of 17 patients and stable disease in five (33%). Cisplatin and etoposide resulted in a partial response in three (25%) of 12 and stable disease in four (33%) of 12 in the whole population, and a partial response in two (22%) of nine and stable disease in three (33%) of nine in the population with metastases.

In a number of small studies, temozolomide was evaluated for the treatment of BP carcinoids.[186–188] In a study by Ekeblad et al.,[188] 13 patients with BP carcinoids (10 typical and 3 atypical carcinoids) were treated with temozolomide; four (31%) had a partial response and an additional four patients had stabilization of disease. Crona et al.[187] evaluated 31 patients (14 with typical carcinoid and 15 with atypical carcinoid) also treated with temozolomide and found that 14% of patients had a partial response, 52% had stable disease, and 33% had progressive disease.

Other agents that have resulted in tumor shrinkage include capecitabine and oxaliplatin; capecitabine and liposomal doxorubicin; and 5-FU, dacarbazine, and epirubicin.[189–192] In small studies and case reports of these agents, patient responses fall in the range of 20% to 30% and generally have a short duration. Given the small size of these studies and lack of prospective data, no specific recommendation for a specific chemotherapy regimen can be made and patient participation in a clinical trial should be strongly encouraged.

Liver Metastases-Directed Therapy

The liver is the predominant site of metastases. Hepatic resection may be considered in selected patients with BP carcinoids who have isolated, low-volume liver metastases. Although not curative in nature, this may provide palliation of symptoms secondary to paraneoplastic syndromes and may result in potentially prolonged survival.[193] If liver resection is not feasible, other liver-directed therapies may be performed, including hepatic artery embolization and chemoembolization, radiofrequency ablation, and cryoablation. Treatment of liver metastasis has been shown to be associated with a biochemical response as high as 96%[193] and to reduce carcinoid-related symptoms.[159,194]

Managing Hormonal Symptoms

Somatostatin receptor analogs such as octreotide control symptoms caused by secretion of biologically active peptides or amines in 60% of patients with BP carcinoids. Although partial response is rare (5% to 10%), stable disease occurs in 30% to 50% of patients.[190] Interferon-alpha (IFN-α) is another option, with symptomatic remission reported in 30% to 70% of patients.[195–202] Acromegaly secondary to paraneoplastic growth hormone-releasing hormone secretion is rare, but usually responds to

somatostatin or surgical debulking. Cushing syndrome may be treated with ketoconazole, aminoglutethimide, metyrapone, or mifepristone.[159] Octreotide was compared with placebo and shown to have antiproliferative effects in midgut carcinoids with an increase in progression-free survival from 6 months to 14 months (HR, 0.34; *p* < 0.0001).[203] Whether these data can be extrapolated to foregut tumors is uncertain.

Palliative Radiotherapy

BP carcinoid tumors are relatively radiotherapy resistant, and radiotherapy may only be considered when surgery is not feasible or after an incomplete resection. It may also provide pain relief in the case of bone metastases.[182,204]

Peptide receptor radiotherapy uses either [90]yttrium, [111]indium, or [177]lutetium radionuclides linked to a somatostatin analog to allow for targeting of somatostatin receptor-expressing tumor cells. Studies have shown complete and partial response rates of 0% to 8% with [[11]In-DTPA[0]]octreotide;[205,206] 4% to 33% with ^{90}Y-DOTA[0]-Tyr[3]octreotate;[207–211] and 17% to 38% with [117]Lu DOTA[0]-Tyr3octreotate.[212–215] One of the agents, DOTA[0]-Tyr[3]octreotate, was evaluated in 16 patients with foregut carcinoids, of which nine were BP carcinoids. Of the nine patients with BP carcinoids, five had a partial response, one had a minor response (tumor size reduction between 25% and 50%), two had stable disease, and one had progressive disease. The median time to progression was 31 months.[216] Long-term side effects of radiopeptide treatment may include decreased renal function, pancytopenia, and myelodysplastic syndrome. This therapeutic strategy is being evaluated further in several ongoing randomized, prospective trials. While the results are awaited, the use of radiopeptides for the treatment of advanced bronchial carcinoids remains investigational. Ongoing trials include the randomized registration trial of [117]Lu-octreotate plus octreotide acetate injection (30 mg every 4 weeks), compared with high-dose octreotide acetate injection (60 mg every 4 weeks) in midgut carcinoids only.

Surgery

In patients with indolent-behaving BP carcinoids and limited metastatic disease, surgical intervention may be warranted. Not only has surgery been shown to palliate symptoms, but it also may provide a disease-free survival benefit and potential cure. Que et al.[217] demonstrated that resecting liver metastases in liver-only metastatic bronchial carcinoids could result in a so-called cure in 20% of the treated patients.

Interferon

IFN-α has been shown to have a tumor response rate of 12% in a pooled analysis of several studies;[218] it has also been studied in combination with somatostatin analogs. Compared with octreotide alone, the combination of octreotide and IFN-α improved progression-free survival (HR, 0.28; 95% confidence interval, 0.16–0.45).[219] However, objective response rates were equally low in a study comparing IFN-α (4%), lanreotide (4%), or lanreotide plus IFN-α (7%).[220]

Molecularly Targeted Therapy

A subgroup of 44 BP carcinoids was included in a randomized phase III trial (RADIANT-3) comparing octreotide acetate injection with or without everolimus in 429 patients with advanced carcinoid tumors. Thirty-three patients were randomly assigned to everolimus plus octreotide and 11 to placebo and octreotide. The median progression-free survival was increased in the group receiving everolimus (13.6 months vs. 5.6 months). However,

almost half of patients who received everolimus had grade 3 or grade 4 adverse events, including stomatitis, diarrhea, and thrombocytopenia.[221] RAMSETE is a phase II trial evaluating everolimus as monotherapy in advanced nonpancreatic neuroendocrine tumors (35% foregut). Of the 19 patients with foregut carcinoids, none had a complete response or partial response, 12 had stable disease, and 7 patients had progressive disease. The median progression-free survival was 189 days.[222]

In a small series of 17 typical carcinoids, 5 tumors were shown to be IHC positive for c-Kit, 9 for platelet-derived growth factor beta, 12 for platelet-derived growth factor receptor alpha, and 7 for epidermal growth factor receptor. This raised the question of whether the use of specific tyrosine kinase inhibitors targeting these pathways is of clinical utility.[184]

Antiangiogenic agents have been assessed in several small phase II trials in advanced neuroendocrine tumors; however, foregut or BP carcinoids were only included in three studies.[223–226] Yao et al.[223] evaluated bevacizumab and octreotide LAR in 22 patients (4 bronchial carcinoid) and reported an overall response rate of 18%; Kulke et al.[224] investigated sunitinib in 107 patients (14 foregut) and reported an overall response rate of 2.4% and disease stabilization in 82.9% of patients. The median time to disease progression was 10.2 months. Castellano et al.[225] evaluated sorafenib and bevacizumab in 44 patients (19 foregut carcinoids) and found an overall response rate of 10%; however, Chan et al.[226] found no objective responses in the group of patients with carcinoid tumors in a phase II trial who were treated with temozolomide and bevacizumab. Based on these data, no definite conclusions can be made on the efficacy of antiangiogenic agents for the treatment of bronchial carcinoids.

An ongoing phase III trial (RADIANT-4) is comparing everolimus with placebo for advanced neuroendocrine tumors of gastrointestinal or lung origin (ClinicalTrials.gov identifier: NCT01524783). Other ongoing trials include the LUNA study, a randomized three-arm trial of pasireotide compared with everolimus alone or in combination for patients with advanced neuroendocrine tumors of the lung or thymus (ClinicalTrials.gov identifier: NCT01563354). Both trials have progression-free survival as the primary end point.

Therapy for Metastatic Large Cell Neuroendocrine Carcinoma

There is minimal evidence supporting the use of systemic therapy for metastatic LCNEC. As previously mentioned, LCNEC is a rare disease and diagnosis is based on histology from larger surgical biopsy specimens. In metastatic lung cancer, surgical biopsies are scarce. In the majority of studies reporting on advanced LCNEC, the diagnosis is based on a small biopsy sample or resected LCNEC case series containing metastatic recurrence of disease after surgical resection.

At the time of publication, two small single-arm, prospective multicenter phase II studies have been conducted in metastatic LCNEC. Both studies evaluated an SCLC chemotherapy regimen; in a European study of 42 patients, the regimen was cisplatin and etoposide; in a Japanese study of 44 patients, the regimen was cisplatin and irinotecan.[227,228] All patients had stage IIIB or IV disease, were chemotherapy naïve, and had an Eastern Cooperative Oncology Group performance status of less than 2. A central pathology review was performed in more than 95% of the patients. The diagnosis was revised in 25% of the patients who received cisplatin and etoposide and 28% of the patients who received cisplatin and irinotecan. The majority of revised diagnoses were SCLC.

In the cisplatin and irinotecan study, patients with confirmed LCNEC had a response rate of 47%; no patients had a complete response, 14 had a partial response, 10 had stable disease, and

6 had progressive disease. The median progression-free survival time was 5.8 months (range, 3.8 months to 7.8 months), and median overall survival was 12.6 months (range, 9.3 months to 16.0 months). Compared with the 10 patients who were diagnosed with SCLC in this study, patients with LCNEC had a significantly shorter overall survival time (12.6 months vs. 17.3 months; p = 0.047), although median progression-free survival was similar. Thirty patients (65%) completed four cycles of chemotherapy. Second-line chemotherapy consisted mostly of amrubicin (a drug registered only in Japan), platinum-based chemotherapy, and docetaxel. The response rate of second-line chemotherapy was not reported.

In the study of cisplatin and etoposide, patients with confirmed LCNEC had a response rate of 34%: no patients had a complete response, 10 had a partial response, and 9 had stable disease, with progression-free survival of 5.0 months (range, 4.0 months to 7.9 months) and overall survival of 8.0 months (range, 3.7 months to 7.9 months). In the other histology group, which consisted of nine patients with SCLC, one with atypical carcinoid, and one with neuroendocrine-expressing NSCLC, the progression-free survival was 3.1 months (range, 2.8 months to 8.5 months) and overall survival was 7.0 months (range, 3.0 months to 9.0 months). There was no significant difference between patients with LCNEC and the other histology group (p = 0.55). The reported median follow-up was 37.2 months.

The published literature includes several retrospective studies in which NSCLC-based regimens are evaluated; however, only a limited number of cases are reported. Rossi et al.[172] reported on 15 patients with resected LCNEC who were treated with cisplatin and gemcitabine or carboplatin and paclitaxel and gemcitabine monotherapy at the time of disease recurrence. None of the patients who received NSCLC-based therapy had a response, but six patients who received an SCLC regimen had an objective response. Sun et al.[229] performed a study of 45 patients with LCNEC treated with regimens specifically for SCLC or NSCLC. The authors reported a response rate of 73% (8 of 11 patients) in the group treated with SCLC regimens compared with a rate of 50% (17 of 34 patients) in the group treated with NSCLC regimens (p = 0.19). Platinum-based regimens combined with etoposide or irinotecan yielded a response rate of 73% in the SCLC group and 100% in the NSCLC group. Platinum-based regimens containing gemcitabine resulted in a response in 41% of the patients. In another study, approximately five of seven patients had a response to a combination of a platinum agent and paclitaxel.[230]

Available information about second-line chemotherapy for the treatment of LCNEC is almost nonexistent. In one retrospective study, a response rate of 23% (3 of 13 patients) was documented for second-line amrubicin monotherapy.[231] A single-arm, nonblinded phase II study of bevacizumab and docetaxel for second-line chemotherapy after platinum-based chemotherapy has been initiated in Japan (Trial identifier: UMIN000011713).

Molecularly Targeted Therapies

Targeted therapies have yet to be fully investigated for the treatment of LCNEC. In addition, the role of octreotide analogs has not been investigated in LCNEC.

There has only been one study in which SSTR-targeted therapies have been described, and prolonged overall survival was reported in patients with SSTR-positive metastatic disease.[232]

In a multicenter open-label, single-arm phase II study in Germany that was ongoing at the time of publication, the mTOR inhibitor everolimus is combined with paclitaxel and carboplatin for the treatment of advanced LCNEC. Recruitment is ongoing, and results have not been presented as yet.

COMBINED LCNEC

LCNEC can be expressed as a pure form of the disease, but it can also be expressed in combination with other solid tumors. LCNEC is commonly seen in combination with an adenocarcinoma or squamous cell carcinoma component (Fig. 55.5). Other rare forms are combinations of LCNEC and giant cell carcinoma or spindle cell carcinoma. The exact incidence of combined LCNEC is unknown, but it has been reported to be between 6% and 31% in large series of surgically resected LCNEC (Table 55.3).[6,134,233,234] At the present time, combined tumors with an LCNEC component should be classified as combined LCNEC and treated as LCNEC, with the exception of LCNEC combined with SCLC, which should be classified as a combined SCLC and treated as SCLC.

PROGNOSIS

Bronchopulmonary Carcinoids

Patients with typical carcinoids have an excellent prognosis after surgical resection, with 5-year survival rates of 87% to 100% and 10-year survival rates of 82% to 87%. Typical carcinoids tend to be indolent tumors, with only 7% metastasizing after adequate resection. The prognostic effect of lymph node positivity is controversial. In some studies, no negative impact of node involvement was found, although other studies have shown a negative impact.[119,216,235,236] The only accepted negative prognostic feature is incomplete resection.

Atypical carcinoids have lower 5-year survival rates, ranging from 30% to 95%, depending on the series; corresponding 10-year survival rates are 35% to 56%. Atypical carcinoids have a higher propensity to metastasize (16% and 23% in two large series) and to recur locally (3% and 23% in the same two series).[237] In contrast to typical carcinoids, lymph node metastases in atypical carcinoids have a clear negative effect on prognosis.[238] In a series from the Mayo Clinic, 19 (83%) of 23 patients with typical carcinoids and lymph node metastases remained alive and disease free; however, four (17%) had distant recurrence, two of whom died.[239] Conversely, only four of 11 patients with atypical carcinoids and lymph node involvement were alive without recurrence, and six of seven in whom distant metastases developed died. More recently, evaluation of potential prognostic

biomarkers was performed by quantitative real-time polymerase chain reaction. Low mRNA expression levels of CD44 and orthopedia homeobox and high levels of ret proto-oncogene (RET) were strongly associated with a low 20-year survival in patients with carcinoids. A direct link between gene expression and protein levels was confirmed for CD44 and orthopedia homeobox, but not for RET.[144,240]

Large Cell Neuroendocrine Carcinoma

Asamura et al.[234] reported that the survival curve for LCNEC is superimposable to that for SCLC. Depending on the series, 5-year survival rates ranged from 33% to 62% for stage I, 18% to 75% for stage II, 8% to 45% for stage III, and 0% for stage IV.[171,172,174,234]

CONCLUSION

Bronchial neuroendocrine tumors are a class of tumors arising from the neuroendocrine cells of the BP epithelium. The behavior of bronchial neuroendocrine tumors varies with their degree of differentiation: typical carcinoids have a more indolent behavior, rarely metastasizing; atypical carcinoids that are intermediate grade have an increased tendency to spread systemically; and LCNECs are high grade, with an aggressive phenotype similar to that in SCLC. Surgical resection of localized disease remains the standard of care for bronchial neuroendocrine tumors. For metastatic carcinoids, no current standard of care exists and participation in clinical trials should be considered for patients with these rare entities. Although metastatic LCNEC resembles SCLC in clinical behavior, the optimal chemotherapy regimen is not clear in this setting.

56 Thymic Tumors

Enrico Ruffini, Walter Weder, Pier Luigi Filosso, and Nicolas Girard

SUMMARY OF KEY POINTS

- Thymic tumors are rare malignancies and represent a wide array of tumors.
- Histologic classification distinguishes three separate entities: thymomas, thymic carcinomas, and neuroendocrine thymic tumors.
- Thymomas are characterized by variability in histologic appearance as well as in clinical behavior.
- Systemic paraneoplastic syndromes occur in almost 40% of patients, with myasthenia gravis being the most commonly reported.
- Patients with thymoma have an increased risk for the development of second malignancies and less than 40% of the patients will die from the original neoplastic disease, with the percentage being stage dependent.
- Several staging systems have been proposed, with the Masaoka staging system being more frequently used. A new tumor, node, metastasis (TNM) staging system will be implemented as the result of a global collaboration.
- Stage at presentation is the main prognostic factor.
- Surgery is the main treatment for thymic tumors, and radical resection is the goal.
- Other treatment modalities including radiotherapy and chemotherapy are used in the context of a multimodality approach.
- Thymic tumors are generally chemosensitive, with thymomas being more sensitive than thymic carcinomas. Exclusive chemotherapy is usually considered for patients medically or technically not qualified for surgical resection or in the presence of metastatic disease.

Thymic tumors are rare, although they are the most common tumors in the anterior mediastinal compartment. Despite their common term, thymic tumors represent a wide variety of tumors that, until recently, have been considered within one category. The most recent histologic classification, however, clearly distinguishes thymic tumors as three separate entities: thymomas, thymic carcinomas, and neuroendocrine thymic tumors (NETTs). In the past decade, the scientific community has been increasingly interested in thymic malignancies, resulting in the creation of many thymic tumors working groups and international thymic interest groups. As a consequence, dramatic advances have been made in our knowledge of the clinical and basic aspects of these rare diseases, providing important benefits for patients.

This chapter provides an overview of the most recent findings in the diagnosis, staging, histology, and management strategies of thymic tumors.

THYMOMA

Demographics and Clinical Presentation

Thymomas are rare neoplasms arising from the thymic epithelial cells. They are characterized by an extreme variability in histologic appearance, as well as in clinical behavior. The actual incidence of these diseases is unknown, but data from 2003 show an overall incidence in the United States of 0.15 cases/100,000 person-years.[1] Thymomas are the most common anterior mediastinal tumors in adults, accounting for about 50% of all mediastinal tumors. They can occur in all ages, but a peak in the incidence of thymomas associated with myasthenia gravis has been noted among individuals between the ages of 30 years and 40 years. A peak has also been noted among people (primarily women) aged between 60 years and 70 years who do not have myasthenia gravis.[2] Although in most series the gender distribution differs, the difference is not significant, and men and women are equally affected, especially when clinical series of more than 100 patients are considered.[3] Other malignant lesions (e.g., lymphoma, parathyroid and thyroid tumors, germ cell tumors, and mesenchymal and neurogenic neoplasms) as well as nonmalignant masses in the anterior mediastinum (e.g., aneurysms, granulomas, pericardial and esophageal cysts, and Morgagni hernias, as well as thymic hyperplasia) should be taken into account in the differential diagnosis. About 30% of patients with thymoma are asymptomatic. In these cases, the lesion is incidentally discovered, usually on chest radiographs. Among symptomatic patients, approximately 40% have local symptoms related to the intrathoracic mass, 30% have systemic symptoms, and the remaining have symptoms related to associated myasthenia gravis.[4] The most common local symptoms are chest pain, cough, and shortness of breath. In case of invasive neoplasms, common symptoms include superior vena cava (SVC) syndrome (Fig. 56.1), hemidiaphragm paralysis caused by phrenic nerve involvement (Fig. 56.2), and hoarseness due to recurrent laryngeal nerve infiltration. Pleural effusion and chest pain have also been noted in cases of pleural spread of the tumor.

Systemic paraneoplastic diseases occur in about 40% of patients with thymoma (Table 56.1).[4]

Myasthenia Gravis

Myasthenia gravis is, by far, the most commonly associated paraneoplastic disease in patients with thymoma. Thymoma has been found in 10% of patients with myasthenia gravis, and myasthenia gravis ultimately develops in 30% to 50% of patients with thymoma. Between 4% and 7% of patients with thymoma and myasthenia gravis have more than one paraneoplastic syndrome. Myasthenia gravis is very rarely associated with thymic carcinoma or type A or type AB thymoma, but, according to the World Health Organization (WHO) histologic classification, myasthenia gravis is significantly present in type B tumors and is usually found in early-stage disease.[5,6] Patients with thymoma and myasthenia gravis tend to be 10 to 15 years older than patients with myasthenia gravis who do not have thymoma, and slightly younger than patients with thymoma who do not have myasthenia gravis. Although the association between thymoma and myasthenia gravis is concurrent, it is not unusual to diagnose

Fig. 56.1. Superior vena cava syndrome in a patient with advanced thymoma causing superior vena cava obstruction. The superficial chest venous network and the upper limb edema are evident.
Fig. 56.2. Phrenic nerve involvement in an invasive thymic carcinoma.

thymoma up to a few years after myasthenia gravis. Kondo and Monden[7] reported that postoperative myasthenia gravis developed in about 1% of their patients who underwent complete thymoma resection. The authors concluded that resection of the thymus gland does not prevent myasthenia gravis from developing postoperatively.

Other Neurologic Syndromes

Neuromyotonia, isolated or in association with central nervous system involvement (Morvan syndrome), is frequently found in patients with thymoma.[8] Neuromyotonia is characterized by the presence of generalized muscle twitching and cramps, with electromyographic findings that are consistent with hyperexcitability of peripheral motor nerves (myokymic and neuromyotonic discharges). Other neurologic syndromes have been reported in association with thymic tumors.[9]

Hematologic Disorders

Pure red cell aplasia and hypogammaglobulinemia (Good syndrome) are the other two conditions more frequently associated with thymoma, occurring in 2% to 5% of cases.[10] Patients with pure red cell anemia are usually older than patients with thymoma alone (mean age, 60 years), and the mean age is 50 years for patients with Good syndrome. Women are slightly more commonly affected than men.

Extrathymic Second Malignancies

According to the scientific literature, patients with thymoma have an increased risk for the development of second malignancies. Filosso et al.[11] reported that patients with thymoma have an approximately twofold higher risk for the development of a second cancer, compared with the normal population. An intrinsic immune abnormality, of which the tumor itself may be a marker, was suggested as a possible explanation. As noted by Welsh et al.,[12] these tumors are true second cancers rather than cancers related to possible postoperative treatment (e.g., radiotherapy) of thymoma.

Diagnostic Imaging Techniques

Imaging plays a central role in diagnosing and staging thymoma. The initial decision to either perform surgery or further investigate the tumor with tissue analysis is primarily based on the findings of computed tomography (CT), magnetic resonance imaging (MRI), and/or positron emission tomography (PET)/CT. The chosen imaging modality should allow the physician to determine the tumor size, local invasion, and the presence of distant spread of the disease. Based on the information, the physician decides if direct surgery is indicated or if preoperative (induction) therapy (stage III or IV disease) is needed. Follow-up imaging of treated patients is used to identify recurrence and resectable recurrent disease. Patients with completely resected recurrent disease have similar outcomes to those without recurrence.[13] Conventional chest radiography is usually the chosen imaging modality for the initial investigation of thymoma, followed by chest CT. It is important to differentiate between nonneoplastic thymic enlargement and thymoma. In young children, the thymus and the hyperplastic thymus can mimic a mediastinal mass. On CT images, thymic hyperplasia appears as a diffusely and symmetrically enlarged thymus with smooth borders and preservation of the normal thymic shape.[14] It may also alter the shape to a more nodal appearance, and it can even show an uptake of ^{18}F-2-deoxy-D-glucose (FDG).[15] Chemical-shift magnetic resonance (MR), with in-phase and out-of-phase gradient echo sequences, may be

TABLE 56.1 Paraneoplastic Syndromes Associated With Thymoma

Hematologic syndromes	Red cell aplasia
	Pancytopenia
	Multiple myeloma
	Megakaryocytopenia
	Hemolytic anemia
Neuromuscular disorders	Myasthenia gravis
	Lambert–Eaton syndrome
	Myotonic dystrophy
	Myositis
	Neuromyotonia (Morvan syndrome)
	Stiff-person syndrome
	Limbic encephalopathy
Collagen diseases and autoimmune disorders	Systemic lupus erythematosus
	Sjögren syndrome
	Rheumatoid arthritis
	Polymyositis
	Myocarditis
	Sarcoidosis
	Scleroderma
	Ulcerative colitis
Endocrine disorders	Addison disease
	Hashimoto thyroiditis
	Hyperparathyroidism
Immunodeficiency syndromes	Hyopogammaglobulinemia
	T-cell–deficiency syndrome
Dermatologic disorders	Pemphigus
	Alopecia areata
	Chronic mucocutaneous candidiasis
Renal diseases	Nephrotic syndrome
	Minimal change disease
Bone disorders	Hypertrophic osteoarthropathy
Malignant diseases	Carcinomas (lung, colon, stomach, breast, thyroid)
	Kaposi sarcoma
	Malignant lymphoma
Fig. 56.3. Computed tomography of thymoma.

helpful for differentiation because it identifies the normal fatty infiltration that is unlikely in thymoma.[16,17]

CT with an intravenous contrast medium is the imaging modality of choice for evaluating thymoma and can help distinguish thymoma from other anterior mediastinal abnormalities (Fig. 56.3). Typically, on CT images, thymomas appear as spherical or ovoid, smooth, 5-cm to 10-cm anterior mediastinal masses. They have been described as ranging from a few millimeters to 34 cm in diameter. The tumor enhances homogeneously and may present with lobulated borders. In cases of hemorrhage or necrosis, it becomes heterogeneous or even cystic. The tumor can be partially or completely outlined by fat and may contain punctate,

coarse, or curvilinear calcifications.[18] Ipsilateral pleural nodules are suggestive of stage IVA (disseminated pleural) disease. CT has been thought to have a limited role in the detection of tumor invasiveness. Retrospective studies showed that partial or complete obliteration of fat planes around the tumor was not helpful in differentiating stage I thymoma from more advanced disease. Lobulated or irregular contours, cystic or necrotic regions within the tumor, and multifocal calcifications were more suggestive of invasive thymoma.[14,19]

Although the use of MR has decreased with the advances in multidetector CT and has been insufficiently studied for staging and follow-up, it still plays an important role in the investigation of the anterior mediastinal masses and in the staging of thymoma in patients with contraindication to CT. Thymoma presents with low to intermediate signal intensity on T1-weighted images and with high signal intensity on T2-weighted images.[20] Signal intensity is heterogeneous in tumors with necrosis, hemorrhage, or cystic change. Especially in patients with cystic masses, MR allows a distinction between congenital cyst and cystic thymoma, because fibrous septa and/or mural nodules are typically present in cystic thymoma but absent in a congenital cyst. These septa and nodules are often not evident on CT. Although CT is superior to MRI in the depiction of calcification within thymomas, MRI can occasionally reveal fibrous septa within the mass and can permit better evaluation of the tumor capsule. The presence of fibrous septa was shown to be associated with a less aggressive histologic classification.[21] In addition, the predominance of a necrotic or cystic component and heterogeneous enhancement were seen as signs of aggressiveness and were much more common with thymic cancer than with thymoma.[21]

Nuclear medicine plays a minor role in the routine evaluation of thymoma. Indium-111 octreotide shows uptake in thymoma and is used to identify patients who may respond to treatment with octreotide, which is considered to be the second or third choice of therapy when conventional chemotherapy fails.[22] The precise role of FDG-PET in the management of thymomas is unclear. One difficulty is that increased physiologic FDG uptake is common in a normal or hyperplastic thymus, especially in children and in adults younger than 40 years of age.[14]

Imaging During Follow-Up

The International Thymic Malignancies Interest Group (ITMIG) and the European Society for Medical Oncology (ESMO) Clinical Practice Guidelines suggest that, at a minimum, yearly chest CT should be performed for 5 years after surgical resection, and then alternating annually with chest radiography until year 11, followed by annual chest radiography alone, because late recurrences are common.[23,24] For patients with advanced-stage disease (stage III or IVA), thymic carcinoma, or for those who had incomplete tumor resection, chest CT every 6 months for 2 to 3 years is recommended. The ITMIG also suggests using MR to reduce the cumulative radiation dose. However, there is no study comparing the accuracy of CT with that of MR for identifying tumor recurrence.

Histologic Diagnosis

When the results of imaging techniques are equivocal for a diagnosis of a thymic tumor, cytohistologic diagnosis is required. In the past, it was suggested that, to obtain a definite diagnosis, every anterior mediastinal lesion should be subjected to biopsy before deciding on final treatment. In more recent years, however, refinements in imaging techniques have resulted in an improved diagnostic yield, and the need for a mediastinal biopsy has dramatically decreased. In a survey among European Society of Thoracic Surgeons (ESTS) members, 90% of the interviewed centers stated that they do not routinely look for a histologic confirmation of a suspected thymoma.[25] However, there is a general

agreement that biopsy should be considered in the case of unde-fined CT findings that may suggest lymphoma, or in the case of unresectable tumors before induction chemotherapy or definitive chemoradiation therapy.[26–29]

Mediastinal Biopsy Techniques

Nonsurgical Biopsies. Nonsurgical biopsies include fine-needle aspiration biopsy and core-needle biopsy using transthoracic ultrasound or CT. Both techniques are performed with the patient under local anesthesia and light sedation and require patient compliance. Because of the broad spectrum of tissue types in the anterior mediastinum and the variety of cell morphologies even within the same lesion, the results of pathologic evaluation are extremely dependent on the area where aspiration is performed. In one report, the accuracy of evaluation of fine-needle biopsy samples was relatively poor in several areas, including differentiation between invasive and noninvasive thymoma, differentiation between thymoma and lymphoma, diagnosis of thymic hyperplasia, diagnosis of Castleman disease, subtyping of lymphoma, and differentiation among nonseminomatous germ cell tumor, carcinoma, and large cell lymphoma.[30] Percutaneous core-needle biopsy is suitable for large tumors located mostly in the anterior mediastinum. This procedure provides a larger volume of tissue than fine-needle aspiration does, and the architecture of the material sampled is preserved, allowing for more sophisticated laboratory analysis, such as electron microscopy, flow cytometry, immunocytochemistry, and measurement of surface tumor markers, all of which increase diagnostic specificity.[31] In a series of 70 patients who had percutaneous core cutting-needle biopsy for masses in the anterior mediastinum, adequate material was obtained in 89% of the patients, with an overall sensitivity of 92%.[32] Evaluation of a specimen obtained by CT-guided fine-needle aspiration established the diagnosis in 69% of cases, with a sensitivity and a specificity of 71% and 94%, respectively, and with fewer side effects than are associated with core-needle biopsy. However, this technique decreases the possibility of an adequate discrimination between thymic carcinoma and thymoma, which is crucial for the correct treatment of patients.[33] The advantages of the percutaneous image-guided fine-needle aspiration and core-needle biopsies are that they are minimally invasive, safe, and reproducible. They can be done in an outpatient setting, achieve good cosmetic results, and are cost-effective. The disadvantages are the low diagnostic accuracy and higher morbidity in small lesions, an unnecessary delay in diagnosis and therapy if not conclusive (thymoma and lymphoma), and the requirement for an expert investigator and an experienced cytopathologist. Accuracy of biopsies are also dependent on the use of immunocytochemical and histochemical markers, including cytokeratins (CKs) and p63 expression for normal and neoplastic epithelial cells and terminal deoxynucleotidyl transferase expression in immature T cells (usually observed in types AB, B1, B2, and B3 thymomas, and absent in carcinomas and type A thymomas).[28]

Surgical Biopsies

Surgical biopsies include anterior mediastinotomy (Chamberlain procedure), video-assisted thoracoscopic surgery (VATS), and mini-thoracotomy.[34] VATS permits excellent exposure of the entire medi-astinum and allows precise dissection. This technique is a valuable tool, particularly in cases of masses with difficult access that require direct vision, such as tumors with proximity to neurovascular struc-tures or to the vessels of the heart.[35] In addition to the possibility of allowing selective and large biopsies of mediastinal masses, VATS provides a better evaluation of the relationship to other thoracic organs as well as an evaluation of invasion of extracapsular spread.[36]

The sensitivity of the surgical techniques is far higher (more than 98%) than that of nonsurgical techniques, although the morbidity and the surgical stress should be taken into consider-ation in the choice of the technique.

The complication rate is generally low after histologic tech-niques on the mediastinum, and pneumothorax is the most com-mon complication of nonsurgical techniques, occurring in 5% to 30% of the cases, depending on the location of the mass. Compli-cations of surgical procedures are minimal. Seeding of the pleural space or the biopsy site has been a concern in the past, but there is no evidence to support that in the literature.[37]

Staging Systems

Before an official stage classification system for thymic malig-nancies has been defined by the Union Internationale Contre le Cancer and The American Joint Commission on Cancer,[38] several different systems (Masaoka, Masaoka–Koga, TNM Classification of Malignant Tumours [TNM], Groupe d'Etude des Tumeurs Thymique) are actually being used.[25] Historically, the proposed staging systems were designed on single-center experience of small series of patients who had surgery. In most cases these systems are empirically derived. Although several studies have provided some correlation with outcomes, the limited number of patients and infrequent validation in an independent set of patients generally provide little basis for choosing between one system and another.

Non-TNM Staging Systems

During the 1960s, thymoma was classified as invasive and non-invasive, and four histologic subtypes were recognized. The first staging system was proposed by Bergh et al. in 1978.[39] They designed a three-stage classification system based on 43 patients with thymoma who were treated from 1954 to 1975. Wilkins and Castleman[40] proposed a second staging system, based on minor changes to the system by Bergh et al. Masaoka et al.[41] first high-lighted that the clinical course of thymoma is influenced by its local invasion, infiltration, and, finally, by distant spread with lymphogenous or hematogenous metastases. They also dem-onstrated the clinical importance of tumor local invasiveness as compared with lymphogenous or hematogenous metastasis, with a step-wise decrease in survival. A four-stage system was proposed in 1981, based on 93 patients (Box 56.1). Lastly, Koga et al.[42] pro-posed a revised Masaoka staging system in 1994 (see Box 56.1). The Masaoka–Koga staging system was clinically validated in a large series by Kondo et al.,[43,44] and it was recommended by the ITMIG in 2011. In 2012, Moran et al.[45] proposed a four-tiered staging system designed exclusively for thymomas. The major changes from the Masaoka system were the addition of stage 0 for encapsulated tumors (Masaoka stage I) and the shifting to a stage I, II, and IIIA,B from Masaoka stages II, III, and IVA,B, respectively. Moran et al.[45] considered stage 0 thymoma similar to an in situ malignancy or a premalignant neoplasm.

TNM-Based Staging Systems

In thymomas, the rate of lymphogenous and hematogenous metastases is about 2% and 1%, respectively. Local spread is the most common pattern of tumor invasion, and it may be precisely evaluated by the surgeon at the time of intervention. In this case, a staging system based on local invasion (such as Masaoka or Masaoka–Koga) seems to be suitable. However, thymic carcino-mas and NETTs frequently present with lymphogenous (25%) and hematogenous metastases (12%). For these tumors, a TNM-based staging system is advisable. Several TNM-based stag-ing systems for thymic tumors have been proposed in the past. Yamakawa and Masaoka[46] translated the Masaoka system into a

new TNM-based system. In their new system, the T descriptor was the same as in the Masaoka system, and the anterior mediastinal lymph nodes around the thymus were considered the primary lymph nodes, and classified as N1. Tumors were classified as M0 or M1 according to the absence or presence of hematogenous spread. Tsuchiya et al.[48] proposed a TNM system specifically for thymic carcinoma. In their system, the N descriptor was the same as in the Yamakawa and Masaoka system, but tumors penetrating through the mediastinal pleura or pericardium were classified as T3, and the stage grouping allowed a much greater role for node involvement. In 2004, a TNM-based staging system for thymic tumors was proposed by the WHO, in which the T descriptor paralleled the stratification in the Masaoka system, and the N descriptor included involvement of anterior mediastinal nodes (N1), intrathoracic nodes other than anterior mediastinal ones (N2), and extrathoracic nodes (including scalene, supraclavicular, etc., N3; see Box 56.1). The stage grouping divided stage III (N1) from stage IV (N2). All TNM-based systems, however, lack validation. Staging became even more confusing when Weissferdt and Moran[47] proposed a three-stage TNM classification for thymic carcinoma in 2012. In this system, the major features are the classification of T1 as a tumor confined to the thymus and T3 as direct extension outside the chest, the limitation of node categories to intrathoracic, and the grouping of any T3, N1, or M1 tumors as stage III.

A new TNM-based system is expected in 2017, based on a collaborative effort between the ITMIG and the International Association for the Study of Lung Cancer (IASLC), through the analysis of survival in a retrospective international database of more than 10,000 cases (Table 56.2).[48] Given the major switch that the TNM system represents and the limited amount of fair level of evidence data to support our current treatment strategies (especially postoperative radiotherapy), the value of the TNM system to drive the therapeutic strategy has to be assessed. Meanwhile, the new TNM staging may even provide more help in formalizing resectability: T1–T3 level of invasion refers to structures amenable to surgical resection, whereas T4 level of invasion includes unresectable structures. A proposed nodal map is available from the ITMIG.[49] The proposed N descriptor in the staging system includes:

- the anterior region (N1), which involves the anterior mediastinal nodes (prevascular, para-aortic, ascending aorta, superior and inferior phrenic, and supradiaphragmatic) and the anterior cervical nodes (low anterior cervical); and
- the deep region (N2), which includes the middle mediastinal (internal mammary, upper and lower paratracheal, subaortic, subcarinal, and hilar) and the deep cervical (lower jugular and supraclavicular).

HISTOLOGY OF THYMIC TUMORS

Thymoma

Thymomas are epithelial tumors mixed with reactive lymphocytes. They are ultrastructurally characterized by desmosomes and tonofilaments and are primarily found in the anterosuperior mediastinum.[2] Atypical localization within the thyroid, the pericardium, the lung parenchyma, and hilum is documented, and they can even coat the pleura in a mesothelioma-like fashion.

Overall, thymomas are generally solid, lobulated, yellow-gray tumors. Eighty percent are encapsulated, and the remainder infiltrates the surrounding structures. Foci of necrosis and cystic degeneration, with eventual hemorrhage, are common, sometimes making a differential diagnosis against multilocular thymic cyst difficult.

The histologic classification of thymomas has been debated for more than 50 years. Lattes and Jonas[50] (in 1957) and Bernatz et al.[51]

(in 1961) proposed a classification based on the major morphologic pattern, including predominantly lymphocytic, predominantly epithelial, predominantly mixed, and predominantly spindle-cell-type thymoma. In 1978, Levine and Rosai[52] separated thymoma from a variety of other thymic neoplasms, such as thymic carcinoid, various lymphomas, and germ cell tumors. They divided thymomas into benign, or noninvasive, and malignant, or invasive, tumors. In 1985, Muller-Hermelink and Marino[53] proposed a system that used both topography and morphology. Their system included six subtypes: medullary, mixed, predominantly cortical, cortical, well-differentiated carcinoma, and thymic carcinoma. Lastly, in 1999, WHO reached a consensus on thymoma classification based on both morphology and the epithelial cell-to-lymphocyte ratio.[54] Six subtypes were identified: type A (spindle cell, medullary), type AB (mixed), type B1 (organoid), type B2 (cortical), type B3 (well-differentiated thymic carcinoma), and type C (thymic carcinoma).

Type A thymomas consist of cells with a spindle- or oval-shaped nucleus and a uniform bland cytology, reminiscent of cells in the atrophic adult thymus (Fig. 56.4). Rosette-like, storiform, or gland-like formations can be seen. Few intermingled lymphocytes are found. In nearly all cases, the epithelial tumor cells are positive for CK19, and in 50% of cases, they are positive for the B lymphocyte marker CD20. If staining for CK19 is negative, monophasic synovial sarcoma, or solitary fibrous tumor, must be ruled out. Reticulin stains are very useful in assessing the spindle cell, type A pattern. A well-recognized variant is called micronodular thymoma with lymphoid stroma, presenting epithelial micronoduli with intraepithelial CD1a-positive immature T cells and florid lymphoid follicular hyperplasia of the stroma. Myasthenia gravis occurs less frequently with type A thymomas, although secondary mucosa-associated lymphoid tissue (extranodal marginal zone B cell) lymphoma may develop.

Type B thymomas consist of round or polygonal epithelioid cells. They are further subdivided based on the proportional increase in epithelial cell content in relation to the reactive lymphocytes and the degree of cytologic atypia: from B1 (number of lymphocytes greater than number of epithelial cells) to B2 (number of lymphocytes epithelial cells equal) to B3 (number of lymphocytes less than number of epithelial cells). B1 thymomas are lymphocyte rich (organoid), containing only small nonatypical, CK19-positive epithelial cells. They resemble a normal functional thymus: cortical areas have CD1a-positive lymphocytes; edematous perivascular spaces include CD20-positive lymphocytes; and nodularity is vague. Unfortunately, positivity for epithelial CK19 and lymphocytic CD1a is physiologic in the cortex. Thus the differential diagnosis between normal thymus, thymoma, and lymphoblastic lymphoma may be very challenging, particularly with evaluation of a frozen section. In newborns and children less than 3 years of age, it will mostly be a true thymic hyperplasia, but in older children or adolescents, T-cell lymphoblastic lymphoma must be ruled out. Although thymomas in children are unusual, a few documented cases have occurred in children around puberty. Thymomas are p63 positive, but this marker may also be present in mediastinal B-cell lymphomas.

In type B2 thymomas (cortical), scattered plump tumor cells show vesicular nuclei with prominent nucleoli. Perivascular spaces eventually include palisading of lymphocytes, and Hassall bodies are rare. In type B3 thymomas (epithelial, atypical), proliferative invasive CK19-positive epithelium is associated with immature lymphocytes positive for CD99 and CD1a (Fig. 56.5). A diagnosis of combined thymoma is made if, for example, the components B2 and B3 both achieve 50% of tumor surface. Thymomas combining type A with type B features are designated as type AB (mixed) and they contain lymphocyte-rich and lymphocyte-poor areas. Rare thymomas include the metaplastic, the microscopic, and the sclerosing variant, and the so-called lipofibroadenoma.

BOX 56.1 Staging Systems for Thymic Tumors

NON–TNM SYSTEMS

MASAOKA STAGING SYSTEM

Stage	Description
I	Macroscopically encapsulated tumor without microscopic invasion of capsule
IIA	Macroscopic invasion into surrounding fatty tissue or mediastinal pleura
IIB	Microscopic invasion into capsule
III	Macroscopic invasion into nearby organs (i.e., pericardium, great vessels, or lung)
IVA	Pleural or pericardial dissemination
IVB	Lymphogenous or hematogenous metastasis

MASAOKA–KOGA STAGING SYSTEM

Tumor Stage	Description
I	Grossly and microscopically completely encapsulated tumor
IIA	Microscopic transcapsular invasion
IIB	Macroscopic invasion into thymic or surrounding fatty tissue, or grossly adherent but not breaking through mediastinal pleura or pericardium
III	Macroscopic invasion of nearby organs (pericardium, great vessels, or lung)
IVA	Pleural or pericardial dissemination
IVB	Lymphatic or hematogenous metastasis

WORLD HEALTH ORGANIZATION TNM-BASED STAGING SYSTEM

T Descriptor

T1	Macroscopically completely encapsulated and microscopically no capsular invasion
T2	Tumor invades pericapsular connective tissue
T3	Invasion into nearby organs (i.e., pericardium, great vessels, lung, pleura)
T4	Pleural or pericardial dissemination

N Descriptor

N0	No lymph node metastasis
N1	Metastasis to anterior mediastinal lymph nodes
N2	Metastasis to intrathoracic lymph nodes, except anterior mediastinal lymph nodes
N3	Metastasis to scalene or supraclavicular lymph nodes

M Descriptor

M0	No hematogenous metastasis
M1	Hematogenous metastasis

Stage Grouping

Stage	T	N	M
I	T1	N0	M0
II	T2	N0	M0
III	T1	N1	M0
	T2	N1	M0
	T3	N0–N1	M0
IV	T4	Any N	M0
	Any T	N2–N3	M0
	Any T	Any N	M1

TNM, tumor, node, metastasis.

TABLE 56.2 The Proposed Tumor, Node, Metastasis Staging (International Association for the Study of Lung Cancer Prognostic Factors Committee/International Thymic Malignancy Interest Group)[4,49]

Stage		Descriptors
TUMOR		
T1	T1a	Encapsulated or unencapsulated, with or without extension into the mediastinal fat
	T1b	Extension into the mediastinal pleura
T2		Direct invasion of the pericardium (partial or full thickness)
T3		Direct invasion of the lung, the brachiocephalic vein, the superior vena cava, the chest wall, the phrenic nerve, and/or hilar (extrapericardial) pulmonary vessels
T4		Direct invasion of the aorta, arch vessels, the main pulmonary artery, the myocardium, the trachea, or the esophagus
NODE		
N0		N0, no nodal involvement
N1		N1, anterior (perithymic) nodes (IASLC levels 1, 3a, 6, and/or supradiaphragmatic/inferior phrenics/pericardial)
N2		N2, deep intrathoracic or cervical nodes (IASLC levels 2, 4, 5, 7, 10, and/or internal mammary nodes)
METASTASIS		
M0		No metastatic pleural, pericardial, or distant sites
M1	M1a	Separate pleural or pericardial nodule(s)
	M1b	Pulmonary intraparenchymal nodule or distant organ metastasis
STAGE GROUPING		**CORRESPONDING MASAOKA–KOGA STAGE**
I	T1N0M0	I, IIA, IIB, III
II	T2N0M0	III
IIIA	T3N0M0	III
IIIB	T4N0M0	III
IVA	T any N0,1 M0,1a	IVA, IVB
IVB	T any N0-2 M0-1b	IVB

IASLC, International Association for the Study of Lung Cancer.
Fig. 56.4. Spindle cell type A thymoma with micronodular pattern.
Fig. 56.5. Type B3 thymoma with atypical epithelial cells intermingled with sparse lymphocytes. Fine capsule with ink marking of the cauterized resection margin.

With the challenging criteria, it is evident that the opportunity for achieving interobserver agreement on histologic classification of thymomas is limited. The recent proposal of major and minor morphologic and immunohistochemical criteria to better individualize each thymic epithelial tumor entity aims at addressing those issues and has been integrated into the updated WHO classification.[6,55] As previously mentioned, immunohistochemistry may be valuable, and a list of useful markers is integrated into the WHO classification.

Diagnosis on evaluation of core biopsies may differ from the follow-up analysis of whole tumor sections. To overcome these problems, Suster and Moran, in 2008,[56] proposed a simplified classification into three subtypes: thymoma (well-differentiated tumors), atypical thymomas (intermediate differentiation), and thymic carcinomas (poorly differentiated tumors); others, maintaining the WHO classification, demonstrated that among the six subtypes, only three WHO categories were prognostically significant: types A, AB, and B1; types B2 and B3; and type C. Ultimately, thymoma subtyping on small biopsies is usually not needed for the therapeutically relevant distinction between lymphoma and solid tumor. In any case, diagnostic discrepancies between core-needle and resection specimen histology can be anticipated, given the frequent occurrence of histologic tumor heterogeneity that may be missed due to sampling error. Of note, histologic switch from lymphocytic lesions to more epithelial tumors has been reported, and may be related to tumor heterogeneity, as well as the effect of previous corticosteroid and chemotherapy treatment.[57,58]

Thymic Carcinoma

The 2004 WHO update maintained the range from type A to B3, but separated thymic carcinomas from thymomas with the rationale that thymomas are organotypic, unique tumors, because the combination of epithelial tumor cells with reactive lymphocytes may not be found in other organs (Table 56.3).[55] For this reason, the C category was abandoned. Thymic carcinomas display the common neoplastic morphologies found in other body sites, and they do not have the capacity to promote the maturation of intratumoral immature T cells. For thymic carcinomas, 11 histologic variants are recognized. The most common are squamous cell carcinomas, lymphoepithelioma-like carcinomas, and neuroendocrine tumors (considered as a separate entity in some series). As in other organs, the precise clinical relevance concerning therapy and prognosis is difficult to assess, and tumor heterogeneity is often found.

TABLE 56.3 World Health Organization Histologic Types of Thymic Tumors

Type of Thymic Tumor	Histologic Types
Thymoma	Type A (spindle cell; medullary)
	Type AB
	Type B1 (lymphocyte rich, lymphocytic, predominantly cortical, organoid)
	Type B2 (cortical)
	Type B3 (epithelial, atypical, squamoid; well-differentiated thymic carcinoma)
	Micronodular thymoma
	Metaplastic, sclerosing, microscopic thymoma
	Lipofibroadenoma
Thymic carcinoma	Squamous cell, epidermoid keratinizing
	Epidermoid nonkeratinizing
	Basaloid
	Lymphoepithelioma-like
	Mucoepidermoid
	Sarcomatoid
	Clear cell
	Mucoepidermoid
	Papillary
	Undifferentiated
	Combined
Neuroendocrine tumors	Well-differentiated neuroendocrine tumors or carcinomas, including typical and atypical carcinoids
	Poorly differentiated neuroendocrine carcinomas, including large and small cell neuroendocrine carcinoma

TABLE 56.4 International Thymic Malignancy Group Recommendations for Outcome Measures for Thymic Tumors

Outcome Measure	End Point	Patient Population
Overall survival	Death from any cause	All patients
Freedom from recurrence	Recurrence	Complete resection (R0), complete response after nonsurgical treatment
Time to progression	Disease progression	Incomplete resection (R1 or R2), stable disease, or progression of disease after nonsurgical treatment

Most patients with thymic carcinomas are symptomatic, reflecting the high stage III to stage IV at diagnosis. Autoimmune phenomena associated with thymoma, such as myasthenia gravis or pure red cell aplasia, are rarely found. Lymph node and distant metastases are common. Squamous cell carcinoma may be keratinizing or nonkeratinizing, and no thymopoiesis or autoimmunity is present. Immunohistochemistry is of some help for the differential diagnosis. In contrast to lung squamous cell carcinoma, staining for CD117 (c-Kit) may be positive in thymic squamous cell carcinomas, but less than 10% of patients have a CD117 mutation. Epstein-Barr virus may be found in lymphoepithelioma-like carcinomas and in nasopharyngeal carcinomas. Many thymic adenocarcinomas are CD5 positive, a lymphocyte marker considered to be rare in carcinomas, but negative for thyroid transcription factor 1 and thyroglobulin.

Neuroendocrine Thymic Tumor

The thymus exhibits the same spectrum of neuroendocrine tumors as the lung, although with different frequencies. In the lung, typical carcinoid and small cell lung carcinoma (SCLC) are the most common histotype, but in the thymus, the most frequent histotype is atypical carcinoid. According to the WHO 2004 classification (see Table 56.3), carcinoids are classified as well-differentiated neuroendocrine tumor/carcinoma and considered separate from the high-grade tumors, large cell neuroendocrine carcinoma, and SCLC. Thymic carcinoids are often locally invasive and metastasize distantly. Endocrine manifestations, other than Cushing syndrome, are infrequent. They can also be associated with multiple endocrine neoplasia (MEN) type 1 or 2a, and they are very rarely associated with myasthenia gravis. Morphologic variants include the spindle cell pattern, which can be confused with a type A thymoma if diagnosis is not corroborated by immunohistochemical results for neuroendocrine markers, such as synaptophysin. For diagnosis of primary thymic SCLC, a mediastinal metastasis of a lung neoplasm must be carefully ruled out. SCLC can be present in combination with squamous cell carcinoma or carcinoid.

OUTCOME MEASURES AND PROGNOSTIC FACTORS IN THYMIC TUMORS

Outcome Measures

The standard outcome measure for most clinical studies is overall survival. Although easily reproducible and comparable across different series, overall survival has some limitations in slow-growing malignancies like thymic tumors. Indeed, many patients with thymoma have a long life expectancy, and it is not unusual to have survival of 30 years or more. Overall, less than 40% of patients with thymoma die from the thymoma, and this percentage is also stage dependent (stage I, 3%; stage II, 30%; stage III, 58%; stage IV, 78%). In addition, unlike other more aggressive solid neoplasms, in which patients with a recurrence almost invariably die from that neoplasm, many patients with thymoma may live many years with a recurrence and may die from causes unrelated to thymoma. For these reasons, other outcome measures seem more appropriate in thymic tumors. Among other measures, some have been discussed and proposed in the literature. They include disease-related survival, disease-specific survival, cause-specific survival, cancer-specific survival, disease-free survival, freedom-from-recurrence, progression-free survival, and time to progression. All these survival measures considered a specific end point (death and different causes of death, recurrence after complete resection, disease progression after incomplete resection) and a specific patient population (all patients, complete resection [R0], and incomplete resection [R1 or R2]). In a 2011 report, the ITMIG addressed this important issue and came to the conclusion that the assessment of efficacy of any treatment in thymic malignancy is best measured when recurrence is considered as the end point.[23] Therefore the ITMIG recommends that, along with the calculation of overall survival, any study in which outcomes after treatment of thymic tumors are reported should indicate freedom from recurrence for any patient undergoing a treatment aimed at obtaining complete disease eradication, as indicated by a complete resection (R0) in surgically treated patients or complete radiographic response in nonsurgically treated patients (Table 56.4). For any patients in whom a residual disease is expected after treatment (partial radiographic response or incomplete resection [R1 or R2]), time to progression should be used.

Prognostic Factors

A prognostic factor can be defined as a variable that can be used to estimate the chance of recovery from a disease, or the chance of disease relapse. Prognostic factors are divided into tumor-related, host-related, and environmental-related factors.[59] The most important prognostic factor in all human cancers is the stage at presentation, which is the anatomic extent of the disease. By using a set of definitions indicating the anatomic tumor

TABLE 56.5 Prognostic Factors in Thymic Tumors[38]

Variable	Significance		
	Consistent Prognostic	Inconsistent	Consistent Nonprognostic
Stage (Masaoka)	X		
Complete resection	X		
Gender			X
Myasthenia gravis			X
Tumor size		X	
Age		X

spread, we can allocate each individual's tumor into a category that is associated with a different outcome. As a consequence, the inclusion of any nonanatomic variable into a stage classification (completeness of resection, histology, etc.) seems inappropriate, and the term "prognostic model" should be used instead. A number of studies investigating possible prognostic factors in thymic tumors have been published in the past decades. The authors of one review analyzed prognostic factors for thymic tumors in the literature.[60] When only studies using multivariate analysis were considered, a total of 29 studies reporting prognostic predictors for survival were identified, and 12 studies reporting prognostic predictors for recurrence were identified. Most prognostic predictors for survival were also predictors for recurrence. The only validated prognostic factors for both survival and recurrence were the stage at presentation (Masaoka or Masaoka–Koga staging systems) and the completeness of resection. As for the stage, the majority of studies did not find a significant difference between stage I and stage II, which were collapsed into a single stage in some cases. Gender and myasthenia gravis are consistently reported as not being significant predictors for either survival or recurrence. Histology, according to WHO classification, does not seem to be a validated prognostic factor, with the exception of thymic carcinoma. Other prognostic factors, including age, tumor size, and other parathymic syndromes, were inconsistently reported as significant prognostic factors (Table 56.5). The next step will be the integration of the different prognostic factors (tumor related, host related, and environmental related) into a prognostic model. This is a necessary step to get to a prediction of prognosis from a population basis to an individual basis.[61] Any

proposed prognostic model should be validated, either internally or externally, and it should be flexible enough to include any new factor as it emerges, and should also indicate the degree of uncertainty, especially when the prognostic index is applied to individual patients.

TREATMENT OF THYMOMA

Surgery

Surgical resection is the mainstay for the treatment of thymoma, with a reported operative mortality of 2% and a complication rate of approximately 20%.[62] Treatment of thymoma depends on the location and its stage.[63] Early-stage thymomas are eligible for complete surgical resection, with an excellent early and long-term outcome. Complete resection should always be the primary goal. Results depend on the localization and the size of the tumor. The ITMIG recommends en bloc resection, including complete thymectomy and resection of the surrounding mediastinal fat, because of the possibility of subtle macroscopically invisible invasion of the tumor.[64] Some studies recently reported good results in early-stage, nonmyasthenic thymomas, after thymomectomy only, and without thymectomy, although results after long-term follow-up are expected before drawing definite conclusions.[64] The 10-year survival rates after surgical resection of thymomas are 90%, 70%, 55%, and 35% for stages I, II, III, and IVA thymoma, respectively. The recurrence rate is 3%, 11%, 30%, and 43% in resected stage I, II, III, and IVA thymoma, respectively. The disease-free survival at 10 years is 94%, 88%, 56%, and 33% for stages I, II, III, and IVA, respectively.[65]

Extent of Resection

Significantly better survival rates have been noted in patients who underwent complete resection.[3] After complete resection, 10-year survival is expected at 80%, 78%, 75%, and 42% for stages I, II, III, and IVA, respectively. Of interest, long-term survival rates for patients with stage I and III are similar when complete resection is performed. In a large series Regnard et al.[3] have shown that complete resection was the only significant prognostic factor in multivariate analysis.

Surgical Approach

Most of the experts recommend a sternotomy as the optimal incision for thymoma, because it might not be possible to perform a complete thymectomy via thoracotomy.[66,67] The transcervical approach has also been used for this purpose.[24] Minimally invasive approaches, including VATS and robotic-assisted thoracoscopic surgery (RATS) for early-stage thymomas, have been reported and are gaining popularity in specialized centers.[68–73] In particular, RATS allows an excellent exposure and precision of resection in tumors of adequate size and location (Fig. 56.6).[74] An alternative approach that we use at our institution in Zurich is a hybrid approach, which includes RATS and anterolateral thoracotomy. In this approach, we use RATS to release the left innominate vein and part of the thymus from the side where there is less tumor extent and then we dissect and retrieve the tumor from the contralateral side through an anterolateral thoracotomy. ESMO guidelines suggest that minimally invasive surgery is an option for presumed stage I and possibly stage II tumors in the hands of appropriately trained thoracic surgeons, given its similar results to those of open approaches.[75,76] Recently, a subxiphoid approach has been proposed, using either VATS or a combined VATS/RATS assistance, with excellent results for early-stage thymoma. The technique has been associated with a lower postoperative pain and a better exposure of both phrenic nerves.[77]

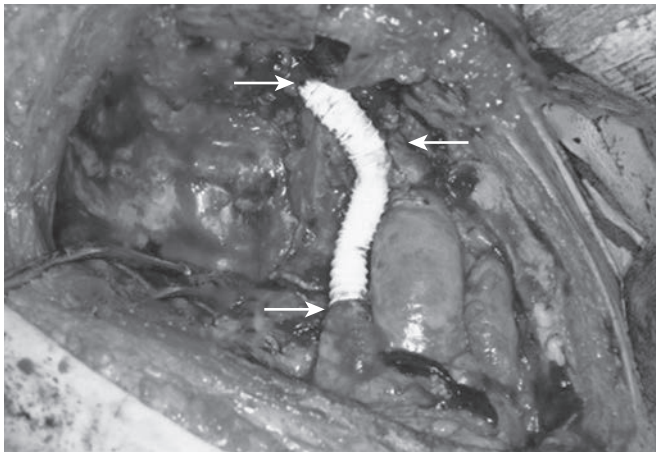
Fig. 56.7. Right-sided hemiclamshell incision for resection of thymoma.


Fig. 56.8. Intraoperative view of a patient with Masaoka stage III disease who had resection of the superior vena cava, including part of the right and left innominate veins. Right upper lobectomy and partial resection of the pericardium were also done. Reconstruction was performed with a polytetrafluoroethylene-ringed graft between the atriocaval junction and the right and left innominate veins *(white arrows)*.

Surgical Management of Stage III Thymoma

Thymoma is classified as stage III, locally advanced stage, when it has invaded the surrounding structures, such as pericardium, great vessels (SVC, innominate veins, ascending aorta, and main pulmonary artery), lung parenchyma, phrenic nerves, and chest wall. Median sternotomy is the standard approach for all stage III thymomas. This approach provides an excellent exposure if the tumor invades the adjacent mediastinal and lung structures. A clamshell (bilateral anterolateral thoracotomy with transversal sternotomy) incision has also been proposed for large tumors extending in both pleural cavities.[78] Alternatively, a hemiclamshell incision, which allows excellent exposure of the mediastinum and the involved pleural space, is recommended (Fig. 56.7). This exposure starts with anterolateral thoracotomy through the

fourth or fifth intercostal space and is completed with partial median sternotomy.[79] This incision provides an excellent exposure of the brachiocephalic vessels and phrenic nerve, compared with standard sternotomy incision. As in early-stage thymoma, complete resection is mandatory for a good outcome in any stage III thymoma. The left brachiocephalic vein, SVC, right atrium, pericardium, lung, and diaphragm should be resected if necessary. Resection of one phrenic nerve, and resection and reconstruction of the ascending aorta and main pulmonary artery, may occasionally be indicated to achieve a complete resection. Invasion of the myocardium precludes the resection.[78]

Direct invasion into the lung is generally not difficult to manage. The infiltrated part should be en bloc resected depending on the respiratory function of the patient. Wedge resection, segmentectomy, or lobectomy can be performed based on the extent of invasion into the lung. Pneumonectomy or extrapleural pneumonectomy is rarely performed, but should be considered to achieve a complete resection if the patient has adequate physiologic reserve to tolerate this procedure. In patients with appropriate lung reserve, one phrenic nerve may be resected, but resection of both nerves should be avoided. Meanwhile, phrenic nerve preservation does not affect overall survival, but increases the risk of local recurrence.[80] If the phrenic nerve is resected, plication of the diaphragm should be considered.[81] The SVC and the brachiocephalic vein(s) can be resected and reconstructed, if a complete resection could be achieved.[82] Partial resection of the wall of the SVC, with direct repair or patch, can also be done. If more than 30% of the circumference is involved, complete resection and reconstruction are needed. In such a case, reconstruction of the SVC can be done with a polytetrafluoroethylene graft (Fig. 56.8). When there is intra-atrial involvement of the SVC, resection and reconstruction of the ascending aorta and main pulmonary artery require using cardiopulmonary bypass.[83] Routine removal of anterior mediastinal nodes and anterior cervical nodes is recommended,[75,84] particularly in thymic carcinomas. Systematic sampling of other intrathoracic sites is encouraged (i.e., paratracheal, aortopulmonary window, and subcarinal areas, depending on tumor location) in stage III/IV tumors. Systematic lymphadenectomy (N1 + N2) is strongly recommended in case of thymic carcinoma. Meanwhile, the new IASLC/ITMIG TNM staging system of thymic tumors leads to the recommendation that local–regional lymphadenectomy should be carried out during resection of all types of thymic tumors.[85]

Minimally Invasive Resection

Although open surgical approaches are generally accepted as the criterion standard for thymoma resection, the use of both VATS and RATS for thymoma resection has been reported.[68–73] The main concerns for a minimally invasive thymoma resection are complete resection and the size of the tumor. With advances in the instrumentation and techniques, VATS thymectomy is being performed more frequently at many institutions. VATS thymectomy for thymoma is indicated for encapsulated or early-stage tumors (Masaoka stage I–II); generally, there is no indication for using VATS or RATS resection in more advanced stages (Masaoka stage III–IV). Although thymomas larger than 5 cm are technically difficult to remove with VATS, Takeo et al.[71] reported that 15 of 35 thymomas were larger than 5 cm in diameter. These authors use a method that lifts the sternum and takes the tumor out using a subxiphoid incision. They recommend that VATS can be used safely for clinical Masaoka stages I and II. Ye et al.[69] evaluated short-term outcomes of 46 patients who underwent surgery for Masaoka stage I thymoma with VATS and RATS. They reported comparable results between these two technologies. In a retrospective study, Rückert et al.[73] compared thymectomy by VATS and RATS and reported significant improvement in the RATS group compared with the VATS group, which included
Fig. 56.9. Coronary view of a patient with Masaoka stage IVA disease. After induction chemotherapy, we performed right pleuropneumonectomy using a right-sided hemiclamshell incision. The patient had partial resection of the superior vena cava, pericardium, and diaphragm, as well as reconstruction with synthetic patches.

17 cases of thymoma. We reported on 20 thymoma cases that involved thymectomy with RATS; the median tumor size was 4 cm, and the median follow-up was 26 months with no local, but two pleural, recurrences.[70] For our studies, and for other studies, longer follow-up is needed to conclude that the results are oncologically sufficient.

Stage IVA Thymoma

Stage IVA thymoma is defined as intrapleural or intrapericardial dissemination of tumor cells without any distant metastasis (see Fig. 56.4). Surgical options in this stage, in addition to thymus and thymoma resection, are excision of pleural/pericardial implants, total pleurectomy, and pleuropneumonectomy.[86] Although it seems to be a very aggressive approach, pleuropneumonectomy has been shown to be feasible with good outcomes in these patients (5-year survival rates between 75% and 78% in selected series).[87] In one case, after induction chemotherapy, we performed a right pleuropneumonectomy using right-sided hemiclamshell incision (Fig. 56.9). The patient had partial SVC resection and reconstruction with a pericardium patch. We also performed pericardium and diaphragm resection and reconstruction with a synthetic patch. This patient (male) did not receive any adjuvant treatment, and he was alive, without recurrence, after 48 months of follow-up. Most patients may also require diaphragm and pericardium resection as performed in mesothelioma surgery.[88]

Radiotherapy

Thymic tumors have a tendency toward local recurrence and show moderate-to-high radiosensitivity profiles. This has always been considered a prerequisite for the adoption of radiotherapy in the whole treatment strategy. Unfortunately, the rarity of these tumors, and the lack of prospective, randomized trials, makes it difficult to draw evidence-based recommendations about the efficacy of radiotherapy in the different clinical settings. It may be

delivered before surgery or after surgery, either in patients not eligible for surgical intervention or for treatment of recurrent tumors. The standard radiotherapy technique in thymic tumors is three-dimensional (3-D) conformal radiotherapy, but in most centers, to reduce the exposure of thoracic structures, such as the heart, lung, and esophagus, intensity-modulated radiotherapy (IMRT) is gradually being substituted for 3-D conformal radiotherapy. There have been no dedicated studies comparing the outcomes (efficacy and toxicity) of 3-D conformal radiotherapy with IMRT in thymic neoplasms. In other thoracic tumors such as lung cancer, toxicity was lower for IMRT.[89] Four-dimensional (4-D) CT is an advance in technology that further improved target localization and, in the process, reduced the dose to normal structures. It allows for quantitative tumor motion evaluation during treatment planning and delivery. Motion management may be important, especially when the target includes structures in the lower portion of the thoracic cavity, closer to the diaphragm. By several methods, margins can be reduced and the dose to normal tissues decreased when the clinical volumes are large. This may often occur in adjuvant radiotherapy. Proton therapy has been adopted for treating invasive thymomas, especially when the anterior mediastinum is involved. The dosimetric advantages of proton therapy in such situations should be proven to offer better clinical outcomes. In several institutions, a combination of intensity-modulated proton therapy, 4-D imaging, and adaptive radiotherapy is under investigation, with the aim of maximizing the therapeutic index.[90] The delivered doses vary based on the clinical setting, ranging from 45 Gy as neoadjuvant therapy, to 45 to 55 Gy as postoperative therapy, to 60 to 66 Gy as exclusive treatment, with conventional fractionation (1.8 Gy/day to 2.0 Gy/day).[91]

Preoperative Radiotherapy

To improve resectability rates, preoperative radiotherapy has been used alone or in combination with chemotherapy (sequential or concurrent) in a neoadjuvant (induction) setting.[92–94] Unfortunately, with the exception of a few reports, most of the studies failed to show significantly better resectability rates and survival when compared with neoadjuvant chemotherapy alone.

Postoperative Radiotherapy

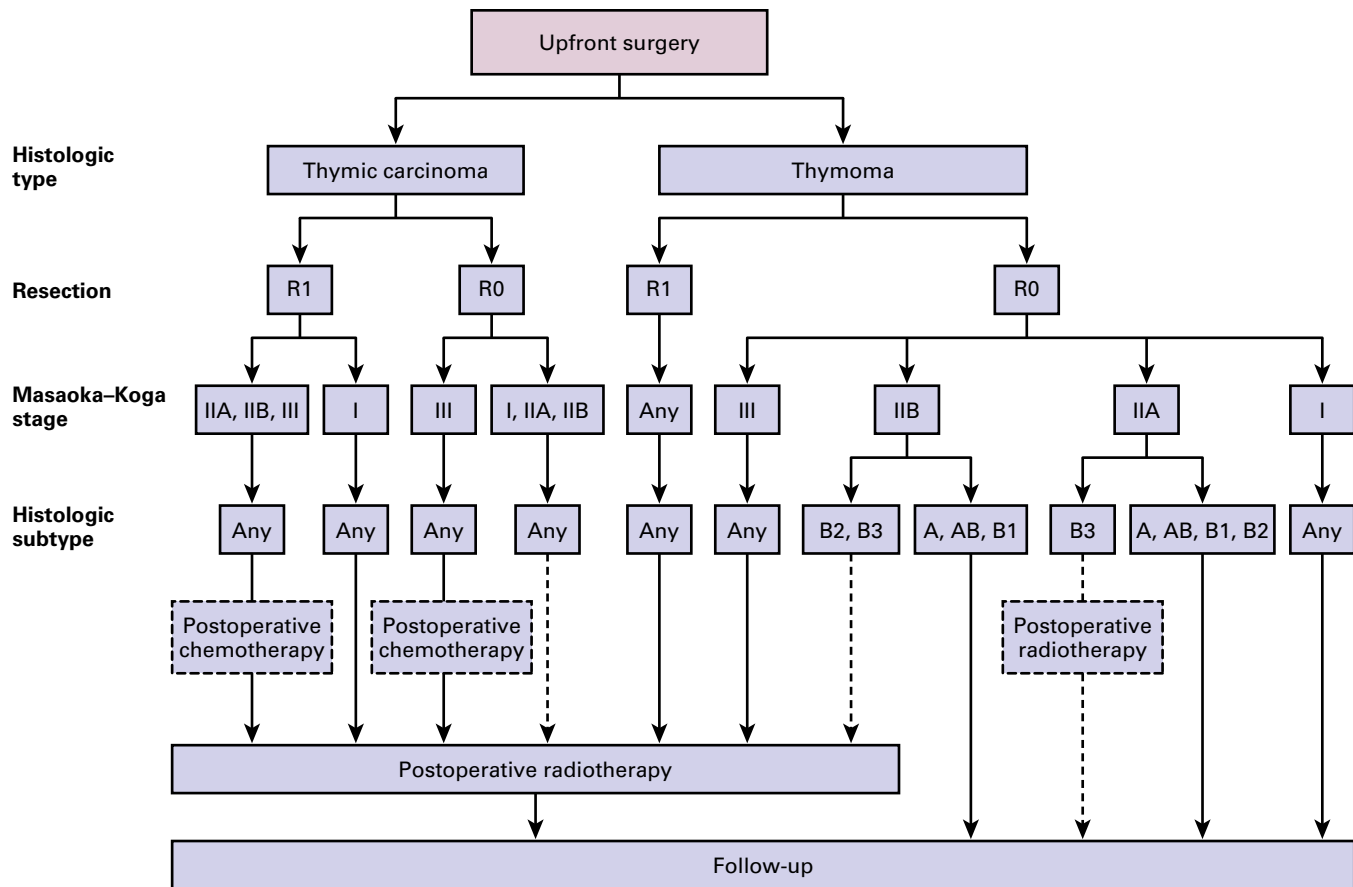
Postoperative radiotherapy is usually performed within 3 months after the surgical procedure, for a total dose of 50 to 54 Gy in 1.8-Gy to 2.0-Gy fractions. Indications for postoperative radiotherapy depend on the stage at surgery, complete or incomplete resection, and factors such as WHO histology, and possibly tumor size and presence of necrosis (Fig. 56.10).[75] In Masaoka stage I disease, adjuvant radiotherapy has no role. For stage II disease, the largest series so far found either no differences with or without radiotherapy or a detrimental effect.[43,95] However, it should be noted that a more recent series suggested an improved disease-free survival using postoperative radiotherapy for WHO type B2 or B3 thymoma and thymic carcinoma.[96–98] Adjuvant radiotherapy has a well-established role in the treatment of stage III disease in clinical practice, although the level of evidence is low. Several earlier studies demonstrated a decrease in the rate of recurrence (0% to 20%) after complete resection and postoperative radiotherapy, which was significantly lower than after surgery alone.[99] More recent studies have demonstrated the efficacy of postoperative radiotherapy for stage III to stage IV disease,[100,101] whereas other trials have failed to show any significant advantage.[51,102] A study of data on 626 invasive thymomas in the US Surveillance, Epidemiology and End Results (SEER) registry showed a similar cause-specific survival for postoperative radiotherapy and surgery alone (91% vs. 86%, $p = 0.12$).[103] Similar results were obtained in a 2009


Fig. 56.10. Postoperative management of thymoma and thymic carcinomas: European Society for Medical Oncology clinical practice guidelines algorithm.[75]

meta-analysis incorporating stage II and III disease.[104] Among 592 patients from 13 different studies, no significant difference was found between surgery alone and surgery plus radiotherapy (odds ratio, 1.05; p = 0.63).

Ultimately, the global trend over the past years has been toward a less frequent use of postoperative radiotherapy in thymoma, and to keep it in reserve for high-risk cases.[75] This is based on recent reports from large databases,[103,105–109] as well as pooled analyses of retrospective studies,[104] indicating

- the absence of survival benefit after radiotherapy in stage I thymoma, or after R0/1 resection of stage II to stage III thymoma;[103,106,107]
- a similar rate of recurrence in patients who received postoperative radiotherapy or not after complete resection of thymoma;[104,110] and
- a recurrence-free survival and overall survival benefit with postoperative radiotherapy after resection of thymic carcinoma.[106,108,109]

Stage and completeness of resection are thus the most relevant criteria in the decision making, followed by histology. Those factors are the most significant predictors of survival; however, one must take into account that retrospective analyses are likely to be biased, because postoperative radiotherapy is most likely administered in patients with incomplete resection or high-grade tumors. Therefore the absence of survival differences may then suggest that postoperative radiotherapy reduced or overcame the risk of recurrence in those patients. Another point to consider is that recurrences of thymic epithelial tumors occur outside the mediastinum in more than 60% of cases.[111]

Therefore it appears that the evidence to support using postoperative radiotherapy for completely resected, invasive thymomas is lacking. Incorporating additional factors, including high-risk WHO histologic subtypes, large tumors (more than 8 cm), and close margins, may be taken into account when considering whether postoperative radiotherapy is indicated for an individual patient. Conversely, a higher level of evidence seems to support the use of adjuvant radiotherapy for patients who have an incomplete resection (R1 or R2). The ESMO Clinical Practice Guideline recently proposed a decision algorithm for postoperative radiotherapy, integrating those data (see Fig. 56.10).

Definitive Radiotherapy

Radical (so-called curative) radiotherapy is customarily used for patients who are not surgical candidates, or for patients who have inoperable disease after induction chemotherapy. For such patients, chemoradiation therapy is usually delivered in a sequential manner, to a total dose of 54 to 70 Gy. The response rate reaches 70%, with a 5-year survival projection of 70% to 80%. These results are similar to those reported after surgery with incomplete resection.[92,112]

Chemotherapy

As for other thoracic malignancies, chemotherapy regimens are selected in accordance with the intended use in patients with thymic neoplasms. This depends on the tumor size, signs of infiltration on imaging, stage, and histology. Thymic tumors are generally chemosensitive, although thymomas are more sensitive

TABLE 56.6 Polychemotherapy Regimens in Stage III to Stage IV Thymic Tumors in Small Series

Author (Year)	No. of Patients	Percentage of Complete Resection (R0)	Treatment		Polychemotherapy		Partial Response or Better (%)
			Induction	Postoperative	Regimen	Schedule

NG, Not given.

to chemotherapy than thymic carcinomas. As described earlier, the primary goal of treatment is the complete surgical resection (R0) of the thymic neoplasm. Chemotherapy strategies include chemotherapy used both as initial treatment and as treatment in case of recurrence. Chemotherapy as initial treatment can be further divided into chemotherapy with curative intent (primary or preoperative chemotherapy or postoperative chemotherapy) and chemotherapy with palliative intent.[75,110] Exclusive (palliative) chemotherapy is administrated in patients medically or technically not qualified for surgical procedures, or for patients with metastatic disease.

Primary (Induction, Preoperative) Chemotherapy

The major goal of induction chemotherapy is to downstage the tumor prior to surgery. Therefore, chemotherapy regimens have to be evaluated based on their ability to induce response (Table 56.6). In 2013, a Cochrane meta-analysis was performed to evaluate the role of induction therapy. Forty-nine relevant, randomized studies were identified, but none of them met the criteria necessary for a Cochrane analysis.[113] Therefore all published guidelines related to multimodal treatment of thymic neoplasm continue to be based on expert opinions. The majority

TABLE 56.7 Selected Chemotherapy Combination Regimens for Thymomas and Thymic Carcinomas

Regimen	Agents	Doses
ADOC	Adriamycin	40 mg/m^2/3 weeks
	Cisplatin	50 mg/m^2/3 weeks
	Vincristine	0.6 mg/m^2/3 weeks
	Cyclophosphamide	700 mg/m^2/3 weeks
CAP	Cisplatin	50 mg/m^2/3 weeks
	Adriamycin	50 mg/m^2/3 weeks
	Cyclophosphamide	500 mg/m^2/3 weeks
PE	Cisplatin	60 mg/m^2/3 weeks
	Etoposide	120 mg/m^2 × 3/3 weeks
VIP	Etoposide	75 mg/m^2 × 4 d/3 weeks
	Ifosfamide	1.2 g/m^2 × 4 d/3 weeks
	Cisplatin	20 mg/m^2 × 4 d/3 weeks

AUC, Area under the curve.

of reported primary chemotherapy regimens are part of multi-modality treatments. This may include presurgical or additional postoperative radiotherapy with and without chemotherapy. Therefore, the rate of complete resections (R0) and the response rates after induction chemotherapy are often difficult to evaluate, because different regimens are used. On average, for patients with stage III to stage IV thymic neoplasm, induction therapy achieved a response rate of 71% (29% to 100%) and surgery resulted in a complete resection in 68% (22% to 86%). All regimens consisted of a combination of multiple drugs. The backbones of the induction therapies were cisplatin, anthracyclines, etoposide, and cyclophosphamide. A 2013 study showed that a combination of a taxane and cisplatin achieved response rates of 63% and 79% in complete resections (R0).[114] Overall, about 75% of patients with advanced thymic neoplasm who received multimodal therapy survived 5 years.[115] These induction chemotherapy regimens are associated with toxicities that have to be taken into account. Predominantly, the induction regimens resulted in hematologic toxicity. Patients treated with induction treatment with multiple-drug chemotherapy have to be medically fit enough to have a performance status after induction that allows major surgery. However, patients with thymic malignancies tend to be younger with less comorbidities compared with patients who have lung cancer. This means that even intense chemotherapy regimens with multiple drugs can be administered in this patient population.

Postoperative (Adjuvant) Chemotherapy

In the majority of the cases, postoperative therapy after resection of thymic tumors consists of radiotherapy or both radiotherapy and chemotherapy. In contrast to lung cancer, improved local control is the main focus of adjuvant therapy in thymic neoplasms. For this reason, chemotherapy alone is rarely used in an adjuvant setting. Authors of a Japanese retrospective study that included more than 1300 patients with thymoma found no improvement of survival in a subgroup of 473 patients with complete resection (R0) who were treated with induction therapy and postoperative chemotherapy, compared with patients treated with induction therapy only.[43,75]

Exclusive (Palliative) Chemotherapy

In cases when metastatic spread, or other reasons, prohibits local treatment with surgery or radiotherapy, exclusive chemotherapy with palliative intent is offered. Patients with relapse after curative-intent therapy are also treated with palliative chemotherapy. Monotherapies with cisplatin, ifosfamide, and paclitaxel were used in these patients.[123] Recently, amrubicin, a new anthracycline, was tested in nine patients with platinum-refractory disease, resulting in a 44% response rate.[124] In addition, for 13 patients who were pretreated with pemetrexed, the overall response rate was 17%.[125] The combination of steroids and octreotide was used for symptom and tumor control. Overall, patients treated with single-agent therapies achieved a response rate of 28%, and a median overall survival of about 2 years.[126]

The current standard is combination chemotherapy, based on cisplatin regimens (Table 56.7).[127–129] No randomized studies have been conducted, and which regimen should be considered standard remains unknown. Multiagent combination regimens and anthracycline-based regimens appear to have improved response rates compared with etoposide-based regimens. A combination of cisplatin, doxorubicin, and cyclophosphamide is preferred.[75]

Combined Radiotherapy and Chemotherapy

Radiotherapy is the mainstay of postoperative therapy, and is included in the majority of multimodal therapy concepts. The rationale for combining chemotherapy and radiotherapy (chemoradiation therapy) is to augment cytotoxicity against remaining tumor cells. In one study, chemoradiation therapy was used as induction therapy, resulting in a response rate comparable to chemotherapy alone.[93] Chemoradiation therapy can also be used in the postoperative setting if a large unresectable tumor volume remains in the thorax after resection (i.e., an R2 resection). In addition, chemoradiation therapy is the definitive treatment for patients who are not medically fit for surgery or who have a thymic neoplasm that is technically not resectable.[91] Twenty-three patients with unresectable thymoma were treated with a combination of cisplatin, doxorubicin, and cyclophosphamide, and thoracic radiation. A total of 5 complete and 11 partial responses to chemotherapy (overall response rate of 69.6%) were reported. The 5-year survival rate was 52.5%.[130]

Targeted Therapy

When it comes to targeted therapies, the differences between thymomas and thymic carcinomas become even more obvious at the molecular level. The expression of major histocompatibility molecules, autoimmune regulator, and the capacity to mature lymphocytes are different because both entities are differentially developed from their common epithelial progenitor cell. This results in different expression of target molecules, such as KIT mast/stem cell growth factor receptor, epidermal growth factor receptor, and insulin-like growth factor receptor-1.[131]

When analyzed by immunohistochemical methods, KIT is overexpressed in 2% of thymomas and in 79% of thymic carcinomas.[132] There are activating mutations in exons, 9, 11, 13, and 17 only in thymic carcinomas.[75,129,132,133] Imatinib is a small-molecule multikinase inhibitor that blocks KIT, Bcr-Abl, and platelet-derived growth factor receptor. Treatment with imatinib resulted in short disease stabilization in phase II studies.[134]

Angiogenesis is of special importance during the development of thymic neoplasm. Vascular endothelial growth factor-A levels were elevated in serum samples from patients with thymic carcinomas, and vascular endothelial growth factor-R1 and R2 were expressed in the malignant thymic tissue. Therefore
Fig. 56.11. Thymic carcinoma: computed tomography images, surgical access, and operative specimen.

angiogenesis appears treatable with small-molecule, multi-tyrosine kinase inhibitors, such as sunitinib.[135,136] A phase II trial recently demonstrated the efficacy of sunitinib in terms of response and disease control rate (DCR) in thymic epithelial tumors, including thymic carcinomas (objective response rate, 26%; DCR, 91%) and, to a lesser extent, thymomas (objective response rate, 6%; DCR, 81%).[109] Sunitinib may then represent an off-label option as a second-line treatment of thymic carcinomas, independently from KIT status.[137]

More recently, everolimus was evaluated in thymic epithelial tumors in a recently reported phase II trial reporting on a 22% response rate, as well as a 93% DCR. Everolimus may, therefore, represent an off-label option for refractory tumors.[136]

THYMIC CARCINOMA

Thymic carcinomas are rare tumors of the mediastinum, with a prevalence of one to three cases per 10 million people.[1] Among thymic tumors, 15% to 20% are thymic carcinoma. Until recently, thymic carcinoma has been considered a subtype of thymoma (type C thymoma). The 2004 WHO histologic classification clearly defines thymic carcinoma as a distinct tumor from thymoma. In contrast to thymomas, thymic carcinomas show a distinct histology (cytologic atypia, lack of an organotypic appearance, and resemblance to carcinomas occurring elsewhere in the body), have a more aggressive clinical behavior, and have a poorer prognosis. Population-based studies show an average 16% resection rate in patients with thymic carcinoma. The 5-year survival rate is 17% for patients who do not have surgery.[138]

Clinical Presentation and Diagnosis

Approximately 60% of patients with thymic carcinoma are symptomatic; approximately 40% have node metastases at the time of presentation and 10% have distant metastases. Symptoms include chest pain, dyspnea, cough, or sign of SVC compression. Associated paraneoplastic syndromes—represented by polymyositis or dermatomyositis or erythropoietin hypersecretion—are rare in thymic carcinoma.[2] Myasthenia gravis is rarely seen with thymic carcinoma, with a prevalence reported in the literature of 0% to 15%.[139] Imaging techniques most often reveal a poorly defined mediastinal mass showing radiographic signs of infiltration of the surrounding organs (loss of surrounding fat plane), sometimes with associated pleural effusion, pleural nodules, and lymph nodal enlargement, as evidence of advanced disease (Fig. 56.11). MRI may be of help to better define the direct vascular invasion. Some investigators have found FDG-PET to be useful in the differential diagnosis with thymomas and in detecting node or distant metastases.[140]

Histology

The 2004 WHO classification clearly separates thymic carcinomas from thymomas. This classification also recognizes 11 subtypes of thymic carcinoma, including NETTs, which are considered, by most authors, as a separate entity. The most frequent subtype thymic carcinoma is squamous cell carcinoma (40%), followed by lymphoepithelioma-like (15%).[141] According to some studies, the squamous cell type is associated with a better

prognosis than other subtypes.[142] The differential diagnosis of thymic carcinoma from more aggressive subtypes of thymomas (type B3, well-differentiated thymic carcinoma) may be difficult, and large interobserver variability in the histologic allocation to these two groups has been reported. The ITMIG addressed this important issue with a dedicated consensus statement that tried to establish objective criteria for optimal differentiation among the histologic categories.[28]

Staging System

There is no general agreement about optimal staging of thymic carcinoma. The ITMIG recommends using the Masaoka and Masaoka–Koga staging systems, which are consistently applied in thymomas. Some authors, however, did not find a good survival stratification among Masaoka stages and have proposed modifications of the original Masaoka staging system, including the collapse of stages I and II and stages III and IV into a two-tiered system.[147] The high prevalence of node metastases in thymic carcinoma prompted some authors to suggest the use of a TNM-based system, as recommended by WHO.[47] A further staging classification that recognizes three-stage categories based on the extent of the regional involvement (stage I and II) and metastatic/distant disease (stage III) has been proposed.[144]

The new TNM-based system expected in 2017 will be most suitable for thymic carcinomas, given the integration of nodal and metastatic involvement, which are more frequent as compared with thymomas (see Table 56.2).[49,85]

Treatment

As in other thymic malignancies, surgery represents the cornerstone of therapy for thymic carcinoma. A complete resection should always be attempted, because it represents the single most important prognostic factor. The approach to treatment for most patients with thymic carcinoma involves using a median sternotomy access, which allows an excellent view of the anterior mediastinum and both pleural cavities. As in NETT, the surgeon should be ready to perform extended resection to neighboring structures, including mediastinal pleura, lung, pericardium, phrenic nerve (monolateral), and the SVC. When the tumor invades nonresectable intrathoracic structures (aorta, heart, bilateral phrenic nerves), residual tissue is left behind, and clips are placed to facilitate postoperative radiotherapy. Very often, in locally advanced tumors, a combined sternothoracic approach, using extended accesses (clamshell, hemiclamshell, sternothoracotomy), is performed to gain a view to the intrathoracic structures, which should be resected. Similar to the situation with NETT, when treating thymic carcinoma, there is little room for minimally invasive techniques (VATS and RATS). Resection of the tumor should be associated with a regional lymphadenectomy for staging.

The role of chemotherapy and radiotherapy as adjuncts to surgery is far less established in thymic carcinoma than it is in thymomas, due to the rarity of the condition. Most cases include in their population both thymomas and thymic carcinoma, and sometimes it is difficult to extrapolate the results for thymic carcinoma. As evidenced in an ESTS survey, most surgeons agree that thymic carcinoma should be approached in a multimodality setting.[25] When the tumor is considered nonresectable, induction (primary) chemotherapy may be indicated, followed by surgical resection. After resection, the role of adjuvant therapies (mostly radiotherapy) remains undefined. In a landmark Japanese series, including 92 patients with thymic carcinoma who had complete resection, survival was better after adjuvant chemotherapy than after no additional treatment, radiotherapy, or chemoradiation therapy.[43] Some series failed to find any survival advantage with the use of postoperative radiotherapy after resection of thymic

carcinoma,[144] but others found a marginal benefit.[145,146] A study based on a retrospective review of data in the ESTS database found that surgery followed by radiotherapy conferred a significant survival advantage over surgery alone.[139] The lack of prospective studies and the unavoidable selection bias of all the published retrospective studies somehow present a limitation. Therefore, a reasonable suggestion, based on the published literature, seems to recommend postoperative chemoradiation therapy after resection of thymic carcinoma—if there was no preoperative treatment—and radiotherapy only if primary chemotherapy was used (see Fig. 56.10).[75,147,148] For patients who are considered to be inoperable, chemotherapy and radiotherapy have produced response rates of 20% to 60%. The discovery of an overexpression of some molecular markers (such as KIT) in thymic carcinomas (up to 79% of the cases) stirred some enthusiasm for a possible biologic therapy.[149] Unfortunately, despite the high overexpression of KIT, only a small percentage of patients with thymic carcinoma have KIT mutations (9%), consisting of mutations observed in gastrointestinal stromal tumors or melanomas (V560del, L576P), or restricted to thymic carcinomas (H697Y, D820E).[75,147] Responses were reported with the use of KIT tyrosine kinase inhibitors imatinib, sunitinib, or sorafenib, mostly in single-case observations.[121] KIT sequencing (exons 9–17) is an option for refractory thymic carcinomas in the setting of potential access to such inhibitors, particularly in the context of clinical trials.[75]

Immunotherapy using the program death-1 checkpoint inhibitor pembrolizumab was recently assessed in refractory thymic carcinomas.[150] An ongoing phase II trial enrolled 30 patients, with a 24% response rate. Most of the responses were durable, an observation similar to that observed in nonsmall cell lung cancer in the second-line setting; the safety profile was characterized by some frequent and severe toxicities such as myositis, myocarditis, and pemphigus.

Survival and Prognostic Factors

In almost all cases, thymic carcinoma portends a poorer prognosis than do thymomas. Five-year survival rates vary from 30% to 85% according to most authors;[145,151] improved survival rates have been reported in later series. Based on results from the most recent studies, complete resection is associated with the best survival rates, although incomplete resection seems to confer a survival advantage over simple biopsy.[152] Therefore some authors advocate a debulking resection rather than no resection at all, in the case of nonresectable tumors.[139] Among different prognostic predictors, complete resection and early stages seem to be the most consistent factors among all the published series, and tumor size, associated paraneoplastic syndromes, and histologic subtypes are not uniformly reported to be significant in the largest series (Table 56.8).

NEUROENDOCRINE THYMIC TUMOR

NETTs represent around 2% of all neuroendocrine tumors and about 5% of all thymic malignancies.[156] Similar to their counterparts in other organs, they are often associated with endocrinopathies or other paraneoplastic syndromes. About 400 cases of NETT have been reported in the literature so far.

Clinical Presentation and Diagnosis

NETTs are more often seen in men, with a male-to-female ratio of 3:1. Mean age at presentation is 54 years, with a wide age range (16–97 years). Unlike thymomas, NETTs are usually symptomatic (70% of the cases).[157] The most frequent symptoms include cough, asthenia, chest pain, dyspnea, and, sometimes, SVC syndrome. On other occasions, patients present with signs and

[a]Study included advanced-stage disease only, and no surgery was performed (chemotherapy was given).

symptoms of associated endocrinopathies or of distant metastases. Twenty percent of patients have metastases at presentation, with a prevalence of extrathoracic metastases as high as 30%. CT and MRI both show a large, lobulated mass, with radiographic evidence of invasion of the surrounding organs. Less often, they present as a well-circumscribed, capsulated lesion with few signs of invasion. [18]FDG–PET/CT is of little diagnostic use in NETT. Among new diagnostic tools, promising results involving the use of ^{68}Ga-1,4,7,10-tetraazacyclododecane-N[I],N[II],N[III],N[IIII]-tetraacetic acid (D)-Phe1-thy3-octreotide (DOTATOC) PET/CT have been published.[158] The presence of receptors for somatostatin (subtype 2, sst2) suggests the use of specific scintigraphy (octreotide scan) using 111-indium-diethylenetriamine pentaacetic acid-D-phenylalanine-octreotide.[159] As with other neuroendocrine malignancies, NETTs are frequently associated with paraneoplastic syndromes (endocrinopathies), including adrenocorticotropic hormone secretion (Cushing syndrome), MEN type 1 (MEN-1 or Wermer syndrome, with tumors of the parathyroids, pancreatic islet cells, and pituitary gland), and growth hormone-releasing hormone hypersecretion with ectopic acromegaly. Other less frequent syndromes include prolactin secretion, MEN-2, peripheral neuropathy, and Lambert–Eaton syndrome. Unlike lung and gastrointestinal neuroendocrines, carcinoid syndrome is unusual. Lastly, the association with myasthenia gravis is also unusual, with only one case reported in the literature.[159]

Histologic Classification

According to the 2004 WHO classification, NETTs are considered a subtype of thymic carcinomas and separate from thymomas.[55] Several histologic subtypes of NETTs have been proposed. The two most used classifications are the WHO and the Armed Forces Institute of Pathology. Some authors still use the standard classification of NETTs as typical and atypical carcinoids, and large and small cell neuroendocrine carcinomas. The WHO classification categorizes NETT into well-differentiated neuroendocrine carcinomas (including typical and atypical carcinoids) and poorly differentiated neuroendocrine carcinomas (including small and large cell neuroendocrine carcinomas).[160] The Armed Forces Institute of Pathology classification divides NETT into well, moderately, and poorly differentiated forms, based on morphologic criteria and mitotic count.[161] The pivotal roles of the proliferation index (mitotic count) and the Ki-67 index have been recognized, and both indexes have been incorporated into the European Neuroendocrine Tumor Society grading classification. The European Neuroendocrine Tumor Society system includes three groups: G1 (<2 mitoses per 10 high-power fields [HPFs] and/or Ki-67 index of ≤2%); G2 (2–20 mitoses per 10 HPFs and/

or Ki-67 index of 3% to 20%); and G3 (>20 mitoses per 10 HPFs and Ki-67 index >20%.).[162] In 2010, the revised WHO classification of neuroendocrine tumors confirmed the importance of proliferative indexes and defined three groups of tumors according to the combination of morphologic features and of mitotic count and/or Ki-67 index: neuroendocrine tumor/neoplasm G1, neuroendocrine tumor/neoplasm G2, and neuroendocrine carcinomas.[163] The validity of this classification has been successfully tested in gastroenteropancreatic neuroendocrine tumors and, more recently, in NETTs.[164]

Staging System

There is no official staging system for NETTs. Customarily, most series used the Masaoka or Masaoka–Koga staging systems, which are currently used for other thymic malignancies. A TNM staging system for thymic tumors has been proposed by the WHO and has been used in some series, based on the finding that node or distant metastases are present in about 50% of NETTs at the time of diagnosis.[47] Recently, Gaur et al.,[167] using the SEER database, proposed a staging system based on the localized, regional, or distant extension of disease. According to this staging system, tumors that remain in situ or confined to the organ are regarded as localized. Tumors that locally invade or metastasize to regional lymph nodes are considered to be regional, and tumors that spread to distant organs are categorized as distant. The IASLC/ITMIG Staging Committee is working on the forthcoming eighth edition of the TNM staging manual of thoracic malignancies and will propose a common TNM staging system for all thymic tumors, including NETTs. This system is expected to be fully operative by 2017.

Treatment

Surgery remains the mainstay of therapy for NETTs. As in other thymic malignancies, the possibility of performing a complete resection (R0) is the most important prognostic factor. The efficacy of treatment of NETT has been evaluated in several published series (Table 56.9). The preferred surgical access is median sternotomy, which allows an optimal view of the anterior mediastinum and both pleural spaces. If the tumor invades the lung, it may be necessary to use a combined sternothoracotomic approach, with a hemiclamshell or clamshell incision (Fig. 56.12). Resection of the tumor should be associated with a regional lymphadenectomy for staging. Because of the frequent local extent of the tumor, minimally invasive techniques have no indications in NETTs. In case of associated MEN-1 syndrome with hyperparathyroidism, a concurrent thymectomy and cervical

neck exploration should be considered to prevent recurrent disease from spreading to the supernumerary glands. Some authors suggest a routine prophylactic thymectomy in male patients with MEN-1 who are undergoing cervical neck exploration for hyperparathyroidism.

Resectability rates largely depend on the centers and their experience in major resection of intrathoracic structures. Sometimes, the surgeon is forced to leave residual tissue on nonresectable structures (e.g., heart, aorta, the phrenic nerves). Incomplete resection has been recommended by some authors for symptom relief (associated endocrinopathies) and to facilitate adjuvant treatments.

The role of chemotherapy and radiotherapy in NETT is far less established than in other thymic tumors. Preoperative

(primary or induction) chemotherapy or radiotherapy has been suggested in the case of tumors that are not considered to be resectable at the time of diagnosis.[170] Radiotherapy has been investigated as a way to reduce recurrence and to improve long-term survival after surgery. Although postoperative radiotherapy is commonly used, a report based on data in the SEER database demonstrated that postoperative radiotherapy had a detrimental effect on long-term survival, although the authors pointed out a potential preselection bias in this group of patients.[167] Other series, however, have demonstrated a reduced risk of recurrence with postoperative radiotherapy.[159] Lastly, postoperative chemotherapy is associated with limited efficacy and a non-negligible toxicity. Cisplatin-based chemotherapy is currently used for patients with poorly differentiated tumors presenting with

metastatic or nonresectable disease. Other authors reported good response rates using a combination of temozolomide and a platinum-based regimen. They suggest using temozolomide as first-line therapy for patients with well- or moderately differentiated NETT, because of fewer side effects.[156]

The expression of somatostatin receptors in NETT, and the antiproliferative activity of somatostatin, led some investigators to evaluate somatostatin analogs (octreotide and lanreotide) for the treatment of these tumors. Unfortunately, the results have not been promising so far, and their use cannot be recommended outside approved clinical trials. A promising new therapeutic strategy includes the use of radiolabeled (^{111}IN-DTPH 3) octreotide for radionuclide therapy.[171] The radionuclide could theoretically be replaced with a chemotherapeutic agent specific to NETT. The efficacy of this therapy, although theoretically appealing, is yet to be defined. Ultimately, everolimus represents an approved treatment for advanced, lung, and digestive non-functional NETTs, which may be used off-label in refractory thymic NETTs.[172]

Prognostic Factors, Recurrence, and Follow-Up

NETTs are more aggressive than neuroendocrine tumors in other organs. In addition, among thymic tumors, NETTs are associated with the lowest survival rate and the highest rate of local–regional, lymph node, and distant metastases. Five-year survival rates after treatment of NETT vary considerably, from as low as 28% to 84% (see Table 56.9). This variation may reflect the different accrual of the centers, as well as the evolving management strategies over the years. More recent series generally demonstrate better results than do historical ones.[137] A number of prognostic factors have been correlated with survival. The most important prognostic factors reported in almost all of the largest series include the stage (Masaoka, TNM, or system used by Gaur et al.[167]), the completeness of resection, and the degree of histologic differentiation. According to some series, the association of endocrinopathies (MEN-1 and Cushing syndrome) is also associated with a poorer survival. Less validated prognostic factors include tumor size (5-cm or 7-cm cutoff) and Ki-67 index.[169,173] As with other thymic tumors, recurrence is not uncommon in NETT. According to the ITMIG recommendations, recurrences may be divided into local, regional, or distant. Treatment of recurrence largely depends on its extent. Repeat resection may be considered for local or regional recurrence, with reported satisfactory long-term survival.[159,166] Systemic therapy should be considered for unresectable or distant recurrences. Because of the high risk of long-term recurrences, lifelong follow-up is mandatory in NETT; CT is the recommended imaging technique. In case of suspected recurrence, MRI or octreotide scan should be considered for the assessment of resectability.

RECURRENT THYMIC TUMORS

Although surgery remains the mainstay of treatment for all thymic tumors, relapse after surgery is not infrequent. Because of the relatively slow-growing nature of these tumors (with the notable exceptions of thymic carcinoma and NETT), and the fact that many patients with relapse may live a long time and die of another cause, the issue of treatment for recurrence of these tumors is of particular importance. Even after complete resection, recurrence rates are reported in the range of 10% to 30%, and up to 50% in more aggressive tumors.[174–176] The average time to recurrence is 5 years, although recurrences have been recorded up to 20 years after initial resection. Time to recurrence has been reported to be longer for stage I than stage II to stage IV disease (10 vs. 3 years). The recurrence rate largely depends on the stage, being negligible after resection of stage I thymomas (<4%) and progressively increasing from stage II to stage IVA (20% to 50%).[142] Recurrence

rates increase with histology from type A to B3 in thymoma (from 5% to 15%), and they also increase in thymic carcinoma (30% to 40%) and NETT (40%). Until recently, there has been confusion regarding the exact terminology in recurrent thymic tumors. The ITMIG addressed this issue and proposed using the term recurrence only after a complete resection (R0).[23] In addition, three patterns of recurrence were identified: local, in which recurrent disease appears in the anterior mediastinum or lower neck or is contiguous to the initial thymoma; regional, in which intrathoracic recurrent disease occurs in the pleura (visceral or parietal) or pericardium not contiguous with the thymus bed; and distant, in which recurrence is outside the thorax or lower neck or in the form of intrapulmonary nodules. Overall, the distribution pattern includes local recurrence in 30% to 35%, regional recurrence in 50% to 55%, and distant recurrence in 5% to 10% of patients.[177] An increased prevalence of distant recurrences has been reported in thymic carcinoma and NETT. The ITMIG analyzed 12 studies evaluating prognostic factors for recurrence; the single most important predictor of recurrence was the stage at presentation (almost all these studies used Masaoka or Masaoka–Koga stage).[61] Many studies did not find a significant difference between stage I and stage II disease (which were collapsed into one stage in some studies) and between stage III and stage IV disease. Completeness of resection, with safe surgical margins, is obviously a determinant for recurrence, and is part of the definition of recurrence. WHO histology (for thymic carcinoma), although prognostic for survival, was of less prognostic significance when recurrence was analyzed; furthermore, many authors tend to dichotomize the different WHO subgroups to achieve the so-called best results. Among other prognostic factors, only tumor size and invasion of great vessels were occasionally reported as prognostic for recurrence.

Diagnosis

Recurrence after resection of thymic tumors is diagnosed at follow-up, which raises the issue of the frequency and duration of follow-up for these tumors. There is a general agreement that, due to the possibility that disease will not recur until very late in the disease history, a life-long follow-up is mandatory for all thymic tumors.[139] As for the frequency of follow-up, some authors recommend yearly CT for the first 5 years, followed by alternating CT and chest radiography on a yearly schedule until year 11, and then chest radiography thereafter.[20] For high-risk thymomas (WHO stage B2 or B3), incomplete resections, and thymic carcinomas or NETTs, CT every 6 months is advisable for the first 3 years. MRI may be an attractive alternative, especially for young patients. PET/CT is not indicated for routine follow-up, and its use should be reserved for selected cases. Histologic confirmation of a suspicious recurrence is not routinely indicated, because treatment may be instituted in the presence of imaging evidence. There is a great amount of literature that investigates the role of postoperative (adjuvant) treatments (chemotherapy, radiotherapy, or chemoradiation therapy) in reducing recurrence rates after complete resection of thymic tumors. Adjuvant therapy (radiotherapy or chemoradiation therapy) is currently used for as many as 60% of patients with invasive (stage II–IV) thymic tumors, according to a survey by the ESTS.[25] This empirical attitude, however, seems to be mostly based on historical single series and retrospective series, lacking consistent validation. The authors of two studies questioned the usefulness of postoperative radiotherapy after complete resection of stage II to stage IV thymic tumors.[43,103] A 2009 meta-analysis confirmed the results of these two studies, indicating no evidence of a survival advantage associated with the use of postoperative radiotherapy after complete resection of thymic tumors (all stages).[104] Although many of these series focused their results on survival, similar results have also been obtained for recurrence.[26] Indeed, most thymomas

relapse in the pleura, which is outside the radiation field of postoperative radiotherapy.[178] Using low-dose, whole hemithorax radiation to prevent pleural relapse has also been advocated by some authors.[179] In the absence of approved guidelines for the use of postoperative radiotherapy after complete resection of invasive thymomas, radiation therapy should be considered on an individual basis and further refined based on different covariates (tumor size, distance of free margins, WHO histology, invasion of great vessels).

Treatment

Treatment of recurrent thymic tumors after curative treatment is not standardized and depends on the extent of the relapse. The pattern of relapse has been found to be significantly different in thymoma and in thymic carcinoma. Thymic carcinoma has been associated with a higher rate of distant recurrence, earlier onset, and lower progression-free survival compared with thymomas.[180]

Surgical resection seems to be the optimal treatment for single, local, and easily resectable relapse and should be recommended. At the other end of the spectrum, surgery should not be considered for patients with bulky, local–regional unresectable recurrence or distant metastases. Instead, chemoradiation treatment may be offered (chemotherapy only for cases of distant relapse).[176] In patients with marginally resectable recurrent disease without distant metastases, surgery may be challenging, with the need for repeat sternotomy or extended surgical accesses and extended resection, or iterative surgery. In these cases, a multimodality approach using induction chemotherapy seems an attractive option, potentially increasing the resectability of residual tumor. The paucity of studies and patient series addressing this issue may partly explain the individualized approach that is being used at most centers. Overall, the resectability rate of recurrent thymic tumor ranges from 50% to 75%.[95,175,181,182] All series but one demonstrated improved survival,[183] if complete resection of recurrence was feasible (which occurs in about 65% of the cases), with survival rates comparable with those of the initial stages, ranging from 50% to 70% at 10 years for complete resections, compared with 0% to 20% for incomplete resections. In one series, published in 2012, surgical resection was associated with a better outcome in recurrent thymoma, but played a limited role for recurrent thymic carcinoma.[184] Chemotherapy seems to be a more effective treatment strategy. Iterative surgery is also indicated in case of subsequent resectable relapse. Surgery should be extensive and complete, particularly in case of pleural dissemination. The authors of two series reported excellent survival rates after aggressive surgery, including extrapleural pneumonectomy and the use of hyperthermic intrapleural chemotherapy, in the management of pleural recurrence of thymic malignancies.[178,185] Nonsurgical treatments of recurrence include chemotherapy or chemoradiation therapy, which have been associated with reasonable outcomes (5-year survival of 25% to 50%).[26,175,177]

RECOMMENDED MANAGEMENT OF THYMIC TUMORS

Several reviews on the management of thymic tumors are available in the literature.[2,26,147,186–188] In addition, the US National Cancer Institute developed guidelines that are available on its website (http://www.cancer.org/cancertopics/pdq/treatment/thymoma/healthprofessional) and that are periodically updated. Lastly, two volumes of *Thoracic Surgery Clinics* (February 2009 and February 2011) and a supplement of the *Journal of Thoracic Oncology* (July 2011) have focused on thymic tumors. ESMO Clinical Practice Guidelines dedicated to thymic tumors were in 2015. These resources provide an excellent overview of all the major aspects and topics related to thymic malignancies. The interested reader is strongly advised to refer to these sources.

Based on the published information, a treatment algorithm can be proposed according to the stage at presentation (Masaoka) and the type of thymic tumor (thymoma, thymic carcinoma, NETT, or recurrent tumor).

Thymoma

Upfront surgery should be done for stage I tumors. The use of any adjuvant therapy is not recommended. A complete resection is expected in all patients.

Stage II tumors should be treated as stage I tumors. A complete resection is expected in more than 90% of the patients. No adjuvant therapy is recommended after complete resection. Postoperative radiotherapy may be considered for incomplete resections and high-risk thymomas (type B2 or B3).

For stage III to stage IV tumors, the multidisciplinary team should make a decision about whether the tumor is resectable. For resectable tumors, upfront surgery is recommended, with the intent of a complete resection. Postoperative radiotherapy may be considered if there is concern about positive surgical margins, high-risk thymomas (type B2 or B3), thymic carcinoma, or NETT. For nonresectable tumors, primary chemotherapy is indicated. Surgery, with the intent of a complete resection, is performed for patients who have radiographic response.

Thymic Carcinomas and Neuroendocrine Thymic Tumor

Although the treatment strategies for thymic carcinoma and NETT are similar to those used for thymomas, the more aggressive behavior of thymic carcinoma and NETT very often requires a multidisciplinary approach, with the use of postoperative radiotherapy and/or chemotherapy, even in early stages, and the use of primary chemotherapy before surgery.

Recurrence

The extent of the recurrence should be carefully evaluated with use of imaging techniques. Histologic confirmation of recurrence is seldom required. In case of distant recurrence, definite chemotherapy is administered. In case of local or regional recurrence, the multidisciplinary team should decide if the recurrence is resectable. If it is, upfront surgery is indicated. Nonresectable recurrences should be treated with chemoradiation therapy.

THE GLOBAL EFFORTS

Thymic tumors are classified as an orphan disease because of their low prevalence. For this reason, robust scientific progress has been hampered, and advancements in management strategies have been slow. In addition, the lack of coordination among centers that have sufficient experience to provide consistent results has been a major obstacle. In an era of globalization and ease of communication, there is no excuse for the lack of cooperation that has occurred so far. To address this issue, several important thoracic societies have promoted the development of dedicated thymic groups.

A major step forward in the scientific advancement of thymic tumors has been the creation, in 2010, of the ITMIG (http://www.itmig.org), which was endorsed and supported by the most representative medical and surgical societies around the globe.[189] The mission of the ITMIG is to promote the advancement of clinical and basic science related to thymic malignancies. It provides infrastructure for international cooperation, maintains close collaboration with other related organizations, and facilitates the spread of knowledge about thymic neoplasms. The ITMIG works in close cooperation with thymic groups of international societies, including ESTS, the European Association of Cardio-Thoracic Surgeons, and

the Japanese Association for Research of the Thymus. The ITMIG is a multidisciplinary organization, involving thoracic surgeons, radiation and medical oncologists, pathologists, pulmonologists, radiologists, and basic science researchers. It includes more than 500 members from all continents.

The ESTS (http://www.ests.org) started its thymic working group in 2010, and, since then, it has launched a retrospective thymic database that collects patient data among interested centers. In 2011, ESTS published the results of a survey of its members about the management of thymic malignancies.[25] Multiple articles about prognostic factors in thymic tumors and in thymic carcinomas have been published in the *European Journal of Cardio-Thoracic Surgery* and the *Journal of Thoracic Oncology*.[105,109,139,190] The ESTS also has a prospective database integrated into the official ESTS database platform (https://ests.dendrite.it/csp/ests/intellect/login.csp).

In France, the Réseau Tumeurs THYMiques et Cancer (RYTHMIC, http://www.rythmic.org), which is supported by the French National Cancer Institute, is a very active network. Its objective is to coordinate, at a national level, the diagnostic and therapeutic process in patients with thymic tumors. RYTH-MIC initiatives include the creation of a national reference book for thymic tumors (Referentiel RYTHMIC), the organization of periodical regional and national thymic tumor boards, the establishment of a Web-based image and diagnostic archive, the development of a system for systematic double-checking histologic consultation, and the sponsorship of an annual educational meeting.[191]

The ultimate effort in thymic research is the institution, within the IASLC International Staging Committee (now the Staging & Prognostic Factors Committee; SPFC) of the SPFC Thymic domain, which is charged with developing a staging classification proposal for the *Eighth Staging Manual in Thoracic Oncology*, expected in 2017. The committee includes members from different countries, representing a variety of specialties (thoracic surgery, medical and radiation oncology, pathology, radiology). The committee is currently working at analyzing a collaborative database from the three main thymic organizations in the world (Japanese Association for Research of the Thymus, ITMIG, and ESTS). Overall, data on more than 8000 cases have been collated for analysis, representing the most important collaborative effort in the history of thymic research. The committee was asked to present a proposal for a consistent TNM-based staging classification for all thymic tumors (thymomas, thymic carcinomas, and NETTs).

CONCLUSION

A dramatic improvement in our knowledge of the diagnosis and management of thymic tumors has occurred in the last few years. This improvement has primarily resulted from an increased interest in these rare tumors at some dedicated centers, and, above all, from the creation of a worldwide international effort that succeeded in putting together large-volume, top-quality centers all over the world. The results of this amazing international cooperation will soon be available, resulting in a major improvement in the outcomes for a patient population that, until now, has had the same challenges as patients with an orphan disease.

57 Lung Cancer Emergencies

Ken Y. Yoneda, Henri Colt, and Nicholas S. Stollenwerk

SUMMARY OF KEY POINTS

- The main oncologic emergencies most germane and specific to lung cancer are central airway obstruction, massive hemoptysis, and massive pleural effusion.
- Central airway obstruction due to lung cancer is traditionally classified as exophytic (intraluminal tumor), extrinsic (compression of the airway by tumor within or external to the wall of the airway), or mixed.
- Treatment of central airway obstruction generally correlates with the type of lesion: ablative modalities (e.g., laser, cryotherapy, argon plasma coagulation) for exophytic lesions; airway stenting for extrinsic compression; and combined therapies for mixed lesions.
- While treatment of central airway obstruction can improve survival, the major aim is the relief of symptoms.
- Massive hemoptysis may present in a dramatic fashion and with a rapidly fatal outcome. Rapid, efficient, and expert management and treatment are therefore of paramount importance.
- Patients with massive hemoptysis generally die of asphyxiation, not exsanguination, and although not all patients with massive hemoptysis require endotracheal intubation and mechanical ventilation, airway management with vigilant ongoing attention to airway assessment and management is a primary concern.
- Endovascular embolization (bronchial artery in 90% of cases) is the mainstay treatment of massive hemoptysis.
- Malignant pleural effusion is the most common cause of a massive pleural effusion.
- Point-of-care ultrasound is an important part of the evaluation and management of massive pleural effusions.
- Indwelling pleural catheters are an effective and safe method to help in the management of symptoms for patients with malignant pleural effusions.

The oncologic emergencies encountered by patients with lung cancer are not exclusive to lung cancer and, for the most part, may affect all cancer patients. Nevertheless, some circumstances and aspects of lung cancer emergencies are unique. Worldwide, lung cancer ranks first in cancer incidence and mortality,[1] but in the United States, it ranks third in incidence behind prostate and breast cancer.[2] Yet, among patients who present to the emergency department, more than three times as many have lung cancer as the next most common type, colorectal cancer. Not surprisingly, respiratory problems are the most common chief complaint for patients with lung cancer on presentation to the emergency department.[3,4] These patients also appear to be more acutely ill; more than five times as many patients with lung cancer die in the emergency department as compared with patients with colorectal cancer.[5] Although most lung cancer emergencies, such as pneumonia, respiratory failure, neutropenic sepsis, shock,

intracranial catastrophe, spinal cord compression, and pathologic fracture, also occur among patients with other cancers, three problems stand out as being most specific and germane to lung cancer, including central airway obstruction, massive hemoptysis, and massive pleural effusions. This chapter offers practical insights and perspectives into the etiology, evaluation, and management of these three complex, controversial, and dreaded complications of lung cancer.

CENTRAL AIRWAY OBSTRUCTION

For the purposes of this chapter, central airway obstruction is defined as obstruction of the trachea and main bronchi as well as of the lobar and segmental bronchi. Central airway obstruction is a complex and frequent sign of progressive disease in patients with lung cancer and in patients with malignancies that metastasize to the lungs and airways. Lung cancer-related central airway obstruction often requires emergent evaluation and treatment to prevent hospitalization and admission to the intensive care unit, to control progression of disease, to palliate and treat other life-threatening diseases, and to avoid immediate death.

Central airway obstruction is associated with many presenting signs and symptoms, a handful of diagnostic modalities used in its evaluation, a multitude of available interventional therapies, and, most importantly, a number of patient-related issues relevant to the diagnostic and therapeutic management of this emergency. In this chapter, we briefly address some of these issues as they relate to the oncologist, radiologist, cytopathologist, interventional pulmonologist, critical care specialist, thoracic surgeon, medical ethicist, and radiation oncologist operating as members of a multidisciplinary team for lung cancer management.

Types of Central Airway Obstruction Presenting as Emergencies

Traditionally, central airway obstruction is classified as exophytic (intraluminal), extrinsic (i.e., compression of the airway from tumor beyond or involving the airway wall), or mixed (Fig. 57.1). This classification is enhanced by specifying the location and extent of the airway abnormality; describing whether the obstruction is focal, multifocal, or diffuse; and indicating whether associated abnormalities are present, such as edema, bronchitis, airway necrosis, purulent secretions, obvious infection (which may be primary or secondary), bleeding, perforation or fistula, dehiscence, or airway distortion. It is also helpful to ascertain whether the abnormality is a primary or secondary disorder. For example, central airway obstruction may be a result of new, progressive, or recurrent disease, or it may be an iatrogenic complication after a procedure, such as airway intubation, mechanical ventilation, stent insertion, brachytherapy or laser resection, other bronchoscopic airway manipulation, external-beam radiotherapy, or thoracic surgical intervention.

Additional features that may be relevant in management decisions include whether the obstructing lesion is dynamic (alters the size of the airway during inspiration and expiration) or fixed (airway diameter remains unchanged during respiratory cycles), whether the lesion has associated malacia (softening of airway
Fig. 57.1. Bronchoscopic images of four types of central airway obstruction prompting emergency intervention. (A) Exophytic lesion causing nearly total obstruction. Thermal ablation can be performed to restore airway patency. Note the external view of rigid bronchoscopy in the upper left-hand corner. (B) Nearly total tracheal obstruction by multilobulated hypervascular tumor involving the posterior membrane. Stent insertion will restore airway patency. Bronchoscopic tumor resection is not absolutely necessary. (C) Mixed obstruction (exophytic and extrinsic compression) by easily bleeding tumor involving the airway wall. Thermal ablation can be used to resect much of the intraluminal tumor. A stent will help maintain airway patency in the case of rapid tumor regrowth. (D) Nearly total airway closure from extrinsic compression by a mediastinal mass at the level of the carina and origin of the right main bronchus. Palliation is possible by airway stent insertion.

cartilage) or excessive dynamic airway collapse (exaggerated invagination of the posterior membrane), and the extent to which symptoms adversely affect the patient's functional status and quality of life. When the airway obstruction has caused an emergency, one must determine whether the emergency is immediately life-threatening. This last point has important implications for diagnosis, treatment, and ethical aspects of care.

Symptoms of Lung Cancer-Related Central Airway Obstruction

The symptoms of central airway obstruction associated with lung cancer are similar to those found in other instances of central airway obstruction and include dyspnea, cough, hemoptysis, hoarseness, and respiratory failure. These symptoms may be progressive or of sudden onset, and can easily be considered to be consistent with the patient's preexisting symptoms of the lung cancer itself. They can be signs of progressive although manageable disease or represent an immediate precursor or cause of death. Central airway obstruction should be suspected in all cases of new onset or increasing symptoms in any patient with known or suspected lung cancer and in patients who have recently undergone palliative or curative therapeutic interventions for their lung cancer. Of course, a patient's comorbidities may be contributing to or causing these nonspecific symptoms. The medical evaluation, therefore, must ascertain the presence, severity, and contributing roles of possible heart failure; esophageal extension; pleural disease; other malignancies extending to the lung, mediastinum, and airways; emphysema and chronic bronchitis; pneumonia; radiation-induced lung or airway injury; clinical depression; malnutrition; and failure to thrive.

Central airway obstruction can be suspected during an outpatient clinic visit, prompt the patient to make an emergency room
Fig. 57.2. Chest radiograph showing resolved right atelectasis after emergency intervention with flexible bronchoscopy in a patient with a known right lower-lobe tumor. In this case, respiratory insufficiency and radiographic abnormalities (ipsilateral mediastinal shift and atelectasis) were due to mucus plugging seen and removed at the time of emergent inspection bronchoscopy. visit, or be responsible for sudden deterioration requiring intubation, hospitalization, or both. Central airway obstruction often requires admission to the intensive care unit. On some occasions, the obstruction is discovered only after a patient has emergency intubation and is placed on mechanical ventilation. In other cases, symptoms of significant obstruction may warrant intubation, raising issues about life-sustaining treatment, appropriate use of medical resources, costs, and roles of palliative care and procedures. A third scenario may involve a patient with dyspnea or other complications who is denied admission to the intensive care unit and further diagnostic evaluation, either because the diagnosis of central airway obstruction is not considered or because the condition is diagnosed but may be considered irreversible. This last scenario raises issues of professionalism, competency, and resource allocation because levels and quality of care depend, in part, on physician expertise, team experience, institutional biases, finances, and societal philosophies regarding extent of care for patients with life-threatening illnesses. Good communication with the patient and with other health-care providers involved in the patient's care is essential, and a properly executed informed consent is a prerequisite to a thorough understanding of available therapeutic alternatives, including the potential consequences of choosing to accept or refuse minimally invasive surgical interventions.

The setting of emergency central airway obstruction is often complex and stressful for health-care providers, patients, and their families. Patients with malignant central airway obstruction may have a median survival as short as 3 months. One-year survival may be only 15%.[6] In general, the survival rate beyond 90 days in nonsurgical patients with lung cancer requiring admission to the intensive care unit is only 37%,[7,8] and in the case of associated acute respiratory failure, the prognosis is very poor.[9] Usually, respiratory failure in patients with lung cancer is caused by pneumonia, acute lung injury or acute respiratory distress syndrome, diffuse alveolar hemorrhage, airway bleeding, or venous thromboembolism, as well as central airway obstruction. Mortality increases with the number of failed organs, severity of comorbidities, and presence of airway obstruction. In one study, the hospital mortality rate was 83% for patients with lung cancer and central airway obstruction who were receiving mechanical ventilation, compared with 62% in patients without an obstructed airway.[10] In other studies, when respiratory failure was caused by airway obstruction, only 25% of patients were successfully weaned from mechanical ventilation,[9] although some patients with malignant central airway obstruction benefited from interventional bronchoscopic procedures aimed at restoring airway patency.[11]

Diagnosis of Central Airway Obstruction

The diagnosis of central airway obstruction is made with a combination of clinical findings, radiographic imaging, and bronchoscopic techniques. Because they are noninvasive, chest radiography or computed tomography (CT) is usually performed first. In some life-threatening situations, flexible bronchoscopic inspection is performed to provide immediate information to assist in establishing indications for or against therapeutic interventions to restore airway patency, alleviate dyspnea, postpone or prevent the onset of respiratory failure requiring intubation, or palliate other symptoms (such as hemoptysis).

Clinical Findings

Findings related to central airway obstruction may include decreased breath sounds on chest auscultation, prolonged expiration, and unilateral wheezing. Patients may lose the ability to phonate in cases where an airway stent has migrated proximally to impinge on the vocal cords from below. Vocal cord paralysis may be suggested by cough, hoarseness, change in voice, or episodes of recurrent aspiration and may be related to a primary lung mass or enlarged mediastinal lymph node impinging on the recurrent laryngeal nerve. Hemoptysis may suggest central airway obstruction in patients with known lung cancer or cancers that are known to metastasize or otherwise spread into the airways (such as colon cancer, malignant melanoma, renal cell carcinoma, thyroid cancer, esophageal cancer, adenoid cystic carcinomas, sarcomas, and some lymphomas).

Chest Radiographs Often Aid in Diagnosis

Chest radiographs may show atelectasis, ipsilateral mediastinal shift, lobar consolidation, stent migration, or a mass impinging on the central airway (Fig. 57.2). CT is used to confirm the diagnosis and obtain more detailed information about the cause, extent, type, and morphology of the obstructing lesion. Associated

findings include, among others, mediastinal widening, other lung or airway lesions, pleural disease, volume loss, atelectasis, and consolidation. Patients with a history of radiotherapy may have signs of fibrosis or radiation pneumonitis. CT may also provide information regarding the extent of peribronchial involvement and airway distortion, which may be underestimated by bronchoscopy alone. In some instances, ventilation–perfusion scans can be performed to ascertain whether functional lung exists beyond the level of the obstruction, but the results are not always precise and negative findings do not necessarily preclude successful reestablishment of airway patency and restored ventilation.

Flexible Bronchoscopic Examination

Flexible bronchoscopy provides information about the morphology, extent, etiology, and severity of the airway obstruction. It also provides information pertaining to associated airway abnormalities that may affect management decisions and indications for or against palliative or curative interventions to restore airway patency. In experienced hands, airway inspection is performed very quickly with minimal risk to the patient. Depending on the setting, bronchoscopy can be performed through the nares or the mouth (using a bite block), from behind the head of the patient or standing in front of and to the side of the patient, always in conjunction with supplemental oxygen and with or without sedation. For example, in a patient with impending respiratory failure, bronchoscopy can be performed with the patient receiving high-flow oxygen and/or through a continuous positive airway pressure mask, without sedation (to avoid risks of iatrogenic respiratory suppression), and with the patient in the seated position (to avoid aspiration or respiratory suppression related to the supine position).[12] Such a procedure done in the emergency department, hospital ward, or procedure suite may prompt an immediate referral to the operating room for a therapeutic bronchoscopic intervention. If absolutely necessary, the patient can be intubated temporarily with an endotracheal tube over the flexible bronchoscope, or, after appropriate sedation and airway management, intubation can be performed via laryngoscopy before transport to the operating room or interventional bronchoscopy suite.

Evaluation of Patients

Patients with a diagnosis of lung cancer–related central airway obstruction require a careful evaluation to obtain information that will guide management. Many decision points must be considered, some of which are disease related, whereas others are lesion related, patient related (e.g., clinical status and treatment preferences), and health-care team related (Table 57.1). To be certain that information is obtained to address each of these aspects of care, a four-step approach can be used that includes an initial evaluation, a review of procedural strategies, procedural techniques and expected/known results, and a long-term management plan (Table 57.2).[13,14] Many examples for dealing with cancer-related central airway obstruction can be found in the textbook *Bronchoscopy and Central Airway Disorders: A Patient-Centered Approach*.[15]

Treatment Modalities for Emergency Management of Lung Cancer–Related Central Airway Obstruction

The goals of therapy are to restore airway patency, improve symptoms, enhance quality of life, improve patients' functional status so they may undergo additional systemic or local–regional therapies, transfer hospitalized patients to a lower level of care (from the intensive care unit to the wards or from the wards to home), and increase survival. In recent years, a commonly used therapeutic palliative approach is the combination of endobronchial

TABLE 57.1 Examples of Factors That May Influence Management Decisions for Patients With Lung Cancer–Related Central Airway Obstruction in the Emergency Setting

Category	Description
Disease related	Severity and extent of comorbid conditions
	Extent of disease (organ failure, metastases)
	Prognosis without further systemic therapy
	Prognosis with additional systemic therapy
Lesion related	Extent of abnormalities
	Duration of central airway obstruction and symptoms of respiratory insufficiency
	Amenable to bronchoscopic removal or palliation
	Amenable to stent insertion
	Potential response to radiotherapy
Patient status and preference related	Functional status
	Expected survival in the absence of central airway obstruction
	Do-not-resuscitate status
	Response to informed consent
	Family support system
	Risk tolerance
	Desire to live: goals, expectations
Health-care team related	Team experience with bronchoscopic techniques
	Physician competence and experience
	Multidisciplinary team management
	Palliative care and medical ethics consultation availability
	Resource availability (intensive care unit beds, equipment, instruments)
	Proactive versus reactive behavioral profiles
	Realistic, nihilistic, or unrealistic desires and expectations
	Cost, health-care insurance, societal philosophies regarding resource allocation

TABLE 57.2 Four-Step Evaluation for Possible Intervention in Patients With Lung Cancer–Related Central Airway Obstruction

Initial Evaluation	Procedural Strategies
1. Physical examination, complementary tests, and functional status assessment	1. Indications, contraindications, and expected results
2. Patient's significant comorbidities	2. Operator and team experience and expertise
3. Patient's support system (including family)	3. Risk–benefits analysis and therapeutic alternatives
4. Patient's (and family's) preferences and expectations	4. Respect for persons

Procedural Techniques and Results	Long-Term Management Plan
1. Anesthesia and other perioperative care	1. Outcome assessment
2. Techniques and instrumentation	2. Follow-up tests, visits, and procedures
3. Anatomic dangers and other risks	3. Referrals to medical, surgical, or palliative/end-of-life subspecialty care
4. Results and procedure-related complications	4. Quality improvement and team evaluation of clinical encounter

debulking (using thermal, nonthermal, or mechanical techniques) with or without stent insertion, followed by external-beam radiotherapy and/or systemic therapy, if indicated or possible.

Bronchoscopic Laser Resection

Bronchoscopic laser resection, usually using the neodymium: yttrium aluminum garnet (Nd:YAG) laser, is a mainstay of emergency bronchoscopic intervention for patients with central airway obstruction. Laser can be used in conjunction with mechanical debulking and stent insertion, but requires that

the health-care team have experience with laser technologies and, most importantly, knowledge of various laser–tissue interactions related to the use of low- and high-power densities. According to numerous studies, laser resection is an effective palliative procedure for central airway obstruction. Complications are uncommon in well-trained hands, but physicians should always consider the possibility of failure to control the airway, airway fires (especially with indwelling airway stents or endotracheal tubes), failure to control bleeding, and airway necrosis. In general, the depth of penetration of the Nd:YAG laser allows excellent coagulation of vessels that are several millimeters in diameter because this thermal ablative technique achieves substantial vasoconstriction and vaporization of tissues.[16]

Airway Stenting

Silicone airway stents are extremely valuable for emergency treatment of central airway obstruction. Not only can these stents be deployed, if necessary, without prior thermal ablative techniques, but they also ensure airway patency and give health-care providers time to address other issues relevant to a patient's care. Data from numerous studies confirm the efficacy of silicone stents to restore and maintain airway patency, although complications such as stent migration, kinking, obstruction by tumor or mucus, and even infection have been reported.[17] Silicone stents, however, require rigid bronchoscopy and general anesthesia. Models are available in all shapes and sizes, including stents that fit onto the carina or secondary bifurcations. By improving functional status, stent insertion allows the medical team to proceed with palliative chemotherapy or radiotherapy if indicated (Fig. 57.3).

Stent insertion becomes necessary when symptomatic airway stenosis is mixed, when stenosis is caused by extrinsic compression, or when a patient has had repeated removal of an intraluminal lesion at short intervals because of a fast-growing tumor. Stent selection has traditionally been based on an operator's previous experience with a particular stent and the local availability of various stents and other equipment. Stent retrievability is important among patients with malignancy for whom a temporary stent placement is expected; these include patients with malignant central airway obstruction who will undergo further surgical or systemic chemotherapy and/or radiotherapy (e.g., patients with thyroid cancer, primary lung cancer, and esophageal cancer impinging on or involving the airways).

In addition to the morphology and consistency of the tumor, the mechanical properties of the stent should be considered in selecting the appropriate stent. The expansile force (strength) and ability to withhold angulation (also known as buckling) vary among different types of stents. The studded-silicone-type stent has a high expansile force. In a distorted, curved airway, angulation properties are important because they determine whether a stent can conform to the acutely angulated airway and remain patent (Fig. 57.4).[18] Patients with indwelling airway stents benefit from having a stent medical-alert card, which informs emergency room physicians about stent type, size, location, and construction and provides instructions about emergency procedures in case of stent-related complications.[15]

External-Beam Radiotherapy

External-beam radiotherapy is a feasible, noninvasive therapeutic alternative, but when the patient has associated severe airway obstruction resulting in atelectasis, the response rate is 20% to 50% in studies involving more than 50 patients.[19] Smaller studies showed that bronchial obstruction can be relieved in
Fig. 57.3. Nearly total tracheal obstruction responsible for respiratory insufficiency required emergency intervention with rigid bronchoscopy and silicone stent insertion. (A) Computed tomography (CT) image demonstrates airway obstruction. (B) Central airway obstruction viewed at the time of emergency rigid bronchoscopy. (C) CT image shows restored airway patency after silicone stent insertion.

up to 74% of patients, resulting in complete or partial reexpansion of the collapsed lung. The time to initiation of treatment matters, because 71% of patients who had radiotherapy within 2 weeks after radiographic evidence of atelectasis had complete reexpansion of their lungs, compared with only 23% among patients having radiotherapy after 2 weeks.[20] The main limitation of external-beam radiotherapy is unwanted exposure
Fig. 57.4. Example of nearly total left bronchial obstruction. (A) Exophytic central airway obstruction from tumor extending from the origin of the left main bronchus to the entrance of the left upper-lobe and lower-lobe bronchi. (B) Proximal aspect of studded silicone Y stent in the left main bronchus extends slightly above the main carina. (C) More distally, the bifurcated silicone Y stent ensures patency of the left upper-lobe and left lower-lobe bronchi.

of the normal lung parenchyma, heart, spine, and esophagus. Improvements in imaging and treatment planning using three-dimensional conformational radiation and respiratory gating can precisely target radiation delivery and, by decreasing normal tissue margins included to account for uncertainties in position, can diminish the risk of clinically significant pneumonitis and esophagitis.[21] The restoration of airway patency usually improves a patient's functional status and performance score, accelerates the initiation of systemic therapy if indicated, and can improve survival.

Endobronchial Brachytherapy

Endobronchial brachytherapy has proven efficacy in patients with endoluminal tumor even when a substantial extrabronchial component is present. This treatment is based on the principle of the inverse square law, which states that dose rate decreases as a function of the inverse square of the distance to the source center, making it possible to achieve a high radiation dose in the center of the radiation source with a fast decrease toward the periphery. Endobronchial brachytherapy offers palliation, with rates of recanalization ranging from 60% to 90%. Symptomatic improvement is seen in 70% to 80% of well-selected patients. The variability in reported results is explained by patient selection, different treatment schemes, and the use of additional treatments. For palliation of symptoms of nonsmall cell lung cancer (NSCLC), however, a Cochrane meta-analysis concluded that endobronchial brachytherapy alone was less effective than external-beam radiotherapy.[22] Endobronchial brachytherapy is usually performed via flexible bronchoscopy. Treatment effects are delayed and complications include hemoptysis, which can be fatal in up to 21% of patients. Other complications include fistula formation, radiation bronchitis (10%), and bronchial stenosis. Squamous cell histology and, most importantly, treatment in the upper lobes are associated with the highest incidence of hemoptysis, probably because of the proximity of the great vessels. Radiation delivered anywhere in the vicinity of major vessels, however, probably increases bleeding risk, as does combined therapy such as laser resection plus endobronchial brachytherapy,

which together may augment the likelihood of tissue necrosis. Patients with poor performance status may also be at higher risk for periprocedural complications such as cough, bronchospasm, and pneumothorax caused by placement of the brachytherapy catheter.

Photodynamic Therapy

Photodynamic therapy can also be performed via flexible bronchoscopy and is approved for local–regional palliation for advanced NSCLC. This modality is most effective when the patient has more than 50% narrowing from mucosal disease.[23] The outcome of photodynamic therapy seems to be the best, however, when patients have a relatively good performance status.[24] In addition, this therapy is less than ideal in the emergency setting because the therapeutic effect is delayed for at least 48 hours and the associated risk of phototoxicity is approximately 20% at 4 weeks after the intervention. Photodynamic therapy may actually worsen airway obstruction during the initial posttreatment period because of sloughing of airway mucosa and retained tumor debris. Sloughed tissue can occlude the airway and cause complete obstruction, resulting in worsening symptoms and postobstructive pneumonia.[25] Similar to endobronchial brachytherapy, photodynamic therapy is contraindicated among patients at high risk for fatal massive hemoptysis. Hemorrhage has been reported for 0% to 2.3% of patients, but the risk may be higher when the disease involves major blood vessels.

Cryotherapy

Cryotherapy causes thrombosis and necrosis of tumor tissues. Although cryotherapy poses no risk of airway fire or perforation, it can cause cold-induced bronchospasm. Cryotherapy has been shown to be most effective when performed in combination with external-beam radiotherapy.[26] Similar to photodynamic therapy and endobronchial brachytherapy, cryotherapy has a delayed effect and initially may worsen airway obstruction, causing postobstructive pneumonia from sloughed necrotic tissue. Among patients with lung cancer and endoluminal obstruction,

cryotherapy is reportedly effective in up to 75% of cases, but it is not a therapy of choice in the emergency setting or when extrinsic compression is present.

Argon Plasma Coagulation

Argon plasma coagulation and electrocautery allow removal of exophytic disease and provide superficial cauterization (3 mm to 6 mm), which may not be sufficient to stop large airway bleeding. Depth of penetration and distribution of heat-induced necrosis within tissues are not as predictable as they are with lasers because electrical current follows the path of least electrical resistance within different tissue types. Argon gas is heavy, inert, and much less soluble in the body than carbon dioxide. As gas is forced into the airway wall, perforation may occur, or gas may collect in a blood vessel and pass into the systemic circulation, causing life-threatening gas embolism.[27] Erosion from tumor also presents a risk to major vessels. Risks may be increased when treating highly vascularized lesions and in the proximity of large blood vessels.

Covered Self-Expanding Metal Stents

Self-expanding metal stents, also called hybrid stents, have been used to relieve airway obstruction and seal off fistulae to avoid symptoms of aspiration. Among patients receiving mechanical ventilation, self-expanding metal stents can be inserted via rigid bronchoscopy under general anesthesia or via flexible bronchoscopy under fluoroscopic guidance.[28] Some patients, however, are not suitable candidates for rigid bronchoscopy with a general anesthetic because of the severity of their illness and comorbidities or their unwillingness to have an operation. Fluoroscopy requires special facilities that may not be available in every intensive care unit. Self-expanding metal stents are more costly than silicone stents and can be difficult to remove.

Bronchoscopic Balloon Dilatation

Balloon dilatation is usually performed for airway strictures and is probably not ideal for cases of mixed obstruction from malignant disease. A balloon can be used to expand the airway lumen to facilitate the atraumatic passage of a rigid bronchoscope or endotracheal tube in cases where the operator has limited procedural experience. Mechanical resection of exophytic disease is possible using a specially designed resector balloon.[29]

Expected Outcomes of Emergency Bronchoscopic Management of Central Airway Obstruction

It is not the purview of this chapter to cite the results of bronchoscopic treatment of central airway obstruction. It is common sense, and many studies show, that restoring airway patency improves symptoms, quality of life, exercise capacity, and survival. Therefore, bronchoscopic treatments have universally become the standard of care and should be considered for all patients with a diagnosis of central airway obstruction related to lung cancer.

In some settings, referral to the appropriate specialist is necessary. When in doubt, it is better to ask the specialist to evaluate the patient than to assume that intervention is not technically possible, that the patient cannot tolerate or survive the procedure because of a poor functional status, or that the intervention will not improve quality of life or survival. To enhance the care of all patients with lung cancer, including patients who require emergency treatment for central airway obstruction, the benefits of consulting a multidisciplinary team cannot be overemphasized. Such a team can help make lung cancer management decisions, has ready access to airway specialists with experience and knowledge of minimally invasive interventional techniques, and is well trained in one or more therapeutic bronchoscopy procedures.

Because this section is dedicated to airway emergencies in patients with central airway obstruction, it is reasonable to comment on the subject of patients with respiratory failure due to central airway obstruction. In these cases, interventional bronchoscopic procedures such as mechanical debulking, thermal ablation, and stent insertion have more immediate results than external-beam radiotherapy, help obviate the need for continued mechanical ventilation,[30,31] provide time to initiate additional therapies, and prolong survival and quality of life.[32] In many instances, patients who seem close to death are able to live productive, comfortable lives after airway patency is restored.

The Society of Critical Care Medicine recommends admission to the intensive care unit for all patients with advanced cancer who have a reversible condition such as pulmonary embolism, cardiac tamponade, or airway obstruction.[33] Accompanying this recommendation is a prioritization scale identifying patients who will benefit most from admission to the intensive care unit (priority 1) and patients who will not benefit at all (priority 4). Patients with cancer complicated by airway obstruction are assigned priority 3, defined as unstable patients who are critically ill but have a reduced likelihood of recovery because of underlying disease or the nature of their acute illness. It is well recognized that emergency bronchoscopic intervention can be beneficial in many critically ill patients. In 2012, we reported the results of emergent therapeutic bronchoscopic intervention in 12 patients with NSCLC who had intubation and mechanical ventilation in the intensive care unit during a 6-year study period.[34] Airway patency was restored in 11 (92%) of 12 patients. Bronchoscopic intervention resulted in immediate extubation and discontinuation of mechanical ventilation in 9 (75%) of 12 patients. The overall median survival was 228 days (range, 6 days to 927 days). For 9 individuals who were extubated within 24 hours after intervention, the median survival was 313 days (range, 6 days to 927 days).

In another study, Jeon et al.[32] reported the results for 36 patients with respiratory failure and malignant central airway obstruction from various tumors. They noted that patients who had systemic therapy or radiotherapy in addition to bronchoscopic intervention survived longer than patients who had bronchoscopic palliation of central airway obstruction alone (median survival, 38.2 months vs. 6.2 months).[32] In a retrospective study from Holland, 14 patients with advanced disease from esophageal cancer (5 patients) or NSCLC (9 patients) had immediate symptomatic relief after bronchoscopic intervention. As a result, Dutch general practitioners responsible for terminal home care remarked that bronchoscopic intervention and airway stent insertion are worthwhile elements of a patient-focused treatment plan.[35]

MASSIVE HEMOPTYSIS

Hemoptysis is not a rare event, and it will occur at some point in approximately 20% of patients with lung cancer. Massive hemoptysis is far less common, but 3% of patients will have massive hemoptysis as their terminal event.[36] When hemoptysis is trivial in amount, it is usually straightforward to diagnose and treat; yet it may also foreshadow a more critical or fatal event. At times, hemoptysis has such a sudden onset and large volume that it prompts emergent hospitalization and treatment, yet is not considered massive by all definitions in the literature. At other times, it may arise or advance in such dramatic volume and fashion as to be truly shocking to both patient and clinician. With this unmistakable presentation, it is universally acknowledged as massive and is clearly recognizable as a critical life-threatening condition. However, no universally accepted term is used (major, massive, catastrophic, life-threatening, and severe have all been used) to describe these different scenarios, and even more elusive is a precise volume or clinically relevant definition. Perhaps most important is the physiologic effect of hemoptysis; for example,

although 500 mL of blood loss is insufficient to cause exsanguination, it can lead to rapid asphyxiation and death. Rapid and efficient evaluation and treatment of hemoptysis are therefore of paramount importance. Mobilizing the resources to accomplish this task is a challenge, particularly in centers that may have limited experience and resources. Therefore, not surprisingly, the reported mortality rate is highly variable, ranging from 0% to 78%, depending on the definition, etiology, era, treatment center, study design, and, potentially, the treatment approach.[37–39]

For the purposes of this review, the term massive hemoptysis is used to encompass the various terms and definitions encountered in the medical literature, but the reader is encouraged to consider the broader context of potentially life-threatening hemoptysis. Data regarding massive hemoptysis specifically in the context of lung cancer are limited. Therefore much of the following discussion is derived from data regarding hemoptysis in general, but, wherever possible, the discussion is focused on lung cancer. Accumulating, albeit imperfect, evidence suggests the benefit of a multidisciplinary approach to the diagnosis and management of massive hemoptysis for patients with lung cancer.

Definition

The volume of expectorated blood that has been used to define massive hemoptysis varies from more than 100 mL to more than 1000 mL in 24 hours,[40,41] but is often considered to be greater than 600 mL. The volume of expectorated blood has long been recognized to correlate with disease severity and outcome, including mortality. In a retrospective, single-institution review of 887 patients with hemoptysis of greater than 200 mL in 24 hours, Corey and Hla[41] found that the mortality rate was 58% for patients with hemoptysis greater than 1000 mL in 24 hours, whereas the rate was 9% for patients with less than 1000 mL in 24 hours. However, the volume of expectorated blood is difficult for patients to quantify and is somewhat subjective. Furthermore, the expectorated volume may vastly underestimate the amount of blood remaining in the alveolar spaces and airways. For this reason, a chest x-ray may reflect more accurately the clinical significance of the bleeding. Perhaps more important than the precise volume of expectorated blood is its physiologic effect. It has been estimated that 400 mL of blood in the alveolar spaces is sufficient to impair oxygen transfer.[42] The same volume of blood can cause significant obstruction of the large airways, asphyxiation, and death. In addition, the rate of bleeding, underlying morbidity, and the patient's ability to maintain a patent airway all affect severity, independent of the absolute volume. Alternative definitions based more on the physiologic effects of airway obstruction and hemodynamic instability have been proposed.[43–45]

In a large series published in 2012, Fartoukh et al.[38] shed light on predicting the in-hospital mortality and severity of hemoptysis and hence clarified how we may consider, define, characterize, and manage this disorder. In their study, the volume of expectorated blood was an apparent predictor of mortality in a univariate analysis, but no longer remained an independent predictor of death after adjustment for other factors. Using data from a retrospective review of 1087 patients with hemoptysis admitted to the intensive care unit or step-down unit over 14 years at a single institution, they developed and validated a multiregression model for predicting in-hospital mortality. They devised a simple scoring system assigning points for chronic alcoholism (1 point), cancer (2 points), aspergillosis (2 points), pulmonary artery involvement (1 point), two or more chest x-ray quadrants (1 point), and initial mechanical ventilation (2 points). In-hospital mortality increased with increasing score, as follows: 0 = 1%, 1 = 2%, 2 = 6%, 3 = 16%, 4 = 34%, 5 = 58%, 6 = 79%, and 7 = 91%. These results suggest that rather than using a cutoff of expectorated volume for defining massive hemoptysis, a scoring system

might better define hemoptysis and stratify patients according to the level of risk. Only with this type of objective and standardized definition can we begin to study how best to triage, manage, and treat these patients.

Etiology of Hemoptysis

Regarding massive hemoptysis in general, infectious etiologies (tuberculosis, bronchiectasis, mycetomas, and necrotizing pneumonia) predominate worldwide. Lung cancer is the cause in 3% to 10% of the cases that are severe enough to require bronchial artery embolization and in 17% of patients admitted to the intensive care unit.[37,38,46,47] Tuberculosis is the most common cause in specific areas of the world, yet is a rare cause in other areas.[48] Lung cancers, like most other cancers, are highly vascular and, particularly when endobronchial, may lead to massive hemoptysis. Patients with lung cancer may have chemotherapy-induced thrombocytopenia, comorbidities such as renal disease and/or liver disease, vascular disease requiring antiplatelet therapy, or thrombotic disorders requiring anticoagulation, and these factors compound the problem. Some of these conditions and medication effects can be mitigated, corrected, or reversed. Of special note are the antiangiogenesis factors and tyrosine kinase inhibitors (some of which also have significant angiogenesis inhibition) that can lead to massive hemoptysis.[49] The biologic effect of these medications cannot be reversed and lasts for weeks.

Massive hemoptysis in a patient with lung cancer should not be automatically assumed to be coming directly from the lung cancer lesion. As already discussed, patients often have comorbidities that may predispose them to various other etiologies of hemoptysis, including cancer-related hypercoagulability leading to pulmonary emboli, coagulopathy leading to alveolar hemorrhage, and immunosuppression leading to necrotizing pneumonia. The clinician must therefore thoroughly evaluate hemoptysis in patients with lung cancer without assuming that the lung cancer is the source of the hemoptysis. This evaluation is important in treatment considerations; for example, patients with diffuse alveolar hemorrhage and/or coagulopathy respond to specific treatments and are not likely to derive benefit from invasive therapeutic procedures such as endovascular embolization.

Vascular Source of Bleeding

In approximately 90% of cases of hemoptysis, the bronchial artery circulation is the source of bleeding. This circulation is of relatively low flow, representing only a small percentage of cardiac output. Consequently, the bleeding may be self-limited and minimal in quantity. However, the bleeding is at the same time driven by high systemic pressures that may flow directly into the airways, where no counter-pressure exists to provide tamponade against the bleeding. This so-called high-pressure–low-flow source of bleeding can rapidly overwhelm the patient's ability to keep the airways clear and avoid suffocation. Malignancy and chronic lung inflammation promote neovascularization, recruitment, hypertrophy, and proliferation of bronchial arteries. Chronic pleural inflammation promotes abnormalities in the circulation, which may originate from the mammary, subclavian, intercostal, thoracic, pericardial, phrenic, and thyrocervical arteries. These vessels may enter the lung through the pulmonary ligament or parietal or diaphragmatic pleura and represent another high-pressure–low-flow source, which has been reported in 3% to 25% of cases of hemoptysis.[39,46,47] Conversely, although the pulmonary artery circulation is driven by relatively low right ventricular pressures, a pulmonary artery bleed may represent a significant percentage of the cardiac output. This relatively low-pressure–high-flow circulation is responsible for only a minority

TABLE 57.3 Vascular Source of Hemoptysis

Source	Approximate Incidence (%)
Bronchial circulation	90
Other systemic circulation	3–25
Pulmonary vascular circulation	6

of cases of massive hemoptysis, but may be just as dramatic in presentation, such as with a ruptured Rasmussen artery in patients with tuberculosis. Remy et al.[50] detected a pulmonary vascular source of bleeding in 11 (6%) of 189 patients treated with transcatheter bronchial or pulmonary artery embolization for massive or repeated hemoptysis, and Wang et al.[51] recognized a pulmonary artery source in 2 of 30 patients. The authors of other large series have failed to report the pulmonary artery circulation as a significant source of hemoptysis. However, failure to consider the pulmonary circulation as a potential source of hemoptysis may explain why angiography fails to identify a definitive source of hemoptysis in approximately 11% of cases.[47,52] Of final note, the pulmonary venous circulation is also not well recognized as a potential source of massive hemoptysis. It has even lower pressures, equivalent to left atrial pressures, and represents a potential very-low-pressure–high-flow source of massive hemoptysis (Table 57.3).

Bronchial artery anatomy can be quite variable, and a thorough understanding and evaluation are necessary to determine the precise vascular origin of hemoptysis. The bronchial arteries originate from the descending aorta between T5 and T6 in 70% of people. Another 20% of people have ectopic branching arising from the subclavian, internal thoracic, pericardiacophrenic, innominate, thyrocervical trunk, and inferior phrenic arteries or abdominal aorta. In 10%, the bronchial arteries arise from other regions of the descending thoracic aorta and aortic arch.[53] Branching patterns of the bronchial arteries themselves are highly variable, with nine patterns described.[54] Multidetector CT provides an accurate road map for embolization by identifying the etiology and origin of the hemoptysis. It can depict the precise anatomy and nature of the bronchial and nonbronchial arteries involved, their course and size, and their relationship to the spinal artery.

Clinical Assessment, Initial Resuscitation, and Stabilization

Although assessment, resuscitation, and stabilization will be addressed separately from the approach to diagnosis, in reality all of these tasks are performed in parallel and are to a great degree integrated. As in most critical care situations, the initial clinical assessment, resuscitation, and stabilization of massive hemoptysis generally take precedence over complex or comprehensive diagnostic testing. Given that most patients die of asphyxiation rather than exsanguination, airway assessment and management are the priority. Initial hospital management should take place in the emergency room or the intensive care unit, with the most experienced personnel available rendering care. Whenever possible, these patients should be cared for at centers with the expertise and resources to optimally manage them. Transfer to tertiary centers may be advised.

Airway assessment is similar to that for any emergency patient, and the decision to perform endotracheal intubation and initiate mechanical ventilation rests on sound clinical judgment. If the patient has evidence of respiratory distress, one should not hesitate to secure an airway. However, not all patients with massive hemoptysis require endotracheal intubation. The aims of endotracheal intubation are to establish a secure airway, achieve adequate ventilation and oxygenation, and maintain airway clearance, which, in the nonintubated patient, are dependent on several

factors, including the flow, volume, and duration of hemoptysis; cough and airway clearance mechanics; and cardiopulmonary reserve. Prophylactic intubation is not usually warranted for a patient with massive hemoptysis who is not in distress. Nevertheless, one must pay careful attention to signs that a patient is failing to maintain airway clearance, such as tachycardia, tachypnea, hypertension, hypotension, and hypoxemia. A chest x-ray with two or more quadrants involved indicates a large volume of aspirated and incompletely cleared blood, suggesting that these patients are at an increased risk of death.[38] Early intubation may be warranted for these and other selected patients. Again, clinical judgment must be exercised, taking into consideration such factors as the patient's ability to tolerate transport, supine positioning, and sedation for angiography or other procedures.

Patients should be confined to bed rest and should be in a decubitus position with the bleeding lung down. When intubation is deemed necessary, a large-bore tube, size 8 or larger (to facilitate bronchoscopy and suctioning), should be inserted by the most experienced operator available. Bronchoscopic intubation is often preferred because it not only facilitates intubation, but may also be diagnostic and therapeutic. Furthermore, it allows selective intubation of the nonbleeding right or left lung when it is deemed necessary. Selective intubation of the left main bronchus can rapidly establish a secure airway as well as isolate and protect a nonbleeding left lung. Selective intubation of the right main bronchus is more problematic given the very proximal right upper-lobe takeoff. Placement of a balloon in the bleeding bronchus will cause tamponade and terminate hemoptysis, as well as further protect the nonbleeding lung. A double-lumen endotracheal tube can accomplish the same goals. Although placement of a double-lumen endotracheal tube has been advocated to isolate and protect the nonbleeding lung, its use is not without problems: misplacement occurs in about 50% of cases,[55] life-threatening trauma to the airway has been reported,[56] and the small diameters of the lumen make bronchoscopy and suctioning difficult.

Rigid, as opposed to flexible, bronchoscopy has been advocated as a means of securing an airway and simultaneously providing a platform to diagnose and control massive hemoptysis.[45,57] However, it is not readily available at all centers, and two large series on the management of massive hemoptysis suggested that flexible bronchoscopy (preferred as first-line therapy over rigid bronchoscopy) can be used safely, with a mortality rate of 0% to 4%.[37,52] Without head-to-head comparisons, the choice of rigid or flexible bronchoscopy remains largely based on individual experience, availability, and institutional practice.

Two large-bore intravenous catheters should be placed, and a central venous catheter should be considered. Appropriate aggressive volume resuscitation including blood and, when necessary, intravenous vasoactive medications should be administered. Chest x-ray, laboratory testing, and type and screening for blood should be performed. Disorders of coagulation should be corrected whenever possible.

As discussed earlier, the in-hospital mortality rate is 34% for patients with a score of 4 or more on the scoring system by Fartoukh et al.,[38] and admission to the intensive care unit should be strongly considered for these patients. Death from massive hemoptysis is difficult to predict, and even patients with a score of 3 or less may benefit from admission to the intensive care unit; clinical judgment must be exercised.

A thorough history and physical examination should be performed, with attention paid to the following: (1) the quantity, duration, and quality of hemoptysis; (2) the patient's lung cancer history including type, status, radiotherapy, surgical procedures, and antineoplastic drug therapy; (3) medication history; (4) underlying liver, kidney, and cardiopulmonary diseases; (5) signs and symptoms of respiratory distress; (6) signs and symptoms of other sites of bleeding; and (7) history of alcohol use.

Fig. 57.5. Computed tomography of the chest shows invasion of a lung mass into the left pulmonary vein and right atrium, indicating multiple potential vascular sources of hemoptysis.

Approach to Diagnosis

The major diagnostic studies for massive hemoptysis are laboratory tests to evaluate for coagulopathy and other potential causes of hemoptysis (e.g., vasculitis and alveolar hemorrhage), chest x-ray, CT of the chest, and bronchoscopy. Laboratory testing is aimed at identifying correctible or treatable causes of hemoptysis, whereas the remaining diagnostic studies are aimed at rapid and efficient triage of patients for definitive invasive interventional treatment. Although a chest x-ray should be performed as an important prognostic indicator and may guide triage decisions,[38] chest x-rays are not helpful in approximately 50% of cases.[48]

In the critical setting of massive hemoptysis, localization of bleeding to a specific site or at least the relevant side is crucial in allowing the interventional radiologist to narrow his or her focus and to perform endovascular embolization in an efficient manner. CT images provide information on the site and potential causes of bleeding and may indicate the precise vascular origin and source (Fig. 57.5). Bronchoscopy more accurately identifies endobronchial lesions and provides a potentially temporizing and, on occasion, a definitive therapeutic option. A practical approach is to perform CT if the bleeding has been stabilized and to perform a diagnostic and potentially therapeutic bronchoscopic procedure on patients who are not stable enough for transport to CT because of uncontrolled bleeding. When necessary, these procedures can be performed sequentially.

Computed Tomography

In cases of severe and massive hemoptysis, CT identifies the side and specific site of bleeding in approximately 70% to 100% of patients and a specific cause in 60% to 100% of patients.[58,59] How well this information applies specifically to patients with lung cancer is unknown.

More recently, multidetector-row CT angiography has been used to identify bronchial and nonbronchial sources of bleeding as well as to depict the anatomy of the pathologic vessels. These results may help when planning endovascular embolization,[60] particularly for massive hemoptysis.[61] This road map may be extremely helpful because bronchial artery branching is highly variable and the origin and anatomy of the bronchial artery responsible for massive hemoptysis are not always easily identifiable.[62] Although the bronchial arteries usually arise from the aorta between T5 and T6, they may also arise from the lower thoracic aorta, subclavian arteries, brachiocephalic artery, internal mammary artery, costocervical trunk, pericardiacophrenic artery, thyrocervical trunk, or inferior phrenic artery. Multidetector-row CT may identify ectopic bronchial artery origins in more than 30% of cases of hemoptysis.[63,64] In a prospective study of multidetector-row CT for hemoptysis, this modality was diagnostic in 25 of 27 cases of massive, moderate, and/or recurrent hemoptysis.[60]

Bronchoscopy

For hemoptysis in general, CT identifies the side and specific site of bleeding in approximately 63% of patients.[65,66] The addition of bronchoscopy improves the yield to 93%,[48] and its routine use has long been advocated.[43,67] To what degree these studies can be extrapolated to massive hemoptysis in patients with lung cancer is unclear, and no clear consensus exists on the diagnostic role of bronchoscopy in this population. These studies do, nevertheless, provide insight and evidence that the two modalities are complementary. In cases of massive hemoptysis, bronchoscopy should certainly not supersede clinical evaluation, establishment of a secure airway, and hemodynamic stabilization. In the limited case series comparing flexible bronchoscopy and CT for massive hemoptysis, bronchoscopy and CT appeared equivalent in identifying the side or site of bleeding, and both methods had more than 70% yield. The two modalities may be complementary, but both are not always necessary. For identifying the specific cause of bleeding, CT appears to be far superior to bronchoscopy, but again the methods may be complementary.[58,59,68]

Treatment

Until the 1950s, the management of massive hemoptysis was mainly supportive and included rest, sedation, cough suppression, vitamin K supplementation, and systemic coagulants. For the most severe cases, emergency phrenic nerve crush, intentional induction of a pneumothorax and/or pneumoperitoneum, plombage (extrapleural introduction of inert substances), and/or thoracoplasty was used to collapse and induce tamponade in the hemorrhaging lung. Although pulmonary resection for traumatic pulmonary hemorrhage had been widely recognized, pulmonary resection for nontraumatic massive hemoptysis was not an accepted option until Ryan and Lineberry[69] in 1950, and Ross[70] in 1953, reported the first successful emergent surgical pneumonectomies for massive hemoptysis due to underlying lung disease (tuberculosis in both cases). By the late 1960s, conservative medical management of massive hemoptysis was increasingly recognized as having an unacceptably high mortality rate of 78% to 85%, compared with a rate of 0.9% to 19% after surgical intervention for patients who were considered operative candidates.[39,71,72] An aggressive surgical management approach was therefore advocated. However, up to 39% of the patients with massive hemoptysis were not considered operative candidates, and emergency surgical procedures carried a mortality rate of 37% to 43%.[39,73,74] Therefore by the late 1970s and early 1980s, coinciding with, and perhaps relating to, a decline in tuberculosis as the leading cause of hemoptysis in the United States, a number of centers advocated a return to more conservative management of even operable patients with massive hemoptysis. The mortality rate of this approach to major and massive hemoptysis was reported to be low, at 11% for operable patients who did not undergo an operation or endovascular embolization.[41] A paradigm shift to the modern era of hemoptysis management began with the first description of bronchial artery embolization by Remy et al.[75] in 1973, and by the late 1980s, its use was widespread.[41] Endovascular (including bronchial artery) embolization is now the standard first-line treatment for massive hemoptysis due to lung cancer, with surgical intervention reserved for

selected refractory cases.[52] Although not useful in the acute setting of massive hemoptysis, radiotherapy may prevent recurrence of hemoptysis once the patient has been stabilized with conservative measures, such as bronchoscopic intervention and/or endovascular embolization.[76]

Bronchoscopy

Bronchoscopic intervention alone may be a definitive treatment, but in most cases of massive hemoptysis, bronchoscopy is used as a means of controlling airway bleeding until endovascular embolization or, rarely, a surgical procedure can be employed as the definitive treatment.[52] Occasionally, bronchoscopy can be used as a stopgap measure for controlling hemoptysis until an underlying coagulopathy or other reversible cause can be corrected. No consensus exists on the role of therapeutic bronchoscopy in the management of massive hemoptysis, and its use varies with local and regional practice and expertise. In two large case series, flexible bronchoscopy was routinely used in the management algorithm of massive hemoptysis with very low mortality rates of 0% and 4%, suggesting that it is an important intervention in the management of massive hemoptysis.[37,52] As discussed previously, when flexible bronchoscopy is used to guide endotracheal intubation, it may be reasonable and practical to proceed to a quick but thorough diagnostic and potentially therapeutic bronchoscopic intervention. Also, as mentioned earlier, when persistent bleeding renders a patient too unstable for transport for more definitive treatment, bronchoscopy may be considered the treatment of choice. When bronchoscopic intervention is undertaken, the bronchoscopist should be prepared for and have resources available for managing any complications that may occur.

Rigid bronchoscopy, or a combination of rigid and flexible bronchoscopy, has been advocated over flexible bronchoscopy alone, largely because it establishes a secure airway, allows selective isolation of the unaffected airway, and has greater suctioning capacity for maintaining airway clearance, while providing a platform for further endoscopic interventions.[47,57] However, no prospective studies have validated this approach as being superior, and the decision to use one over the other is largely based on individual experience and availability.

A variety of bronchoscopic means have been used to mitigate bleeding in patients with massive hemoptysis, all of which, with the exception of direct-pressure tamponade with the rigid bronchoscope, can be performed with either flexible or rigid bronchoscopy. The superiority of one method over another has not been studied in a systematic fashion; the choice is somewhat subjective and highly dependent on the operator's expertise and the available resources. Cold saline lavage is widely used and has been shown to be effective in controlling bleeding in massive hemoptysis due to lung cancer.[77,78] It is therefore considered a standard primary bronchoscopic treatment for massive hemoptysis.[79] Endobronchial instillation of topical vasoconstrictive agents such as epinephrine and norepinephrine has been recommended for the management of postbiopsy hemoptysis,[80,81] but in general this strategy is not very effective in massive hemoptysis because the drug is diluted and cleared by the active bleeding. Nevertheless, the combination of cold saline followed by epinephrine has been found to be effective in individual cases.[82] Potentially fatal arrhythmias have been reported with endobronchial instillation of epinephrine,[83] and norepinephrine has been offered as an alternative agent because of its reduced beta-adrenergic effect.[81] Concerns regarding the use of both epinephrine and norepinephrine have been raised, and experts in the field have called for the removal of vasoactive drugs for the management of airway bleeding.[84] However, phenylephrine may be a safe and acceptable alternative, given its pure alpha-adrenergic vasoconstrictive properties.

When endobronchial instillation of cold saline and vasoactive drugs fails to control bleeding, endobronchial balloon catheter tamponade can be used to temporize massive hemoptysis from lung cancer and can be performed without great difficulty by most bronchoscopists.[85] The balloon can be left in place until more definitive treatment and/or until transfer to a regional center with greater expertise in the management of hemoptysis. More advanced bronchoscopic techniques, such as endobronchial laser and argon plasma coagulation, are not widely available but have been reported to be effective in controlling massive hemoptysis when bleeding from an endobronchial tumor is visible and within reach of the bronchoscope.

Endobronchial application of the Nd:YAG laser for control of massive hemoptysis due to lung cancer was first reported by Edmondstone et al.[86] in 1983. Various types of lasers are available today, but Nd:YAG remains the most common laser used within the airway. Multiple case series have demonstrated its effectiveness in relieving airway obstruction and dyspnea due to endobronchial and endotracheal tumors, but few studies have addressed its effectiveness in controlling hemoptysis, particularly massive hemoptysis. Although it has been generally reported to be approximately 60% effective in controlling hemoptysis,[36,45,87] a substantially higher rate of 94% was reported in a case series published in 2007.[88] The effectiveness of the Nd:YAG laser in controlling massive hemoptysis is not clear, but its use for this purpose is common and continues to be advocated.[36,45,89]

In one study, endobronchial application of argon plasma coagulation was used to control hemoptysis in 56 of 56 patients (6 of whom had hemoptysis >200 mL/d) without recurrence during a mean follow-up of 97 days.[90] Like Nd:YAG laser therapy, argon plasma coagulation is a noncontact application, but it differs in that it delivers electrically conducted argon (plasma) that produces rapid coagulation at a lower depth of penetration than Nd:YAG. Like the Nd:YAG laser, its use for massive hemoptysis has not been well validated, but its use continues to be advocated.[36,45]

Endobronchial electrocautery has been used to control hemoptysis due to lung cancer,[91,92] but limited evidence is available for its use in massive hemoptysis. Its routine use therefore cannot be advocated.

Other advanced bronchoscopic procedures, including endobronchial instillation of tranexamic acid,[93] fibrinogen–thrombin,[94,95] airway stent tamponade,[96] and oxidized regenerated cellulose hemostatic plug,[82] have all been reported to be successful for at least temporarily terminating massive hemoptysis from lung cancer, but none has been well validated. In addition, airway placement of a silicone spigot and endobronchial instillation of *n*-butyl cyanoacrylate glue have been used to temporize massive hemoptysis in patients without lung cancer.[97,98] Routine use of these agents and devices cannot be recommended, and their use should be determined only on a case-by-case basis.

Probe cryotherapy and brachytherapy have been used to treat endobronchial tumor and hemoptysis.[99–104] However, their effects are not rapid enough to control massive hemoptysis, and their use cannot be recommended for this indication.[36] Spray cryotherapy has also been used to treat endobronchial tumor and hemoptysis,[105,106] and although its use in massive hemoptysis has not been reported, it offers a potentially novel means of controlling massive hemoptysis.

Endovascular Embolization

Angiographic signs that confirm a source of bleeding are as follows (Figs. 57.6–57.8):[107,108]

- hypertrophy or enlargement (diameter >3 mm)
- tortuous bronchial arteries
- parenchymal hypervascularity
Fig. 57.6. Right bronchial arteriogram demonstrates (A) tortuous bronchial arteries and parenchymal hypervascularity; and (B) parenchymal staining.
Fig. 57.7. Bronchial arteriogram shows hypertrophied, tortuous bronchial arteries with parenchymal hypervascularity.

- parenchymal staining
- bronchial artery aneurysms or pseudoaneurysm
- bronchial artery to pulmonary vein shunting
- bronchial artery to pulmonary artery shunting
- extravasation of contrast medium
- thrombus

Endovascular embolization is now the accepted first-line treatment for massive hemoptysis, and it is preferred to surgical resection because it is minimally invasive. Two large case series showed 0% and 4% mortality for severe or massive hemoptysis, and these results support a strategy of bronchial embolization as first-line treatment over surgical intervention.[37,52] Angiography identifies a definitive site of bleeding in approximately 90% of patients who undergo angiography for hemoptysis.[47,52] The findings of large case series suggest that endovascular embolization is successful in controlling bleeding in 81% to 98.5% of patients for whom a site of bleeding is identified.[47,52,109–111] Recurrent hemoptysis leading to death or requiring a surgical procedure or reembolization occurs in 10% to 25% of patients who require embolization for hemoptysis, and the highest failure rate is found for patients with cystic fibrosis and aspergilloma.[47,52,109,110] However, among all patients with hemoptysis who require bronchial artery embolization, individuals with cancer have the highest mortality rate, at up to 92%.[112]

Failure of embolization or recurrence after embolization may be due to incorrect technique, incomplete embolization, failure to visualize nonbronchial systemic vessels responsible for hemoptysis, development of new vessels, recanalization of embolized vessels, or failure to recognize a pulmonary artery or vein as the source of hemoptysis. Thorough mapping before the procedure is essential in avoiding incomplete exclusion of all branches involved. Embolization should be as peripheral as possible to prevent deep branches from receiving collateral flow from other systemic sources. Polyvinyl alcohol is probably the most commonly used embolic material. It consists of industrially manufactured, nonabsorbable particles between 150 μm and 700 μm in diameter,[47,113] although the use of material with a diameter greater than 325 μm has been recommended because this is the size of the largest bronchopulmonary anastomosis found in the human lung.[114]

Although serious complications from endovascular embolization are rare, minor complications are not. Spinal artery embolization with infarction is the most dreaded complication of bronchial artery embolization. This complication has been reported in 1% to 6% of cases and occurs because of unintended embolization of an anomalous spinal artery arising from a bronchial artery. With increased awareness and technical improvements over time, the incidence appears to be much lower and is now probably less than 1%.[47] Superselective bronchial artery embolization with a coaxial microcatheter system allows more stable cannulation distal to the spinal artery and has been reported to reduce spinal artery complications.[115] Minor complications of endovascular embolization include chest pain (24% to 91%) and dysphagia (0.7% to 18%).[47,116] Dysphagia may occur 2 days to 7 days after embolization and is likely due to compromise of small arterial branches supplying the esophagus.[117] Other rarer complications of endovascular embolization have been reported, such as myocardial infarction, possibly due to embolization via coronary-to-bronchial artery fistula; multiple systemic embolization; bronchial necrosis; and stroke (Table 57.4).[47,118,119]
Fig. 57.8. Bronchial arteriogram shows (A) bronchial artery aneurysm/pseudoaneurysm *(arrow)*; and (B) shunting from the bronchial artery to the pulmonary artery or vein *(arrows)*.

TABLE 57.4 Complications of Endovascular Embolization

Complication	Incidence (%)
Chest pain	24–91
Dysphagia	0.7–18
Spinal artery embolization	<1–6
Myocardial infarction	<1
Stroke	<1
Multiple systemic embolization	<1
Bronchial necrosis	<1

Surgery

Although surgery plays a primary role in the prevention of recurrent hemoptysis in benign disorders such as aspergilloma, its role in lung cancer is limited, mainly because of the overall poor condition and prognosis of patients with lung cancer and hemoptysis. As an emergent procedure, it carries a high mortality rate, and it is rarely indicated for patients with lung cancer. Although emergent surgical intervention for massive hemoptysis has been widely quoted to cause death in approximately 40% of cases,[120] more recent data suggest hospital morbidity and mortality rates of approximately 27.5% and 11.5%, respectively.[121] Nevertheless, surgery remains warranted only for selected patients with lung cancer after conservative therapy, including endovascular embolization, has failed.

Outcomes

Hippocrates recognized hemoptysis as a herald to death. Even today, massive hemoptysis is a terrifying event for the lay person and is pathognomonic for death when depicted in movies and on television. Even the seasoned clinician is moved to a state of heightened awareness, knowing that despite efficient and appropriate diagnosis and treatment, death may be imminent. Only in the modern era has the short-term mortality rate been reduced to approximately 6.5% for severe hemoptysis of all etiologies.[52] Nevertheless, among all patients with hemoptysis, patients with lung cancer have among the highest in-hospital and 1-year mortality rates (up to 59% and 92%, respectively).[38,41,48,112] Treatment of patients with lung cancer and massive hemoptysis should therefore be considered largely palliative.

MASSIVE PLEURAL EFFUSIONS

A pleural effusion is considered large when it opacifies two-thirds or more of a hemithorax on chest x-ray. Massive pleural effusion is defined as complete or almost complete opacification of a hemithorax on chest x-ray.[122] Approximately 10% of patients with a pleural effusion have a massive effusion at the time of presentation. These patients are usually symptomatic and malignancy causes most of these cases, reported as 65% in two studies.[123,124]

Pleural Physiology

Pleural fluid arises from systemic pleural vessels in both the visceral and parietal pleura. Under normal physiologic conditions, fluid flows passively into the pleural space and exits via the parietal pleural lymphatics.[122] Pleural effusions occur because of an imbalance between pleural fluid flowing into and out of the pleural space. Most commonly, pleural fluid accumulates because of increased interstitial hydrostatic pressure in the lung, increased negative intrapleural pressure, increased pleural space oncotic pressure, and/or blockage of parietal pleural lymphatics.[125–127] Malignant effusion is believed to result directly from one or more of the following: pleural metastasis with increased pleural permeability, pleural metastasis with obstruction of pleural lymphatics, mediastinal lymph node involvement with decreased pleural lymphatic drainage, thoracic duct interruption, bronchial obstruction leading to increased negative pleural pressure, or pericardial disease.[122]

Massive pleural effusions lead to compressive atelectasis of the lung and a restrictive respiratory physiology in one of two settings: (1) increased intrapleural pressure with associated mediastinal shift away from the side of the pleural effusion, or (2) trapped lung physiology without a mediastinal shift or with a mediastinal shift toward the side of the effusion. Both underlying processes cause symptoms and impair respiratory physiology.[122,128,129]

Etiology and Pathogenesis

Pleural malignancies are usually metastatic, but primary pleural malignancies such as mesothelioma and lymphoma must also be considered. Lung carcinoma is the most common malignancy that metastasizes to the pleura, accounting for nearly 40% of all malignant pleural effusions.[130] Although breast cancer and lymphoma are the second and third most common causes, respectively, nearly all neoplasms have been reported to involve the pleura.[131,132] Mesothelioma should be considered in persons with an appropriate environmental exposure and geographic location; however, mesothelioma is not always associated with asbestos exposure.[133] In approximately 10% of patients, a primary site for malignancy is not identified.[130]

Pleural metastases occur via lymphatic spread, hematogenous spread, or direct invasion. Pleural tumors can then directly lead to pleural effusions, as detailed previously in the "Pleural Physiology" section.[134] Pleural effusions can also result indirectly from a tumor, a phenomenon referred to as a paramalignant effusion.

This cause of effusion can be associated with local inflammation and leaky capillaries, downstream lymphatic obstruction, or trapped lung physiology due to bronchial obstruction or lung parenchymal invasion by a tumor.[135]

Clinical Presentation

Malignant pleural effusions most commonly cause dyspnea, but patients may also present with cough and chest pain.[131] Because of the systemic effects of malignancy, the respiratory symptoms are generally accompanied by weight loss, malaise, and anorexia.[130] Although similar in presentation, massive pleural effusions should be expected to cause more severe symptoms because of more extensive pleural disease.

A massive pleural effusion often results in increased intrapleural pressure and a mediastinal shift away from the side of the pleural effusion. This massive volume and pressure can result in decreased chest wall compliance, compressive atelectasis of the ipsilateral lung, central airway compression, and hemodynamic effects related to the mediastinal shift.[136,137]

When a mediastinal shift is not evident or is toward the side of the effusion, one should suspect a trapped lung with fixation of the mediastinum, occlusion of the mainstem bronchus by a tumor, or extensive pleural involvement.[138] Whether the lung is trapped or not, the patient's symptoms will be similar because of decreased lung volume and compliance, as well as stimulation of chest wall and parenchymal lung receptors.

These two distinct underlying pathophysiologies of a massive pleural effusion (trapped lung or compressed lung) are important to understand and recognize. Therapeutic thoracentesis of a massive pleural effusion with a trapped lung will not satisfactorily address the underlying physiologic defect, will not completely relieve the patient's symptoms, and may lead to complications.[122,136]

Clinical examination is expected to be abnormal when a massive effusion is present. Ipsilateral breath sounds should be absent and dullness to percussion should be present on examination. Additional signs and symptoms including adenopathy, breast mass, neck mass, and cachexia support an associated diagnosis of malignancy.[131]

Initial Management

Guidelines for the management of malignant pleural effusion from the American Thoracic Society, British Thoracic Society, and European Respiratory Society separate diagnosis from treatment.[130,138,139] In our review, the initial treatment and diagnostic evaluation are deliberately presented simultaneously. A massive pleural effusion can be an emergency and, at minimum, it warrants an organized and efficient evaluation. In the clinical setting, management and diagnosis often occur simultaneously, or in whichever order is best for the patient's safety and management of symptoms.

Initial Presentation

Patients with a massive pleural effusion, whether it is malignant or nonmalignant, often present with dyspnea, cough, and chest pain. Nonmassive pleural effusions can also present with these symptoms, however, patients with massive pleural effusions tend to present with more severe symptoms and/or impaired cardiac or respiratory physiology.[122,128,129]

Guidelines from the American Thoracic Society, British Thoracic Society, and European Respiratory Society all recommend history, physical examination, and chest x-ray as the initial steps in evaluating a malignant pleural effusion.[138,139] These are sound recommendations; however, we believe that in the setting of massive pleural effusion, thoracic point-of-care ultrasonography

should be employed early. In skilled hands, lung ultrasound is more sensitive and specific for a pleural effusion than is chest x-ray.[140] Ultrasound of the lung and pleural space also has the advantage of distinguishing simple from complex effusions, as well as identifying pleural or lung masses suggestive of malignancy.[141] Algorithms have been developed for the evaluation of massive pleural effusion, with and without point-of-care ultrasonography (Fig. 57.9).

Point-of-care ultrasonography is a rapidly performed bedside examination that is focused and goal directed. It should have a defined purpose linked to improving the patient's outcome.[142] When point-of-care ultrasonography is performed in the critical care setting, it is also referred to as critical care ultrasonography. Both techniques have been widely adopted by many physicians in emergency medicine, pulmonary medicine, and critical care medicine.

Point-of-care ultrasonography is particularly helpful in the evaluation of dyspnea, hemodynamic instability, and undifferentiated shock.[143–145] In the setting of suspected massive pleural effusion, point-of-care ultrasonography also allows the physician to assess for cardiovascular compromise and to evaluate for alternative causes among patients presenting with dyspnea, cough, and chest pain.[146,147] Although this chapter focuses on massive pleural effusions, it is important to recognize that patients with malignancy and pleural effusion are at risk of pulmonary embolism, pneumothorax, postobstructive pneumonia, congestive heart failure, acute kidney injury, and hepatic dysfunction.

Ultrasound is not available in all clinical settings; however, the use of point-of-care ultrasonography in the emergency room is becoming the standard of care,[148] and many clinics now have access to portable ultrasound machines, making the implementation of bedside ultrasound for the initial evaluation of massive effusion a realistic consideration. The value of chest x-ray should not, however, be minimized. Chest x-ray is often available for review at the time of the physician's initial assessment. Furthermore, the clinical environment may not allow the use of point-of-care ultrasonography. Chest x-ray can improve the clinical assessment by confirming the presence and size of a suspected effusion, identifying an associated lung mass or airspace disease, ruling out a large pneumothorax, and helping to detect a mediastinal shift (Fig. 57.10).[137] Chest x-ray and ultrasound are complementary in the evaluation of possible massive pleural effusions. When available, lung and pleural ultrasound should not be delayed in favor of a chest x-ray, and in the appropriate clinical setting, point-of-care ultrasonography should be integrated into the initial physical examination and history.

Initial Therapeutic Intervention

The initial intervention for a massive pleural effusion is aspiration of pleural fluid to alleviate symptoms (Fig. 57.9). Thoracentesis should be performed under ultrasound guidance, unless ultrasound is not available and the aspiration is an emergency. The complication rate for thoracentesis performed under ultrasound guidance is very low (0% to 2.5%) when performed by skilled groups of physicians.[149–151] This rate is notably less than the commonly quoted complication rate of more than 10% for thoracentesis performed in the preultrasound era.[152,153] In addition to locating a safe site for pleural puncture, ultrasound is helpful for assessing a complicated pleural space.[154] This information helps the clinician avoid potential complications and optimize both diagnostic yield and safety.

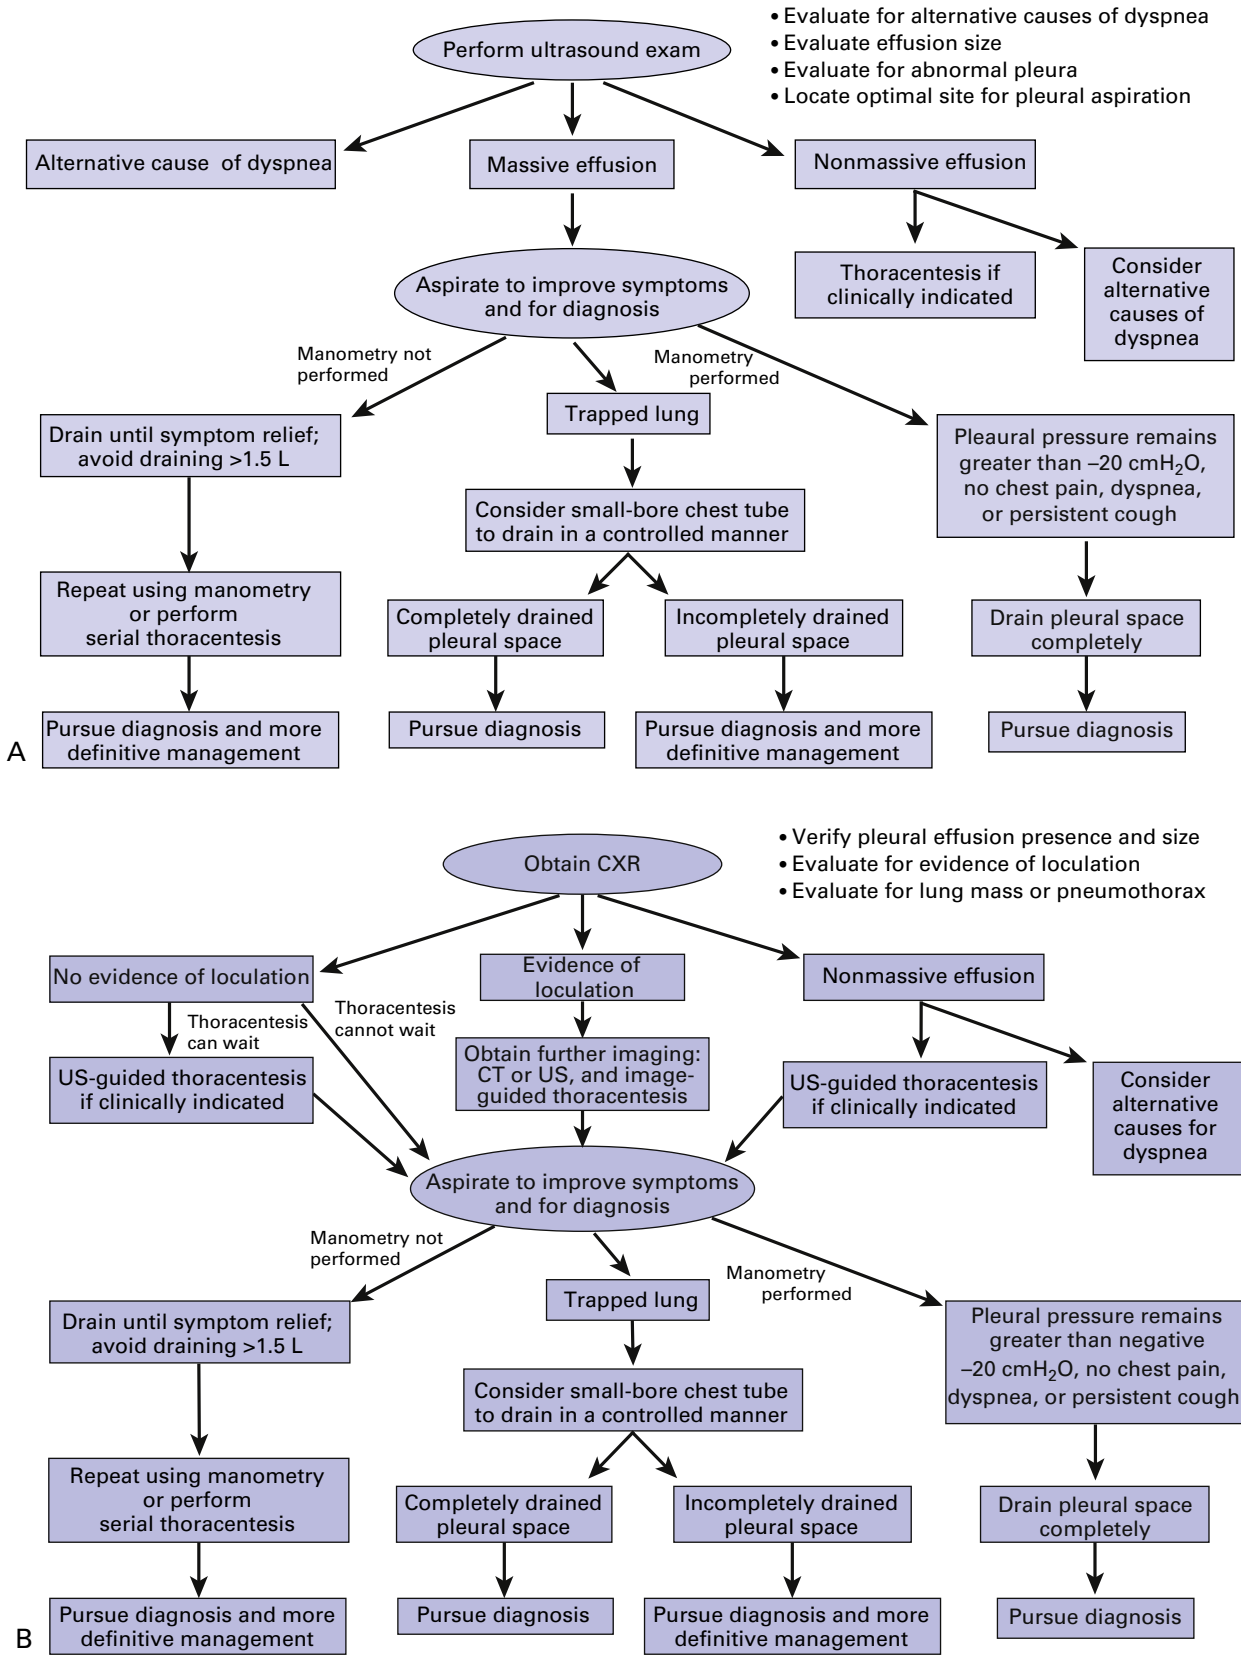
The amount of fluid to remove and the method of removal depend on the patient and the clinical situation. For most patients, thoracentesis is the preferred method. It is recommended that pleural pressure be monitored during fluid drainage.


Fig. 57.9. Management algorithms for massive pleural effusion in two scenarios: (A) using point-of-care ultrasonography; and (B) without the availability of point-of-care ultrasonography. *CT*, computed tomography; *CXR*, chest x-ray; *US*, ultrasonography.
Fig. 57.10. Comparative images of massive pleural effusions. (A) Chest x-ray with nearly complete opacification of the right hemithorax. (B) Chest x-ray with complete opacification of the left hemithorax. The trachea is deviated to the right, consistent with a massive effusion. (C) Computed tomography of the chest of the same patient as in image A. Pleural effusion (Pleff), lung atelectasis, and mediastinal shift can be seen. (D) Thoracic ultrasonography of the same patient as in image A. Pleural effusion, lung atelectasis, and an abnormal right hemidiaphragm (HD) are visualized. Note the thickened diaphragm rather than the expected thin hyperechoic line. This finding is consistent with pleural metastasis.

Pleural manometry has many advantages for patients with massive pleural effusion. It can diagnose trapped lung, which will help in future management.[155] In addition, pleural manometry helps indicate when to stop fluid removal. Pleural pressure of less than -20 cmH_2O is associated with discomfort and reexpansion pulmonary edema.[156]

Common teaching and many experts recommend drainage of no more than 1.5 L of fluid.[122,130,157] However, this one-size-fits-all approach is flawed, especially for very large or complicated pleural effusions. Reexpansion pulmonary edema has been shown to be rare, and large-volume thoracentesis is generally well tolerated. In a series of 185 patients undergoing large-volume thoracentesis (1 L to 6.5 L withdrawn), only one patient had clinical reexpansion pulmonary edema, and this patient had only 1.4 L of fluid withdrawn. Only 22% of patients had pleural closing pressure less than -20 cmH_2O after large-volume thoracentesis.[158] In his text, Light recommends stopping fluid drainage if cough or pain develops or, based on animal studies, when pleural pressure reaches less than -20 cmH_2O, because of the risk of reexpansion pulmonary edema; significant edema commonly develops if pleural

pressure is less than -40 cmH_2O. Patients who had discomfort after thoracentesis were more likely to have a more negative closing pleural pressure and a larger total change in pleural pressure.[156]

We recommend that the pleural space be completely drained, when possible and safe, both for controlling symptoms and improving physiologic parameters. Limiting the volume of pleural fluid drained will decrease the effectiveness of this procedure. We recommend both manometry and monitoring of symptoms, including cough, chest tightness or pain, and vasovagal symptoms.[156] However, if pleural pressure is not monitored, then an approach to large effusions as outlined by the British Thoracic Society guidelines is reasonable. The pleural effusion should be drained in a controlled fashion, with initial drainage of no more than 1.5 L and any additional fluid drained 1.5 L at a time at 2-hour intervals. Symptoms should be monitored, and the procedure should be stopped if the patient reports chest discomfort, persistent cough, or vasovagal symptoms.[130]

Small-bore pleural catheters that can be placed using a modified Seldinger technique and under ultrasound guidance should also be considered for appropriate patients. The small

bore of the catheter and modified Seldinger technique make the procedure not much more invasive than therapeutic thoracentesis. This approach has the advantages of removing the fluid slowly, or at a constant pressure (setting the pleural drain to no less than -20 cmH$_2$O). In addition, if fluid is accumulating quickly, this approach avoids the need for multiple repeat thoracenteses. The major disadvantage to this approach is the need for pleural tube management after placement, meaning that this procedure is generally not appropriate for patients returning home immediately after placement. In addition, physician familiarity and skill are required for performing this procedure.

Subsequent Management

After the initial assessment and intervention, a plan is needed for subsequent and long-term management. This is best accomplished after the patient has a diagnosis. As noted earlier, 65% of massive pleural effusions are malignant, and the type of malignancy should be identified.

Additional Chest Imaging

Chest CT aids in identifying pleural-based masses, pleural thickening, loculated effusions, lung masses, parenchymal lung disease, and mediastinal adenopathy.[159] More complicated diagnostic imaging, such as positron emission tomography and magnetic resonance imaging, can have a role in evaluating for chest wall involvement and distant metastasis. Magnetic resonance imaging is most helpful in evaluating mesothelioma and differentiating benign from malignant pleural masses; however, it should be reserved for the appropriate setting, whether for staging, treatment, or long-term management.[160–163]

Pleural Fluid Analysis

Pleural fluid is often analyzed for lactate dehydrogenase, total protein, cholesterol, glucose, pH, amylase, and nucleated cell count. The initial pleural fluid analysis should be focused.[122] Heffner et al.[164] showed that the analysis of pleural fluid for lactate dehydrogenase and cholesterol alone was comparable to Light's criteria and avoided the need for simultaneous serum laboratory testing. Malignant effusions are commonly bloody, but less than half are grossly bloody. Lymphocytes or monocytes often predominate, but this is a nonspecific finding.[165]

In addition to focused chemistries, determination of pleural fluid pH can be helpful in the setting of both inflammation and malignancy. Malignant effusions have a pH less than 7.3 about one-third of the time, and this finding appears to be associated with increased tumor mass in the pleural space.[166] In addition to helping make a diagnosis, pH measurement has been shown to aid in prognosis. Malignant effusions with a low pH and glucose concentration have been shown to have a higher initial diagnostic yield on cytologic evaluation, a worse survival rate, and worse response to pleurodesis than those effusions with normal glucose and pH.[166–168] However, this dictum is not universally accepted. Aelony et al.[169] showed that talc pleurodesis was effective in a case series of patients with pH less than 7.3. Their findings are supported by Heffner et al.'s[170] analysis showing that pleural pH did not have adequate predictive value to recommend against pleurodesis, either because of pleurodesis failure or predicted short survival.[171] Although biochemical analysis and cell count of the pleural fluid are helpful when evaluating the etiology and management of pleural disease, ultimately the most important predictor of survival is likely to be the patient's overall health. In a study performed by Burrows et al.,[172] Karnofsky performance status was the most important predictor of survival at the time of pleuroscopy.

Histologic Analysis

In the absence of a clear cause for a massive unilateral effusion, and given the high percentage of massive effusions associated with malignancy, a sample should be sent for cytologic analysis. Positive results of pleural fluid cytology can be used to identify a specific malignant cell type, to perform immunohistochemical analysis, to test for molecular markers, and to indicate advanced disease. Initially, a cytologic sample alone should be sent. Although the purported yield of cytology varies considerably, a commonly referenced study of 414 patients had a diagnostic yield of nearly 60%.[173] The addition of closed pleural biopsy increased the yield by only 7%. The volume of fluid sent also improves yield; 150 mL of pleural fluid has been recommended.[174]

No single tumor marker can identify malignancy. A panel of markers can help guide further diagnostic procedures. In the initial evaluation, the routine use of tumor markers is not recommended and does not warrant the increased cost.[175]

As noted, closed pleural biopsy provides only a small additive diagnostic yield and hence is not part of the routine initial evaluation of a massive pleural effusion. Closed pleural biopsy should be considered when the initial focused evaluation, including thoracentesis and fluid cytology, is negative. Alone, closed pleural biopsy has a diagnostic yield of only approximately 40% and is associated with serious complications, including vasovagal syncope, hemothorax, pneumothorax, empyema, and death. In medical centers where it is available, CT-guided pleural biopsy using a cutting needle offered a yield of nearly 80%.[176] Neither closed pleural biopsy nor CT-guided pleural biopsy is warranted at initial evaluation; however, both can be considered subsequently, depending on local expertise.

More Definitive Management

Medical Thoracoscopy and Video-Assisted Thoracoscopic Surgery

The decision to pursue video-assisted thoracoscopic surgery as opposed to medical thoracoscopy will depend on local availability and expertise with each procedure. As a diagnostic procedure, medical thoracoscopy has the advantage of not requiring general anesthesia. This approach allows a less invasive and less expensive procedure. The diagnostic yield of medical thoracoscopy (95%) is much better than that of pleural fluid cytology and closed pleural biopsy combined (74%).[177] As described earlier, the initial therapeutic management and diagnostic evaluation does not include thoracoscopy. If the expertise in medical thoracoscopy is available and the initial evaluation does not yield a diagnosis, thoracoscopy should be used early.[178]

Serial Thoracentesis

Reaccumulation of fluid is common, and repeated thoracentesis is associated with pleural adhesions, making future management difficult. For these reasons, observation with as-needed thoracentesis is generally reserved for patients with minimal symptoms who require thoracentesis less than once per month.

However, in patients with limited life expectancy, this option can be less invasive and should be considered.[130,172]

Pleurodesis and Indwelling Pleural Catheter

For patients who are expected to survive longer than 1 month and who have a Karnofsky performance greater than 30%, more definitive management must be considered.[172] The optimal method to use, however, is not clear. Pleurodesis using tetracycline, bleomycin, or talc is commonly used. Talc has been shown to be the most effective sclerosant, with evidence suggesting

that thoracoscopic talc poudrage is preferred over talc slurry. The benefit of, and decision to pursue, thoracoscopic talc poudrage over talc slurry is debatable and beyond the scope of this discussion for the emergency management of massive pleural effusion.[179,180] Indwelling pleural catheters have both advantages and disadvantages when compared with talc pleurodesis. These catheters can be placed in an outpatient setting[181] and have been shown to improve quality of life and dyspnea scores compared with talc slurry.[182] However, a large study did not show a significant difference in dyspnea, quality of life, or survival. Indwelling pleural catheters did reduce hospitalization time, but caused more adverse events, including catheter malfunction and infection.[183] The decision to pursue talc pleurodesis instead of an indwelling pleural catheter should be made on an individualized basis. However, it is generally accepted that indwelling pleural catheters are the preferred therapy for loculated malignant effusions and trapped lung.

CONCLUSION

Central airway obstruction, massive hemoptysis, and massive pleural effusions are three lung emergencies that are the most specific to lung cancer. Rapid diagnosis, careful evaluation, and a well-coordinated and carefully implemented treatment plan will satisfactorily address the problems that arise in the care of most patients with central airway obstruction due to lung cancer. Effective management will give patients improved functional status, better exercise tolerance, enhanced quality of life, reduced need for prolonged high-level care during hospitalization, longer survival, and the ability to consider and more safely undergo additional systemic therapy if indicated. The physician's technical ability to palliate severe central airway obstruction can improve with experience as he or she takes on increasingly difficult and challenging cases. Of course, one must never perform procedures for the procedure's sake, and bronchoscopic intervention must be considered within a patient-focused philosophy of care. A careful risk–benefit analysis helps safeguard against unnecessary interventions, although some may argue that when the alternative is death, even the most potentially heroic palliative interventional procedures may be warranted. Such attempts must be carefully weighed against the benefits and reasonableness of supportive care. In case of doubt, it is extremely beneficial to discuss decisions with a palliative care specialist, medical ethicist, and other members of the lung cancer multidisciplinary team, including with an expert more experienced with airway management procedures. In addition, bronchoscopists should track the indications and outcomes of their procedures, including procedure-related complications and postprocedure survival. As for any medical or surgical procedure, treatment of central airway obstruction requires a system of accountability to ensure that patients undergoing these interventions are appropriately selected, cared for, and monitored.

Hemoptysis is not a rare event for patients with lung cancer, but it may arise or advance in such dramatic volume and fashion as to be shocking to both the patient and clinician. With this unmistakable presentation, hemoptysis is universally acknowledged as massive and is easily recognized as a critical life-threatening condition. However, no universally accepted definition of massive hemoptysis exists. Although the volume of expectorated blood has traditionally been used to define massive hemoptysis, a grading system incorporating the patient's underlying disease, physiologic state, chest x-ray findings, and vascular source of bleeding more accurately predicts mortality. Rapid and efficient evaluation and treatment are of paramount importance, yet mobilizing the

resources to accomplish these tasks is a challenge. A multidisciplinary approach focused on rapid evaluation, stabilization in the intensive care unit, and endovascular embolization is recommended. Bronchoscopy may play an important diagnostic and therapeutic role, whereas surgery is rarely indicated. Transfer of these patients to a tertiary care center with the experience, personnel, and resources required for a multidisciplinary approach to the management of massive hemoptysis should be considered.

Massive pleural effusion can be a life-threatening emergency and therefore necessitates an organized, efficient, and safe approach to treatment. Therapeutic management and diagnosis often occur simultaneously. However, it is important to recognize that the initial intervention for the relief of symptoms and improvement in respiratory physiology—while ensuring patient safety—takes precedence over diagnosis. Pleural aspiration remains the key intervention in the initial management of massive pleural effusions. We have outlined an approach that we believe is both thoughtful and efficient.

Massive pleural effusions are usually associated with malignancy. For this reason, there must be a high clinical suspicion of malignancy when evaluating and managing a massive pleural effusion.

We recommend that, whenever possible, ultrasound be integrated early into the evaluation algorithm and that pleural pressure be monitored and managed during pleural fluid drainage. This approach will help minimize complications and maximize pleural fluid drainage.

Long-term management will depend on the cause of effusion, local expertise, and the available therapeutic and diagnostic modalities.

58 The Role of Palliative Care in Lung Cancer

Mellar Davis and Nathan Pennell

SUMMARY OF KEY POINTS

- The best palliative outcomes are obtained when palliative care is involved early in advanced lung cancer.
- Integration of palliative care early in the advanced cancer patient has important health utilization and economic outcomes besides patient-related outcomes.
- Supportive oncology and palliative care are not the same. Supportive oncology involves therapies to treat or minimize anticancer therapy toxicity.
- There is in general a misunderstanding of palliative care as hospice care. This misunderstanding is a barrier to referral.
- Patient-related outcome measures predict relevant outcomes such as survival, tolerance to chemotherapy, and performance status.
- Hope in advanced lung cancer can be maintained without the promise of therapies that are unlikely to alter the cause of cancer.
- There are multiple symptom and quality-of-life tools with lung cancer–specific items that can be used to assess pain, nonpain symptoms, and quality of life in lung cancer.
- Pain, fatigue, dyspnea, cough, and anorexia can be successfully treated using guidelines established for specific symptom management.

DEFINITION OF PALLIATIVE CARE

The World Health Organization (WHO) defines palliative care as the "holistic care of patients with advanced progressive illness. Managing pain and other symptoms, and providing psychosocial and spiritual support are paramount. The goal of palliative care is to achieve the best quality of life for patients and their families. Many aspects of palliative care also apply earlier in the course of illness, in conjunction with curative, disease-modifying or rehabilitating treatments."[1,2] This definition establishes three important points: (1) palliative care is patient-oriented rather than disease-oriented; (2) palliative care is interdisciplinary, using multiple medical and nonmedical specialties to achieve the best quality of life for the patient and family; and (3) palliative care is complementary to disease-related care.[3] However, this definition does not provide clinical guidelines for successfully implementing early integration of palliative care. Specific guidelines are necessary for defining when and how palliative care needs to be integrated into clinical pathways for successful implementation.[3]

Many palliative care programs have adopted multiple names, including supportive care, to facilitate early integration. According to National Council for Hospice and Specialist Palliative Care Services, supportive care helps the patient and family cope with cancer and treatment, from before diagnosis through the process of diagnosis, treatment, cure, continuing illness or death, and (family) bereavement. Supportive care helps patients maximize the benefits of cancer treatment and live as well as possible with the side effects of the disease and its treatment. Supportive care is of equal priority with diagnosis and treatment. Supportive care

originally focused on side effects from anticancer therapies, such as neutropenic fever and nausea, related to chemotherapy agents. Unlike palliative care, supportive care does not have a recognized subspecialty status. Like palliative care, supportive care is multidisciplinary. Many trials have used the term best supportive care, but this term is not defined in trial documents. In one review, best supportive care was largely limited to biomedical support, such as transfusions, antibiotics, and antiemetics, and did not include advance directives, communication, and psychosocial or spiritual care or support.[4]

End-of-life care has been largely associated with hospice care. In the United States, because of the hospice Medicare benefit, end-of-life care is assumed to be the 6 months, or less, prior to the patient's death.[5] Definitions of end-of-life care have broadened considerably regarding disease trajectory, when end-of-life care should be introduced, and the clinical conditions on which it focuses. As noted previously, there are multiple of terms and definitions for end-of-life care and palliative care. The fact that programs frequently use several descriptors leads to confusion.[6–8] The reason palliative care programs have adopted the term supportive care is largely due to the fact that physicians and patients find the term more acceptable than palliative care.[9]

The first inpatient palliative care unit in North America was established by Dr. Balfour Mount at the Royal Victoria Hospital, Montreal, Canada in 1975. The establishment of this unit was just 8 years after St. Christopher's Hospice was opened in London, England by Cicely Saunders.[10] The term "palliative" was adopted at that time to describe the function of the unit and the purpose of the program. The main reason for opening this inpatient palliative care unit within an acute care hospital was because of disturbing deficiencies in the care of patients with incurable illnesses.[10] Dr. Mount recognized the misalignment between the goals for treating incurable and terminal illnesses, and the main goals of the acute care hospital, which were to investigate, diagnose, cure, and prolong life. In contrast, the three main goals of cancer treatment were to cure, prolong life, and palliate. Prior to the establishment of the palliative care unit, most, if not all, effort and resources were being applied toward curing or prolonging life. The palliative needs of terminally ill patients and their families, including medical, emotional, and spiritual needs, were generally neglected in an acute care hospital.

PHILOSOPHICAL DIFFERENCES BETWEEN ONCOLOGY AND PALLIATIVE CARE

A shift to a scientific-based, disease-oriented medical model, which occurred in the latter half of the 19th century, resulted in major advances in health care. Louis Pasteur's germ theory led to Joseph Lister's management of surgical wounds and the remarkable reduction in postoperative mortality and morbidity due to infections. Florence Nightingale used statistics and collected mortality data to prove that sanitary conditions reduce mortality,[11–19] and the randomized clinical trial based on disease models and evidence-based therapeutics became the language of medicine. However, the adverse outcome of this shift was to objectify patients and identify them with their disease (e.g., cancer patients) and to depersonalize the healing process through reductionism. Quantification of outcomes became a priority when treating large populations.[11]

The curative and the disease-modifying models include the inherent assumptions that analytical, rational, and clinical encounters are the basis for scientific inquiry.[20] The object of analysis is the disease rather than the patient and their experience of illness. Symptoms are valued as clues to a diagnosis instead of a disease worthy of treatment. Cure is contingent on effective diagnosis and treatment. Treatment is largely empiric, uniformly applied, rather than person-centered, and based on stringently controlled trials of persons with similar disease states and measurable disease-related objective outcomes that are viewed as most important (survival, disease-free survival, or progression-free survival).[20] Laboratory and radiographic data are trusted more than the patient's self-report, and patient-related outcomes are of secondary importance to disease-related outcomes. In fact, most physicians are unfamiliar with patient-related outcomes and outcome measures.[21] Few oncologists routinely use patient-related outcome measures in practice and largely depend on laboratory and radiographic disease states to guide treatment and clinical decisions. The disease-oriented and curative model tends to ignore phenomena that cannot be scientifically explained.[20] Patients are perceived as component parts, and treatment is delivered by subspecialists. Physicians tend to think in terms of molecules, cells, organ systems, and genomes, particularly those with critical cancer-related (so-called addicted) pathways.[20,22,23] They place secondary importance on relational perspectives.[20] Oncology within the cancer center is largely hierarchical and physician centered. Multidisciplinary tumor boards are almost entirely comprised of physicians from various subspecialties and rarely involve nonmedical and noncancer medical specialties such as nursing, palliative care, social work, and rehabilitation services. Discussions within tumor boards are almost entirely centered on managing the disease; treatment recommendations are largely biomedical in nature and limited to radiotherapy, surgery, and chemotherapy, or a combination of antitumor therapies. Death in a curative model is seen as defeat. There are no so-called good deaths in oncology.[20] The most commonly heard excuses are that treatment failed, or, even worse, the patient failed the treatment, or nothing more can be done. The curative model fosters the involvement of palliative care in a transitional approach, in which palliative care is considered only when anticancer therapy is exhausted, rather than as simultaneous care. As a result, in the absence of palliative care support, physicians do what they have been trained to do; they give chemotherapy or targeted agents even in a terminally ill patient with little-to-no expected benefit.[24,25] Reviews published regarding management of nonsmall cell lung cancer (NSCLC) have sometimes explicitly used an either-or approach when comparing chemotherapy with palliative care.[26] In the curative model, palliative care is considered end-of-life care, and referral is made once treatment is no longer effective.[27,28]

In the palliative-care approach, treatment centers around the patient and family, with the goals of providing relief of pain and other symptoms, reducing psychosocial and spiritual stressors, restoring function, including social life and the role within the family, and improving quality of life. Palliative care supports patient values, concerns and personal choices. Treatment of pain and other symptoms is a legitimate outcome and goal of medicine. Diagnosis is not a predetermined goal, but is pursued if compatible with the patient's personal goals.[20,29] Treatment is individualized based on evidence from guidelines. Palliative care, like hospice, seeks neither to hasten nor delay death and sees death as a natural part of living.[20,30] The structure of palliative care services is nonhierarchical, with multiple medical and nonmedical specialists, including physicians, forming an interdisciplinary team that recognizes different roles and responsibilities. Encounters are usually lengthy. To achieve the most favorable outcome, palliative care is best practiced within multiple encounters over a prolonged period of time and is best used early in the course of illness, rather than as a crisis intervention or as a death management service at the end of life.[20,25,31–34]

There are three basic integrated palliative care models. The first involves the oncologist playing both roles in cancer care. This requires extensive time and expanded expertise, and, in general, it is impractical, because of time constraints and the need for secondary training. Oncologists should be skilled in basic palliative care. In areas where there is a lack of palliative care services, this is the default model.[35] The second approach is the so-called cafeteria model, in which the oncologist forms an interdisciplinary team by arranging multiple consultations with specialists in radiotherapy, surgery, palliative care, social work, psychology, and spiritual care. The oncologist makes up the hub of the wheel and multiple specialists serve as the spokes of the wheel. This approach is time-consuming and expensive for patients who have to make multiple visits to many consultants. A breakdown in communication is also more likely to occur, and knowing which specialist to contact for which symptom, stressor, family concern, or financial matter may be problematic for the patient.[35] The third model involves a simultaneous consult with a palliative care specialist and the oncologist, early in the course of cancer treatment. Communication and rapport can be established with both specialists, and the oncologist is free to focus on cancer management. This is a time-efficient practice that improves communication between two services.[35] In this model, the palliative care specialist may potentially act as a so-called treatment broker. As the patient and oncologist gain trust in the palliative care specialist, the patient may feel free to use the palliative care specialist as a sounding board to clarify preferences and goals of care.[24,36] Palliative care includes several components, and interdisciplinary palliative care teams have many distinct characteristics (see Boxes 58.1 and 58.2).

WHY PALLIATIVE CARE IS NEEDED EARLY IN THE MANAGEMENT OF ADVANCED LUNG CANCER

Symptoms

Individuals presenting with lung cancer are usually highly symptomatic. Most patients with advanced disease have at least four distressing symptoms.[37–41] Their average pain severity is 6 to 7, which is considered moderate, based on a numerical

---

BOX 58.1 Palliative Care Structure

1. Outpatient clinics
   - Early referral
2. Consultation services
   - Inpatient/outpatient
   - Crisis intervention
3. Inpatient units
   - Direct care
4. Association or affiliation with hospice services
5. Home palliative care services
6. Education
   - Fellowships
   - Grand Rounds and other teaching modalities
   - Provision for teaching internal medicine residents, oncology fellows, other fellows (gynecology, oncology, radiation, pain management)
7. Research
   - Quality-improvement projects
   - Prospective observational and interventional studies
   - Dedicated time, fellows, personnel, and resources
   - Integration into oncology as supportive care trials

1. Continuity: reconciliation of service lines
2. Assessment of symptoms: expert use of patient-related outcome measures
3. Treatment of cancer complications and associated symptoms (expertise in pharmacologic and nonpharmacologic management of symptoms)
4. Communication
   - Treatment goals and prognosis
   - Assess values and preferences and understanding regarding disease stage, course, outlook, and goals of care
   - End-of-life care and decisions, preference for site of care
   - Advance directives
5. Transition facilitation
   - Active cancer treatment plus palliative care to active palliative care
   - Active palliative care to hospice
6. Family care
   - Facilitate family meetings
   - Understand family systems
   - Management of family distress, dysfunction, and family grief
7. Psychosocial care
   - Management of distress, depression, demoralization
   - Management of anticipatory grief, complicated grief, and depression in grief
8. Spiritual care
   - Recognize existential suffering
   - Able to take a spiritual history
   - Understand diverse religious practices
9. Rehabilitation
   - Referral to pulmonary and nonpulmonary rehabilitation, physical therapy, and occupational therapy
10. Supportive care
    - Treatment of toxicity and complications related to anticancer therapy
11. Care of the actively dying
12. Bereavement
13. Research in supportive and palliative care interventions, service structures, and complex research designs

rating scale with 0 being no pain and 10 being severe pain.[42] The most frequently reported symptoms are anorexia, cough, dyspnea, fatigue, pain, and insomnia. Individuals with lung cancer experience a greater prevalence of depression and anxiety than individuals with other cancers and also have more frequent and prolonged fatigue compared with patients with other cancers.[43,44] Breathlessness occurs in 70% of patients, is associated with a substantially greater symptom burden, and can adversely influence the experience of caring for a loved one.[45] Symptom burden may, in fact, be greater than patients indicate. That is why it is important to use a standardized symptom questionnaire. Studies have shown that, when presented with a symptom checklist, patients report three to four times more symptoms than they volunteer.[46]

Even individuals with relatively early-stage lung cancer (stages I–IIIB) have substantial symptoms. When using the Lung Cancer Symptom Scale at disease presentation, patients reported an average of 11 symptoms, and, even when successfully treated, they reported an average of 6 to 7 symptoms still present a year after treatment.[39] As mentioned previously, individuals with early-stage lung cancer experience lack of energy, worry, dyspnea, cough, and insomnia. The Karnofsky performance status often remains impaired at 36 to 52 weeks after treatment, but symptom

distress gradually declines by 1 year. Symptom distress is the primary reason for clinical encounters in the outpatient setting and the primary reason for unscheduled admissions.[47] Despite treatments for NSCLC, there is gradual deterioration in physical function, activities of daily living, and cognitive function and an increasing need for social support.[48]

Physicians frequently believe that tumor reduction is a surrogate for improved patient-related outcomes. However, based upon a systematic review of quality of life associated with standard chemotherapy for advanced NSCLC, there are no major changes in the global quality of life for patients on standard chemotherapy regimens.[49] There is only a modest correlation (0.35) between objective tumor size and symptoms. Improved patient-related outcomes with treatment last a much shorter time (3.8 months on average) than duration of objective tumor response (6.4 months). Objective tumor response and patient-related outcomes contribute unique, independent information. One cannot be substituted for the other.[50] Unfortunately, most oncologists are unfamiliar with standard symptom questionnaires, and most are not aware of clinically meaningful differences in patient-related outcome measures.[21] However, having patients complete quality-of-life and symptom questionnaires gives patients a sense of better continuity with their physician and the feeling that their treating oncologist has considered their daily activities and emotional state. Patients think that such questionnaires are helpful and not burdensome.[51] Longitudinal assessment of symptoms is also important because treatment reduces certain symptoms but increases others.[52]

At least 40% of outpatients with cancer are undertreated for pain, as measured by the Pain Management Index. This reflects inadequate analgesic choices based on pain severity, but does not reflect pain response. Despite the fact that greater than 60% of patients have substantial pain, there is no change in the Pain Management Index score with follow-up. Oncologists self-rate their ability to manage pain as high (7 to 10, with 10 being the best management), but rate their colleagues' ability to control pain lower (3 to 10). Oncologists perceive lack of assessment, time constraints, and patient reluctance to complain as barriers to pain management.[53] Most oncologists know the WHO analgesic stepladder and prescribe opioids around-the-clock for chronic pain. However, most (greater than 60%) fail to correctly answer questions regarding opioid management (dose, schedule, conversion and rotation ratios, and titration) when tested through clinical scenarios.[53] This has been documented in several studies.[54,55] Symptom burden increases in intensity and number of symptoms as cancer progresses and then plateaus in the last month of survival. Eighty percent have increasing fatigue, dyspnea, and anorexia, and most have chest pain in the last 3 months of life.[39] Left poorly managed, these individuals experience a painful death, and families experience complicated grief or depression in bereavement.[56] Integrating palliative care into outpatient oncology practice early in the course of cancer reduces symptom burden, improves quality of life, and provides the care and support patients and families want (see Box 58.3).[25,57]

Communication

Honest communication is important but can be marred when a patient and physician maintain false hope in anticancer therapy. Good communication includes discussions about alternative therapies, prognosis, the goals of therapy, advance directives, and end-of-life care. Giving bad news requires some special skills, and few oncologists have had that type of communication training. In the US Cancer Care Outcomes Research and Surveillance (Can CORS) study, only half of patients with advanced cancer had discussions about hospice care, and yet greater than 70% died within 6 months.[58] Of the more than 4000 physicians caring for Can CORS patients, most would not initiate discussions

---

BOX 58.3   Patients and Families Need and Want To

Be treated as individuals
Be heard
Be valued for their skills and knowledge
Exercise real choice about treatment and services
Receive detailed, high-quality information about the disease, disease trajectory, prognosis, and goals of care
Know options and alternatives, including access to support groups, self-help services, and complementary therapy
Know they will undergo interventions that they have been informed of and have agreed to
Have excellent face-to-face communication
Know that services are well coordinated and are of high quality
Know that physical symptoms will be assessed and managed to their satisfaction and within the physician's current expertise and knowledge
Have services available that can provide support and advice about financial concerns, including employment
Have access to spiritual care and be supported spiritually
Die in the place of choice
Be assured that the family will be supported throughout their illness and into bereavement

Modified from National Institute for Clinical Excellence. *Improving Supportive and Palliative Care for Adults with Cancer*. London: NICE; 2004.

---

about prognosis, advance directives, resuscitation, and hospice care, even if death was expected within 6 months and despite national guidelines. Most physicians stated that they would postpone these discussions until the patient was highly symptomatic or failed disease-modifying therapy. Some will not conduct these discussions unless initiated by the family or patient.[59] Medical oncologists explain the disease course in 53% of consultations and discuss the absence of cure in 84%.[60] However after consultation, most patients with advanced lung cancer still believe there is some chance of cure with chemotherapy.[61] Even after being fully informed using decision aids, one-third of patients with incurable cancer feel that their cancer has some chance of being cured with chemotherapy.[62] Patients do want to be fully informed about the stage at diagnosis and the prognosis, but comprehension often lags behind.[62] Within consultations, oncologists address symptoms in 35% of patient encounters and discuss prognosis in 39%. Patients may perceive prognosis differently than incurability, which has no time line.[60] Even when prognosis is discussed, physicians tend to be overly optimistic.[63,64] Documentation of discussions about prognosis appears in less than 40% of medical charts.[65] However, documented discussions about prognosis are also associated with documented discussions about options regarding ongoing anticancer therapy (odds ratio 5.8), and documented do-not-resuscitate (DNR) orders (odds ratio, 2.2).[65] Individuals with advanced cancer who overestimate their prognosis or who are given an overly optimistic estimate of survival are more likely to choose therapies for which the burden outweighs the benefit, are less likely to discuss preferences with surrogates, and are less likely to obtain information that would improve the quality of end-of-life care.[58,66,67]

The picture may be a bit different from the patient's perspective. In a study involving 276 patients from four major medical centers, 40% of patients rated communication with their oncologist about the potential for cure of their lung cancer low, and 80% gave low ratings about communication regarding resuscitation, life-sustaining treatments, and preparation of advance directives. Over half of patients reported that communication with their oncologist was inadequate.[68] These findings may be related to a patient's perception and inability to comprehend the seriousness of the situation, which is only realized as cancer progresses.

A large number of patients choose palliative chemotherapy at the end-of-life, for little to no benefit, because it helps them maintain a sense of control. Adverse effects are less of a concern for patients who value quantity of life.[69] In this situation, alternatives are frequently not discussed.[70] There are few, if any, decision aids to help patients make choices when considering palliative chemotherapy.[71] Patients who have a priority of a longer life rather than better quality of life and who have had a previous response to anticancer treatment are likely to choose aggressive treatment.[72] Patients experience cognitive dissonance when oncologists attempt to discuss end-of-life care and palliative chemotherapy within the same visit. Few patients with advanced cancer have completed advance directives, and less than one-quarter of patients want to discuss advance directives with their oncologists.[73] Sixty percent of oncologists prefer not to discuss advance directives and end-of-life care, including resuscitation and hospice, until anticancer treatments are exhausted.[74]

A collusion of hope surrounding anticancer therapy is maintained by continuing aggressive anticancer therapies despite little or no benefit. Although once important, patients seem to disregard quality of life and give precedence to quantity of life in choosing salvage chemotherapy.[69] Physicians are inclined to continue anticancer therapy, despite lack of benefit, to maintain hope rather than provide supportive and palliative care.[69] Paradoxically, this occurs despite the fact that there is little survival benefit with chemotherapy given within 1 to 3 months of death. In fact, chemotherapy may shorten survival, and early palliative care and hospice care may prolong survival.[25,75]

As a result, the average time from the last chemotherapy to death is 50 to 60 days, and the time from the last targeted therapy to death is 40 to 50 days. Fourteen to eighteen percent of individuals receive chemotherapy or targeted therapy within 30 days of dying.[76,77] The most common targeted agents used at the end of life are erlotinib and bevacizumab. Patients with lung cancer had greater odds (2.6) of being on a targeted agent within the last 30 days of life than individuals with other advanced cancers.[76] In one study at a large cancer center, the median time from palliative care consult to death was 1.4 months (interquartile 0.5 to 4.2 months) but the median length of time from the first encounter with an oncologist to consultation about palliative care was 20 months (interquartile 6 to 45). Therefore, there were multiple missed opportunities to include palliative care as part of patient care earlier in the course of disease.[78] Half of patients with lung cancer are within 2 months of death before end-of-life care and hospice are mentioned.[58] The average stable performance score of patients with lung cancer, as measured by the Palliative Prognostic Index, a modification of the Karnofsky performance score, is 8 to 9 months. Once the Palliative Prognostic Index has dropped to 30 or less, the average survival is 0.38 months. At this stage, very few patients (less than 5%) will have improvement in their performance score.[31] Consulting palliative care services after the patient has become bedridden, or has a poor performance score, provides little time to manage symptoms and primarily requires crisis intervention. Offering additional anticancer therapy when a performance score improves is unlikely to occur and, if discussed with the patient, will lead to a false sense of hope and will delay advanced care planning and hospice referral. Even patients with technically treatable small cell lung cancer and an Eastern Cooperative Oncology Group performance score of 3 or 4 do poorly. Only 20% of them will finish the standard four cycles. With a performance score of 4, the median survival is 7 days, and, with a performance score of 3, it is 64 days.[79]

The end results of poor communication and a collusion of hope in anticancer therapy are aggressive care at the end of life, chemotherapy in the last 14 days of life, intensive care unit admissions in the last 30 days of life, and acute hospital-based care in the last 30 days of life. About half of patients with advanced lung cancer will have aggressive therapy at the end of life.[77,80,81] The

detrimental effect of aggressive care at the end of life is not just economic. It also creates a greater risk of caregiver depression and complicated grief.[82] In retrospect, many patients and families regret their choices of aggressive therapy near the end of life.[69,72,83,84]

In general, patients feel that advance directives should be discussed earlier than physicians do,[85] and the majority of families wished palliative care had been involved earlier in the course of cancer treatment.[86] In one study, end-of-life care discussions took place a median of 33 days before death.[87] In hospitalized patients with advanced cancer, palliative consults usually occur late within the hospital stay, when death is imminent, after a substantial hospital stay, or after admission to an intensive care unit. Consultations often involve the transfer of care.[88]

Most patients in large cancer centers do have a DNR directive in place at the time of death. The average time of signing a DNR directive is less than 3 days before death, and one-third are signed by surrogates.[89] As few as 5% of individuals with advanced cancer who die in the hospital have signed outpatient DNR directives.[89]

BENEFITS OF EARLY INTEGRATION OF PALLIATIVE CARE INTO ONCOLOGY

Symptom Management, Prognostic Information, and Hope

One of the benefits of integrating palliative care into outpatient oncology is decreased symptom burden.[25,34,57] The use of symptom assessment questionnaires will uncover more bothersome symptoms, which can then be managed by the palliative care team.[46,90] Individuals referred to palliative care early in the course of treatment are more likely to perceive and retain accurate information about prognosis and are less likely to receive aggressive chemotherapy at the end of life.[91,92] Prognostic discussions do not dampen hope. They empower individuals by providing realistic expectations to help them make informed choices about their medical care.[62,93] Early palliative care is associated with longer intervals between the last chemotherapy and death and increased hospice enrollment more than 7 days before death (60% compared with 33%).[94] Individuals who have less than 30 days of exposure to palliative care are more likely to receive chemotherapy within 30 days of death.[92] Hope is more influenced by a caring relationship between patient and physician than by prognostic disclosure.[95] The great majority of caregivers feel that avoiding discussions about prognosis is an inappropriate way of maintaining hope.[96]

Communication, Quality of Life, and Patient-Related Outcomes

Palliative care programs use quality-of-life questionnaires that have been shown to improve communication.[97] Providing palliative care during anticancer therapy improves quality of life.[25,41] Patient-centered communication takes time and involves sensitivity. Physicians must be able to respond to emotive verbal and nonverbal cues. Oncologists respond to approximately 20% to 30% of emotional cues and are quite responsive to informational cues.[98,99] Within family meetings, physicians often do most of the talking (71%) compared with family members (29%).[97,100] One of the core competencies required of physicians completing a fellowship in palliative medicine is to be able to conduct a family meeting. Therefore, when compared with oncology trainees, palliative medicine specialists are more likely to be better equipped to effectively communicate within the family conference. Emotional and psychosocial issues assume greater importance at the end of life. Communication training, which is part of a palliative medicine fellowship, can improve physicians' attitudes and their responses to emotions, as well as the satisfaction of the

patients' families. Time constraints are a major issue for cancer specialists because cancer treatment and related issues need to be addressed.[101–103] Paradoxically, despite the intensive involvement oncologists have with their patients, patients prefer to have conversations and communications about end-of-life care with physicians other than their oncologist. They want their oncologist to remain "optimistic" and focused on treating their cancer.[73,104]

Rehabilitation

General rehabilitation, exercise with strength training, and aerobics and pulmonary rehabilitation are often neglected in the various phases of treating patients with lung cancer. Many individuals with lung cancer have chronic obstructive lung disease (COPD), and evidence indicates pulmonary rehabilitation in chronic lung disease improves quality of life, dyspnea, and fatigue and empowers patients to be involved in their own therapy.[105] Although moderate physical activity reduces fatigue and improves symptoms, function and quality of life three-fourths of patients with lung cancer in the United States do not meet physical activity guidelines, and 51% do not participate in moderate activities.[106-112] For some individuals with cancer who have undergone potentially curative therapy, physical exercise can actually reduce recurrences and all-cause mortality.[113–115] Physical exercise is safe and feasible and may even potentially benefit individuals with advanced incurable cancer.[116,117] There is an open trial that is investigating the benefits of 2 months of a physical exercise intervention on fatigue and quality of life in patients with unresectable lung cancer.[118] Rehabilitation and physical exercise are most often discussed in palliative care, interdisciplinary team meetings rather than in oncology tumor boards.[119] Therefore, patients who are seen by the palliative care team are more likely to be considered for pulmonary rehabilitation and exercise training.

Research and complementary therapies of integration of palliative care into cancer treatment have resulted in supportive and complementary therapeutic trials during standard chemotherapy. In one trial, patients using American ginseng had improved cancer-related fatigue, particularly during chemotherapy.[120] In another trial, patients using omega-3 fatty acids during chemotherapy for NSCLC experienced improved muscle mass compared with standard treatment.[121,122]

Health-Care Economics

Early integration of palliative care into cancer care not only reduces aggressive care at the end of life, but also has economic advantages, without adversely influencing survival.[5,25,123] Nearly 40% of Medicare dollars are spent in the last months of life.[124] Even when palliative care is used as crisis intervention, transfer of appropriate patients from inpatient acute care to inpatient palliative care reduces costs by 66%.[125] Palliative care inpatient consult teams reduce daily inpatient costs by US $239.[126] The authors of two randomized trials and a cohort study found that care provided in inpatient palliative care units reduced costs by 38% to 50% compared with care provided in regular hospital wards.[124,127,128] Likewise, using in-home palliative care teams reduces readmissions to the hospital and emergency department compared with standard outpatient cancer care. The average costs per day for in-home outpatient care was $95, which was substantially less than the usual care ($213).[129] Financial comparisons of acute care hospital services have been possible using the Centers for Medicare & Medicaid Services case mix index (CMI) and All Patient Refined-Diagnosis Related Group (APR-DRG) data. Based on CMI and APR-DRG data, Cleveland Clinic's Inpatient Palliative Medicine acute care unit's total mean charges per admission are $7800 lower than at peer institutions without palliative care inpatient units, despite an equivalent severity of illness, longer length of stay, and higher mortality. The lower

charges are due primarily to lower laboratory and pharmaceutical charges.[130] A systematic review of costs and cost-effectiveness of palliative care has been published,[131] but the quality of the studies varied, studies used different methods, and some studies were small. Cohort studies were at risk of bias through potentially unobserved confounding variables. However, all palliative care service structures (inpatient, home, and outpatient palliative care) were found to have economic advantages, largely due to reduced health-care utilization (readmissions and referral to hospice) and direct-care cost savings. For example, earlier palliative care enrollment reduced acute care days.[131]

Survival

Early integration of palliative care into cancer care does not shorten survival, and may actually prolong survival.[5,25,35,84,132] Early palliative care also leads to earlier hospice transition, which has a short-term survival advantage for patients with lung cancer.[133] The survival advantage of palliative care needs to be confirmed by other studies because this information was based on a post hoc analysis in the Boston Study,[25] and there has been much speculation about the mechanism used to calculate the survival advantage. Quality of life and mood are associated with survival; reduced quality of life and depression are associated with shortened survival; and improved quality of life is associated with improved survival.[134–140] Interventions such as palliative care improve quality of life and reduce depression, and may have a biologic effect related to prolonged survival.[25] It is interesting to note that, in the Boston Study, mood was improved without increased use of antidepressants.[25] Survival benefits also may be related to reduced aggressive care at the end of life.[25,75] Lastly, greater social support fostered by the palliative care team and the integration of the family into the plan of care may improve survival.[141,142]

STUDIES DOCUMENTING BENEFITS TO INTEGRATING PALLIATIVE CARE INTO CANCER CARE

The feasibility of integrating palliative care into oncology has been demonstrated in multiple clinical trials. In general, patients participating in these trials have experienced improved symptoms, quality of life, patient satisfaction, less aggressive care at the end of life, and no decrease in survival. It is important to note that the greatest benefit occurred when palliative care was integrated early in the course of advanced cancer.[25,129,132,143–147]

Several studies involving different cancers have evaluated benefits to home nursing and symptom-support visits during chemotherapy and after treatment. Certain symptoms, including depression and dyspnea, improved. In addition, chemotherapy toxicity was lower than in the control group, patient satisfaction improved, and there were fewer emergency room visits and hospitalizations.[129,148,149]

The benefits of inpatient palliative care consultations are relatively small unless palliative care teams assume direct care of patients. Without the palliative care team's involvement in direct care, recommendations for medical management are carried out in less than a quarter of patients. Also, although mild improvements in anxiety and dyspnea were noted, compared with care given without palliative care consultation, there was no improvement in depression or pain.[145,147]

Acute inpatient palliative care units with an interdisciplinary palliative care team have some advantages. Individuals directly managed by a palliative care team in an inpatient unit have fewer intensive care admissions, longer median hospice stays, and a greater number of completed advance directives. There were no detrimental effects on survival.[144]

Benefits to early integration of palliative care into cancer care were found in two large studies. The Educate, Nurture, Before Life Ends (ENABLE) study involved education, problem-solving, symptom management, advanced-care planning, and monthly telephone follow-up. A full palliative care interdisciplinary team was not involved in care. The primary outcomes of mood and quality of life improved. There were no changes in symptom intensity or health-care utilization. There was a trend toward better survival with the intervention (14 vs. 8.5 months) ($p = 0.14$).[132,143] The second trial, conducted by Temel et al[25] involved individuals with newly diagnosed advanced lung cancer. Patients were randomly assigned to either usual care or integrated palliative care. The interdisciplinary team saw patients as outpatients within 8 weeks of diagnosis. Individuals were repeatedly seen when they returned to the clinic, or at least monthly. Management was guided by the National Consensus Project for Quality Palliative Care. The primary criteria were mood and quality of life at 12 weeks, using patient-related outcome measures (Functional Assessment of Cancer Therapy-Lung and Hospital Anxiety and Depression Scale). Other criteria were aggressive care at the end of life and survival. The results were improved mood without an increase in antidepressant use, improved quality of life as demonstrated by a clinically meaningful change in the quality-of-life scale, earlier referral to hospice, and significant improvement in survival.[25] The study was not powered for survival. As a result of several prospective studies, multiple national and international organizations have recommended early integration of palliative care into cancer treatment.[150–153]

BARRIERS TO INTEGRATING PALLIATIVE CARE INTO CANCER CARE

The collusion of hope between patient and physician, associated with aggressive anticancer therapy, leads to a belief that survival benefit increases with each salvage therapy, and delays or prevents palliative care referrals.[69,154] If discussions about prognosis and end-of-life care are put off, or not introduced, until crisis episodes, it is likely that palliative care will not be used until needed for crisis intervention, or not at all. Continuing to offer therapies that are unlikely to offer benefit, and then attempting to introduce discussions regarding end-of-life care, can confuse patients. Under these circumstances, end-of-life care discussions are not likely to be well received, or may be put off by patients in favor of continuing anticancer therapy.[104,155] Continuing aggressive care may be perceived by patients as the only reasonable choice and may be framed in terms of wanting to live, implying a survival advantage to ongoing aggressive therapy. These patients will have a false "either or" dichotomy between cancer therapy and palliative care.[154] Physicians delay referral because they don't want to destroy the patient's hope by recommending a palliative care specialist.[37] There is a false impression that palliative care services are dependent on disease outcomes and prognosis, rather than symptom burden, regardless of stage or expected disease outcomes. To overcome these barriers, the term supportive care has been adopted because it is more acceptable to patients and physicians and does not imply end-of-life care.[35,156,157]

Palliative care is under resourced. Although most patients with advanced cancer have a substantial symptom burden, and nearly 40% die from cancer, only 1% of the National Institutes of Health budget is devoted to palliative care.[158] Although palliative care services are available in more than 90% of National Cancer Institute (NCI) designated facilities and more than 75% of community cancer centers, and despite the fact that the great majority (over 80%) of cancer specialists rate palliative care as important to cancer care, less than 20% of cancer programs are likely to devote resources toward integrating palliative care into cancer treatment.[159,160] The average number of full-time equivalent physicians per cancer program is only two, and they are largely overworked.[159,160]

Other reasons for late referrals to palliative care include inequitable access to services and lack of standardized criteria for

referral. In addition, physicians often lack an understanding of the extent and availability of services.[161–163] They also lack education and information about palliative care.[59,164,165] These factors can lead to delayed referral or no referral. Although standardized symptom assessment and measured patient-related outcomes are key to understanding symptom burden and patients' needs, most oncologists do not routinely use symptom assessment tools and have had little palliative care experience during training.[158,165,166] Because most patients do not report the full extent of the symptoms they are experiencing, the oncologist will remain unaware of the needs of patients.[167]

A review of 12 textbooks published by multiple medical specialties found that hematology-oncology textbooks ranked 10th in the palliative care content.[168,169] There has been improvement over the decade since that review was written, but it is interesting that, among reviews in managing advanced lung cancer published in major journals, palliative care often is either not included or is added as the last paragraph; outcomes of therapy are usually described in terms of progression-free survival and overall survival.[170,171] Although there are exceptions,[172] these data seem to indicate that oncologists have little exposure to information on palliative care in the materials they are reading to remain current in their specialty.

Some palliative care services, such as hospice, will not follow-up on patients who are being treated with chemotherapy.[163] Integration of palliative care into cancer treatment may be difficult if palliative care specialists do not have an understanding of the natural history of cancer, treatment by stage and histology, common chemotherapy side effects, and new developments in anticancer therapies, including new targeted agents and their toxicity. As a result, palliative care specialists may refer patients to hospice programs prematurely, because they mistake treatment toxicities for progressive cancer. To overcome this barrier, palliative care specialists need to have a fundamental knowledge of oncology, a basic understanding of new developments, and close communication with the oncologists.

Public exposure to information on palliative care is minimal, but public exposure to information on cancer is usually high, because of major news stories about sensational new discoveries and individual reports of dramatic successes based on N-of-1 experiences.[160] Because public fundraising is largely motivated by cure rather than care (e.g., Race for the Cure campaigns),[173] funding care may be seen as less important than funding cure.

Health-care policy involving changing from pay for services to value-based reimbursement may be responsible for either improving or diminishing palliative care services.[174] Value-based reimbursement is based upon cost-effectiveness and requires quality indicators. Palliative care quality indicators are different from those of oncology, and consensus about quality indicators is not universal. Palliative care quality indicators related to cancer care are underdeveloped.[175] Based on value-based reimbursement determined by health-care policy, inpatient units with high mortality may be viewed as unfavorable. In addition, if direct costs alone, rather than direct costs plus indirect cost savings, are not taken into account within the administrative matrix, then inpatient palliative care units may be seen as losing propositions.[131] Compared with general inpatient wards, the type of patient admitted to palliative care units may have higher or lower costs; but deaths are certainly higher than in the general wards. Patients on palliative care inpatient units have greater symptom severity, more serious psychosocial problems, and higher complexity of care.[176,177] The All Patient Refined-Disease Related Index, although useful, may not adequately reflect the complexity of care, severity of illness, or risk of mortality seen on inpatient palliative care units.[178] Part of the art of demonstrating case mixed severity is to use the appropriate word codes for symptoms and diseases to demonstrate for administrators and policymakers the type of patient treated on inpatient palliative care wards.[178]

As palliative care expands to chronic nonmalignant illnesses and moves upstream to comanage cancer patients undergoing disease modifying therapy, there will be negative consequences based on availability of services. There is not enough funding, enough training programs, or enough time to train the number of palliative care specialists needed to meet the demand.[179] It is unlikely that the medical system can take another layer of specialized care for seriously ill patients on top of expensive and already complex health care.[179] Bundling payments will discourage the practice of multiple consultations. If palliative care specialists are able to assume all of the tasks of palliation, other specialists will begin to believe that basic symptom assessment, management and psychosocial care are not part of their responsibility.[179]

To address these barriers, programs in all medical specialties should include training in basic palliative care skills, with treatment centered on patient goals and values, and basic symptom assessment and management. Core competency would include symptom assessment using standardized instruments, basic management of pain and nonpain symptoms, and screening for distress and psychosocial and spiritual concerns. Oncologists should discuss prognosis, goals of care, suffering, and advance directives and assess the patient's understanding of these issues.[180–182] To give providers an opportunity to assess the value of palliative care in improving the quality of oncologic care, the American Society of Clinical Oncology, through a grant from the Agency for Healthcare Research and Quality, in collaboration with the American Academy of Hospice and Palliative Medicine, is developing and disseminating a primary palliative care curriculum based on best evidence. The aim is to enhance oncologists' understanding of basic palliative care, while palliative care specialists concentrate on more complex or refractory symptoms and problems.[179,183]

END-OF-LIFE CARE

As lung cancer and its symptoms progress, the preference for information also progresses. Although the preference for information regarding diagnosis, prognosis, and treatment options does not change, the preference for information about palliative care and end-of-life decisions (if not integrated early into cancer care) does change. Preferences may be for either more information or less information.[184] As a result, it is important that oncologists update patients on disease status and prognosis and ask patients if they want information about palliative care, advance directives, and end-of-life care.

There are no universal definitions of end-of-life care, regardless of whether it is any length of time or a disease state or the patient's preference. Unfortunately, the WHO definition of palliative care is used as a master definition for end-of-life care.[6] Although the term end-of-life care is commonly used, there is no consensus about the components of its definition. It tends to imply either a time frame of survival or boundaries between cure and care that can be detrimental to integrating palliative care into cancer care (if palliative care is used synonymously with end-of-life care).[6]

ASSESSING SYMPTOMS AND QUALITY OF LIFE IN LUNG CANCER

Symptom control remains one of the most important practices in cancer care, palliative care, and end-of-life care and should be done continuously throughout the course of cancer treatment and into survival.[185,186] System assessment is one of the major limitations to symptom management. Fatigue, dyspnea, pain, anorexia, and cachexia are the most common physical symptoms related to lung cancer.[187–191] As symptom burden increases, global health and survival decreases.[188,192] For patients with lung cancer, symptom burden, when measured by the number of symptoms and severity, inversely correlates with quality of life

and prognosis.[193,194] Symptom burden increases up to the last 4 weeks of life and then plateaus.[194]

Over the last decade, more than 50 tools have been developed to measure quality of life in individuals with lung cancer.[192] Commonly used quality-of-life measurement tools include the Functional Assessment of Cancer Therapy-Lung (FACT-L) and its modification (NCCN-FACT-17), Lung Cancer Symptom Scale (LCSS), and the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire-Lung Cancer (EORTC-LC-13).[38,195–197] The FACT-L and the EORTC-LC-13 are generic, quality-of-life instruments with specific items related to lung cancer symptoms attached as a disease-specific module.

The FACT-L consists of 41 self-assessment questions, of which 34 pertain to five domains. Combining the physical, functional, and lung cancer modules creates the Trial Outcome Index, a tool that is sensitive to change over time and has provided clinically meaningful, patient-related outcomes in clinical trials.[25] Symptoms (dyspnea, difficulty breathing, cough, chest tightness, appetite and weight loss, and cognitive function) are assessed using a categorical scale with a time frame of 1 week. A change of 2 points on the 7-item symptom scale is clinically significant.[196,198,199] The questionnaire is relatively insensitive to treatment-related symptoms.

The LCSS consists of two scales, one rated by physicians and one rated by patients. The patient questions include six symptoms and three summary questions that are marked on a visual analog scale (a 100-mm horizontal line). The mean of the six symptom items is the average symptom burden. Physician items involve six main lung cancer symptoms. A change of 10 mm in the patient's scale is clinically meaningful. The LCSS does not measure social or affect quality-of-life domains, which is a drawback.[200]

The EORTC-LC-13 is a 13-item, lung cancer symptom module that includes cough, hemoptysis, dyspnea (3 items), sore mouth or tongue, dysphagia, hair loss, tingling hands, tingling feet, pain (3 items), and pain medications. All questions are framed in a 4-point categoric scale and a 7-point numerical scale, with the time frame of 1 week. This quality-of-life scale is clinically valid and useful. It is also sensitive to treatment-related symptoms.[197]

There are problems with measuring quality of life. There can be intraobserver and interobserver errors, missing data, fatigued patients, particularly for long questionnaires, and attrition, which can favorably influence the outcomes, because patients who fail to complete questionnaires are usually sicker or have dropped out of the study. In the case of attrition, statistical adjustments need to be made to prevent bias.[201,202] Comparison across studies is difficult because of differences in patient mix. Visual analog scales are more difficult for patients to understand and complete.[203,204] A shift response may occur as patients recalibrate the severity of their symptoms or change their priorities and feelings about the relative importance of quality-of-life domains over time.[205–208] More severe symptoms will tend to lower the mean over time.[208–211] Lastly, the quality of dying cannot be measured by quality-of-life questionnaires.[212,213] What patients and their loved ones want at the end of life has been identified (see Box 58.4).

Patients should complete quality-of-life questionnaires during the initial consultation and whenever there is a reevaluation of cancer response during treatment. In between, a symptom scale may be helpful. The Edmonton Symptom Assessment System (ESAS) is a nine-question scale with an additional question for patient-specific symptoms not covered in the nine questions. It gauges symptom burden by the number and severity of symptoms using a numerical rating scale (0 = no symptoms, 10 = severe symptoms). Completion rate is high, and it can be completed daily in the inpatient setting.[214–216] The ESAS may be a good way to screen for distress.[217] Distress is a multifactor, unpleasant, emotional experience of a psychosocial and spiritual nature that may interfere with the ability to effectively cope with cancer. Pain

---

BOX 58.4   What Patients and Families Want at the End of Life

Mental awareness
Peace with God or a supreme being
Legacy (being of some help to others)
Ability to pray and/or meditate
Ability to make funeral arrangements
Absence of burden to others
Feeling that one's life is complete
Closure on relationships (being able to reconcile and say goodbye)

---

and fatigue are the major contributors to distress.[218,219] It is recommended that all patients with cancer be assessed for distress. It is most often recommended that a so-called 11-point distress thermometer be used to screen patients and that a triage system be used to manage patients with distress.[220,221]

MANAGING LUNG CANCER SYMPTOMS

Symptoms are present both at diagnosis and with recurrent cancer. Symptoms recur, or new symptoms develop, with relapse after definitive therapy, or with progression on maintenance therapy, and are usually associated with weight loss. At least half of individuals with lung cancer make emergency department visits for intolerable symptoms sometime during the course of their cancer.[222] Part of the reason for high emergency department utilization is that disease progression—not symptoms—is used frequently as an indicator of relapse. As mentioned earlier, symptom progression, on average, occurs before disease progression. An alternative to detection of relapse would be symptom monitoring, using self-assessed symptom forms that are completed by outpatients on a weekly basis. A categoric, self-assessment scale, which measures the severity of weight loss, fatigue, pain, cough, and breathlessness on a weekly basis, has been developed and used in a feasibility study.[223] Sensitivity, specificity, and positive predictive value of these sentinel symptoms and weight loss were 86%, 93%, and 86%, respectively. Relapses were detected 6 weeks earlier on average than would have occurred with planned imaging. Use of this assessment tool may reduce the number of imaging procedures (which usually have a low yield in asymptomatic individuals) and allow for earlier intervention before symptoms become severe and require emergency department visits or emergency inpatient admissions.

Fatigue

Fatigue is almost universally experienced by individuals with advanced cancer and is the main symptom that detrimentally influences quality of life.[224,225] Fatigue is a distressing persistent sense of tiredness or exhaustion that interferes with daily activities. Unlike normal physical fatigue, it occurs with normal activity and can occur without any physical activity. It is pervasive and lasts beyond the normal expected recovery time. Descriptors for fatigue, such as tiredness, induration, lack of vigor, and asthenia, may not exactly describe every patient's experience.[226] Fatigue can be screened through a numerical rating scale (0 = no fatigue, 10 = severe fatigue), with fatigue ratings greater than 4 being clinically significant.[227,228] People with cancer who have fatigue should be screened for depression. Cancer-related fatigue is not associated with anhedonia, hopelessness, or worthlessness.[229] Insomnia and pain should be treated. Patients with obstructive sleep apnea will also experience fatigue and may benefit from continuous positive airway pressure while sleeping.[230] Anemia, hypothyroidism, and hypogonadism will contribute to the severity of fatigue, and treatment for these conditions may improve

fatigue. Comorbidities, such as heart failure and COPD, should be assessed and treatment maximized.

In one randomized double-blind trial, cancer-related fatigue was improved with corticosteroids.[231] However, the long-term use of corticosteroids is associated with side effects, including osteoporosis, myopathy, insomnia, thromboembolism, and psychotomimetic side effects. Dexamethasone (4 mg in the morning and at noon) was used in this trial. Doses should be tapered to the lowest effective dose, or discontinued if no response is observed after a 2-week trial period. In a second randomized, double-blind trial, American ginseng was effective in reducing cancer-related fatigue. The side effects were similar to those with placebo, and ginseng had few drug interactions.[120] Psychostimulants were reported to be effective in prospective, single-arm studies, but these positive results have not been duplicated in randomized trials.[232,233] Strength and endurance training may help to address fatigue and loss of physical function during chemotherapy, as such training has been shown to increase the 6-minute walk time, stair climbing, strength capacity, and, in patients with dyspnea, perception of shortness of breath during submaximal walking.[234]

Dyspnea

Dyspnea can be described as chest tightness, rapid shallow breathing, air hunger, and not getting enough air,[235] and each descriptor reflects a different pathophysiology. Chest tightness is associated with coronary artery disease. Rapid shallow breathing is the result of a mismatch between respiratory drive and lung capacity. Air hunger is associated with increasing retention of carbon dioxide. Not getting enough air is associated with hyperinflation. Most patients with cancer have dyspnea at the end of life.[236]

In advanced cancer, particularly lung cancer, there are usually a multitude of reasons for dyspnea. These reasons include loss of lung volume from treatment and tumor size, pleural effusions, cardiac tamponade, COPD, coronary artery disease, thromboembolism, pneumonia and wasting, anxiety and depression, and uncontrolled pain.[237] Wasting is associated with quantitative and qualitative changes in the diaphragm muscle, which leads to reduced tidal volume with exertion and inspiratory capacity.[238,239]

Dyspnea can be screened by the numerical scale within the Edmonton Symptom Assessment System.[240] The Cancer Dyspnea Scale and the Dyspnea Numeric Scale, which assess dyspnea interference with activities, may also be used.[241]

Depending on the underlying etiology, treatment for cancer-related dyspnea may include surgery, chemotherapy, radiotherapy, thoracentesis, pericardiocentesis, the use of drainage tubes, bronchoscopy with laser or stenting, brachytherapy, corticosteroids and antibiotics, and transfusions. Nonintervention approaches may also reduce dyspnea. Pulmonary rehabilitation and walking aids that activate accessory muscles can improve dyspnea.[242] Oxygen should be used for patients who are hypoxic (oxygen saturation of less than 90%). Blowing air across the face, by way of a room or handheld fan, may reduce dyspnea in those who have normal oxygen levels.[243–245] Noninvasive ventilation, using bilevel positive airway pressure, reduces dyspnea and avoids intubation.[246] It does not require sedation.

Morphine reduces dyspnea without causing hypercapnia. Initial dose is 2.5 mg to 5 mg every 4 hours, as needed. If patients are opioid tolerant, a 25% increase in the opioid dose may be helpful.[247–249] Nebulized opioids and furosemide should not be used as standard therapy, because of lack of evidence supporting their effectiveness.[250,251] Most individuals with chronic dyspnea also have episodes of worsening dyspnea, or air hunger, that should be treated with an opioid, as needed. Benzodiazepines and sedating phenothiazines have been used to treat dyspnea, but there is conflicting evidence. There are negative and positive trials with few high-quality randomized studies.[252–255] Both benzodiazepines and sedating phenothiazines may be added or substituted for opioids if patients are intolerant of opioids or wish not to go on opioids. Lastly, for patients with refractory dyspnea, palliative sedation, using subcutaneous phenobarbital, or using parenteral haloperidol plus a benzodiazepine (e.g., midazolam or lorazepam), may be necessary to control dyspnea. Palliative sedation should be discussed with patients and families before instituting treatment. The patient should have a DNR order, and, if gastric tube feedings are in place, they should be removed.[256–258]

Cough

Symptomatic cough will occur in at least half of patients with lung cancer.[259] Patients with advanced lung disease have greater dependence on cough for mucus clearance than healthy individuals. In patients with lung cancer, the cough response is prompted by excessive noxious stimulation of afferent sensory fibers through the vagus. There also can be central sensitization of neurons governing the cough reflex.[260,261] Evaluation of cough should include whether the cough is productive or not, what triggers the cough, the timing of the episodes (daytime or nocturnal), the patient's medications, (e.g., angiotensin-converting enzyme inhibitors), and the underlying comorbidities. A cough scale can be used to gauge frequency and severity.[260–262] The Manchester Cough and Lung Cancer Scale uses 10 items to assess cough in lung cancer. It is presently being validated.[263] Chest radiographs and computed tomography (CT) images may demonstrate an obstructive bronchus, pleural or pericardial effusions, atelectasis, pneumonia, bronchopleural or bronchoesophageal fistula, lymphangitic carcinomatosis, superior vena cava obstruction, or treatment-related pneumonitis.[260–262]

Radiotherapy, laser therapy, brachytherapy, or stenting may relieve an obstructive bronchus. Thoracentesis, chest tube drainage plus pleurodesis, or placement of tunnelled indwelling pleural catheter can reduce cough and dyspnea associated with pleural effusions. Pericardiocentesis may be relieved with a cardiac tamponade. Simple hydration, humidification, and mucolytics may be helpful, particularly with mobilization of secretions. However, there are no well-conducted randomized trials that support the use of mucolytics in the management of cough.[264,265] There is also sparse evidence for chest wall vibration and manual clearance of secretions.[266] Flutter valve oscillation through a mouthpiece has been used.[267] Positive end-expiratory pressure, via face mask, for 45 minutes per day improves cough and dyspnea.[268,269]

Cough suppression is desirable when cough is no longer useful as a function or if cough produces pain or is fatiguing. Opioids commonly used as cough suppressants include codeine, dextromethorphan, and morphine. Dextromethorphan controls the intensity of cough better than codeine.[270] Sustained-release morphine reduces cough severity by 40%. There is no evidence of a dose–response relationship when using morphine, or of one opioid being superior for the treatment of cough.[271–274]

Proton-pump inhibitors can reduce cough caused by gastric reflux, and gabapentin has been shown to reduce cough stemming from central sensitization.[275] Prednisone (30 mg daily for 2 weeks) may reduce cough associated with bronchospasm, or pleural, pericardial, or diaphragmatic irritation caused by the tumor or treatment.[272] Baclofen may also work, if standard therapies have been ineffective. For patients who are imminently dying, treatment with a cholinergic inhibitor, such as glycopyrrolate, may reduce secretions and the so-called death rattle.[276] The recommended glycopyrrolate dose is 0.1 mg to 0.2 mg (IV or subcutaneous) every 6 to 8 hours. It is best given around-the-clock because it prevents, rather than treats, secretions. Glycopyrrolate is a quaternary scopolamine derivative that does not cross into the central nervous system, thus preventing anticholinergic-induced cognitive dysfunction or delirium.[277] Alternatives are inhaled ipratropium or scopolamine ophthalmic solution dropped onto the tongue.[278]

Cachexia and Anorexia

Cachexia is most often recognized as involuntary weight loss. Precachexia is defined as a weight loss of less than 5%, and cachexia is defined as weight loss greater than 5%. However, if the body mass index (BMI) is less than 20, then a greater than 2% body weight loss would be defined as cachexia. Symptoms associated with cachexia include sarcopenia, loss of fat mass, anorexia, fatigue, and elevated inflammatory cytokines and acute phase reactants.[279] Anorexia is a cluster of symptoms that includes bloating, early satiety, taste and smell changes, dysgeusia, and diurnal variations in food intake.[280]

Peripheral and central mechanisms generate cachexia and anorexia. Inflammatory cytokines upregulate the transcription factor NF kappa-B in muscle that in turn, upregulates myostatin, proteasomes, and prostaglandins. Satellite cell proliferation is inhibited and muscle synthesis, through MyoD and mTOR/Akt, is blocked. Mitochondrial function and calcium metabolism) are also adversely affected, leading to reduced oxidative phosphorylation. In addition, there is an increase in reactive oxygen species.[281,282] Anorexia results from increased neurotransmission of proopiomelanocortin-containing neurons within the arcuate nucleus of the hypothalamus. There is also a simultaneous reduction of neuropeptide Y signals. Neurotransmission through proopiomelanocortin neurons is increased through activation of serotonin receptors (5-HT2C) as well as throughout regulation of interleukin-1.[281,282]

Inflammatory cytokines (tumor necrosis factor-alpha, interleukin-1, and interleukin-6) increase production of C-reactive protein from the liver and muscle. Hypoalbuminemia develops from loss of the endothelial barrier and extravasation into interstitial spaces.[283] Elevated C-reactive protein is associated with progressive weight loss and is a poor prognostic indicator in lung cancer.[284] Both serum albumin and C-reactive protein are combined in the Glasgow Prognostic Score.[285–287] Pretreatment Glasgow prognostic score is a useful and important predictor of cancer-specific survival in patients with inoperable NSCLC. It is predictive of the most important aspects of platinum-related toxicity.

Assessment of cachexia is complex. Factors that have been used to follow the course of cachexia and sarcopenia include changes in weight, BMI, anthropometric measurements, bioelectrical impedance, dual-energy x-ray absorptiometry, and measurement of muscle area at the level of the L3 vertebral body. Using CT to measure muscle mass at the L3 vertebral body level has been validated. These measurements can be done routinely to follow the course of cancer.[288] Assessment of anorexia can be made through the Edmonton Symptom Assessment Score. The Functional Assessment of Anorexia Cachexia Therapy scale, which is a 12-item module attached to the Functional Assessment of Cancer Therapy quality-of-life tool, can also be used.[289,290] There are multiple other nutritional scales, but they do not separate starvation from cachexia. In a study evaluating use of the Mini Nutritional Assessment scale for individuals with lung cancer, the score on the scale correlated with laboratory parameters of inflammation and was independently associated with survival.[291]

The best method for treating cancer-related cachexia is to cure the cancer. If this is not possible, then the goals of therapy are to maintain muscle mass, nutritional intake, and function.[292] Because it is unlikely that a single drug will have a major impact on cancer cachexia and anorexia, treatment should be multimodal. Appetite stimulants include corticosteroids, progesterone, and olanzapine.[293] In a randomized trial, the combination of megestrol acetate and olanzapine was superior to megestrol acetate as a single agent, with substantial improvements in appetite, nausea, weight gain, and quality of life.[294] Cachexia has been treated with single-agent antioxidants, l-carnitine, omega-3 fatty acids, thalidomide, nonsteroidal antiinflammatory drugs (NSAIDs),

and megestrol acetate, with little to marginal benefit. Recent trials of drug combinations have proven to be more effective than single agents in increasing lean body mass, decreasing energy expenditures, and improving appetite.[295] Ghrelin analogs and selective androgen receptor modulators are presently in development.[296–299]

Pain

At least half of individuals with advanced cancer will have chronic pain.[300] There are well-described cancer pain syndromes. Approximately 75% of individuals with cancer have pain related to their cancer, and 25% have pain related to treatment or comorbid illnesses. Many individuals with cancer have cancer pain syndromes because of widespread metastases, and these syndromes have been well described.[301–304] Clinicians can mistake existential suffering for physical pain. Characteristically, somatic pain does not respond to treatment with opioids.[305,306]

To properly assess pain, clinicians need to know pain intensity, the point from where it radiates, temporal pattern, pain quality, and provocative and relieving factors. The cause, pathophysiology, and pain syndrome can be inferred from the history and confirmed by physical examination and radiographs.[306] Pain intensity is largely used when choosing analgesics and adjusting doses, but interference with activity and function are equally important. Pain intensity may change little, but function, mood, sleep, and vitality may improve with treatment.[307] Another area that needs to be assessed when considering treatment is the side effects associated with analgesics. Pain can be assessed on a numerical rating scale. Mild pain is less than 4 on an 11-point numerical rating scale; moderate pain is 5 to 7; and severe pain is greater than 7. A reduction of baseline pain severity between 30% and 50% is clinically significant.[308–310] The Brief Pain Inventory is a validated tool and can be used in the initial assessment.[311,312] Before prescribing opioids for moderate to severe pain, the patient's substance abuse history, family substance abuse history, and the patient's history of depression, anxiety disorder, or personality disorder should be obtained.[306]

Classifying pain into somatic, visceral, or neuropathic is an oversimplification of clinical reality. There are features of neuropathic pain in patients who have visceral metastases, as demonstrated in animal models. Central sensitization can occur in all three subclasses of pain.[313–315]

For mild pain, acetaminophen or NSAIDs can be used as the analgesics of choice, but should not be used for patients with coagulopathy, or heart or kidney failure. NSAIDs are also not recommended for treating older individuals. Prophylaxis with proton-pump inhibitors should be considered.[316] There is evidence that the combination of NSAIDs and acetaminophen may improve analgesia.[317]

For moderate pain, tramadol, tapentadol, codeine, or low doses of a potent opioid, such as morphine, are reasonable choices.[318,319] Although it had been assumed that codeine is an analgesic—through conversion to morphine via the cytochrome CYP 2D6—newer evidence suggests that there is actually synergy between codeine and morphine. Therefore, codeine may have to be converted to morphine for analgesia.[320] If patients were originally treated with nonopioid analgesics, such as acetaminophen or NSAIDs, these drugs can be added or continued.

For severe pain, potent opioids such as oxycodone, morphine, hydromorphone, or fentanyl may be used as first-line analgesics.[321] Starting doses are as follows: morphine, 5 mg every 4 hours by mouth; oxycodone, 5 mg every 4 hours; hydromorphone, 1 mg every 4 hours; and transdermal fentanyl at 12 µg per hour. If pain is acute or unstable, transdermal fentanyl should not be used.[321–323] Sustained-release morphine (15 mg every 12 hours) or oxycodone (10 mg every 12 hours) may be used in place of immediate-release preparations. Most patients

have breakthrough pain. A rescue dose of one-sixth of the total daily opioid dose should be provided every 1 to 2 hours.[324–327] Transient flares of pain may be related to activities (incident pain) or spontaneous. End-of-dose failure is considered suboptimal around-the-clock opioid dosing. If this occurs, the around-the-clock dose should be increased. There are considerable differences in dose requirements between patients who will require dose titration of no less than 25% and no more than 100% of the total daily dose. As an alternative, transmucosal, buccal, sublingual, or intranasal fentanyl have been approved for breakthrough pain. These preparations are expensive and should be reserved as second-line treatments for individuals whose breakthrough pain is unresponsive to oral, immediate-release opioids.[328–330]

Titration of potent opioids is required to control pain in most individuals. To reach steady-state levels, the dose of immediate-release opioids should not be changed more often than every 24 hours. The dose of sustained-release opioids should not be changed more often than every 48 hours, and the dose of trans-dermal fentanyl should not be changed more often than every 48 to 72 hours. If pain remains a problem, then the rescue dose can be titrated to response, and the around-the-clock dose adjusted once steady-state is reached.[306,331] Patients with severe liver disease should be treated with morphine or hydromorphone because these opioids are conjugated and glucuronidation is relatively spared.[332] For patients who are in renal failure, methadone or buprenorphine are the opioids of choice.[333–336] Because of its unique pharmacology, methadone should be used only by designated prescribers.[306]

Adjuvant analgesics can improve pain and reduce opioid requirements. Antiseizure drugs, predominantly gabapentinoids, tricyclic antidepressants, and selective norepinephrine serotonin reuptake inhibitors (duloxetine and venlafaxine), can improve neuropathic pain. Because tricyclic antidepressants have substantial side effects, secondary amine tricyclic antidepressants may be better tolerated.[337] When adjuvant analgesics are used, the number needed to treat to substantially reduce neuropathic pain in an individual patient ranges from three to five.[338–340] Corticosteroids reduce symptoms and pain from tumor-related compressive neuropathy, brain metastases, and bowel obstruction.[341–343] Bisphosphonates have been used for bone pain.[344,345] For patients in whom pain does not respond to a first-line opioid, or in whom dose-limiting toxicity develops (e.g., confusion, myoclonus, hallucinations, nightmares, or severe nausea), switching to or rotating with an alternative opioid will improve pain control and reduce side effects.[346–348] Because of noncross tolerance, doses that are 50% to 70% of the equianalgesic dose should be used and further dose adjustment should be made, based on clinical context, including potential drug interactions and organ function. Routine use of analgesic tables can be dangerous.[349,350] As an alternative, switching to spinal opioids may improve the opioid therapeutic index by reducing side effects. Spinal adjuvant analgesics include bupivacaine and clonidine.[351,352]

Side effects related to opioids can add symptom burden to patients or may be mistaken for progressive cancer. Constipation, if severe, not only produces nausea and vomiting, but can also resemble a bowel obstruction. Because there is no tolerance for constipation, stool softeners and laxatives should be started proactively when opioids are prescribed.[353,354] Opioid-induced constipation that is unresponsive to laxatives and enemas should be treated with methylnaltrexone.[355] Opioid-induced sedation may respond to a methylphenidate.[356] The anticholinergic side effects of opioids, (dry mouth, urinary retention, and nausea) may require targeted approaches to management. Antiemetics, such as metoclopramide, prochlorperazine, or ondansetron, may be used to manage nausea.[357] For most individuals, nausea is mild and tolerance develops over several days. Most opioids, except for buprenorphine, induce hypogonadotropic hypogonadism, which can result in altered mood, hot flashes, loss of libido and

sexual function, and, over a period of time, loss of muscle and bone.[358] When treatment with an opioid is started or doses are adjusted, there can be mild sedation and mild muddled thinking, which usually resolves over several days. Patients should be taking stable doses of opioids for approximately 2 weeks before they consider driving a car. Overt confusion and delirium induced by opioids require opioid rotation or change in route rather than antipsychotics. Nonpharmacologic modalities should be considered concurrently with analgesics. Mind-body approaches and integrative interventions can be helpful, both in improving pain and in reducing the opioid requirements.[306] Correction of impending fractures of long bones; kyphoplasty; and brachial, celiac, or hypogastric blocks can improve pain and improve opioid responses.[359]

LUNG CANCER AND THE INTENSIVE CARE UNIT

In selected individuals in the United States, intensive care unit survival and hospital survival can be excellent depending on the clinical situation. Intensive care unit survival and hospital survival are 72% and 60%, respectively, but hospital survival is substantially decreased if mechanical ventilation is required (62% compared with 47%). In cancer specialty hospitals, intensive care unit survival is reported to be 40%, and only 30% of patients survive mechanical ventilation. This may be related to differences in the patient population.[360–365] For patients who require intensive care and survive hospitalization, fewer than 30% survive for 6 months. Individuals with lung cancer and progressive cancer prior to intensive care admission, and patients with preexisting poor performance status or progressive organ dysfunction, or both, have very high mortality rates in intensive care.[362] For patients with advanced lung cancer, admission to the intensive care unit should be considered a sign that hospice care is warranted. End-of-life care discussions should take place. Patients with progressive cancer, poor performance status, or progressive organ failure should be discouraged from being admitted to the intensive care unit because the outlook is so dismal. Unfortunately for most individuals, discussions about resuscitation preferences and intensive care admissions usually do not take place before transfer to intensive care.

LUNG CANCER AND CARDIOPULMONARY RESUSCITATION

For patients with lung cancer, survival to discharge after cardiopulmonary arrest is 16%, and only 8.5% return home. Many do not recover neurologic function and require placement in extended care facilities or inpatient hospices. Survival is even worse if either vasopressors or mechanical ventilation, or both, are required postarrest.[366–368] Cancer is not an independent predictor of the success of resuscitation, but progressive cancer prior to arrest, along with the number and severity of comorbidities, are predictive of a low chance for survival. Rather than simply asking patients whether or not they want to be resuscitated, discussions should be based on goals of care, outlook, benefits, and detriments.

CONCLUSION

The advances in oncologic therapies for lung cancer have prolonged the short-term survival of patients with advanced lung cancer. Along with increased survival, patients experience multiple cancer symptoms and impaired quality of life as the disease course evolves. There is now a shift in cancer treatment that favors early integration of palliative care, based on clinical and patient-related outcomes. Delivery of effective palliative care will require financial resources for palliative care fellowships, outpatient and inpatient palliative care services, and medical and public education. It will also require changes in health-care policy that promote integration of palliative care into cancer treatment.[369]

59   Clinical Trial Methodology in Lung Cancer: Study Design and End-Point Considerations

Sumithra J. Mandrekar, Mary W. Redman, and Lucinda J. Billingham

SUMMARY OF KEY POINTS

- Lung cancer is increasingly understood at the molecular level; N-of-1 trials are becoming more relevant with the use of biomarker assessment and targeted therapies.
- The failure of promising agents in randomized studies has prompted reconsideration of the standard dose-finding paradigm in early phase trials, with the recognition that improved drug development strategies for single agents and combination therapies are required.
- The choice of end points and trial design options in the phase II and phase III setting is driven by the purported mechanism of the action of the drug and the availability of a biomarker to "enrich" patient population leading to either (a) larger randomized phase II, phase II/III, or phase III trials (all-comers design with retrospective subgroup assessment), or (b) smaller (including nonrandomized) phase II trials in an enriched subpopulation targeting larger differences.
- Adaptive designs are becoming a reality with advances in mobile computing, electronic data capture, and integration of research records with electronic medical records.
- Master protocols incorporating a central infrastructure for screening and identification of patients who can be funneled into multiple subtrials testing targeted therapeutics have become an efficient way to conduct definitive trials in lung cancer.
- Newer approaches to clinical trial end points and design strategies that challenge the historical paradigm of drug development are critical to accelerate the drug development process so that the right therapies can be delivered to the right patients.

In oncology, the development of new therapeutics typically follows the phase I, phase II, and phase III drug development paradigm. In phase I, the primary goal is to understand the safety profile of a new treatment in a small group of patients before further investigation. In the phase II setting, the primary goal is to determine if there is an efficacy signal worthy of further investigation; a secondary objective is to gain a better understanding of the treatment's safety. Phase II trials may have a single arm or may be a randomized trial in a homogeneous study population, with the trial size varying from less than 100 patients to as many as 300 patients. If the drug is considered safe and has a promising efficacy signal, then a phase III trial is initiated. The primary goal of the phase III trial is to compare the new treatment with the standard of care to demonstrate a clinical benefit or, in some cases, cost-effectiveness. Phase III trials are usually large, comprising a few hundred to thousands of patients, and they are conducted in a homogeneus group of patients at multiple institutions.

As biomarker assessment and use of targeted therapies increase in cancer treatment, N-of-1 trials—studies in which an individual is the single subject of study—are becoming more relevant. Biomarker assessment is a critical aspect of targeted therapy because biomarkers can identify patients who are more likely to benefit from a particular treatment. The Biomarkers Definitions Working Group defined a tumor marker or a biomarker as "a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention."[1] In oncology, the term biomarker refers to a broad range of measures derived from tumor tissues, whole blood, plasma, serum, bone marrow, or urine. In principle, the pathway from basic discovery of a biomarker to its use in clinical practice is similar to a traditional drug development process, but there are some basic differences, which will be described here.[2] An extensive guideline for reporting studies on tumor markers has been developed and published.[3]

Biomarker-based trials deviate from the standard paradigm for developing a treatment or regimen. In the context of biomarkers, a phase I study tests the methods of assessing marker alteration in normal and tumor tissue samples. Results from this study may help to determine the cut points for quantitative assessment and meaningful interpretation of test results. The feasibility of obtaining the specimens, as well as the reliability and reproducibility of the assay, needs to be established at this stage. A phase II study is typically a careful retrospective assessment of the marker to establish its clinical usefulness. In phase III trials, the marker is prospectively evaluated and validated in a large, multicenter population that provides adequate power to address issues of multiple testing.[2]

For a biomarker to be useful in clinical practice, its assay results should be accurate and reproducible (analytically valid) and its value should associate with the outcome of interest (clinically valid). Further, for a biomarker to be useful in clinical practice there must be a specific clinical question, proposed alteration in clinical management, and improved clinical outcomes (the so-called clinical utility).[4] An elaborate tumor marker utility grading system was developed that defined the data quality or level of evidence needed for grading the clinical utility of markers.[5] In brief, level I evidence, which is similar to a phase III drug trial, is considered definitive. Levels II to V represent varying degrees of hypothesis-generating investigations, similar to phase I or II drug trials.

The high failure rate of phase III trials in oncology, including lung cancer, may be attributable to several factors, including inaccurate predictions of efficacy based on the hypothesis-generating phase II trials; failure to identify an appropriate dose or schedule (the so-called optimal dose) in a phase I trial; or problems with the phase III trial design.[6] Assessing the safety profile and establishing the maximum tolerated dose remain the primary focus of phase I trials, including trials of targeted therapies and vaccines. However, it is becoming more common for phase I trials to assess preliminary efficacy signals and identify the subsets of patients most likely to benefit from the new treatment. Tumor size response metrics based on longitudinal tumor size

models are promising new end points in phase II clinical oncology studies;[7,8] however, these metrics have not been validated yet for routine use in clinical trials. Response is being measured as progression-free survival instead of using the Response Evaluation Criteria in Solid Tumors (RECIST). Variants of progression-free survival, such as disease control rate at a predetermined time point, have been shown to be acceptable alternate end points for rapidly screening new agents in phase II trials in patients with extensive-stage small cell lung cancer and advanced-stage nonsmall cell lung cancer (NSCLC).[9–12] For phase III trials, overall survival, defined as the time from random assignment or registration to death from any cause, is still the standard criterion end point because it is a measure of direct clinical benefit to a patient. As an end point, overall survival is unambiguous and can unequivocally assess the benefit of a new treatment relative to the current standard of care. Although improving overall survival remains the ultimate goal of new cancer therapy, an intermediate end point such as disease-free survival in early-stage disease has been used in the phase III setting to evaluate the treatment effect of new oncologic products.[13,14] However, overall survival continues to be an appropriate end point in trials without an intermediate end point or validated surrogate end points, such as for phase III trials in extensive-stage small cell lung cancer and advanced-stage NSCLC.[9]

This chapter is organized into sections that focus on the end points and design considerations for cytotoxic agents and targeted therapies for early phase, dose-finding trials; phase II trials; and phase III trials. Where possible, examples of ongoing or completed lung cancer clinical trials are used to explain the concepts. The chapter ends with a brief summary and a discussion of future perspectives on clinical trial design in lung cancer research.

EARLY PHASE TRIALS

Historically, dose-finding trials in oncology have been designed to establish the maximum tolerated dose of a therapeutic regimen, with safety as the primary outcome. These trials, which are usually the first to test a new agent in humans, may include patients with multiple tumor types when no other treatment is available. A fundamental assumption of these designs is that toxicity and efficacy are directly related to dose, that is, the higher the dose, the greater the risk of toxicity and greater the chance of efficacy.[15] Although this paradigm works for cytotoxic agents, it is not readily applicable for molecularly targeted therapies, vaccines, or immunotherapy. The postulated mechanisms of action for these agents are not straightforward because (a) the dose–efficacy curves are usually unknown and may follow a nonmonotone pattern such as a quadratic curve or an increasing curve with a plateau (Fig. 59.1), and (b) dose–toxicity relationships are expected to be minimal.
Fig. 59.1. Examples of dose–efficacy curves for molecularly targeted agents. *a,* Monotonic increasing; *b,* increasing with a plateau; *c,* unimodal.

With regard to targeted therapies, erlotinib, gefitinib, and bevacizumab have demonstrated clinical benefit in several cancers, including lung cancer, whereas others such as R115777 and ISIS 3521 have produced negative results.[16–18] Problems with the design of phase I studies provide plausible explanations for the lack of clinical activity seen with these drugs, despite understanding the pathway of action for such drugs. The phase I studies were designed primarily to assess maximum tolerated dose, and the patients enrolled in these studies were unselected (e.g., all-comers vs. patients whose tumors express a specific molecular target). Consider, for example, an immunotherapy administered to stimulate the patient's own immune system to fight the tumor. Overstimulation of the immune system could interfere with the drug's efficacy or prove harmful for the patient.[19]

Ideally, dose-finding studies for immunotherapies or targeted agents would include a secondary measure of efficacy to identify the biologically optimal dose or the minimum effective dose, instead of the maximum tolerated dose. However, barriers to measuring efficacy in early phase trials are the absence of validated assays or markers of efficacy, the time required to measure an efficacy outcome, and incomplete understanding of drug metabolism and its pathway. These limitations also preclude patient selection for phase I trials, although an enrichment strategy is being used more often—either during the dose-escalation or dose-expansion phase—to identify subsets of patients who are likely to benefit most from the treatment. Successful examples of using enrichment strategy in early phase trials include the development of vemurafenib to treat patients with melanoma positive for v-raf murine sarcoma viral oncogene homolog B (*BRAF*) mutation and crizotinib for patients with NSCLC-positive anaplastic lymphoma kinase (ALK) rearrangement.[20,21]

Phase I trial designs can be broadly categorized as either model based or rule based (also called algorithm based).[22] In the rule-based designs, small numbers of patients are treated starting at the lowest dose level. The decision to escalate, deescalate, or treat additional patients at the same dose level is based on a prespecified algorithm related to the occurrence of unacceptable dose-limiting toxicity. The trial is terminated once a dose level is reached that exceeds the acceptable toxicity threshold. The initial dose level often is derived from animal studies or trials conducted in a different setting. The interval between successive dose levels is usually based on a modified Fibonacci sequence.[15,23] Examples of rule-based designs commonly used in oncology studies include the traditional cohorts-of-three design and its variants, the accelerated titration design, and the two-stage design.[23]

The continual reassessment method introduced the concept of dose–toxicity models to guide the dose-finding process.[24,25] The dose–toxicity model represents the investigator's a priori belief in the likelihood of dose-limiting toxicity according to the delivered dose. The model is updated sequentially using cumulative patient toxicity data. Several modifications have been proposed to address the safety concerns associated with the original continual reassessment method, such as starting the trial at the lowest dose level, prohibiting skipping of dose levels during escalation, and requiring at least three patients at each dose level prior to escalation.[26–28] The trials with a model-based design using the continual reassessment method have demonstrated better operating characteristics than trials with rule-based designs in simulation settings. Specifically, a higher proportion of patients are treated at levels closer to the optimal dose level, and fewer patients are needed to complete the trial. A key characteristic of all these designs, model based or rule based, is that they use only toxicity to guide dose-escalation and do not incorporate a measure of efficacy in the dose-finding process.

Current statistical approaches extend the standard continual reassessment method in two directions to allow toxicity and efficacy outcomes to be modeled in a phase I trial. One example is the bivariate continual reassessment model, which uses a marginal

logit dose–toxicity curve and a marginal logit dose–disease progression curve with a flexible bivariate distribution of toxicity and progression.[29] Other examples are the design proposed by Thall and Cook[30] that uses efficacy–toxicity trade-offs to guide dose finding;[30] the dose-finding scheme proposed by Yin et al.[31] using toxicity and efficacy odds ratios; and bivariate probit models for toxicity and efficacy proposed by Bekele and Shen,[32] and Dragalin and Fedorov.[33] Another statistical approach assumes that the observed clinical outcomes follow a sequential order: no dose-limiting toxicity and no efficacy, no dose-limiting toxicity but efficacy, or severe dose-limiting toxicity, which renders any efficacy irrelevant. In this case, the joint distribution of the binary toxicity and efficacy outcomes can be collapsed into an ordinal trinary (three-outcome) variable, which may be appropriate in the setting of vaccine trials and viral-reduction studies in patients with human immunodeficiency virus, among others.[34,35]

The design and end-point considerations are further complicated in the study of combination therapies. Ideally, the underlying biologic rationale for the combination would be known; for example, whether the efficacy of the two agents is additive, complementary, or synergistic. Understanding the interaction between the drugs may help investigators to anticipate whether the toxicity profiles of the agents are overlapping or additive. Typically, a set of predetermined dose-level combinations are explored based on either the maximum tolerated dose of one agent or other preclinical data demonstrating synergy. The dose of one agent under investigation is escalated, while the dose of the second agent remains constant until a tolerable combination dose level is achieved. Often it is unfeasible to explore all possible combination levels. Despite increased testing of combination treatments in oncology, few designs for dose escalation of two or more agents have been proposed.[36–39] Gandhi et al.[40] used a nonparametric, up-and-down, algorithmic-based sequential design to explore 12 dose combinations out of a possible 16 combinations. The maximum-tolerated-dose combinations were chosen based on the highest tolerated dose of each agent, achieving a targeted dose-limiting toxicity rate less than 33%. Two maximum-tolerated-dose combinations were identified using this design: 200 mg neratinib plus 25 mg temsirolimus and 160 mg neratinib plus 50 mg temsirolimus.[40]

The failure of promising agents in randomized studies has prompted reconsideration of the standard dose-finding paradigm, with the recognition that improved drug development strategies for single agents and combination therapies are required. Although the assumption of a monotonically increasing dose–toxicity curve is almost always appropriate from a biologic standpoint, a monotonically increasing relationship between dose and efficacy has been challenged by the recent development of molecularly targeted therapies, vaccines, and immunotherapies. Model-based designs are certainly not perfect or recommended for every dose-finding study, but they can be an attractive alternative to the traditional algorithm-based, up-and-down methods. However, the application of these designs to dose-finding studies in oncology has been limited for considerable scientific and pragmatic reasons.[22,41,42] The acceptance and use of these designs may be quicker and easier if they are developed in concert with a clinical paradigm.[40,43]

PHASE II TRIALS

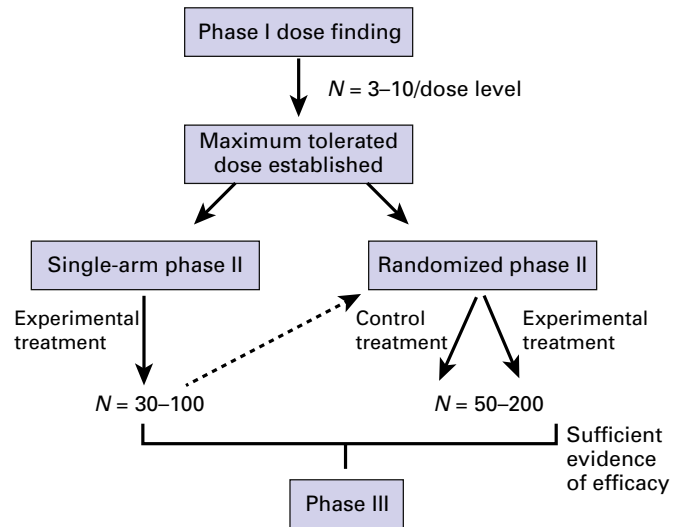
The primary objective of a phase II trial is usually to determine whether there is sufficient evidence of efficacy to warrant further evaluation of a treatment (Fig. 59.2). Secondary goals of phase II trials are to establish which patients are most likely to benefit from this treatment and to evaluate toxicity in a larger study population. Phase II trials are often called screening trials, because they screen new agents or regimens for definitive evaluation in a phase III study. These trials usually include the minimum number of


Fig. 59.2. Typical drug development pathway. *N*, total number of study participants.

patients necessary to achieve the study goals and are relatively short in duration so that the experimental treatment can continue to phase III testing. As with any phase of testing, the study goals dictate the specifics of design and end-point selection.

End-Point Considerations

Generally, different end points are used for phase II and III trials of the same treatment. For example, although overall survival is the criterion standard outcome for phase III studies, it is not time efficient to use it in phase II studies. For a phase II trial to be informative, the selected end point should be a surrogate for the phase III outcome of interest, and the magnitude of changes in the surrogate end point should relate directly to changes in the main end point.[44,45] Because clinically relevant outcomes depend on so many disease- and treatment-related variables, validation of a surrogate outcome is challenging.

As discussed earlier, commonly used end points for phase II trials in patients with advanced disease are response rate, progression-free survival, and disease control rate; for trials in patients with early-stage disease, disease-free survival is frequently used. The best outcome measure for a phase II study depends on the experimental agent's mechanism of action. For example, response rate was often used for cytotoxic treatments that were expected to affect survival by shrinking the tumor or reducing overall tumor burden. Since the early 2000s, trials of cytostatic agents, which are thought to prolong survival by shrinking the tumor or stabilizing tumor growth, have been designed to measure progression-free survival or disease control rate. In fact, there is evidence that stable disease predicts overall survival better than tumor response does, which is a reason for including measures of disease stability in chemotherapy trials.[11] The effect of agents that act on the immune system rather than directly on the tumor may not be adequately captured by the traditional measures defined by the RECIST; new criteria for immunotherapies have been developed.[46,47]

The choice of a summary statistic for time-to-event outcomes, such as progression-free or disease-free survival, should also be disease and treatment related. The median times summarize the point at which the event of interest has occurred in at least 50% of study participants. A landmark time can be used to summarize a single time point, for example, the percentage of patients who are progression free at 6 months. The hazard ratio, which is a summary measure of the relative benefit found in the

treatment arm averaged over the entire study period, places equal value on differences between the study arms at every point. For treatments expected to have a delayed effect, such as immunotherapies, the average may not represent the treatment's efficacy; for these agents, a landmark time may be a better representation of the treatment effect. End points that may prove useful in the future are imaging-based measures or longitudinal biomarker measures.[48]

Randomized and Single-Arm Designs

Since the early 2000s, phase II trials have shifted from single-arm to randomized design. In a single-arm study, all participants receive the experimental treatment and study results are compared with historical data from patients receiving the standard of care. Studies with a single-arm design typically have 90% power and 5% one-sided type I error, with sample sizes ranging between 20 patients and 100 patients. The validity of this type of study depends on the availability of accurate historical data for the patient population. Biased historical data have been blamed for numerous failed phase III studies after a positive phase II study. In addition, single-arm biomarker studies cannot differentiate between a prognostic and predictive association with the clinical outcome.

Randomized phase II studies avoid the problem of bias in historical data by directly comparing patients who have been randomly assigned to receive an experimental treatment or the standard of care. Randomized studies are typically two to four times larger than single-arm phase II studies and have larger error rates (e.g., type I error of at least 10%).[49,50] A sufficiently powered, randomized phase II trial can differentiate between prognostic and predictive biomarkers.

Assessing Biomarker-Based Subgroups: Design Considerations

Information from phase II studies is often used to establish the patient population for a phase III study. Because therapies are being developed to target a specific biologic mechanism of the tumor or host, biomarker evaluation is an important consideration when designing a phase II study. Possible design choices are an all-comers design with secondary marker evaluation; a biomarker-stratified design with specific accrual targets within biomarker-defined subgroups; enrichment or targeted designs, which enroll only marker-positive patients; and multiple hypothesis designs, which specify both an overall population assessment and a subgroup assessment (Fig. 59.3).[51,52] Any of these designs may be used for the randomized phase II trial in an overall drug development strategy (Fig. 59.2).

In an all-comers design with secondary marker evaluation, the marker can be evaluated either at registration or at the end of the study. When the marker is evaluated at registration, the random assignment can be stratified to ensure balance of the marker between the treatment arms. Secondary evaluation is a reasonable approach when multiple biomarkers are to be assessed and little is known about the markers. However, depending on the prevalence of a marker, studies using this approach may be unpowered. For example, if the prevalence of the marker is 10%, in a two-armed study of 100 patients with 1:1 randomization, there would be only about five patients per arm for subgroup evaluation.

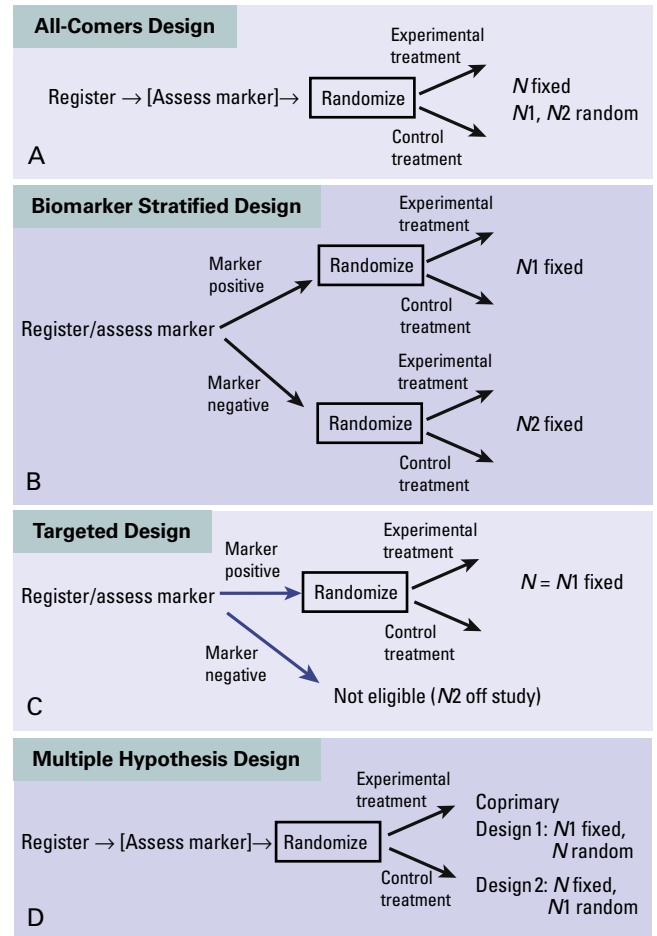
In a study with a biomarker-stratified design, specific accrual targets are established per stratum, based on stratum-specific objectives. All patients are assessed for marker status at registration, and this design ensures adequate power to detect effects within biomarker subgroups.[53] However, accrual for each stratum could differ substantially based on the marker prevalence, making this design impractical. In all cases, it is important to keep


Fig. 59.3. Phase II designs incorporating potential biomarkers. (A) All comers; (B) biomarker stratified design; (C) targeted design; (D) multiple hypothesis design. N, total number of study participants; $N1$, patients with marker-positive tumors; $N2$, patients with marker-negative tumors.

in mind that the apparent differences in effect estimates across subgroups could be due to random variation alone.

In studies with an enrichment or targeted design, only individuals with the biomarker are enrolled and studied. Although this approach may be the most efficient design to screen a biomarker–drug combination, this design provides no information about how the therapy performs in the population with marker-negative tumors.[53]

A multiple hypothesis design specifies coprimary objectives for evaluating the treatment within a biomarker-defined subgroup and the overall study population, splitting the study-wide type I error between the two objectives. Determining the target sample size is a key distinction between an all-comers design and a multiple hypothesis design. If the multiple hypothesis study is designed to have a specific number of patients with marker-positive tumors ($N1$), then the total sample size is the number of patients (N) needed to accrue $N1$ patients. Alternatively, if the study is designed around the entire study population (N), then the percentage of the study population that has marker-positive tumors determines $N1$. In this design, marker status can be either evaluated at registration or during the study.

Any of these strategies for establishing biomarker-based subgroups may be used in a single-arm trial by simply assigning all registered patients to the experimental therapy. However, except for studies of patients with rare tumors and small biomarker subsets, a randomized phase II design is typically used, so that

the prognostic value of the biomarker can be evaluated in the control arm. For example, in studies evaluating ALK inhibitors, it appears that patients who have tumors with the echinoderm microtubule-associated protein like 4 (EML4)–ALK fusion may also derive greater benefit from pemetrexed plus an ALK inhibitor than do patients who have tumors negative for the fusion.[21]

Adaptive Designs

In its 2010 draft guidance, the US Food and Drug Administration defines an adaptive design clinical study as a study with a prospectively planned opportunity for modification of one or more of the study design features based on analysis of (usually interim) data from participants in the study.[54] Examples of adaptations are modification of the randomization ratio between treatment arms, the study population, the treatment arms, and target treatment effect. A noteworthy example of an adaptive design study is the Biomarker-Integrated Approaches of Targeted Therapy for Lung Cancer Elimination phase II program, in which the randomization ratio is altered within biomarker-defined subgroups based on interim estimates of treatment efficacy within the treatment arm–subgroup combinations; the goal of the trial is to identify biomarker–drug combinations for further study.[55]

The usefulness of adaptive randomization is the subject of debate.[56] Parmar et al.[57] have described an approach to expedite drug development by allowing investigators to drop and add treatment arms to an ongoing study. It is important to note that a group sequential design, which is a design using interim monitoring with prespecified rules for early stopping due to either efficacy or futility, is not an adaptive design because the design features are not modified based on analysis of study data.

PHASE II/III AND PHASE III TRIALS

Traditional Designs

The primary objective of a phase III trial is to gather sufficient evidence of the benefits of a new treatment to potentially change clinical practice. Any design that achieves this objective is permissible, but phase III trials typically are large randomized controlled trials in which the new treatment is compared directly with the current standard treatment in a robust, unbiased manner. Generally, the comparison is made in terms of superiority of efficacy, with the result that progressively better treatments become the standard of care. However, designs that test for noninferiority are becoming more common and will be discussed in greater detail.

The choice of a primary outcome measure for comparing treatments in phase III oncology trials is related to the type of cancer, stage of disease, and type of intervention. In advanced lung cancer, survival time is generally considered to be the most clinically relevant measure of benefit to patients and hence it is the most commonly chosen primary outcome measure. Survival time is defined as the time from random assignment to a treatment arm to death. Patients who are still alive at the time of analysis are included in the comparison with a survival time that is censored at the date last known to be alive. Analysis of such data requires a specialized statistical methodology.[58]

Quality of life also has been recognized as being an important outcome, particularly to patients with advanced disease. Quality of life is often included as a secondary outcome measure and can be combined with survival data to compare treatments in terms of quality-adjusted survival time.[59,60] In some situations, such as trials of cytostatic drugs, progression-free survival time may be considered a relevant primary outcome. In early-stage lung cancer when the treatment is potentially curative, local or distant recurrence-free survival time may be either the primary outcome measure or an important secondary outcome. For time-to-event

outcomes, a hazard ratio is the most commonly used statistic. The hazard ratio compares the relative benefits of the new treatment with the standard treatment in terms of the overall risk of the chosen end point at any point in time; values less than 1 indicate benefit with the new treatment.

Phase III trial designs are traditionally based on hypothesis testing for a difference between treatments. Typically, this approach tests the null hypothesis that there is no difference between treatments (i.e., $\theta = 1$, where θ is the unknown true hazard ratio in the population) against the alternative hypothesis that there is difference (i.e., $\theta \neq 1$ for a two-sided test of a difference in either direction, or $\theta < 1$ for a one-sided test of the superiority of the new treatment). The size of the trial is based on maximizing the chances of drawing a correct conclusion from the trial data. Trials are designed to (a) have a small chance of incorrectly rejecting the null hypothesis (i.e., a false-positive conclusion, known statistically as a type I error) by setting the decision boundary known as the significance level to 5% and (b) have a good chance (usually 90%) of rejecting the null hypothesis (at a 5% significance level) when a prespecified minimum clinically relevant treatment effect truly exists, a feature known as power (the false-negative error, known statistically as a type II error).

Noninferiority Designs

Noninferiority trials are conducted when the underlying hypothesis is that the investigational treatment may not provide additional efficacy but may benefit patients or society in terms of quality of life and cost. For example, less toxicity should improve a patient's quality of life and reduce the cost of supportive care; easier administration should be more convenient to patients, thereby improving their quality of life and reducing health service costs for administration; and a less expensive treatment would benefit society by reducing health-care costs. Demonstrating noninferiority shows that the new treatment has an acceptable level of efficacy to be adopted into clinical practice as an alternative to the current standard therapy. Use of such trial designs to study antineoplastic agents has increased in recent years; 17 noninferiority studies in patients with lung cancer were identified in a 2012 review.[61] As drugs with better outcomes are produced, it will become more difficult to develop new drugs that are superior to existing drugs, so the objective of clinical trials is likely to change.

Key examples of noninferiority trials in lung cancer include the following: (a) a randomized phase III trial comparing pemetrexed with docetaxel for patients with advanced NSCLC previously treated with chemotherapy, which resulted in Food and Drug Administration approval for pemetrexed in this setting;[62] (b) IRESSA NSCLC Trial Evaluating Response and Survival against Taxotere (INTEREST), a study in the same setting, but investigating gefitinib rather than pemetrexed;[63] and (c) a randomized phase trial comparing cisplatin and pemetrexed with cisplatin and gemcitabine as first-line treatment for advanced NSCLC.[64]

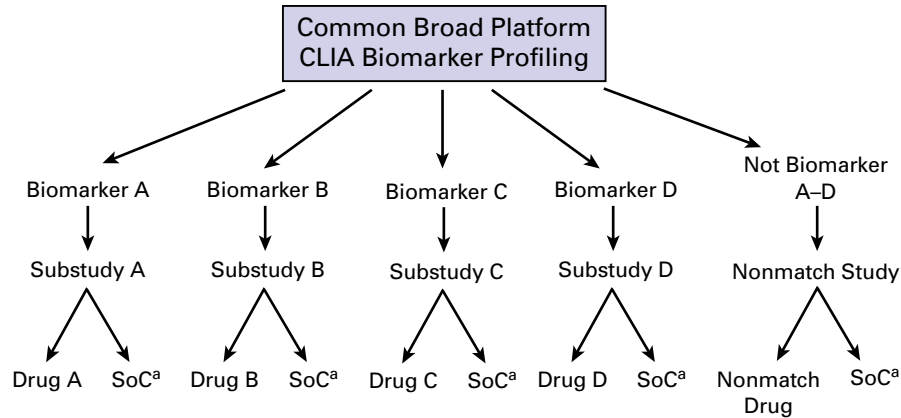
Special guidelines have been developed to address the unique challenges of designing noninferiority trials, as well as analyzing and interpreting data, and reporting the results.[65] Because the crux of this type of trial is that the new treatment is noninferior to the standard treatment, defining what that means is a crucial aspect of the design and interpretation. The trial is meant to demonstrate beyond reasonable doubt that the new treatment is not worse than the currently accepted standard of care by a small, prespecified margin, called the noninferiority margin. There are various approaches to selecting this margin, such as the conventional method and the effect-retention method.[61] The conventional method, also known as the fixed-margin method, is a subjective approach. A level of inferiority is selected that is considered to be of no clinical relevance or outweighed by other benefits of the experimental treatment. With the effect-retention


Fig. 59.4. Master Lung Protocol (Southwest Oncology Group S1400) study design schema. [a]Experimental drug or regimen could be single agent or a combination with the current standard of care (SoC). The standard of care can vary by biomarker. *CLIA,* Clinical Laboratory Improvements Amendment.

method, also known as the percent-retention or putative-placebo method, a noninferiority margin is selected that ensures a substantial fraction (typically 50%) of the benefit demonstrated for the standard treatment over placebo is still retained by the new treatment. In a review of lung cancer trials, hazard ratios for the noninferiority margin ranged from 1.18 to 1.37.[61] Ultimately, the value chosen has to be sufficiently small that the clinical community accepts the new treatment as the preferred option, given the other benefits demonstrated.

In terms of hypothesis testing, if a trial is set up to test the null hypothesis that there is no difference between treatments and the results are nonsignificant, then one can only conclude that the trial does not provide evidence of a difference between treatments. Although it is tempting to conclude that the treatments are equivalent, especially if the observed hazard ratio is close to 1, this conclusion is invalid. Therefore the hypotheses that are tested in a noninferiority trial are opposite to the hypotheses specified when testing for superiority. In a noninferiority trial, the null hypothesis is that the new treatment is inferior to the standard control treatment. The alternative research hypothesis is that the experimental treatment is not inferior to the standard control arm by the prespecified margin. The aim of a noninferiority trial is to collect data that provide sufficient evidence to reject the null hypothesis in favor of the research hypothesis; that is, if θ is the unknown true hazard ratio in the population, as specified previously, and k is the prespecified noninferiority margin, then the analysis will compare the null hypothesis that $\theta > k$ with the alternative hypothesis that $\theta < k$. These hypotheses are one-sided, which is the statistical approach usually taken; however, two-sided hypotheses can be specified in a similar way to test for equivalence rather than noninferiority. The significance level and power for the trial are selected to minimize the chance of erroneously concluding that an inferior treatment is noninferior.

The final methodologic consideration in noninferiority trials is the choice of the population included for analysis. In traditional comparative designs, the criterion standard is the intent-to-treat population, which includes all patients within their randomly assigned treatment allocation, despite what treatment they may have actually received. The intent-to-treat population is a conservative analysis strategy for assessing potential treatment benefit. Sole use of this approach in a noninferiority trial may dilute a clinically important difference between treatments, leading to an incorrect conclusion about noninferiority. Therefore the recommendation is to perform an additional analysis of the per-protocol population, which includes only the patients who have received a prespecified minimum level of treatment. Guidelines state that a robust interpretation of noninferiority can be achieved only if

both analyses lead to similar conclusions and that any differences between the intent-to-treat and per-protocol analyses need careful and close examination.[66,67]

Phase II/III Designs

The phase II/III design, also known as the multiarm, multistage design, is essentially a phase III design with an early interim analysis that stops the trial for futility alone.[52,68] The primary outcome of the phase II interim analysis may be different than the phase III primary outcome. For example, a phase II/III trial may be designed to assess progression-free survival as the primary end point for the phase II component and overall survival as the primary end point for the phase III component. Patients enrolled in the phase II portion of the trial are included in the phase III trial, provided that the study does not stop for futility at the phase II analysis. The timing of the phase II interim analysis is based on phase II design properties. In contrast to standard interim monitoring plans, which are unlikely to stop early for futility under the alternative hypothesis, the phase II interim analysis typically has a 10% to 20% chance of stopping the trial for futility when the alternative hypothesis is true.

The Southwest Oncology Group (SWOG) is implementing this design in the Master Lung Protocol (SWOG S1400), which is evaluating second-line treatment of squamous cell NSCLC. In this study, multiple parallel but independent phase II/III trials will be conducted such that all clinically eligible patients are assigned to a substudy and randomly assigned to either an experimental regimen or the standard of care (Fig. 59.4). Patients are screened for a specific set of biomarkers and assigned to a biomarker-driven substudy using a targeted design if they have one of the biomarkers. If none of the target biomarkers is present, the patient is assigned to a nonmatch substudy, which is a version of an all-comers design. The design within each substudy is standardized (Fig. 59.5). The phase II interim analysis will occur once 55 progression-free survival events have occurred. If the study continues after the interim analysis, the final phase III analysis will occur after 256 deaths, that is, overall survival events in the study population. These cut points were based on a phase II design with 90% power and 10% one-sided type I error to detect a twofold increase in median progression-free survival, and a phase III design with 90% power and one-sided 2.5% type I error to detect a 50% increase in median overall survival.

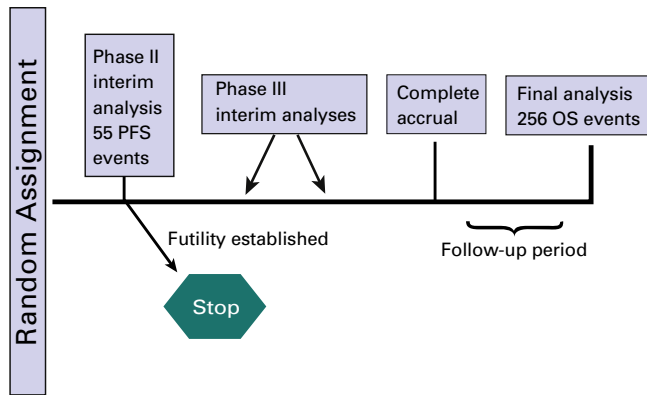
Use of a phase II/III design expedites drug development by streamlining accrual and eliminating the time between phase II and phase III trials. The drawback is that continuation from phase II to phase III is based on one prespecified rule. Study sponsors


Fig. 59.5. Substudy design for the Master Lung Protocol (Southwest Oncology Group S1400). Progression-free survival (PFS) is the primary outcome for the phase II portion, and overall survival (OS) is the primary outcome for the phase III portion.

and investigators cannot review study data at phase II and then decide if they want to continue into phase III, as this would not be an independent assessment. Successful use of a phase II/III design is predicated on having adequate safety data from pilot studies, selecting the best outcome measure, and identifying potential biomarkers before the study is launched.

Biomarker-Based Trial Designs

Biomarkers can be classified as prognostic biomarkers, predictive biomarkers, or surrogate end points; some biomarkers belong in more than one category. Prognostic and predictive biomarkers provide information about individual risk classification and treatment selection, respectively, whereas biomarkers used as surrogate end points aid in evaluating the efficacy of a new treatment. It is crucial to realize that the intended usage of a biomarker determines its classification and the validation methods that are required. A prognostic biomarker predicts the natural course of the disease in a given individual, and it aids in deciding whether a patient needs an intensive, possibly toxic treatment, standard therapy, or no treatment.[69] A predictive biomarker predicts whether an individual will respond to a particular therapy, thereby facilitating individualized therapy. A surrogate end-point biomarker is used in place of a primary clinical outcome to evaluate the efficacy of a new treatment at the population level; this approach is often more cost-effective than studying a clinical outcome such as overall survival.[70]

Predictive biomarker validation is complex, and definitive validation requires the same level of evidence as the adoption of a new treatment does.[71] Thus predictive marker validation is prospective in nature, and the obvious strategy is to conduct an appropriately designed prospective randomized controlled trial. Evidence from a randomized controlled trial provides the only assurance that patient outcomes are comparable across treatment arms and are not confounded by other artifacts. However, a prospective phase III randomized controlled trial is not always possible because of ethical and logistical considerations, such as size or duration. In this case, a well-conducted, prospectively specified validation study using retrospectively collected data can provide valuable information in a timely manner to guide treatments in marker-defined patient subgroups.[72] For example, retrospective validation was used to establish that the presence of Kirsten rat sarcoma (KRAS) mutation predicted the efficacy of panitumumab and cetuximab in patients with advanced colon cancer.[73] Enrichment and all-comer designs have been used in oncology for prospective biomarker validation; variations of the all-comers design used for this purpose include hybrid designs, marker by treatment

interaction designs, sequential testing strategy designs, and adaptive analysis designs.[71,74–79]

Trial Designs for Rare Tumors

Tumors with an incidence of less than 2 per 100,000 are typically deemed rare. Lung cancer is certainly not a rare tumor but in the emerging world of stratified medicine, development of treatments will be increasingly based on small biomarker-defined subsets of patients, and the disease will be transformed into a collection of multiple rare tumors. Clinicians caring for patients with rare tumors have to make difficult treatment decisions on a daily basis, and patients with rare tumors have the same right to evidence-based decisions as patients with common tumors. The problem with the traditional approach to sample size calculations for a phase III trial in the context of rare cancers is that it demands an unfeasibly large number of patients, and a smaller trial would be underpowered and unlikely to generate the correct conclusion. Trials based on traditional designs may be possible if patients with rare tumors are recruited internationally. An example of this approach is the International Rare Cancers Initiative, which facilitates trials in a selection of rare cancers (www.irci.info).[80]

Less conventional methodologic approaches are acceptable if they improve the interpretability of trial results, and a variety of alternative approaches have been proposed.[80,81] One alternative view is to abandon the use of hypothesis testing to reach a definitive conclusion about a treatment effect and, instead, use the unbiased study data to reduce uncertainty about the size of the treatment effect. Given the premise that there is considerable uncertainty about a treatment effect, having data from a small but well-designed clinical trial reduces that uncertainty and provides information to help clinicians make necessary treatment decisions. This alternative statistical view lends itself to using a bayesian approach to analysis, but there are issues in its implementation that need to be considered.[82–85] One key issue in bayesian analysis relates to the incorporation of prior information. Strategies have been proposed to develop an evidence-based prior distribution, but in the context of rare disease, previous evidence is often of poor quality, making its use problematic.[86,87] However, the bayesian approach can still be implemented with noninformative priors. One of the great advantages of this method is that the trial results can be expressed as direct probabilities that the treatment effect is a certain size. Data reported this way can be used practically by clinicians in discussion with patients and enable evidence-based treatment decisions, whereas a nonsignificant result from hypothesis testing might simply be regarded as inconclusive or incorrectly interpreted as evidence of no treatment effect.

CONCLUSION

Clinical trial design has evolved rapidly in the last decade. The focus of oncology research has shifted from the traditional anatomic staging systems to selecting treatment based on the genetic makeup of the tumor and the patient's genotype, and predicting individual outcomes. For dose-finding trials, a preliminary assessment of efficacy along with safety has become a necessity to identify a so-called minimum effective dose to take forward into phase II trials. A better understanding of the tumor biology (e.g., identifying patient subsets and rare tumor subtypes), advancement in assay techniques, and availability of commercial kits with rapid turnaround times have enabled the use of enrichment designs in phase II and phase III trials, allowing only patients with a particular molecular profile to enroll in the trial. Tailored treatments with effective biomarker-driven hypotheses are leading to smaller clinical trials targeting larger treatment effects. Phase II/III designs using small patient subsets are becoming more popular, streamlining accrual and random assignment to maximize

enrollment. With integrated phase II/III designs, multiple experimental agents are assessed simultaneously against the standard of care in the phase II portion using an intermediate (or surrogate) end point. This approach eliminates the need to conduct separate, large-scale phase II trials to evaluate each experimental regimen. The promising experimental arms continue on to phase III testing, in which they are compared with the standard of care. Advances in technology such as mobile computing, electronic data capture, and integration of research records with electronic medical records have made real-time access to clinical trial and biomarker data a reality, allowing adaptive designs to take on a much greater role in clinical trials.

How to Promote and Organize Clinical Research in Lung Cancer

Fabrice Barlesi, Julien Mazieres, Yang Zhou, Roy Herbst, and Gérard Zalcman

SUMMARY OF KEY POINTS

- Despite two decades of progress, the prognosis for patients with lung cancer remains poor. Therefore forming new hypotheses and conducting clinical trials to investigate this patient population are still important.
- Accordingly, in the past 25 years, the number of clinical trials involving patients with lung cancer has increased dramatically (Fig. 60.1); however, only a minority of these trials have been conducted on an academic basis. In addition, only a few of these trials have led to a real change in practice. For example, fewer than 10 new drugs were approved for the management of cancer during 2013, with only one drug having a new indication and two drugs having an expanded indication for patients with lung cancer.[1]
- While international societies, including the International Association for the Study of Lung Cancer,[2] have encouraged patient participation in clinical trials, the number of patients actually included in such trials worldwide is very low. The actual proportion of patients with cancer who participate in oncology clinical trials is difficult to determine, usually ranging from 2% to 7% in Western countries.[1] However, if we compare the 7.5 million people who die of lung cancer worldwide per year with the reported accrual in clinical trials, the actual proportion of patients with lung cancer who are included in clinical trials worldwide is probably closer to 0.1% to 1%.
- Therefore the improvement and promotion of clinical research related to lung cancer are of crucial importance. This chapter provides some proposals that are intended to enable researchers to better organize and promote clinical trials that are designed to advance research and science toward reducing the burden of thoracic malignancies worldwide.

HOW TO ORGANIZE CLINICAL TRIALS IN LUNG CANCER

Issues

Definition of Lung Cancer Today

Does lung cancer still exist as an entity? The answer is that it probably does not, considering the progress that had been made in developing a better clinical, pathologic, and biologic definition of this disease. Consequently, including all of these patients in a single trial is irrelevant. However, most clinical studies focus on obtaining a reliable estimate of the average treatment effect in a broad population of patients. In practice, clinical trials in oncology involve a delicate balance between the need for reliable evidence for a large population and the need to integrate biomarkers and thus to focus on the population carrying these biomarkers against which the targeted therapies are supposed to be efficient. For example, many drug developments have been stopped because

of the absence of focus on predefined biomarkers. The first clinical trials analyzing the effect of epidermal growth factor receptor (EGFR)-tyrosine kinase inhibitors such as gefitinib independently of EGFR status or cetuximab with an inappropriate biomarker threshold led to disappointing results, despite the high number of patients enrolled.[3,4] Conversely, the selection of patients on the basis of the accurate biomarker (EGFR-activating mutation, anaplastic lymphoma kinase [ALK] translocation) recently led to impressive results with fewer patients.[5–7] Therefore lung cancer is now considered to comprise a mosaic of rare diseases, and clinical trials should be designed adequately.

Expectations for Quick Progress and Impact on Financial Issues

Patients are obviously waiting for rapid improvement in the treatment of the disease, and the delay between the discovery of a new biologic target, preclinical proof of principle, and the approval of a new drug (or a new strategy) is generally viewed as unacceptably long. From this perspective, at least, the expectations of drug companies are consistent with those of patients. Is this situation changing? Perhaps, indeed, the delays between the results of the first phase I study and the European Medicines Agency (EMA) and/or the US Food and Drug Administration (US FDA) approval of new biomarker-guided drugs appear shorter when compared with those for previous standard chemotherapy (Fig. 60.2). In addition, the results presented during the 2013 American Society of Clinical Oncology (ASCO) meeting by Canadian colleagues suggest that biomarker-guided treatments clearly have the greatest chance of demonstrating an activity after starting clinical development than do standard, nonbiomarker-guided, treatments.[8] Indeed, after the assessment of more than 2400 trials, the authors found that the likelihood of a new drug passing all phases of clinical testing and being approved (i.e., the cumulative clinical trial success rate) was 11%, which was less than the expected industry aggregate rate (16.5%). The success of phase III trials was found to be the biggest obstacle for drug approval, with a success rate of only 28%. Biomarker-guided targeted therapies (with a success rate of 62%) and receptor-targeted therapies (with a success rate of 31%) were found to have the highest likelihood of success in clinical trials.[8] Accordingly, Subramanian et al.[2] conducted a survey to review ongoing clinical trials involving patients with nonsmall cell lung cancer (NSCLC) as listed in the ClinicalTrials.gov registry in 2012 and found that the number of clinical trials with biomarker-based treatment selection for lung cancer had significantly increased since 2009 (from 7.9% to 25.8%; $p < 0.001$).

The costs of a clinical trial depend on many factors. An audit of industry-sponsored clinical trials in oncology recently indicated that the average cost is $165 million for basic research and discovery, $87 million for preclinical development, $130 million for a phase I trial, $190 million for a phase II trial, and $268 million for a phase III trial. It seems that the use of a validated biomarker, such as human EGFR-2 for breast cancer, reduces clinical trial risk by as much as 50%, resulting in cost savings of 27% in advanced and metastatic breast cancer.[9] This percentage
Fig. 60.1. Number of published phase II and phase III clinical trials involving lung cancer from 1988–2013.
Fig. 60.2. Time (in years) between the publication of the first phase I trial and the first phase III trial for some chemotherapies and biomarker-guided treatments available for melanoma, breast cancer, and lung cancer.

is comparable with the results of a large study in which the use of biomarkers decreased the cost of drug development by 26%.[8] It is difficult to have a worldwide picture of the funding of clinical trials in oncology. However, one recent example in the United States showed how academic-sponsored clinical trials in oncology are fragile. At the time of the federal budget cuts in 2013, a survey showed that a large proportion of US oncologists consequently reduced the end points of trials (36.9%), closed or participated in fewer cooperative group trials (28.3%), postponed the launch of clinical trials (26.7%), and limited enrollment in clinical trials (23.1%).[1] Therefore adapting the design of oncology clinical trials and durably ensuring their funding are important.

Selection of Hypotheses for Clinical Trials and Impact of Biomarkers on Design

Instead of testing therapeutic strategies or new chemotherapeutic drugs, clinical researchers now face a huge amount of basic-science data and preclinical concepts. The challenge is to build the most appropriate trials to validate some of these hypotheses. A dispensable time in the building of a clinical trial is to deeply analyze the preclinical data and to anticipate all issues that may impair the development of the drugs (efficacy, toxicity, pharmacokinetics, etc.).

Advances in biotechnology and genomics gradually have uncovered the biology of lung cancer. Deeper understanding of the biology of the disease can facilitate the development of new treatments, whereas deeper understanding of the heterogeneity of the disease can facilitate the development of effective

biomarkers or diagnostic tests that can be used to select appropriate treatments for individual patients. In particular, the recent establishment of high-throughput molecular assay technologies, such as high-throughput sequencing, single-nucleotide polymorphism arrays, gene-expression microarrays, and protein arrays, has allowed for the discovery of potential new biomarkers and the development of composite genomic signatures for personalized medicine.

Consequently, different trial designs have been proposed on the basis of the incidence of a given biomarker. For example, early phase trials initially tested the efficacy of a drug in a population harboring a rare molecular abnormality such as v-raf murine sarcoma viral oncogene homolog B (BRAF) mutation or ALK translocation.[6,10] Then, randomized trials were conducted in populations with a more frequent or better characterized molecular alteration. Nevertheless, those studies can be criticized, as the prognostic value of the biomarker by itself (independent of its predictive value) is often underestimated. Therefore we again need new designs of clinical trials in oncology.

National, Multinational, and International Cooperation or Competition

Thousands of studies are carried out every year around the world, involving thousands of patients and billions of dollars of investment. In addition, conducting clinical trials, especially when the patient population is small, as is the case for the current development of the vast majority of biomarker-guided inhibitors, is necessarily competitive. First, at the time of targeted clinical trials in oncology, only centers with high-level facilities can still test and enroll patients, and, when two or more studies are in competition, substantial time and resources that otherwise could have been applied to other valuable projects inevitably will be wasted. Second, the winner is not necessarily the best treatment, as the trials are conducted sequentially. Third, there is also a competition between industrial and academic trials in that they often involve the same patients but have different trial designs. Fourth, there is competition between countries as each country has its own way of funding trials. Thus it is sometimes harder to conduct international trials because of the complexity of administrative procedures. Therefore collaborations, networks, and simplified rules are needed.

Possible Solutions
New Designs for Modern Clinical Trials

Freidlin et al.[11] recently proposed three designs for biomarker-based clinical trials (Fig. 60.3). If there are two or more existing treatment options with no definitive evidence for one being preferred, the most efficient trial design for evaluating biomarker utility is the biomarker-stratified design. Biomarker status is assigned, and two groups are established: one group is biomarker positive, and the other is biomarker negative. In each group, randomization is performed for treatment assignment. The analysis plan will be centered on determining treatment effect dependence according to the biomarker status. The biomarker-stratified design maximizes the advantage of randomization by providing unbiased estimates of benefit-to-risk ratios across different biomarker-defined subgroups and for the entire randomly assigned population. For predictive biomarkers, the biomarker-stratified design can assess whether the marker is useful for selecting the best among two or more treatments for a given patient.

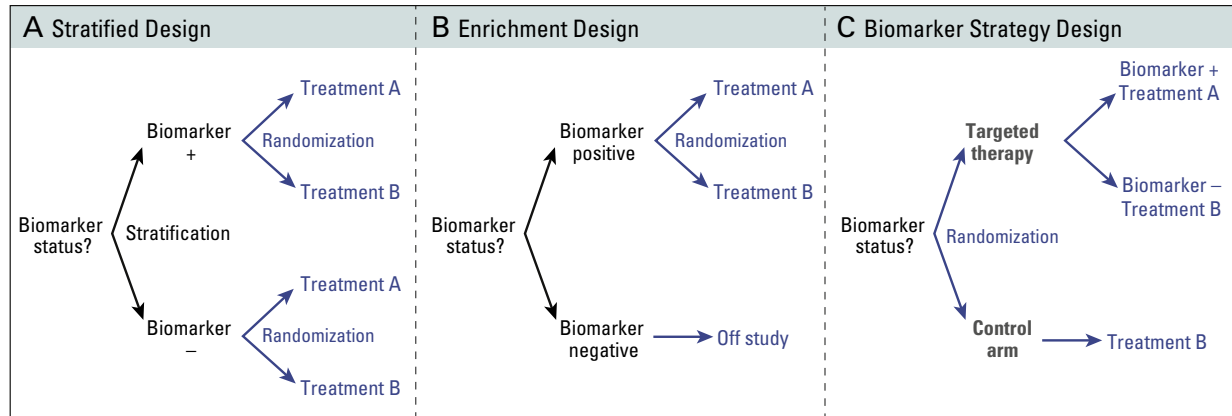
In some situations, sufficiently convincing evidence based on preclinical or clinical data is available and suggests that the potential treatment benefit is limited to a certain biomarker-defined patient subgroup. In these situations, the clinical utility of the biomarker can be partially assessed in a trial with an enrichment


Fig. 60.3. Examples of designs for biomarker-based oncology clinical trials.
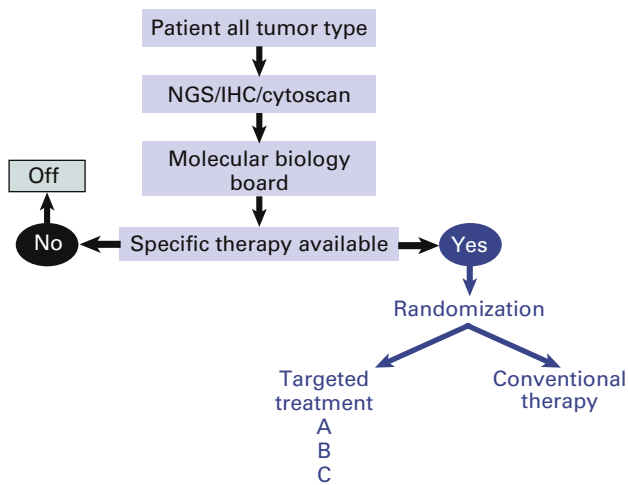

Fig. 60.4. Example of design for biomarker-based oncology clinical trials based on multigene-screening techniques. *IHC,* immunohistochemistry; *NGS,* next-generation sequencing.

design: the biomarker is evaluated in all patients, but random assignment is restricted to patients who have biomarker-positive tumors.

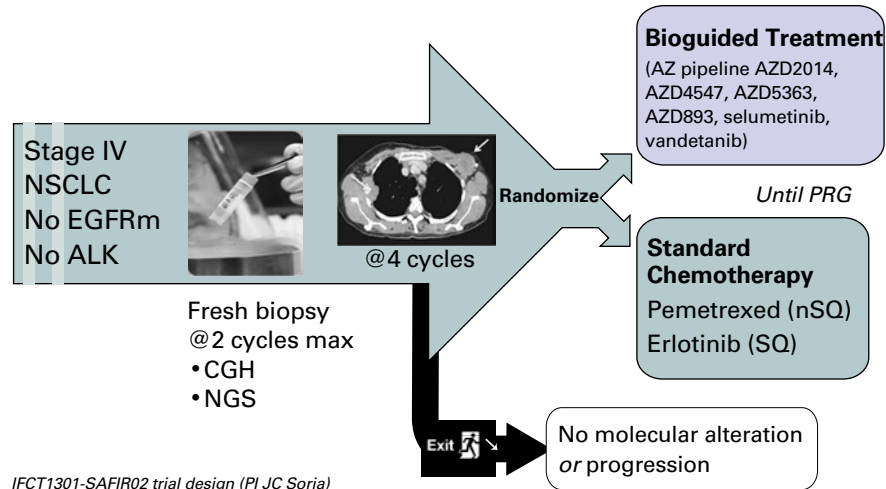
In the third type of trial, with a biomarker-strategy design, patients are randomly assigned to an experimental treatment arm in which the biomarker is used to determine therapy or to a control arm in which a biomarker is not used.

Because of the multiplicity of biomarkers and limited resources, some recent trials have been designed to analyze several targets and subsequently to test several dedicated drugs (Fig. 60.4). The main objectives of this type of trial are to determine the feasibility of such a wide molecular screening, the superiority of tailored treatment, and, in some cases, the effect of new drugs on selected targets. The first example of such a design is the Biomarker-integrated Approaches of Targeted Therapy for Lung Cancer Elimination (BATTLE) trial. Following an initial equal randomization period, patients with NSCLC that was refractory to chemotherapy were adaptively randomly assigned to treatment with erlotinib, vandetanib, erlotinib plus bexarotene, or sorafenib on the basis of relevant molecular biomarkers.[12] Following this trial, BATTLE-2 randomly assigned patients to erlotinib, erlotinib plus MK-2206, MK-2206 plus AZD6244, or sorafenib, stratified by Kirsten rat sarcoma (KRAS) status.[13] Other trials of the same type are currently being conducted in France and other countries. In the Molecular Screening for Cancer Treatment Optimization trial (initiated at Institut Gustave

Roussy in France), the molecular profile of patients with refractory cancer is determined using comparative genomic hybridization array and a panel of hot-spot mutations in 96 amplicons from a biopsy sample taken from a metastatic site.[14] Patients are enrolled into specific phase I trials according to the presence of a molecular abnormality. Each patient who is enrolled in the trial with a matched molecular-targeted agent is used as his or her own control for the evaluation of the efficacy of this approach. As another example, the SHIVA trial was a randomized proof-of-concept phase II trial in which therapy based on tumor molecular profiling was compared with conventional therapy in patients with refractory cancer. One hundred and ninety-five patients were randomly assigned to each arm, with a crossover at disease progression whenever possible. In the experimental arm, patients were treated with an approved molecularly targeted agent based on an actionable molecular abnormality. However, an actionable molecular abnormality might not be identified in every patient. In contrast to traditional randomized trials in oncology that are performed in a homogeneous population of patients with a specific type of tumor and in a specific setting, the goal of this trial was to look for heterogeneity in tumor types to establish the proof of concept of whether targeted agents should be developed according to their tumor molecular profile rather than according to tumor type.[15,16]

Similarly, the design just described now has been adapted to lung cancer with the SAFIR02 lung trial (Fig. 60.5). This open-label phase II randomized trial involves the use of high-throughput genome analysis as a therapeutic decision tool for patients with stage IV NSCLC that has not progressed after induction chemotherapy. The trial will compare a maintenance treatment administered according to the identified molecular anomaly of the lung tumor with a maintenance treatment administered without consideration of the tumor genome analysis; pemetrexed will be given to patients with nonsquamous cell carcinoma, and erlotinib will be given to patients with squamous cell carcinoma.

The Lung Master Protocol (Lung-MAP) trial is another study that was designed to test several targeted therapies for patients with advanced squamous cell lung cancer. The trial is a biomarker-driven phase II/III with multiple substudies that open and close independently. A common platform of next-generation DNA sequencing is used to identify a patient's actionable molecular abnormalities, and the patient is assigned to the investigational drug that targets the mutation or to a "nonmatch" substudy that consists of an immunotherapy or combination therapy.[17]

Lastly, another way to test several hypotheses in a clinical trial is to test a targeted drug in patients with several cancer types harboring the target. For example, the VE-BASKET trial tests the efficacy of vemurafenib (which is known to be efficient for the treatment of melanoma that harbors the BRAF V600E mutation)


IFCT1301-SAFIR02 trial design (PI JC Soria)

General design of the SAFIR02 lung randomized clinical trial. *ALK,* anaplastic lymphoma kinase gene; *CGH,* comparative genomic hybridization; *EGFRm,* epidermal growth factor receptor mutation; *NGS,* next-generation sequencing; *NSCLC,* nonsmall cell lung cancer; *nSQ,* nonsquamous cell carcinoma; *PRG,* progression; *SQ,* squamous cell carcinoma.

for the treatment of other solid tumors. This trial enrolls patients with histologically confirmed cancers or myelomas (excluding melanoma and papillary thyroid cancer) that harbor a BRAF V600 mutation and are refractory to standard therapy or for which standard or curative therapy does not exist.

New Designs: Mixing Avatar Models and Clinical Trials

Targeted therapies have demonstrated efficacy against specific subsets of molecularly defined cancers. Although most patients with lung cancer are stratified according to a single oncogenic driver, cancers harboring identical activating genetic mutations show large variations in their responses to the same targeted therapy.[6,18,19] The biology underlying this heterogeneity is not well understood, and the impact of coexisting genetic mutations, especially the loss of tumor suppressors, has not been fully explored. Chen et al.[20] used genetically engineered mouse models to conduct a so-called co-clinical trial that mirrors an ongoing human clinical trial in patients with KRAS-mutant lung cancers. The aim of this trial is to determine if the mitogen-activated protein kinase kinase (MEK) inhibitor selumetinib (AZD6244) increases the efficacy of docetaxel, a standard-of-care chemotherapy. The authors demonstrated that concomitant loss of either p53 (also known as TP53) or Lkb1 (also known as Stk11), two clinically relevant tumor suppressors, markedly impaired the response of KRAS-mutant cancers to docetaxel monotherapy. They observed that the addition of selumetinib provided substantial benefit for mice with lung cancer caused by KRAS and p53 mutations, but mice with KRAS and Lkb1 mutations had primary resistance to this combination therapy. These co-clinical results identified predictive genetic biomarkers that should be validated by interrogating samples from patients enrolled in the concurrent clinical trial. These studies also highlight the rationale for synchronous co-clinical trials, which is not only to anticipate the results of ongoing human clinical trials but also to generate clinically relevant hypotheses that can inform the analysis and design of human studies.

Cooperation and Networks

The issues described can be partially solved by organizing clinical research in a national and/or transnational way. Our ability to strengthen international collaborations will result in maximization of resources and the access of patients to clinical trials in oncology.

On the one hand, drug companies and clinical research organizations, which are mainly international companies, usually know how to use the various resources that are nationally or internationally available. Pending budget availability, these entities built the so-called ideal clinical and translational network needed to conduct a defined trial. The influence of clinicians, cooperative groups, and even national health authorities (except for the EMEA and FDA) on the study design is often limited.

On the other hand, academic clinical trials in oncology initially were mainly organized by local or regional centers. This organization responds first to the wishes of patients who want to be treated closer to home and second to the opportunity to easily have access to a clinical trial, as the distance from a physician's practice to the nearest clinical trial site is inversely associated with referral and recruitment.[21,22] Cooperation between centers is essential for the successful conception, funding, and performance of clinical trials in oncology. Consequently, national groups have been created to promote clinical and translational research. For example, in the United States, the National Cancer Institute (NCI) Clinical Trials Cooperative Group Program has served as the leading network for federally funded clinical research on cancer. In Asia and Europe, many countries have organized themselves according to the same model, with one or more cooperative groups involved in clinical trials focusing on lung cancer. In Europe, the European Organisation for Research and Treatment of Cancer Lung Cancer Study Group and the European Thoracic Oncology Platform are performing multinational clinical trials.

Regulatory, logistic, and financial hurdles, however, often hamper the conduct of joined trials. Working together should help researchers to overcome these barriers, with the International Association for the Study of Lung Cancer (IASLC) as a central link.

Worldwide Standardization of Oncology Clinical Trials Allowing Cross-Trial Comparisons

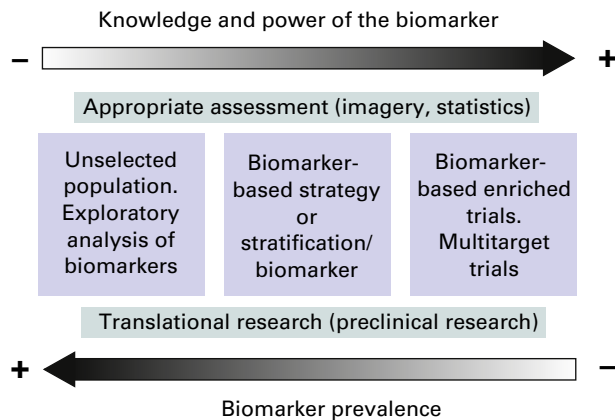
Besides rules regarding publication,[3,4] the issue of cross-trial comparison raises the problem of worldwide standardization of oncology clinical trials, and, more widely, clinical research in oncology. The best example in this field is the increasing number of biomarker-based prognostic and predictive studies aiming to define which subset of patients may actually benefit best from a specific drug or therapeutic strategy (Fig. 60.6). One of the major issues encountered in these studies is the reproducibility


Fig. 60.6. Illustration of the different strategies to include biomarkers in the design of oncology clinical trials.

of published results, that is, the stability of the biomarkers across different series of patients, across different geographic areas, and over time. Once the question of variability of molecular assays is fixed across different laboratories, an issue that is not trivial, limiting the confusion bias is a major step of the analysis. Multivariate analyses aim to control for stratification factors of the trial and for the confounding clinical or pathologic characteristics influencing survival in the univariate analysis at a given p value (<0.1 or <0.2, depending on the study). However, the strategy of such multivariate analyses is rarely comparable within multiple trials or series, often making such comparisons hazardous.

The next step is to check that the results obtained in one specific series of patients simply could not have been obtained by chance, taking into account possible variations across different series of patients, from various geographic origins, smokers or nonsmokers, chemo-naive or not, with varying sex ratios, performance status, or ages. The first step is actually to limit the risk of false-positive results by limiting the multiplicity of analyses performed within a single series of patients. The only way is to check, before any publication, that the power calculation was prespecified, with a fixed number of analyses planned, at the initiation of the study when the trial was registered in the ClinicalTrials.gov database. Otherwise, any retrospective study with unplanned analyses, no prespecified power calculation, or no prespecified multivariate analysis strategy should be considered as only hypothesis-generating and needing external and/or prospective validation. Accordingly, multiple sequential publications over the time of prognostic studies, within the same series of patients or the same clinical trial, should be discouraged if not preplanned in the initial statistical design, or, alternatively, should be externally validated in an independent new series of patients. The use of statistically recognized techniques such as Bonferroni, Holm, or Hochberg correction,[23] which are widely used for complementary DNA microarray analyses, also should be encouraged in oncology clinical trials with biomarker-driven multiple subgroup analyses. Such methods take into account not only the multiplicity of variables but also the number of sequential analyses performed during the period of follow-up and required in subset analyses.

The reproducibility of a molecular assay analysis needs to be addressed in independent series of patients studied by distinct research groups; however, these series, to the extent possible, should be comparable with the initial series in terms of all identified clinical and pathologic variables. This external validation mainly has been used in microarray studies of NSCLC specimens, as a complete lack of concordance across studies has been reported in the numerous gene signatures published to date and claimed to be of prognostic value.[24,25] In such replication studies,

hazard ratios for death or progression based on biomarker(s) are usually inferior to those of the initial study,[26] reflecting the variability of biomarker prognostic impact, driven by the patient characteristics in each series.

Lastly, a highly significant hazard ratio for death does not mean that a prognostic signature or biomarker will be of clinical utility, as it does not imply that the accuracy of the predictive biomarker is sufficient to justify its use in clinical practice. For instance, a molecular signature with a positive predictive value of 0.80, meaning that about one-fifth of the patients with poor prognosis signature will not die, does not accurately help to predict which patients will or will not die, and therefore modify therapeutic strategy. Such clinical utility could be approached with the highest level of evidence by prospective trials with an interaction design, in which all patients are stratified according to biomarker level and then are randomly assigned to one of two treatments.[27] Standardization of biomarker studies has been theorized with international guidelines already published by the Reporting Recommendations for Tumor Marker Prognostic Studies (REMARK) group, providing an opportunity for worldwide standardization.[28]

Regulatory Issues

The primary goal of all of our research is to provide patients with new and more efficient strategies as soon as possible. Strategies that are based on drugs require approval from national or multinational agencies, such as the FDA and EMEA and their equivalents worldwide. The agencies ensure that drugs work correctly and that their health benefits outweigh their known risks. In recent studies investigating the use of biomarker-guided therapies for stage IV NSCLC, the number of patients needed to demonstrate the benefits has been relatively low (100 patients to 200 patients).[6,7] However, what is the ideal number for assessing the risks? If frequent adverse events are usually identified in phase I/Ib trials, the assessment of rare (<1%) adverse events requires more patients, leading to more time for accrual, a longer interval before results are available, and a need for more funding. What is the best way to assess the most efficient balance between benefit (rapid access of patients to a new strategy) and risk (rare but potentially severe side effects)? In the United States, ASCO has worked with partners, including the FDA and NCI, and, at its 2013 annual meeting, provided an update on its initiatives to articulate the desired end points of clinical trials that will produce results that are clinically meaningful to patients.[1] ASCO also proposed recommendations to avoid unnecessary exclusion of patients from trials, worked with the FDA to streamline data collection, and advanced the development and use of end points that will allow clinical trials to demonstrate earlier safety and efficacy.[1] In Europe and Asia, the same work probably should be done by the national agencies and the EMEA.

Financial Issues

In the United States, as a result of budget cuts affecting the National Institutes of Health (NIH), approximately 750 fewer new patients were expected to be enrolled in all clinical trials at the NIH Clinical Center hospital (Bethesda, MD, USA) in 2013,[1] illustrating how the funding of clinical trials in oncology is crucial and should be ensured. In fact, many national or international sources of funding (NCI, Translational Cancer Research, FP7, etc.) are potentially available. However, the multiplicity of the sources, the specific restrictions or exigencies related to each call for proposals, and the administrative constraints when several countries or continents are involved can make the system inefficient. Sharing experiences and training clinicians (or even cooperative group leaders) should allow researchers to overcome these difficulties, with the IASLC serving as a possible network worldwide.

TABLE 60.1 Challenges and Solutions Related to Organization of Clinical Trials in Lung Cancer

	Challenges	Possible Solutions
Lung cancer	A mosaic of molecularly defined rare diseases	New designs eventually integrating avatar models to test several hypotheses simultaneously
Quick progress	Decrease the time between biologic discoveries and available drugs	
Hypotheses	Increasing number of hypotheses to be tested on the base of the molecular alterations	
Clinical trial costs	Increasing costs	Standardization of designs and analyses of oncology clinical trials and simplification of regulatory issues
Cooperation	National and international competitions with sometimes wasted resources	

In summary, a better organization of clinical trials in thoracic oncology will help to solve numerous issues (Table 60.1).

HOW TO PROMOTE CLINICAL TRIALS

Issues

Goal and Philosophy of Different Systems

Cancer care is variably organized worldwide. In some countries, almost all patients with cancer are treated in public hospitals, whereas in others, they are treated in a private system. In addition, the costs of care are covered by national health insurance, private insurance, or both, and the payment of health-care professionals and medical structures vary widely according to these different systems. Will financial issues influence participation of patients in clinical trials? In a cohort of patients with newly diagnosed lung and colorectal cancer in the United States, the type of health insurance and whether a physician practiced at an NCI-designated cancer center or received increased income from trial enrollment were factors that were independently associated with trial enrollment.[29]

Moreover, medical structures in which financial resources are linked to the number of patients treated and the number of treatments administered may lead to reluctance to send patients to another center to participate in a clinical trial. Where applicable, a solution should be proposed to compensate these medical structures (academic network, financial compensation, etc.).

Therefore we must rethink how our systems are valorizing clinician involvement and patient participation in clinical trials to give patients the same chance to be enrolled in a clinical trial.

Increasing Difficulty of Conducting Clinical Trials

Basic regulatory requirements for conducting clinical trials are based on the Declaration of Helsinki and Good Clinical Practices. However, a major issue in achieving high-quality clinical research in thoracic oncology is to increase the level of professionalization of all health-care professionals and cancer centers.

In the end, one important remaining point is how to select centers for clinical trials.[30] Although the selection is partially based on the expected quality of the team, it is mostly based on the ability of the team to quickly include many consecutive patients, a goal that may be at odds with quality and the respect for inclusion criteria or research basic rules, especially in terms of the collection of adverse events. For example, an analysis of more than 300 randomized controlled trials indicated that the methodology for the collection of adverse events was adequately reported in only 10% of the studies.[31] In addition, clinical research organizations and sponsors also consider the aura of the principal investigator and his or her regional or national influence to meet clinical research excellence, but with no absolute guarantee.

Time and Effort

Both time and effort are required to organize centers and to enroll and treat patients in clinical trials. The income provided by industry-sponsored trials may be the compensation for these efforts, but that is not always the case for academic-sponsored trials. Nonetheless, public encouragement and efforts for funding and structuring professional clinical research also should include financial compensation for the medical time. Similarly, universities should promote such time-consuming activity; for instance, the number of annual inclusions in clinical trials could be monitored and credited to the departments and investigators responsible for such activity, either by directly refunding their structures or research staff or by taking into account such activity for continuing medical education credit or university/hospital career advancement. However, strict and clear rules with transparency should be applied to ensure that public hospital means are not used for private interest without any control but rather are used to provide broader access to innovative drugs for the largest population.

Patient Education

Several studies have evaluated the factors related to patient participation in clinical trials. While older age is associated with a lower rate of participation in clinical trials in oncology,[32] this association seems to be mostly related to the eligibility for trials. However, among eligible patients, the rate of participation among older patients is similar to that among younger patients.[33] Moreover, the impact of ethnic or racial minority status and socioeconomic characteristics on enrollment in clinical trials is debated. If the rate of participation in clinical trials in oncology is indeed lower among ethnic/racial minority populations,[32] this relationship is not significant when adjusted for socioeconomic characteristics.[34] Conversely, a low income level negatively influences the rate of participation in clinical trials in oncology.[35]

Lastly, many patients, especially in populations with a low socioeconomic status, may misunderstand trial information,[36] mainly because of less discussion of the purpose and risks associated with the trials.[37] In the same way, family members are also important, as family members in some ethnic/racial populations frequently argue against trial participation.[36]

Possible Solutions

Train Physicians Early and Continuously

The values, beliefs, and awareness of clinical trials among oncologists play an important role in the accrual of patients for clinical trials.[38] Therefore the initial training of medical students, as well as the continuous training of physicians, is important. The type of training probably should be adapted to the various specialties, as, for example, it has been suggested that medical oncologists are more likely than surgical or radiation oncologists to discuss the possibility, benefits, and risks of clinical trial enrollment with their patients.[22]

Therefore specific academic training should be offered to all clinicians (e.g., with use of e-learning) under the supervision of health agencies, universities, or collaborative groups. Several tools are already available, usually at a national level, but also

TABLE 60.2 Challenges and Solutions Related to Promotion of Clinical Trials in Lung Cancer

	Challenges	Possible Solutions
Public versus private systems	Reluctance to propose clinical trials or to send patients to dedicated centers	Better valorization of direct or indirect participation in clinical trials for clinicians
Time consumption	Proposal of and participation in clinical trials are time-consuming	Better financial and nonfinancial (career, etc.) valorization
Difficulties in conducting clinical trials	Increasing level of exigency from sponsors	Professionalization of cancer centers for clinical research. Train physicians and health-care professionals
Population and patient views of clinical trials	Low participation in clinical trials (fear, low comprehension of risks, underestimation of benefits)	Education and development of multimedia resources for trial information

through the Web. Interestingly, several drug companies joined efforts to develop a common tool including a Good Clinical Practices training of investigators. Therefore the same certificate will be valid for several trials across different drug companies.

Educate the General Population and Patients With Lung Cancer About Clinical Trials

Mancini et al.[39] reported that 43.0% of patients with breast cancer expressed mild regret and 25.8% expressed moderate to strong regret after participating in a clinical trial. A quarter of these women (25.6%) said that the doctor made the decision alone, and 13.5% said that the decision was not consistent with their own wishes. An involuntarily passive role in decision making was found to be associated with greater regret.[39] Therefore educating and informing patients are of primary importance to increase their active participation in clinical trials in oncology. Indeed, when patients feel greater self-efficacy and have more knowledge, they feel more prepared to make the decision to participate in a clinical trial. A reduced decisional conflict is also associated with the decision to enroll in a clinical trial.[40]

On a patient level, multimedia resources (audiovisual, Web, etc.) may enhance the delivery and acceptance of information regarding clinical trials.[41–44] These resources are an important source of information that also help to educate families and to enhance the communication between patients and their health-care providers.[45]

On a larger level, business-model approaches and marketing techniques might be used.[46] Many national public or nonprofit organizations as well as drug companies have developed information tools. For example, the Center for Information and Study on Clinical Research Participation is a nonprofit organization dedicated to educating and informing the public, patients, medical and research communities, the media, and policymakers about clinical research and the role that each party plays in the process (www.ciscrp.org/patient).

Simplify Regulation

The various national cancer institutes and their equivalents worldwide, such as the NCI in the United States or the NCI in France (INCa), have used several strategies, which are used directly or indirectly, to harmonize the available resources and the opportunities offered to patients with cancer regarding clinical trials. These resources include molecular testing and labeled units for trials, to support and funding of research programs.[47–49]

Concomitantly, support should be offered to patients to travel to the specific centers where clinical trials are available. Such support is already provided in many industry-sponsored trials, but it should also be organized for academic-sponsored clinical trials.

In summary, better promotion of clinical trials will resolve many issues (Table 60.2).

CONCLUSION

Although participation in clinical trials provides patients with new therapeutic opportunities and helps physicians to implement new techniques, the number of patients with lung cancer who participate in clinical trials remains too low. The barriers are multiple, with some problems to be solved globally through a worldwide approach and others to be solved locally with the IASLC as a possible network to provide help.

61   The Role of Advocacy Groups in Lung Cancer

Glenda Colburn, Selma Schimmel[†], and Jesme Fox

SUMMARY OF KEY POINTS

- To describe the functions of advocacy.
- To describe how lung cancer advocacy groups accomplish their goals.
- To describe how they can influence lung cancer outcomes.

Advocacy is defined as the act or process of supporting a cause or proposal. Effective advocates in the health-care field influence disease awareness and education, research and drug development, public policy, and legislative and governmental issues. Cancer advocates have become an instrumental and influential force on behalf of cancer care.

Cancer advocacy is rooted in the early work of the breast cancer movement in the United States beginning in the 1970s. The political and social activism of the HIV/AIDS movement during the 1980s and 1990s further influenced US breast cancer advocacy. Foundations and charitable organizations emerged to fund efforts on behalf of breast cancer information, education, emotional support, and research. Media played an essential role, and with an engaged public, policymakers and decision makers were paying attention to the vision and demands of the breast cancer advocacy community,[1] which eventually led the way for advocacy efforts for other disease types. The common goals of cancer advocates include raising awareness and education; ensuring patient access to screening, diagnosis, and treatment; stimulating research and clinical trials; addressing the psychosocial and emotional issues associated with cancer; and empowering individuals to gain control of their disease. Advocates are directly responsible for challenging public perceptions, stigma, and disease identity; they can influence and shape research and policy agendas.

Today, in many parts of the world, cancer advocates work in conjunction with medical experts, political leaders, the pharmaceutical and biotech industries, corporations, and government and legislative representatives. Each country and region of the world presents unique issues for advocates that are based on culture, society, economics, and existing governmental and health policy infrastructures. Global patient advocacy must tailor its tactics and activities to meet and respond to these needs.

LUNG CANCER ADVOCACY GROUPS

In 2001, a global search revealed the existence of only nine not-for-profit organizations with an interest in lung cancer advocacy. Of these, only two were lung cancer specific; the others were representing generic cancer or respiratory diseases. In coming together, these organizations established the Global Lung Cancer Coalition (GLCC), an allied group of registered not-for-profit, nongovernment organizations dedicated to improving lung cancer outcomes. By 2016, the GLCC had grown to 35 member organizations, from 25 countries, and now provides a centralized referral network to these organizations within its website. Lung Cancer Europe is a relatively new coalition, which provides a European platform for already existing lung cancer patient advocacy groups and supports the establishment of new national groups in European countries, where they do not currently exist. More information is available at http://www.lungcancereurope.eu. There are also additional lung cancer advocacy groups in the United States, and there may well be others across the world advocating in this disease.

CHALLENGES IN LUNG CANCER ADVOCACY

Despite the recent formation of several advocacy groups in lung cancer, the number of these groups is still low. Lung cancer advocacy is most developed in North America, Australia, and the European Union, in particular, the United Kingdom. We see small groups emerging elsewhere in the world, even though in Eastern Europe national lung cancer organizations are not common. As with other health-related agendas, sustaining and building advocacy groups is a challenge. Negative issues associated with lung cancer, such as those described in the following section, make it particularly difficult to advocate for change and improvement.

Lack of Advocates

Individuals who advocate for a particular disease tend to be directly affected by the disease, such as patients and caregivers. Sadly, few people with lung cancer are well enough or survive long enough to become advocates. Lung cancer is the number 1 cancer claiming more lives than any other cancer in the world and has a less than 17% 5-year survival rate. An additional issue is that compared with other common cancers, there are relatively few high-profile celebrity supporters of this disease. As such, there are relatively few lung cancer voices championing the cause.

Stigma Surrounding the Association With Tobacco

Lung cancer is often seen as self-inflicted because of its association with tobacco. An Ipsos MORI consumer poll, commissioned by the GLCC in 2011,[2] showed that, although there was national variation across the 15 countries surveyed, on average, 20% of people felt less sympathy for people with lung cancer than for people with other common cancers (Fig. 61.1). The national variation was 10% to 29%.

People with lung cancer have reported higher levels of perceived cancer-related stigma compared with people with breast or prostate cancer.[3] The belief that one has caused one's own cancer has been correlated with higher levels of guilt, shame, anxiety, and depression.[3] The stigma caused by a tobacco-related disease can create hardship for patients, many of whom suffer in silence and isolation and feel a sense of hopelessness and helplessness about their condition.[3] In fact, irrespective of whether people with lung cancer smoked or have never smoked, they feel stigmatized because of the tobacco association.[4–6]

[†]Deceased.

635

Lung cancer is mainly caused by smoking cigarettes and other tobacco products. Bearing this in mind, to what extent do you agree or disagree with the following statement…

I have less sympathy for people with lung cancer than people with other types of cancer

	Agree (%)	Base
Australia	29	1200
Brazil	28	1000
Great Britain	24	1000
Slovenia	23	1039
Canada	22	1000
USA	22	1000
Japan	20	1272
The Netherlands	18	1004
Norway	17	1000
Denmark	17	1000
Italy	16	1026
Sweden	16	1000
Switzerland	16	1008
Spain	14	1005
Argentina	10	1000
Fig. 61.1. Results of Global Lung Cancer Coalition/Ipsos MORI consumer poll (2011) to evaluate sympathy for people with lung cancer compared with other types of cancer.

The stigma and blame associated with lung cancer are also a contributing factor to late presentation.[7–9] Stigmatization has a negative impact on the disease and on advocacy initiatives. Central to the lung cancer advocacy community is its focus on reducing the stigma associated with this disease because it can profoundly affect not only patients in their personal identity, social life, and economic opportunities, but also their families. Many diseases are lifestyle related, yet the patients are not affected in this way. It is important that messages such as "no one deserves lung cancer" and "smoker, former smoker, or never-smoker—anyone can get lung cancer" are widely disseminated.

Low Public Profile

Because of poor outcomes overall, a lack of advocates, and a relative lack of celebrity supporters, engaging the media in lung cancer has been challenging. Journalists in many countries consider lung cancer to be depressing and so have been reluctant to report on lung cancer issues. In addition, there is a reluctance from those living with lung cancer to speak out, given the stigma and fear of self and community blame.

LUNG CANCER ADVOCACY GROUP ACTIVITY

All organizations engaging in lung cancer advocacy are different and respond to the particular culture and need of their regions or countries. However, they campaign for some or all of the following.

Integrated Tobacco Control Programs

Many lung cancer advocacy groups have an interest in disease prevention and campaign for the development and implementation of antitobacco strategies. These strategies include smoking cessation services; legislation, where necessary (e.g., to ban smoking in enclosed public places, point-of-sales advertising, cigarette vending machines, and to ensure plain packaging for cigarette packs); educational programs in schools; and public awareness campaigns, all of which underscore the importance of not smoking and the value of quitting.

Increased Funding for Lung Cancer Research

Globally, lung cancer is the most common cancer. Yet, compared with other common cancers, there has been relatively little investment in lung cancer research. The GLCC has commissioned the Institute of Cancer Policy to undertake a review of "The State of Global Lung Cancer Research."[10] As many as 32,000 published lung cancer research articles were examined, from 2085 different journals. Of these, only 5.6% of all global cancer research was in lung cancer (2013), an increase of only 1.2% since 2004. As many as 24 countries were found to be responsible for more than 95% of lung cancer research outputs. Individual country reports are available at http://www.lungcancercoalition.org. The majority of lung cancer research (53%) is focused on medicines, genetics, and biomarkers, with only 1% on supportive and palliative care issues.

In 2013, the National Cancer Research Institute reported that only 6.7% of cancer site-specific spending in the United Kingdom was on lung cancer (charities and government).[11] Although this rate represents an increase from the 3.9% spent on lung cancer in 2006, the rate is still poor despite the fact that lung cancer accounts for more than 20% of cancer deaths in the United Kingdom annually.

In 2015, Cancer Australia reported that only 5% of cancer site-specific spending in Australia was on lung cancer (charities and government).[12] Total funding to lung cancer research (including pleural mesothelioma) decreased from 2006–2008 to 2009–2011 and showed that the proportional funding to lung cancer research was very low compared with incidence, mortality, and burden of disease on the Australian population. Lung cancer accounts for 19% of cancer deaths in Australia annually.

Campaigning to increase investments in lung cancer research is a core function of lung cancer advocacy. Many lung cancer advocacy groups are also funders of research, working in conjunction with scientists and clinicians to build research capacity in the lung cancer community to ensure better future outcomes.

Increased Number of People With Lung Cancer Enrolled in Clinical Trials

Unless a person with lung cancer is being treated at a center that participates in clinical trials relevant to his or her disease, it can be very difficult to access clinical trials or even be aware of them. Many advocacy groups play a key role in this area, both in raising awareness of clinical trials in general and in directing people with lung cancer to appropriate trials and trial sites. Some advocacy groups have included links to clinical trial databases from their websites to make it easier for people with lung cancer to find appropriate trials; the lack of a national service that can provide adequate and updated information is a barrier for people who wish to participate in clinical trials. The GLCC has also collated links to websites in various countries, where details on clinical trials are available.[13]

Earlier Diagnosis

Diagnosing more people with lung cancer at an early stage, when curative treatments are an option, can save lives. In recent years, there has been increased focus on lung cancer screening. In countries where lung cancer screening is available, advocates

are directing high-risk individuals to these services. Advocates are also calling for further research to evaluate the benefit of screening tools.

Raising general public awareness of the signs and symptoms associated with lung cancer is a key function of many lung cancer advocacy groups; however, there is a variety of associated signs and symptoms, so this can be a difficult task. In England, the Department of Health, in 2012, funded the national "Be Clear on Cancer—Lung Cancer" campaign.[14] This campaign, focusing on persistent cough, and results from the pilot study noted a 22% increase in the number of patients who visited their general practitioner with relevant symptoms and also noted an increase in chest computed tomography scans being performed. This campaign was repeated in 2013 and in 2014. Results of the 2012 campaign showed that an extra 700 diagnoses were made (9% higher than same period in 2011) and around 400 patients were picked up in early stage (300 of whom were offered surgery).[15] Using nationally agreed-upon guidelines, advocacy groups have produced community information such as the GLCC awareness-raising leaflets, which are translated into 13 languages and available for download.[16]

Equitable Access to Best-Practices Treatment and Care

Ensuring equitable access to the best care is of ever-increasing importance in lung cancer advocacy because of current global financial issues, pressures on health services budgets, and the rising cost of new diagnostics and therapies. It is the advocate's ultimate goal that all people with lung cancer will be treated within nationally agreed-upon treatment guidelines, that they will be offered high-quality support and information, and that they will have access to up-to-date, evidence-based diagnostics and therapies. Across regions and countries of the world, realistic expectations vary. However, using the Internet and social media, people with lung cancer are able to learn about available lung cancer treatments and technologies, but may not be able to access them, which may result in considerable distress.

The production of patient-focused information materials on all aspects of lung cancer diagnosis, treatment, and care is a core function of most advocacy groups. Such information ensures that patients and their families have a better understanding of their disease and are better equipped to make informed decisions about care. Some advocacy groups have positioned themselves as an extension to the health-care system and a supportive care service for patients and caregivers whilst away from their treating centers. Information can be delivered in many formats, such as print, the Web, DVD, and other new media formats. A challenge for all patient information providers is to ensure that these materials are current, evidence based, and easily accessible.

In recent years, financial pressures across the globe have resulted in health-care providers undertaking formal health technology assessments, particularly in the area of new developments, including targeted therapies and immunotherapies. Cancer advocacy groups play a substantial role in making sure that national health technology assessment bodies understand the importance of segmented populations, biomarkers, and issues of study crossover. In this new research area, in particular in the United States, cancer advocacy groups have taken on a key role in tissue banking and molecular testing; the National Lung Cancer Partnership has collaborated with 14 top cancer centers to form the Lung Cancer Mutation Consortium, which is the largest effort to date to promote molecular testing for people with lung cancer. Elsewhere, groups are raising awareness of new lung cancer diagnostics, evidence-based clinical pathways, and campaigning for widely available pathology services.

High-Quality Data

Underpinning all issues is the need for advocates to access high-quality, timely data on survival, quality of life, and patient experience. Such data not only provide a benchmark for the quality and outcomes of lung cancer services, but also give advocates a tool with which they can campaign for improvement and showcase best practices. A good example of this is the work of the International Cancer Benchmarking Partnership,[17] which has shown a huge variation in 1-year and 5-year survival rates in lung cancer across the study countries, prompting health-care policymakers to investigate reasons for these differences.

In November 2015, the GLCC launched a global interactive lung cancer altas,[18] allowing clinicians and advocates to easily source and compare lung cancer data from every World Health Organization (WHO) country. Data available include mortality, incidence, survival, and other country-specific data on cancer registry, cancer planning, and implementation of the WHO Framework Convention on Tobacco Control.

An important national initiative is the United Kingdom's National Lung Cancer Audit.[19] Year after year, this audit has shown improvement in areas such as the rate of surgical resection. These audit data have been extensively used by advocacy groups in the United Kingdom, as in the Web-based Smart Map,[20] which displays the data in a patient-friendly, easily accessible format. Elsewhere, a European Respiratory Society taskforce has completed a feasibility study regarding the prospective collection of clinical data for people with lung cancer in 27 European countries. Their hope is that a Pan-European database of people with lung cancer can soon be a reality.

Help for People With Lung Cancer and Their Families

Living with the disease, the diagnosis, and treatment of cancer are traumatic events for people with cancer and their loved ones. It can be a time of a great emotional distress and can evoke a wide range of emotions. The expression of these feelings is crucial in order to cope with a diagnosis of cancer and side effects from treatment; emotional support, physical care, and practical help may be of benefit to both patients and their families.

LUNG CANCER ADVOCACY STRATEGIES

In their efforts to achieve these outcomes, advocacy groups use a variety of strategies.

Use of Mass Media, Including New Social Media

Advocacy groups are increasingly using mass media in facilitating community education and building awareness about lung cancer and its impact. Social media outlets such as Facebook allow a cost-effective broader reach into the community and for those who have been touched by lung cancer to share the messages within their networks. This form of media plays a significant role in forming and influencing people's attitudes and behavior. Common use of lung cancer-themed hashtags and approaches are becoming more visible. New technologies within social media platforms such as Thunderclaps allow advocates to amplify the message with the power of crowdsourcing and help people be heard by saying something together.

Public Awareness Campaigns

A main focus of the lung cancer advocacy community has been the November "Lung Cancer Awareness Month" initiative, initially developed in the United States by the Alliance for Lung Cancer Advocacy, Support and Education

(now the Lung Cancer Alliance), and adopted by the global community in 2002. A cross-country initiative, "Shine a Light on Lung Cancer," is the largest coordinated awareness event in the world, with more than 125 vigils in the United States, 30 events in Australia, and additional vigils held in Brazil, Egypt, New Zealand, and Poland (http://www.shinealightonlungcancer.org). The purpose of each vigil is to build the lung cancer community, and each year more voices are added to this movement.

There are many methods of raising awareness of lung cancer, including public meetings and petitions, position statements, advertising, and mass publication of informational leaflets. The West Japan Oncology Group, for example, has hosted 25 public lectures in 11 cities across Japan between 2001 and 2012. These lectures on lung cancer have attracted more than 11,000 attendees, consisting of people with lung cancer (29%), their families (34%), and others. The format of the meetings has included a lecture from a key specialist on a topic (e.g., epidemiology, diagnosis, pathology, or treatment), testimony from a lung cancer survivor, and a question-and-answer period. The lectures have also gained public awareness through articles in local and national newspapers, with articles published in 89 million printed newspapers. A key product of this initiative is the creation of a guidebook for people with lung cancer.

Political Lobbying

In the United States, political lobbying by the Lung Cancer Alliance, including campaigning for legislative change and print/Web efforts to harness public opinion, has led to a $68.5 million congressional authorization for lung cancer research by the Department of Defense.[21]

Informing and Influencing Health Services Providers

Advocacy groups can play a large part in influencing health services workers to provide better care to their patients with lung cancer. Lung Foundation Australia has campaigned to support lung cancer specialist nurses in Australia, and in the United Kingdom, the Roy Castle Lung Cancer Foundation and the National Forum for Lung Cancer Nurses have developed a report on the value of lung cancer nurses.[22]

People with lung cancer who seek emotional and/or practical support from cancer organizations geared toward people with the disease may find psychologic support and programs specifically designed with the aim to help alleviate emotional distress for them and their families. Advocacy groups lead in the formation and conduct of lung cancer patient support groups, which include face-to-face and telephone formats. Other programs may include webinars, mindfulness classes, make-up sessions for women receiving treatment, relaxation technique sessions, cooking classes, and art and music therapy.

CONCLUSION

Despite recent advances, lung cancer remains a devastating disease for many people and is still characterized by much negativity and poor outcomes. Advocacy groups have much to offer in changing this picture, particularly in light of recent advances in screening for the early detection of lung cancer. There is increasing hope that more survivors will produce more advocates and a stronger global voice in this disease.

With the current research focus on biomarkers and immune therapy in lung cancer, it is clear that, over the next few years, lung cancer will be a disease of interest in the development of targeted therapy and immunotherapy treatments.

Educating patients about genomics therefore represents a new advocacy task. In addition to the direct benefits of new therapy options, this will likely mean more people with lung cancer in clinical trials, more clinicians engaged in lung cancer research, and a higher profile for the disease in general. The challenge for lung cancer advocates will be to ensure that these benefits are realized. Advocates, however, cannot make a difference in isolation. Working with scientists and health-care professionals at the local, national, and international level is much more effective and will result in a focus on local priorities. At a global level, the International Association for the Study of Lung Cancer has engaged with the advocacy movement through representation on key committees and at professional meetings. Closer collaboration can only be beneficial when working toward better future outcomes for those affected by this disease.

62 | The Role of Health Services Research in Improving the Outcomes for Patients With Lung Cancer

William J. Mackillop, Shalini K. Vinod, and Yolande Lievens

SUMMARY OF KEY POINTS

- Health services research aims to improve the outcomes to treatment for lung cancer by optimizing the accessibility, quality, and efficiency of treatment programs.
- Achieving optimal outcomes for patients with lung cancer requires that every patient should receive optimal treatment, but many patients today do not receive optimal treatment or experience optimal outcomes.
- Deviations from optimal treatment may be due to resource limitations that compromise the accessibility of treatment, to errors in clinical decision-making, or to flaws in the implementation of treatment decisions.
- Delay in the diagnosis and treatment of lung cancer is widespread. Setting standards and streamlining referral processes may reduce waiting times, but these strategies only work if there are adequate resources available to provide the necessary care.
- Lack of treatment resources may be the inevitable consequence of the low levels of funding available in low- and middle-income countries, but it also may be due to poor planning in high-income countries.
- Multidisciplinary team (MDT) management improves the quality of care for patients with lung cancer and probably improves outcomes.
- Practice guidelines improve clinical decision-making, but one size does not fit all. Patients' values and preferences must be factored into treatment decisions. Decision aids can help patients to participate in decisions about their care.
- The outcomes of surgery for lung cancer are better at high-volume centers. The same is probably true of radiotherapy. Centralizing treatment services may improve overall outcomes, if this can be achieved without compromising access to care.

Health research may be considered as a continuum of four overlapping domains: basic or biomedical research, clinical research, health services research, and population health research. Health services research is defined as a "multidisciplinary field of scientific investigation that studies how social factors, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately, our health and well-being."[1] Clinical research and health services research overlap to some degree, but their purposes are distinct. Clinical research is primarily intended to guide decisions of physicians about the care of individual patients, whereas health services research is intended to guide the decisions of managers and policymakers about the design and implementation of health-care programs.[2]

HOW CAN HEALTH SERVICES RESEARCH IMPROVE THE OUTCOMES FOR PATIENTS WITH LUNG CANCER?

At any point in time, the state of knowledge and the state of technology set an upper limit on what is achievable for patients with cancer. However, what is actually achieved depends not only on what would be achievable with optimal care but also on how close we come to delivering optimal care, a quantity that has been termed the attainment factor.[2] This relationship can be expressed with the following equation.

$$\text{Achieved outcome} = \text{Achievable outcome} \times \text{Attainment factor}$$

Thus, outcomes can be improved by increasing the achievable outcome through innovation or by increasing the attainment factor through the optimization of health-care systems. The goal of biomedical and clinical research is to improve outcomes through innovation, whereas the goal of health services research is to improve outcomes through the optimization of health system performance. Innovation and optimization are complementary rather than competitive activities. Innovative biomedical and clinical research both have the potential to improve outcomes greatly in the long term, but health services research may offer the best opportunity of improving outcomes in the short term.[3] The optimal balance of expenditure between innovation and optimization is unknown. However, in the case of diseases such as lung cancer, for which innovative biomedical and clinical research has been slow to yield real improvements in outcome, it is important to put a high priority on health services research in order to achieve the maximum societal benefits from existing treatments.

THE THREE DIMENSIONS OF HEALTH SYSTEM PERFORMANCE

Health system performance may be characterized in three different dimensions: accessibility, quality, and efficiency.[2] Accessibility describes the extent to which patients are able to get the care they need when they need it. Quality describes the extent to which the right care is delivered in the right way. Efficiency describes the extent to which accessibility and effectiveness are optimized in relation to the resources expended. Each of these dimensions of health system performance must be optimized in order to achieve optimal outcomes. Health services research is concerned with measuring access, quality, and efficiency; understanding the factors that influence them; and discovering ways to enhance them. The three dimensions of health system performance are clearly not independent of one another. For example, interventions aimed at enhancing quality have the potential to adversely affect accessibility and/ or efficiency. It is therefore unwise to focus on one dimension of health system performance without at least keeping an eye on what is happening in the other two dimensions.

Health-Care Accessibility

The term health-care accessibility originally was used narrowly to describe the ability of patients to obtain entry into the health system.[4] Today, it is used more broadly to encompass all of the factors that influence the level of use of a health service in relation to the level of need for the service in a population.[5] The concept of access has been described as representing the overall "degree of fit between the clients and the system."[6] Several factors have been shown to influence the overall degree of fit.[6] Availability describes the volume and type of services available in relation to the number of patients and their needs. Spatial accessibility describes the relationship between the location of supply of service and the location of the patients who need the service, taking into account travel times and costs.[6] Accommodation describes the extent to which the system is designed to facilitate patient access to service, for example, by operating at convenient hours or by providing lodging for those who require treatment that is only available far from their homes.[6] Affordability describes the relationship between prices and the ability of patients to pay. It also encompasses indirect costs, for example, loss of earnings during treatment that may deter use of the service.[6] Awareness describes the extent to which those who need the service are aware that it is available and that they might benefit from it.[2]

Quality in Health Care

Almost half a century ago, Donabedian[7,8] defined the quality of health care as "a property of, and a judgement upon, some definable unit of health care, and that care is divisible into at least two parts: technical and interpersonal." The quality of technical care is measured by the extent to which "the application of medical science and technology maximizes its health benefits without correspondingly increasing its risks." The quality of interpersonal care is measured by "how well the physician–patient interaction meets the socially defined norms of the relationship." Today, the Institute of Medicine describes health-care quality as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[9]

Donabedian[8] also provided a framework for evaluating the quality of health care in terms of structure, process, and outcome. The term structure is defined broadly to include facilities, equipment, personnel, and organizational structures. The term process includes both the type of care that is delivered and the way in which it is delivered. The term outcome refers to the consequences of the care that has been provided. Donabedian reasoned that optimal process is necessary for optimal outcome; that adequate structure is necessary, although not sufficient, for optimal process; and that outcomes may be enhanced by identifying and correcting deficiencies in structure and/or process.

Efficiency in Health Care

The resources available for health services are always limited, even in high-income nations. What is achievable in terms of cancer control depends on the total health-care budget, on how much of that total budget is directed to cancer care, and on how efficiently the available resources are used in providing cancer care. Efficiency measures whether we are getting the best value for money from the available health-care resources. Inefficiency is said to be present when using those resources in a different way would provide greater health benefits.[10] Health economists distinguish between technical efficiency, productive efficiency, and allocative efficiency. As stated by Palmer and Torgerson,[11] "technical efficiency addresses the issue of using given resources to maximum advantage; productive efficiency of choosing different combinations of resources to achieve the maximum health benefit for a given cost; and allocative efficiency of achieving the right mixture of healthcare programs to maximize the health of society." Methods for measuring each of these quantities are well established[12] and have been used to address some important issues in the treatment of lung cancer, but the sphere of health economics is beyond the scope of this chapter and therefore we will not deal with it in detail here.

In this chapter, we will review the results of research studies that have sought to optimize the accessibility and quality of programs of care for patients with lung cancer. This work involves identifying barriers to optimal care as well as designing and evaluating interventions to overcome those barriers. However, before one can identify deviations from optimal health system performance, one must first identify appropriate indicators of performance and establish standards of performance with respect to those indicators. We will therefore begin by reviewing the prescriptive research that has been undertaken to establish standards of care for patients with lung cancer. We will distinguish between standards of care for the individual patient and standards for the operation of the health programs that are required to deliver care to a population of patients. Standards of care for the individual patient should be based, whenever possible, on the results of randomized clinical trials that directly compare the outcomes of alternative forms of treatment. Likewise, standards for the operation of health programs should be based on the results of randomized trials that directly compare the effectiveness of alternative approaches to health-care delivery or at least on the results of well-controlled observational studies. However, we will show that the empirical evidence that underpins program standards today is usually much weaker than the evidence that supports guidelines for the care of the individual patient.

STANDARDS FOR THE CARE OF INDIVIDUAL PATIENTS

For more than half a century, treatment guidelines for the management of specific clinical problems have been widely used to guide clinical decision-making.[13] In the past, guidelines were based largely on expert opinion, but it is now generally accepted that practice guidelines must be based on a thorough evaluation of all relevant evidence. This concept is the essence of evidence-based medical practice, defined by Sackett et al.[14] as "the conscientious, explicit and judicious use of current best evidence in making decisions about the care of the individual patient." Sackett et al.[15,16] also provided a useful system for the classification of the types of clinical evidence that may be available and rules for their use in creating guidelines. The Institute of Medicine (IOM) has defined practice guidelines as "systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances."[17]

Given the importance of practice guidelines, many individuals and agencies have sought to give direction on how to create them. The Cochrane Collaboration has been instrumental in promoting systematic reviews of the medical literature. The Collaboration provides guidance for undertaking the systematic reviews necessary to identify all of the relevant evidence, for evaluating the quality of the evidence, and for synthesizing the evidence through meta-analysis.[18,19] The IOM monograph entitled Clinical Practice Guidelines We Can Trust examines the current state of clinical practice guidelines and provides guidance on how to improve them.[20] Recognizing the societal importance of practice guidelines, government agencies have also played a role in this activity, and there also have been international efforts to optimize and harmonize the process of guidelines development.[21]

Guidelines for the Care of Individual Patients With Lung Cancer

Guidelines for the treatment of lung cancer have been developed by many different agencies and organizations around the world, including specialty societies such as the American Society of Clinical Oncology (ASCO),[22] the European Society for Medical Oncology,[23,24] the American College of Chest Physicians,[25] and the American Society for Radiation Oncology;[26] groups of health-care institutions such as the National Comprehensive Cancer Network (NCCN) in the United States;[27,28] and government agencies such as the National Institute for Health and Care Excellence in the United Kingdom,[29] Cancer Care Ontario in Canada,[30] and the Cancer Council Australia.[31] Some of these agencies attempt to provide comprehensive guidelines that cover the entire spectrum of possible presentations of the disease,[23–25,27,29,30] whereas others have focused on providing detailed guidelines for management in specific clinical contexts.[22,26,30,31] Most guidelines are written primarily for the use of physicians, but some agencies also provide a version that targets patients directly.[28] It is recognized that practice guidelines that are created in one country may not be applicable in other societies with very different resources and/or different populations of patients. The NCCN, an alliance of 23 major cancer centers in the United States, is now endeavoring to provide international adaptations and translations of its guidelines to make them suitable for use in countries with different levels of economic development.[32] Nonetheless, it is probably preferable for each society to develop its own guidelines. Repeating work that has already been done elsewhere may seem to be a waste of resources, but the process of guideline development is important in its own right and may have as much normative effect on practice as the guideline itself.[33]

Challenges to the Development and Application of Practice Guidelines

Variation in patient values and the biologic heterogeneity of tumors pose particular challenges for the creation and application of treatment guidelines.

Variation in Patient Values

Patients differ in their values and preferences. Treatments that offer only modest benefit but substantial toxicity may be desirable to some but not to others. Under these circumstances, there is no standard treatment, and patients and physicians are faced with the choice between what Eddy[34] described as options with preferences split. It has been shown that this is exactly the situation that prevails in decisions about the use of chemotherapy for nonsmall cell lung cancer (NSCLC). In an early study of decision-making related to the treatment of locally advanced NSCLC, Brundage et al.[35] found that patients varied widely in terms of the degree of improvement in survival that they believed would justify the added toxicity of chemotherapy.

Once it is recognized that optimal decisions depend on patient values, it becomes imperative to engage patients actively in decisions about their medical care. However, it is well known that patients with cancer, particularly lung cancer, often overestimate the potential benefits of treatment and may have little understanding of potential toxicities.[36,37] Better communication with patients about the benefits and risks of treatment is therefore necessary for patient-centered decision-making.

Since the late 1990s, there has been a sustained effort to develop and evaluate decision aids to provide patients with the information that they need in order to make informed decisions and also to provide them with ways of clarifying their values.[38] A systematic review demonstrated (1) that cancer-related decision aids usually are acceptable to patients and (2) that such aids do help patients to make treatment choices that are based on realistic expectations of outcomes.[38] A decision aid for patients with locally advanced NSCLC, developed more than a decade ago, was favorably reviewed by patients and their physicians. The decision aid was shown to help patients understand the benefits and risks of treatment and also was shown to help them make the treatment choice that was most consistent with their values.[39–41] In a positive recent development, ASCO has created a series of decision aids for patients with lung cancer and has made them available online as a supplement to its treatment guidelines.[42]

Biologic Heterogeneity

The biologic heterogeneity of cancers and the genetic heterogeneity of the human population present ongoing challenges in the development and application of evidence-based treatment guidelines. The evidence on which the treatment of any individual patient is based is derived from reports of the outcomes observed in a reference group of similar patients who were similarly treated in the past.[43] The validity of this type of inductive reasoning depends on the degree of similarity between the present patient and the patients in the reference group. It goes without saying that this type of inference is only valid when the present patient is classified in the same way as the patients in the reference group. However, the predictive value of previous observations in the present patient also depends on the degree of similarity in the outcomes observed among the patients in the reference group. If the patients in the reference group experienced widely different outcomes, in spite of having tumors of the same origin, morphology, and extent of disease, then the benefits of treatment in the individual patient remain unpredictable.[43] As a result, there has been an unrelenting search for prognostic and predictive factors that might reduce uncertainty about the natural history of lung cancer and its response to treatment.[44] Dramatic advances in molecular genetics over the past 20 years have led to the discovery of genetic variations that are associated with tumor behavior and response to therapy. These advances have provided the basis for new targeted therapies and predictive tests that reduce the degree of uncertainty about the response to therapy in the individual patient.[45] In the context of NSCLC, for example, it has been shown that the probability of response to tyrosine kinase inhibitors is very high in patients with epidermal growth factor receptor (*EGFR*) mutations but patients without *EGFR* mutations are more likely to benefit from chemotherapy.[46] Some authors have seen these developments as heralding the start of a new era of personalized medicine. In the context of lung cancer, Gazdhar[46] describes a transition from the era when "patients with specific types and stages of cancer" were "treated according to standardized, predetermined protocols" to a new era of "individualized selection of treatment as determined by the characteristics of the patient and the tumor." In reality, these developments will not change the fundamental nature of clinical decision-making. We will still need the standardized, predetermined protocols that we call guidelines, but eligibility for treatment according to those protocols will be determined with use of new and better predictive assays.

Do Guidelines Guide Practice?

A quarter of a century ago, Lomas et al.[47] famously asked this question after the dissemination of a nationally endorsed consensus statement recommending decreases in the use of cesarean deliveries in Canada. Their answer was a qualified "no." Lomas et al.[47] found that, although one-third of the hospitals and obstetricians reported changing their practice as a consequence of the guidelines, actual practice changed very little. The authors concluded that "guidelines for practice may predispose physicians to consider changing their behavior, but unless there are other

incentives or the removal of disincentives, guidelines are unlikely to affect rapid change in actual practice." It is therefore important to evaluate the extent to which guidelines for the treatment of lung cancer actually guide practice.

A number of studies have evaluated the degree of concordance between clinical practice and guidelines for the treatment of lung cancer. Some studies have assessed whether treatment recommendations were concordant with guidelines,[48,49] whereas others have assessed whether actual treatment was concordant with guidelines.[50–55]

In two recent studies, clinician recommendations for treatment were compared with the corresponding guidelines. Vinod et al.[48] evaluated the degree of concordance between treatment recommendations and Australian practice guidelines in a study involving a cohort of patients with lung cancer who were discussed in a multidisciplinary management meeting (MDM). The MDM recommendations were deemed to be concordant if the general plan of treatment that was recommended corresponded with the guidelines. The rate of concordance was 71% for overall management, 58% for surgery, 88% for radiotherapy, and 71% for chemotherapy. Couraud et al.[49] asked oncologists and pulmonologists specializing in thoracic oncology for their treatment recommendations in four hypothetical clinical scenarios and compared their recommendations with the corresponding French guidelines. Their criteria for concordance required consideration of the details of treatment, including the specific chemotherapeutic agents and the number of cycles of chemotherapy recommended. On the basis of these fairly strict criteria, the rate of concordance with the guidelines ranged from 25% to 63% in the four scenarios. Clinicians who worked in public practice were more likely to comply with the guidelines than those who worked in private practice. Overall, only 15% of clinicians applied the guidelines appropriately to all four cases, and 10% did not apply them in any of the cases.[49] Not surprisingly, these two studies illustrate that the observed degree of concordance depends on how strictly concordance is defined.

A number of population-based studies have assessed the concordance between the treatment that patients actually receive and the prevailing guidelines for the treatment of lung cancer.[50–58] In a population-based study in the United States that was initiated in 1996, Potosky et al.[50] described the treatment of NSCLC and compared the observed treatment with best practice as defined by the authors based on the evidence at the time. Overall, 52% of the patients received guideline-recommended treatment, but this rate varied significantly from 41% for patients with stage IV disease to 69% for patients with stage I and II disease ($p < 0.05$). The rate of guideline-recommended treatment was significantly lower for older patients, for patients who were single, and for the nonwhite population ($p < 0.05$).[50] A decade later, in a similar US population-based study, the actual treatment of NSCLC was compared with recommended treatment in the prevailing NCCN guidelines.[51] The rate of guideline-recommended treatment was only 42% overall, 37% for patients with stage I or II disease, 58% for those with stage III disease, and 29% for those with stage IV disease. Older patients and African-American patients were less likely to receive guideline-recommended treatment. In a population-based study from the Netherlands, de Rijke et al.[52] found that only 44% of patients with stage I–III NSCLC received guideline-recommended treatment. The rate of guideline-recommended treatment again varied according to stage and was reported to be 82% for patients with stage I or II disease, 48% for patients with stage IIIA disease, and 54% for patients with stage IIIB disease.[52] Rates of guideline-recommended treatment were significantly lower among older patients, and higher levels of comorbidity and lower Eastern Cooperative Oncology Group (ECOG) performance status were associated with a lower rate of guideline-recommended treatment for patients with stage I and II disease. Duggan et al.[53] reported very similar findings in

a population-based study in which the actual treatment of lung cancer was compared with treatment recommended in Australian guidelines. The rate of guideline-recommended treatment was 54% for patients with small cell lung cancer (SCLC) and 51% for patients with NSCLC. Increasing age and poorer ECOG performance status were associated with lower rates of guideline-recommended treatment.

Thus, population-based studies from three continents have shown that, at best, only half of all patients with lung cancer are treated according to guidelines. All of these studies showed that older patients are less likely to receive guideline-recommended treatment. Although these studies did not consistently evaluate other patient characteristics, taken together, they provide evidence that patients with poorer performance status or higher levels of comorbidity are less likely to receive guideline-recommended treatment. These general findings have been supported by the results of several similar studies in more selected populations of patients with lung cancer.[54,55] Other studies of compliance with guidelines focusing on specific clinical situations have provided similar results. Allen et al.[56] found low rates of adherence to surgical guidelines for the treatment of operable NSCLC; Salloum et al.[57] noted low rates of guideline-recommended treatment with respect to the use of chemotherapy in patients with stage II to stage IV NSCLC; and Langer et al.[58] found low rates of guideline-recommended treatment with respect to the use of concurrent chemotherapy and radiotherapy in patients with limited-stage SCLC and stage I to stage III NSCLC.

Two recent studies showed that there may be cogent reasons why patients do not receive guideline-recommended treatment. Landrum et al.[59] found that many patients who did not have surgery for the treatment of stage I or II NSCLC, as indicated in the guidelines, were either in poor health (61%) or had declined the operation (26%). Poor health was defined as encompassing advanced age, comorbidity, poor performance status, and poor lung function. In a presentation focusing on a cohort of patients with lung cancer who were discussed at an MDM, Boxer et al.[55] noted that the main reasons why patients did not receive guideline-recommended treatment were a decline in performance status (24%), large tumor volume precluding radical radiotherapy (17%), comorbidities (14%), and patient preference (13%).

Thus, discordance between practice and guidelines for cancer treatment does not always indicate inappropriate patient care. It may instead indicate that the existing guidelines do not adequately take into account variations in the health status of patients with cancer in the general population. This consideration is particularly important in the context of lung cancer, with more than 50% of patients having at least one other substantial medical problem that may affect their care.[60,61]

Does Adherence to Guidelines Improve Outcomes in the General Population?

It is important to ask whether adherence to evidence-based guidelines actually yields the improvements in outcome in the general population that would be expected on the basis of the results of the relevant clinical trials. Only a small proportion of all cases of lung cancer are included in clinical trials, and these cases are not necessarily representative of the overall population of patients with lung cancer. Furthermore, the institutions and physicians likely to engage in clinical trials are unlikely to be representative of the heath-care system as a whole.

Two studies showed that patients with lung cancer who are seen in routine practice are indeed different from those who are enrolled in clinical trials.[62,63] De Ruysscher et al.[62] found that 59% of patients with stage III NSCLC and limited-stage SCLC who were seen at their clinic would not have been eligible for entry into the clinical trials that showed a benefit from concurrent chemoradiation therapy, mainly because of their advanced

age. Firat et al.[63] found that 33% of the patients who were treated with chemoradiotherapy at their center did not meet eligibility criteria for any Radiation Therapy Oncology Group (RTOG) trials being performed at the time, primarily because of weight loss or comorbidity.

Thus, there are good reasons to be concerned that the efficacy established by randomized controlled trials may not translate into an identical level of effectiveness in the general population. Some empirical studies have called into question whether adherence to guidelines is associated with better outcomes. Allen et al.[56] showed no difference in survival or mortality rates between patients who were and were not treated according to NCCN-defined surgical treatment guidelines. In a study of patients with stage I–III NSCLC, Duggan et al.[64] noted that patients who were treated in accordance with prevailing Australian guidelines experienced slightly better outcomes than those who did not receive guideline-recommended treatment, but that trend was not significant.

It has therefore been suggested that, after evidence-based guidelines have been adopted, phase IV population-based outcome studies should be done to confirm the value of the new treatment in the general population.[65] The results of a recent Canadian study were surprisingly reassuring.[66] Following the publication of the positive results of a Canadian trial of adjuvant chemotherapy for resected NSCLC, this practice was rapidly adopted in Canada.[67] Booth et al.[66] evaluated the results of a phase IV population-based study that documented the rapid adoption of adjuvant chemotherapy in Ontario and reported that such therapy was associated with an increase in survival commensurate with that expected on the basis of the results of the preceding randomized controlled trial. The fact that the results of this particular trial were reproduced in routine practice does not guarantee the generalizability of the results of other randomized controlled trials, and additional phase IV population-based outcome studies are required to evaluate the societal benefit of the adoption of other promising new treatments.[65]

To achieve optimal outcomes at the societal level, every patient must receive the correct treatment, and that treatment must be delivered correctly. Thus, in addition to practice guidelines for the selection of the appropriate treatment, additional standards are required to ensure the quality and accessibility of treatment.

QUALITY STANDARDS FOR CANCER TREATMENT PROGRAMS

General Quality Standards

In order to provide the optimal quality of treatment, the necessary structures and processes must be in place to deliver the treatment correctly. The term structure is used here to include human resources, physical resources, and organizational resources, and the term process includes all of the activities and procedures used to ensure the quality of treatment, as described earlier. Although practice guidelines target precisely defined subgroups of patients, the structures and processes required to ensure optimal quality of care are often applicable to much broader groups of patients. The same facilities usually serve the needs of diverse groups of patients, and the structures and processes that determine the quality of care are often common to many different types of cancer. Thus, the quality of the care that patients with lung cancer receive is in large measure determined by the degree of institutional adherence to general standards of practice that are applicable to the care of every patient with cancer.

The American College of Surgeons has been a leader in this field. In 1930, its Committee on the Treatment of Malignant Diseases released its first set of cancer program standards and created an accreditation program to evaluate the performance of a cancer clinic against those standards. As the management of

cancer became increasingly multidisciplinary, the membership of this committee was broadened to include individuals from non-surgical disciplines and its name was changed to the Commission on Cancer. Today, it provides a suite of program standards aimed at ensuring comprehensive, patient-centered, high-quality, multidisciplinary care for all patients with cancer.[68]

Multidisciplinary Team Management

No individual specialty has all of the knowledge and expertise necessary for optimal decision-making related to the management of a complex disease in the modern era. The primary rationale for introducing MDTs is to bring together the expertise of all of the key professional groups in making clinical decisions for individual patients.[69] Treatment decisions are made by consensus, reducing the risk that the bias of any individual physician will determine the final decision. There is usually considerable overlap in expertise among team members, providing a built-in opportunity for peer review of treatment decisions. The organized and open decision-making process provides a suitable forum for applying treatment guidelines and for identifying patients who are eligible for participation in clinical trials.[70] When several different health professionals are involved in the overall plan of care for the individual patient, the team structure fosters communication among all those involved. MDT management therefore has been recommended as a mechanism for improving the quality of care for patients with various complex diseases, including diabetes, stroke, ischemic heart disease, and cancer.[69]

On the basis of the persuasive arguments in favor of its use, the MDT approach has been widely adopted in cancer care systems throughout much of Europe, the United States, and Australia.[69] At the outset, there was very little empirical evidence that this approach actually improved the quality of patient care or the outcomes of treatment.[69] Although some observers remain skeptical about the value of MDT work,[71] accumulating evidence suggests that this approach does lead to better decision-making and that it may improve outcomes, at least for patients with certain types of cancer.[70–72] In one study from the United Kingdom, the vast majority of health professionals reported that they enjoyed working within the framework of an MDT and many reported that doing so had increased their job satisfaction.[73]

Multidisciplinary Team Management of Lung Cancer

MDT management of lung cancer is particularly important as studies have shown that practice varies widely,[74–76] that physician views are not always concordant with guidelines,[77,78] and that the different specialists involved in treatment tend to be biased in favor of their own modality of treatment.[79,80] It is also essential in the setting of lung cancer because multimodality treatment is common, pathologic subtyping is continually evolving, and patient comorbidities can have a substantial impact on the safety of therapeutic options.

The MDT should involve all of the clinicians who are involved in the diagnosis and treatment of lung cancer, including respiratory physicians, cardiothoracic surgeons, medical oncologists, radiation oncologists, palliative care physicians, and lung cancer nurses. The presence of a pathologist, radiologist, and nuclear medicine physician is also essential for accurate interpretation of the pathologic and imaging findings that underpin management recommendations. Ideally, all patients should be discussed at an MDM where all of these disciplines are represented. The presence of clinicians from different specialties should serve to reduce specialty bias in the treatment of patients and to inform colleagues of the role of different treatment modalities. The potential benefits of an MDM are increased compliance with evidence-based guidelines, improved utilization of treatment, increased referrals

for psychosocial care, improved timeliness of treatment, and increased recruitment to clinical trials.

The impact of an MDM ideally would be tested in a randomized controlled trial, but this type of study is difficult to conduct for such a complex intervention. However, a number of investigators have sought to evaluate the impact of MDMs either by comparing patterns of care before and after the implementation of an MDM or by comparing cases discussed in an MDM with contemporaneous controls who were not discussed in the MDM.[81–85] Both of these approaches are susceptible to bias. The longitudinal "before-and-after" design is vulnerable to changes in case mix, staging, and management over time, whereas the use of contemporaneous controls is susceptible to bias in the selection of patients for the MDM. In analyzing the results of such observational studies, it is therefore important to control, as much as possible, other factors that may influence the choice of treatment or its outcome.

Forrest et al.[81] evaluated the impact of the introduction of a multidisciplinary lung cancer team on the treatment of patients with inoperable NSCLC.[81] The pre-MDM data were collected retrospectively for 1997, the year preceding introduction of the MDM, and the post-MDM data were collected prospectively for 2001. The authors found a significant increase in formal staging of lung cancer (81% vs. 70%; $p = 0.04$), a significant increase in the use of chemotherapy (23% vs. 7%; $p < 0.001$), a decrease in the use of palliative care alone (58% vs. 44%; $p = 0.05$), and no significant change in the use of radiotherapy. The median survival was significantly greater for patients who were discussed at the MDM (6.6 vs. 3.2 months; $p < 0.001$). The two cohorts were not balanced for stage, with the post-MDM group including fewer patients with stage IIIA disease, which one would expect to result in poorer survival.

The improvement in survival therefore was attributed to the increased use of chemotherapy. However, it seems somewhat improbable that this factor alone could have been responsible for the large difference in survival. It remains possible that differences in case mix between the groups, not fully controlled for in the analysis, may have contributed to the difference in survival.

Erridge et al.[82] compared patterns of care in Scotland before and after the implementation of a number of changes related to the treatment of lung cancer, including the introduction of MDMs at which all patients with newly diagnosed lung cancer were discussed, the introduction of management guidelines, and an increase in the number of oncologists specializing in the treatment of lung cancer. Although the overall active treatment rate was unchanged, the investigators found a significant increase in the use of curative radiotherapy (5% vs. 15%; $p < 0.001$) and chemotherapy (7% vs. 18%; $p < 0.001$) for patients with NSCLC. The median survival time improved from 4.1 to 5.2 months ($p = 0.004$). As there were multiple concurrent changes in cancer care over time, it was not possible to tease out the impact of MDMs alone.

Seeber et al.[83] compared the treatment of lung cancer before and after the implementation of an MDM videoconference that was held at a peripheral site. The investigators found that the MDM changed the treatment recommendations of the presenting team in 25% of the cases. The use of radiotherapy increased from 30% to 70% ($p = 0.001$) following the introduction of the MDM. There was no change in the use of chemotherapy, and the authors did not comment on the use of surgery.

The largest study to evaluate the impact of the introduction of an MDM at a single institution was performed by Freeman et al.,[84] who compared the care of 535 patients who were treated before the implementation of an MDM with that of 687 patients who were treated after its introduction. The investigators found increased completeness of staging (93% vs. 79%; $p < 0.0001$), greater adherence to NCCN guidelines (97% vs. 81%, $p < 0.0001$), and reduced time from diagnosis to treatment (17 vs.

29 days; $p < 0.0001$) after the introduction of the MDM. There was also greater use of neoadjuvant chemotherapy and surgical resections for patients with stage IIIA NSCLC who were treated after the introduction of the MDM.

Two studies have compared the treatment of and outcomes for patients who were discussed at an MDM with those who were not in a cohort of patients who were seen at the same center over the same time period.[85,86] Bydder et al.,[85] in a small study of patients with inoperable NSCLC, found no difference between the MDM and non-MDM subgroups in terms of treatment but reported that the MDM subgroup had a longer median survival time (280 vs. 205 days; $p = 0.05$). However, the authors noted some imbalances between the groups in terms of tumor characteristics and acknowledged that selection bias may have affected the results. In a much larger study of 988 patients who were diagnosed with lung cancer between 2005 and 2008, Boxer et al.[86] compared 504 patients who were discussed at the MDM with 484 patients who were not. The investigators found that patients in the MDM subgroup were significantly more likely to be treated with radiotherapy (66% vs. 33%, $p < 0.001$), to be treated with chemotherapy (46% vs. 29%, $p < 0.001$), and to be referred for palliative care (66% vs. 53%, $p < 0.001$). The groups did not differ with respect to the rate of surgical treatment. Multivariate analysis showed that discussion at an MDM was an independent predictor of nonsurgical treatment and palliative care referrals but was not predictive of survival. Clinician selection bias may have had some influence on these results. Patients with better performance status may have been selected for presentation at the MDM on the assumption that they would receive treatment. Unfortunately, ECOG performance status was not available for the patients in the non-MDM cohort, and the authors therefore were unable to control for this factor in the analysis. The authors tried to minimize potential bias by assigning population-derived ECOG data to compensate for this limitation, but the potential for confounding remains.

Single-arm studies also may provide some useful information about the quality of care for patients who are discussed in an MDM. Conron et al.[87] described the activity of a lung cancer multidisciplinary clinic at which 431 patients were discussed between 2002 and 2004. Management was compared with prospectively identified measures of quality of care. They found that 98% of patients with stage I to stage IIIA NSCLC have macroscopically complete surgical resection, that 100% of patients with stage IIIB NSCLC have positron emission tomography before curative chemoradiation therapy, that 84% of patients with stage IIIB NSCLC complete curative radiotherapy, that 86% of patients with stage IV NSCLC are referred for palliative chemotherapy, and that 100% and 85% of patients with limited-stage SCLC have complete staging and receive thoracic radiotherapy, respectively. In a study that was described earlier, Vinod et al.[48] found 71% concordance between MDM recommendations and guidelines, but, in a follow-up study, Boxer et al.[55] found that only 51% of patients actually received guideline-based care.

The efficacy of MDMs has been evaluated in terms of whether recommendations are translated into practice and whether deviations from these recommendations affect outcomes.[88,89] Leo et al.[88] analyzed the concordance between MDM-planned treatment and administered treatment in a study involving a cohort of French patients who were discussed in 2003 and 2004. Patients who did not receive the recommended treatment had poorer survival, although this finding did not reach significance. In the United States, Osarogiagbon et al.[89] compared the outcomes for patients with any thoracic malignancy who received treatment that was concordant or discordant with MDM recommendations. Patients who received concordant treatment had a shorter time to clinical intervention (14 vs. 25 days, $p < 0.002$) and better median survival (2.1 vs. 1.3 years, $p < 0.01$). The authors were unable to identify the reasons for discordance in their study; however,

Black race and lack of medical insurance were the two factors associated with the receipt of discordant care.

In summary, although there is no level 1 evidence to support the use of MDMs, observational studies have shown that patients who are discussed at an MDM are more likely to receive treatment (particularly radiotherapy and chemotherapy), more likely to receive potentially curative treatment, and more likely to be referred for palliative care. The increased use of all and any of these modalities, including palliative care,[90] has the potential to improve survival, although there is little direct evidence that discussion at an MDM is associated with improved survival. For these reasons, case discussion at an MDM has been adopted as an indicator of quality of lung cancer care in some jurisdictions.[91–93]

Although it is now widely accepted that multidisciplinary management is effective for improving the quality of care for patients with lung cancer, the optimal structure and operations of the MDT have yet to be defined. Taylor and Ramirez,[73] in a study commissioned by the National Cancer Action Team in the United Kingdom, recently surveyed members of multidisciplinary cancer teams, with three objectives: (1) to identify the attributes of an effective MDT, (2) to learn how best to measure MDT effectiveness, and (3) to determine what support or tools MDTs need to be most effective. More than 2000 MDT members responded to the survey, of whom 53% were physicians, 26% were nurses, and 15% were MDT coordinators. The results of the survey demonstrated a high degree of consensus about the domains that are important for effective functioning of the MDT, including the membership, leadership, and governance of the team; the physical environment of the venue, technologic resources, preparation for meetings, administration of meetings, and attendance at meetings; the decision-making process, case management, and coordination of service; data collection, analysis, and auditing of outcomes; and development and training of participants. This very useful report provides many additional details of the elements of an effective MDT from the perspective of experienced team members. It should be essential reading for any member of a cancer program who is contemplating the introduction of an MDT.[73]

If MDT care is worth doing, it is worth doing well. In England, the Improving Lung Cancer Outcomes Project brings together multidisciplinary health-care teams from different regions under the leadership of the Royal College of Physicians. A recent report from this group described a quality-improvement exercise in which each of 30 randomly selected MDTs were paired with one another in visiting the others' services for a day, attending the MDM, and reviewing audit results.[94] The most commonly identified problems concerned the way in which MDMs operated, including deficiencies in the amount of information available at the meetings, the way in which decisions were made, and methods for capturing outcomes. The teams then used standard quality-improvement methods to target specific problems that were identified in the peer-review process. Ultimately, the impact of this peer-review process will be evaluated by comparing the outcomes achieved by the 30 MDTs that participated in the intervention with outcomes achieved by MDTs that did not.[94] This exercise may prove to be a very useful approach for enhancing the effectiveness of MDT care in the future.

MDT management necessarily generates added costs, and the cost-effectiveness of this approach has not been well evaluated. One small study from the United Kingdom, which considered only the salaries of senior staff and excluded preparation time and management costs, estimated the cost of discussing each patient to be £36.6 (US$60.64),[95] whereas another study from the United Kingdom, which considered all costs, including use of audiovisual equipment, clerical time, preparation time for radiographic and pathologic examinations, and room overhead, estimated the cost per treatment plan to be £87.41 (US$144.83).[96] If multidisciplinary management really results in improvements

in treatment and outcome, then MDMs may still be very cost-effective.[96] However, the cost of MDMs is clearly not trivial and further research on MDT management should seek to find ways to enhance its efficiency as well as its effectiveness.

Modality-Specific Quality Standards for Cancer Programs

Standards that target the quality of the major modalities of cancer treatment are also necessary to ensure the optimal treatment of lung cancer. For example, both Australia and Canada have established quality standards for radiotherapy programs,[97,98] which are clearly pertinent to the optimal care of patients who have lung cancer and other malignant diseases. While these guidelines also deal with general aspects of patient care, they are most important for prescribing the structures and processes required for the safe delivery of radiotherapy, which are not stipulated in more general cancer program guidelines.[97,98]

Standards for Acceptable Patient Volumes for Cancer Programs

The results of recent studies suggest that the outcomes of cancer may be better among patients who are treated at larger institutions.[99,100] The initial observations were made in the field of cancer surgery, in which many studies have shown an inverse association between surgical mortality and the number of operations performed in a given hospital or by a given surgeon. von Meyenfeldt et al.[99] recently performed a meta-analysis to explore the relationship between volume and outcome in the surgical treatment of lung cancer. The 19 studies that were included in the analysis proved to be very heterogeneous, particularly with respect to the definition of volume categories. However, pooled estimates showed a significantly lower surgical mortality in favor of larger hospitals (odds ratio, 0.71; 95% confidence interval [CI], 0.62–0.81) but no significant difference in terms of long-term survival (odds ratio, 0.93; 95% CI, 0.84–1.03). In a subsequent study of 4460 patients who underwent surgery for the treatment of lung cancer at 436 hospitals in the United States, Kozower and Stukenborg[100] compared three alternative measures of volume for evaluating the volume-outcome relationship. The authors found no significant association between hospital procedure volume and in-hospital mortality when volume was measured as a continuous variable. A significant relationship was found when volumes were categorized into quintiles, but the magnitude of the association was small. The authors concluded that the apparent impact of hospital volume on mortality is dependent on how volume is defined, that volume is not consistently related to mortality, and that volume should not be used as a proxy measure for the quality of surgery.[100] However, Lüchtenborg et al.[101] recently found a strong and significant association between institutional volume and survival in a study from England involving 134,293 patients who had been diagnosed with NSCLC between 2004 and 2008, of whom 12,862 (9.6%) underwent surgical resection. The authors found that rates of resection are higher at high-volume hospitals, where surgery is performed more often on patients who were older and had more comorbidities. Despite these findings, survival was significantly better at hospitals at which more than 150 surgical resections were performed each year than at those at which fewer than 70 surgical resections were performed each year (hazard ratio, 0.78; 95% CI, 0.67–0.90).

There have been far fewer studies investigating the impact of case volume on the outcomes of radiotherapy, but there are good reasons to expect that a similar relationship may be found, particularly in the context of complex types of treatment. Lee et al.[102] combined the results of two RTOG trials (RTOG 91-06 and RTOG 92-04) to address this question in the context of chemoradiation therapy for inoperable lung cancer. After controlling

for other prognostic factors as much as possible, the investigators found significantly better survival among patients who were treated at institutions that enrolled five or more patients each year as compared with those who were treated at lower-volume centers (31% vs. 13% at 3 years). The magnitude of this volume effect did not diminish over the study period, and the authors concluded that collective institutional experience contributed more to the difference in outcome than the learning curve effect did. The investigators did not attempt to distinguish the effect of the experience of the individual oncologist from institutional experience.

These so-called volume effects are potentially very important. If they are real, they represent an extraordinary opportunity for improving the outcomes for patients with lung cancer. Intervention studies are now urgently required to confirm that limiting treatment to high-volume facilities improves overall outcomes. Further explanatory studies are also required to try to identify the underlying differences in care that are responsible for the differences in outcomes between low- and high-volume centers. If these causative factors can be identified, then it may be possible to develop strategies to increase the quality of care at smaller centers to the level provided at the larger centers, thus avoiding the need for centralization of services, which may come at the cost of decreased accessibility.

STANDARDS FOR THE ACCESSIBILITY OF CANCER MANAGEMENT PROGRAMS

Standards for Waiting Times

Delays in the diagnosis and treatment of cancer are distressing for every patient, and there is good evidence that delays in treatment also may have an adverse impact on long-term outcomes.[103,104] Long waiting times for radiotherapy and cancer surgery have been reported in many health systems since the late 1990s,[105,106] and many jurisdictions therefore have established standards or targets for maximum acceptable waiting times. Waiting times for cancer diagnosis and treatment may be regarded as indicators of the accessibility of care or as indicators of quality.[2] Some organizations have confined themselves to setting standards for waiting times between diagnosis and treatment.[105] Others have correctly recognized that even greater delays may precede the diagnosis and therefore also have set standards for the acceptable interval between the initial presentation and consultation with the appropriate specialist.[29,107] Once waiting time targets have been established, it is important to monitor compliance with those targets and to identify factors associated with delay. Cancer care is complex, and process mapping can help to identify rate-limiting steps in patient flow.[2] Redesign of systems then may be useful for reducing treatment delays.[2] However, no amount of fine-tuning of patient flows will have any impact on waiting times for treatment if the available resources are not sufficient to meet overall demand.[2,108] A recent study in the United Kingdom showed that the introduction of waiting time targets was associated with reduced delays in consultations with lung cancer specialists, but delays in treatment persisted, primarily because of a lack of capacity to meet the demand for radiotherapy and thoracic surgery.[107]

Standards for Rates of Treatment Utilization

A long waiting list is often a symptom of inadequate resources, but the length of a waiting list provides no information about the magnitude of the shortfall between supply and demand.[2] Furthermore, the absence of a waiting list does not mean that access is optimal. Waiting lists develop only in response to inadequate availability of services. Waiting times are entirely insensitive to problems with respect to spatial accessibility, affordability, or awareness, as already noted. Problems in those dimensions of accessibility limit demand and actually may reduce or eliminate waiting lists.[2] Thus, the absence of a waiting list does not imply that access is optimal. To ensure appropriate access to care, it is therefore also necessary to set standards for, and monitor, rates of treatment utilization.[2]

The best quantitative measure of the accessibility of any service is the rate of its appropriate utilization, that is, the proportion of patients who actually receive the treatment that they need.[2] The term need is used here as defined by Cuyler,[109] who stated that "the need for medical care exists when an individual has an illness for which there is effective and acceptable treatment." Two objective methods have been developed for estimating the appropriate rate of treatment utilization for cancer: (1) evidence-based requirements analysis and (2) criterion-based benchmarking. Much of the early work on estimating appropriate rates of cancer treatment focused on radiotherapy, probably because of well-known and widespread problems in access to radiotherapy in the 1990s. However, these methods are readily applicable to other treatment modalities.

Methods for Setting Standards for Appropriate Rates of Treatment Utilization

Evidence-Based Requirements Analysis

Evidence-based requirements analysis is an objective method that may be used to estimate the need for any medical intervention or service. In the field of oncology, it was first used by Tyldesley et al.[110] to estimate the need for radiotherapy for lung cancer. The process was as follows: first, the indications for radiotherapy were identified by means of a systematic review; next, an epidemiologic approach was used to estimate how frequently each indication for radiotherapy occurs in the population of interest; and finally, the results of the systematic review and the epidemiologic analysis were combined to estimate the appropriate rate of utilization of radiotherapy for lung cancer. The strengths of the method are that all of the involved assumptions are explicit and that models can readily be adapted to reflect the case mix in any community of interest or to explore the implications of changes in the indications for radiotherapy. The main weaknesses of the approach are that it is complex and time-consuming and that the results are only as good as the information on which it is based. This method can be expected to produce valid results only when it is applied to major cancers for which the indications for radiotherapy are well defined and there is sufficient epidemiologic information available to estimate the frequency with which each indication occurs. Other investigators have since extended the use of this method to measure the need for radiotherapy across the entire spectrum of malignant disease, and it is now being widely used to predict requirements for radiotherapy equipment.[111]

Criterion-Based Benchmarking

An alternative way of estimating the appropriate rate of utilization of any treatment is to use a series of observations to derive a so-called benchmark. In the business world, benchmarking has been defined as "measuring products against the toughest competitors or those recognized as industry leaders."[112] Similarly, the rate of treatment use in privileged communities where there are no barriers to access to treatment may serve as benchmarks for the appropriate rate of utilization. This method was first used by Barbera et al.[113] to determine the appropriate rate of utilization of radiotherapy for lung cancer. In that original study from Ontario, benchmarks for the utilization of radiotherapy were set in counties where radiotherapy centers with short waiting times were located. This inductive method, grounded in observations in the real world, provides benchmarks that are demonstrably achievable and is unlikely to overestimate the need for treatment. The

estimates of the appropriate rate of use of radiotherapy derived from the benchmarking approach were almost identical to those derived from evidence-based requirements analysis.[113] This cross validation suggested that either method may reasonably be used to set utilization targets and to plan treatment capacity. The simpler benchmarking approach has been adopted by the provincial cancer agency in Ontario and is used by the Cancer Quality Council of Ontario to evaluate the performance of the provincial radiotherapy system on an ongoing basis. Shortfalls in the rates of use of radiotherapy for lung cancer in relation to benchmarks are routinely mapped at the county level and are posted on the Internet (http://www.csqi.on.ca/all_indicators/#.UnxoyeJih-w).

BARRIERS TO THE OPTIMAL CARE OF PATIENTS WITH LUNG CANCER

One of the most consistent findings in health services research is the gap between evidence and practice.[114] Even if continuous efforts are made and substantial resources are invested to improve the quality of care, it is a regretful fact that only a limited fraction of novel evidence-based health-care interventions makes it into practice, and, even then, implementation can take many years. Studies in both the United States and Europe have shown that between 30% and 50% of patients fail to receive clinical interventions that are justified according to the best scientific evidence. Conversely, 20% to 25% or more of the care that is provided is not needed and may even be harmful. While the use of inappropriate treatment may have a negative impact on patient well-being or even survival, the inappropriate consumption of resources translates into further wasting of these limited resources and placing additional burdens on overloaded health services.[114,115]

The lack of implementation of guideline-recommended treatment is in line with the observation that passive dissemination of information generally has little or no effect in terms of altering professional practices. In order to accelerate the rate at which existing and new evidence on optimal care is implemented in health-related settings around the world, it is first necessary to identify the specific barriers to change and to develop systematic and strategic approaches to address these barriers.[116,117] The process of implementing evidence-based health innovations is complex and involves the interplay of many different factors and stakeholders. Several research groups have suggested a framework to categorize these factors.

Classification of Barriers to Optimal Care

The European Assessment Subgroup on Dissemination and Impact of Technology (EUR-ASSESS) Project[117] defined three categories of barriers: (1) environmental barriers, such as political climate, lobbying by special interest groups, cultural and professional practice characteristics, and financial disincentives; (2) personal characteristic barriers, such as perception of risk, clinical uncertainty, and information overload; and (3) prevailing opinion barriers, such as standards of professional practice and opinion leaders.

Haines et al.[115] described barriers situated in different environments. Some barriers are embedded within the health-care system itself, such as lack of resources, inappropriate financial incentives, inadequate human resources (in terms of both quantity and quality), and lack of access to care. Other barriers are external to the health-care system and are found within the practice environment (e.g., time limitations, poor practice organization), the educational environment (e.g., failure of curricula to reflect research evidence, inadequate continuing medical education), the social environment (e.g., inappropriate demands and/or beliefs created by the influence of the media), or the political environment (e.g., ideologic beliefs that may be inconsistent with research evidence or dominance of short-term thinking). Lastly, the introduction and implementation of optimal care may be hampered by the interaction between practitioners (who may be insufficiently knowledgeable or influenced by the beliefs and attitudes of opinion leaders) and patients (who may demand ineffective care on the basis of their preconceptions or cultural beliefs).

Chaudoir et al.[118] categorized factors that are expected to have an impact on the implementation of innovation into five distinct levels: structural, organizational, provider, innovation, and patient. The structural level encompasses a number of factors that represent the broader sociocultural and economic context in which a specific organization is nested. The organizational level involves aspects of the organization itself in which an innovation is being implemented. These aspects include leadership effectiveness, culture or climate, and employee morale or satisfaction. The provider level relates to individual health-care providers and covers attitudes toward evidence-based practice or perceived behavioral control. The innovation level deals with aspects of the innovation itself (e.g., the relative advantage of using an innovation rather than existing practices). The patient level includes patient characteristics such as health-relevant beliefs, motivation, and personality traits.

Regardless of how barriers are defined and organized, it is clear that, in order to promote change, we must take into account the specific social, organizational, and structural setting in which health-care professionals work and address the barriers at the different levels. The most successful examples of evidence and guideline implementation have acted on predisposing factors (e.g., knowledge and attitudes in the target group), enabling factors (e.g., capacity, resources, and availability of services), and reinforcing factors (e.g., opinions and behavior of others).[119] Moreover, the roles of all key players, including policymakers, the public, patients, and service providers alike, should be addressed.[115]

Barriers to Optimal Care: Case Studies From High-Income Countries

The first important barrier relates to the knowledge and beliefs of physicians who treat lung cancer. In the mid-1990s, a Canadian study showed how the beliefs of physicians regarding the natural history of NSCLC and the response to treatment varied widely and were strongly associated with their treatment recommendations.[120] As these physicians were in charge of therapy or treatment referral, it can be postulated that such variable perceptions may have an impact on the delivered care and, potentially, on prognosis. Another study analyzed survival estimates, treatment perceptions, and referral patterns for NSCLC on the basis of a survey of pulmonologists and thoracic surgeons in the United States. The results of the survey demonstrated both overestimation and underestimation of survival as well as considerably different beliefs regarding, for example, the benefit of radiotherapy for patients with stage I to stage III disease or the benefits of chemotherapy for those with metastatic disease. The authors found that a longer time interval since training and a lower volume of patients with NSCLC were associated with beliefs discordant with evidence-based recommendations.[121] A subsequent analysis from the same group focused on physician beliefs in comparison with guidelines. Although the authors found that the vast majority of American thoracic physicians consulted and used guidelines, there were some specific therapeutic areas—for example, the use of palliative chemotherapy for patients with metastatic NSCLC—in which their personal beliefs differed considerably from the evidence.[77]

Physician beliefs and therapeutic choices are but one small part of the total picture. Examples of the complex and multifactorial interplay that can hamper optimal lung cancer treatment have been described at all stages of the disease. A study from Auckland, New Zealand, analyzed reasons for delay in the diagnosis of lung cancer.[122] Apart from two central themes (access to health services and processes of care), issues related to symptom

interpretation, health beliefs, provider continuity, relationships, and perceived expertise contributed to patient and general practitioner delay. System complexity, information, and resourcing issues were identified as barriers at the primary care–secondary care interface as well as within secondary care. At the other end of the spectrum, the authors found that many individuals with advanced-stage lung cancer who perceive pain resulting from both the disease and the treatment do not want to use analgesics because of personal concerns of addiction, the cost of treatment, or lack of recommendation of analgesics from their health-care providers.[123]

Studies in the United Kingdom have shown a relationship between the accessibility of oncology services and the chance of receiving a correct diagnosis and optimal care for lung cancer. In South East England, patients with lung cancer whose first hospital attendance was at a radiotherapy center were found to be more likely to receive active treatment, radiotherapy, and chemotherapy.[124] Similarly, in Northern England, living in a deprived region (as determined with the Index of Multiple Deprivation) reduced the likelihood of obtaining a histologic diagnosis and undergoing definitive treatment for lung cancer, with the exception of chemotherapy for the treatment of small cell lung cancer.[125] These findings were further strengthened by reduced access expressed in travel time to the health service.

Socioeconomic factors are known to play an important role in the implementation of optimal care, especially if new interventions are more costly and more resource-demanding than the existing strategies, which is often the case. Whereas a lack of resources typically translates into the use of fewer, less complex, less costly, and, potentially, less qualitative treatments, the opposite scenario—i.e., more frequent use of advanced technology and costly and potentially inappropriate treatments—is found if resources are abundant.

At the individual level, physicians tend to adapt their clinical behavior to the reimbursement offered, more or less independently from the available resources.[126] If reimbursement lags behind the development of innovative treatments, which is typically the case in many European countries, the uptake of these new treatments will be hampered, even if effectiveness is proven. In contrast to data on clinical outcomes, there is often less evidence on cost-effectiveness, global budgetary impact, cultural appropriateness, and effects on health inequalities, all of which are important considerations at the macro level of health policy-making and financing.[115,127]

Barriers to Optimal Care in Low- and Middle-Income Countries

Whereas socioeconomic determinants already play a role in high-income countries, it seems evident that they have an even larger impact on health-care delivery in low- and middle-income countries. The lack of resources (e.g., to purchase medicines or to invest in radiotherapy facilities) typically represents a more important barrier in low-income countries than in most high-income settings. Besides purely financial factors, additional challenges to the use of research evidence, such as the weakness of health systems with unregulated commercial interests, the lack of professional regulation and continuing professional development, and limited access to research evidence, are found in low- and middle-income countries.[128]

Radiotherapy, one of the core modalities of lung cancer treatment, is a resource-demanding specialty and, consequently, is highly sensitive to the economic status of the country or region. An analysis of the data for 33 countries that were registered in the Directory of Radiotherapy Centers database, administered by the International Atomic Energy Agency, showed how a lower economic status, expressed as gross national income per capita, translates into a higher throughput on the machines and a relative shortage in equipment.[129] This finding is in line with the earlier observation, from the European Society for Radiotherapy and Oncology–Quantification of radiation therapy infrastructure and staffing needs (ESTRO-QUARTS) project, that guidelines for machine requirements recommend, on the average, 1 accelerator per 183,000 inhabitants in high-resource countries, compared with only 1 per 500,000 in low-resource countries.[130] Even if both examples disregard epidemiologic needs and the impact of treatment complexity, the findings suggest that, in some countries referrals for radiotherapy may be more difficult to accomplish than in other countries. Moreover, the adoption of today's standard of care in radiotherapy, requiring optimal imaging equipment and treatment machines as well as highly educated personnel, may become problematic. A patterns-of-care study in Spain showed how limitations in technology and infrastructure in the Spanish health-care system delayed the uptake of evidence-based practices related to the use of radiotherapy for lung cancer.[131] Similarly, variations in the use of specific diagnostic and treatment modalities related to radiotherapy for lung cancer in Central and Eastern European countries have been traced to shortages in equipment and the need for educational support for health-care providers in these countries.[132]

Do Variations in Patterns of Care Affect the Outcomes of Lung Cancer?

Lung cancer is the most common type of cancer worldwide. In 2012, there were an estimated 1.8 million new cases of lung cancer, representing 12.9% of all new cancers. Lung cancer is also the most important cause of cancer-related death, leading to an estimated 1.59 million deaths annually and representing 19.4% of the total cancer-related mortality.[133] The highest rates are seen in Central-Eastern and Southern Europe, Northern America, and Eastern Asia, with still very low rates in Middle Africa and Western Africa.[133] However, over the past decades, a geographic shift has occurred in terms of the absolute numbers of cases of lung cancer. Whereas in the middle of the last century lung cancer typically was a disease affecting those in industrialized countries, today 55% of the cases occur in developing regions. There is often a different pattern for men and women. In Europe, for instance, the incidence is highest among men in Central and Eastern European countries such as Hungary, Macedonia, Serbia, and Poland, and the incidence is lowest in Northern European countries, such as Finland and Sweden. The reverse holds for women, with the rates being higher in Northern Europe (e.g., Denmark and the Netherlands) and lower in Eastern Europe (e.g., Ukraine and Belarus).[134]

Because of the high fatality of lung cancer—the ratio of mortality to incidence is 0.86—with very little variability in cure rates in developed and developing countries, geographic patterns of mortality are quite similar to those of incidence.[133,134] This finding seems to suggest, at least at the macro level, that patterns of care do not have a substantial impact on the survival of patients with lung cancer. However, at the micro level (i.e., within countries or even regions), differences in care have been described, resulting in differences in outcomes.

Two studies from the Netherlands demonstrated that treatment, especially surgical intervention and the use of chemoradiation therapy for stage III NSCLC, varied by region.[76,135] Although the surgery rate tended to be higher in specialized centers or higher-volume hospitals, the variation among individual hospitals was much more distinct, suggesting that hospital characteristics per se are no guarantee of optimal treatment. Regardless of the type of hospital, however, more aggressive treatment translated into better survival.

A similar strong link between dissemination of optimal care and survival was found in a Dutch study on stereotactic ablative radiotherapy (SABR) for early-stage NSCLC in older patients. Between

1999 and 2007, before and after the introduction of SABR, an absolute increase in radiotherapy use was seen in the Amsterdam region, along with a decline in the proportion of untreated older patients and an improvement in overall survival in this population.[136] This example demonstrated how a well-structured and unobstructed introduction of a therapeutic innovation can translate into a substantial improvement in outcome. Unfortunately, as described previously, many countries in Europe currently do not have the necessary resources to support the wide dissemination of SABR, even for a proven indication such as inoperable early-stage NSCLC.[129,130] The delayed uptake of actual state-of-the-art radiotherapy techniques and the variation among countries in this regard have both been related to economic factors.[131,132]

CONCLUSION

Achieving optimal outcomes for patients with lung cancer requires that every patient receive optimal treatment. However, as we have shown, there is abundant evidence that many patients do not receive optimal treatment or experience optimal outcomes. Deviations from optimal treatment may be due to resource limitations that compromise the accessibility of treatment, to errors in clinical decision-making, or to flaws in the implementation of treatment decisions.

Problems in the accessibility of treatment may be the inevitable consequence of the low levels of health funding available in low- and middle-income countries, but they also may be due to suboptimal planning of treatment services or to the inequitable distribution of those services in high-income nations. Health services research has provided methods for needs-based system planning, which permit the design of health systems that will fully meet the needs of patients with lung cancer in high-income nations, and which also may be used to design health systems that will, as far as economically possible, meet the needs of patients in low- and middle-income countries. Health services research has demonstrated the importance of ongoing auditing of access to treatment as a way of identifying underutilization of effective treatments for lung cancer. It has also been valuable for identifying vulnerable subgroups of patients who are most likely to experience problems in obtaining access to treatment.

There is good evidence that clinical decision-making in cases of lung cancer is not always optimal. It has been shown that the treatment that patients with lung cancer receive is only concordant with evidence-based guidelines in about 50% of cases. Furthermore, some evidence indicates that such deviations may be associated with inferior outcomes. The reasons for deviation from guidelines are complex, but the personal beliefs of physicians about optimal care vary widely and discipline bias may have a substantial effect on their individual treatment recommendations. Evidence suggests that MDT management effectively overcomes discipline bias and is associated with increased compliance with evidence-based guidelines, resulting in better outcomes. Although the results of MDT management are very promising, the optimal structure and process of the team remain to be defined and the cost-effectiveness of this approach still needs to be established. Deviations from guidelines do not always mean that patients are receiving suboptimal treatment. Today's guidelines may not adequately take into consideration the overall health status or the personal values and preferences of the patient. Physicians and patients therefore may have cogent reasons for choosing to deviate from guidelines. There is a need for the development of guidelines that more fully reflect the wide variation in the health status of patients with lung cancer as well as for the wider use of decision aids that explicitly factor patient values into treatment decisions.

Factors affecting the quality of treatment delivery have been less extensively studied, but there is evidence that the outcome of surgery for lung cancer may depend on the level of experience of the institution or the individual surgeon. This so-called volume effect still requires further study, but it does suggest that the experience and skill of the health-care team may affect the quality of care and hence the outcomes achieved. There are good reasons to extend this research beyond the field of surgery to determine whether the outcomes of other technically challenging interventions, including modern radiotherapy techniques, are also volume-dependent.

Health services research has identified many ways in which the outcomes of lung cancer can be improved by making better use of existing knowledge, technology, and resources, and we believe that research aimed at optimization of health system performance should be a high priority within any overall program of lung cancer research.

Diagnostic Algorithms

Thomas Hensing, Isa Mambetsariev, Nicholas Campbell, and Ravi Salgia

SUMMARY OF KEY POINTS

- Mind maps are used as a tool to illustrate the principles involved in the diagnostic evaluation of a patient with known or suspected lung cancer.
- Addressed are factors important in establishing the diagnosis and defining the extent of disease; the histologic and molecular classifications of lung cancer; and the potential role for repeat biopsy in patients with acquired resistance to targeted therapies.
- Reviewed are diagnostic platforms for tumor profiling in the clinical setting and the use of these technologies in the noninvasive evaluation of surrogate tissues for both disease monitoring and early diagnosis.

The personalized treatment of lung cancer begins with an accurate diagnosis and assessment of both the extent of disease and other clinically relevant prognostic and predictive factors that are necessary to define the optimal treatment approach. Treatment decision making relies on a number of both patient- and tumor-specific factors. Lung cancer is a heterogeneous disease, and recent advances in molecular analysis and the development of targeted therapy approaches have added to the complexity of the diagnostic evaluation. In addition, revisions in the staging system, changes in the pathologic classification, and the addition of minimally invasive diagnostic modalities have increased the importance of a coordinated multidisciplinary team approach to establish both the diagnosis and the tumor stage as efficiently as possible.[1–4]

Mind mapping was developed as a technique to visually represent ideas and their nonlinear relationships.[5] Mind maps have been used as teaching tools in a number of different fields, including medical education, to present complex information and improve recall.[5,6] Originally developed by Tony Buzan, a mind map starts with a central idea or key concept, which is then linked by branches to related ideas. Mind maps include color and pictures to illustrate the intra- and inter-relationship between ideas. Unlike a linear algorithm or a concept map, a mind map begins with a central idea, and its relationships are depicted radially (i.e., radial or spider map). The information is organized hierarchically, with the most general information at the center and more detailed information depicted at the extremes of each relationship branch.

In this appendix, we use mind maps as a tool to illustrate the principles involved in the diagnostic evaluation of a patient with known or suspected lung cancer. The initial mind maps address the factors that are important in establishing the diagnosis and defining the extent of disease. Because of the growing importance of targeted therapies, we use this technique to illustrate both the histologic and molecular classifications of lung cancer. In addition, we address the potential role for repeat biopsy in patients with acquired resistance to targeted therapies. Lastly, we use mind maps to review diagnostic platforms for tumor profiling in the clinical setting and to assess the potential to use these technologies in the noninvasive evaluation of surrogate tissues for both disease monitoring and early diagnosis.

INITIAL EVALUATION

History and Physical

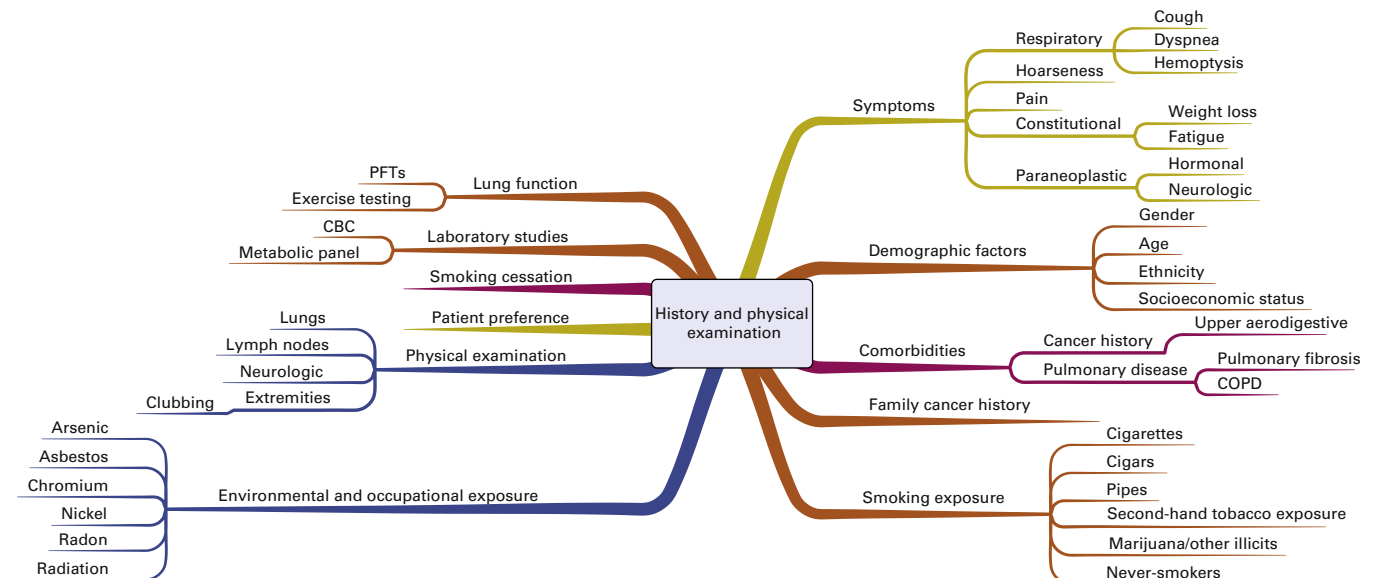
Fig. A.1 includes a mind map that outlines the factors that are important to address during the initial history and physical examination of a patient suspected of having lung cancer. The objectives of the initial evaluation are to estimate the probability that lung cancer is present and to assess for evidence of distant metastatic disease.[7] In addition, the initial evaluation should clarify patient-specific factors that may affect treatment decision making


Fig. A.1. History and physical examination. *CBC,* Complete blood count; *COPD,* chronic obstructive pulmonary disease; *PFTs,* pulmonary function tests.
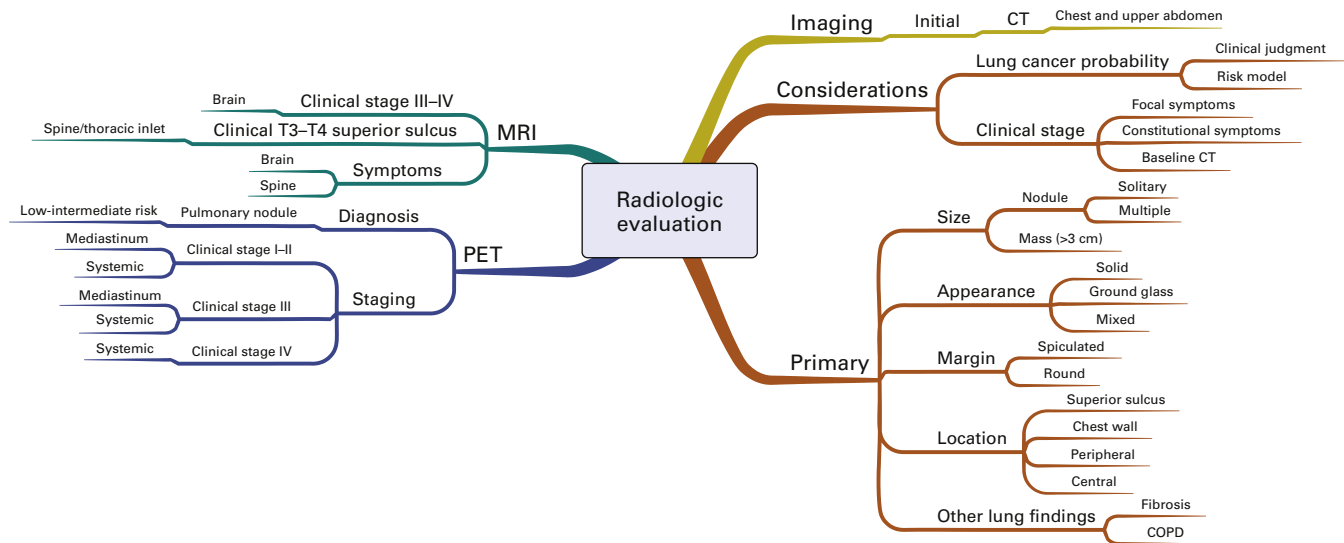

Fig. A.2. Radiographic evaluation of lung cancer. *COPD,* Chronic obstructive pulmonary disease; *CT,* computed tomography; *MRI,* magnetic resonance imaging; *PET,* positron emission tomography.

if cancer is confirmed, including comorbidities, performance status, underlying lung function, and the patient's values and goals.

The initial risk assessment for lung cancer includes an evaluation of symptoms. Most patients with lung cancer will have symptoms at presentation.[7] Symptoms may be due to the primary tumor or due to regional or distant spread of disease. Constitutional symptoms, including weight loss or fatigue, are important to consider because they may reflect an advanced stage of lung cancer. Several paraneoplastic syndromes have also been described, each with potentially unique clinical manifestations. Early recognition of a paraneoplastic process is important to minimize the risk for long-term morbidity and mortality.[7]

The most common risk factor for lung cancer remains tobacco smoking. Lung cancer is 10 to 20 times more likely to develop in individuals with a history of smoking than in persons who have never smoked.[8] The individual risk is affected by age as well as the duration and intensity of smoking.[9] Lung cancer develops in only a minority of smokers, however, so inherited factors may also play a role in lung cancer risk. Other environmental and occupational exposures are also important to consider (see Fig. A.1).[10] For example, pollution is increasingly being recognized as a risk factor for lung cancer.[11] Important personal risk factors include age, gender, ethnicity, socioeconomic status, and comorbidities, including acquired lung disease.[10] Although more men than women will die of lung cancer, the gender gap is narrowing, and lung cancer is the leading cause of cancer-related mortality among women in the United States.[12] Although the rates of lung cancer are similar for black and white women, the incidence of lung cancer is higher among black men than among white men.[12] Both the incidence of and mortality from lung cancer are higher in populations of lower socioeconomic status.[13,14]

Radiographic Evaluation

Fig. A.2 is a mind map that illustrates the radiologic evaluation. All patients should have initial computed tomography (CT) of the chest and upper abdomen that extends through the adrenal glands.[7,15] The decision to pursue additional imaging for diagnosis and staging depends on both the estimated risk of lung cancer and the initial clinical stage. When patients have focal symptoms suggestive of metastatic disease, directed imaging (e.g., magnetic resonance imaging of the spine or brain) is recommended for confirmation. The radiographic characteristics of the primary abnormality in the lung that affect the risk assessment include the size, radiographic appearance, margin, and location of this lesion,

as well as any underlying lung disease or additional lesions.[16] Positron emission tomography (PET) is used in the diagnostic evaluation to characterize pulmonary nodules considered to be at low to intermediate risk for lung cancer.[17] PET is not recommended to characterize abnormalities considered to be at high risk for lung cancer.[17] However, PET is frequently recommended for mediastinal and systemic staging in most patients, including patients with early (stage I–II), locally advanced (stage IIIA–IIIB), and metastatic (stage IV) disease. In addition to PET, magnetic resonance imaging of the brain is frequently recommended for staging of patients with clinical stage III or IV disease.[4,15]

Invasive Diagnosis

Options for tissue confirmation of the lung cancer diagnosis are outlined in Fig. A.3. Important considerations before pursuing biopsy include the probability of lung cancer and the estimated clinical stage, as well as the feasibility, risk, diagnostic yield, and the potential to obtain adequate tissue for both histologic confirmation and molecular analysis. Patient-specific factors outlined previously are also important to consider, including performance status, comorbidities, pulmonary function, and the patient's values and goals. Given the complexity of treatment decision making, multidisciplinary tumor boards are generally recommended, if available, to help coordinate the diagnostic plan.

The most important principle is to take a biopsy specimen from the most distant site of disease to confirm both diagnosis and stage.[16] If obtaining this type of specimen is not considered feasible or safe, but the patient has a high likelihood of distant metastatic disease on the basis of clinical presentation and imaging, then a biopsy specimen of the safest site is generally recommended. Solitary abnormalities at a distant metastatic site evident on PET images warrant tissue confirmation because false-positive imaging will affect both treatment planning and intent. Likewise, clinical stage III disease should be confirmed by pathologic analysis. Mediastinoscopy remains the criterion standard for pathologic confirmation of N2 and N3 disease. However, image-guided needle techniques, including endobronchial ultrasound-guided transbronchial needle aspiration and endoscopic ultrasound-guided biopsy, are increasingly being recognized as valid alternatives to mediastinoscopy for mediastinal staging.[4]

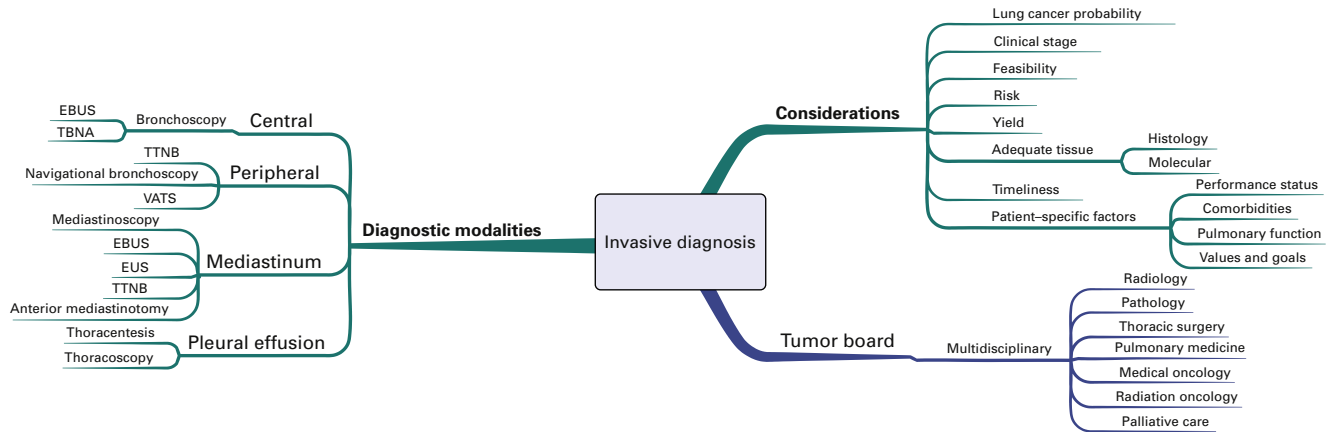
If a patient is considered to have an early stage (I–II) lung cancer, a thoracic surgery evaluation should be pursued before a needle biopsy is performed for tissue confirmation because resection could be used as the primary means of both diagnosis


Fig. A.3. Invasive diagnosis and staging of lung cancer. *EBUS,* Endobronchial ultrasound; *EUS,* endoscopic ultrasound; *TBNA,* transbronchial needle aspiration; *TTNB,* transthoracic needle biopsy; *VATS,* video-assisted thoracoscopic surgery.

and treatment. If that patient is not considered a surgical candidate because of comorbidities, poor underlying lung function, or unwillingness to have an operation, then tissue confirmation should be pursued. The specific procedure will depend on tumor location as well as the other factors indicated earlier (see Fig. A.3).

PATHOLOGIC CLASSIFICATION OF LUNG CANCER

Tumor Histology

In 2011, the International Association for the Study of Lung Cancer, the American Thoracic Society, and the European Respiratory Society published a new pathologic classification system for lung cancer.[2,3] This new system is separated into two components by the method in which the tissue was obtained; standardized diagnostic criteria are provided for small biopsy specimens and cytologic specimens as well as for resected specimens. A mind map shows this new classification system (Fig. A.4). Most patients will have advanced disease at presentation, and the diagnosis will be confirmed by evaluation of a small biopsy specimen. Given the therapeutic implications, emphasis is placed on

establishing the specific histologic subtype, including adenocarcinoma, squamous cell carcinoma, and small cell carcinoma. The previous designation of large cell neuroendocrine carcinoma is now classified as nonsmall cell lung cancer (NSCLC) with neuroendocrine morphology and positive or negative neuroendocrine markers. For those tumors without classic morphologic features, the new system includes recommendations for limited special stains to determine the subtype of carcinoma beyond NSCLC, not otherwise specified. If an adenocarcinoma marker is positive (e.g., thyroid transcription factor-1), then the tumor is classified as NSCLC-favor adenocarcinoma, and if a squamous cell marker is positive (e.g., p40), then the tumor is classified as NSCLC-favor squamous cell carcinoma.

For resected specimens, the term bronchioloalveolar cell carcinoma has been discontinued, and the terms adenocarcinoma in situ and minimally invasive adenocarcinoma have been added.[3] Both of these adenocarcinomas are defined as small tumors (3 cm or less) with a lepidic growth pattern. Minimally invasive adenocarcinoma includes tumors with no more than 5 mm of invasion. Larger tumors with more than 5 mm of invasion are designated as invasive adenocarcinoma, and the subtype is determined based on

the predominant growth pattern.[3] In validation studies, the proposed subtyping contained in this new system was shown to have prognostic significance.[18–20] In addition to the histologic subtype, the reporting of resected tumors should include descriptions of the size, location, grade, margins, pleural involvement, lymphovascular invasion, and lymph node involvement by station.[21]

Molecular Classification

This IASLC/ATS/ERS pathologic classification system also emphasizes the importance of molecular testing based on tumor histology.[3] An institutional multidisciplinary strategy for obtaining and processing small biopsy specimens should be established to make sure that sufficient tissue is available for both histologic classification and molecular analysis. Given the clinical validation of mutations in the epidermal growth factor receptor (EGFR) and translocations of anaplastic lymphoma kinase (ALK) as therapeutic targets, current guidelines from the American Society of Clinical Oncology and the National Comprehensive Cancer Network, as well as a joint guideline from the College of American Pathologists, International Association for the Study of Lung Cancer, and the Association for Molecular Pathology, recommend testing adenocarcinoma of the lung for these two markers at diagnosis before selecting patients for directed therapy.[22–24]

Fig. A.5 is a mind map that illustrates the molecular classification of adenocarcinoma of the lung. In addition to EGFR mutations and ALK translocations, increasing numbers of other so-called driver mutations and gene fusions have been described.[25–27] Given the limited overlap, these molecular alterations define unique subsets of lung adenocarcinoma and can potentially be used to select patients with advanced adenocarcinoma of the lung for molecularly targeted therapy as well as targeted immunotherapy indicated by increased activity of PD-1/PD-L1 pathway inhibitors.[28] Investigators from the Clinical Lung Cancer Genome Project and Network Genomic Medicine (CLCGP/NGM) characterized genome alterations in 1255 clinically annotated lung tumors.[25] Overall, more than 55% of the tumors had at least one genomic alteration

that was potentially amenable to targeted therapy. The pattern of genomic alterations differed among histologic subsets. This mind map includes an illustration of the genomic alterations that were relatively common in lung adenocarcinoma.

In addition to clinically validated genomic alterations that can be used to guide treatment selection, the recently reported KEYNOTE-024 trial validated PD-L1 protein expression by immunohistochemistry (IHC)[29,30] to guide the selection of an immune checkpoint inhibitor in the first line treatment of patients with advanced squamous and nonsquamous NSCLC. In the KEYNOTE-024 trial, 305 patients, with previously untreated advanced NSCLC with PD-L1 expression on at least 50% of tumor cells and no sensitizing mutations of EGFR or ALK translocations, were randomly assigned to receive either pembrolizumab at a fixed dose of 200 mg every 3 weeks or the investigator's choice of platinum-based chemotherapy.[28] The results of this randomized study showed a marked improvement in the median progression-free survival of 10.3 months for the pembrolizumab arm versus 6.0 months for patients treated with platinum-based chemotherapy (hazard ratio [HR] for disease progression or death, 0.50; 95% confidence interval (CI), 0.37–0.68; $p < 0.001$). The estimated rate of overall survival at 6 months also favored pembrolizumab with a rate of 80.2% versus 72.4% in the chemotherapy group (HR, 0.60; 95% C, 0.41–0.89; $p = 0.005$). This was further accentuated by a higher response rate of 44.8% in the pembrolizumab group compared to 27.8% in the chemotherapy group. Patients in the pembrolizumab arm also experienced fewer treatment-related adverse events of any grade as well as a less frequent occurrence of high-grade (grade III–V) treatment-related adverse events. The results of this study recently led to the U.S. Food and Drug Administration approval of pembrolizumab as first line therapy for patients with metastatic NSCLC whose tumors have high PD-L1 expression (Tumor Proportion Score (TPS) greater than or equal to 50%) and no EGFR or ALK genomic tumor alterations.[28]

Although no molecular targets for squamous cell carcinoma or small cell lung cancer have yet been validated, the genomic

characterization of both tumor histologies has recently been described.[31–34] This information has led to clinical trials evaluating molecular therapeutics for both tumor types. Mind maps are useful to illustrate the genomic alterations found in squamous cell carcinoma (Fig. A.6) and small cell carcinoma (Fig. A.7) of the lung, as reported in the genomic data set.[25] Both mind maps include examples of potential therapeutic targets, some of which are being evaluated in ongoing clinical trials.

In a prospective testing of the CLCGP/NGM genomics-based diagnostic algorithm,[28] genomic testing was feasible in 75% of paraffin-embedded tumor samples obtained by routine diagnostic procedures from 5145 patients with lung cancer.[28] In a multivariate analysis controlling for tumor stage and histology, the patients whose tumors had been successfully genotyped had an improvement in overall survival ($p = 0.002$) compared with patients for whom a genetic diagnosis was not feasible.[25] The improvement in survival is most likely due to improved outcomes among patients treated with molecularly selected kinase inhibitors. Although this study was not randomized, this observation supports the routine incorporation of molecular testing in the diagnosis of lung cancer for the clinical selection of patients for targeted therapy.

Repeat Biopsy for Acquired Resistance

Both intrinsic (de novo) and acquired resistance can complicate the treatment of patients with a targeted tyrosine kinase inhibitor (TKI). Acquired resistance to an EGFR inhibitor has been defined as systemic progression of disease (by Response Evaluation Criteria in Solid Tumors [RECIST] or World Health Organization [WHO] criteria) while receiving treatment with an EGFR TKI within the past 30 days in a patient whose tumor has a sensitive EGFR mutation or in a patient who had objective clinical benefit from therapy (defined as partial or complete response or more than 6 months of stable disease).[35] Potential mechanisms of resistance for both EGFR-, ROS1, and ALK-selected therapy have been described and can either be present at baseline or evolve by selective pressure during therapy.[36–39] These mechanisms of resistance for EGFR-, ROS1- and ALK-directed therapy, including include alterations in the molecular target, activation of accessory pathways, impairment in apoptotic pathways (e.g., BIM), and histologic transformation (Fig. A.8). Identification of the resistance mechanism by repeat biopsy offers the potential to identify another therapeutic target that may improve clinical outcome. In reported series, repeat biopsies to reassess the tumor histology and genomic profile have been shown to be feasible and safe.[40,41] As strategies to overcome de novo and acquired resistance become validated, repeat biopsies will likely become a standard component of the long-term management of disease in this patient population.

Molecular Diagnostic Platforms

Since the clinical validation of EGFR mutations and ALK translocations as therapeutic targets, the number of diagnostic platforms available for genomic profiling of lung cancer has increased

rapidly (Fig. A.9). In the molecular testing guideline mentioned earlier, single-gene assays are recommended to select patients for EGFR or ALK TKI therapy, including testing based on polymerase chain reaction for EGFR mutation and the fluorescence in situ hybridization assay using dual-labeled break-apart probes for ALK.[23] In the case of ALK, the break-apart fluorescence in situ hybridization assay was developed and validated as a predictive biomarker in parallel with the development of crizotinib.

Multiplex genotyping platforms offer the potential to simultaneously assess many genes of interest. Both SNaPshot (Applied Biosystems, Foster City, CA, USA) and Sequenom (San Diego, CA, USA) are multiplex polymerase chain reaction–based platforms that are used to analyze tumor genomic DNA in formalin-fixed, paraffin-embedded specimens.[42] Both can analyze for selected, known hotspot mutations and oncogenes. Next-generation

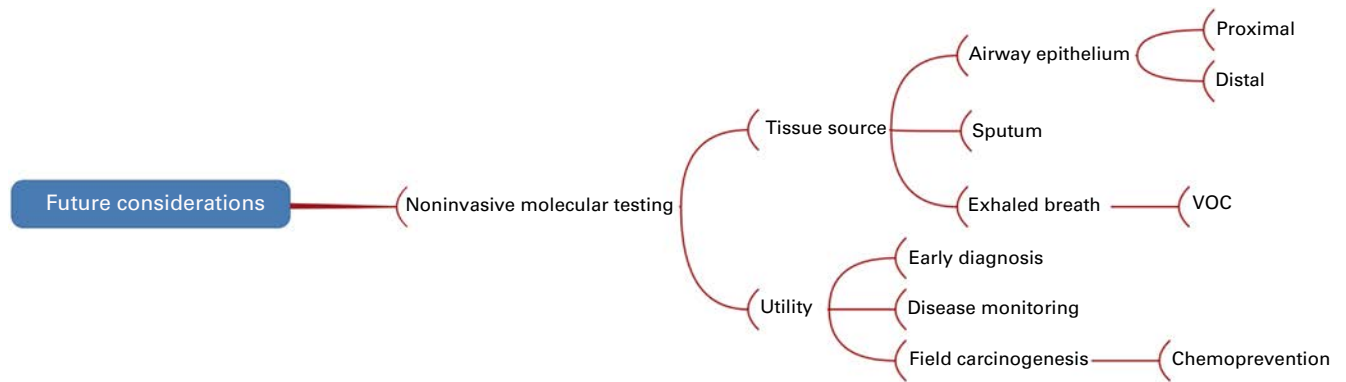
sequencing (NGS) platforms are also being applied increasingly in both research and clinical settings. In addition to screening patients for therapeutically actionable targets, NGS platforms can aid in the discovery of novel drug targets. NGS platforms can be used for genome-wide characterization of tumor DNA, messenger RNA, transcription factor regions, microRNA, chromatin structure, and DNA methylation. Sequencing platforms are available for whole-genome, whole-exome, whole-transcriptome, and whole-epigenome analysis.[42] All platforms generate a large amount of sequencing data in a relatively short period of time. Analysis of these data takes longer, however, and requires a robust informatics infrastructure. The application of multiplex, high-throughput systematic genomic testing for patients with NSCLC has been shown to be feasible and to influence treatment decision making. However, the turnaround times vary, and both cost


Fig. A.10. Future considerations. *CTC,* Circulating tumor cell. *VOC,* volatile organic compound.

and reimbursement remain potential limitations. Furthermore, extensive genotyping using multiplex or NGS platforms has not been shown to improve clinical outcomes in prospective trials.[42]

As our understanding of the biology of lung cancer improves, it will be feasible to determine the relevance and expression of altered proteins with immunohistochemistry. Immunohistochemistry can be used more universally than the more complex and expensive technologies.

FUTURE CONSIDERATIONS

The noninvasive analysis of surrogate tissues for molecular markers (Fig. A.10) has been investigated as a strategy for disease monitoring and for early diagnosis of lung cancer. The potential effectiveness of using circulating tumor cells to detect resistance mutations during treatment with an EGFR TKI has been described.[43–46] The recent advances in the development of high-throughput platforms for genomic analysis have also facilitated biomarker discovery for early diagnosis and molecular screening. Circulating tumor DNA(ctDNA) is a potential screening options that would allow for molecular detection of oncogene-driven targeted therapy markers in instances where invasive tissue biopsy may not be possible, cost expensive or associated with high morbidity. A non-invasive liquid biopsy would allow for physicians to periodically monitor disease progression, response to therapy, and development of treatment resistance. In a first clinic-based research study of NSCLC patients that assessed outcomes of targeted therapies using a commercially available ctDNA assay, over 80% of patients had detectable ctDNA with high concordance between paired tissue and blood for truncal oncogenic drivers, and patients with biomarkers identified in plasma had PFS in the expected range.[47] The landmark National Lung Screening Trial established the potential of low-dose CT screening to reduce mortality due to lung cancer in a high-risk population as defined by smoking history and age. However, the prevalence of lung cancer in this clinically defined population is low. The testing of surrogate tissues for molecular alterations that may be present early in the course of lung cancer has been investigated as a complement to clinical factors to improve patient selection for low-dose CT screening. This strategy has included interrogating surrogate tissues in the airway epithelium, sputum, and blood for molecular alterations as well as analyzing exhaled breath for endogenous products of cellular metabolism. Several candidate biomarkers have been discovered, although none has been validated. Prospective trials are expected to provide further information on the use of surrogate tissues for molecular analysis.

CONCLUSION

Lung cancer is a complex and heterogeneous disease. Personalized therapy requires assessment of factors specific to both the patient and tumor to help guide treatment decision making. Because most patients will present with advanced-stage disease, tissue confirmation will usually be established with evaluation of a small biopsy specimen or cytologic examination. With the clinical validation of EGFR mutations and ALK translocations to select patients for targeted therapy, molecular characterization of tumors is becoming a standard component of the diagnostic evaluation. Furthermore, genomic changes that occur during therapy have also established the potential role for repeat biopsies to help guide the long-term care of patients. Given the complexity of the ongoing diagnostic evaluation of patients with lung cancer, integrated multidisciplinary teams have become essential to efficiently guide management decisions and the overall care of patients with this disease.
